Alkylpyridines and Miscellaneous Organic Nitrogen Compounds

Henry J. Trochimowicz, Sc.D., Gerald L. Kennedy, Jr., Ph.D., CIH, Neil D. Krivanek, Ph.D.

A. Alkylpyridines

Table 60.1. Acute Toxicity of Five Alkylpyridines (36)

	Approximate Oral LD_{50} (mg/kg)		Approximate Dermal LD_{50} (mg/kg)	Inhalation Toxicity in Rats		
Pyridine	**Rats**	**Mice**	**Guinea Pigs**	**Concn (ppm)**	**Time (h)**	**Mortality**
2-Ethyl	—	—	—	5400	3	100
4-Ethyl-	—	—	—	2500	5	100
2-Methyl-5-Ethyl	800–1600	800–1600	2,500–5,000	1700	3.7	100
2-*n*-Amyl	100–200	200–400	5,000–10,000	400	6	0
4-*n*-Amyl	200–400	200–400	5,000–10,000	300	6	0

Table 60.2. Acute Toxicity of Vinylpyridines (36)

	Approximate Oral LD_{50} (mg/kg)		Approximate Dermal LD_{50} (mg/kg)	Inhalation Toxicity in Rats	
				Concn	**Time**

Pyridine	Rats	Mice	Guinea Pigs	(ppm)	(h)	Mortality
2-Vinyl	100–200	400–800	<500	160	6	0
		Rabbits	300 (56)	5500	1.5	100
4-Vinyl	100–200	200–400	<500	150	6	0
				2000	2	100
2-Methyl-5-vinyl	1167 (57)	775 (58)	718 (57)	1000	4.5	0
			Rabbits	6000 (52)	3–5	100

Note: Numbers in parentheses are references.

Table 60.3. Acute Toxicity of Nicotine

Species	Route	Dose (mg/kg)	Response	Ref.
Cat	i.v.	2	LD_{50}	108
	i.v.	1.3	LD_{50}	109
	i.m.	9	Paralysis, convulsions, ataxia	98
Dogs	i.v.	15 (over 8 h)	Respiratory failure	110
	i.v.	5	LD_{50}	108
Mouse	Oral	24	LD_{50}	111
	s.c.	16	LD_{50}	111
	i.v.	7.1	LD_{50}	108
	Oral	50–60	Approx. LD_{50}, convulsions, paralysis	98
	i.p.	5.9	LD_{50}	112
Monkey	i.m.	6	Convulsions, paralysis	98
Rabbit	i.v.	9.4	LD_{50}	108
	Dermal	50	LD_{50} (estd.)	113
	i.p.	14	LD_{50}	114
	i.m.	30	Convulsions, paralysis	98
Rat	Oral	50–60	Convulsions, paralysis	115
	i.p.	14.6	LD_{50}	116
	Dermal	140	LD_{50}	117
	i.v.	7	LD_{50}	118
	Intratracheal	19.3	LD_{50}	119
Human	Rectal	1.4	Hallucinations, nausea	120

Table 60.4. Acute Toxicity of Three Substituted Uracils[a]

Test	Bromacil	Lenacil	Terbacil
Oral LD_{50}			
Rat (mg/kg)	5200 (167)	>11,000 (168)	>5000 (169) >7500 (170)
Dog (mg/kg)	>5000 (170)	—	>5000 ALD (170)
Skin ALD			
Rabbit (mg/kg)	>5000 (171) >2000 (174)	>5000 (172)	>5000 (173)
Skin irritation			
Rabbit	None (175) Slight (174, 176)	None (172)	None (173)
Guinea pig	Mild (177)	Mild to moderate (171)	None (173)
Sensitization			
Guinea pig	None (178, 179)	None (178, 180)	Mild (173)
Eye irritation			
Rabbit	Mild (181)	Mild (171)	Mild (182)
Inhalation			
LC_{50} (4 h)	>4.8 (183)	>5.2 (184)	>4.4 (185)
Rat (mg/L)	>5.2 (186)		

[a] Numbers in parentheses are references.

Table 60.5. Genetic Toxicity Tests on Substituted Uracils[ab]

Assay/End Point	Bromacil	Lenacil	Terbacil
Salmonella typhimurium	–(214–218) +(219, 220)	–(221)	–(215, 216, 222, 223)
Escherichia coli	–(218, 222, 224, 225)		–(216, 222)
Saccharomyces cerevisiae	–(217, 225–227)		
Drosophila melanogaster	+(205, 217, 218, 224, 225) –(220, 238)		–(206, 229)
Mouse lymphoma assay	+(217, 218, 224,		

	225)	
Chinese hamster ovary	–(224, 225, 230)	–(229, 231)
Unscheduled DNA/human fibroblasts	–(225, 230)	
in vivo mouse micronucleus	–(224, 225, 232)	
in vivo mouse dominant lethal	–(217, 225, 233–235)	

[a] + = positive result; – = negative result.
[b] Reference numbers in parentheses.

Table 60.6. Acute Toxicity of Quaternary Herbicides in Various Species[a] (240, 241)

	Oral LD_{50} (mg/kg)			Dermal LD_{50} (mg/kg)			Inhalation LC_{50} (mg/m^3)		
	PQ	**DQ**	**DFQ**	**PQ**	**DQ**	**DFQ**	**PQ**	**DQ**	**DFQ**
Rat	100–200	130–400	270	80–350	650	—	1–10	35–83	—
Mouse	—	125–170	31–44	62	430	—	—	—	—
Rabbit	—	101–190	470	236–500	>400	3540	—	—	—
Guinea pig	22–80	100–123	—	319	400	—	4	38	—
Monkey	50	100–300	—	—	—	—	—	—	—

[a] PQ = paraquat; DQ = diquat; DFQ = difenzoquat; — = No data.

Cyanides and Nitriles

Barbara Cohrssen, MS, CIH

A. Cyanides

Table 61.1. Physical and Chemical Properties of Cyanides a

Compound	CAS Number	Molecular Formula	Physical Formula	Molecular Weight	Boiling Point (°C)	Melting Point (°C)
			Cyanides			
Hydrogen cyanide	[*74-90-8*]	HCN	Colorless liquid	27.03	25.7	–13.2
Sodium cyanide	[*143-33-9*]	NaCN	White crystals	49.01	—	563
Potassium cyanide	[*151-50-8*]	KCN	White crystals	65.12	—	634
Calcium cyanide	[*592-01-8*]	$Ca(CN)_2$	White powder	92.11	—	—
Cyanamide	[*420-04-2*]	CH_2N_2	Elongated tablets	42.04	—	—
Calcium Cyanamide	[*156-62-7*]	$CaCN_2$	White crystals	80.11	—	1300
Cyanogen	[*460-19-5*]	C_2N_2	Colorless gas	52.04	–27.17	–27.9
Cyanogen chloride	[*506-77-4*]	ClCN	Colorless liquid or gas	61.47	13.8	–6
Cyanogen bromide	[*506-68-3*]	BrCN	Colorless crystals	105.9	61.6	52
Dimethyl cyanamide		$(CH_3)_2CN_2$	Colorless liquid	70.1	—	–41
			Nitriles			
Acrylonitrile	[*107-13-1*]	$CH_2{=}CHCN$	Colorless liquid	53.06	77.5–77.9	–83.5
Methyl acrylonitrile	[*126-98-7*]	$CH_2{=}C(CH_3)CN$	Colorless liquid	67.09	90.3	–35.8
Acetonitrile	[*75-05-8*]	CH_3CN	Colorless liquid	41.05	81.6	–43
Propionitrile	[*107-12-0*]	CH_3CH_2CN	Colorless liquid	55.08	97.1	–98
n-Butyronitrile	[*109-74-0*]	$CH_3CH_3CH_2CN$	Colorless liquid	69.11	116	–112.6
Isobutyronitrile	[*78-82-0*]	$(CH_3)_2CHCN$	Colorless liquid	69.11	107	–75
3-Hydroxypropionitrile	[*109-78-4*]	$HOCH_2CH_2CN$	Colorless or straw liquid	71.08	221	–46
Lactonitrile	[*78-97-7*]	C_3H_5NO	Colorless or straw liquid	71.08	103	–40
2-Methyllactonitrile	[*75-86-5*]	C_4H_7NO	Liquid	85.11	95	–20
Glycolonitrile	[*107-16-*		Colorless	57.05	183	

	4]	$HOCH_2CN$	oily liquid			
Succinonitrile	[*110-61-2*]	$CNCH_2CH_2CN$	Colorless waxy solid	80.09	265–267	57–57.
Adiponitrile	[*111-69-3*]	$CN(CH_2)_4CN$	Colorless liquid	108.1	295	1–3
Glycolonitrile	[*107-16-4*]	$HOCH_2CN$	Clear pale yellow liquid	57.05	183	<–72
3-Dimethylaminopropionitrile	[*1738-25-6*]	$(CH_3)_2NCH_2CH_2CN$	Colorless liquid	98.15	172	–44.2
3-Isopropylaminopropionitrile	[*7249-87-8*]	$(CH_3)_2CH_2NHCH_2CN$	Liquid	112.2	87	–20
3-Methoxypropionitrile	[*110-67-8*]	$CH_3OCH_2CH_2CN$	Colorless liquid	85.1	160	–62.9
3-Isopropoxypropionitrile	[*110-47-4*]	$(CH_3)_2CH_2OCH_2$	Liquid	113.2	177	–67
3-Chloropropionitrile	[*542-76-7*]	$ClCH_2CH_2CN$	Colorless liquid	89.52	132	–51
3-Aminopropionitrile	[*151-18-8*]	$NH_2CH_2CH_2CN$	Liquid solid	70.09	79–81	—
3,3'-Iminodipropionitrile	[*111-94-4*]	$HN(CH_2CH_2CN)_2$	Colorless liquid	123.6	173	–5.5
Malononitrile	[*109-77-3*]	$CH_2(CN_2)_2$	White powder	66.06	218	32
Cyanoacetic acid	[*372-09-8*]	$CNCH_2COOH$	White cystals	85.06	108	66
2-Cyanoacetamide	[*107-91-5*]	$CNCH_2CONH_2$	White powder	84.08	Decomposes	119
Chloroacetonitrile	[*107-14-2*]	C_2H_2ClN	Colorless liquid	75.5	1.193	—
Methyl cyanoacetate	[*105-34-0*]	CH_3OOCCH_2CN	Liquid	99.09	203	–22.5
Ethyl cyanoacetate	[*105-56-6*]	$CH_2(CN)COOC_2H_5$	Colorless liquid	113.1	205	–22.5
Methyl cyanoformate	[*17640-15-2*]	$CNCOOCH_3$	Colorless liquid	85.03	97	—
Ethyl cyanoformate	[*623-49-4*]	$CNCOOC_2H_5$	Colorless liquid	99.05	116	—
Methyl isocyanate	[*624-83-9*]	CH_3NCO	Colorless liquid	57.05	39–40	–80
Cyanuric chloride	[*108-77-0*]	$(CNCl)_3$	Colorless crystals	184.4	190	145.8
Bromophenylacetonitrile	[*5798-79-8*]	C_6H_5BrCN	—	196.1	225	25

Toluene-2,4-diisocyanate	[*584-84-9*]	$C_9H_2N_2O_2$	White liquid	174.2	250	—
Sodium dicyanamide	—	$NaN(CN)_2$	Colorless crystals	89.04	—	315
Dicyanodiamide	[*461-58-5*]	$C_2H_2N_4$	Crystal solid	84.08	Decom-poses	209
Sodium cyanate	[*917-61-3*]	NaOCN	Colorless solid	65.01	—	—
Potassium cyanate	[*590-28-3*]	KOCN	White solid	81.11	—	315
Potassium ferricyanide	[*13746-66-2*]	$K_2Fe(CN)_6$	Red solid	329.2	—	—
Potassium ferrocyanide	[*13943-58-3*]	$K_4Fe(CN)_6 \cdot 3H_2O$	Yellow solid	422.4	—	Loses H_2O a 60°C
Sodium nitroprusside	[*14402-89-2*]	$Na_2[Fe(CN)_5NO]$ H_2O	Red crystals	280.92	—	

Table 61.2. Physiological Response to Various Concentrations of Hydrogen Cyanide in Air—Animals[a]

	Concentration		
Animal	**mg/L**	**ppm**	**Response**
Mouse	1.45	1300	Fatal after 1–2 min
Mouse	0.12	110	Fatal after 45 min exposure
Mouse	0.05	45	Fatal after 2.5–4 h exposure
Cat	0.350	315	Quickly fatal
Cat	0.20	180	Fatal
Cat	0.14	125	Markedly toxic in 6–7 min
Dog	0.350	315	Quickly fatal
Dog	0.0125	115	Fatal
Dog	0.1	90	May be tolerated for hours; death after exposure
Dog	0.07–0.04	65–35	Vomiting, convulsions, recovery; may be fatal
Dog	0.035	30	May be tolerated
Guinea pig	0.035	315	Fatal
Guinea pig	0.23	200	Tolerated after 1.5 h without symptoms
Rabbit	0.350	315	Fatal
Rabbit	0.13	120	No marked toxic symptoms
Monkey	0.14	125	Distinctly toxic after 12 min

Rat	0.12	110	Fatal after 1.5-h exposure

[a] Refs 46, 47.

Table 61.3. Physiological Response to Various Concentrations of Hydrogen Cyanide in Air—Humans[a]

	Concentration	
Response	**mg/L**	**ppm**
Immediately fatal	0.3	270
Estd. human LC_{50} after 10 min (18)	0.61	546
Fatal after 10 min	0.2	181
Fatal after 30 min	0.15	135
Fatal after 0.5–1 h or later, or dangerous to life	0.12–0.15	110–135
Tolerated for 0.5–1 h without immediate or late effects	0.05–0.06	45–54
Slight symptoms after several hours	0.02–0.04	18–36

Table 61.4. Toxicity of Cyanogen in Air for Various Animal Species[a]

	Concentration			
Animal	**mg/L**	**ppm**	**Duration**	**Response**
Mouse	0.5	235	15 min	Recovered
Mouse	5.5	2,600	12 min	Fatal
Mouse	31.5	15,000	1 min	Fatal
Rat	0.59	350	1 hr	LC_{50} (74a)
Rabbit	0.21	100	4 hr	Practically no effect
Rabbit	0.42	200	4 hr	Slight symptoms
Rabbit	0.63	300	3.5 hr	Severe symptoms; delayed death
Rabbit	0.84	400	1.8 hr	Fatal
Cat	0.1	50	4 hr	Severe symptoms but recovered
Cat	0.21	100	2–3 hr	Fatal
Cat	0.42	200	0.5 hr	Fatal

Cat	4.26	2,000	13 min	Fatal

[a] Ref. 47

Table 61.5. Effects of Cyanogen Chloride Inhalation on Various Animal Species (13)

	Concentration			
Animal	**mg/L**	**ppm**	**Duration**	**Response**
Mouse	0.2	80	5 min	Tolerated by some animals
Mouse	0.3	120	3.5 min	Fatal to some animals
Mouse	1.0	400	3 min	Fatal
Rabbit	3.0	1200	2 min	Fatal
Cat	0.1	40	18 min	Delayed fatalities after 9 days
Cat	0.3	120	3.5 min	Fatal
Cat	1.0	400	1 min	Fatal
Dog	0.05	20	20 min	Recovered
Dog	0.12	48	6 hr	Fatal
Dog	0.3	120	8 min	Severe injury, recovered
Dog	0.8	320	7.5 min	Fatal
Goat	2.5	1000	3 min	Fatal after 70 h

Table 61.6. Effects of Varying Concentrations of Cyanogen Chloride in Air or Humans[a]

Concentration		
mg/L	**ppm**	**Response**
0.4	159	Fatal after 10 min
0.12	48	Fatal after 30 min
0.05	20	Intolerable concentration, 1-min exposure
0.005	2	Intolerable concentration, 10-min exposure
0.0025	1	Lowest irritant concentration, 10-min exposure

[a] Ref. 41, 47

Table 61.7. Response of Animals to Various Concentrations of Cyanogen Bromide in Air[a]

Concentration		Response	
mg/L	**ppm**	**Mice**	**Cats**
1	230	Fatal	Fatal
0.3	70	Paralysis after 3-min exposure	Paralysis after 3-min exposure
0.15–0.05	35–12	—	Severe injury; fatal on prolonged inhalation

[a] Ref. 47

Table 61.8. Response of Humans to Various Concentrations of Cyanogen Bromide in Air[a]

Concentration		
mg/L	**ppm**	**Response**
0.4	92	Fatal after 10 min
0.085	20	Intolerable concentration, 1-min exposure
0.035	8	Intolerable concentration, 10-min exposure
0.006	1.4	Lowest irritant concentration, 10-min exposure

Cyanides and Nitriles
Barbara Cohrssen, MS, CIH

B. Nitriles

Nitriles are often considered derivatives of carboxylic acids and are named according to the carboxylic acid that is produced upon hydrolysis of the nitrile. For example, cyanomethane (methyl cyanide) is named acetonitrile because hydrolysis of its cyano group yields acetic acid. Nitriles

which contain additional functional groups are typically named as cyano-substituted compounds (e.g., cyanoacetic acid). Nitriles that contain a hydroxy (—OH) group on the carbon atom that is bonded to the cyano moiety are known as *cyanohydrins*. According to *Chemical Abstracts*, aliphatic nitriles are named as derivatives of the longest carbon chain and the carbon of the nitrile is included.

Table 61.9. Physiological Response to Various Concentrations of Acrylonitrile in Air—Animals

	Concentration		
Animal	**mg/L**	**ppm**	**Response**
Rat	1.38	636	Fatal after 4 h exposure
Rat	0.28	129	Slight transitory effect
Rat	0.21	97	Slight transitory effects
Rabbit	0.56	258	Fatal during or after exposure
Rabbit	0.29	133	Marked transitory effects
Rabbit	0.21	97	Slight transitory effects
Cat	0.60	276	Markedly toxic
Cat	0.33	152	Markedly toxic, sometimes fatal
Guinea pig	1.25	576	4 hr LC_{50}
Guinea pig	0.58	267	Slight transitory effect
Dog	0.24	110	Fatal to 75% of the dogs
Dog	0.213	98	Convulsions and coma; no death
Dog	0.12	55	Transitory paralysis; 1 dog died
Dog	0.063	29	Very slight effects

Table 61.10. Acute Toxicity of Acetonitrile in Animals

Route of Administration	**Species**	**LD_{50} or LC_{50}**	**Remarks**	**Ref.**
Oral	Rat	3.8 g/kg		116
Oral	Rat	2.45 g/kg		117
Oral	Rat	0.16–3.5 g/kg	Young more sensitive	118
Dermal	Rabbit	3.9 g/kg		116
Inhalation	Rat	16,000 ppm	4 h	119
Inhalation	Guinea pig	5,655 ppm	4 h	119
Inhalation	Rabbit	2,828 ppm	4 h	119

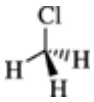
Saturated Methyl Halogenated Aliphatic Hydrocarbons
Jon B. Reid, Ph.D., DABT

1.0 Methyl Chloride
1.0.1 CAS Number:
[*74-87-3*]
1.0.2 Synonyms:
Chloromethane; monochloromethane
1.0.3 Trade Names:
Artic; RCRA Waste Number U045; R40, Refrigerant R40, R-40; UN 1063
1.0.4 Molecular Weight:
50.49
1.0.5 Molecular Formula:
CH_3Cl
1.0.6 Molecular Structure:



1.1 Chemical and Physical Properties

Physical state	Colorless gas
Melting point	–97°C
Boiling point	–24.2°C
Solubility	0.9 g/100 mL water at 20°C; 7.8 g/100 mL ethanol at 20°C; soluble in ethyl ether, chloroform, acetone
Autoignition temperature	634°C
Flash point	< 0°C
Flammability limits	8–19% in air 1 mg/L = 484 ppm and 1 ppm = 2.06 mg/m^3 at 25°C, 760 torr

1.1.1 General Methyl chloride is a natural and ubiquitous constituent of the oceans and atmosphere. It is a product of biomass combustion and also created from biogenic emissions by wood-rotting fungi. It has been detected in surface waters, drinking water, groundwater, and soil as well as in industrial leachate. It is an impurity in vinyl chloride.

1.1.2 Odor and Warning Properties Methyl chloride has a faint sweet odor. Charcoal used in most organic respirator cartridges and canisters is not totally effective as a sorbent.
1.2 Production and Use
Methyl chloride has been used in rubber adhesives and other rubber solutions; in the pharmaceutical industry; as a paint and varnish remover, in solvent degreasing; in aerosol formulations; in food and drug processing; in the plastics industry; in hairsprays, insecticides, and spray paints; as a cosolvent or vapor pressure depressant; as a blowing agent for flexible polyurethane foams; as a cleaning solvent for printed-circuit boards; as a stripper solvent for photoresists; as a solvent for cellulose acetate fiber; in plastic film; in protective coatings; in chemical processing; as a carrier solvent for herbicides and insecticides; to extract heat-sensitive, naturally occurring substances such as cocoa, edible fats, spices, and beer hops; for decaffeinating coffee; as a refrigerant; in oil dewaxing; as a dye and perfume intermediate; in the textile industry; as a postharvest fumigant for strawberries; as a grain fumigant; for degreening citrus fruits; as an industrial solvent; in low temperature extraction; as

a solvent for oil, fats, bitumen, esters, resins, and rubber; in coating photographic films; as a food additive; in synthetic fibers and leather coatings; as a spotting agent; and in organic synthesis.

Methyl chloride is a ubiquitous environmental contaminant because it is produced in very large quantities by fire, fungi, terrestrial plants, seaweed, algae, and possibly other organic processes. An estimated 5×10^6 tons are produced annually by global biologic processes (9). Less than 1% of environmentally occurring methyl chloride is the result of industrial processes.

Most industrially produced methyl chloride is consumed as a chemical intermediate, primarily in methylating reactions. However, published reports of human exposure have primarily been the result of its previous use as a refrigerant gas and as a blowing agent for plastic foams. Both of these uses have virtually disappeared, although it is possible that some methyl chloride may be present in old refrigeration systems and foams.

Because methyl chloride has a sweet odor which is not noticeable at dangerous concentrations, it must be used in closed or well-ventilated systems, preferably with continuous monitoring to prevent excessive exposure. Inhalation is the only significant route of toxic exposure. Respirators containing activated charcoal have been shown to have only limited capacity for removing the gas.

Methyl chloride has been identified in at least 172 of the 1467 current or former EPA National Priorities List (NPL) hazardous-waste sites.

1.3 Exposure Assessment

Numerous analytical methods are given in the ATSDR Toxicological Profile Update (10).

1.3.1 Air As discussed in the ATSDR Profile for methyl chloride (10), in air, methyl chloride can be analyzed by NIOSH method 1001, using gas chromatography (GC) with flame ionization detector, for a range of 66–670 mg/m^3 (11). Methyl chloride can also be trapped cryogenically from an aliquot of air collected into an evacuated canister followed by determination using GC with either electron capture or mass spectrometric detection (12). Extreme care must be taken to ensure that no contamination is introduced into the sampling and analysis method and correction for loss of the compound from air samples stored in canisters. See Section 1.3.3.

1.3.2 Background Levels: NA

1.3.3 Workplace Methods NIOSH Method 1001 is recommended for determining workplace exposures to methyl chloride (11).

1.3.4 Community Methods: NA

1.3.5 Biomonitoring/Biomarkers The ATSDR profile (10) indicates several analytical methods in the analytical section. Several studies have unsuccessfully attempted to correlate exposure levels in air with urinary excretion of *S*-methylcysteine. Use of blood and breath analysis to monitor exposure levels immediately after exposure were of limited value.

1.3.5.1 Blood No analytical methods were found for blood.

1.3.5.2 Urine *S*-Methylcysteine may be a urinary metabolite of methyl chloride in some humans (13, 14). *S*-Methylcysteine can also be analyzed as methanethiol following alkaline hydrolysis and acidification (14).

1.3.5.3 Other Breast milk can be analyzed for chloromethane, after suitable preparation using gas chromatography and mass spectroscopy (15).

1.4 Toxic Effects

Methyl chloride is poisonous intravenously; moderately toxic by ingestion, subcutaneous, and

intraperitoneal routes; mildly toxic by inhalation. It is an experimental carcinogen and tumorigen, an experimental teratogen, produces experimental reproductive effects, an eye, respiratory tract, and skin irritant, and it is mutagenic to humans. When heated to decomposition it emits toxic fumes of chlorine, hydrogen chloride gas, carbon monoxide, carbon dioxide, and phosgene.

Chronic and subacute exposure predominantly affect the nervous system. Symptoms observed are ataxia, staggering gait, weakness, tremors, vertigo, drowsiness, confusion, personality changes, loss of memory, difficulty in speech, and blurred vision. In severe acute poisoning, GI disturbances such as nausea, vomiting, abdominal pain, and diarrhea may be observed. Acute animal experiments have indicated pulmonary congestion and edema. Histopathological changes of the internal organs are not common and laboratory values are unaffected.

In a practical sense, the major problem encountered in mild exposure is “drunkenness” or inebriation. The resulting incoordination and impaired judgment may lead to unsafe manual manipulation. The employee may be injured or endanger others by mechanical misoperation. Because this condition may persist for some time, the employee is a hazard if he or she drives a vehicle after such exposure. The symptoms may be delayed in onset. They may also continue for some hours after the exposure has stopped.

Although most experience would indicate complete recovery in a matter of hours following acute exposure, symptoms may persist for several months and chronic effects following a massive, almost lethal, exposure have been reported to last as long as 5–13 years.

Studies in laboratory animals have shown adverse effects on the brains, kidneys, liver, testes, spleen, and sperm in several species. Kidney tumors have been produced in male mice but not female mice or rats of either sex. These effects have generally been at neurotoxic levels of exposure, and a threshold of about 50 to 100 ppm appears to exist for adverse effects following repeated 6–7 h inhalation exposures of animals.

Because methyl chloride is a gas, ingestion is not of practical concern.

1.4.1 Experimental Studies 1.4.1.1 Acute Toxicity In an unpublished study, Sprague Dawley rats were exposed to 99.5% chloromethane at 0, 200, 500, 1000, or 2000 ppm for 48 or 72 h. At 2000 ppm at 48 h, rats were either lethargic, moribund, or dead. At 2000 ppm rats were all dead or moribund. The cause of death was thought to be kidney failure (16).

Morgan et al. (17) studied lesions induced by inhalation exposure of methyl chloride in C3H, C57BL/6, and B6C3F1 mice and Fischer 344 rats. In mice exposed to 2000 ppm, all male B7C3F1 mice were moribund or died by day 2, one C576BL/6 male died on day 2, and others were moribund by day 5. All other mice survived except one male C3H exposed to 1000 ppm, which died by day 11. This study confirmed the existence of species, sex, and strain differences in susceptibility. Deaths are due to effects on the central nervous system (CNS). Histological effects have been shown to occur in the cerebellum of animals exposed to concentrations causing obvious CNS changes, including ataxia, severe diarrhea, incoordination of fore-limbs and in some cases the hind limbs, and convulsions. In addition, lesions have been reported in the liver, kidneys, adrenals, spleen, testes, and epididymis particularly on repeated exposure.

Dogs exposed acutely to 15,000 ppm died within 4–6 h after an initial rise in heart rate and blood pressure, followed by reduced respiration, decreased heart rate, and progressive fall in blood pressure (18, 19).

1.4.1.2 Chronic and Subchronic Toxicity In an unpublished study with Fischer 344 rats and B6C3F1 mice (20), 120 animals per sex per exposure level were exposed in whole body chambers to 0, 50, 225, or 1,000 ppm, 6 h/day, 5 days/week. During the acute exposure (< = 14 days), there was no effect on survival curves of male or female rats or mice. During the intermediate time (15–364 days)

there was some increased mortality in female mice at 1,000 ppm, but no effect on survival of male mice or male or female rats. During the chronic period (> = 365 days), there was increased mortality in 1000 ppm exposed male mice. There was no effect on survival of male or female rats. See Section 1.4.1.5 for the carcinogenicity aspects of this study.

Although old reports suggest no effect after 6 months of 6-h daily exposure to 300 ppm (21), newer studies suggest that 50 ppm is the NOEL in rats and mice after 2 years of repeated exposure (22). The seminiferous tubules of the testes of rats were severely affected by exposure to 1000 ppm after 6 months or more. Exposure to 250 or 50 ppm caused no adverse effect in either male or female rats except for a questionable decrease in growth of female rats at 250 ppm. $B6C3F_1$ mice were in general much more severely affected than rats, but 50 ppm was considered to be without effect after 2 years of exposure. At 1000 ppm, severe neurofunctional impairment (tremors and paralysis) with supporting histopathological injury was observed, as were splenic atrophy and hepatocellular necrosis and degeneration in the livers of male mice. Renal tubuloepithelial hyperplasia and karyomegaly were seen in mice after 12 months of exposure to 1000 ppm as well as kidney tumors in male mice only.

1.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms The 1998 ATSDR Toxicological Profile (10), in the section on metabolism, indicates that methyl chloride is rapidly absorbed from the lungs and rapidly reaches equilibrium with levels in blood and expired air approximately proportional to the exposure concentrations. At high concentrations, kinetic processes such as metabolism or excretion may become saturated, limiting the rate of uptake. Animal studies show that methyl chloride is absorbed from the lungs and extensively distributed througout the body. Methyl chloride is metabolized by conjugation with glutathione to yield *S*-methylglutatione, *S*-methylcysteine, and other sulfur-containing compounds that are excreted in the urine or further metabolized to methanethiol. Cytochrome P450–dependent metabolism of methanethiol may yield formaldehyde and formic acid, whose carbon atoms are then available to the one-carbon pool for incorporation into macromolecules or for formation of CO_2. Alternatively, formaldehyde may be directly produced from chloromethane via a P450 oxidative dechlorination.

The conjugation of chloromethane with glutathione is primarily enzyme-catalyzed. In contrast to all other animal species investigated (rats, mice, bovine, pigs, sheep, and rhesus monkeys), human erythrocytes contain a glutathione transferase isoenzyme that catalyzes the conjugation of glutathione with methyl chloride. There are two distinct human subpopulations based on the amount or forms of this transferase.

Considerable variation in toxic response related to sex, species, and strain in animal studies may be due to qualitative and quantitative differences in metabolism. Differences in individual metabolism are also apparent in controlled human exposure studies, with two distinct subpopulations identified in several studies. Methyl chloride does not appear to methylate directly, and incorporation into macromoleculars such as RNA, DNA, protein, and lipid is due to rapid conversion to formate and metabolism as part of the one carbon pool.

The metabolism scheme presented in the previous edition is still appropriate (23) and is shown in Figure 62.1.

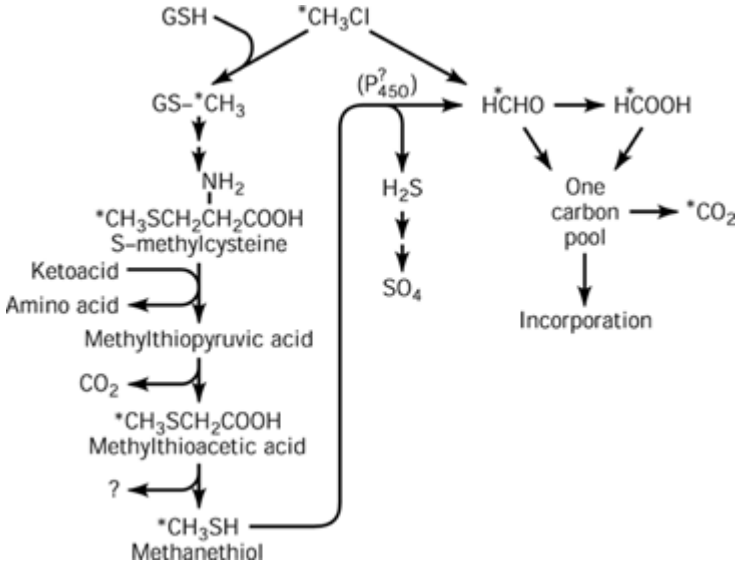


Figure 62.1. Proposed metabolism of methyl chloride in the rat (From Ref. 23).

Conjugation with glutathione is the major pathway. In discussing this diagram the authors state "The metabolic scheme depicted ... accounts for the present as well as previous findings on the metabolism of methyl chloride." The reaction of CH_3Cl with glutathione was previously demonstrated both *in vitro* (24) and *in vivo* (25). The reaction appears to be primarily enzyme-catalyzed, probably by glutathione-transferase, as has been demonstrated for methyl iodide (26). The product of this reaction, methylglutathione, may be metabolized by transpeptidases to *S*-methylcysteine, which has been detected in the urine of rats (27) and humans (28) exposed to methyl chloride.

However, no relationship between urinary *S*-methylcystine excretion and 6 h of exposure to 50 or 10 ppm of methyl chloride was found in human studies (13); nor was *S*-methylcystine a sensitive indication of exposure in beagle dogs, although the metabolite did occur in rats (27).

Peters et al. (29) have shown that erythrocyte cytoplasm from rats, mice, bovines, swine, sheep, and rhesus monkeys did not convert methyl chloride. However, 60% of human blood samples showed conversion to *S*-methylglutathione whereas 40% did not. An enzyme, glutathione-*S*-transferase, present in some blood samples and not in others, accounted for the differences. This is consistent with the observation by Landry et al. (27) that human blood samples being analyzed for methyl chloride *per se* had to be quickly heated to 100°C for 1 min to stop enzymatic reactions whereas rat blood samples were stable for several hours.

Because the major metabolic pathway involves conjugation with reduced glutathione, possibly leading to production of potent vasoconstrictors (leukotrienes), it has been postulated that the toxic action on sperm, the subsequent "dominant lethal affect," as well as effects in the liver, kidneys, and brain, are the result of these inflammatory responses (30).

In a study comparing biochemical effects in rat and mice livers and kidneys, it was concluded that renal tumors observed in male mice at 1000 ppm are probably not evoked by intermediates or *in situ*–produced formaldehyde (31).

1.4.1.4 Reproductive and Developmental Reproduction studies in animals have been conducted and the specific action of methyl chloride on the epididymis clearly influenced the results. Exposures that did not cause inflammation of the epididymis did not affect reproduction in rats.

NIOSH (32) reviewed studies on the reproductive and/or developmental effects from exposure to

methyl chloride. Pregnant mice were exposed via inhalation at concentrations of 0, 100, 250, 500, 750, or 1500 ppm methyl chloride on days 6–18 of gestation. Exposure at 1500 ppm was terminated due to excessive maternal morbidity. Exposure at 500 or 750 ppm caused a statistically significant increase in the numbers of cardiac malformations. Exposure at concentrations of 250 or 100 ppm was considered to be nonteratogenic. Offspring of rats exposed similarly to methyl chloride showed no terata.

Daily exposure of male F344 rats at 1500 ppm for 10 weeks by Hamm et al. (33) caused severe testicular degeneration; no males sired litters during a subsequent 2-week breeding period. The highest no-observed-adverse-effect level (NOAEL) concentration was 150 ppm; however, the authors stated that the actual no-effect concentration was more likely 475 ppm.

In a study by Wolkowski-Tyl et al. (34), the authors concluded that in $B6C3F_1$ mice, an inhalation exposure to 1492 ppm chloromethane resulted in severe maternal toxicity; exposure to 102 and 479 ppm chloromethane resulted in severe maternal toxicity. No deaths were observed in female rats. In a reproductive and developmental effects study of methyl chloride inhalation Wolkowski-Tyl et al. (35) concluded that an inhalation exposure to methyl chloride during Gd 6-17 resulted in maternal toxicity at 750 ppm, but not 500 ppm. Exposure to pregnant mice to 250 ppm chloromethane produced neither maternal nor fetal toxicity nor teratogenicity. Although teratological studies in rats have been negative and at most questionable in mice, methyl chloride has been shown in longer studies to have a severe effect on epididymis and sperm, with significantly altered reproductive capability. Furthermore, fetal toxicity, possibly secondary to maternal toxicity, has been shown to be severe at neurotoxic concentrations.

1.4.1.5 Carcinogenesis Classifications are

IARC	Group 3, Not classifiable as to its carcinogenicity to humans.
MAK	Group 3, Possible human carcinogen.
NIOSH	Carcinogen, with no further categorization.
TLV	A4, Not classifiable as a human carcinogen.

The National Institute for Occupational Safety and Health (NIOSH) (36) reviewed the final report from an inhalation carcinogenesis bioassay by Pavkov (37) in which $B6C3F_1$ mice and F344 rats of both sexes were exposed at methyl chloride concentrations of 0, 50, 225, or 1000 ppm for 6 h/day, 5 days/week for 2 years. This study showed renal degenerative changes (cortical tubular epithelial hypertrophy and hyperplasia with or without karyomegaly) and hepatocellular degeneration. A statistically significant increase in both malignant and nonmalignant renal tumors occurred in only the male mice exposed at 1000 ppm, including renal cortical adenomas and adenocarcinomas, papillary cystadenomas and cystadenocarcinomas, and tubular cystadenomas. Additionally, chronic inhalation of 1000 ppm methyl chloride induced functional limb muscle impairment and degeneration and atrophy of the internal granular layer of the cerebellum in male and female mice. Male and female mice exposed at 1000 ppm also exhibited atrophy of the spleen. Male and female rats exposed to methyl chloride failed to exhibit a significant increase in neoplastic lesions or to develop the other gross and histopathologic lesions observed in mice. Male rats developed bilateral atrophy of the testicular seminiferous tubules; no such change occurred in the male mice, indicating that male mice were more sensitive to the toxic effects of inhaled methyl chloride than female mice and that both sexes of mice were more sensitive than were male or female F344 rats.

In a 2-year oncogenicity study by CIIT (20), a high incidence of renal tumors was found in male mice exposed to 1000 ppm methyl chloride, no evidence of carcinogenicity was found in male or female rats exposed to concentration of 1000 ppm in this study.

In 1986 IARC concluded that there was inadequate evidence for the carcinogenicity of methyl

chloride in animals; however, NIOSH (36) has classified methyl chloride as a potential occupational carcinogen.

1.4.1.6 Genetic and Related Cellular Effects Studies When studied in rats, there has been no evidence of alkylation of DNA, even in a study designed to maximize analytic sensitivity (38). However, in certain *in vitro* and *in vivo* studies, methyl chloride appears to be a weak, direct-acting mutagen for bacteria, *Drosophila*, and mammalian cells. Although positive in a dominant lethal study in rats, the effect appears to be secondary to injury of a specific area of the epididymis.

Dominant lethal mutations were indicated by increased preimplantation loss in male F344 rats exposed 6 h/day at 3000 ppm administered for 5 consecutive days throughout the 8 weeks following exposure (*i.e.*, after treatment of spermatogonia, spermatocytes, spermatids, and spermatozoa), and a slight increase in postimplantation loss was found only during the first week after exposure (*i.e.*, after treatment of spermatozoa) (39). Subsequently the authors indicated that the postimplantation loss was a secondary effect due to methyl chloride-induced inflammation of the epididymis (40).

1.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization Exposure to animals results in neurological effects. Rats, mice, rabbits, guinea pigs, dogs, cats, and monkeys exposed to chloromethane until death all displayed signs of severe neurotoxicity (41, 42).

A limited number of animal (not human) studies report ocular effects but the results are mixed.

1.4.2 Human Experience Since the mid-1960s or so, methyl chloride was used as a refrigerant, and many human deaths resulted from exposure to methyl chloride vapors from leaks in home refrigerators and industrial cooling and refrigeration systems (43).

The principal route of absorption is by inhalation, but methyl chloride can be absorbed through the skin. Symptoms may include headache, elevated blood concentrations of carboxyhemoglobin, nausea, and irritation of the skin and eyes. Central nervous system depression, pulmonary edema, hemolysis, chronic intoxication, and paresthesia may also occur. Other symptoms include narcosis, temporary neurobehavioral effects, increase in serum bilirubin, increased urinary formic acid concentrations, and increased risk of spontaneous abortion. In addition, intravascular hemolysis, unconsciousness, lack of response to painful stimuli, rapid followed by slowed respiration, erythema, blistering, toxic encephalopathy, painful joints, swelling of the extremities, mental impairment, diabetes, skin rash, aspiration pneumonia, gross hematuria, reduction of blood pH, gastrointestinal injury, and narrowing of the intestinal lumen may also occur. Symptoms may include upper respiratory tract irritation, giddiness, stupor, irritability, numbness, tingling in the limbs, and hallucinations. A dry, scaly, and fissured dermatitis, skin burns, coma and death may also result. Other symptoms may include dizziness, sense of fullness in the head, sense of heat, dullness, lethargy, and drunkenness. In addition, mental confusion, lightheadedness, vomiting, weakness, somnolence, lassitude, anorexia, depression, fatigue, vertigo, liver damage, nose and throat irritation, anesthetic effects, smarting and reddening of the skin, blood dyscrasias, acceleration of the pulse, and congestion in the head may result. Staggering may also occur. Symptoms of exposure may include neurasthenic disorders, digestive disturbances and acoustical and optical delusions. Arrhythmias produced by catecholamines may also result. Additional symptoms include edema, faintness, loss of apetite, and apathy. Hyporeflexia, gross hemoglobinuria, epiglottal edema, metabolic acidosis, GI hemorrhage, ulceration of the duodenojejunal junction, and diverticula may also occur. Other symptoms may include kidney damage, lung damage, corneal injury, abdominal pain, and an increase in salivary gland tumors. Cyanosis may also occur. Exposure may also cause altered sleep time, convulsions, euphoria and a change in cardiac rate.

1.4.2.1 General Information Generally, case reports do not describe respiratory effects in human exposures. No effects on pulmonary function were observed in volunteers who were exposed to 150 ppm (44).

Cardiovascular effects (electrocardiogram abnormalities, tachycadia, increased pulse rate, and decreased blood pressure) have been described in case reports of humans exposed occupationally or accidentally to refrigerator leaks (45).

In an extensive study with human subjects, Stewart et al. (46) gave males single or repeated exposures to 0, 20, 100, or 150 ppm and females to 0 or 100 ppm. Exposures were generally held at a constant level, but in one case were allowed to range from 50 to 150 ppm, averaging 100 ppm. Exposures were for 1, 3, or 7 h/day, 5 days/week. Using a wide battery of behavioral, neurological, electromyographic, and clinical chemical tests, no significant decrements were found. No increase in methyl alcohol was found in the urine, and methyl chloride in expired air dropped so rapidly as to be of little or no value in quantifying exposure. There was a remarkable difference in individual responses, with some subjects consistently showing several times the blood and expired air concentrations found in others. This bimodal distribution has also been reported by Putz et al. (47).

Kegel et al. (48) and McNally (49) reported clinical cases of acute poisoning from leaking refrigerators.

Hansen et al. (50) observed the effects of excessive exposure after a spill. Fifteen workers manifested signs of dizziness, blurred vision, incoordination, and GI complaints. Recovery was complete in 10–30 days. Although rarely in the United States, some methyl chloride may still be used as a refrigerant in other countries. A 1976 report describes poisoning of four members of a family due to a leaking refrigerator (45).

Klimkova-Dentschova (51) observed the neurological pictures in 100 workers. The report stated: “Involvement of the internal organs (kidney, optic disturbances) was absent even where nervous and mental changes indicated a severe form of poisoning.” Levels of exposure were not indicated.

Numerous other studies described the effect of acute exposure, but reports of chronic low level exposure are less common. One report described the nonspecific nature of six cases and reports many of the symptoms discussed earlier (52). Recovery seemed to occur in all subjects, but often several months were required. Another report of eight cases is given by MacDonald, who described similar effects, ascribing them to exposure below 100 ppm in one subject, and to have resulted in permanent injury in another. However, there is uncertainty in the exposure estimates.

Exposure to methyl chloride in excess of 200 ppm resulted in serious disturbances in CNS function in a husband and wife who stored foamed plastic panels in their new house (53). The house was of tight, energy-efficient construction (0.06 air changes/h), and the foam sheets were being stored prior to installation. After several days, complete exhaustion, labyrinthitis, and unsteadiness of gait were observed. Recovery appeared to have been complete. It was concluded that the foam panels had not offgassed adequately before being placed in the house.

An epidemiological study by Holmes (54) is discussed in Section 1.4.2.3.5.

1.4.2.2 Clinical Cases Numerous case reports of humans exposed to methyl chloride vapors as a result of industrial leaks describe neurological effects (43). In general, symptoms develop within a few hours after exposure and include fatigue, drowsiness, staggering, headache, blurred and double vision, mental confusion, tremor, vertigo, muscular cramping and rigidity, sleep disturbances, and ataxia. The symptoms may persist for several months, and depression and personality changes may develop. In some cases, complete recovery occurs, but in severe poisoning, convulsion, coma, and death are possible. Microscopic examination of the brain of an individual who died following an exposure showed accumulation of lipoid-filled histiocytes in the leptomeninges of the hemispheres, hyperemia of the cerebral cortex, and lipoid droplets in the adventitia cells of the capillaries throughout the brain (55). Exposure to animals also results in neurological effects. Rats, mice, rabbits, guinea pigs, dogs, cats, and monkeys exposed to chloromethane until death all displayed signs of severe neurotoxicity (41, 42).

Exposure to high concentrations of methyl chloride can result in moderate to severe neurological effects. Refrigerator repairmen developed neurological symptoms after exposure from leaks at concentrations as high as 600,000 ppm, but there were no deaths (56).

Numerous case reports of humans exposed to methyl chloride describe symptoms of nausea and vomiting, but these symptoms may be associated with the concomittant CNS toxicity (43). Generally animal studied do not support gastrointestinal damage.

Case reports of humans exposed to methyl chloride describe indicators of renal toxicity, such as albuminuria, increased serum creatinine and blood urea nitrogen, proteinuria, and anuria (45). Animal studies generally support kidney injury.

1.4.2.3 Epidemiology Studies A retrospective epidemiologic study of workers exposed in a butyl rubber manufacturing plant found no statistical evidence that the rate of death due to diseases of circulatory system was increased when compared to U.S. mortality rates (54) discussed in the next section.

1.4.2.3.5 Carcinogenesis A retrospective epidemiology study of male workers exposed to chloromethane in a butyl rubber manufacturing plant produced no statistical evidence of cancer deaths (54).

Rafnsson and Gudmundsson (57) reported excess mortality from cancer in a long-term follow-up after an acute high level exposure of crew members to a leaking refrigerator. The authors reported an excess mortality from all causes associated with chloromethane exposure, including an elevated mortality from all cancers and lung cancer, but conclusions from the study are limited because of possibly faulty assumptions with regard to matching the control group.

The USEPA has not assigned a carcinogenicity classification. Health advisories published by the EPA Office of Water assign chloromethane to cancer group C, which indicates that the substance is a possible human carcinogen. IARC has classified chloromethane as group 3 (not classifiable). The NTP has not classified the chemical with regard to carcinogenicity. NIOSH recommends that methyl chloride be treated as a potential occupational carcinogen.

1.4.2.3.6 Genetic and Related Cellular Effects Studies Uniquely, human erythrocytes contain a glutathione transferase isoenzyme that catalyzes the conjugation of glutathione with methyl chloride. There are two distinct human subpopulations based on the amount or forms of this transferase. They are known as “fast metabolizers” and “slow metabolizers” or *conjugators* and *nonconjugators*. There is considerable variation among ethnic groups and this aspect has significant effect on toxicity.

1.5 Standards, Regulations, or Guidelines of Exposure

ACGIH TLV TWA is 50 ppm (103 mg/m^3) and the ACGIH TLV STEL is 100 ppm (207 mg/m^3).

NIOSH considers methyl chloride a carcinogen and recommends that exposures be limited to the lowest feasible concentration; NIOSH IDLH is 2000 ppm. The OSHA PEL is 100 ppm, the ceiling is 200 ppm and 300 ppm is 5-min the maximum peak in any 3 hours.

In the provisions of the Clean Air Act Amendments (CAAAs) of 1990, methyl chloride is among 189 compounds designated as hazardous air pollutants.

Regulations in other countries include Australia—50 ppm, STEL 100 ppm (1990); (Former Federal Republic of) Germany—50 ppm, short-term level 100 ppm, 30 min, 4 times per shift, group 3, Possible human carcinogen, pregnancy group B, a risk of damage to the developing embryo or fetus must be considered to be probable and cannot be excluded when pregnant women are exposed under conditions where MAK and BAT values are observed (1998); Sweden—50 ppm, 15-min short-term

value 100 ppm (1990); United Kingdom—50 ppm, 10-min STEL 100 ppm (1991); U.S. NIOSH—lowest feasible concentration, carcinogen, IDLH 2000 ppm.

Saturated Methyl Halogenated Aliphatic Hydrocarbons
Jon B. Reid, Ph.D., DABT

2.0 Methyl Bromide
2.0.1 CAS Number:
[*74-83-9*]
2.0.2 Synonyms:
Monobromomethane; bromomethane
2.0.3 Trade Names:
Dowfume MC-2; Dowfume MC-33; Edco; Embafume; Halon 1001, Iscobrome; MB, MBX, MEBR; Metafume; Methogas; Pestmaster; Profume; Rotox; Terr-O-Gas 100; Zytox
2.0.4 Molecular Weight:
94.95
2.0.5 Molecular Formula:
CH_3Br
2.0.6 Molecular Structure:

2.1 Chemical and Physical Properties

2.1.1 General

Physical state	Colorless gas
Specific gravity	1.732 (0/0°C)
Melting point	–93.66°C
Boiling point	3.56°C
Solubility	0.09 g/100 mL water at 20°C; soluble in ethyl ether, ethanol, benzene, carbon tetrachloride
Flammability	Practically nonflammable; flame propagation is in the narrow range of 13.5–14.5% by volume in air; ignition temperature is 537°C

1 mg/L = 257 ppm and 1 ppm = 3.89 mg/m^3 at 25°C, 760 torr

2.1.2 Odor and Warning Properties Methyl bromide has practically no odor or irritating effect and therefore no warning, even at physiologically hazardous concentrations. At high concentrations it has a chloroform odor. Some mixtures of methyl bromide used for fumigation contain chloropicrin as another active ingredient or as a warning agent. The chloropicrin may give warning of significant concentrations of methyl bromide from leaking containers; however, experience has shown that chloropicrin vapor may disappear before methyl bromide vapor and therefore the warning properties are lost. Charcoal-gas mask canisters also preferentially remove chloropicrin. With prolonged use,

methyl bromide may penetrate the charcoal in harmful concentrations with no odor of chloropicrin.
2.2 Production and Use
Methyl bromide is used in ionization chambers, refrigerants, fire extinguishing agents, organic synthesis as an methylating agent, preparation of quarternary ammonium compounds, organotin derivatives, and antipyrine. It is also used as a soil and space fumigant; in the disinfestation of potatoes, tomatoes, and other crops; as an acaricidal fumigant; as an industrial solvent for extraction of plant oils; as a fungicide, herbicide, nematocide, rodenticide, and insecticide; and in degreasing wool, nuts, seeds, and flowers. Other uses include food sterilization for pest control in fruits, vegetables, and dairy products.

Much environmentally occurring methyl bromide is the result of biologic activity, particularly by seaweed (58). Automobile exhaust from leaded gasoline was formerly a significant source.

The largest single industrial use for methyl bromide is as a fumigant used to treat soil, a wide range of grains, and other commodities, mills, warehouses, and houses. The principal problems have been associated with the fumigating personnel and control of other people who may enter the area being fumigated.

Some methyl bromide is used as a chemical intermediate. In the United States use as a refrigerant is no longer significant. It once was used as a fire-extinguishing agent, particularly in automatic equipment for the control of engine fires on aircraft, but because of the toxicity of this material, its use as a fire extinguisher must be limited to specialized applications. A number of reports of injury from use as a fire extinguisher can be found in the European literature.
2.3 Exposure Assessment
Because methyl bromide is a gas at ordinary temperatures and has essentially no warning properties, dangerous concentrations may rapidly accumulate in a work area without warning to the operator. Owing to the high volatility, one can readily attain high concentrations in a work atmosphere. Such high concentrations can be attained without recognition. These factors and the fact that methyl bromide is quite toxic create a potentially high hazard. It must be used only by individuals who are well acquainted with proper methods of handling and fully cognizant of the consequences of exposure to excessive amounts. In industrial operations regularly using methyl bromide, it is advisable to have some kind of warning or monitoring system for continuous analysis of the air. In fumigation operations, suitable analytic equipment is required and personnel must have proper protective equipment for the operation. Charcoal used in respiratory protective devices has limited capacity to remove methyl bromide. A survey by NIOSH estimated that between 1981 and 1983, about 105,000 workers were exposed to methyl bromide. The primary route of potential occupational exposure is inhalation, although some intoxications have also been reported after dermal exposure.

2.3.3 Workplace Methods NIOSH Method 2520 is recommended for determining workplace exposures to methyl bromide (11).

2.3.5 Biomonitoring/Biomarkers Blood bromide levels in humans are elevated by exposure to methyl bromide and may be useful in establishing whether exposure to methyl bromide has occurred, but bromide ion determination is not totally satisfactory for quantifying exposure. Numerous other sources of bromide, such as food, water, and medications, may interfere, particularly at the low blood levels that result from repeated exposure to concentrations considered acceptable for occupational exposure. “Normal” bromide ion concentration is below 1 mg/100 mL of blood serum, in the absence of the above dietary sources. A concentration of 5 mg/100 mL may be considered evidence that exposure to methyl bromide has occurred; 15 mg/100 mL of blood is consistent with toxic symptoms. Because bromide from ingested drugs may reach 150 mg/100 mL% or more, it is obvious that the source of the bromide must be considered in interpreting the analytic results
2.4 Toxic Effects
Methyl bromide is toxic by inhalation, by ingestion, or through skin absorption. It is readily absorbed through the skin. It is irritating to the eyes, skin, mucous membranes, upper respiratory tract, and lungs. It is narcotic at high concentrations. It may cause lacrimation from irritation of the eyes. When

heated to decomposition it may emit toxic fumes of carbon dioxide. It may also emit toxic fumes of hydrogen bromide.

Methyl bromide is one of the most toxic of the common organic halides and is reported to be 8 times more toxic on inhalation than ethyl bromide. Moreover, because of its greater volatility, it is a much more frequent cause of poisoning. Fatal poisoning has always resulted from exposure to relatively high concentrations of methyl bromide vapors (8600–60,000 ppm). Nonfatal poisoning has resulted from exposure to concentrations as low as 100–500 ppm.

Inhalation is by far the most significant route of exposure, although serious skin burns may occur from confined contact, especially under clothing or in shoes and gloves. Absorption through the skin has been reported, but very high vapor concentrations were involved, and some inhalation may have occurred as leakage around the respirators. Unless the concentration is high enough to cause rapid narcosis and death from respiratory failure, the most striking response to exposure at high concentrations will be lung irritation with congestion and edema. These symptoms are observed in both animals and humans and often develop into a typical confluent bronchial pneumonia. At lower levels of exposure, this lung condition may account for delayed deaths. If it leads to secondary infection, the delay may be a matter of days. At threshold concentrations, this lung condition is not observed. The response is almost entirely referable to the nervous system and usually shows up only after prolonged and repeated exposures. Excitation and even convulsions have been observed in animals; but if they survive repeated exposures, the later signs are paralysis of the extremities. Paralysis of the extremities is most typical of threshold toxic response from repeated exposures over a long period of time. Animals that have been seriously paralyzed have recovered, although the recovery is somewhat slow. Human experience indicates that there is a high probability of complete recovery although the time necessary may be quite long, even months. Several reviews are available (59–61).

2.4.1 Experimental Studies 2.4.1.1 Acute Toxicity Because methyl bromide is a gas at 4°C, oral toxicity is of minor concern. Nevertheless oral doses of 60–65 mg/kg were reported to be the minimal amount lethal to rabbits (62); a dose of 100 mg/kg, to be lethal to rats 5–7 h after exposure (63); and 214 mg/kg, to be an oral LD_{50} (64).

Toxic response appears to differ significantly between test animal strains and species (65). The 8 h survival dose for rats was reported to be approximately 1 mg/L (260 ppm). Rats survive 5200 ppm for 6 min and 2600 ppm for 24 min. The 6-h survival dose for rabbits is approximately 2 mg/L (520 ppm). The authors studied rats, rabbits, guinea pigs, and monkeys. They described the response of most animals as typically one of lung irritation. If the exposure was severe enough, this resulted in lung edema and usually a typical confluent bronchial pneumonia.

An 8 h LC_{50} of 302 ppm (267–340 ppm) was determined for male rats. (Sprague–Dawley/Charles River Japan) (66). Deaths were accompanied by lung hemorrhages and convulsions.

Mice were exposed for 1 h to concentrations of 0.87–5.93 mg/L (220–1500 ppm). An LC_{50} of 1200 ppm was determined for the 1 h exposures. At ≤1.72 mg/L no toxic response was noted. Exposure for 1 h to 2.2–2.7 mg/L was reported to cause decreased lung and liver weight. Above 3.5 mg/L kidney lesions were observed. Mortality occurred above 3.82 mg/L (980 ppm) accompanied by weight loss and other clinical signs. At still higher concentrations, liver lesions, decreased motor coordination, tremors, seizures, paralysis, and other effects also occurred. Gluthathione depletion and an increase in blood bromide were observed and related to exposure concentration (67).

Rats were exposed 6 h/day for 5 days to 0, 90, 175, 250, or 325 ppm in order to study histopathology (68). Exposure to 325 ppm required premature sacrifices after 4 days, but the other groups were anesthesized and perfused 1–2 h after their fifth exposure. Clinical signs confined to the 250- and

325-ppm groups were diarrhea, hemoglobinuria, gait disturbances, and convulsions. At all concentrations except 90 ppm there were degenerative changes in the adrenals, cerebellar granular cells, and nasal olfactory epithelium. Hepatocellular degeneration was confined to the 250- and 325-ppm groups. The kidneys and epididymides were not affected, but cerebral cortical degeneration and minor testicular changes were seen in the 325-ppm group.

Male rats were exposed 4 h/day to four different concentrations of methyl bromide gas, 150 ppm for 5 days/week, 11 weeks (55 times), and to 200, 300, or 400 ppm for 6 weeks (30 times) (69). Body weight, hematology, organ weight, residual bromide concentrations, and histopathology of several organs were studied. In addition, a 4 h acute LC_{50} was determined to be 780 ppm with 95% confidence limits of 760–810 ppm. As in other studies, a remarkably steep dose response was observed with 0 and 100% lethal concentrations of 650 and 900 ppm. Neurological signs were manifest at 300 and 400 ppm with necrosis of the brain at 400 ppm. Necrosis of the heart was apparent at all concentrations with little response in other organs. Certain blood enzyme levels generally considered to be associated with pathological changes in the heart were not changed at either 150 or 200 ppm, but at 300 and 400 ppm aspartic transaminase, lactic dehydrogenase, LAP (not defined by the authors), and hydroxybutyrate dehydrogenase were elevated.

2.4.1.2 Chronic and Subchronic Toxicity Oral Exposure According to IRIS (online), the USEPA determined critical effect for oral exposure as epithelial hyperplasia of the forestomach with an NOAEL of 1.4 mg/kg/day [LOAEL: 7.1 mg/kg/day] and a RfD of 1.4×10^{-3}. The previous *oral* RfD [4.0×10^{-4} mg/kg/day] was based on the inhalation studies by Irish et al. (65). According to the EPA (IRIS), inhalation studies are inappropriate for oral risk assessment extrapolation for bromomethane because portal-of-entry effects are observed for both the inhalation route (lung pathology) and oral route (stomach hyperplasia). In addition, neurological effects reported after inhalation exposures have not been reported after oral exposures.

The current EPA reference dose (RfD) for oral exposure is based on the Danse et al. (64) study, on carcinogenic effects in the rat forestomach for the oral route of exposure. Treatment of groups of 10 male and 10 female Wistar rats by gavage 5 days/week for 13 weeks with bromomethane at 0, 0.4, 2, 10, or 50 mg/kg resulted in severe hyperplasia of the stratified squamous epithelium in the forestomach at a dose of 50 mg/kg/day and slight epithelial hyperplasia in the forestomach at a dose of 10 mg/kg/day. At the 50-mg/kg/day dose level, decreased food consumption, body weight gain, and anemia were observed in the male rats. Slight pulmonary atelectasis was observed, at the two higher dose levels, in both male and female rats; however, the investigators stated that the possible inhalation of bromomethane-containing oil during the gastric intubation procedure might have been responsible for this effect. No neurotoxic effects were observed at any dose level tested. Renal histopathology was not evaluated. Adverse effects were not observed at 0.4 or 2 mg/kg. This 90-day gastric intubation study was conducted in groups of Wistar rats (10 of each sex) given 0, 0.4, 2, 10, or 50 mg/kg methyl bromide in peanut oil. Findings included squamous cell papillomas (2 males) and carcinomas (7 males and 6 females) of the forestomach at the 50-mg/kg dose level.

In a similar study by Boorman et al. (70) 6-week-old male Wistar rats were gavaged 5 times/week at 50 mg/kg, either for 13 weeks with a 12-week recovery period or continuously for a period of 25 weeks. At week 13, inflammation, acanthosis, fibrosis, and a high incidence of pseudoepitheliomatous hyperplasia of the forestomach were observed. At week 25, rats previously treated with methyl bromide still exhibited more severely perplastic lesions than vehicle controls. One of 15 rats showed malignancy, which was considered an early carcinoma. However, there was a clear regression of the overall incidence of proliferative lesions at the end of the recovery period.

Mitsumori et al. conducted a 2-year oral chronic toxicity/carcinogenicity study (71) in F344 rats fed a diet containing 80–500 ppm total bromide following fumigation with methyl bromide. Of 60 male and 60 female rats per dosage group, 10 were sacrificed at 52 and 104 weeks, respectively, in order to perform urine analysis, hematology, blood chemistry, and pathology. Rats killed in moribund

condition or found dead and all survivors sacrificed at the end of the 2-year dosing period were examined for pathologic lesions. No marked toxic effects were observed at any of the dose levels administered except for a slight decrease in body weight gain in males fed the 500-ppm methyl bromide-containing diet at week 60 onward. The conclusion was that residues of ≤ 500 ppm total bromide in the diet fumigated with methyl bromide are *not carcinogenic* in F344 rats of either sex. The NOEL in males was given as 200 ppm [6.77 mg total bromide/kg/day]. None was determinable from the data in females because they showed slightly higher incidence of focal fatty change of the adrenal cortex than controls. However, control values in this study were lower than historical controls with regard to this very common lesion in aging female F344 rats.

Inhalation Exposure For inhalation, the EPA (IRIS) considers the *critical effect* for chronic inhalation to be degenerative and proliferative lesions of the olfactory epithelium of the nasal cavity with a LOAEL of 11.7 mg/m^3 (3 ppm), adjusted to 2.08 mg/m^3, giving a RfC of 5.0×10^{-3} based on a 29-month rat inhalation study by Ruezel in 1987 and 1991 (72, 73) where a series of inhalation toxicity studies of bromomethane were conducted under the sponsorship of the National Institute of Public Health and Environmental Hygiene of the Netherlands. In a chronic inhalation study, 50 male and 60 female Wistar rats were exposed to 0, 3, 30, or 90 ppm (0, 11.7, 117, or 350 mg/m^3, respectively) 98.8% pure bromomethane 6 h/day, 5 days/week (duration-adjusted concentrations are 0, 2.08, 20.9, or 62.5 mg/m^3, respectively) for up to 29 months. Three satellite groups of 10 animals/sex/exposure level were sacrificed at 14, 53, and 105 weeks of exposure. Animals were observed daily, and body weight was recorded weekly for the first 12 weeks and monthly thereafter. Hematology, clinical chemistry, and urinalyses were conducted at 12–14 weeks and 52–53 weeks in the satellite groups. Eleven organs were weighed at necropsy, and approximately 36 tissues, including the lungs with trachea and larynx; 6 cross sections of the nose; heart; brain; and adrenal glands were examined histopathologically. The test atmosphere was measured by gas chromatography every 30 min during exposure. Males and females exposed to 90 ppm exhibited decreased body weight gains; no treatment-related changes in hematological, biochemical, or urine parameters were observed. A significant concentration-related decrease in relative kidney weights was reported in the 30- and 90-ppm males. A decrease in mean absolute brain weight was reported to occur in the 90-ppm females at weeks 53 and 105, but there was no change in relative brain weight or in brain histology. Microscopic evaluation revealed that the nose, the heart, and the esophagus and forestomach were the principle targets of bromomethane toxicity in this study. Very slight to moderate hyperplastic changes in the basal cells accompanied by degeneration in the olfactory epithelium in the dorsomedial part of the nasal cavity were observed in all exposed groups of both sexes at 29 months of exposure. At the lowest concentration, the lesion is described as very slight. These changes were concentration-related in both incidence and severity and were statistically significant at 29 months. Incidence of basal cell hyperplasia in control, 3-, 30-, and 90-ppm groups were 4/46, 13/48, 23/49, and 31/48 in males and 9/58, 19/58, 25/59, and 42/59 in females, respectively. Slight increases in incidence of basal cell hyperplasia in the 30- and 90-ppm groups (n = 7–10) at 53 and 105 weeks were not statistically significant. Lesions in the heart were statistically significant in the males (cartilaginous metaplasia and thrombus), and the females (myocardial degeneration and thrombus) exposed to 90 ppm. The authors attributed part of the increased mortality in the high concentration animals to the cardiac lesions. A statistically significant increase in hyperkeratosis of the esophagus was observed in the 90-ppm males after 29 months of exposure. Slight increases in forestomach lesions were not statistically significant. No effects were observed in the tracheobronchial or pulmonary regions of the respiratory tract. No other exposure-related effects were noted. Based on these results, a LOAEL of 3 ppm for nasal effects was established.

Male Sprague–Dawley rats were exposed by inhalation for 24 h at 120 ppm or continuously for 3 weeks at 10 ppm methyl bromide, which resulted in a dose-dependent decrease in the concentration of norepinephrine in the hypothalamus, cortex, and hippocampus (74). Typical high dose effects of methyl bromide inhalation in rats (200, 300, or 400 ppm for 6 weeks; 150 ppm for 11 weeks) are liver necrosis with sinusoidal infiltration, degeneration of the kidney tubular epithelium, necrosis of

the excretory pancreas epithelium, focal necrosis of the heart muscle, and necrosis of the brain cortex (69). Additional high dose effects reported were diarrhea, hemoglobinuria, and degeneration of the zona fasciculata of the adrenals and of the olfactory epithelium (68). The latter appeared reversible 10 weeks after cessation of exposure (75). These effects were corroborated by other studies and also in other species (76, 77). Expected similarities between the toxicity profile of methyl bromide and methyl chloride were also noted.

Inhalation by rabbits at 27 ppm methyl bromide for 8 months for a total exposure duration of 900 h resulted in no observable neurotoxic or other adverse signs. At 65 ppm, severe neuromuscular losses were seen. These subsided 6–8 weeks after exposures were terminated (78, 79). Rats exposed at 55 ppm via inhalation of methyl bromide for 36 weeks with a total affective duration of 1080 h showed no signs of a neurologic deficit (79).

In a chronic mouse study, virtually the same lesions were reported as observed in subchronic studies at somewhat lower doses than expected (77). This mouse (77) and rat (73) inhalation bioassay has been performed. These studies show clear mutagenicity but not carcinogenicity under the conditions of the bioasssays. The NTP 2-year inhalation study (77) was carried out with 70 male and female $B6C3F_1$ mice exposed 6 h/day, 5 days/week at 0, 10, 33, or 100 ppm of methyl bromide. After 20 weeks, exposure of the high dose group (100 ppm) was discontinued because of excess mortality (31% in males, 8% in females). Similar lesions were observed as reported in Section 2.4.1.2 of this TLV documentation, without the occurrence of excess neoplastic lesions. A NOEL was not presented in the NTP (77) study, but there were no effects at 33 ppm.

Male and female Wistar rats were exposed by inhalation 6 h/day, 5 days/week for 29 months at 0, 3, 30, or 90 ppm methyl bromide (73). Interim sacrifices were conducted after 3, 12, and 24 months. Excess mortality was first observed at 114 weeks in the high dose group. Dose-dependent increases in the incidences of degenerative and hyperplastic changes of the nasal olfactory epithelium were observed. The lesions were characterized as very slight, slight, or moderate. A statistically significant difference was found between controls and the low dose group (3 ppm) at the end of the exposure period (29 months) in terms of total lesions. At the highest dose level, effects (thrombi, myocardial degeneration, hyperkeratosis of the esophagus and forestomach) were observed.

2.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Methyl bromide is converted to bromide ion, *in vivo*. At all concentrations that could be tolerated by animals, inhaled methyl bromide was rapidly eliminated (65). Circulating bromide concentrations in untreated rabbits were approximately 10 ppm and those in rabbits with methyl bromide–induced paralysis were approximately 110 ppm (65).

The blood bromide level tends to correlate with the severity of the clinical signs (80).

Although methyl bromide is metabolized to methanol, the quantities of methanol produced are insufficient to account for methyl bromide's toxicity (65, 80). The toxicity of methyl bromide is with the intact molecule. The bromide ion has been shown to be much slower in leaving the body following exposure to methyl bromide. A half-life of 5 days has been reported for rats (66). The investigators also concluded that neither bromide ion nor methanol was involved in the toxicity but rather the parent compound or an incorporation of the methyl group into some other substance was involved. Bonnefoi et al. (81) have shown that glutathione depletion occurs and may be related to subsequent toxic effects.

Methyl bromide showed a significant non-enzymatic conjugation in human erythrocyte cytoplasm. In the majority of the subjects there was also enzymatic conjugation but a minority lack this enzymatic activity. Methyl bromide had a higher affinity for the conjugating enzyme(s) (possibly erythrocyte glutathione transferases) than methyl chloride or methyl iodide (82).

2.4.1.4 Reproductive and Developmental Adult male F344 rats were exposed to 0 or 200 ppm 6 h/day for 5 days and examined after 1, 3, 5, 6, 8, 10, 17, 24, 38, 52, and 73 days. The only effects were a transient decrease in plasma testosterone and testicular nonprotein sulfhydryl. In contrast to the very specific effects of methyl chloride there were no lasting effects on sperm quality or spermatogenesis. However, Eustis et al. (76) reported testicular degeneration in male rats exposed to 160 ppm 6 h/day, 5 days/week for 3–6 weeks, and Kato et al. (69) reported testicular atrophy after 6 weeks of repeated 4 h/day, 5 days/week exposures to 400 ppm but not 300 ppm.

In an abstract reporting preliminary results in the F_0 generation of a two-generation reproduction study in CD rats (83), there were no reproductive effects reported after repeated 6 h/day, 5 day/week exposures to 0, 3, 30, or 90 ppm.

There are little data to indicate anything but extremely low, if any, potency for methyl bromide for teratogenic/reproductive toxicity. Although methyl bromide, acutely and subchronically, causes varying degrees of testicular alterations and transiently reduced plasma testosterone concentrations, inhalation exposure of male Fischer 344 rats for 6 h/day at 200 ppm methyl bromide for 5 days had "no lasting effect on sperm quality or spermatogenesis" in this rat strain (75). In a study by Sikov et al. (84), neither maternal or fetotoxic nor teratogenic effects were observed in Wistar rats exposed by inhalation to methyl bromide 5 days/week at 20 and 70 ppm for 3 weeks prior to mating and during gestation.

2.4.1.5 Carcinogenesis The USEPA consideres the animal data for carcinogenesis as "Inadequate" (IRIS) (5). Bromomethane was administered by gavage to groups of 10 male and female Wistar rats (64). Animals were administered doses of 0, 0.4, 2, 10, or 50 mg/kg/day bromomethane in arachis oil 5 days/week for 13 weeks, at which time the experiment was terminated. There was an apparent dose-related increase in diffuse hyperplasia of the forestomach. The authors reported a forestomach papilloma incidence of 2/10 in the high dose males and forestomach carcinoma incidences of 7/10 and 6/10 in the high dose males and females, respectively. These results were subsequently questioned (85, 86). A panel of NTP scientists reevaluated the histological slides and concluded that the lesions were hyperplasia and inflammation rather than neoplasia.

Rosenblum et al. (87) reported a 1-year study in which beagle dogs (4 per treatment group, 6 per control) were provided diets fumigated to residue levels of 0, 35, 75, or 150 ppm bromomethane. No tumors were observed at any dose level; however, there was no indication that the dogs were examined for tumors. In addition, 1-year observation is considered to be inadequate by the EPA for tumor induction in dogs.

Bromomethane is structurally related to *bromoethane* which, when tested in mice and rats of both sexes, has shown clear evidence of carcinogenicity in some cases and equivocal in others. NTP (88) conducted an inhalation bioassay on bromoethane, and the results were recently released in a draft report. Groups of F344/N rats (50/sex) and B6C3F1 mice (50/sex) were exposed to 0, 100, 200, or 400 ppm bromoethane 6 hours/day for 5 days/week. A statistically significant increase in uterine adenomas, adenocarcinomas, or squamous cell carcinomas was observed in female mice exposed to 200 and 400 ppm, indicating clear evidence of carcinogenic activity. Equivocal evidence of carcinogenic activity was reported for male and female rats and male mice. Although alveolar and bronchiolar adenomas or carcinomas and pheochromocytomas were observed in male rats, the incidences were not dose-related and were within the historical ranges for NTP studies. Granular cell tumors of the brain were also observed in male rats and, although not statistically significant, the incidence was higher than historical incidence in either the study lab or NTP studies. The incidence of alveolar/bronchiolar neoplasms in exposed male mice was marginally greater than control or historical incidence. An increased incidence of gliomas in exposed female rats was significant by the trend test; however, the incidence was not significantly greater when compared with the controls in the study and the controls used in NTP studies.

In a rather short oral gavage study, squamous-cell carcinomas were reported to be produced in 13/20 rats dosed 5 days/week with 50 mg/kg body weight (64). Marked diffuse hyperplasia of the epithelium of the forestomach was reported at this level after only 90 days, with less effect at 10 and 2 mg/kg and none at 0.4 mg/kg. However, in rats similarly exposed in a second study (70) with an extended recovery period, it was found that nearly all lesions regressed, suggesting they were not malignant. Furthermore, the 29-month inhalation study in Wistar rats discussed subsequently failed to support the finding of carcinogenicity in the rat forestomach.

In the 29-month study male and female rats were exposed to 0, 3, 30, or 90 ppm of methyl bromide gas 6 h/day, 5 days/week (47). Ten rats per sex were killed at 13, 52, and 104 weeks for interim information. Mortality was increased at week 114 but only in the 90-ppm group, which also had lowered body weights. Increased incidences of degenerative and hyperplastic changes in the nasal olfactory epithelium were observed in a dose-related manner in all groups. The lesions did not appear to progress with time. Exposure to 90 ppm was associated with an increased incidence of thrombi and myocardial degeneration in the heart and hyperkeratosis in the esophagus and forestomach. There was no indication of a relationship between exposure and tumor incidence.

In the a 2-year oral chronic toxicity/carcinogenicity study, Mitsumori et al. (71) concluded that residues of ≤ 500 ppm total bromide in the diet fumigated with methyl bromide are not carcinogenic in F344 rats of either sex. More information on this study was given in Section 2.4.1.2.

2.4.1.6 Genetic and Related Cellular Effects Studies Bromomethane has been shown to produce mutations in *Salmonella* strains sensitive to alkylating agents and to *Escherichia coli* both with and without the addition of a metabolic activation system (89–92). Bromomethane was also mutagenic in a modification of the standard *Salmonella* assay employing vapor-phase exposure (93–96). Bromomethane was observed to be mutagenic for *Drosophila* and for mouse lymphoma cells (89, 91). Methyl bromide is genotoxic in *in vivo* and *in vitro* tests. Positive results were obtained in the *Salmonella* (90, 91), and *Drosophila* (97), gene mutation assays, the sister chromatid exchange (SCE) test with human lymphocytes (97), the test for SCE induction in female mice, and the micronuclei test (98) (the latter two on peripheral erythrocytes).

2.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization In a subsequent study performed by this group (78) that was designed to assess the neurotoxic effects of bromomethane in rabbits with longer-term exposures at low concentrations, male New Zealand white rabbits were exposed to 0 (n = 2) or 26.6 ppm (103 mg/m^3, n = 6) 99% pure bromomethane 7.5 h/day, 4 days/week for 8 months (78). Exposure concentrations were monitored every 12 min by an infrared analyzer. Neurobehavioral tests examined the latency rates of the sciatic and ulnar nerves and the amplitude of the eyeblink reflex of the orbicularis oculi muscle. No other parameters, including respiratory effects, were monitored. No exposure-related neurological effects were observed. As part of this study, the animals exposed to 252 mg/m^3 bromomethane for 4 weeks (79) were allowed to recover for 6–8 weeks and the neurological tests were repeated. The animals demonstrated partial, but not complete, recovery within the 6-week period. Therefore rabbits, which are sensitive to the neurotoxic effects of high level exposures to bromomethane, can tolerate long-term low level exposure to bromomethane, and appear to be able to recover from severe neurological effects after cessation of exposure.

2.4.2 Human Experience According to IRIS, the most common signs of acute intoxication with bromomethane in humans are neurotoxic in nature and include headache, dizziness, fainting, apathy, weakness, tiredness, giddiness, delirium, stupor, psychosis, loss of memory, mental confusion, speech impairment, visual effects, limb numbness, tremors, muscle twitching, paralysis, ataxia, seizures, convulsions, and unconsciousness. Several studies have been conducted on the longer-term effects of occupational exposure to bromomethane. None of these studies can serve as the basis for the derivation of an RfC for bromomethane because of concurrent exposures to other chemicals,

inadequate quantification of exposure levels and/or durations, and other deficits in study design.

Possible symptoms include anorexia, nausea, vomiting, corrosion to the skin, severe skin burns, enlarged liver, kidney damage with development of albuminuria, and in fatal cases, cloudy swelling and tubular degeneration. Central nervous system effects include blurred vision, mental confusion, numbness, and tremors. Death following acute poisoning is usually caused by its irritant effect on the lungs. In chronic poisoning, death is due to injury to the central nervous system. Direct skin contact may cause prickling, itching, cold sensation, erythemia, vesication, damage to peripheral nerve tissue, and delayed dermatitis. It may also cause double vision, dizziness, headache, convulsions, muscular tremors, fatal pulmonary edema, and neurological and GI disturbances. It may cause skin irritation. Other symptoms may include mental excitement, acute mania, bronchitis, pneumonia, and severe eye damage. It may cause abdominal pain and death from respiratory or circulatory collapse. It may also cause unconsciousness leading to a prompt “anesthetic” death, malaise, ataxia, myoclonus, exaggerated (or absent) deep reflexes, positive Romberg's sign, paroxysmal abnormalities of the EEG, great agitation, change of personality, coma, and mild euphoria. Exposure to this compound may also cause muscle weakness, loss of coordination and gait, hyperthermia, hepato- and nephrotoxicity, behavioral changes, paralysis of extremities, delirium, epileptiform attacks, and skin lesions. It may cause respiratory tract irritation, organic brain syndrome, psychological depression, seizures, prominent cerebellar and parkinsonian signs, renal failure due to tubula necrosis, jaundice, elevations of liver enzyme activity in serum and abnormal liver function, lassitude, slurring of speech, staggering gait, diplopia, epileptiform convulsions, perhaps with a Jacksonian-type of progression, rapid respirations, cyanosis, pallor and collapse, areflexia, impaired superficial sensation, absent or hypoactive distal-tendon reflexes, and bronchopneumonia after severe pulmonary lesions. It may also cause severe mucous membrane burns. Other symptoms may include DNA mutations and large chromosome alterations and congestion with coughing, chest pain, shortness of breath, confusion, shaking and unconsciousness, severe pulmonary irritation and neurotoxicity, narcosis at high concentrations, vertigo, tremor of the hands, dyspnea, hallucinations, anxiety, inability to concentrate, conjunctivitis and dry, scaling, and itching dermatitis. It may also cause lacrimation from irritation of the eyes, transient dimming of vision and blindness for 12 h, nystagmus on lateral gaze, delirium, apathy, and aphasia, edema of the papilla, and punctiform hemorrhages may be found, as well as optic atrophy. In addition, it causes sleepiness, digestive problems, loss of stability, lack of motor coordination, sensorial problems, and impaired hearing. Somnolence, permanent brain damage, lethargy, and sensory disturbances can occur. It may cause anuria, hyperactivity, blood pressure fall, papilledema, fainting attacks, and bronchospasm. It may also cause retinal and submucous hemorrhages, stomach congestion, and congestion of the brain with multiple hemorrhages associated with degenerative changes, such as necrosis.

2.4.2.1 General Information Reports of a toxic absorption of methyl bromide gas through the skin have been published, but very high exposure concentrations (8000–10000 ppm) were involved and it is possible some leakage around or through respiratory protective devices occurred (99). Obviously skin contact with the liquid and vapor must be minimized in addition to prevention of vapor exposure.

There are difficulties in handling methyl bromide in the drug industry. Repeated splashes on the skin resulted in severe skin lesions. Severe cases showed “vesicles or blebs.” In a less rigorous exposure, severe itching dermatitis was observed. One report by Longley and Jones (100) describes serious systemic effects following gross skin contact with liquid methyl bromide, but inhalation may have been significant despite the absence of lung damage. Methyl bromide may cause difficulty when it is held in contact with skin by clothes. This is a special problem with gloves and shoes. In the case of shoes, it is suspected that a fairly high concentration of vapor near the floor may actually be absorbed into the leather and cause skin irritation. Spills onto or into a shoe may cause a severe burn if allowed to remain in contact with the skin. When methyl bromide is handled, care should be taken to avoid splashes onto the clothing or shoes. When there is a fairly high vapor concentration, as in an accidental spill, care should be taken to prevent seepage into the shoes or on protective clothing, and exposure to the vapor should be minimized.

Liquid methyl bromide can cause severe corneal burns but the vapors do not appear to be painful. Furthermore, a full-face respirator should always be used if vapor concentrations are significant; hence the eyes will be protected from exposure.

Numerous reports attest to the high toxicity of methyl bromide to humans. Many reports indicate failure to use reasonable recommended handling precautions. The symptoms observed in humans from acute exposure have been reported by a number of authors whose reports have been reviewed by von Oettingen (59, pp. 15–30). The early symptoms may be a feeling of illness, headache, nausea, and vomiting. Tremors and even convulsions may be observed, much as they are in animals, as well as lung edema and an associated cyanosis. If the patient survived an acute exposure for the first 2 or 3 days, the probability of complete recovery was very high.

Observations of 10 cases acutely and chronically exposed have been summarized by Hine (101) and electroencephalographic studies on seven cases by Mellerio et al. (102).

2.4.2.2 Clinical Cases Cases of severe methyl bromide poisoning in humans, some of them fatal, were frequently reported. For example, von Oettinger (59) recorded 47 fatal and 174 nonfatal cases of methyl bromide intoxication between 1899 and 1952. Acute poisoning was characterized by lung irritation. The toxicity was manifested as paralysis of extremities, delirium, convulsions, and even typical epileptiform attacks. Some of these symptoms were persistent, and recovery occurred in a matter of months, sometimes incompletely with permanent disability. In all cases, the conditions of exposure are inadequately described, neither the methyl bromide concentration nor the exposure duration are exactly known. However, by retrospective estimate, the methyl bromide concentration could have been as high as 60,000 ppm (103) in some instances.

Severe poisoning with some fatalities resulted from soil disinfection by injection of methyl bromide into greenhouse soil (104). These workers measured methyl bromide levels following application rates ranging from 30–3000 ppm. They found peak values of 200 ppm persisting for a few seconds on initial injection with airborne levels above the soil declining to 4 ppm 5 days posttreatment. Tilling the soil can produce exposures at 15 ppm as long as 9 days after soil treatment (105). Tourangeau and Plamondon (106) reported that tests made in date-processing and date-packing houses, where a number of employees had been stricken, showed concentrations ranging up to 100 ppm in the general workroom air, up to 500 ppm near the walls of ineffectively sealed chambers, and over 1000 ppm at the breathing zone of workers entering the chamber to remove the fumigated fruit. Tourangeau and Plamondon (36, 106) found concentrations up to 390 ppm in a plant where one fatal and one nonfatal case of intoxication occurred. Hine (101) reported concentrations of about 100 ppm in plants where two of his clinical cases were found. Johnstone (107) reported mass poisoning (34 cases) in the date-packing industry. The industrial hygiene survey conducted by the California Department of Health, Division of Industrial Hygiene, indicates that the packers were exposed to less than 50 ppm; however, during the purging of a fumigation chamber, the methyl bromide concentrations in the packing room reached 100 to 500 ppm. Watrous (108) described nausea, vomiting, headache, skin lesions, and symptoms of mild systemic poisoning in workers (90 people) exposed for 2 weeks at concentrations generally below 35 ppm.

Liquid methyl bromide may penetrate through all articles of clothing and may cause superficial burns with much vesication when in contact with skin. Three authors (99, 100, 109) demonstrated the possibility of absorption by the skin of toxic quantities of methyl bromide. Longley and Jones (100) reported severe skin irritation in workers fumigating a medieval castle. Six people were occupationally exposed to ~ 35 g/m^3 (9000 ppm) methyl bromide during a 40-minute fumigation process in spite of adequate airway protection. After a few hours, all fumigators developed sharply demarcated erythema with multiple vesicles and large bullae. Particularly affected were the axillae, groin, and abdomen. Histopathological examination of early skin lesions revealed necrosis of keratinocytes, severe edema of the upper dermis, subepidermal blistering, diffuse infiltration of

neutrophils, and to a lesser extent, eosinophils. Two of the patients developed an urticarial rash about one week post exposure. These late lesions showed the combined features of spongiotic dermatitis and urticaria. No immunopathology was observed. The skin returned to normal in all workers after 4 weeks except for some residual hyperpigmentation. Average plasma bromide levels immediately following exposure (9 mg/L) and 12 h postexposure (6.8 mg/L) strongly suggest dermal absorption of methyl bromide.

2.4.2.2.5 Carcinogenesis Assessment of EPA Classification D (Not classifiable as to human carcinogenicity on the basis of inadequate human and animal data) was based on a single mortality study from which direct exposure associations could not be deduced and studies in several animal species with too few animals, too brief exposure, or observation time for adequate power. A prospective mortality study was reported for a population of 3579 white male chemical workers. The men, employed between 1935 and 1976, were potentially exposed to 1,2-dibromo-3-chloropropane, 2,3-dibromopropyl phosphate, polybrominated biphenyls, DDT, and several brominated organic and inorganic compounds (110). Overall mortality for the cohort, as well as for several subgroups, was less than expected. Of the 665 men exposed to methyl bromides (the only common exposure to organic bromides), two died from testicular cancer, as compared with 0.11 expected. This finding may be noteworthy as testicular cancer is usually associated with a low mortality rate. Therefore, there could be more cancer cases than there appear to be based on mortality. The authors noted that it was difficult to draw definitive conclusions as to causality because of the lack of exposure information and the likelihood that exposure was to many brominated compounds.

2.5 Standards, Regulations, or Guidelines of Exposure

OSHA PEL	In 1989, OSHA established a PEL TWA of 5 ppm, with a skin notation, for methyl bromide. This limit was promulgated to protect workers from the significant risk of incapacitating neurotoxic disease and other systemic effects. As a consequence of the 1992 decision by the U.S. Court of Appeals for the Eleventh Circuit the PELs promulgated under the 1989 rulemaking where vacated; however, it currently has a ceiling limit of 20 ppm, with a skin notation.
NIOSH REL/IDLH	The NIOSH REL for methyl bromide is an exposure to the lowest feasible limit. NIOSH based the REL on its position that methyl bromide be considered a potential occupational carcinogen. NIOSH did not concur with the 1989 PEL and recommended that methyl bromide be addressed in a full section 6(b) rulemaking. NIOSH established an IDLH value of 250 ppm (NIOSH Carcinogen) for this substance.
ACGIH Rationale for TLVs that Differ from the PEL or REL	Methyl bromide remains as a substance suspected of carcinogenic potential. In addition, its capacity for dermal absorption, marked neurotoxicity and significant nasal and dermal irritation warrant a greater degree of caution and a reduction in the previously recommended TLV for occupational exposure. The ACGIH TLV for methyl bromide is 1 ppm.

Carcinogenic classification:

IARC	Group 3, Not classifiable as to its carcinogenicity in humans
MAK	Group IIIB, Justifiably suspected of having carcinogenic potential
NIOSH	Carcinogen, with no further categorization.
TLV	A4, Not classifiable as a human carcinogen.

Other nations: Australia—5 ppm, skin (1990); (Former Federal Republic of) Germany—no MAK value, skin, group IIIB, Justifiably suspected of having carcinogenic potential (1996); Sweden—15 ppm, short-term value 10 ppm, 15 min, skin (1990); United Kingdom—5 ppm, 15-min STEL 15 ppm, skin (1997).

2.6 Studies on Environmental Impact:

NA

Saturated Methyl Halogenated Aliphatic Hydrocarbons
Jon B. Reid, Ph.D., DABT

3.0 Methyl Iodide
3.0.1 CAS Number:
[*74-88-4*]
3.0.2 Synonyms:
Iodomethane; monoiodomethane; methyl iodide; Halon 10001; methyl iodine; methyl iodide (iodomethane).
3.0.3 Trade Names:
Halon 10001
3.0.4 Molecular Weight:
141.95
3.0.5 Molecular Formula:
CH_3I
3.0.6 Molecular Structure:

3.1 Chemical and Physical Properties
3.1.1 General Methyl iodide is a colorless liquid that turns yellow, red, or brown when exposed to light and moisture.

Specific gravity	2.279 (20/4°C)
Melting point	–66.5°C
Boiling point	42.50°C
Vapor pressure	400 torr (25°C)
Refractive index	1.5293 (21.0°C)
Percent in “saturated” air	53 (25°C)
Solubility	1 vol/125 vol water at 15°C; soluble in ethanol, ethyl ether
Flammability	Methyl iodide is nonflammable by standard tests in air
UEL, LEL	Not available (UEL, LEL = upper, lower exposure limits)

3.1.2 Odor and Warning Properties Methyl iodide has a sweet ethereal odor with poor warning properties.
3.2 Production and Use
Methyl iodide has had very limited use as a chemical intermediate (methylations), and in microscopy because of its high refractive index, as imbedding materials for examening diatomes, and in tests for pyridine. It has been proposed as a fire extinguisher and insecticidal fumigant. It is a product of natural biologic processes.
3.3 Exposure Assessment
3.3.1 Air: NA

3.3.2 Background Levels: NA

3.3.3 Workplace Methods NIOSH Method 1014 is recommended for determining workplace exposures to methyl iodide (11).

3.4 Toxic Effects

Little new information (from previous editions) was found. Methyl iodide has not been used extensively; therefore, toxicological investigations and experience have been limited. It is primarily a CNS depressant, but there are also indications of lung irritation and kidney involvement from acute exposures. Because radioactive iodine can be released as methyl iodide, the nuclear industry has investigated its absorption, distribution, and to some extent toxicity when inhaled, ingested, and injected.

3.4.1 Experimental Studies 3.4.1.1 Acute Toxicity Few new data have been published since the last edition.

Buckell (111) determined the LD_{50} for rats dosed either subcutaneously or orally to be 150–200 mg/kg of body weight. This author also reported that it would produce a "vestibular burn" if closely held to the human skin. It was indicated that clothing contaminated with methyl iodide should be removed immediately. Johnson (112) reported that the acute oral LD_{50} for mice was 76 mg/kg, but that repeated doses of 30–50 mg/kg were without effect. Single oral doses of 70 mg/kg were lethal to rabbits, but several oral doses of 50 mg/kg were necessary before they caused death. Penetration of methyl iodide through the skin (species not indicated) was reported by Shugaev and Mazkova (113), who considered absorption to be of more concern than local irritative effects. Von Oettingen (33, pp. 30–32), reported a 15-min exposure at 3800 ppm that was fatal to rats. Buckell (111) reported a LC_{50} for mice at 900 ppm (57-min exposure). A 4 h LC_{50} of 232 ppm was reported by Deichman and Gerarde (114).

Bachem (115) studied the response of mice to methyl iodide. His work is summarized in Table 62.1. Chambers et al. (116) reported the lethal concentration for rats for a 15-min exposure to be 22 mg/L in air (3790 ppm). The rats died within a period of 11 days. They showed lung irritation and pulmonary edema. Buckell (111) reported the LC_{50} for mice to be 5 mg/L in air from a 57-min exposure.

Table 62.1. Acute Effects of Methyl Iodide

Concentration		
mg/L	**ppm**	**Response**
454.4	78,700	Rapid narcosis; death after 10-min exposure
105.1	18,100	Death after 30-min exposure
42.6	7340	After 15–50 min, side position, no complete narcosis, death 1 h after beginning of exposure
21.3–31.6	3670–5370	Death after 2–2.5 h of exposure
0.43–4.26	73–730	Death of all animals within 24 h
0.31	54	Death of all animals within 24 h; no marked toxic

symptoms

3.4.1.2 Chronic and Subchronic Toxicity Blank et al. (117) exposed rats by inhalation for 14 weeks at 30 and 60 ppm. Findings were ocular irritation and depressed body weights but no clinical or microscopic pathologic changes. Mortality occurred in 4 weeks at an exposure of 143 ppm.

The studies by Druckery et al. (118) and Poirier et al. (119) are discussed in Section 3.4.1.5.

3.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms The metabolism of methyl iodide is not yet certain, but there appears to be rapid release of iodide ion and methylation of glutathione in rats dosed orally. The process is enzymatically catalyzed (112). Subcutaneous injection produced similar results (120).

In the available abstract (121), more recent investigators indicate that the addition of reduced, but not oxidized, glutathione inhibited methyl iodide toxicity to rat brain neocortical cultures *in vitro*.

Alveolar absorption of inhaled ^{132}I-methyl iodide by humans resulted in retention of 53–93% depending on the concentration inhaled and the rate of respiration (122).

3.4.1.4 Reproductive and Developmental No data on teratogenesis were found.

3.4.1.5 Carcinogenesis Carcinogenicity classification:

IARC Group 3, Not classifiable as to its carcinogenicity to humans.

MAK Group 2, probably human carcinogen.

NIOSH Carcinogen, with no further classification

NTP has not conducted genetic toxicology or long-term toxicology and carcinogenesis effects studies on methyl iodide.

Druckrey et al. (118) reported local sarcomas following weekly subcutaneous injection in BD-strain rats. Strain A mice (a susceptible strain) that were injected with methyl iodide were reported to have a slight but significant increase in the number of lung tumors per mouse.

3.4.1.6 Genetic and Related Cellular Effects Studies Mutagenic tests on *Salmonella* have been reported by McCann et al. (123) to be weakly positive, but details of the study are lacking. Newer data confirm reported positive results in mutagenic tests in *Salmonella*, mouse lymphoma, Chinese hamster ovary, and mouse lymphoma.

Binding of methyl iodide in male and female rat organs has been reported (124). According to the abstract,

Male and female F344 rats were exposed to ^{14}C-labelled methyl iodide orally or by inhalation in a closed exposure system. DNA adducts were detected in the liver, lung, stomach, and forestomach of the exposed animals. [^{14}C]3-Methyladenine, [^{14}C]7-methylguanine and [^{14}C]O6-methylguanine could be identified by a combination of three different methods of hydrolysing DNA and subsequent HPLC or GC/MS analysis. The highest values of methylated guanines were determined in the stomach and forestomach of the animals following both oral and inhalative exposure. These results demonstrate a systemic genotoxic effect of methyl iodide.

Binding appeared to be due to alkylation rather than metabolic incorporation into DNA.

Methyl iodide was mutagenic for *Salmonella typhimurium* bacterial strains TA1535 and TA100 and also a direct acting mouse lymphoma L5178Y/%K±cells (36).

3.4.2 Human Experience 3.4.2.1 General Information Garland and Camps (125) reported two cases of exposure of humans to the vapors of methyl iodide from industrial operations. The first case was quoted from Jaquet as reported in 1901. This case showed symptoms of vertigo, diplopia, and ataxia, there was evidence of urinary iodine, and the individual developed delirium and serious mental disturbances. The second case was one observed by Garland and Camps. The patient was found to be drowsy and unable to walk, with slurred, incoherent speech. He had iodine in the urine. Death occurred 7–8 days after exposure. Serious CNS involvement was also reported in a chemical worker by Baselga-Monte et al. (122), but the route of exposure was not given. Depression and psychological disturbance persisted for several weeks; complete recovery required 122 days. A report by Appel et al. (126) of a 41-year-old chemist exposed to the vapor of methyl iodide presents similar symptoms. These authors summarize much of the available literature. Skin irritation has been reported even while wearing protective gloves (127).
3.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV TWA is 2 ppm (12 mg/m^3). The OSHA PEL is 5 ppm and the NIOSH REL is 2 ppm.

Other countries (8): Australia—2 ppm, category 3, Suspected human carcinogen, skin, (1990); (Former Federal Republic of) Germany—no MAK, 2, Probably human carcinogen (1998); Sweden—1 ppm, 15-min short-term value 5 ppm, skin, carcinogenic (1991); United Kingdom—5 ppm, 10-min STEL 10 ppm, skin (1991).

4.0 Methylene Chloride
4.0.1 CAS Number:
[*75-09-2*]
4.0.2 Synonyms:
Dichloromethane; methylene dichloride; methane dichloride; methylene bichloride
4.0.3 Trade Names:
Aeothene MM, DCM, Narkotil, Solaesthin, Solmethine, NCI-C50102, R30, UN 1953; Refrigerant 30; Freon 30; DCM; Plastisolve
4.0.4 Molecular Weight:
84.93
4.0.5 Molecular Formula:
CH_2Cl_2
4.0.6 Molecular Structure:

4.1 Chemical and Physical Properties
Methylene chloride is a clear, colorless, nonflammable, volatile liquid with a penetrating ether-like odor. It is slightly soluble in water, alcohols, phenols, aldehydes, ketones, and organic liquids. Methylene chloride is miscible with chlorinated solvents, diethyl ether, and ethanol. It will form an explosive mixture in an atmosphere with a high oxygen content, or in the presence of liquid oxygen, nitrite, potassium, or sodium. When heated to decomposition, it emits highly toxic fumes of phosgene.

4.1.1 General

Physical state	Colorless liquid
Specific gravity	1.3266 at 20°C
Melting point	–95.1°C
Boiling point	40°C
Vapor pressure	440 torr (25°C)
Refractive index	1.4237 (20°C)
Percent in “saturated” air	55 (25°C)
Solubility	2 g/100 mL water at 25°C; soluble in ethanol, ethyl ether, acetone
Flammability	No flash point or fire point by standard tests in air 15.5–66 vol%
Autoignition temperature	624°C
UEL, LEL	19%, 12%

1 mg/L = 288 ppm and 1 ppm = 3.48 mg/m^3 at 25°C, 760 torr

4.1.2 Odor and Warning Properties Methylene chloride has a “not unpleasant,” sweetish odor at concentrations above 300 ppm, but at about 1000 ppm the odor becomes unpleasant for most people. At 2300 ppm the odor is strong, intensely irritating; there may be dizziness after 5 min exposure. It has a chloroformlike odor.
4.2 Production and Use
Methylene chloide is used principally as a solvent in paint removers. It is also used as an aerosol propellant, processing solvent in the manufacture of steroids, antibiotics, vitamins, and tablet coatings; as a degreasing agent; in electronics manufacturing; and as a urethane foam blowing agent. Methylene chloride is also used in metal cleaning, as a solvent in the production of polycarbonate resins and triacetate fibers, in film processing, in ink formulations, and as an extraction solvent for spice oleoresins, caffeine, and hops. Methylene chloride was once registered for use in the United States as an insecticide for commodity fumigation of strawberries, citrus fruits, and a variety of grains.

Methylene chloride has been used as a blowing agent for foams and as a solvent for many applications, including coating photographic films, pharmaceuticals, aerosol formulations, and to a large extent in paint stripping formulations. It is used as a solvent in a number of extraction processes, where its high volatility is desirable. It has high solvent power for cellulose esters, fats, oils, resins, and rubber, and is more water soluble than most other chlorinated solvents. Formulations for paint stripping may contain other solvents as well as methylene chloride and are frequently found outside the workplace. These formulations often contain other ingredients that retard evaporation and in the process increase the likelihood of skin irritation.
4.3 Exposure Assessment
The exposure characteristics of methylene chloride are discussed in the 1993 ATSDR Toxicological Profile (128). The primary routes of potential human exposure to methylene chloride are inhalation and ingestion. Dermal absorption has been observed, although it occurs more slowly than absorption after ingestion or inhalation. The principal route of exposure for the general population to methylene chloride is inhalation of ambient air. Inhalation exposure may also occur through the use of consumer products containing methylene chloride. USEPA has estimated that over one million workers are currently exposed to methylene chloride. The National Occupational Hazard Survey,

conducted by NIOSH from 1972 to 1974, estimated that 2.5 million workers were potentially exposed to methylene chloride vapors. On the basis of health hazard evaluations of various U.S. companies conducted in 1973 and 1974 by NIOSH, the concentrations of methylene chloride to which workers might be exposed in the following occupations were determined: servicing diesel engines, 11 ppm; spray-painting booths, 1–74 ppm; chemical plant, 0–5520 ppm with an 8-h TWA of 875 ppm; ski manufacture, 0–36 ppm; cleaning foam heads, 3–29 ppm; cleaning nozzles in plastics manufacture, 5–37 ppm; plastic tank construction, several ppm. A 1973 study of occupational exposure to hairspray propellants determined that methylene chloride exposure of beauticians exceeded a daily mean concentration of 1–2 ppm. The use of methylene chloride in hairsprays has been banned by the FDA. An estimated 500 million lb methylene chloride was produced in the United States in 1988. From the data obtained in the EPA Consumer Use and Shelf Survey, the CPSC calculated average individual 45-year risks. They ranged from zero for some of the automotive products to highs of 409 per million for adhesive removers and 95 per million for paint strippers, when the risk was based on malignant tumors in mice in the NTP bioassay; the risks were 924 per million for adhesive removers and 214 per million for paint strippers when the risks were based on malignant plus benign tumors in mice in the NTP bioassay. The Toxic Chemical Release Inventory (EPA) listed 1475 industrial facilities that produced, processed, or otherwise used chloromethane in 1988. In compliance with the Community-Right-to-Know Program, the facilities reported releases of methylene chloride to the environment that were estimated to total 127 million lb. Methylene chloride occurs in surface water, groundwater, finished drinking water, commercially bottled artesian well water, and surface water sites in heavily industrialized river basins. Methylene chloride was the sixth most frequently detected organic contaminant in groundwater from hazardous disposal sites investigated in 1987; it had a frequency detection of 19%.

4.3.2 Background Levels See above (Section 4.3).

4.3.3 Workplace Methods NIOSH Method 1005 is recommended for determining workplace exposures to methylene chloride (11).

4.3.4 Community Methods: NA

4.3.5 Biomonitoring/Biomarkers DiVincenzo et al. (1927) and Stewart et al. (129) discussed biologic monitoring for methylene chloride in expired air. The latter report includes graphs of expired air concentrations following exposures to known concentrations of methylene chloride. Within certain limits these may be useful in determining the exposures of workers. Carboxyhemoglobin levels in blood may also be of some value but interpretations are complicated by other sources of carbon monoxide and because carboxyhemoglobin is not elevated in a linear dose-dependent manner (130).

4.3.5.1 Blood See above (Section 4.3.5).
4.4 Toxic Effects
Methylene chloride is a poison by intravenous route and is moderately toxic by ingestion, subcutaneous, and intraperitoneal routes and mildly toxic by inhalation. It is an experimental carcinogen and tumorigen and an experimental teratogen, and it has experimental reproductive effects. It is severe eye and skin irritant.

Methylene chloride is the least acutely toxic of the four chlorinated methanes. The toxic effect is predominantly narcosis. Methylene chloride and some other dihalomethanes are metabolized to carbon monoxide. The principal problem from use is the “drunkenness” that may cause inept operation, which may result in injury to the employee or other workers in the area. The symptoms of excessive exposure may be dizziness, nausea, tingling or numbness of the extremities, sense of fullness in the head, sense of heat, stupor, or dullness, lethargy, and drunkenness. Exposure to very high concentrations may lead to rapid unconsciousness and death. Prompt removal from exposure prior to death usually results in complete recovery.

Epidemiological data indicate no increase in cancer in workers exposed to methylene chloride.

Positive results have been found in experimental mice (Section 4.4.1.5).

Numerous reviews are available (128, 131, 132), and detailed studies of pharmacokinetics and risk assessments have been published (133–135).

Industrial experience with methylene chloride has resulted in few reports of serious adverse effects. Although dermatitis has been reported due to its common usage in paint remover formulations, only a few anesthetic deaths have occurred, all at very excessive concentrations. Reports of systemic injury are rare, and many are of questionable authenticity. Methylene chloride is known to be metabolized to carbon monoxide, but carboxyhemoglobin levels alone are not a good measure of the toxic effect of methylene chloride. Other sources of carbon monoxide such as automotive exhaust and smoking must be considered in evaluating occupational exposure to methylene chloride.

4.4.1 Experimental Studies 4.4.1.1 Acute Toxicity Methylene chloride has a low to moderate acute oral toxicity in laboratory animals. The acute oral LD_{50} of methylene chloride in rats is about 2000 mg/kg. Slight narcosis occurs at 4000–6100 ppm in several species of animals (136). The lethal concentration for an exposure of 7 h is about 15,000 ppm (33, pp. 35–41; 136, 137).

Instillation of liquid methylene chloride directly into eyes of rabbits produced inflammation of the conjunctiva and eyelid, which persisted for 2 weeks; keratitis and irritis; and a 59% increase in corneal thickness at 6 h, which returned to normal by 9 days (138). Methylene chloride is mildly irritating to the skin of rabbits on repeated contact if allowed to evaporate. Svirbely et al. (137) reported that the LC_{50} for mice was approximately 50 mg/L or 15,000 ppm for an 8-h exposure. Survival of all animals was observed at approximately 11,000 ppm. Lehmann and Schmidt-Kehl (139) reported levels of narcosis in cats; 32 mg/L or 9000 ppm caused “displacement of equilibrium” in 20 min but no narcosis. At 37.5 mg/L or 10,000 ppm, light narcosis occurred in 220 min and deep narcosis at 293 min. They reported that cats and rabbits tolerated 6–7 mg/L for 8–9 h/day for 4 weeks with no significant observable changes. Subsequent studies have confirmed these early data. Plaa and Larson (140) and Gehring (141) investigated the renal and hepatotoxicity of methylene chloride and concluded that the compound had a very low toxicity toward these organs.

4.4.1.2 Chronic and Subchronic Toxicity Heppel and associates (142) reported no pathology or growth depression in dogs, puppies, rats, guinea pigs, or rabbits exposed to 5000 ppm 7 h/day, 5 days/week for 6 months. They did not detect CNS depression by ordinary observation but did not conduct specific tests. At 10,000 ppm they observed light to moderate narcosis. Several animals died, apparently from pulmonary congestion. Heppel and Neal (143) reported experiments with young male rats in an activity cage. At a concentration of 5000 ppm the animals showed definite reduction in activity.

Lifetime exposure of rats and hamsters to 3500, 1500, or 500 ppm 6 h/day for 2 years resulted in “non-life-shortening treatment-related changes, similar to those seen in aging animals, in the livers of male and female rats at all exposure levels.” The details of this study are discussed in Section 4.4.1.5 (144). Hamsters were less affected than rats, with survival of female hamsters much higher than in the control group.

Haun et al. (145) summarized the data from exposure studies in which animals were exposed repeatedly and also described the results of continuous (24 h daily) exposure of rats, mice, monkeys, and dogs for 100 days to either 25 or 100 ppm of methylene chloride vapors. Except for increased carboxyhemoglobin levels, dogs and monkeys were unaffected by this continuous exposure. Mice exposed to 25 ppm were likewise without effect, but the livers of the mice exposed to 100 ppm and rats exposed to both concentrations showed positive fat stains. Cytoplasmic vacuolization was noted in rats, as well as degenerative and regenerative changes in the kidneys. Carboxyhemoglobin was more elevated in the monkeys than in the dogs, which showed no elevation at 25 ppm and about 1.5% elevation at 100 ppm. Levels in monkeys were increased by ~ 1% at 25 ppm and 3–4% at

100 ppm.

In a second continuous exposure study, gerbils appeared to be unusually susceptible to methylene chloride (146). Continuous exposure to 700 ppm resulted in premature termination of the study after 7 weeks and 350 ppm at 10 weeks. Gerbils exposed continuously to 210 ppm were exposed for the intended 3 months. Survivors from the 350- and 210-ppm groups were kept on recovery for 4 months. One female exposed to 210 ppm died, but no control gerbils died. The gerbils exposed to 210 ppm were reported to gain weight normally. Carboxyhemoglobin in the 210-ppm group was 11.5%, versus 10.3% in the 350-ppm group after 3 weeks, which is consistent with other findings of 10 weeks.

An extensive study of neurotoxicologic effects in rats following exposure to 50 ppm (below metabolic saturation), 200 ppm (just below metabolic saturation), and at 2000 ppm (well above metabolic saturation) failed to show deleterious effects (147). Carbon monoxide was similarly studied at 135 ppm in air. Exposure to both substances were 6 h/day, 5 days/week for 13 weeks. Carboxyhemoglobin levels of 10% were attained with the CO as they were with 200 ppm methylene chloride. Postexposure functional tests included an observational battery, hind-limb grip strength, and a battery of evoked potentials (flash, auditory brainstem, somatosensory, caudal nerve). After functional tests were completed, rats from all groups were perfused with fixative and a comprehensive set of nervous tissues from the high exposure group and from controls were examined by light microscopy. The investigators concluded that subchronic exposures as high as 2000 ppm methylene chloride or 135 ppm CO had no deleterious effects on any of the measures of this study.

Methylene chloride is mildly irritating to the skin of rabbits on repeated contact if allowed to evaporate.

Additional studies are discussed in Section 4.4.1.5.

4.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms The metabolism of methylene chloride to carbon monoxide and the subsequent production of carboxyhemoglobin (COHb) has been studied in animals and man. In the rat, metabolism appears to be saturable with disproportionately less COHb formed and more unchanged methylene chloride expired as exposure increased (148). Production of carbon monoxide and carboxyhemoglobin has been shown to occur in animals (149) as well as humans.

Von Oettingen et al. (18) studied the absorption and excretion of methylene chloride. They reported that it was rapidly absorbed and largely excreted by the lungs. Although this appears to be partly true, a significant amount is metabolized to carbon dioxide and carbon monoxide.

Figure 62.2 taken from Andersen et al. (133), indicates that CO_2 is produced by either a route involving glutathione *S*-transferase or a route using cytochrome P450 mixed-function oxidase (MFO). Carbon monoxide, however, is produced only in the MFO route. According to Reitz et al. (134), the MFO system plays a protective role, has a higher affinity for methylene chloride, and metabolizes most of the methylene chloride at low concentrations. They conclude that after saturation of the MFO pathway at about 300–500 ppm, the glutathione pathway increases disproportionately.

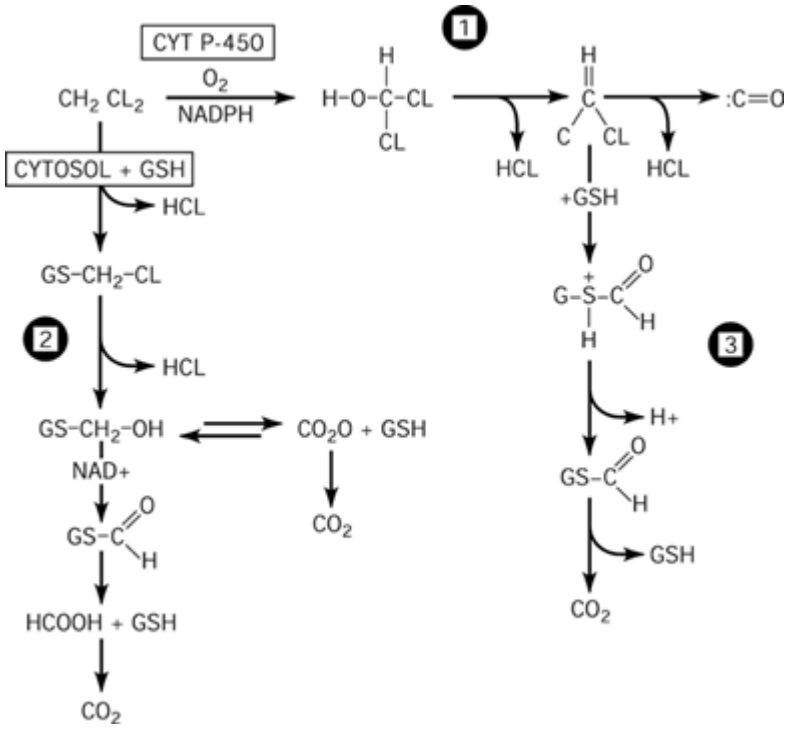

Figure 62.2. Proposed metabolic pathways for methylene chloride metabolism. From Ref. 133.

Different routes of exposure, dosage level/rates of metabolism, respiratory rates, and other factors have been used to develop a physiologically based pharmacokinetic model useful in explaining differences in response in the carcinogenic studies described previously (133). Perhaps the most important result is the calculation that target tissue doses in humans are 140–170-fold lower (by inhalation) or 50–210-fold lower (by drinking water) than would be expected from the customary linear extrapolation and body surface area adjustment used in older risk assessments. However, in 1988 USEPA felt that a nine-fold reduction was more appropriate, despite a report (150) cited in Section 4.4.2 that after a 30-year latency human cancers were not elevated and were well below that predicted by animal studies. *In vitro* data (134) provide support for the Andersen et al. Model.

4.4.1.3.1 Adsorption See above (Section 4.4.1.3).

4.4.1.3.2 Distribution See above (Section 4.4.1.3).

4.4.1.3.3 Excretion See above (Section 4.4.1.3).

4.4.1.4 Reproductive and Developmental Schwetz et al. (151) found no teratogenic effects in rats or mice exposed to 1225 ppm vapor, 7 h/day on days 6–15 of gestation. The young of exposed (4500 ppm) pregnant rats were reported by Bornschein et al. (152) to show retarded behavioral habitation to novel environments. The authors did not attempt to determine whether the effect was due to methylene chloride, carboxyhemoglobin, or the combination of the two. They were also hesitant to extrapolate to possible effects at concentrations of 200–500 ppm. Rats fed up to 4% methylene chloride in their diet showed no teratological effect (153). Neonatal weight was reduced during an 8-week observation period following exposure to 4% in the diet but not after 0.4%.

Wistar rats fed about 2.8 mg/kg of body weight/day in their drinking water (125 ppm) for 91 days were mated or sacrificed at the end of the exposure period; no adverse effects were noted on estrus or reproduction (154).

Nitschke et al. (130) exposed rats and reported the following. Reproductive parameters in Fischer

344 rats were evaluated following inhalation of methylene chloride ($MeCl_2$) for two successive generations. Thirty male and female rats were exposed to 0, 100, 500, or 1500 ppm $MeCl_2$ for 6 h/day, 5 days/week for 14 weeks and then mated to produce F_1 litters. After weaning, 30 randomly selected F_1 pups/sex/group were exposed to $MeCl_2$ for 17 weeks and subsequently mated to produce F_2 litters. Reproductive parameters examined included fertility, litter size and neonatal growth, and survival. All adults and selected weanlings were examined for grossly visible lesions. Tissues from selected weanlings were examined histopathologically. No adverse effects on reproductive parameters, neonatal survival, or neonatal growth were noted in animals exposed to methylene chloride in either F_0 or F_1 generation. Similarly, there were no treatment-related gross pathologic observations in F_0 or F_1 adults or F_1 or F_2 weanlings. Histopathologic examination of tissues from F_1 or F_2 weanlings did not reveal any lesions attributed to methylene chloride. Thus, exposure of rats to concentrations as high as 1500 ppm methylene chloride, which has been shown in a 2-year study to produce treatment-related effects, did not effect any reproductive parameters.

4.4.1.5 Carcinogenesis IARC classifies methylene chloride in group 2B, Probably carcinogenic in humans; MAK, group B, Suspected of having carcinogenic potential; NIOSH, Carcinogen, with no further classification; ACGIH TLV, A3, Confirmed. Animal carcinogen with unknown relevance to humans.

Animal evidence is considered by EPA to be "sufficient" for carcinogenesis. Methylene chloride administered in the drinking water induced a significant increase in combined hepatocellular carcinoma and neoplastic nodules in female F344 rats and a nonsignificant increase in combined hepatocellular carcinoma and neoplastic nodules in male $B6C3F_1$ mice (155, 156). Two inhalation studies with methylene chloride have shown an increased incidence of benign mammary tumors in both sexes of Sprague–Dawley (144) and F344 (157) rats. Male Sprague–Dawley rats had increased salivary gland sarcoma (144) and female F344 rats had increased leukemia incidence (157). Both sexes of $B6C3F_1$ mice developed liver and lung tumors after methylene chloride treatment (157).

In a 2-year study by the National Coffee Association (155, 156), groups of 85 F344 rats/sex/dose received 5, 50, 125, or 250 (mg/kg)/day of methylene chloride in the drinking water. Control groups consisted of 135 rats/sex. In female rats the incidence of combined hepatocellular carcinoma and neoplastic nodules was statistically significantly increased in the 50- and 250-mg/kg dose groups when compared with matched controls (0/134, 1/85, 4/83, 1/85, and 6/85 in the five dose groups 0, 5, 50, 125, and 250 (mg/kg)/day, respectively). The incidence of hepatocellular carcinoma alone was not significantly increased (0/134, 0/85, 2/83, 0/85, 2/85). The combined incidence of hepatocellular carinoma and neoplastic nodules in controls and the four dose groups (472 rats: 4 with carcinoma and 8 with neoplastic nodules) was similar to that for historical controls (419 rats; 5 with carcinoma, 19 with neoplastic nodules). Male rats showed no increase in liver tumors. Also, in this study, $B6C3F_1$ mice received 0, 60, 125, 185, or 250 mg/kg/day of methylene chloride in drinking water. Treatment groups consisted of 50 female mice and 200, 100, 100, and 125 male mice (low to high dose). One hundred females and 125 males served as controls. Male mice had an increased incidence of combined neoplastic nodules and hepatocellular carcinoma (24/125, 51/200, 30/100, 31/99, 35/125). The increase was not dose-related, but the pairwise comparisons for the two middose groups were reported to be statistically significant (132). The hepatocellular carcinoma incidence alone for male mice (which was about 55–65% of the total) was not significantly elevated. Female mice did not have increased liver tumor incidence. The EPA (158) regarded this study as suggestive but not conclusive evidence for carcinogenicity of methylene chloride.

Inhalation exposure of 107–109 Syrian hamsters/sex/dose to 0, 500, 1500, or 3500 ppm of methylene chloride for 6 h/day, 5 days/week for 2 years did not induce neoplasia (144). Sprague–Dawley rats (129/sex/dose) were exposed under the same conditions. Female rats administered the highest dose

experienced significantly reduced survival from 18–24 months. Female rats showed a dose-related increase in the average number of benign mammary tumors per rat (1.7, 2.3, 2.6, 3.0), although the numbers of rats with tumors were not significantly increased. A similar response was observed in male rats, but to a lesser degree. In the male rats there was a statistically significant positive trend in the incidence of sarcomas of the salivary gland (1/93, 0/94, 5/91, 11/88); the incidence was significantly elevated at the high dose. There is a question as to whether these doses reached the MTD, particularly in the hamsters and the male rats.

Groups of 50 each male and female F344/N rats and B6C3F1 mice were exposed to methylene chloride by inhalation, 6 h/day, 5 days/week for 2 years (157). Exposure concentrations were 0, 1000, 2000, or 4000 ppm for rats and 0, 2000, or 4000 ppm for mice. Survival of male rats was low; however, this apparently was not treatment-related. Survival was decreased in a treatment-related fashion for male and female mice and female rats. Mammary adenomas and fibroadenomas were significantly increased in male and female rats after survival adjustment, as were mononuclear cell leukemias in female rats. Among treated mice of both sexes there were significantly increased incidences of hepatocellular adenomas and carcinomas, and of alveolarbronchiolar adenomas and carcinomas, by life-table tests. Adenomas and carcinomas were significantly increased alone as well as in combination. In addition, there were significant dose-related increases in the number of lung tumors per animal multiplicity in both sexes of mice.

4.4.1.6 Genetic and Related Cellular Effects Studies Methylene chloride was mutagenic for *Salmonella typhimurium* with or without the addition of hepatic enzymes (159) and produced mitotic recombination in yeast (160). Results in cultured mammalian cells have generally been negative, but methylene chloride has been shown to transform rat embryo cells and to enhance viral transformation of Syrian hamster embryo cells (161, 162). Although chlorinated solvents have often been suspected of acting through a nongenotoxic mechanism of cell proliferation, Lefevre and Ashby (163) found methylene chloride to be unable to induce hepatocellular division in mice.

Jongen et al. (164) have used methylene chloride in an Ames test with *Salmonella typhimurium* TA98 and TA100. Increased reversions occurred in both strains of bacteria. The activity was only slightly increased by the addition of rat liver homogenate.

4.4.2 Human Experience Symptoms of exposure to this compound may include headache, elevated blood concentrations of carboxyhemoglobin, nausea, and irritation of the skin and eyes. Central nervous system depression, pulmonary edema, hemolysis, chronic intoxication, and paresthesia may also occur. Other symptoms include narcosis, temporary neurobehavioral effects, increase in serum bilirubin, increased urinary formic acid concentrations, and increased risk of spontaneous abortion. In addition, intravascular hemolysis, unconsciousness, lack of response to painful stimuli, rapid followed by slowed respiration, erythema, blistering, toxic encephalopathy, painful joints, swelling of the extremities, mental impairment, diabetes, skin rash, aspiration pneumonia, gross hematuria, reduction of blood pH, GI injury, and narrowing of the intestinal lumen may also occur. Other symptoms may include upper respiratory tract irritation, giddiness, stupor, irritability, numbness, tingling in the limbs, and hallucinations. A dry, scaly and fissured dermatitis, skin burns, coma, and death may also result. Other symptoms may include dizziness, sense of fullness in the head, sense of heat, dullness, lethargy, and drunkenness. In addition, mental confusion, lightheadedness, vomiting, weakness, somnolence, lassitude, anorexia, depression, fatigue, vertigo, liver damage, nose and throat irritation, anesthetic effects, smarting and reddening of the skin, blood dyscrasias, acceleration of the pulse, and congestion in the head may result. Staggering may also occur. Other symptoms of exposure to this compound may include neurasthenic disorders, digestive disturbances, and acoustical and optical delusions. Arrhythmias produced by catecholamines may also result. Additional symptoms include edema, faintness, loss of appetite, and apathy. Hyporeflexia, gross hemoglobinuria, epiglottal edema, metabolic acidosis, gastrointestinal hemorrhage, ulceration of the duodenojejunal junction, and diverticula may also occur. Other symptoms may include kidney damage, lung damage, corneal injury, abdominal pain, and an increase in salivary gland tumors. Cyanosis may also occur. Exposure may also cause altered sleep time, convulsions, euphoria, and a

change in cardiac rate.

4.4.2.1 General Information Experience in use of methylene chloride has generally been favorable, confirming the low toxicity observed in animals. Most commonly, recovery of exposed workers, even from anesthetic concentrations, has been rapid and without sequelae other than carboxyhemoglobin, which appears to persist slightly longer than that resulting from carbon monoxide itself.

Between 1961 and 1980, 33 excessive exposures to methylene chloride were reported to the British Health and Safety Executive (166). Thirteen subjects were unconscious, 9 had headaches, 11 were dizzy, and 13 had GI symptoms, but liver injury was reported only in one subject who also had xylene exposure. One death was reported.

Several laboratory and epidemiologic studies in humans have been reported. An extensive laboratory study of healthy adult test subjects exposed repeatedly 7 h/day to 250 ppm showed no untoward subjective health responses (129). McKenna et al. (148) exposed six healthy male volunteers "to 100 and 350 ppm methylene chloride (CH_2Cl_2) during each of two 6-h exposure periods. Measurement of blood CH_2Cl_2 and carboxyhemoglobin (COHb) levels and CH_2Cl_2 and carbon monoxide (CO) in expired air were performed during exposure and for the first 24 h thereafter. Dose-dependent metabolism of CH_2Cl_2 was evident from both CH_2Cl_2 blood levels and the concentration of CH_2Cl_2 in the expired air when the data from the 100 and 350 ppm exposure experiments were compared. Blood COHb levels and exhaled CO were less than expected following exposure to 350 ppm CH_2Cl_2, indicative of dose-dependent or saturable metabolism of CH_2Cl_2 to CO. The rate of total CH_2Cl_2 metabolism for each subject was calculated from the inspired–expired air concentration and minute ventilation rate obtained at apparent steady-state. The relationship of the rate of CH_2Cl_2 metabolism during exposure to the CH_2Cl_2 exposure concentration followed apparent Michaelis–Menten kinetics." These authors derived a pharmacokinetic model to allow prediction of the extent of methylene chloride metabolism and production of carboxyhemoglobin following exposure to methylene chloride in laboratory animals and humans.

An assessment of the carcinogenic risk to humans has been published in which it is concluded the risk to humans is very low particularly at levels of exposure producing no other adverse effect (135).

4.4.2.2 Clinical Cases See Section 4.4.2.1.

4.4.2.2.1 Acute Toxicity Severe skin burns were observed in a worker found unconscious after about 30 min in a vessel with a high concentration of methylene chloride (165). He was in severe shock and almost pulseless after being taken to the hospital while on oxygen. He was continued on oxygen and 1 h after being rescued still had 12% carboxyhemoglobin despite being on oxygen. When he was discharged 8 days later, the blood protein was reported to be normal, as were liver and renal function tests.

The problem in humans may be accentuated if the chemical is confined to the skin by shoes or tight clothing. The situation may be more severe with paint-remover formulations that form a skin or film to prevent evaporation. Limited absorption through skin occurs, but probably is not of toxicologic significance in industrial situations (167).

4.4.2.2.5 Carcinogenesis An IARC Working Group reported that the data available on methylene chloride were inadequate for an evaluation of its carcinogenicity in humans. The data from a study of 751 occupationally exposed workers also were considered inadequate to assess the carcinogenicity of methylene chloride in humans by later IARC Working Groups.

An epidemiological mortality analysis of a male population exposed to methylene chloride has been reported (168). This study, a follow-up of previously published reports, confirms earlier findings of no increase in cancer.

In a series of five papers the health status and mortality experience of a group of several hundred exposed workers has been described (169). Industrial hygiene measurements indicated exposure of 140 to 475-ppm 8-h time-weighted averages. Cause of death, included ischemic heart disease and cancer, was unaffected. Except for the expected effects of carbon monoxide there were no health affects related to exposure.

4.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV is 50 ppm with an A3 designation. NIOSH considers methylene chloride a carcinogen and recommends the lowest feasible exposure level and an IDLH of 2300 ppm. The OSHA PEL is 25 ppm and a STEL of 125 ppm.

USEPA has published water-quality criteria under CWA and established a reportable quantity (RQ) of 1000 lb for methylene chloride under CERCLA. This chemical is exempted from a tolerance for residues, and is regulated as a toxic inert ingredient of pesticides under FD&CA.

Methylene chloride is a listed hazardous substance under RCRA. USEPA has included methylene chloride on a list of priority hazardous substances under SARA. Further regulatory testing is proceeding under TSCA. FDA regulates methylene chloride as a limited food additive. Specified residues are permitted in spice oleoresins, hops extract, and decaffeinated coffee.

4.6 Studies of Environmental Impact

129.39

5.0.5 Molecular Formula:

CH_2ClBr

5.0.6 Molecular Structure:

5.1 Chemical and Physical Properties

Physical state	Colorless liquid
Specific gravity	1.93 at 20°C
Freezing point	–86.5°C
Boiling point	67°C
Vapor pressure	117 torr at 20°C
Refractive index	1.4850 (26°C)
Percent in “saturated” air	21 (25°C)
Solubility	Insoluble in water; soluble in organic solvents
Flammability	No flash or fire points by standard tests in air; it is an effective fire extinguisher

1 mg/L = 189 ppm and 1 ppm = 5.3 mg/m^3 at 25°C, 760 torr

5.1.1 General: NA

5.1.2 Odor and Warning Properties Methylene chlorobromide has a distinctive odor at 400 ppm, and hence has warning properties below any acutely hazardous concentration. Although the odor is distinctive at the acceptable concentration and so gives some warning, it is not disagreeable enough to drive anyone from the area. Employees may tolerate a level well above the acceptable level for chronic exposure.
5.2 Production and Use
This compound is used in fire extinguishers and in organic synthesis.
5.3 Exposure Assessment
5.3.1 Air: NA

5.3.2 Background Levels: NA

5.3.3 Workplace Methods NIOSH Analytical Method: 1003 is recommended (11).
5.4 Toxic Effects
Methylene chlorobromide is one of the least acutely toxic halomethanes. It falls roughly in a class with methylene chloride in acute and short-term toxicity. The primary response to this material is CNS depression. There appears to be very little organic injury following either acute or repeated chronic exposure except possibly lung irritation from acute exposure at high levels. The compound is metabolized to carbon monoxide and produces carboxyhemoglobin as well as inorganic bromide. Few new data were found since the last revised edition. Reviews are available (170, 171).

Methylene chlorobromide is mildly toxic by ingestion and inhalation. This material has a narcotic action of moderate intensity, although of prolonged duration. This compound is corrosive. It is harmful if swallowed, inhaled, or absorbed through the skin. It is extremely destructive to tissue of the mucous membranes, upper respiratory tract, eyes, and skin. It may cause eye, throat, and skin irritation. When heated to decomposition, it emits toxic fumes of carbon monoxide, carbon dioxide, hydrogen chloride gas, and hydrogen bromide gas.

5.4.1 Experimental Studies 5.4.1.1 Acute Toxicity Highman et al. (172) reported that administration of methylene chlorobromide by stomach tube to mice caused no changes at doses of 500 mg/kg. Single doses of 3000 and 4500 mg/kg were followed by fatty degeneration of the liver and kidneys. These same authors observed no liver or kidney injury in animals exposed to the vapors. They commented that the difference in liver injury could be due to a different pathway of absorption from the GI tract than from the lungs.

Svirbely et al. (137) reported the LC_{50} by inhalation for mice exposed for 7 h to be 12.03 mg/L of air

(2273 ppm). Comstock et al. (173) reported that concentrations as low as 3000 ppm produced light narcosis in rats. Transient pulmonary edema was observed at concentrations below 27,000 ppm. At higher concentrations, interstitial pneumonitis resulted in delayed deaths. Delayed deaths were also observed after exposure to 20,000 ppm. Deaths during exposure occurred only from exposures above 27,000 ppm. Matson and Dufour (174) reported limited acute studies on guinea pigs. The principal toxicological observation from the exposure was lung injury. Van Stee et al. (175) exposed dogs to 0.3–1.0% in oxygen to determine the effect on the cardiovascular system. Disturbances in myocardial energy metabolism occurred, including cardiac arrhythmias, but the studies were conducted on anesthetized animals and the industrial significance cannot be ascertained.

5.4.1.2 Chronic and Subchronic Toxicity Repeated exposures by inhalation were reported by Svirbely et al. (137). They exposed animals 7 h/day, 5 days/week for a period of ≤14 weeks to a concentration of 1000 ppm. Rats, rabbits, and dogs survived these exposures and showed no evidence of toxic response. Growth was normal, and there were no histopathological changes.

Torkelson et al. (176) indicate that female rats and dogs survived without significant effect, 370 ppm in air, 7 h/day, 5 days/week for 6 months, but that some liver pathology was observed at 500 ppm. Male rats, male and female guinea pigs, and rabbits showed no effect except for elevated blood bromide at 500 ppm. However, at 1000 ppm several effects were noted, including histopathological changes in the livers and testes in addition to increased blood bromide.

In a similar study, rats and dogs were exposed to methylene chlorobromide vapors 6 h/day for a total of 124 exposures in a 6-month period (177). The exposure levels of 500 and 1000 ppm produced no adverse effect except for an apparent failure of rats to gain as much weight as their controls. The authors suggested that the lower weight might have been related to sedation owing to the elevated levels of bromide ion in the blood. In about 20 days serum bromide levels in both rats and dogs reached an equilibrium of about 150 mg/100 mL in dogs and 140 mg/100 mL in rats exposed to 1000 ppm. Exposures to 500 ppm resulted in equilibrium concentrations of 125 and 100 mg/100 mL in the two species.

5.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Svirbely et al. (137) determined inorganic bromide in blood serum and urine in dogs exposed to 1000 ppm of methylene chlorobromide in air. These animals were exposed 7 h/day, 5 days/week. During the third week, the blood serum inorganic bromide had increased from a normal of 5–10 mg/100 mL to >200 mg. By the 13th and 14th weeks, the concentration was greater than 300 mg of inorganic bromide per 100 mL of blood. The same authors determined the blood concentration of volatile bromide expressed as milligrams of methylene chlorobromide per 100 mL of blood. Taken immediately at the end of the exposure, concentrations between 5 and 9 mg of methylene chlorobromide per 100 mL were observed. At periods of 17–65 h after the end of the last exposure, no volatile bromide was observed in one dog and concentrations of <1 mg in the other. It would appear that methylene chlorobromide as such appears in the blood during exposure to vapors in air, but disappears rapidly on cessation of exposure. Apparently, a significant amount of material is hydrolyzed or metabolized to yield inorganic bromide, which may be useful to determine whether exposures to methylene chlorobromide have occurred.

Female rats exposed to 370 ppm 8 h/day, 5 days/week, had a whole-blood bromide ion concentration of about 70 mg/100 mL; dogs similarly exposed were found to have concentrations of 25–30 mg Br/100 mL whole blood (176).

Although not studied as extensively as methylene chloride, methylene chlorobromide also produces carboxyhemoglobin (178). Intraperitoneal doses of 3 mmol/kg (390 mg/kg) to rats resulted in a maximum carboxyhemoglobin of about 5% at 4 h (methylene chlorobromide) and 8% at 2 h (methylene chloride). Prior administration of phenobarbital, 3-methylcholanthrene, and SKF 525-A did not alter these levels of carboxyhemoglobin. These authors found elevations in carboxyhemoglobin with several dihalomethanes but not with certain other chloromethanes

including carbon tetrachloride, chloroform, and monochloromethane, or with carbon disulfide, methanol, formaldehyde, dimethoxymethane, trichlorofluoromethane, and dichlorodifluoromethane.

5.4.1.4 Reproductive and Developmental No data on teratogenicity or carcinogenicity were found.

5.4.1.5 Carcinogenesis The USEPA classification is D, Not classifiable as to human carcinogenicity. Bromochloromethane is structurally similar to dichloromethane (methylene chloride), which is classified B2, Probable human carcinogen. The classification is based on the lack of data regarding the carcinogenicity of bromochloromethane in humans or animals; however, there are data indicative of genotoxic effects and structural relationships to halogenated methanes classified as B2, Probable human carcinogens.

5.4.1.6 Genetic and Related Cellular Effects Studies When tested in *Salmonella typhimurium* and *Saccharomyces cerevisiae* D3, methylene chlorobromide did not cause a mutagenic response in one study (The Dow Chemical Co., Midland, MI, unpublished data) but was positive in other test systems, including an Ames test and *in vitro* SCE tests with Chinese hamster FAF cells (179).

Mutagenicity tests with bromochloromethane in microorganisms yielded consistently positive results. Osterman-Golkar et al. (180) reported positive responses in reverse mutation assays with *S. typhimurium* TA100 and TA1535 exposed to bromochloromethane in the absence of activation at 20–60 mM and with or without activation in the vapor phase at 10 uL/plate. Similarly, Simmon (94), Simmon et al. (96), and Simmon and Tardiff (93) reported positive results in *S. typhimurium* exposed without activation at 10–50 uL/dessicator. Reverse mutations were observed at the *tyr* locus in *Escherichia coli* WU361089 exposed at 10 uL/plate without activation (180). Prophage induction was also observed in *E. coli* K394 exposed without activation at 10 mL/plate (180).

5.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization Methylene chlorobromide, when applied repeatedly to the open skin of rabbits, resulted in some hyperemia and exfoliation. When bandaged on, it produced moderate irritation and hyperemia (181). This material would be expected to have a rather mild effect from ordinary contact, but gross and prolonged contact might cause dermatitis (182).

5.4.2 Human Experience 5.4.2.1 General Information Symptoms of exposure to this compound include disorientation; dizziness; irritation of the skin, eyes and throat; pulmonary edema; headache; anorexia; nausea; vomiting; abdominal pain; weight loss; memory impairment; paralysis; weakness; tremors; convulsions; and narcosis. It may cause coughing, chest pain, and difficulty in breathing. It may also cause transient corneal epithelium damage.

Few reports of adverse effects in humans from exposure to methylene chlorobromide are found in the literature. This is probably because of its low toxicity as well as its limited usage. One report describing exposure was to a mixture of materials, including methyl chloride (183). The neurological effects described fit more closely those expected from methyl chloride than from methylene chlorobromide. A second report by Rotstein (182) describes an incident in which three men were grossly exposed during its use and misuse as a military fire extinguisher. All survived, but two required extensive therapy to prevent anesthetic deaths. The third victim, who was sprayed in the face with the liquid for more than 40 s, did not lose consciousness. All subsequently recovered with no evidence of persistent sequelae. Liver biopsies of the first two victims revealed normal microanatomy, and liver function studies were normal a few days after exposure.

5.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV is 200 ppm (1060 mg/m^3) based on CNS and liver effects. The OSHA PEL and NIOSH REL is also 200 ppm.

6.3.5 Biomonitoring/Biomarkers Blood bromide and carboxyhemoglobin determinations may be of value in assessing whether exposure to methylene bromide has occurred. However, available data are inadequate to quantify exposure.
6.4 Toxic Effects
Methylene bromide is more acutely toxic than either methylene chloride or methylene chlorobromide. Only limited toxicologic data are available. Carbon dioxide, carbon monoxide, and bromide are among its metabolites. It has the capacity of producing significant liver and kidney injury in animals on repeated exposure. The vapors are anesthetic and are reported to cause cardiac arrhythmias (184). It is apparently produced by marine macroalgae (185). A review is available (186).

6.4.1 Experimental Studies 6.4.1.1 Acute Toxicity Methylene bromide has a low acute oral toxicity; the LD_{50} for rats is > 1000 mg/kg. It is only slightly irritating to the eye and skin of rabbits and does not appear to be absorbed significantly even when applied repeatedly (The Dow Chemical Co., Midland, MI, unpublished data). Although it has been shown by increased blood bromide and increased carboxyhemoglobin that some absorption of the liquid and vapor does occur through rat skin, the investigator concluded that only 5% of the inhaled dose would penetrate the skin during vapor exposure (187). It is sufficiently volatile that inhalation of the vapors can cause anesthesia and

even death. A concentration of 17–20 mg/L (2400–2800 ppm) caused “disorders in the central nervous system” (188). The duration of the exposure and other details were not stated in the available abstract.

When an essentially saturated atmosphere was inhaled by rats, anesthesia occurred in 3 min, with 50% mortality in 18 min (The Dow Chemical Co., Midland, MI, unpublished data).

6.4.1.2 Chronic and Subchronic Toxicity In a very limited study methylene bromide was administered orally to a small group of rabbits at the rate of 300 mg/kg/day (60 doses in 92 days) with no alteration in weight gain, general appearance, or histopathology of the liver. Similar treatment with ≥ 400 mg/kg produced marked anesthesia (The Dow Chemical Co., Midland, MI, unpublished data).

In limited studies in which 10 rats and one rabbit of each sex were exposed to a nominal concentration of 1000 ppm (900–1000 ppm recovered analytically), there was no overt evidence of adverse effect in the rabbits, but liver and kidney degeneration was observed at autopsy following 54 exposures in 73 days (The Dow Chemical Co., Midland, MI, unpublished data). Blood bromide was elevated. Rats were much more affected. Incoordination and staggering were apparent during exposure. Failure to gain weight, possible increased mortality, and histopathological changes in the lungs, liver, and kidneys were observed in rats receiving 30–40 7 h exposures.

In a second equally limited study by this same group, 79 exposures in 114 days to 200 ppm resulted in much less effect, but evidence of stress was still present. The weights of the livers of male rats were elevated when compared to the controls, and histological changes were found in the livers and kidneys of rats and rabbits.

When inhaled 4 h/day for 2 months, 0.25 mg/L (35 ppm) methylene bromide was reported to cause “disorder in the protein-prothrombin and glycogenesis functions of the liver and the filtration capacity of the kidneys.” It was considered less toxic than bromoform (189). The same investigator reported that 2.5 mg/L of the vapor for 10 days (duration of exposure not stated) when inhaled by rabbits produced the same effects with dystrophic changes in these organs. A “threshold” concentration of 0.23 mg/L (32 ppm) was claimed for chronic exposures. When doses of 100–200 mg/kg were injected subcutaneously for 10 days in guinea pigs, pronounced liver and kidney effects were reported. Dykan's report is not consistent with a more extensive study on rats and dogs discussed below.

In another study, 115 male rats, 15 female rats, 4 male and 4 female rabbits, and 3 male beagle dogs were exposed to 0, 25, 75, or 150 ppm methylene bromide vapor 6 h/day, 5 days/week for 13 weeks (190). Male rats received 62 exposures, female rats 63 exposures, and dogs 70 exposures. On the day after their last exposure, 15 male and 15 female rats and the dogs were necropsied. The balance of the male rats were kept for 2 years in a very limited oncological study. Female rats showed a slight increase in liver weight at 75–150 ppm, but other parameters were normal, including mortality, clinical observations, body weight, hematology, clinical chemistry, and gross pathology and histopathology. There was definite evidence of metabolism of methylene bromide; free bromide ion, total bromine, and blood carboxyhemoglobin were increased in a dose-related manner. In the male rats kept for a limited oncological study there were no treatment-related effects grossly or microscopically after 1 year or at the termination of the study except for a possible decrease in body weight beginning on day 121 of the study. Only gross pathological examination of the 2-year animals was conducted and no oncological changes related to exposure were observed at any of the three exposure levels.

6.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Methylene bromide was determined in the plasma of dogs following repeated 6-h exposures to 25, 75, or 150 ppm for 90 days. The plasma clearance was at least biphasic with an ill-defined alpha phase and a terminal phase ($t_{1/2}$ of

103 ± 14 min) at all three concentrations. Blood bromide was elevated markedly in rabbits exposed to ~ 1000 ppm of the vapors, 7 h/day for a month. After 54 exposures in 73 days the blood levels had reached 280–315 mg Br/100 mL of blood. After 79 exposures in 114 days to a vapor concentration of about 200 ppm, blood bromide levels of 85–100 mg Br/100 mL were found in rabbits (190).

Methylene bromide, like many of the dihalomethanes, is metabolized to produce carbon monoxide (149, 178, 191, 192). Intraperitoneal injection of 520 mg/kg of methylene bromide in corn oil elevated carboxyhemoglobin in rats to 14% 5 h after injection. Repeated daily injection did not result in any significant difference in carboxyhemoglobin concentrations from single injection. *In vitro* studies (178, 193) show that microsomal enzymes in the presence of NADPH and molecular oxygen convert methylene bromide to carbon monoxide and inorganic bromide. There was not significant contribution of glutathione to the overall metabolism of methylene bromide (194). Cytochrome P450 is involved in its metabolism.

6.4.1.4 Reproductive and Developmental No teratological or reproductive data were found, and only the unusual oncological study reported above is available. Methylene bromide has been shown to be mutagenic in certain test systems with bacteria. Methylene bromide has been tested in three strains of *Salmonella typhimurium* activated with liver homogenate and in *Saccharomyces cerevisiae* D3. It was at most weakly mutagenic in *Saccharomyces* and negative in *Salmonella* (The Dow Chemical Co., Midland, MI, unpublished data).

In a study attempting to relate chemical reactivity, glutathione transferase activity, and mutagenicity for a series of dihalomethanes, there was no strong correlation (180). Mixed results were obtained, and methylene bromide was not strongly mutagenic in *E. coli* and *S. typhimurium* systems. Incubation with rat liver microsomes inhanced mutagenic activity (195).

UEL, LEL	Not available

1 mg/L = 206 ppm and 1 ppm = 4.89 mg/m^3 at 25°C, 760 torr

7.1.1 General Chloroform is a colorless, volatile nonflammable liquid with a pleasant, nonirritating odor and slightly sweet taste. It is slightly soluble in water and is miscible with oils, ethanol, ether, and other organic solvents. It is unstable when exposed to air, light, and/or heat, which cause it to break down to phosgene, hydrochloric acid, and chlorine. It is usually stabilized by the addition of 0.6–1% ethanol. When heated to decomposition, chloroform emits toxic fumes of hydrochloric acid and other chlorinated compounds.

7.1.2 Odor and Warning Properties Chloroform has a sweetish odor. Lehmann and Flury (136) indicated that the lowest concentration that could be detected was 200–300 ppm. This might be considered as some warning from exposure to acutely hazardous amounts, but it is by no means low enough to be considered a warning from chronic exposure.

7.2 Production and Use

Chloroform is used primarily in the production of chlorodifluoromethane (hydrochlorofluorocarbon 22 or HCFC-22) used as a refrigerant for home air conditioners or large supermarket freezers and in the production of fluoropolymers. It has also been used as a solvent, a heat-transfer medium in fire extinguishers, and an intermediate in the preparation of dyes and pesticides. Its use as an anesthetic has been discontinued. Chloroform is still used as a local anesthetic and solvent in certain dental endodontic surgery procedures.

Significant commercial production in the United States began in 1992. Since the 1980s, production increased by 20–25% because of a higher demand for HCFC-22. Estimated annual production capacity from the major facilities was 460 million lb. In 1994 it was 565 million lb.

Chloroform has been identified as a hazardous waste by USEPA, and disposal is regulated under RCRA. Ultimate disposal can be accomplished by controlled incineration. Complete combustion must be ensured to prevent phosgene formation and an acid scrubber should be used to remove the haloacids produced.

Miscellaneous uses of chloroform include use as a solvent in the extraction and purification of some antibiotics, alkaloids, vitamins, and flavors; as a solvent for lacquers, floor polishes, artificial silk manufacture, resins, fats, greases, gums, waxes, adhesives, oils, and rubber; as an industrial solvent in photography and dry cleaning; as a heat-transfer medium in fire extinguishers; and as an intermediate in the preparation of dyes and pesticides. At least one grain fumigant mixture had contained chloroform with carbon disulfide. Chloroform formulated with other ingredients is used to control screw worm in animals. Its use as an anesthetic has been largely discontinued.

7.3 Exposure Assessment

An ATSDR Toxicological Profile (Update) for 1998 summarizes relevant material (196). Chloroform is both a synthetic and naturally occurring compound, although anthropogenic sources are responsible for most of the chloroform in the environment. Chloroform is released into the environment as a result of its manufacture and use; its formation in the chlorination of drinking water, municipal and industrial wastewater, and swimming-pool and spa water; and from other water treatment processes involving chlorination. Most of the chloroform released into the environment will eventually enter the atmosphere. In the atmosphere chloroform may be transported long distances before ultimately being degraded by indirect photochemical reactions with such free radicals as hydroxyl. The compound has been detected in ambient air in locations that are remote from anthropogenic sources. Chemical hydrolysis is not a significant removal process. Under aerobic conditions, some bacteria can dehalogenate carbon tetrachloride to release chloroform. While microbial biodegradation of chloroform can take place, such reactions are generally possible only at low concentration levels. Microbial biodegradation may also be inhibited because of high levels of other aromatics, chlorinated hydrocarbons, or heavy metals. Because of its low soil adsorption and slight water solubility, chloroform will readily leach from soil to groundwater. In groundwater, chloroform is expected to persist for a long time.

The general population is probably exposed to chloroform through drinking water and beverages, eating food, inhaling contaminated air, and through dermal contact with water.

The occupations that may involve significant exposure include chemical plants or chlorination process in drinking-water plants, paper-and-pulp plants, and hazardous- and municipal-waste incinerators. A maximum of 3.8×10^{-3} ppm was found in the air in an activated sludge waste-water treatment plant (197).

The National Occupational Hazard Survey, conducted by NIOSH from 1972 to 1974, estimated that 215,000 workers were potentially exposed to chloroform in the workplace.

A National Occupational Exposure Survey (NOES) conducted by NIOSH from 1981 to 1983 estimated that 95,778 workers in the United States are potentially exposed to chloroform (198).

The NTP database (4) indicates the following. The primary routes of potential human exposure to chloroform are ingestion, inhalation, and dermal contact. Potential human exposure may occur by breathing air contaminated with chloroform, eating food or drinking water that contains chloroform, or absorption of chloroform through the skin. Chloroform has been detected in the atmosphere at concentrations ranging from 0.02 to 13 g/m^3 and in indoor air at 0.07–3.6 g/m^3. Foods such as dairy products, oils/fats, vegetables, bread, and beverages may contain small amounts of chloroform. Drinking-water supplies may contain chloroform as a by-product of chlorination for disinfection purposes. Occupational exposure may occur during the manufacture of chloroform or during one of its uses. Chloroform is used in a number of industries, including building and paperboard industries, iron and steel manufacturing, internal-combustion engine industries, pesticide manufacturing, breweries, dry cleaning, and food processing industries. The Toxic Chemical Release Inventory (USEPA) listed 167 industrial facilities that produced, processed, or otherwise used chloroform in 1988. In compliance with the Community Right-to-Know Program, the facilities reported releases of chloroform to the environment which were estimated to total 23.9 million lb.

7.3.1 Air See above (Section 7.3).

7.3.2 Background Levels Information from 1982 to 1985 reported background level of air over the northern Atlantic Ocean as $2–5 \times 10^{-5}$ ppm (199); in 1976–1979, $4\text{-}4 \times 10^{-5}$ ppm. Typical median indoor air concentrations range from 2×10^{-4} to 4×10^{-3} ppm (200). The air around swimming pools may contain chloroform in the range of 10^{-2} ppm (201). Finished drinking water collected in 1988 from 35 sites across the United States contained median concentrations of chloroform ranging from 9.6 to 15 mg/L (202). Chloroform in sediment samples taken in 1980 from 3 passes of a lake in

Louisiana had concentrations ranging from 1.7 to 18 mg/kg (203). Chloroform has been detected in various foods (196). A maximum of 13.8×10^{-3} ppm was found in the air in an activated-sludge wastewater treatment plant (197). Since chloroform is highly volatile and shows little tendency to bioconcentrate or bioaccumulate in higher lifeforms, it is not ordinarily included in the types of persistent pollutants that are the focus of state fish consumption advisory programs.

7.3.3 Workplace Methods NIOSH Method 1003 is recommended for determining workplace exposures to chloroform (11).

Numerous analytical methods for determining chloroform are presented in the ATSDR Toxicological Profile for 1998 (10). It is essential to take precautions during sampling, storage, and analysis to avoid loss of chloroform. Methods commonly used in air are based on either adsorption onto a sorbent column followed by thermal or solvent desorption with subsequent analysis using GC or directly from a parcel of air (cryogenic). The disadvantages of the sorption tubes are that sorption and desorption efficiencies may not be 100%, and that the background impurities in the sorbent tubes may limit the detection limit for samples at low concentrations. In addition, storage may limit the detection at low concentrations.

7.3.4 Community Methods: NA

7.3.5 Biomonitoring/Biomarkers Analytical sample procedures for biological matrices are given in the ATSDR profile for 1998 (10). Methods exist for analyzing chloroform in biological matrices, including breath, blood, urine and tissues. None of these methods have been standardized by an organization or federal agency, although a blood method by Ashley et al. (204) was developed at the Center for Disease Control and Prevention. Sample preparation methods are based on headspace analysis, purge-and-trap, or solvent extraction. Sample preparation for breath samples typically utilizes an absorbent followed by thermal desorption or direct analysis of an aliquot of breath. These methods all use gas chromatography with various detection methods as analytical techniques. No metabolite has been identified in the blood or urine that can be considered as a useful guide for evaluating occupational exposure to chloroform at concentrations considered acceptable for occupational exposure.

7.4 Toxic Effects

Chloroform is a human poison by ingestion and inhalation, an experimental poison by ingestion and intravenous routes. It is moderately toxic experimentally by intraperitoneal and subcutaneous routes. It is a suspected human carcinogen, an experimental carcinogen, neoplastigen, tumorigen, and teratogen.

Much of our toxicological information has been developed because of the interest in chloroform as an anesthetic. The literature is replete with papers on anesthetic potency or liver and kidney injury as measured by changes in some enzyme level or other parameter. Most of these have limited value to the industrial toxicologist or hygienist.

The most outstanding effect from acute exposure is CNS depression. High concentrations of chloroform result in narcosis, anesthesia, and death. Responses associated with exposure to concentrations below anesthetic or preanesthetic level are typically inebriation and excitation, passing into narcosis. Vomiting and GI upsets may be observed. Exposure to high concentrations may result in cardiac sensitization to adrenalin and similar compounds, as well as liver and kidney injury. In cases of more chronic or repeated exposure to chloroform, liver injury is most typical in humans. This is not unlike the effect of carbon tetrachloride. Although injury to the kidney is not as common as that to the liver, it may be observed from either acute or chronic exposure. The sperm of mice were reported to be affected in one study, but injury has not been observed in many other studies. Teratogenic effects have not been consistently found but retarded fetal development has occurred in some studies.

Chloroform has at most weak mutagenic potency and the positive results found in some carcinogenic studies appear to be the result of a nongenetic response to organ injury.

There appears to be considerable difference in toxic potency between sexes, strains, and species, probably due to differences in the rate of metabolism and other pharmacokinetic parameters.

ATSDR has prepared a Toxicological Profile for Chloroform (10), which provides references to much of the pertinent literature. Extensive effort has been spent developing physiologically based pharmacokinetic models which are described in great detail in the ATSDR update.

Chloroform is considered to be highly fetotoxic, but not teratogenic (205).

7.4.1 Experimental Studies 7.4.1.1 Acute Toxicity When chloroform was administered to rats and mice, the oral LD_{50}s have been reported to range within 444–2000 mg/kg for rats and 118–1400 mg/kg for mice (196). Liver and kidney lesions are found at lower dosages. Deaths at high dosages are probably anesthetic, but organ damages related to metabolism caused delayed death at lower dosages. It has been postulated with some supporting evidence that injury to the organs is due to metabolism in each organ and that species, sex, and strain differences are related to the individual organ's ability to metabolize chloroform to phosgene.

Because of marked differences in response in mice dosed orally with chloroform in water or in corn oil in lifetime carcinogenic studies, Bull et al. (206) conducted a 90-day study using water and corn oil as diluents. Male and female mice were fed 0, 60, 130, or 270 mg/kg/day chloroform either in 2% Emulphor in water or in corn oil. Much greater toxicity was observed in mice fed the corn oil solutions. Decreased body weight, increased liver weight, liver pathology, and blood enzyme changes were all significantly less in water-treated mice than oil-treated. Slight evidence of toxic stress was evident even at the lowest dosage level, 60 mg/kg/day in corn oil. In a similar but shorter study a no-effect level of 50 mg/kg/day was reported for CD1 mice treated for 14 consecutive days with chloroform in an aqueous solution in Emulphor (207). Thompson et al. fed pregnant rats 20 mg/kg/day (10 doses) without effect on the dams; 50 mg/kg appeared to cause fatty changes (208). These data are discussed in more detail in the section on teratology.

Oettel (209) indicated that chloroform was more irritating to the skin and eyes than many other chlorinated solvents. Oettel's conclusions have been confirmed by Torkelson et al. (210). One or two 24 h applications on the skin of rabbits resulted in hyperemia and moderate necrosis. Healing of abraded skin appeared to be delayed by application of a cotton pad soaked in chloroform. Absorption through the intact skin of rabbits occurs as indicated by weight loss and degenerative changes in the kidney tubules, but doses as high as 3980 mg/kg were survived. When the liquid was instilled in the eyes of rabbits, some corneal injury was evident in addition to conjunctivitis. The authors concluded that chloroform was more irritating to rabbit skin and eyes than many common organic solvents tested by the same technique in their laboratory.

7.4.1.2 Chronic and Subchronic Toxicity Major target organs for chloroform are the liver, kidney, and CNS for both humans an animals. Chloroform-induced hepatotoxicity in various animal species has been reported in several studies.

Despite its long usage, few reports of histological examination following repeated exposure of laboratory animals are available. Repeated 7 h exposures 5 days/week for 6 months to either 85, 50, or 25 ppm of the vapor of chloroform resulted in adverse effects in all or some of the species studied, rats, rabbits, guinea pigs, or dogs. The effects of 25 ppm were slight and reversible. Rats exposed 4, 2, or 1 h/day were not adversely affected. Cloudy swelling of the kidneys and centrilobular granular degeneration and necrosis of the liver were the principal adverse effects (210).

The paper by Heywood et al. (211) describes beagle dogs that were administered chloroform in a

toothpaste base [0.5 mL of toothpaste base/kg/day] in gelatin capsules. A control group composed of 16 males and 16 females received the vehicle, and additional control groups of eight animals/sex were administered an alternative toothpaste or were left untreated. Experimental groups of eight male and eight female dogs received 15 or 30 mg chloroform/kg/day for 6 days/week. Treatment was continued for 7.5 years. Fatty cysts, considered to be treatment-related, were observed in livers of some dogs in both treatment groups. Nodules of altered hepatocytes were considered treatment-related but not dose-dependent. A dose-related increase in SGPT levels was noted and a less marked increase in SGOT was noted in the high dose animals. The LOAEL was determined to be 12.9 mg/kg/day, and an RfD was set at 0.01 mg/kg/day.

7.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms The metabolism of chloroform is well understood. Approximately 50% of an oral dose of 0.5 g was metabolized to carbon dioxide in humans (212). Metabolism was dose-dependent, decreasing with higher exposure. Approximatly 38% of the dose was converted in the liver, and < 17% was exhaled unchanged from the lungs before reaching the systemic circulation. Metabolism studies indicated that chloroform was, in part, exhaled from the lungs or was converted by oxidative dehydrochlorination of its carbon–hydrogen bond to form phosgene (213). This reaction was mediated by cytochrome P450 and was observed in the liver and kidneys (214). Covalent binding of chloroform to lipids can occur under anaeroic and aerobic conditions, binding to protein occurs only under aerobic conditions (215). Chloroform can induce lipid peroxidation and inactivation of cytochrome P450 in rat liver microsomes under anaerobic conditions (216). Evidence that chloroform is metabolized at its carbon–hydrogen bond is provided by experiments using the deuterated derivative (217).

7.4.1.4 Reproductive and Developmental Several studies indicate that inhalation exposure to chloroform may cause reproductive effects in animals (205). Studies by Bader and Hofmann (218) indicated that exposure to as little as 30 ppm chloroform resulted in increased fetal resorptions. A significant increase in the percentage of abnormal sperm was observed in mice exposed to 400 ppm for 5 days (219).

Chloroform-induced fetotoxicity and teratogenicity were observed in experimental animals (220). The effect of inhaled chloroform on embryonal and fetal development was evaluated in CF1 mice. Pregnant mice were exposed to 0 or 100 ppm of chloroform for 7 h/day on days 6–15, 1–7, or 8–15 of gestation. Exposure to chloroform on days 6–15 or 1–7 produced a significant decrease in the incidence of pregnancy but did not cause significant teratogenicity. In comparison a significant increase in the incidence of cleft palate was observed among the offspring of mice inhaling chloroform on days 8–15 of gestation, but no effect on the incidence of pregnancy was discerned. A significant increase in SGPT activity was observed in mice exposed to chloroform on days 6–15 of gestation; among the mice exposed to chloroform, nonpregnant bred mice had a significantly higher SGPT activity than did pregnant bred mice.

Different results were reported by Dilley et al. (221), who exposed pregnant rats to 20.1 mg/L of chloroform vapor (duration of daily exposure not stated) and produced fetal mortality and decreased fetal weight but no teratological effects. Thompson et al. (208) also failed to produce teratogenic effects in Sprague–Dawley rats by intubation of 0, 30, 50, or 126 mg/kg/day or in Dutch, Belted rabbits given daily doses of 0, 20, 35, or 50 mg/kg. These authors state: “The occurrence of anorexia and weight gain suppression in dams of both species, as well as subclinical nephrosis in the rat and hepatotoxicity in the rabbit, indicated that maximum tolerated doses of chloroform were used. Fetotoxicity in the form of reduced birth weights was observed at the highest dose level in both species. There was no evidence of teratogenicity in either species at any dose tested.” It appears that chloroform has more fetotoxic effect when inhaled than when given by gavage. Thompson et al. (208) speculate that doses given by gavage may result in different blood levels of chloroform, which account for the apparent discrepancy with the effects seen on inhalation. Given the pronounced effect of corn oil on carcinogenic response, it is quite possible that route of exposure might greatly influence reproductive response.

Burkhalter and Balster (222) found no difference in reproductive parameters in control and male and female mice repeatedly gavaged with vehicle (Emulphor-saline) or chloroform. The daily dosage of 31.1 mg/kg was given to both males and females for 21 days prior to mating and throughout mating, and to the dams through gestation and lactation. Pups were dosed beginning on days 7–21. Ruddick et al. (223) treated pregnant rats and rabbits with 200 or 400 mg/kg/day. Fetal weight of only the 400-mg/kg/day rat pups was reduced. Other parameters were unaffected.

7.4.1.5 Carcinogenesis The USEPA classifies chloroform as B2, Probable human carcinogen based on increased incidence of several tumor types in rats and three strains of mice. Chloroform has been tested for carcinogenicity in eight strains of mice, two strains of rats and in beagle dogs.

USEPA derived a $q1^*$ of 8×10^{-2} $[mg/kg/day]^{-1}$ for inhalation exposure to chloroform based on mouse liver tumor data from a chronic gavage study (1976 IRIS). In a gavage bioassay Osborne–Mendel rats and $B6C3F_1$ mice were treated with chloroform in corn oil 5 times/week for 78 weeks. On a daily basis, 50 male rats received 90 or 125 mg/kg; females initially were treated with 125 or 250 mg/kg for 22 weeks and 90 or 180 mg/kg thereafter. Male mice received 100 or 200/mg/kg, raised to 150 or 300 mg/kg at 18 weeks; females were dosed with 200 or 400 mg/kg, raised to 250 or 500 mg/kg. A significant increase in kidney epithelial tumors was observed in male rats and highly significant increases in hepatocellular carcinomas in mice of both sexes. Liver nodular hyperplasia was observed in low dose male mice not developing hepatocellular carcinoma. Hepatomas have also developed in female strain A mice and NLC mice gavaged with chloroform (224, 225).

In 1985 Jorgenson et al. (226) administered chloroform (pesticide quality and distilled) in drinking water to male Osborne–Mendel rats and female $B6C3F_1$ mice at concentrations of 200, 400, 900, and 1800 mg/L for 104 weeks. These concentrations were reported by the author to correspond to daily dosages of 19, 38, 81, and 160 mg/kg for rats and 34, 65, 130, and 263 mg/kg for mice. A significant increase in renal tumors in rats was observed in the highest dose group. The increase was dose-related. The liver tumor incidence in female mice was not significantly increased. This study was specifically designed to measure the effects of low doses of chloroform.

7.4.1.6 Genetic and Related Cellular Effects Studies Very mixed results have resulted from mutagenic studies (227). Chloroform is, at most, a weak mutagen and not likely to be of concern at concentrations considered acceptable for industrial exposure. This conclusion is supported by the low level of binding of chloroform to DNA.

The majority of tests for genotoxicity of chloroform have been negative. These negative findings include covalent binding to DNA, mutation in *Salmonella*, a *Drosophila* sex-linked recessive, tests for DNA damage in a micronucleus test, and transformation of BHK cells. By contrast, one study demonstrated binding of radiolabeled chloroform to calf thymus DNA following metabolism by rat liver microsomes (228). Chloroform caused mitotic recombination in *Saccharomyces* (160) and sister chromatid exchange (SCE) in cultured human lymphocytes and in mouse bone marrow cells exposed *in vivo* (229).

The carcinogenicity of chloroform may be a function of its metabolism to phosgene, which is known to crosslink DNA. A host-mediated assay using mice indicated that chloroform was metabolized *in vivo* to a form mutagenic to *Salmonella* strain TA1537. Likewise, urine extracts from chloroform-treated mice were mutagenic (230). Chloroform administered to mice in drinking water promoted growth and metastasis of Ehrlich ascites cells injected intraperitoneally (IP) (231). Inhalation of 400 ppm chloroform for 5 days increased the percentage of abnormal sperm in mice (219).

7.4.2 Human Experience 7.4.2.1 General Information The NTP DataBase indicates the following: Symptoms of exposure to this compound include nausea, vomiting, eye and skin irritation, unconsciousness, and death. Other symptoms include drowsiness, giddiness, headache, anesthesia, and conjunctivitis. Central nervous system depression may occur. Respiratory failure may also

occur. Exposure may cause lassitude, digestive disturbances, dizziness, and mental dullness. It may also cause coma and an enlarged liver. Other symptoms include hepatotoxicity, nephrotoxicity, reduced cardiac output, cardiac arrhythmias, and abdominal pain. It may also cause cardiac sensitization, GI upset, sensation of fainting, salivation, intracranial pressure, and fatigue. Severe anoxia has been reported. Exposure may lead to chest pain, serious disorientation, hepatomegaly, and, in high concentrations, blepharospasm. It may also lead to ventricular tachycardia, bradycardia, necrosis and hepatomas of the liver, cardiovascular depression, and ventricular fibrillation. Irritation of the upper respiratory tract, nervous system disturbances, and renal or cardiac damage may also occur. Nervous aberrations and profound toxemia may follow exposure. Inhalation may cause hallucinations, distorted perceptions, unspecified gastrointestinal effects, dilation of the pupils, reduced reaction to light, reduced intraocular pressure, feelings of warmth of the face and body, irritation of the mucous membranes, excitation, motor disturbances or loss of reflexes, and loss of sensation. Prolonged inhalation may cause paralysis followed by cardiac respiratory failure. Other symptoms of exposure via inhalation include irritation of the nose and throat, drunkenness, and narcosis. Inhalation of large doses may result in hypotension, respiratory depression, and myocardial depression. Inhalation or ingestion of this compound may cause cardiac irregularities, cardiac arrest, convulsions, reduced blood pressure, and uncontrollable hyperthermia (rare).

Ingestion may cause burning of the throat and mouth. Skin contact may result in smarting and reddening. Prolonged skin contact may result in burns. Prolonged or repeated skin contact may cause dermatitis through defatting of the skin. Eye contact may cause immediate burning pain, tearing, reddening of the conjunctiva, and injury of the corneal epithelium. Chronic exposure may result in jaundice, cirrhosis and damage of the liver, and kidney damage. Alcoholics seem to be affected sooner and more severely.

In humans, chloroform affects the central nervous system, liver, and kidneys. Breathing about 900 ppm in air for a short time causes fatigue, dizziness, and headache. Consuming elevated levels in food can damage liver and kidneys. Large amounts can cause sores on the skin.

Considering the long history of chloroform, there is surprisingly little clinical literature on chronic exposure. There have been almost no quantitative toxicological studies of the response from chronic exposure of humans to chloroform. An attempt to study “causes of death of anesthesiologists from the chloroform era” was limited to too few cases to draw conclusions and certainly did not quantitate exposure (232). Challen et al. (233) studied an industrial operation where chloroform was being used. Groups exposed to concentrations varying between 77 and 237 ppm exhibited definite symptoms. Apparently, there were also some high peak concentrations for very short periods of time. Symptoms were GI distress and depression. Another group with shorter service was exposed to concentrations of 21–71 ppm. They also showed symptoms of comparable nature. Tests of both groups were made to determine possible liver injury, but none were found. It should be remembered, however, that liver function tests are often insensitive to anything except severe liver injury. It is quite possible, as indicated by these authors, that there may have been mild liver injury in these cases. The recommendation of these authors that atmospheric exposure should be kept well below 50 ppm is entirely in order.

Humans are exposed to small amounts of chloroform in drinking water and in beverages made using water that contains chloroform. The amount of chloroform expected to be in air ranges of 0.02–0.05 ppb of air and 2–44 ppb in treated drinking water. The average amount of chloroform that a human may be exposed on a typical day from breathing ranges from 2–5 mg in rural areas to 200 mg in cities to 2200 mg in areas near major sources (10).

7.4.2.2 Clinical Cases See above (Section 7.4.2).

7.4.2.2.1 Acute Toxicity The human lethal dose is 10 mL; the IDLH value is 1000 ppm.

Humans and animals can withstand very high concentrations of chloroform for a short period of

time. Table 62.2, adapted from Lehmann and Flury, gives indications of the response to be expected in humans (136). The response to acute exposures has been indicated in the summary as CNS depression, liver and kidney injury, and possible cardiac sensitization. At the levels of exposure currently considered acceptable for industrial workers, anesthesia and cardiac sensitization are not of practical concern.

Table 62.2. Physiological Response to Various Concentrations of Chloroform in Humans

Concentration		
mg/L	**ppm**	**Response**
70–80	14,336–16,384	Narcotic limiting concentration
20	4096	Vomiting, sensation of fainting
7.2	1475	Dizziness and salivation after a few minutes
5	1024	Dizziness, intracranial pressure, and nausea after 7 min
5	1024	Definite after effects; fatigue and headache still felt later
1.9	389	Endured for 30 min without complaint
1–1.5	205–307	Lowest amount that can be detected by smell

It has been reported that exposures to 40,000 ppm may be lethal unless brief and that surgical anesthesia required 10,000–20,000 ppm. These concentrations and those listed in the table must be used cautiously because the data are old and in many cases involved other drugs during surgery.

7.4.2.2.2 Chronic and Subchronic Toxicity Several studies show kidney toxicity in humans after inhalation exposure. The liver is a primary target of chloroform toxicity in humans.

7.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms Chloroform enters the body by skin contact or breathing contaminated air and quickly enters the blood from lungs or intestines. Chloroform usually collects in body fat, but its volatility ensures that it will eventually be removed once the exposure has been removed. Some of the chloroform leaves unchanged and some is broken down.

7.4.2.2.4 Reproductive and Developmental Whether chloroform has caused harmful reproductive effects or birth defects has not been determined.

7.4.2.2.5 Carcinogenesis The USEPA considers the information Inadequate with regard to human carcinogenesis. There are no epidemiological studies of chloroform itself. Chloroform and other trihalomethanes are formed from the interaction of chlorine with organic material found in water. Several ecological and case-control studies of populations consuming chlorinated drinking water in which chloroform was the major chlorinated organic show small significant increases in the risk of rectal, bladder, or colon cancer on an intermittent basis. Many other suspected carcinogens were also present in these water supplies.

There is a possible link between drinking chlorinated water and colon and urinary bladder cancer. However, it is not determined if liver and kidney cancer would develop after long-term exposure in drinking water. The Department of Health and Human Services (DHHS) has determined that

chloroform may reasonably to anticipated to be a carcinogen. IARC has determined that chloroform is possibly carcinogenic to humans (class 2B). The USEPA has determined that chloroform is a probably human carcinogen.

An IARC Working Group considered the evidence for the carcinogenicity of chloroform in humans to be inadequate. Several epidemiological and ecological studies indicate that there is an association between cancer of the large intestine, rectum, and/or urinary bladder and the constituents of chlorinated water. Although data may suggest a possible increased risk of cancer from exposure to chloroform in chlorinated drinking water, the data are insufficient to evaluate the carcinogenic potential of chloroform.

7.4.2.2.6 Genetic and Related Cellular Effects Studies See Section 7.4.2.2.5.

7.4.2.2.7 Other: Neurological, Pulmonary, Skin Sensitization, etc The CNS is a major target for chloroform toxicity in humans and in animals. Once widely used as an anesthetic for humans, levels of 3000–30,000 ppm were reached. A concentration of approx. 40,000 ppm over several minutes can cause death. Dizziness and vertigo were observed in humans after exposure to 920 ppm chloroform for 3 min; headache and slight intoxication occurred at higher concentrations.

7.4.2.3 Epidemiology Studies Most of the data regarding inhalation exposure in humans were obtained from clinical reports describing health effects under anesthesia.

7.4.2.3.1 Acute Toxicity See above (Section 7.4.2.3).

7.4.2.3.2 Chronic and Subchronic Toxicity Chloroform-induced hepatotoxicity is one of the major toxic effects observed in both humans and animals after inhalation exposure.

Workers exposed to 14–400 ppm chloroform for 1–6 months developed toxic hepatitis and other effects, including jaundice, nausea, and vomiting without fever. In contrast, toxic hepatitis was observed in workers exposed to 2-205 ppm.

7.4.2.3.4 Reproductive and Developmental No studies show reproductive effects or developmental effects in humans after inhalation exposure.

7.4.2.3.5 Carcinogenesis No studies were located regarding cancer in humans or animals after inhalation exposure.

Epidemiological studies suggest an association between cancer in humans and the consumption of chlorinated drinking water, but the results are not conclusive at this time. Many confounding effects in these studies are still unaccounted for. The studies dif-fered regarding the type of cancer associated with consumption of chlorinated water. Confounding factors include the presence of other trihalomethanes, haloacetic acids, halo-acetonitriles, halogenated aldehydes, ketones and furanones, and chlorine. Overall, the human data are insufficient to support a conclusion regarding carcinogenicity in humans.

7.4.2.3.6 Genetic and Related Cellular Effects Studies No studies indicated genotoxic effects in humans after inhalation studies.

7.4.2.3.7 Other: Neurological, Pulmonary, Skin Sensitization, etc Epidemiological studies indicate that chloroform can cause cardiac effects in patients under anesthesia.

7.5 Standards, Regulations, or Guidelines of Exposure

NIOSH recognizes chloroform as a carcinogen, and recommends a STEL of 2 ppm; ACGIH, TLV TWA is 10 ppm, with an A3 designation. OSHA has a ceiling limit of 50 ppm.

WHO has a drinking water guideline of 30 mg/L.

IARC classifies chloroform as a group 2B (possibly carcinogenic to humans, and EPA as a B2, probable human carcinogen

The NTP database gives the following information. EPA regulates chloroform under the Clean Water Act (CWA), Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), Food, Drug, and Cosmetic Act (FD&CA), Resource Conservation and Recovery Act (RCRA), Safe Drinking Water Act (SDWA), and Superfund Amendments and Reauthorization Act (SARA). Chloroform is a toxic pollutant of air and water. EPA has established water-quality criteria for chloroform, effluent guidelines, rules for regulating hazardous spills, general threshold amounts, and requirements for handling and disposal of chloroform wastes. A reportable quantity (RQ) of 10 lb has been established for chloroform under CERCLA and CWA. Chloroform is exempted under FD&CA from tolerances for pesticide chemicals. Chloroform is recognized as an inert ingredient of toxicological concern under FD&CA. A rebuttable presumption against registration of chloroform-containing pesticides has been issued under FIFRA. Chloroform is regulated as a hazardous constituent of waste under RCRA. USEPA requires removal of chloroform from drinking water and establishes a maximum contaminant level (MCL) of 100 mg/L under SDWA. Under EPCRA, EPA identifies chloroform as an extremely hazardous substance and established a threshold planning quantity (TPQ) of 10,000 lb for chloroform. FDA regulates chloroform as an indirect food additive for adhesive components in food packaging materials and as a component of materials that come into contact with food. The use of chloroform in food, drugs (for both humans and animals), and cosmetics for use in cough preparations, liniments, cosmetics, and toothache drops is banned under the Federal Food, Drug, and Cosmetic Act

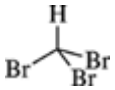
Saturated Methyl Halogenated Aliphatic Hydrocarbons
Jon B. Reid, Ph.D., DABT

8.0 Bromoform
8.0.1 CAS Number:
[*75-25-2*]
8.0.2 Synonyms:
Methenyl tribromide, tribromomethane; methyl tribromide
8.0.3 Trade Names:
NCI-C55130, RCRA Waste Number U225, UN 2515
8.0.4 Molecular Weight:
252.73
8.0.5 Molecular Formula:
$CHBr_3$
8.0.6 Molecular Structure:



8.1 Chemical and Physical Properties
8.1.1 General Bromoform is a colorless, nonflammable, heavy liquid, similar to chloroform in odor

and taste.

Physical state	Colorless liquid
Specific gravity	2.890 (20/4°C)
Melting point	9°C
Boiling point	149.5°C
Vapor pressure	5 torr at 20°C
Refractive index	1.5980 (19°C)
Percent in “saturated” air	0.7 (25°C)
Solubility	0.3 g/100 mL water at 30°C; soluble in ethanol, ethyl ether, benzene
Flammability	Not flammable by standard tests in air

1 mg/L = 97 ppm and 1 ppm = 10.34 mg/m^3 at 25°C, 760 torr

8.1.2 Odor and Warning Properties Bromoform has a sweetish, chloroformlike odor but odor should not be considered as a warning property.

8.2 Production and Use

Bromoform has quite limited use as a chemical intermediate. It was formerly used as an antiseptic and sedative. It is formed during the chlorination of certain water supplies and sewage. It is also used to make high density liquids for geologic analysis and in the shipbuilding and aircraft industries.

8.3 Exposure Assessment

Bromoform may be absorbed through the lungs, from the GI tract, and, to a certain extent, through the skin. The brain contains higher concentrations of bromoform than blood and liver following inhalation (234). After oral administration, bromoform is rapidly absorbed. Gastrointestinal absorption following oral exposure has been estimated to be 60–90% complete following a single gavage dose; this percentage of the administered dose was recovered in the expired air, in urine, or in the tissues (235). Tribromomethane has been identified as a drinking-water contaminant resulting from water chlorination.

8.3.3 Workplace Methods NIOSH Analytical Method 1003 is recommended for determining workplace exposures to bromoform (11).

8.3.4 Community Methods: NA

8.3.5 Biomonitoring/Biomarkers Blood bromide might be useful in monitoring exposure to bromoform, but at this time data are inadequate to quantitate exposure.

8.4 Toxic Effects

This compound is a lacrimator. It can damage the liver to a serious degree and cause death. It is an irritant of the skin, eyes and respiratory tract and has narcotic effects. When heated to decomposition it emits toxic fumes of bromine. It may be absorbed through the skin. Bromoform causes anesthesia and sedation in animals that may take days for recovery following treatment.

The health effects of exposure to tribromomethane have been reviewed (236).

In the early 1900s, tribromomethane was administered as a sedative to children suffering from whooping cough, and several deaths resulted from accidental overdoses (59, pp. 65–67). The most obvious clinical sign in these fatal cases was profound CNS depression that was manifested as unconsciousness, stupor, and loss of reflexes. Death was usually the result of respiratory failure. These case reports are of limited value because doses were not quantified; however, the doses were likely in the range of 20–40 drops (150–300 mg/kg) daily.

Very limited industrial experience is reported for bromoform. Data from studies in animals indicate pronounced CNS effects, moderate acute and chronic liver and kidney toxicity, and a probably carcinogenic response in rats but not mice. An ATSDR review is available (237).

8.4.1 Experimental Studies The principal cause of death in laboratory animals following acute oral exposure to tribromomethane is CNS depression (238). Moody and Smuckler (239) exposed Sprague–Dawley rats ($n = 3$) to single-gavage doses of 1000 mg/kg tribromomethane and observed significant reductions in the liver microsomal cytochrome P450 content and aminolevulinic acid–dehydratase activity and increases in porphyrin and glutathione content. These effects suggest disturbances in hepatic heme metabolism, because porphyrins are major intermediates in heme synthesis. Chu et al. (240) reported that female rats were more sensitive than male rats to lethal doses of tribromomethane based on LD_{50} values of 1388 and 1147 for males and females, respectively.

8.4.1.1 Acute Toxicity Dogs were exposed to an atmosphere of bromoform at ≥ 7000 ppm. The dogs were deeply anesthetized after 8 min and died after a 1 h exposure (241). An inhalation LC_{Lo} of 4500 mg/m^3 for the rat from a 4 h exposure to bromoform has been reported (242). Results of subcutaneous administration have been reported. An LD_{50} of 1820 mg/kg for the mouse was reported by Kutob and Plaa. (243). Narcosis and hepatotoxic effects were observed. Undiluted bromoform was moderately irritating to rabbit eyes, but healing was complete in 1–2 days. Repeated skin contact caused moderate irritation to rabbit skin (244).

8.4.1.2 Chronic and Subchronic Toxicity The results of 2-year gavage study are discussed in the section on carcinogenicity (245).

Low-level inhalation exposure of humans to tribromomethane results in irritation, lacrimation, and reddening of the face, suggesting the potential for portal-of-entry effects. The information available on inhalation exposure in laboratory animals comes primarily from older studies that employed high concentrations for short durations. In these studies, the CNS, liver, and kidney are major target organs following acute inhalation exposures. Exposure to tribromomethane vapors may also cause irritation to the respiratory tract and lacrimation (59, pp. 65–67).

In another study, 10 F344/N rats/sex were gavaged with 0, 12, 25, 50, 100, or 200 mg/kg bromoform and 10 B6C3F$_1$ mice/sex were gavaged with 0, 25, 50, 100, 200, or 400 mg/kg bromoform 5 days/week for 13 weeks. Complete histology was conducted on high dose and vehicle control groups of both species. Liver histology was conducted on all rats and on male mice receiving doses of > 100 mg/kg. Females of both species did not show any chemically-related effects. A decrease in body weight of both sexes of mice was reported, but was not dose-related. The male mice showed fatty metamorphosis of the liver at doses of 200 and 400 mg/kg. The only effect reported for male rats was a dose-related increase in clear cell foci of the liver. A Fisher Exact Test showed that the incidence of the clear cell foci at doses of ≥ 50 mg/kg (the LOAEL) or above was statistically elevated relative to the vehicle control ($p = .035$); therefore, 25 mg/kg is the NOEL for F344/N rats (246).

The health effects data for bromoform (tribromomethane) were reviewed by the USEPA RfD/RfC Work Group (5) and determined to be inadequate for the derivation of an inhalation RfC. The verification status for this chemical is currently “Not verifiable.”

The only studies of subchronic-duration inhalation exposure are reported in abstracts that do not provide sufficient detail for critical evaluation. Tribromomethane had a narcotic effect on rabbits administered single inhalation exposures of 1064–1741 ppm tribromomethane (188). Rats administered 240 ppm tribromomethane vapor for 10 days developed CNS effects and dystrophic and vascular alterations of the liver and kidney (188). Vapor concentrations of 24 ppm for 2 months also induced hepatic disorders, characterized by decreased blood clotting and impaired glycogenesis, and altered renal filtration capacity (189). A concentration of 4.8 ppm tribromomethane in rats did not elicit any adverse effects in rats after 2 months of exposure (188). These reports provide no details regarding exposure generation or characterization, specific effect measures, or results and are

inadequate for derivation of an RfC.

Studies of 14–90 days' duration in rats and mice exposed by gavage have reported liver, kidney, and thyroid effects, as well as transient lethargy at high concentrations (207, 246). In the NTP (246) study, the incidences of hepatocyte vacuolization in male rats were 3/10, 6/10, 5/10, 8/10, 8/10, and 10/10 for the control, 12, 25, 50, 100, and 200 mg/kg groups, respectively. In mice, 5/10 male mice that received 200 mg/kg and 8/10 male mice that received 400 mg/kg tribromomethane developed cytoplasmic vacuolization. This dose-related, minimal-to-moderate change involved only a few cells or was diffuse. Behavioral effects (decreased response rate in an operant-conditioning test) were also reported in mice treated by gavage with 100 or 400 mg/kg daily for 60 days (247).

A 2-year chronic gavage bioassay was conducted in F344/N rats and B6C3F1 mice (50/sex/group), in which doses of 0, 100, or 200 mg/kg (rats and female mice) or 0, 50, or 100 mg/kg (male mice) dibromomethane were administered 5 days/week for 103 weeks (246). In the high dose rats (both sexes), mean body weights were significantly (10–28%) lower than controls throughout the second year of the study. Survival of the male rats administered 200 mg/kg was significantly reduced ($p < .001$) after week 91. Dose-related lethargy was observed in male and female rats. Non-neoplastic changes, including fatty change and scattered minimal necrosis (males) and mixed-cell foci (females), occurred in the liver of treated rats. The incidence of focal or diffuse fatty change in both sexes was increased (males—23/50, 49/50, and 50/50; females—19/50, 39/50, and 46/50). The lowest daily dose tested in this bioassay (100 mg/kg) induced effects on the liver, salivary gland, prostate gland, lungs, and forestomach, and thus is considered a LOAEL for rats. High dose female mice developed an increased incidence of follicular cell hyperplasia of the thyroid gland (5/49, 4/49, and 19/47). Female mice in both groups exhibited increased incidences of minimal-to-mild fatty change of the liver consisting of scattered hepatocyte foci with vacuolated cytoplasm (1/49, 9/50, and 24/50). Thus, 100 mg/kg also is considered a LOAEL for liver changes in female mice.

The database for tribromomethane is inadequate for the derivation of an RfC. No chronic or subchronic inhalation studies on tribromomethane, and no reproductive or developmental studies that employed an inhalation exposure regimen were found. The toxicokinetic data for the inhalation route are insufficient for route-to-route extrapolation from oral data, and the potential for portal-of-entry respiratory tract toxicity has not been adequately characterized.

8.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms The metabolism of tribromomethane is similar to the metabolism of other trihalomethanes (248, 249). Protein synthesis and lipid peroxidation were evaluated in rat liver slices in the presence of oxidants and protein synthesis inhibitors (2, 3). The ability of carbon tetrabromide (and several other halogenated compounds) to inhibit protein synthesis was correlated with its ability to induce lipid peroxidation and was also correlated with their toxicity as indicated by the LD_{50}.

8.4.1.4 Reproductive and Developmental Developmental effects were monitored following gavage administration of 50, 100, or 200 mg/kg/day tribromomethane to pregnant Sprague–Dawley rats (15/group) from days 6–15 of gestation (223). Slight increases in several skeletal anomalies were observed in treated animals and, to a lesser extent, in controls. No other significant maternal toxicity, fetotoxicity, or teratogenicity was observed.

In a reproductive study, effects of tribromomethane were assessed in Swiss CD1 mice ($n = 17–20$/group) exposed by gavage to 0, 50, 100, or 200 mg/kg/day (250). Postnatal survival was significantly decreased in the 200-mg/kg/day group. No other reproductive effects were seen in the F1 or F2 generations.

The reproductive toxicology has recently been reviewed in *Environmental Health Perspectives* (251).

8.4.1.5 Carcinogenesis The USEPA classification is B2, Probable human carcinogen on the basis of inadequate human data and sufficient evidence of carcinogenicity in animals, (*viz.*, an increased incidence of tumors after oral administration of bromoform in rats and IP administration in mice). Bromoform is genotoxic in several assay systems. Also, bromoform is structurally related to other trihalomethanes (*e.g.*, chloroform, bromodichloromethane, dibromochloromethane) that have been verified as either probable or possible carcinogens.

The USEPA considers the animal information "sufficient." Bromoform has been tested for carcinogenicity in two species, rat and mouse (245), by oral or intraperitoneal administration (252).

In a gavage study (245), F344/N rats (50/sex/group) and $B6C3F_1$ mice (50/sex/group) were administered bromoform in corn oil by gavage 5 days/week for 2 years at 0, 100, or 200 mg/kg (rats and female mice) or 0, 50, or 100 mg/kg (male mice). Decreased body weight and survival in rats and female mice suggest that the MTD was reached. In male rats, mean body weight was decreased in the high and low dose groups by 12–28% and 5–14%, respectively. Survival was significantly lower in the high-dose males after week 91. In female rats, body weight was decreased in the high dose group by 10–25%. In male mice, body weight and survival were comparable to controls. In female mice, however, body weight was decreased in the high and low dose groups by 5–16% and 6–11%, respectively; survival was significantly lower in both dose groups after week 77. Neoplastic lesions (adenomatous polyps or adenocarcinomas) were observed in the large intestine (colon or rectum) of male rats (0/50, 0/50, 3/50) and female rats (0/50, 1/50, 8/50). Adenocarcinomas alone were not significantly increased compared with controls. The reduced survival of male rats in the high dose group may account for the lower incidence of lesions in this group. No treatment-related tumors were observed in mice at either dose level. Under the conditions of this study, the NTP judged that there was clear evidence of carcinogenicity for female rats, some evidence of carcinogenicity for male rats, and no evidence of carcinogenicity for male and female mice.

Theiss et al. (252) administered bromoform by IP injection to male A/St mice (20/group). Doses of 100, 48, and 4 mg/kg were given 3 times/week for a total of 24, 23, or 18 injections, respectively. Mice in the control group received 24 IP injections of the vehicle, tricaprylin. Animals were sacrificed 24 weeks after the first injection and the lungs were examined for surface adenomas. Some surface nodules were examined histologically to confirm the morphological appearance of adenomas. The number of lung tumors/mouse for the control, low, mid, and high dose groups were 0.27, 0.53, 1.13, and 0.67, respectively. Only the ratio of the middose group was statistically significantly elevated over that of controls.

In a feeding study with microencapsulated bromoform, Kurokawa (253) observed no evidence of carcinogenicity in male or female Wistar rats exposed for 24 months at concentrations of 400, 1600, or 6500 ppm.

8.4.1.6 Genetic and Related Cellular Effects Studies Bromoform is not strongly mutagenic but positive results have been observed.

Pereira et al. (254, 255) determined that bromoform did not induce GGTase-positive foci in the rat liver at 1 mM (253 mg/kg) or 0.8 mM (202 mg/kg) following a 2/3 hepatectomy and promotion with phenobarbital. However, Pereira found that bromoform is a potent inducer of ornithine decarboxylase, which is an indication of tumor promotion activity in the skin and liver.

Bromoform has been shown to produce mutations in *Salmonella typhimurium* strains TA97, TA98, TA100, and TA1535 with and without rat hepatic homogenates (245). Bromoform also produces mutations at the TK locus in mouse cells (245); SCE induction in Chinese hamster ovary cells, human lymphocytes (*in vitro*) and mouse bone marrow cells (*in vivo*) (245); chromosomal aberrations in Chinese hamster ovary (CHO) cells (256); cell cycle delay in human lymphocytes (229); and an increased incidence of micronuclei in bone marrow erythrocytes from mice given

bromoform IP (245).

8.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization The undiluted liquid was moderately irritating to rabbit eyes, but healing appeared complete in 1–2 days. It was only moderately irritating to rabbit skin even on repeated contact. Single doses of 2000 mg/kg under a cuff on the intact skin of rabbits were survived by two rabbits treated with undiluted bromoform. Lethargy and slight weight loss were noted from these 24 h applications.

8.4.2 Human Experience Exposure to bromoform vapor is reported to have caused irritation of the respiratory tract, pharynx, and larynx, as well as lacrimation and salivation. Accidental ingestion of the liquid has produced CNS depression with coma and loss of reflexes; smaller doses have led to listlessness, headache, and vertigo (59, pp. 65–67).

8.4.2.1 General Information Symptoms of exposure to this compound may include irritation of the eyes, skin, and respiratory tract. Ingestion may cause respiratory difficulties, tremors, and unconsciousness. Dizziness, disorientation, slurred speech, and death may also result from ingestion. Inhalation may be fatal as a result of spasm, inflammation, and edema of the larynx and bronchi; chemical pneumonitis; and pulmonary edema. Other symptoms may include liver and kidney damage and CNS depression. Inhalation may cause irritation of the respiratory tract, pharynx, and larynx, producing lacrimation and salivation. It can also cause skin and eye irritation. Repeated or prolonged contact may cause dermatitis.

Much of the experience in poisoning cases in humans has been from the oral administration of the material. This was summarized by von Oettingen in 1955 (59, pp. 65–67) and ATSDR in 1990 (237). Anesthesia including respiratory failure has been reported. It has been speculated that an oral dose of 250–500 mg/kg may be lethal to a child, with death be due to CNS depression.

8.4.2.2.5 Carcinogenesis The USEPA considers the information with regard to human carcinogenicity as “inadequate.” Cantor et al. (257) suggest a positive correlation between levels of trihalomethane in drinking water and the incidence of several human cancers. Additional geographic studies of bromoform indicate that there may be an association between the levels of trihalomethanes in drinking water and the incidence of bladder, colon, rectal, or pancreatic cancer in humans. However, the information from these studies is considered incomplete and preliminary because their designs do not permit consideration of several possible variables that may be involved (e.g., personal habits, information on residential histories, and previous exposures) (245).

8.5 Standards, Regulations, or Guidelines of Exposure

Bromoform exposure limits (TWAs) are as follows: NIOSH/OSHA 0.5 ppm; NIOSH IDLH 850 ppm.

The ACGIH recommendation (8) is as follows. Because of its irritant qualities and reported skin absorption, in addition to its potential to cause liver damage and by analogy to related bromine compounds, a TLV TWA of 0.5 ppm, with a skin notation, is recommended for bromoform. At this time, no STEL is recommended until additional toxicological data and industrial hygiene experience become available to provide a better base for quantifying on a toxicological basis what the STEL should be. The reader is encouraged to review the section on excursion limits in the “Introduction to the Chemical Substances” of the current TLV/BEI booklet for guidance and control of excursions above the TLV TWA, even when the 8-h TWA is within the recommended limits. In light of the recent reports on the genotoxicity and carcinogenicity of bromoform, this substance is under review by the TLV Committee.

9.0.4 Molecular Weight:
393.78
9.0.5 Molecular Formula:
CHI_3
9.0.6 Molecular Structure:

9.1 Chemical and Physical Properties
Iodoform is a yellow or greenish-yellow powder or crystalline solid that is volatile with steam and contains 96.69% iodine. It has a very characteristic pungent odor. An odor threshold of 0.005 ppm has been reported.

9.1.1 General

Physical state	Yellow solid
Specific gravity	4.008 (20.4°C)
Melting point	119°C
Flammability	Not flammable by standard tests in air
Boiling point	210°C, sublimates, explodes
Refractive index	1.800 (20°C)
Solubility	0.01 g/100 mL water at 25°C
UEL, LEL	Not available

1 mg/L = 62.1 ppm and 1 ppm = 16.1 mg/m^3 at 25°C, 760 torr
9.2 Production and Use
Iodoform has limited use as a chemical intermediate and for medicinal purposes as disinfectant and antiseptic. It may still be used in veterinary medicine.
9.3 Exposure Assessment
9.3.1 Air: NA

9.3.2 Background Levels: NA

9.3.3 Workplace Methods: NA

9.3.4 Community Methods: NA

9.3.5 Biomonitoring/Biomarkers Increased iodine and carboxyhemoglobin levels may occur in the blood but data are inadequate to evaluate their usefulness in monitoring occupational exposure.
9.4 Toxic Effects

Little additional information was found.

This material is irritating to the skin, eyes, and mucous membranes. It may be absorbed through the skin. When heated to decomposition this compound emits toxic fumes of carbon dioxide, carbon monoxide, and hydrogen iodide. Decomposition becomes violent at 204°C (400°F).

Most of the problems associated with iodoform have been related to its topical application as an antiseptic material and to oral administration. Absorption of significant amounts of this material may result in CNS depression and injury to the heart, liver, and kidneys. Serious injury to the eyes has been reported following early use of iodoform as a topical and intravitreal antiseptic.

9.4.1 Experimental Studies 9.4.1.1 Acute Toxicity According to the available information, iodoform has oral LD_{50}s of 355, 810, and 487 mg/kg for rats, mice, and guinea pigs, respectively (258). Drowsiness and low activity were first observed without loss of motor activity, but bloody nasal exudate, breathing disturbances, tonic–clonic convulsions, and paralysis of the extremities preceded death. Daily oral administration of 35.5 mg/kg (carrier not described) caused liver and kidney injury. The report also described changes in the brain and thyroid. This report does not appear to be consistent with the NCI report discussed in the section on carcinogenesis.

Administration of iodoform to rats has produced an acute hepatic necrosis, not unlike that observed following exposure to carbon tetrachloride (259).

No reports on testing of iodoform in the eyes of animals were found. Old medical literature describes serious injury to the eyes following treatment of humans with iodoform as an antiseptic.

According to Grant (260), iodoform formerly was employed as a topical and intravitreal antiseptic. Systemic intoxication and visual disturbances resulted from absorption of excessive amounts applied to wounds or abscesses, or from ingestion of large quantities, but not from application to the eye. Numerous cases of visual disturbance were reported early in the twentieth century. Most characteristically vision was impaired by retrobulbar neuritis with accompanying central scotoma. In rare instances transitory complete blindness occurred. In some cases the bulbar portion of the optic nerve was involved, with neuroretinitis and occasional retinal hemorrhages. As a rule, recovery was slow, requiring many months. In most cases vision was completely or partially recovered, but residual pallor of the temporal part of the optic nervehead was common. Exceptionally the whole nervehead became atrophic and white and little vision was recovered.

A percutaneous LD_{50} of 1184 mg/kg was determined in rabbits for a 70% ointment of iodoform (258). Some veterinary reports indicate toxicity from use on the skin of dogs and cats, but it is not clear whether the material was absorbed dermally or ingested.

Rats were exposed once or 7 times to iodoform vapors (261). A 7 h LC_{50} of 183 ppm was determined for the single exposure of rats. Seven 7 h exposures were given to 0, 1, or 14 ppm (verified analytically). There were no changes in rats' appearance, food or water intake, urine and feces output, or SMR (standardized mortality rate) 12/60 blood value for any group. The only histological manifestation was mineralized deposits in medullary renal tubules of some rats exposed to 14 ppm.

Kutob and Plaa (243) administered iodoform subcutaneously to mice in an investigation of hepatotoxicity of a series of halogenated methanes. The LD_{50} by this route was 1.6 mmol/kg (630 mg/kg) compared to 27.5 mmol/kg for chloroform and 7.2 mmol/kg for bromoform. The doses causing changes in a phenobarbital sleeping time study were 0.59, 1.7, and 2.3 mmol/kg for iodoform, chloroform, and bromoform, respectively. Histological damage to the liver was noted at 1.28 mmol/kg (504 mg/kg) but not at 0.32 mmol/kg.

9.4.1.2 Chronic and Subchronic Toxicity No adequate study to determine the chronic toxicity of iodoform exists. Although survival and body weight were affected in the NCI bioassay reported in Section 9.4.1.1 (262), the doses fed were so high as to be improbable as vapor concentrations. They would indicate a low order of systemic toxicity.

9.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms The limited data that are available indicate iodoform exposure results in increased carboxyhemoglobin levels in rats. A rat liver microsomal fraction requiring both NADPH and molecular oxygen produced the carbon monoxide (248, 263). A mixed-function oxidase has been reported to be involved.

9.4.1.5 Carcinogenesis Iodoform has been included in the NCI daily bioassay program (262). According to their summary: the high and low time-weighted average daily dosages of iodoform were, respectively, 142 and 71 mg/kg for male rats, 55 and 27 mg/kg for female rats, and 93 and 47 mg/kg for male and female mice. A significant positive association between dosage and mortality was observed in male rats but not in female rats or in mice of either sex. Adequate numbers of animals in all groups survived sufficiently long to be at risk from late-developing tumors. No statistical significance could be attributed to the incidences of any neoplasms in rats or mice of either sex when compared to their respective controls. Under the conditions of this bioassay, no convincing evidence was provided for the carcinogenicity of iodoform in Osborne–Mendel rats or $B6C3F_1$ mice.

9.4.1.6 Genetic and Related Cellular Effects Studies Limited data indicate some mutagenic potency, but the data appear inadequate to draw a conclusion toward industrial significance.

9.4.2 Human Experience The 1980s–1990s literature deals mainly with the veterinary uses of the compound. Used as an antiseptic, iodoform produces acute depression of the central nervous system, systemic toxicity, vomiting, coma, and kidney, liver, and heart damage (264). Only one instance of delirium and hallucination has been reported (265).

9.4.2.1 General Information Symptoms of exposure to this compound may include dermatitis, vomiting, varying degrees of cerebral depression or excitation (including delirium, hallucinations, coma, and death), very rapid pulse, possible slight fever, CNS depression, collapse, frequent liquid stools, abdominal pain, thirst, metallic taste, shock, anuria, stupor, esophageal stricture, diarrhea, vesiculation and oozing of skin, intense itching, burning pain, tenderness, nausea, uremia, respiratory distress, and circulatory collapse. Exposure may also result in injury to the heart, liver, and kidneys.

No reports in the literature were found for industrial use of iodoform.

9.4.2.2 Clinical Cases There are several reports of iodoform toxicity caused by medical uses. Authors warn that iodoform toxicity is not as rare as thought and has been underdiagnosed. A case of iodoform toxicity caused by use of 5% iodoformed bandages in occlusive surgical dressings caused signs and symptoms of iodoform toxicity syndrome (266). In another paper (267), where three cases of iodoform toxicity were described following dressings with 10% iodoform gauze on extended wounds, the author indicated that 5, 10, and 16 days after beginning of dressings, the patients became confused, hallucinated, and one of them was subsequently comatose. Within a few days (3–8) after the iodoform dressings were discontinued, the signs of iodoform toxicity disappeared. The author suggests that the toxicity of iodoform is probably unrecognized if the rarity of the observations published and the amount of iodoform gauzes annually sold are compared.

9.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV TWA is 0.6 ppm (10 mg/m^3). The NIOSH REL is also 0.6 ppm.

HSE OES (United Kingdom) 0.6 TWA ppm

TWA mg/m^3	
STEL/CEIL© ppm	1
STEL/CEIL© mg/m^3	16

The ACGIH (8) reports are as follows. Toxicologic data on inhaled iodoform are very limited. Depression of the CNS and damage to the kidneys, liver, and heart following topical application of high, local concentrations to damaged skin have occurred in humans. Accordingly, a TLV TWA of 0.6 ppm is recommended for iodoform. This value is slightly greater than that for bromoform, but on a molar basis, it is considerably higher. Both limits should be used with caution, as there are only scant data and little pertinent use experience with inhaled iodoform. The iodoform TLV approximates that of methyl iodide on an iodine basis. At this time, no STEL is recommended until additional toxicological data and industrial hygiene experience become available to provide a better base for quantifying on a toxicological basis what the STEL should be.

International occupational exposure values:

Australia	TWA 0.6 ppm (10 mg/m^3) January 1993.
Belgium	TWA 0.6 ppm (10 mg/m^3) January 1993.
Denmark	TWA 0.2 ppm (3 mg/m^3) January 1993.
Finland	TWA 0.2 ppm (3 mg/m^3); STEL 0.6 ppm (10 mg/m^3); Skin January 1993.
France	TWA 0.6 ppm (10 mg/m^3) January 1993.
Ireland	TWA 0.6 ppm (10 mg/m^3); STEL 1 ppm (20 mg/m^3) January 1997.
The Netherlands	TWA 0.2 ppm (3 mg/m^3) October 1997.
Switzerland	TWA 0.6 ppm (10 mg/m^3) January 1993.

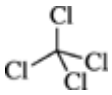
10.0.6 Molecular Structure:



10.1 Chemical and Physical Properties
Carbon tetrachloride is a colorless, highly volatile liquid with a strong ethereal odor similar to chloroform. It mixes sparingly with water. When heated to decomposition, it emits highly toxic fumes of phosgene.

10.1.1 General

Physical state	Colorless liquid
Specific gravity	1.589 at 25°C
Freezing point	–23°C
Boiling point	76.5°C
Vapor pressure	115.2 torr at 25°C
Refractive index	1.46305 (15°C)
Percent in “saturated” air	15 (25°C)
Solubility	0.08 g/100 g water at 20°C; miscible with alcohol, ethyl ether, benzene
Flammability	Not flammable by standard tests in air; will not support combustion
UEL, LEL	Not available

1 mg/L = 159 ppm and 1 ppm = 6.29 mg/m^3 at 25°C, 760 torr

10.1.2 Odor and Warning Properties Carbon tetrachloride has a sweetish odor. It is not considered particularly disagreeable by most people, although some people may be nauseated by small amounts. The odor is one to which the average individual becomes readily adapted. The odor would certainly not be considered a satisfactory warning of excessive exposure. According to one reference, the threshold of detection of the odor of carbon tetrachloride is approximately 79 ppm and the odor is strong at 176 ppm (268). Another reference states that 100% of a small panel of test subjects recognized 21 ppm of carbon tetrachloride produced from carbon disulfide and 100 ppm of carbon tetrachloride produced by chlorination of methane (269).
10.2 Production and Use
Our understanding of the industrial hygiene measures necessary to handle carbon tetrachloride has changed little since Irish prepared his chapter in Patty's Toxicology for the second revised edition of Volume 2. Awareness of its hepato- and renal toxicity and the availability of less hazardous solvents have resulted in virtually no use as a solvent; most of current production is consumed in the production of fluorocarbons. Use of carbon tetrachloride in fire extinguishers has essentially disappeared, as has use in fumigant mixtures.

Carbon tetrachloride is used primarily as a chemical intermediate in the production of the refrigerants Freon 11 and 12. Freon 11 and 12 are also used as solvents, in plastic and resin production, and as foam blowing agents, and previously as aerosol propellants. Carbon tetrachloride also is used as a general solvent in industrial degreasing operations. Its use as a grain fumigant was banned by USEPA in 1985.

Chemical and Engineering News reported that 271 million lb of carbon tetrachloride was produced domestically in 1990. U.S. imports of carbon tetrachloride have tended to increase, and exports have tended to decrease. Carbon tetrachloride imports exceeded 111 million lb in 1987. Imports increased to over 57 million lb in 1985 from 7 million lb in 1983. Exports decreased from 86 million lb in 1980 to 36 million lb in 1985.

10.3 Exposure Assessment

The primary routes of potential human exposure to carbon tetrachloride are inhalation, ingestion, and dermal contact. The greatest risk of occupational exposure to carbon tetrachloride occurred most likely during fumigation processes before this use was banned in 1985. NIOSH estimated that workers exposed to carbon tetrachloride are primarily those at blast furnaces and steel mills, in the air transportation industry, and in motor vehicle and telephone and telegraph equipment manufacturing.

About 4500 workers are possibly exposed during production processes, and 52,000 during industrial use of the chemical. OSHA estimated that 3.4 million workers may possibly be exposed to carbon tetrachloride directly or indirectly.

Exposure to carbon tetrachloride used to occur in dry-cleaning establishments, where ambient-air concentrations have been determined to average between 20 and 70 ppm. Average exposures of 206 and 338 ppm with excursions of 1252 and 7100 ppm have been reported during dry-cleaning machine operations. Occupational exposure is also possible during its use in the manufacture of Freon 11 and 12. Exposure during fluorocarbon production is most likely to be experienced by tank farm and process operators, who may be exposed to emissions arising from storage tank vents or resulting from transfer of the chemical or process equipment leaks or spills. The National Occupational Hazard Survey, conducted by NIOSH from 1972 to 1974, estimated that 160,000 workers were exposed to carbon tetrachloride in the workplace, including 25,000 workers exposed during grain fumigation. The National Occupational Exposure Survey (1981–1983) estimated that 77,315 workers, including 12,605 women, potentially were exposed to carbon tetrachloride. ACGIH has noted the potential contribution to overall exposure by the cutaneous route, including mucous membranes and eyes, either by airborne, or more particularly, by direct contact with the substance.

The Toxic Chemical Release Inventory (EPA) (4) listed 95 industrial facilities that produced, processed, or otherwise used carbon tetrachloride in 1988. In compliance with the Community Right-to-Know Program, the facilities reported releases of carbon tetrachloride to the environment which were estimated to total 3.9 million lb. These releases indicate that a large proportion of the general population is possibly exposed to the chemical. EPA estimated that 8 million people living within 12.5 m of manufacturing sites are possibly exposed to average levels of 0.5 g/m^3, with peaks of 1580 g/m^3. Carbon tetrachloride is readily volatile at ambient temperature and is a stable chemical that is degraded very slowly, so there has been a gradual accumulation of carbon tetrachloride in the environment (270). It is broken down, by chemical reactions in air, but this occurs so slowly that elimination of 50% of the carbon tetrachloride takes between 30 and 100 years. Carbon tetrachloride is formed in the troposphere by solar-induced photochemical reactions of chlorinated alkenes. Concentrations of 0.1 ppb in air are common worldwide with somewhat higher values (0.2–0.6 ppb) in cities (270). Of 113 public water systems surveyed, 10% had mean concentrations of carbon tetrachloride ranging from 2.4 to 6.4 g/L. Investigators also found the chemical in 45% of surface-water supplies and in 25% of groundwater samples, at concentrations of 0.001–0.40 mg/L. Estimates indicate that 19 million people may potentially be exposed to carbon tetrachloride through ambient air, 20 million possibly through contaminated drinking water, and 2 million possibly through contaminated soil or landfills. Assuming inhalation of 20 m^3/day by a 70-kg adult and 40% absorption of carbon tetrachloride across the lung, typical levels of carbon tetrachloride in ambient air (~ 1 g/m^3) yield daily exposure levels of ~ 0.1 g/kg per day (270). Somewhat higher exposures could occur near point sources of carbon tetrachloride. For water, consumption of 2 L/day by a 70-kg adult at a typical carbon tetrachloride concentration of 0.5 g/L yields a typical intake by this route of ~ 0.01 g/kg per day. Carbon tetrachloride may possibly have been ingested as a contaminant of foods that were treated with the chemical prior to its banning as a grain fumigant in 1985. When carbon tetrachloride was used as a fumigant on stored grain, residue concentrations of the chemical ranged from 3.0 to 72 mg/kg. Carbon tetrachloride may possibly be ingested in water contaminated with the chemical (reported concentrations range 0.2–18 ppm). Also, the chemical possibly may be ingested as a contaminant of drinking water treated with chlorine. Investigators have found carbon

tetrachloride in human tissues in concentrations of 1–13 ppm.

10.3.1 Air See above (Section 10.3).

10.3.2 Background Levels See above (Section 10.3).

10.3.3 Workplace Methods NIOSH Method 1003, for halogenated hydrocarbons, is recommended for determining workplace exposures to carbon tetrachloride (11).

10.3.4 Community Methods: NA

10.3.5 Biomonitoring/Biomarkers Unchanged carbon tetrachloride can be measured in the expired air following exposures. Stewart et al. (271) have shown the relationship of exposure concentration and time to exhaled concentration, and it would appear that at the low levels of exposure considered safe for chronic exposure, breath samples are of very limited value. Expired air may be of value in definitive diagnosis of acute exposure and possibly in semiquantitation of the magnitude of exposure.

At present, metabolites in blood or urine appear to be of limited value in monitoring exposure at levels recognized as acceptable for industrial exposure because exposure to 5 ppm vapor permits daily intake of only 4.5 mg/kg (272).

10.4 Toxic Effects

Carbon tetrachloride is a human poison by ingestion and possibly other routes and a poison by subcutaneous and intravenous routes. It is mildly toxic by inhalation; an experimental carcinogen, neoplastigen, tumorigen, teratogen and suspected human carcinogen; and an eye and skin irritant. Individual susceptibility varies widely. It has a narcotic action resembling that of chloroform, although not as strong. The aftereffects following recovery from narcosis are more serious than those of delayed chloroform poisoning, usually taking the form of damage to the kidneys, liver, and lungs. When recovery takes place, there may be no permanent disability. Marked variation in individual susceptibility to this compound exists; some persons appear to be unaffected by exposures that seriously poison their fellow workers. Concentrations on the order of 1000–1500 ppm are sufficient to cause symptoms if exposure continues for several hours. Repeated daily exposure to such concentrations may result in poisoning. Exposure to high concentrations of carbon tetrachloride results in depression of the central nervous system and possibly cardiac sensitization. If the concentration is not high enough to lead to rapid loss of consciousness, other indications of CNS effects such as dizziness, vertigo, headache, depression, mental confusion, and incoordination are observed. Many individuals also show GI responses such as nausea, vomiting, abdominal pain, and diarrhea. This may be a conditioned reflex or a direct CNS effect. Functional and destructive injury of the liver and kidney may occur from a single acute exposure, but it is much more likely to occur from repeated exposures. In a case of long-term chronic exposure to low concentrations, kidney and liver injury dominate the picture. The milder the exposure, the greater the tendency for the injury to be predominantly in the liver. At threshold concentrations, the injury of the liver appears mostly as malfunction and/or enlargement. Many enlarged livers are observed in animals at the threshold of response and enlargement appears reversible. The detection of an enlarged liver in humans should be considered important, although enlargement may occur from a great many other causes. It has been recognized that the concurrent or past intake of significant amounts of alcohol with exposure to carbon tetrachloride may greatly increase the probability of injury. Other chemicals such as isopropyl alcohol, acetone, chlorinated insecticides, phenobarbital, and many other mixed-function oxidase inducers may also be involved. Diabetes and certain nutritional deficiencies have been implicated in enhanced toxic effects from carbon tetrachloride (273).

Because metabolism of carbon tetrachloride is required for most of its toxic effects, there are many examples of species and strain differences in toxicity. Carcinogenic effects ascribed to carbon tetrachloride appear likely to be due to organ injury.

An ATSDR profile (270) exists for carbon tetrachloride, and numerous other reviews are available. Excellent reviews of metabolism, mode of toxic action, and detailed discussion of biochemical effects are presented in two standard reference books (272, 274). Much of our understanding of metabolism by the liver and toxic effects on that organ by other chemicals has come from the numerous studies on carbon tetrachloride.

10.4.1 Experimental Studies 10.4.1.1 Acute Toxicity This compound is toxic by ingestion, inhalation, or skin absorption. It is an irritant of the skin, eyes, mucous membranes, and respiratory tract. It is readily absorbed through the skin. It may cause lacrimation. It is narcotic. When heated to decomposition it emits irritating fumes and toxic fumes of chlorine, carbon monoxide, carbon dioxide, hydrogen chloride, and phosgene. It may also emit other hydrocarbon products (273).

The former availability of carbon tetrachloride in odd containers around the home and shop made ingestion a serious problem. The LD_{50} for rats is reported by McCollister et al. as 2920 mg/kg (275). The Registry of Toxic Effects of Chemical Substances (1983/84 Supplement) lists LD_{50}s of 2800 mg/kg for the rat, 12,800 mg/kg for the mouse, 6380 mg/kg for the rabbit; and 3680 mg/kg for the hamster (276). Numerous values for other routes of exposure are also cited. Liver injury occurs in animals at levels well below those causing death. The therapeutic dose previously used in humans for treatment of ascariasis ranged from 32 mg/kg for infants to 90–100 mg/kg for adults. Consumption of alcohol caused serious complications in some cases.

Because carbon tetrachloride is a good lipid solvent, it removes the fats from the skin and, in so doing, causes a dry disagreeable feeling and may facilitate secondary infection. Contact with the eyes may cause a transient disagreeable irritation but does not lead to serious injury.

10.4.1.2 Chronic and Subchronic Toxicity The IRIS database indicates the study by Bruckner et al. (277) as the basis for subchronic toxicity of the compound. Male Sprague–Dawley rats were given 1, 10, or 33 mg carbon tetrachloride/kg per day by corn oil gavage, 5 days/week for 12 weeks. Liver lesions, as evidenced by mild centrilobular vacuolization and statistically significant increases in serum sorbitol dehydrogenase activity, were observed at the 10- and 33-mg/kg/day doses in a doses-related manner. Therefore, the LOAEL was established at 10 mg/kg/day [converted to 7.1 mg/kg/day] and the NOAEL was 1 mg/kg/day) [converted to 0.71 mg/kg/day].

Adams et al. (278) reported the response of laboratory animals to a single exposure to various concentrations of carbon tetrachloride. The maximum time-concentrations in air survived by rats were as follows: 12000 ppm for 15 min, 7300 ppm for 1.5 h, 4600 ppm for 5 h, and 3000 ppm for 8 h. The maximum time-concentrations in air having no adverse effects in male rats were as follows: 3000 ppm for 6 min, 800 ppm for 30 min, and 50 ppm for 7 h. Similar data were reported for rabbits by Lehmann. The data from these two sources indicated that rabbits and guinea pigs show a somewhat greater tolerance for carbon tetrachloride than rats do. In any case, the acute data given for the different animals are in the same range.

The responses observed in animals and humans are reasonably comparable. There seems to be a higher probability of significant kidney response in humans than is observed in animals. Qualitatively, such injury is observed in both animals and humans. Histopathological and biochemical studies of acutely injured animals show marked hepatic injury, as has been demonstrated by increased plasma prothrombin clotting time, an increase of serum phosphatase, an increase in liver weight, an increase of total lipid content of the liver, and central fatty degeneration of the liver. Renal injury was not apparent in the acute exposure of rats in the studies of Adams (278). Quite significant kidney injury has been reported, however, from what were thought to be single exposures in humans.

Although responses referable to the nervous system or GI tract may still be observed in chronic exposure, they are much less important factors. These effects may not be noticed at all following a

long period of chronic exposure to low concentrations; the organic and functional injury of the internal organs becomes predominant, particularly of the liver and the kidney. It is noticeable in the literature that carbon tetrachloride has become a classic agent for producing liver injury for laboratory investigations.

One comprehensive toxicologic investigation in animals is that of Adams et al. (278). These investigators studied rats, guinea pigs, rabbits, and monkeys, which were given repeated 7 h daily exposures 5 days/week. At a concentration of 400 ppm (2.52 mg/L), rats and guinea pigs suffered severe intoxication. Less than half of them lived for 127 exposures during a period of 173 days. There was an increase in liver weight up to twice that of the controls and a moderate increase in kidney weight. Histological examination of the tissues showed central fatty degeneration with cirrhosis of the liver and slight parenchymatous degeneration of the tubular epithelium of the kidneys. Animals examined after 2 weeks of exposure demonstrated advanced liver and kidney changes by that time. At a concentration of 200 ppm (1.26 mg/L), rats and guinea pigs still showed a definite response and high mortality. Biochemical and histological studies were comparable but less severe than in the 400-ppm exposure. At a concentration of 100 ppm (0.63 mg/L), rats, rabbits, guinea pigs, and monkeys tolerated 146–163 exposures without evidence of adverse effect on gross appearance, behavior, growth, and other parameters. They all showed histopathological changes. The changes were equivocal in the monkey.

A continuous exposure at 61 mg/m^3 (10 ppm) resulted in the deaths of three guinea pigs, as well as growth depression and liver damage in the survivors of all species. A second continuous exposure at 6.1 mg/m^3 (1 ppm) did not cause deaths or visible toxic signs in any species. All species except the rat exhibited slight growth depression but no hematological or histopathological evidence of toxicity, at 6.1 mg/m^3.

Alumot et al. (279) fed rats diets containing carbon tetrachloride for 2 years. On the basis of growth, fertility, reproduction, biochemical tests, and apparently limited histological examination, primarily of the liver, the authors concluded that they had fed a no-effect level of 200 ppm. On the basis of food consumption, this was calculated to be 10–18 mg CCl_4/kg body weight per day. They also reported fatty livers occurred in rats after 5–6 weeks on a diet containing 275 ppm CCL_4, ~ 40 mg/kg/day, and decreased weight gain in male rats fed 520 ppm. Total lipid and triglycerides were significantly higher at 275 and 520 ppm but not 150 ppm after 5–6 weeks.

10.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Early studies to measure absorption and excretion of carbon tetrachloride were handicapped by analytic difficulties. Studies were made only at very high concentrations. McCollister et al. (280) were among the first who studied the absorption, distribution, and elimination of carbon tetrachloride by using radioactive carbon. This allowed them to study these factors at concentrations that were physiologically significant from a chronic exposure point of view. They exposed monkeys to concentrations of 46 ppm (0.290 mg/L) of carbon tetrachloride that was ^{14}C labeled. Approximately 30% was absorbed. The equivalent of at least 51% of the radioactivity due to carbon tetrachloride absorbed during an inhalation period was estimated to have been eliminated in the expired air within 75 days. The remainder was excreted largely in the urine and feces. Approximately 4.4% was eliminated as carbon dioxide. Some 94.3% of the radioactivity in the urine was a nonvolatile, unidentified intermediate. Small amounts occurred as urea and carbonate. Numerous subsequent references to the metabolism of carbon tetrachloride have been published. The review by ATSDR (270) summarized in a diagram the metabolism of carbon tetrachloride as adapted from Shah et al. (281). Metabolism is primarily in the liver but many other organs have also been shown to metabolize it. The identified products underlined in Figure 62.3 support a NADP H-dependent cytochrome P450 isoenzyme reductive dehalogenation, formation of a trichloromethyl free radical, binding to microsomal lipids and proteins, and a number of other reactions to form products such as carbon dioxide, carbon monoxide, hexachloroethane, chloroform, and phosgene. Metabolism is thought to be dose-dependent and saturable, and to involve destruction

of the cytochrome P450 during the metabolism process.

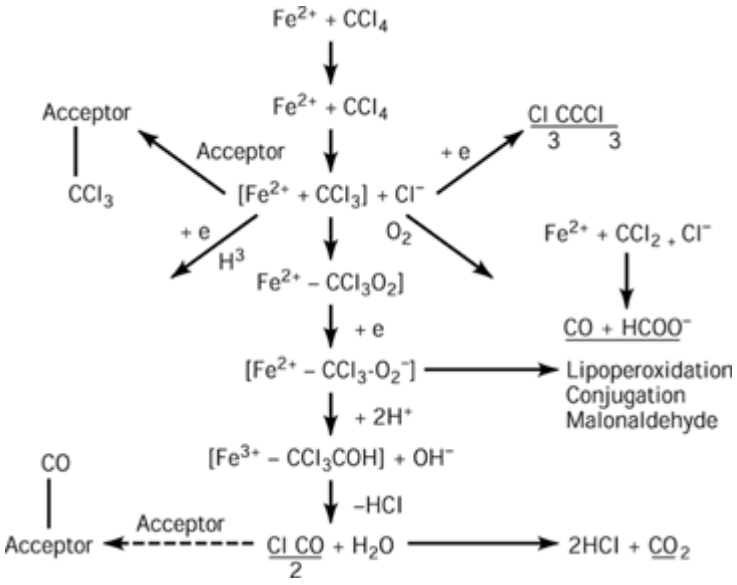


Figure 62.3. Pathways of CCl_4 metabolism. Products identified as carbon tetrachloride metabolites are underlined. [Adapted from Ref. 281.]

Dose–response ratio, time course, and pharmacokinetics following single oral gavage doses of ^{14}C-labeled CCl_4 to rats were studied extensively (282). Carbon dioxide was identified as a major metabolite, with 20–30 times less bound to liver macromolecules. An intermediate amount was excreted in the liver and feces. Metabolism changed extensively as doses were increased. Chloroform, for example, was the least abundant metabolite at low doses, but the second most abundant at high doses. Metabolism by the pathways leading to CO_2 and $CHCl_3$ were more associated with concurrent liver injury as measured by increased transaminase activity than it was to pathways leading to metabolites bound to liver or excreted in urine. Metabolism of CCl_4 clearly impaired the pathway to CO_2 after 2 h of exposure. A significant first-pass effect through the liver is apparent after gavage; unfortunately, few data on metabolism after inhalation are available.

The fatty changes that are characteristic of carbon tetrachloride toxic effect on the liver are due to accumulation of triglycerides, but the mechanism is not yet clear (283). The mechanism is not the same as that producing liver necrosis, another characteristic effect of carbon tetrachloride. Metabolism of carbon tetrachloride is certainly required and lipid peroxidation may play a key role.

10.4.1.3.1 Adsorption Absorption through the skin of monkeys from the vapor phase was studied by McCollister et al. (280). By using radioactive carbon tetrachloride, they were able to detect small amounts in the blood after exposure of the skin to vapor concentrations of 485 and 1150 ppm. Although traces were absorbed through the skin under these conditions, their conclusions were that "absorption through the intact skin would appear to be of no practical significance in considering the hazard to the health of industrial workers exposed to concentrations of at least as high as 1150 ppm in the air."

Stewart and Dodd (167) considered absorption of the liquid through the skin to present a potential problem based on a limited study on human subjects. In view of the high potential hepatotoxicity of carbon tetrachloride, contact of the skin with the liquid should be prevented, particularly if it could lead to repeated exposure.

10.4.1.3.2 Distribution See Section 10.4.1.3.1.

10.4.1.3.3 Excretion See Section 10.4.1.3.1.

10.4.1.4 Reproductive and Developmental Schwetz et al. (283) exposed pregnant rats 7 h/day to either 330 or 1000 ppm carbon tetrachloride vapors from days 6–15 of pregnancy. These exposures had no effect on fetal resorptions but

At both concentrations fetal body weight and crown-rump length were significantly less than that of controls. No anomalies were seen upon gross examination of the fetuses. A significant incidence of subcutaneous edema was observed at 300 ppm but not at 1000 ppm. The incidence of sternal abnormalities was significantly increased in the fetuses of rats exposed to 1000 ppm CCl_4.

Considerable hepatotoxicity was observed in the dams at both concentrations. The authors concluded that carbon tetrachloride is not teratogenic, but is embryo toxic at these concentrations, and that these are not related to hepatotoxicity in the mothers. Smyth et al. (284) observed three generations of rats exposed to 50–400 ppm vapor. In these studies no evidence of reduced fertility or embryonic or fetal abnormalities were observed.

Alumot et al. (279) fed rats diets fumigated with carbon tetrachloride for ≤ 2 years. Storage of diets was in hematically sealed containers and diets were assayed at 80 ± 5 and 200 ± 20 ppm CCl_4. The females were rebred at 2-month intervals for a total of seven matings. From this somewhat unusual experimental design, they concluded that exposure of both male and female rats to diets containing 80–200 ppm had no effect on male fertility, female fertility, or reproductive parameters. On the basis of food consumption during the 2-year period, this amounted to 10–18 mg/kg/day.

After 6 months of repeated 7-h exposure to 200 ppm vapor, the testicular germinal epithelium of rats was adversely affected, perhaps as a secondary effect (278).

10.4.1.5 Carcinogenesis The USEPA (5) classifies carbon tetrachloride as B2 (Animal carcinogenicity data is sufficient); probable human carcinogen on the basis of carcinogenicity in rats, mice, and hamsters. Carbon tetrachloride has produced hepatocellular carcinomas in rats, mice, and hamsters, the species evaluated to date.

Hepatocellular carcinomas developed in Osborne–Mendel, Japanese, and Wistar rats, but not Sprague–Dawley or black rats, following subcutaneous (SC) injection of carbon tetrachloride. Hyperplastic nodules were noted in Buffalo rats treated SC (285–287). Sensitivity varied among strains, and trends in incidence appeared inversely related to severity of cirrhosis. Fifty Osborne–Mendel rats/sex were administered carbon tetrachloride by corn oil gavage at 47 and 94 mg/kg/injection for males and 80 and 159 mg/kg for females 5 times/week for 78 weeks. At 110 weeks, only 7/50 high-dose males and 14/50 high-dose females survived; 14/50 low-dose males and 20/50 low-dose females survived. The incidence of hepatocellular carcinomas was increased in animals exposed to carbon tetrachloride as compared with pooled colony controls. The apparent decrease in the incidence of hepatocellular carcinomas in high dose female rats compared with the low dose females (1/14 *vs.* 4/20, respectively) was attributed by the authors to increased lethality before tumors could be expressed (288–290). In this same study, using the same dosing schedule, male and female $B6C3F_1$ mice received 1250 or 2500 mg/kg carbon tetrachloride. The incidences of hepatocellular carcinomas in males were 5/77, 49/49, and 47/48 in the control, low and high dose groups, respectively, and 1/80, 40/40, and 43/45 in the control, low, and high dose groups, respectively.

Carbon tetrachloride administered by gavage has also been shown to produce neoplastic changes in livers of five additional strains of mice (C3H, A, Y, C, and L). In the last study, 56 male and 19 female L mice, which have a low incidence of spontaneous hepatomas, were treated with 0.1 mL of

40% carbon tetrachloride 2 or 3 times/week over 4 months, for a total of 46 treatments. Animals were killed 3–3.5 months after the last treatment. The combined hepatoma incidence of treated male mice was 47% (7/15 *vs.* 2/71 in the untreated male controls); treated females showed an incidence of 38% (3/8 *vs.* 0/81 in the untreated female controls).

As part of a large study of liver carcinogens, Della Porta et al. (290a) treated Syrian golden hamsters (10/sex/dose) with carbon tetrachloride by gavage, weekly for 30 weeks. For the first 7 weeks, 0.25 mL of 0.05% carbon tetrachloride in corn oil was administered; this dose was halved for the remainder of the exposure period. All animals were observed for an additional 25 weeks. All of the 10 hamsters that were killed or died between weeks 43 and 55 had liver cell carcinomas, compared with none in controls.

IARC (294, 295) states that there is sufficient evidence for the carcinogenicity of carbon tetrachloride in experimental animals. When administered by gavage, carbon tetrachloride increased the incidences of hepatomas and hepatocellular carcinomas in mice of both sexes. By the same route of administration, the compound increased the incidence of neoplastic nodules of the liver in rats of both sexes. When administered by subcutaneous injection, carbon tetrachloride induced hepatocellular carcinomas in male rats and mammary adenocarcinomas and fibroadenomas in female rats. When administered by inhalation, carbon tetrachloride induced liver carcinomas in rats. When administered intrarectally, the compound induced nodular hyperplasia of the liver in male mice.

10.4.1.6 Genetic and Related Cellular Effects Studies Carbon tetrachloride was not mutagenic to either *S. typhimurium* or *E. coli*. At low concentrations, carbon tetrachloride did not produce chromatid or chromosomal aberrations in an epithelial cell line derived from rat liver (291). *In vivo* unscheduled DNA synthesis assays have likewise been negative in male Fischer 344 rats (292). Carbon tetrachloride produced mitotic recombination and gene conversion in *Saccharomyces cerevisiae*, but only at concentrations that reduced viability to 10% (160). Carbon tetrachloride may be metabolized to reactive intermediates capable of binding to cellular nucleophilic macromolecules. Negative responses in bacterial mutagenicity assays may have been due to inadequate metabolic activation in the test systems.

10.4.2 Human Experience 10.4.2.1 General Information Symptoms of exposure to this compound may include headache, mental confusion, CNS depression, fatigue, anorexia, nausea, vomiting, coma, abdominal cramps, dizziness, unconsciousness, weakness, amnesia, paresthesia, tremors, jaundice, and liver and kidney damage. It may also cause depression, loss of appetite, bronchitis, internal irritation, stupor, and damage to the heart and nervous system. Skin contact may remove the natural lipid cover of the skin and it may also lead to a dry, scaly, fissured dermatitis. Other symptoms include GI disturbances, abdominal pain, diarrhea, enlarged and tender liver, toxic hepatitis, diminished urinary volume, red and white blood cells in the urine, and albuminuria. It may also cause narcosis, lung damage, acute nephrosis of the kidney, polyneuritis, narrowing of visual fields and other neurological changes, cirrhosis of the liver, lacrimation, burning of the eyes, malaise, dark urine, renal casts, uremia, epigastric distress, visual disturbances (such as blind spots, spots before the eyes, visual “haze” and restriction of the visual fields), and death. Exposure to this compound depresses and injures almost all cells of the body, including the CNS, liver, kidney, and blood vessels. Depression of the heart muscle may result in ventricular arrhythmias. Damage to the kidneys may result in marked edema and fatty degeneration of the tubules. Other symptoms include slowed respiration, slowed or irregular pulse, fall of blood pressure, sudden weight gain, azotemia, anemia, blurred vision, and loss of peripheral color vision. It may also cause drowsiness, giddiness, oliguria, cellular necrosis of the liver, acute nephritis, and aplastic anemia. Eye and skin irritation, dyspnea, hematemesis, hematuria, proteinuria, weight loss, cyanosis, and miosis have also been reported. Ingestion of this compound with alcohol will intensify the effects of the chemical. Other symptoms include hepatomegaly, optic atrophy, optic neuritis, and pulmonary edema. It may also cause a permanent reduction in vision, deafness, and retrobulbar neuritis. Mucous membrane irritation and anesthesia have also been reported. Hepatic nodular hyperplasia may also occur. Other symptoms include sleepiness, increased peristalsis, erythema, gastroenteritis, and death from

ventricular fibrillation. It may cause disorientation. Alveolitis has occurred. It may cause irritation of the nose and throat, a sense of fullness in the head, convulsions, hepatic steatosis, hypertension, acidosis, and sudden death from depression of vital medullary centers. Other symptoms include flatulence, fatty liver, elevated SGOT, and elevated serum bilirubin. It may also cause incoordination, vertigo, and increased nitrogen retention. Other symptoms are pupillary constriction, unspecified respiratory system and GI system effects, somnolence, severe GI upset, and liver enlargement (273).

Numerous reports of injury and death following acute and repeated exposure of humans to carbon tetrachloride can be found. Few, if any, epidemiological, studies have been completed on an occupationally exposed population, nor have there been laboratory studies of long duration.

Stewart and Dodd (167) and Stewart et al. (271) have conducted experimental human exposure studies with volunteer subjects. These reports indicate that absorption of the liquid through the skin may be significant, particularly in chronic exposure. They have also determined the concentration of carbon tetrachloride in expired air following exposure to the vapor.

10.4.2.2.5 Carcinogenesis An IARC Working Group (294, 295) reported that there were no adequate data to evaluate the carcinogenicity of carbon tetrachloride in humans. Three case reports described liver tumors associated with cirrhosis in humans exposed to carbon tetrachloride. A mortality study of laundry and dry cleaning workers exposed to a variety of solvents suggested an excess of respiratory cancers, liver tumors, and leukemia.

The EPA considers the human data re: carcinogenesis as “inadequate.” There have been three case reports of liver tumors developing after carbon tetrachloride exposure. Several studies of workers (293) who may have used carbon tetrachloride have suggested that these workers may have an excess risk of cancer.

The International Agency for Research on Cancer (IARC) reviewed the available carcinogenicity data in 1972 (294) and again in 1979 (295). Carbon tetrachloride is grouped with 18 chemicals considered “probably carcinogenic for humans” and, according to IARC, is to be regarded “as if it presented a carcinogenic risk to humans.” The EPA reached a similar conclusion in 1988 (296). In a study by the NCI bioassay program, hepatocellular carcinomas developed in mice that received gavaged daily doses of 2500 or 1250 mg/kg for 78 weeks (297). These massive doses also resulted in adrenal tumors. The amount of noncancerous pathology in the liver was not discussed, but may have been significant. Rats were fed doses of 100 (male) or 150 (female) mg/kg, 5 days/week for 78 weeks and then kept for 32 additional weeks. Half of these doses were fed to second groups of rats. According to Weisburger (297), in rats “carbon tetrachloride caused neoplastic nodules and a few carcinomas of the liver. However, the incidence was lower than anticipated.”

Considering the low mutagenic activity and the failure to alkylate DNA, a relationship of liver injury to causation of liver tumors seems plausible.

There appear to be no data on tumors resulting from inhalation of carbon tetrachloride.

10.5 Standards, Regulations, or Guidelines of Exposure

Exposure limits: NIOSH carcinogen, lowest feasible concentration, with a STEL of 2 ppm and an IDLH of 200 ppm. OSHA PEL is 10 ppm, ceiling is 25 ppm and 5-min peak in any 4 hrs is 200 ppm. The ACGIH TLV TWA is 5 ppm and the STEL/C is 10 ppm with an A2 notation.

CPSC banned the use of carbon tetrachloride under the authority of the Federal Hazardous Substances Act (FHSA), as well as mixtures containing the chemical, except for unavoidable manufacturing residues of carbon tetrachloride in other chemicals that do not, during use, result in an air concentration greater than 10 ppm. EPA regulates carbon tetrachloride under the Clean Air Act (CAA), Clean Water Act (CWA), Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), Food, Drug,

and Cosmetic Act (FD&CA), Resource Conservation and Recovery Act (RCRA), Safe Drinking Water Act (SDWA), and Superfund Amendments and Reauthorization Act (SARA). Carbon tetrachloride is designated as a hazardous air pollutant under CAA, hazardous waste under RCRA, and a hazardous substance under CWA. Under CAA, EPA has set emission standards for carbon tetrachloride for point-source categories and any stationary source for which the standards apply. Effluent discharge guidelines have been set under CWA. Carbon tetrachloride is subject to reporting rules under CWA, CERCLA, RCRA, and SARA. Under CERCLA, EPA has lowered the reportable quantity (RQ) of 5000 lb established under CWA to 10 lb (SARA final RQ). EPA has banned the use of carbon tetrachloride as a grain fumigant under FIFRA. Under FD&CA, EPA published data collection and labeling requirements for pesticides containing carbon tetrachloride as an inert ingredient. Carbon tetrachloride is regulated as a hazardous constituent of waste under RCRA (hazardous-waste number, U211; regulatory level, 0.5 mg/L). Under SDWA, EPA set a maximum contaminant level goal (MCLG; 0 mg/L) and a maximum contaminant level (MCL; 0.005 mg/L) for carbon tetrachloride. The World Health Organization (WHO) recommends that no detectable residues (limit: 0.01 ppm) of carbon tetrachloride be allowed on food or feed, but permits 50 mg/kg on cooked cereals. FDA regulates, under FD&CA, the amount of carbon tetrachloride in bottled water and indirect food additives.

10.6 Studies on Environmental Impact:

NA

Saturated Methyl Halogenated Aliphatic Hydrocarbons

Jon B. Reid, Ph.D., DABT

11.0 Carbon Tetrabromide

11.0.1 CAS Number:

[*558-13-4*]

11.0.2 Synonyms:

Tetrabromomethane

11.0.3 Trade Names:

Bromid uhlicity (Czech); Carbon bromide

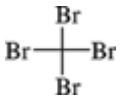
11.0.4 Molecular Weight:

331.63

11.0.5 Molecular Formula:

CBr_4

11.0.6 Molecular Structure:



11.1 Chemical and Physical Properties

11.1.1 General

Physical state	Colorless solid when pure; often yellow to brown
Specific gravity	3.42 (20°C)
Melting point	(*a*) 48.4°C; (*b*) 90.1°C (slight decomposition on melting)
Boiling point	189.5°C (slight decomposition)
Refractive index	1.59998 (99.5°C)
Solubility	0.24 g/100 mL water at 30°C; soluble in ethanol, ethyl ether, chloroform

Flammability Not flammable by standard tests in air

1 mg/L = 74 ppm and 1 ppm = 13.58 mg/m^3 at 25°C, 760 torr

11.1.2 Odor and Warning Properties Carbon tetrabromide has significant lacrimatory effect on the eye at low concentrations. This may be reasonably good warning of acute exposure, but may not be adequate to prevent excessive repeated exposure.

11.2 Production and Use

Carbon tetrabromide is used to a limited extent as a chemical intermediate. It has been isolated from red algae, *Asparagopsis toxiformis*, found in the ocean near Hawaii.

11.3 Exposure Assessment:

NA

11.4 Toxic Effects

Carbon tetrabromide is a highly toxic material, based on the limited amount of toxicologic data available. Little new information is available since the previous edition.

11.4.1 Experimental Studies 11.4.1.1 Acute Toxicity Acute exposure to high concentrations causes upper respiratory irritation and injury to the lungs, liver, and kidneys. The response to chronic exposure at very low concentrations is primarily liver injury. The material is a lacrimator, even at low levels.

The LD_{50} by oral administration was found to be 1800 mg/kg body weight in the rat.

In the eyes of rabbits, the undiluted material caused severe irritation and permanent corneal damage. When the material was promptly washed from the eyes, pain and irritation were noted but the corneal damage was temporary.

Skin contact causes relatively slight irritation in rabbits. If the material is confined tightly to the skin, it may cause hyperemia and a moderate edema. From observations made when the material was repeatedly bandaged onto the skin, there was no indication of toxic absorption, but no attempt was made to quantify the dosage.

The hepatotoxic and nephrotoxic effects of carbon tetrabromide were studied in male Sprague–Dawley rats following a single IP administration in a dose range of 25–125 mL/kg. Carbon tetrabromide did not cause hepatotoxic effects when given alone or in combination wth prior exposure to chlorodecone. It caused renal dysfunction, but these effects were abolished by dietary chlordecone pretreatment. *In vitro* incubation of renal cortical slices obtained from treated animals revealed a significant depression of organic anion transport.

11.4.1.2 Chronic and Subchronic Toxicity Exposure of rats to carbon tetrabromide “fumes” (0.01–1 mg/L) (0.07–74 ppm), 4 h/day for 4 months was reported to cause irritation of the eyes and respiratory tract.

In another (unpublished) study, repeated exposures of rats 7 h/day, 5 days/week for 6 months to the vapors of carbon tetrabromide were studied. When the concentration in air was determined by combustion of air samples and determination of halogen, the concentration without effect was found to be 0.1 ppm by volume. When the concentration in air was determined by a polarographic method, the concentration was 0.3–0.5 ppm by volume. Higher concentrations than this caused poor growth and fatty and degenerative changes in the liver.

11.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms The small amount of data that is available suggests that either hydrolysis or metabolism produces some bromide ion. Carbon tetrabromide would not be expected to produce physiologically significant quantities of bromide ion in the blood at levels of exposure considered acceptable by inhalation. Carbon tetrabromide is metabolized *in vitro* to produce carbon monoxide, but the *in vivo* significance has not been established.

Like classic lipid peroxidation chemicals such as carbon tetrachloride, carbon tetrabromide show similar activity. Protein synthesis and lipid peroxidation were evaluated in rat liver slices in the presence of oxidants and protein synthesis inhibitors (2, 3). The ability of carbon tetrabromide (and several other halogenated compounds) to inhibit protein synthesis was correlated with its ability to induce lipid peroxidation and was also correlated with their toxicity as indicated by the LD_{50}. The authors suggest that oxidant-induced lipid peroxidation and protein synthesis damage occurs concurrently, and that protein synthesis inhibition may be involved in cell injury or death mediated by free radicals.

Carbon tetrabromide (as well as some other brominated and chlorinated methanes) undergoes oxidate metabolism to electrophilic halogens by liver microsomes.

11.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV TWA is 0.1 ppm and the STEL/C is 0.3 ppm.

The NIOSH REL is 0.1 ppm with an STEL of 0.3 ppm. OSHA currently does not have a PEL.

International occupational exposure values:

Australia	TWA 0.1 ppm (1.4 mg/m^3); STEL 0.3 ppm (4 mg/m^3) January 1993.
Belgium	TWA 0.1 ppm (1.4 mg/m^3); STEL 0.3 ppm (4.1 mg/m^3) January 1993.
Denmark	TWA 0.1 ppm (1.4 mg/m^3) January 1993.
Finland	TWA 0.1 ppm (1.4 mg/m^3); STEL 0.4 ppm; “skin” notation January 1993.
France	TWA 0.1 ppm (1.4 mg/m^3) January 1993.
Ireland	TWA 0.1 ppm (1.4 mg/m^3); STEL 0.3 ppm (4 mg/m^3) January 1997.
The Netherlands	TWA 0.1 ppm (1.4 mg/m^3) October 1997.
Switzerland	TWA 0.1 ppm (1.4 mg/m^3) January 1993.
United Kingdom	TWA 0.1 ppm (1.4 mg/m^3) STEL/C: 0.3 ppm.

Saturated Halogenated Aliphatic Hydrocarbons Two To Four Carbons
Jon B. Reid, Ph.D., DABT

Ethyl Chloride
1.0.1 CAS Number:
[*75-00-3*]
1.0.2 Synonyms:
Chloroethane, hydrochloric ether, monochloroethane, and muriatic ether
1.0.3 Trade Names:
Aethylos chloridium, Anodynon, Chelen, Chlorene, Chloretilo, Chloroethyl, Chloryl, Chloryl anesthetic, Dublofix, Ether chloratus, Hydrochloric ether, Kelene, Monochloroethane, Moriatic ether, Narcotile, and NCI-C06224
1.0.4 Molecular Weight:
64.52
1.0.5 Molecular Formula:
CH_3CH_2Cl
1.0.6 Molecular Structure:

1.1 Chemical and Physical Properties
Ethyl chloride is a colorless gas with an ethereal, somewhat pungent odor and burning taste. It is highly flammable, even at ordinary temperature and pressure, and a severe fire and explosion risk. Under increased pressure and lower temperatures, it is a very volatile liquid.

Physical	Colorless gas
Specific gravity	0.8917 (25/25°C)0.897 at 20°C
Melting Point	–138.7
Boiling Point	12.3
Vapor pressure	1200 torr (25°C) 1000 torr at 20°C
Solubility	0.57g/100 mL water at 20°C, 48 g/100 mL ethanol at 21°C 0.6% in H_2O
Flammability limits	3.8–15.4% by volume in air
Autoignition temperature	519°C
Flash point	–50°C (closed cup); –43°C (open cup)

1.1.1 General The principal problem in industrial use of ethyl chloride is that typical of an anesthetic material where “drunkenness” and incoordination may lead to inept operation and therefore the possibility of an injury. Cardiac arrhythmia are possible, but high concentrations are required (6). The older data were summarized by von Oettingen (7), and an ATSDR profile (update) has been published by the U.S. Public Health Service in December, 1998 (8).

1.1.2 Odor and Warning Properties Ethyl chloride has an ethereal, somewhat pungent odor recognizable at concentrations of 100–600 ppm (9). High concentrations are necessary for potentially serious physiological effects, which may be considered a possible warning property for acute effects. According to AD Little (9), in humans, 50% of the subjects detected the odor of ethyl chloride at 140 ppm and 100% detected 680 ppm. An odor threshold of 4.2 ppm has been reported by Amoore (10).

1.2 Production and Use

Ethyl chloride is used in the manufacture of tetraethyl lead, ethylcellulose, dyes, drugs, and perfumes. It is also used as an alkylating and analytical agent, in organic syntheses, and as a solvent for fats, oils, waxes, phosphorus, acetylene, and many resins. It is also used as a propellant, an anesthetic, in refrigeration, and in the formulation of insecticides. Ethyl chloride has been used as a chemical intermediate, as a topical anesthetic, and to a limited degree as a refrigerant. The most serious problems have been with its use as an anesthetic. The major problems encountered in industry has been fire and explosion.

1.3 Exposure Assessment

According to the ATSDR toxicity profile (8), humans can be exposed to chloroethane from environmental, occupational, and consumer sources. In the 1970s and 1980s, chloroethane was found in outdoor air at levels of 41–140 ppt, but current levels are expected to be lower because of decreased production. Extremely low levels of chloroethane are present in drinking water, which may form during chlorination. There are no data on chloroethane in food. Exposure can result from contact with consumer products such as paints and refrigerants via skin. Occupational exposure may result from inhalation or skin contact. According to a NIOSH survey between 1981 and 1983, an estimated 49,212 workers in the United States were exposed to chloroethane in the workplace at that time.

1.3.1 Air See the preceding.

1.3.2 Background Levels See the preceding.

1.3.3 Workplace Methods NIOSH Method 2519 is recommended for determining workplace exposures to ethyl chloride.

1.3.4 Community Methods Environmental methods are given in the ATSDR profile (8). These address: ambient air, air from a contaminated site, air from a landfill, raw/treated water, finished drinking/ raw source water, water, wastewater, groundwater, soil and sediment, solid and liquid

waste.

1.3.5 Biomonitoring/Biomarkers Biological monitoring of expired air would appear to be of little value owing to the physical properties of ethyl chloride, which suggest rapid excretion.

The ATSDR profile (8) gives a table of methods for biological samples, including exhaled air, human milk, blood and urine, urine and adipose tissue, and also for fish and marine biota. The purge and trap method is used for both environmental and biological samples.

1.3.5.1 Blood The ATSDR profile (8) offers a method for blood and urine: The sample is mixed with water and antifoaming agent, purged at 50°C, trapped in Tenax, and thermal desorption, followed by Cryofocus—using high-resolution gas chromatography, flame ionization chromatography, and mass spectrometry. The detection limit is 3 mg/L of blood and 3 mg/L of urine with >80% recovery.

1.3.5.2 Urine See the preceding.

1.4 Toxic Effects

According to Sax (1) ethyl chloride has moderate toxicity via oral and inhalation routes. It is an irritant of skin, eyes, and mucous membranes. The liquid is harmful to the eyes and can cause smoke irritation. In the case of guinea pigs, symptoms attending exposure are similar to those caused by methyl chloride, except that the signs of lung irritation are not as pronounced. It gives some warning of its presence because it is irritating, but it is possible to tolerate an exposure until one becomes unconscious. It is the least toxic of all the chlorinated hydrocarbons, but at high concentrations ethyl chloride can cause narcosis, anesthesia, and even death on single exposure. It can cause narcosis, although the effects are usually transient. Animal experiments show some evidence of kidney irritation and accumulation of fat due to this material in the kidneys, cardiac mucles, and liver. It is also readily absorbed through the skin. It is a highly dangerous fire hazard and forms phosgene on combustion. When heated to decomposition, ethyl chloride may emit toxic fumes of HCl and may also release fumes of CO.

1.4.1 Experimental Studies 1.4.1.1 Acute Toxicity A single reference reports allergic eczematous eruption in two subjects after ethyl chloride was sprayed on the skin in an allergy-testing procedure (11). The wide use of ethyl chloride as a local anesthetic suggests that these must have been rare subjects.

Rats were anesthetized for 2 h with ethyl chloride (12). Complete disappearance of glycogen in the liver, a decrease in acid phosphatase levels, and increases in alkaline phosphatase and succinic dehydrogenase levels were reported.

A 2 h LC_{50} of 152 mg/L (57,600 ppm) has been reported (13). Deaths were anesthetic in nature but hyperemia, edema, and hemorrhages were reported in the internal organs, brain, and lungs. Repeated 2 h exposures for 60 d to 14 mg/L (5300 ppm) were alleged to cause a decrease in the phagocytic activity of the leukocytes, lowered hippuric acid formation in the liver, and histological or pathological changes in the liver, brain, and lungs. However, Troshina's results are not consistent with newer data. In the limited study on rats and dogs, exposures to 0, 1600, 4000, or 10,000 ppm were given 6 h/d, 5 d/wk for 2 wk (14) there were no adverse effects on any of the extensive number of toxicological parameters studied except for a slight increase in liver to body weight ratios in rats exposed to 4000 and 10,000 ppm. Nonprotein sulfhydryl was decreased in rats and mice.

In a 11 d study in which mice were exposed 23 h/d to 0, 250, 1250, or 5000 ppm the only effect was a slight liver weight increase and hepatocellular vacuolization at 5000 ppm (17). In a teratological study at 0, 500, 1500, or 5000 ppm reported in a subsequent section, no toxicologic effects were noted in pregnant mice after 10 consecutive 6 h daily exposures to 500, 1500, or 5000 ppm (18). As part of a lifetime carcinogenic study also reported in a subsequent section, rats and mice were exposed 1, 10, or 65 times (19). Then 6 h exposures 5 d/wk for 14 d to 19,000 ppm also produced no

evidence of toxicity in male and female rats.

Ethyl chloride has been demonstrated to be a cardiac sensitizer (31) in dogs at or near concentrations producing anesthesia, 30,000–45,000 ppm (32). In this condition, cardiac tissue is hypersensitized to the effects of stimulatory endogenous catecholamines, which can result in arrhythmias and cardiac arrest.

1.4.1.2 Chronic and Subchronic Toxicity In a 13 wk study, rats were exposed 6 h/d, 5 d/w (65 exposures) to 0, 2500, 5000, 10,000 or 19,000 ppm. The only effect was a slight liver weight increase at 19,000 ppm as well as slightly lowered body weights in both sexes. Based on the effects seen with similar compounds, and limited data on dogs, sensitization of the heart to adrenaline could be a hazard at very high (anesthetic) concentrations (20, 21). It is not possible to determine whether deaths that occurred during the short period of time it was used as a general anesthetic were due to anesthesia and/or cardiac toxicity or to some other conditions related to surgery.

In an NTP study (19), groups of F344 rats and $B6C3F_1$ mice (50/group/sex) were exposed to either 0 (air) or 15,000 ppm of 99.5% ethyl chloride (39.6 g/m^3) 5 d/wk, 6 h/d for 102 wk (rats) or 100 wk (mice). The duration-adjusted concentration becomes 7.1 g/m^3. The exposure level was set at this limit because of safety considerations for explosions. A single level of exposure was chosen as no exposure-related changes were seen in the 90-d study at a slightly higher concentration (19,000 ppm). Survival of female mice after week 82 was significantly lower than controls, apparently due to an increase in deaths from carcinomas of the uterus; there were no other statistically significant differences in survival between control and treated animals of either species. Mean body weights were decreased in both male and female rats. In females, the maximum difference in body wieghts between exposed and control animals was 13% and occurred at 59 wk of exposure when 49 of 50 test animals were still alive. Although some fluctuations towards normalcy were observed from this time forward, terminal body weights of 23 surviving treated animals were still 10% less than their corresponding controls. In male rats, mean body weights were also decreased when compared with controls, although the decrease achieved a miximum differential of only 8%. The mean body weights of mice were not affected by exposure. Based on the mild decrease in mean body weight gain, 15,000 ppm is judged as a free-standing NOAEL. The NOAEL (HEC) = 7.1 g/m^3.

Groups of F344 rats and $B6C3F_1$ mice (10/group) were exposed to either 0 (air), 2500 ppm (6.6 g/m^3), 5000 ppm (13.2 g/m^3), 10,000 ppm (26.4 g/m^3), or 19,000 ppm (50.1 g/m^3) of 99.5% ethyl chloride 5 d/wk, 6 h/d for 13 wk (19). The duration-adjusted concentrations are 0, 1.2, 2.4, 4.7, or 9.0 g/m^3, respectively. Monitoring for toxicological effects was by daily observation, body weights, and a complete necropsy and histologic examination including tissues of the entire respiratory tract and brian.

No exposure-related clinical signs or gross or histopathological effects were observed in either species. Relative liver weights were slightly increased in the male rats (14%) and female mice (18%) exposed to 19,000 ppm. Slight decreases in mean body weights were noted in the rats (8% in the males, 4% in the females) exposed to 19,000 ppm; no dose-related tendency could be discerned from the data. As no toxicity was apparent, 19,000 ppm is considered as a free-standing NOAEL in this study. The NOAEL(HEC)= 9.0 $g/m.^3$

The results obtained in the two studies of Troshina (13, 22) are not consistent with those of NTP (19) or Landy et al. (14, 17). Deficiencies preclude consideration of these studies as a reliable source of information about the toxic effects of this chemical.

1.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Conjugation with glutathione has been shown to occur at a much higher rate in mice than rats (25). These data suggest that this conjugation,

which is species specific and dose dependent, may be extremely important in understanding the development of toxicity and tumors in female mice. A nongenetic (hormonal) mechanism of uterine tumors induction has been suggested.

1.4.1.4 Reproductive and Developmental In a developmental study conducted in groups of 30 CF-1 mice, Scortichini et al. (18) exposed animals to mean time-weighted averages of 0 (air), 491 ± 37 ppm (1.3 g/m^3), 1504 ± 84 ppm (4000 mg/m^3), and 4946 ± 159 ppm (13,000 mg/m^3) 99.9% ethyl chloride for 6 h/d on days 6 through 15 of gestation. The animals were sacrificed on the eighteenth day of gestation. (These values are not duration adjusted.) This study shows that exposure to ethyl chloride results in fetotoxicity. The exposure concentration of 1504 ppm is the NOAEL of this study NOAEL(HEC) = 4000 mg/m^3 based on foramina of the skull bones. The highest concentration used in this study, 4946 ppm, is a LOAEL, (HEC) = 13,000 mg/m^3.

According to Hanley et al. (23), the reproductive organs were not affected following subchronic inhalation exposures to ethyl chloride. Exposures to mice at concentrations of 500, 1500, or 5000 ppm during organogenesis produced no teratogenic effects. The presence of a few small unossified areas in the skull bones at 5000 ppm suggest very slight fetotoxicity.

Experiments conducted by Breslin et al. (24) suggest that exposure to ethyl chloride may disrupt the estrus cycle of mice. Two groups (10/group) of female B6C3F$_1$ mice were acclimated in exposure chambers over a 2 wk period or until the estrus cycles of most mice was a 4–6 d interval (as judged by a vaginal lavage technique). Males were included in each chamber to synchronize and promote regular estrus cyclicity. Following acclimatization one group was exposed to 15,000 ppm (39.6 g/m^3 ethyl chloride 6 h/d for a minimum of 14 consecutive days (through 3 estrus cycles). No effects on behavior, gross, or histopathology were observed in the group undergoing exposure, although the mean body weights in the exposed group were significantly increased rather than decreased. The mean length of the estrus cycle in exposed mice was 5.6 d, significantly longer in duration than the pre-exposure duration for the same group (5.0 d) and for the corresponding controls (4.5 d). The protraction of the period could not be attributed to an increase in any particular phase of the estrus cycle and is therefore suggestive of a general stress response. A direct exposure-related effect of ethyl chloride on neuroendocrine function cannot be excluded. As this effect is regarded as a systemic effect, the exposure is duration adjusted to establish a free-standing LOAEL of 6.6 g/m^3. The LOAEL(HEC) = 6.6 g/m^3.

1.4.1.5 Carcinogenesis The EPA (IRIS) has not made a carcinogenicity assessment at this time.

Increased cancer of the uterus of female mice has been produced by exposure to 15,000 ppm, but lower concentrations have not been studied. Rats and mice were exposed to 0 or 15,000 ppm of ethyl chloride in an NTP 2-year study with mixed results (19). Results in male rats were considered equivocal based on a combined total of five skin tumors versus none in the control male rats. Likewise female rats results were considered equivocal because three astrocytomas were found versus none in the female control rats. The male mouse group had such poor survival that it was deemed an inadequate study although combined alveolar/bronchiolar adenomas and carcinomas were reported (10/48 versus 5/50 in the control male rats). Female mice exposed to 15,000 ppm had clear evidence of an effect, for 43/50 mice had endometrial uterine carcinomas versus 0/49 in the female control mice. In addition, there was a suggestion of an increase in combined hepatocellular adenomas and carcinomas in the female mice (8/48 exposed versus 3/49 control).

1.4.1.6 Genetic and Related Cellular Effects Studies According to the NTP report of carcinogenic studies, ethyl chloride was found to be mutagenic in *Salmonella* both with and without S-9 activation. The report considers the effect to be consistent with alkylating activity in base substitution strains TA100 and TA1535. Studies of chromosomal aberration in the bone marrow of mice exposed for 2 years were negative (19), as were all transformation studies in mouse BALB/c-

3T3 cells (26).

1.4.2 Human Experience Exposure to ethyl chloride can cause irritation of the eyes. It can also be iritating to the nose, throat, and respiratory tract. At concentrations of approximately 2% (molar), it can cause an anesthetic or narcotic effect. This can result in headache and nausea and also dizziness. At higher concentrations, exposure can cause unconsciousness. It may also produce central nervous system depression. This depression is usually brief and reversible. Due to its rapid rate of evaporation, it can cause tissue freezing or frostbite on dermal contact. Other symptoms include drowsiness, noisy talkativeness, and sensitizing effects on the myocardium. It may also cause irregular heart beat. It may cause liver and kidney damage, incoordination, and abdominal cramps. It may cause slight symptoms of inebriation. Exposure may also cause lung irritation, damage to internal organs, excitement, and paralysis of respiration. It may cause lung damage. Ethyl chloride may irritate the kidneys and cause fat accumulation in the kidneys, cardiac muscles, and liver. It is absorbed readily through the lungs, and rapidly given off through the lungs. Other symptoms reported include cardiac arrhythmias at high concentrations; rare allergic eczematous eruptions when sprayed on skin; and hyperemia, edema, and hemorrhages in the internal organs, brain, and lungs. It may also cause weak analgesia. It may cause stupor. The most serious problem from severe acute exposure, other than the anesthetic effect, is the possibility of the potentiation of adrenalin, and the resultant cardiac problems (27, p. 247). Exposure to this compound may cause death due to respiratory or cardiac arrest. Deaths are anesthetic in nature.

Although used as a surgical anesthetic, ethyl chloride has a narrow margin of safety for this purpose as anesthesia occurs at 20–30 mg % and respiratory failure at 40 mg % (28). Ethyl chloride is explosive at 4% (40,000 ppm, 106 g/m^3) in air, overlapping the concentrations required to produce anesthesia (3–4.5%) Neurological symptoms have been observed in human case studies in instances of ethyl chloride abuse. Hes et al. (29) noted cerebellar-related symptoms including ataxia, tremors, dysarthria (speech difficulties), slowed reflexes, nystagmus (involuntary movement of the eyeball), and hallucinations in a 28-year old female who sniffed 200–300 mL of ethyl chloride off her coat sleeve daily for 4 mo. Examination revealed that her liver was enlarged (3 cm) and slightly tender and was accompanied by a mild and transient disturbance (not clinically described) of liver function. All symptoms were resolved by the end of 4 wks. Similar neurological symptoms were noted in a 52-year-old male who had a 30-year history of intermittent ethyl chloride (as well as alcohol and barbiturate) abuse (30). Questioning upon hospitalization revealed that he had been inhaling at least 100 mL of ethyl chloride daily for the previous 4 mo. No liver effects were reported, and the patient fully recovered from the neurological symptoms by 6 wk after admission.

Ethyl chloride has been used experimentally and clinically as a topical and inhalation anesthetic in human subjects; reviews are available (6, 7).

In a study by Davidson (33) ethyl chloride was administered to humans. Intoxication started at 1.3%, memory loss at 1.9%, incoordination at 2.5%, and at 3.36%, incoordination was followed by cyanosis, nausea, and vomiting.

1.4.2.1 General Information The acute toxicity for animals was reported by Sayers et al. (15) (see Table 63.1) and the narcotic concentrations for humans were reported by Lehann and Flury (16) (see Table 63.2). More recent data have not changed their conclusion significantly.

Table 63.1. Response of Guinea Pigs to Ethyl Chloride Vapor in Air (15)

Concentration (%)	Exposure time (min)	Response
23–24	5–10	Unconscious, some deaths

15.3	40	Some deaths in 30 min; some survived 40 min
9.1	30	Survived; histopathological changes in lungs, liver, etc.
5	40	Survived; lungs congested
4	122	Survived; returned to normal
	270	Survived; histopathological changes in lungs, liver, and kidneys
	540	Some deaths
2	270	Survived; returned to normal
	540	Survived; histopathological changes in liver and kidneys
1	810	Survived; returned to normal

Table 63.2. Narcotic Ethyl Chloride Concentrations in Humans
Concentrations in Humans

Concentration		
mg/L	**ppm**	**Response**
105.6	40,000	After 2 inhalations, stupor, irritation of eyes, and stomach cramps
88.7	33,000	After 30 sec, quickly increased toxic effect
66.0	25,000	Lack of coordination
52.8	20,000	After 4 inhalations, dizziness and slight abdominal cramps
50.4	19,000	Weak analgesia after 12 min
34.3	13,000	Slight symptoms of poisoning

1.4.2.2.4 Reproductive and Developmental Early and late pregnancy toxemias have been observed in women occupationally exposed to ethyl chloride and other chemicals such as ethyl bromide and butanol (34).

Women who were exposed occupationally to unknown concentrations of ethyl chloride along with ethylenediamine, ammonia, polyethylene polyamines, vinyl chloride, and hot summer temperatures had genital disorders that included inflammatory diseases of the cervix and uterus and vaginitis (35).

1.4.2.2.5 Carcinogenesis The EPA (IRIS) has not made a carcinogenicity assessment at this time (36).
1.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV TWA is 100 ppm with an A3 designation (confirmed animal carcinogen with

unknown relevance to humans). The NIOSH considers that ethyl chloride be treated in the workplace with caution because if its structural similarity to chloroethanes shown to be carcinogenic in animals. The OSHA PEL is 1000 ppm.

Other Nations:

Australia: 1000 ppm (1993); Federal Republic of Germany: no MAK, Group B carcinogen, justifiably suspected of having carcinogenic potential (1995); Sweden: 500 ppm, short-term value 700 ppm, 15 min (1993); United Kingdom: 1000 ppm, 15 min STEL 1250 ppm (1995).
1.6 Studies of Environmental Impact
None found.

Saturated Halogenated Aliphatic Hydrocarbons Two To Four Carbons
Jon B. Reid, Ph.D., DABT

1,1-Dichloroethane
2.0.1 CAS Number:
[*75-34-3*]
2.0.2 Synonyms:
Ethylidene chloride, ethylidene dichloride
2.0.3 Trade Names:
Chlorinated hydrochloric Ether, HSDB 64
2.0.4 Molecular Weight:
98.97
2.0.5 Molecular Formula:
CH_3CHCl_2
2.0.6 Molecular Structure:

2.1 Chemical and Physical Properties
Dichloroethane-1,1 is a colorless, oily liquid with a chloroformlike odor.

Physical state	Colorless liquid
Specific gravity	1.175 (20°C)
Melting point	–96.98°C
Boiling point	57.3°C
Vapor pressure	234 torr (25°C)
Refractive index	1.41655 (20°C)
Percent in “saturated;”air	30.8(25°C)
Solubility	0.5 g/100 MI water at 20°C; soluble in (5500 mg/L) ethanol, ethyl ether
Flash point	14°C (open cup); –8.33°C (closed cup)
Flammability limits	5.6–11.4% by volume in air
Ignition temperature	493°C

2.1.1 General

2.1.2 Odor and Warning Properties 1,1-Dichloroethane has been stated to have a “chloroformlike” odor, but the level at which this odor is detectable has not been determined.
2.2 Producton and Use
1,1-Dichloroethane is flammable and has limited use as a solvent. Its major use is as a chemical intermediate. Formerly used as an anesthetic, it is of no importance in this field today. It appears to be an environmental breakdown product of some commonly used chlorinated solvents. An ATSDR toxicology profile is available (3).
2.3 Exposure Assessment
Exposure routes are inhalation, ingestion, skin, and/or eye contat. The substance can be absorbed into the body by inhalation and by ingestion. A harmful concentration in the air can be reached rather quickly on evaporation of this substance at 20°C. The vapor is heavier than air and may travel along the ground; distant ignition possible.

2.3.3 Workplace Methods NIOSH Method 1003 for halogenated hydrocarbons is recommended for determining workplace exposures to 1,1-dichloroethane.

2.3.5 Biomonitoring/Biomarkers Although biologic monitoring for expired 1,1-dichloroethane in air might be useful for determining recent exposure, inadequate data are available to quantify exposure. Urinary metabolites (dichloroacetic acid and monochloroacetic acid) would be expected only in low concentrations if present at all.
2.4 Toxic Effects
1,1-Dichloroethane may be harmful by inhalation, ingestion, or skin absorption. Vapor or mist is irritating to the eyes, mucous membranes, skin, and upper respiratory tract. When heated to decomposition, it emits toxic fumes of carbon monoxide, carbon dioxide, hydrogen chloride gas, and phosgene. It is narcotic in high concentrations. It may also have anesthetic effects at high concentrations. It is a lacrimator.

Much less has been published on the toxicity of 1,1-dichloroethane than on its more toxic isomer 1,2-dichloroethane (ethylene dichloride). 1,1-Dichloroethane is rather low in toxicity. It is capable of causing anesthesia, but has a relatively low capacity to cause liver or kidney injury even on repeated exposure. Massive doses by gavage in oil were questionably carcinogenic in rats and mice, but when fed in drinking water, no increase in liver cancer occurred in a limited study in male mice.

2.4.1 Experimental Studies 2.4.1.1 Acute Toxicity Although the 1985 NIOSH Registry of Toxic Effects of Chemical Substances (42) lists an oral. LD_{50} of 725 mg/kg for rats based on a 1967 article, this must be an error, because repeated daily doses higher than this were given by gavage for 78 wk (43). No original reference is given for a report of an oral LD_{50} of 14.1 g/kg for rats.

In a study by Muralidhara et al. (44), adult male Sprague–Dawley rats were given single doses of 0, 0.5, 1.0, 2.0, 4.0, and 8.0 g/kg in corn oil. There was significant mortality only at 8 g/kg and no evidence of treatment-related effects on serum or urinary enzyme levels, organ weights, or tissue morphology. Rats received repeated oral doses of 0, 0.5, 1.0, 2.0, or 4.0 g/kg 5 d/wk for 12 wk. There was marked CNS depression and high mortality only in the 4-g/kg group but little evidence of toxicity other than transient CNS depression at lower levels.

Inhalation Acute: In 1956, Smyth (45) found that rats survived an 8 h exposure to 4000 ppm but were killed by 16,000 ppm. Deaths were probably due to anesthesia.

Schwetz et al. (46) showed that pregnant and nonpregnant rats survived 10 repeated 7 h exposures to 6000 ppm with no effect except for a slight liver weight increases in nonpregnant rats.

Intraperitoneal: Plaa and Larson (47) found little liver and kidney toxicity following intraperitoneal

injection. Doses of 1000 mg/kg produced no renal necrosis in mice but some evidence of tubular swelling was reported. Urinary protein was increased after injection of 2000 mg/kg and urinary glucose increased after 4000 mg/kg.

Klinkead and Leahy (48) report on a 4 h male, rat, inhalation exposure which gave a LC_{50} of ca. 13,000 ppm. In the same paper the authors reported no toxic effects in rabbits dermally exposed to an upper limit of 2 mL/kg body weight for 24 h for 14 d.

Mueller (49) observed anesthetic effects in mice that inhaled 8,000–10,000 ppm for 2 h with a minimum lethal dose of 17,300 ppm.

2.4.1.2 Chronic and Subchronic Toxicity In two studies by Muralindhara and Ramanthan (44), rats were given a single oral bolus of 0, 500, 1000, 2000, or 4000 mg 1,1-dichloroethane/kg body weight for 5 or 10 consecutive days. Glutathione showed a dose-dependent increase in the kidney after 5 and 10 d of exposure, but liver GSH and other indices were not different from controls. Reported in the same paper was a subchronic study where rats were given single oral doses of 0, 500, 1000, 2000, or 4000 mg/kg body weight 5 d/wk for up to 12 wk. CNS depression, marked and high mortality occurred in the 4000 mg/kg group, but little signs of toxicity were seen at lower dosage levels.

Hofmann et al. (50) reported that rats guinea pigs, rabbits, and cats tolerated 6 h daily exposures to 500 ppm 5 d/wk for 13 wk with no adverse effects. Rats, guinea pigs, and rabbits also tolerated an additional 13 wk at 1000 ppm, but cats showed histological evidence of kidney injury and increased blood urea.

In a study by Schwetz et al. (46) pregnant female rats were exposed on days 6 to 15 of gestation to 3800 or 6000 ppm 1,1-dichloroethane vapors. Exposures were for 7h/d. Essentially no effect occurred in either the dams or fetuses except for slight but statistically significant decreases in food consumption and weight gain by the dams and delayed ossification in the fetuses. No teratological effects were related to exposures. Liver weights of a group of nonpregnant rats were increased by similar exposure, but no histological changes were apparent grossly or microscopically.

2.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms In a study by McCall et al. (51) the authors proposed that 1,1-dichloroethane is metabolized by hepatic microsomal cytochrome P-450 *in vitro*, and this metabolism is important in the toxicity of the compound.

Mitoma et al. (52) studied the metabolism of 1,1-dichloroethane after chronic oral dosing of adult mice and rats at maximum tolerated doses. The results are presented in Table 63.3. The maximum tolerated dose was 700 mg/kg for rats and 1800 mg/kg for mice. Animals were treated 5 d/wk for 4 wk with unlabeled 1,1-dichloroethane prior to a single gavage dose of labeled material in corn oil. The animals were placed in metabolism cages for 2 d following treatment. Rats excreted 86% as unchanged 1,1-dichloroethane and mice 70%. Total metabolism (primarily CO_2) was 7.5 and 29%, respectively, and the metabolic products were similar in the two species. Although the investigators report radioactivity as “bound” the “binding” may have been due to incorporation as metabolites rather than due to alkylation.

Table 63.3. Metabolic Disposition of Chlorinated Hydrocarbons in Rats and Mice

	Percentage of the Administered Dose Average (S.D.)

Species	Dose (mmol/kg)	Expired Air	CO_2 (*a*)	Excrete (*b*)	Carcass (*c*)	Recovery	Metabolized *a* + *b* + *c* Expired Air

Thompson et al. (53) reported *in vitro* studies that confirmed that little 1,1- dichloroethane is metabolized. Cytochrome P450 appears to play a major role in metabolism and the addition of substances that increase P450 increase metabolism of 1,1-di-chloroethane. Addition of glutathione had a protective effect.

2.4.1.4 Reproductive and Developmental See the study by Schwetz et al. (46) reported in the subchronic/chronic section.

2.4.1.5 Carcinogenesis The EPA (IRIS) (2) classifies 1,1-dichloroethane as C; possible human carcinogen based on no human data and limited evidence of carcinogenicity in two animal species (rats and mice) as shown by an increased incidence of mammary gland adenocarcinomas and hemangiosarcomas in female rats and an increased incidence of hepatocellular carcinomas and benign uterine polyps in mice. The EPA offers no estimate of carcinogenic risk from inhalation or oral exposure. The EPA states (IRIS) that because of similarities in structure and target organs, the carcinogenic evidence for 1,2-dichloroethane is considered to be supportive of the classification of 1,1-dichloroethane in group C, a possible human carcinogen.

The EPA considers the animal carcinogenicity "limited." The NCI bioassay (43), provides limited evidence for the carcinogenicity of 1,1-dichloroethane in Osborne–Mendel rats and $B6C3F_1$ mice. This is based on significant dose-related increases in the incidence of hemangiosarcomas at various sites and mammary carcinomas in female rats and statistically significant increases in the incidence of liver carcinomas in male mice and benign uterine polyps in female mice. The study is limited by high mortality in many groups. The low survival rates precluded the appearance of possible late-developing tumors and decreased the statistical power of this bioassay. Technical-grade 1,1-dichloroethane in corn oil was administered by gavage 5 d/wk for 78 wk to groups of 50 Osborne–Mendel rats/sex/dose. All surviving animals were necropsied following a 33 wk observation period. Due to toxicity, dosing was not continuous (3 wk on, then 1 wk off), making the TWAs for 5 d/wk 382 and 764 mg/kg/d for low- and high-dose males and 475 and 950 mg/kg/d for low- and high-dose females, respectively. Both a vehicle and an untreated (not intubated) control group (20 rats/sex/group) were included in the study. A high incidence of pneumonia (approximately 80%) in all 4 groups of each sex was considered to be the cause for the low survival at termination of the study. Survival at 111 wk was 30, 5, 4, and 8% in the untreated control, the vehicle control, the low-dose, and the high-dose male rat groups, respectively. Survival at termination for the female rat groups was 40, 20, 16, and 18% for the untreated control, vehicle control, low- and high-dose groups, respectively. In female rats there was a statistically significant positive dose-related trend in incidence of hemangiosarcomas (0/19 for matched vehicle controls, 0/50 for the low-dose group, and 4/50 for the high-dose group). The incidence of mammary gland adenocarcinomas (1/20 for the untreated group, 0/19 for the vehicle control group, 1/50 for low-dose, and 5/50 for high-dose groups) showed a statistically significant dose-related positive trend in those female rats surviving at least 52 wk; tumor incidence was 0/16, 1/28, and 5/31 for vehicle control, low- and high-dose groups, respectively. (Tumor incidence at termination for the untreated control females surviving at least 52 wk was not reported.) This bioassay was conducted before the life table tests were implemented; so results adjusted for mortality are not available. No mammary gland adenomas or hemangiosarcomas were observed in the dosed-male rats.

In the same NCI (43) study, groups of 50 $B6C3F_1$ mice/sex/group were administered technical-grade 1,1-dichloroethane in corn oil by gavage 5 d/wk for 70 wk. As in the rat study, the dosage pattern was 3 wk on and 1 wk off; the surviving animals were necropsied 13 wk after the termination of dosing. The TWAs for 5 d/wk for the low- and high-dose groups were 1442 and 2885 mg/kg/d for

male and 1665 and 3331 mg/kg/d for female mice.

Control groups, indentical to those in the rat study and consisting of 20 mice/sex/group, were also used. Survival at termination was 80, 80, 80, and 50% for the untreated control group, the vehicle control group, the low- and high-dose females, respectively. In male mice survival was 35, 55, 62, and 32% in the untreated control group, the vehicle control group, the low- and high-dose groups, respectively. An increased incidence of hepatocellular carcinoma in male mice was not statistically significant by either pairwise or trend test (2/17 in the untreated control group, 1/19 in the vehicle control group, 8/49 in the low-dose, and 8/47 in the high-dose groups). The incidence of hepatocellular carcinoma in male mice surviving at least 52 wk was 1/19, 6/72, 8/48, and 8/32 in the matched vehicle control group, a pooled vehicle control group consisting of mice from this and identical controls from other concurrent experiments, and the low- and high-dose groups, respectively; this positive trend was statistically significant. In female mice, liver carcinomas were reported in only the vehicle control (1/19) and the low-dose groups (1/47), no liver tumors were seen in the untreated controls or in the high-dose group. A statistically significant increase in benign uterine endometrial stromal polyps (4/46) was observed in high-dose females; these were not observed in any other group. A preliminary report of the NCI (43) study was published by Weisburger (54).

To determine if 1,1-dichloroethane in drinking water could act as a tumor promoter or a complete carcinogen, Klaunig et al. (55) exposed groups of 35 male B6C3Fl mice to 1,1-dichloroethane in drinking water at 0, 835, or 2500 mg/L for up to 52 wk following a 4-wk treatment with either drinking water containing 10 mg/L diethyl nitrosamine (DENA-initiated groups) or with deionized water (noninitiated groups). The investigators estimated that the approximate weekly dose of 1,1-dichloroethane was 3.8 mg/g/wk (corresponding to 543 mg/kg/d) for the groups exposed to 2500 mg/L. Upon sacrifice at the end of either 24 wk (10 mice/group) or 52 wk (25 mice/group) of promotion, all tissues were examined for gross pathologic lesions and histologic sections of the liver, kidneys, and lungs were examined. Neither the initiated nor the noninitiated 1,1-dichloroethane-treated groups showed a significant increase in the incidence of liver or lung tumors compared with initiated or noninitiated controls, respectively. The authors concluded that 1,1-dichloroethane was not carcinogenic to mice and did not act as a tumor promotor following initiation with DENA. These conclusions may not be entirely justified, since the duration of the study may have been inadequate for the development of tumors in noninitiated 1,1-dichloroethane-treated animals. In addition, the incidence of liver tumors in DENA-initiated controls was 70% at 24 wk and 100% at 52 wk, and the number of tumors/mouse in DENA-initiated controls at these times was 3.00 and 29.30, respectively. Hence, an increase in tumors or decrease in latency in 1,1-dichloroethane-treated DENA-initiated animals would have to be marked in order to be detectable.

Carcinogenicity Classifications:

EPA	Group C, Possible Human Carcinogen
ACGIH TLV	A4, Not classifiable as a Human carcinogen

2.4.1.6 Genetic and Related Cellular Effects Studies As reported in the ATSDR Toxicological profile (56) 1,1-dichloroethane has been shown to be weakly mutagenic in some but not all test systems primarily with metabolic activation and without glutathione, which appears to play a detoxification role. Addition of glutathione reduces the extent of metabolic covalent binding to macromolecules, raising the question of the suitability of bacterial test systems that are low in glutathione in evaluating mammalian toxicity.

2.4.2 Human Experience Symptoms of exposure to this compound may include liver and kidney damage, skin and eye irritation, dermatitis, and skin burns. It may cause unconsciousness, central nervous system depression, and drowsiness. It may also cause nausea, vomiting, faintness, irritation of the respiratory tract, salivation, sneezing, coughing, dizziness, lacrimation, reddening of the

conjunctiva, cyanosis, circulatory failure, and slight smarting of the eyes and respiratory system. It is narcotic in high concentrations.

No reports of human experiments or experience were found.

A published report by Hamilton and Hardy (57) indicated that 1,1-dichloroethane is irritating to the eyes and respiratory tract, produces salivation, sneezing, and coughing, is associated with dizziness, nausea, and vomiting. Hepatic and renal injury were present in severe and fatal cases.

2.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV for 1,1-dichloroethane is 100 ppm with an A4 designation, not classifiable as a human carcinogen. The NIOSH REL is 100 ppm with an IDLH of 3000 ppm. The OSHA PEL is also 100 ppm.

Other Occupational Exposure Values: Australia: 200 ppm, STEL 250 ppm, substance under review (1993); Federal Republic of Germany: 100 ppm, short-term level 200 ppm, 30 min, 4 times per shift, pregnancy group D, insufficient evidence for a final evaluation (1997); United Kingdom: 200 ppm, 15-min STEL 400 ppm (1995).

2.6 Studies of Environmental Impact

Saturated Halogenated Aliphatic Hydrocarbons Two To Four Carbons

Jon B. Reid, Ph.D., DABT

Ethylene Dichloride

3.0.1 CAS Number:

[*107-06-2*]

3.0.2 Synonyms:

1,2-Dichloroethane, sym-dichloroethane, 1,2-bichloroethane, 1,2-ethylene dichloride, alpha, beta-dichloroethane, glycoldichloride

3.0.3 Trade Names:

Borer sol, Brocide, Destruxol Borer-sol, Dichloremulsion, Dutch oil, Di-chlor-mulsion, Dutch liquid, Freon 150, Dichlor-ulsion, Dichloremulsion

3.0.4 Molecular Weight:

98.960

3.0.5 Molecular Formula:

$C_2H_4Cl_2$ or $ClCH_2CH_2Cl$

3.0.6 Molecular Structure:

3.1 Chemical and Physical Properties

Ethylene dichloride is a colorless liquid with an odor typical of chlorinated hydrocarbons. An odor threshold of 88 ppm has been reported (10). Chemical and physical properties include (58):

Physical state	Colorless liquid
Specific gravity	1.2569 at 20°C (20/4°C)
Melting point	–35.5°C
Boiling point	83.5°C

Vapor pressure	87 torr (25°C)
Refractive index	1.44432 (20°C)
Percent in “saturated”air	11.5 (25°C)
Solubility	0.9 g/100 ML water at 20°C; soluble in ethanol, ethyl ether
Flash point	18.3°C (open cup); 13°C (Closed cup)
Explosive limits	6.2–15.9% by volume in air
Ignition temperature	415°C

3.1.1 General An ATSDR Toxicological Profile for this material is available.

3.1.2 Odor and Warning Properties Ethylene dichloride has a sweetish, not particularly disagreeable odor. The odor is barely detectable at 50 ppm in air and is definite but not unpleasant at 100 ppm. Although it is pronounced at 200 ppm, it still would not be considered unpleasant. Even though the odor may be definite enough to act as a warning of acutely hazardous concentrations, it is probably not sufficiently striking to be considered a significant warning of hazardous chronic exposure. This is particularly true because one can adapt to the odor at low concentrations.

3.2 Production and Use

In the United States almost all the current production of ethylene dichloride is used as the starting material for preparation of vinyl chloride monomer. Other applications are much smaller. It was formerly used in antiknock fluids for gasoline, in fumigant mixtures, and as a solvent. Because of its toxicity and flammability, usage as a solvent has decreased considerably as less hazardous replacements have become available.

3.3.3 Workplace Methods NIOSH Method 1003, for halogenated hydrocarbons, is recommended for determining workplace exposures to 1,2-dichloroethane (10a).

3.3.5 Biomonitoring/Biomarkers No references were found that would indicate biologic monitoring to be satisfactory for industrial hygiene control at acceptable levels of exposure.

3.4 Toxic Effects

1,2-Dichloroethane is toxic by ingestion, inhalation, and skin contact. It can be absorbed through the skin. It is an irritant of the skin, eyes, and respiratory tract. The vapor is heavier than air and may travel a considerable distance to a source of ignition and flash back. When heated to decomposition, it emits toxic fumes of carbon monoxide, carbon dioxide, hydrogen chloride gas, and phosgene.

The toxicity of ethylene dichloride has been extensively investigated both in animals and humans. It has been reviewed by several authors (7, 59–62). At very high concentrations, ethylene dichloride is irritating to the eyes, nose, and throat. Other symptoms are largely related to CNS depression or gastrointestinal upset, that is, mental confusion, dizziness, nausea, and vomiting. Cardiac sensitization appears to be less important. At subacute levels, similar symptoms of CNS depression and gastrointestinal upset are observed. Definite liver, kidney, and adrenal injury may occur at these levels. From chronic exposure to lower concentrations, some indications of CNS depression are still observed. Nausea and vomiting are quite common in humans. The sympton of nausea and vomiting for ethylene dichloride is quite striking and similar to that often observed from carbon tetrachloride. The pathological picture from repeated exposure is injury of the liver, kidneys, and adrenals. This general pattern has been consistent in animal investigative work and in experience from human exposure.

Ethylene dichloride does not appear to be teratogenic or to have significant reproductive effects, but current animal data suggest it may have mutagenic, and possibly carcinogenic, potential. There is also a question of its immunologic suppression that remains unanswered. Human studies have not supported the carcinogenic or immunologic effects seen in animal studies, but as is often the case in epidemiology, the study populations have been small.

3.4.1 Experimental Studies 3.4.1.1 Acute Toxicity Animal studies show liver and kidney injury. Smyth et al. (63) calculated an oral LD_{50} in rats of 770 mg/kg. Opacity of the cornea was reported in dogs and foxes following administration of ethylene dichloride (7, p.144).

3.4.1.2 Chronic and Subchronic Toxicity The results of lifetime oral studies are discussed in the carcinogenesis section.

3.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms The metabolism of ethylene dichloride has been recently reviewed (62). Figure 63.1 has a proposed metabolic map taken from Loew et al. (64). It is readily absorbed via the lungs and gastrointestinal tract and to a lesser degree through the skin. Although steady-state blood concentrations in the rat were achieved in 2–3 h at 150 ppm, the equilibrium concentration in blood at 6 h was exponentially related to the inhaled concentration. Blood levels of 1.4, 8.3, and 31.3 mg/mL were found after exposure to 50, 150, and 250 ppm in air for 6 h. About 70% of the inhaled ethylene dichloride was absorbed in a 6 h exposure to 150 ppm, and clearance from the blood was rapid. Elimination following oral doses was also rapid, resulting in both cases in nonlinear kinetics. Approximately 85% of radioactivity was excreted in the urine as thiodiacetic acid and thiodiacetic sulfoxide with some exhalation of unchanged [^{14}C]1,2-dichloroethane. The parent compound, as well as 2-chloroethanol, monochloroacetic acid, and 2-chloroacetadehyde, has been found in the organs of cadavers following acute poisoning (65). Two paths of metabolism involve microsomal cytochrome P450 or cytosolic glutathione transferase. The cytosolic pathway was considered responsible for the mutagenicity and covalent DNA binding (66), but other investigators found no evidence of covalent binding from the cytosol route (67). A physiologically based pharmacokinetic model has been developed that described glutathione depletion and resynthesis in rats and mice (68).

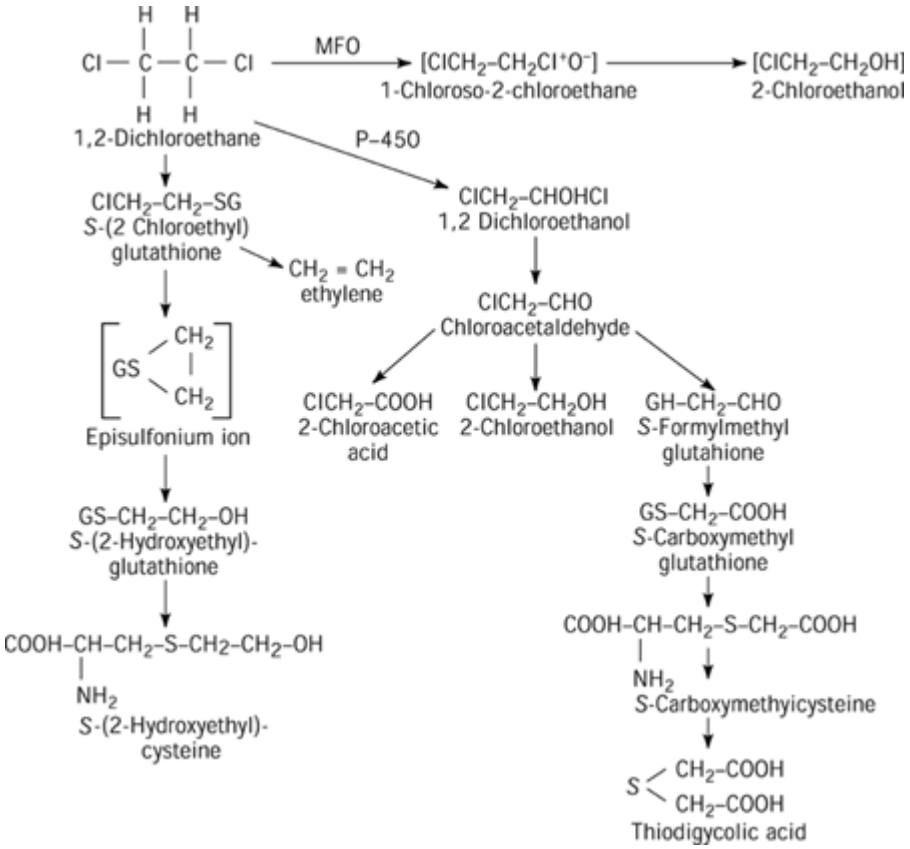

Figure 63.1. Proposed metabolism of 1,2-dichloreothane (from Ref. 64).

3.4.1.4 Reproductive and Developmental In the available abstract, Vozovaya (69) states he produced

decreased fertility and other adverse effects in pregnant female rats and the progeny of the first generation, but not of the second, by giving them repeated 4 h/d exposures to 57 mg/m^3 (14 ppm). However, an attempt to confirm this report failed to do so, even though the rats were exposed to 100 ppm 7 h/d for several months (70). Furthermore, pregnant Sprague–Dawley rats and New Zealand white rabbits were exposed to 0, 100, or 300 ppm of ethylene dichloride on days 6 through 15 (rats) and 6 through 18 (rabbits) of gestation. Severe maternal toxicity was observed among rats exposed to 300 ppm of ethylene dichloride; two-thirds of the dams died during the exposure period. No signs of toxicity were observed among rats at the 100-ppm dose level. Maternal toxicity was noted in rabbits as evidenced by maternal deaths at both dose levels. No adverse effects on embryonal or fetal development were observed among litters from the exposed rats at 100 ppm or among those from exposed rabbits. Owing to the severe maternal toxicity observed, no conclusions could be drawn concerning the teratogenic potential of inhaled ethylene dichloride in the rat at 300 ppm; ethylene dichloride was not embryotoxic or teratogenic in rats inhaling either 100 ppm or in rabbits inhaling 100 or 300 ppm of the compound during gestation (70).

Pregnant CD mice were fed water containing a mixture of potential water contaminants including ethylene dichloride with no effects on the usually teratological parameters (71).

The reproduction and developmental effects of ethylene dichloride were studied in a multigeneration study (72). Male and female ICR Swiss mice received 0, 5.14, 15.4, or 49.7 mg/kg/d. There appeared to be no dose-dependent effects on fertility, gestation, viability, or lactation indices. Pup survival and weight gain were not adversely affected. Gross necropsy of male and female F0 generation mice treated with 1,2-DCE or 1,1,1-TCE failed to reveal compound or dose-related effects.

3.4.1.5 Carcinogenesis The EPA classifies ethylene dichloride as B2; probable human carcinogen on the basis of the induction of several tumor types in rats and mice treated by gavage and lung papillomas in mice after topical application. There are no human carcinogenicity data. An NCI study in 1978 (73) is the basis for the conclusion.

The International Agency for Research on Cancer (74, p. 62) classified ethylene dichloride in group 2B, possibly carcinogenic to humans, based on sufficient evidence for carcinogenicity in animals and no adequate data for humans.

In the NCI (75) study, 1,2-dichloroethane in corn oil was administered by gavage to groups of 50 each male and female Osborne–Mendel rats and B6C3F1 mice. Treatment was for 78 wk followed by an additional observation period of 12–13 weeks for mice or 32 wk for low-dose rats. TWA dosages were 47 and 95 mg/kg/d for rats, 97 and 195 mg/kg/d for male mice, and 149 and 299 mg/kg/d for female mice. All high-dose male rats died after 23 wk of observation; the last high-dose female died after 15 wk. Male rats had significantly increased incidence of forestomach squamous-cell carcinomas and circulatory system hemangiosarcomas. Female rats and mice were observed to have significant increases in mammary adenocarcinoma incidence. Mice of both sexes developed alveolar/bronchiolar adenomas, females developed endometrial stromal polyps and sarcomas, and males developed hepatocellular carcinomas.

In the studies by Spencer et al. (76) and Maltoni et al. (77) inhalation exposure of Wistar, Sprague–Dawley rats, and Swiss mice did not result in increased tumor incidence.

An elevation that was not statistically significant in lung adenomas was seen in A/st mice treated IP with 1,2-dichloroethane in tricaprylin (78).

ICR/Ha Swiss mice treated topically had a significant increase in benign lung papillomas, but not skin carcinomas (79).

Carcinogenicity Classification:

EPA	Group B2, Probable human carcinogen; sufficient evidence from animal studies; inadequate evidence or no data from epdemiologic studies.
IARC	Group 2B, Possibly carcinogenic in humans.
MAK	Group 2, Probable human carcinogen.
NIOSH	Carcinogen, with no further categorization.
NTP	Reasonably anticipated to be a human carcinogen (RAHC).
ACGIH TLV	A4, Not Classifiable as a Human Carcinogen.

3.4.1.6 Genetic and Related Cellular Effects Studies 1,2-Dichloroethane was mutagenic for *Salmonella* in assays wherein excessive evaporation was prevented; exogenous metabolism by mammalian systems enhanced the response (80–82). Both somatic cell mutations and sex-linked recessives were induced in *Drosophila* (83–86).

Metabolites of 1,2-chloroethane have been shown to form adducts with DNA after *in vitro* or *in vivo* exposures.

3.4.2 Human Experience Symptoms of exposure to this compound may include irritation of the skin, eyes, and respiratory tract, corneal clouding, and dermatitis. It may cause conjunctivitis, corneal ulceration, headache, mental confusion, depression, fatigue, albuminuria, central nervous system depression, convulsions, diarrhea, hepatomegaly, hypoglycemia, jaundice, narcosis, and pulmonary edema. It may also cause flaccid paralysis without anesthesia, somnolence, cough, nausea, vomiting, hypermotility, ulceration, fatty liver degeneration, change in cardiac rate, cyanosis, coma, edema of the lungs, and toxic effects on the kidneys. It may cause feelings of drunkeness or drowsiness, unconsciousness, and death from respiratory and cardiac failure, defatting of the skin, swelling of the skin, and chemical pneumonia. Other symptoms may include mental confusion, abdominal pains, and liver and kidney damage. It can also cause watery stool, weak and rapid pulse, and internal bleeding. It may cause corneal opacity. Other symptoms may include edema of the brain, vascular congestion in the lungs, heart, and spleen, weight loss, and oliguria. It may also cause dizziness, narcosis, intestinal hemorrhages, weakness, trembling, and severe shock. Chronic exposure may result in loss of appetite, epigastric distress, tremors, nystagmus, leukocytosis, and low blood sugar levels.

3.4.2.2 Clinical Cases There have been clinical cases of acute exposure to ethylene dichloride reported in the literature that confirm the picture observed in the animals. Menschick (87) reported four acute cases showing a “hepato-renal syndrome.” The author also lists 27 cases of poisoning by inhalation collected from the literature.

Ethylene dichloride does present a problem from oral ingestion. There are a significant number of the poisoning cases reported in the literature by this route. The response is CNS depression, gastrointestinal upset, and injury to the liver, kidneys, and the lungs, and delayed deaths.

The Criteria Document (88) cited papers that indicate fatalities from inhalation in concentrations insufficient to cause anesthesia.

Two epidemiologic studies, one positive and one negative, have been reported, but the results are not conclusive owing to mixed exposures or small sample size (89, 90).

3.4.2.3 Epidemiology Studies Two epidemiologic studies, one positive and one negative, have been reported, but the results are not conclusive owing to mixed exposures or small sample size (89, 90).

3.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV is 10 ppm with an A4 notation, not classifiable as a human carcinogen. The

NIOSH REL is 1 ppm and the STEL is 2 ppm. NIOSH considers this chemical a carcinogen. The OSHA PEL is 50 ppm while the ceiling is 100 ppm and the 5 min peak in any 3 hours is 200 ppm.

Other Occupational Exposure Values: Australia: 10 ppm (substance under review) (1990); Federal Republic of Germany: no MAK, Group 2, probably human carcinogen (1998); Sweden: 1 ppm, 15-min short-term value 5 ppm, skin, carcinogenic (1989); United Kingdom: 10 ppm, 10-min STEL 15 ppm, carcinogenic substance, R45-may cause cancer (1991).

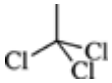
Saturated Halogenated Aliphatic Hydrocarbons Two To Four Carbons
Jon B. Reid, Ph.D., DABT

Methyl Chloroform
4.0.1 CAS Number:
[*71-55-6*]
4.0.2 Synonyms:
1,1,1-Trichloroethane, methyltrichloromethane, alpha-trichloroethane, chloroethene, chlorothene, 1,1,1-TCE
4.0.3 Trade Names:
Aerothene TT, Chloroetene, Chloroethene NU, Chlorothane NU, Chlorothene (inhibited), Chlorothene NU, Chlorothene VG, Chlorten, Inhibisol, NCI-C04626, RCRA Waste Number U226, Solvent 111, Strobane, Alpha-T, Tri-ethane, UN 2831, Trichloroethane, 1,11-Trichloroetano, Tri-ethane
4.0.4 Molecular Weight:
133.42
4.0.5 Molecular Formula:
$C_2H_3Cl_3$
4.0.6 Molecular Structure:



4.1 Chemical and Physical Properties
Methyl chloroform is a colorless, nonflammable liquid with an chloroformlike odor and an odor threshold of 120 ppm. It burns only in excess oxygen or in air if a strong source of ignition is present. Because of its reactivity with magnesium, aluminum, and their alloys, inhibitors (usually 1,4-dioxane, 1,3-dioxolane, isobutyl alcohol, or nitroethane) are often added to increase the stability of the solvent.

Physical state	Colorless liquid
Specific gravity	1.3376 at 20°C
Boiling point	74.1°C
Melting point (°C)	–32.5
Vapor pressure	127 torr (25°C)
Refractive index	1.43765 (21°C)
Percent in “saturated” air	16.7 (25°C)
Solubility	0.09 g/100 mL water at 20°C; soluble in ethanol and ethyl ether

Flammability (see following note)

Note: The flammable characteristics of methyl chloroform are similar to those of trichloroethylene. It has no flash point or fire point by ASTM procedures for Tag closed-up and Cleveland open-cup tests. Limits of flammability of vapors of inhibited 1,1,-trichloroethane have been found to be 10–15.5% in air with hot wire ignition. A considerable amount of energy is required for ignition. It will not sustain combustion (91).

4.1.1 General An ATSDR Toxicological profile exists for 1,1,1-trichloroethane (3).

4.1.2 Odor and Warning Properties Although methyl chloroform has a typical sweetish odor, it is not striking enough to be considered a good warning. The odor may be noticeable at concentrations near 100 ppm, well below those known to cause physiological response. However, the odor at 500 ppm and even 1000 ppm is not so unpleasant as to discourage exposure. The odor has been described as strong and unpleasant at 1500–2000 ppm. Stewart et al. (92) reported that female test subjects exposed to 350 ppm objected to the odor; however, this has not been an industrial problem.

4.2 Production and Use

According to the NTP database, methyl chloroform is used in cold-type metal cleaning, in plastic cleaning, in vapor degreasing, as a chemical intermediate for vinylidene chloride, in aerosols (as a vapor pressure depressant, solvent, and carrier), in adhesives (as a resin solvent), and as a lubricant carrier to inject graphite, grease, and other lubricants. It is used alone and in cutting oil formulations as a coolant and lubricant for drilling and tapping alloy and stainless steels. It is also used to develop printed circuit boards, in motion picture film cleaning, in stain repellants for upholstery fabrics, in wig cleaning, in textile processing and finishing, and as a solvent in drain cleaners, shoe polishes, spot cleaners, insecticide formulations, and printing inks. It is also used as a solvent for cleaning precision instruments.

Methyl chloroform is used almost exclusively as a solvent with a few percent used as an intermediate. As a solvent for adhesives, 69% of the U.S. production is consumed in metal degreasing. Another 23% is used in the manufacture of vinylidene chloride (93). Because of the environmental issue of depletion of stratospheric ozone, future use can be expected to decline.

Most commercial methyl chloroform, which is sold under several trade names, contains inhibitors to prevent reaction of the solvent with aluminum and alloys. This reaction produces hydrogen chloride and in confined vessels may produce high pressures.

4.3 Exposure Assessment

4.3.3 Workplace Methods NIOSH Method 1003, for halogenated hydrocarbons, is recommended for determining workplace exposures to methyl chloroform.

4.3.5 Biomonitoring/Biomarkers Stewart et al. (92) have produced a series of graphs making it possible to quantify exposure based on expired air samples. Analysis of urine for metabolites probably has limited value. Monster (94) has also published extensive studies on biologic monitoring of 1,1,1-trichloroethane. Although it has been suggested that urinary trichloroacetic acid and trichloroethanol may be of value in quantifying exposure to methyl chloroform, and the ACGIH in 1992–1993 recommended biological exposure indices, such indices are of most value in discerning average exposure levels and not peak exposures. Thus it is possible that “acceptable false negative” urinary levels of these substances may be found following exposure considered excessive from the standpoint of anesthetic effects. The same caveat must be considered in considering expired air samples collected at the end of the workday or workweek.

4.4 Toxic Effects

Extensive testing and human experience indicate 1,1,1-trichloroethane is probably the least toxic of the chlorinated solvents, but its high volatility and careless use and abuse have resulted in deaths from gross exposure usually in confined spaces or due to deliberate inhalation.

Methyl chloroform is harmful by inhalation, ingestion, and skin absorption. It can be absorbed through the lungs, gastrointestinal tract, and skin. It is an irritant of the skin, eyes, mucous membranes, and upper respiratory tract. It may be narcotic in high concentrations. It may also cause slight lacrimation. When heated to decomposition, it emits irritating gases and toxic fumes of carbon monoxide, carbon dioxide, hydrogen chloride gas, chlorine, and phosgene.

The principal and first response from acute or chronic exposure to excessive amounts of methyl chloroform is depression of the central nervous system. Possibly as a result of very little metabolism of the compound, it has little capacity to produce organ injury from either single or repeated exposures but at high levels can sensitize the heart to epinephrine, possibly leading in some cases to death. Overall the available human and animal data indicate that the compound is not teratogenic, mutagenic, or carcinogenic, although the 1,1,1-trichloroethane isomer is considerably less toxic than the 1,1,2-trichloroethane isomer. Owing to an error in the literature, several authors have indicated the reverse, as documented by Torkelson et al. (95).

Concentrations in excess of 14,000–15,000 ppm are fatal to animals. Human fatalities due to anesthesia (and/or cardiac arrhythmia) have occurred in confined spaces when exposures to high concentrations have not been promptly terminated. In cases where the victim has been alive when removed from the high concentration, recovery has generally been rapid and complete. Abuse (sniffing) has also resulted in deaths.

Several reviews have been published (5, 62, 96–100).

4.4.1 Experimental Studies 4.4.1.1 Acute Toxicity Torkelson et al. (95) reports that the oral toxicity is low with an LD_{50} in rats, mice, rabbits, and guinea pigs ranging from 5.7 to 12.3 g/kg. The LD_{50} for rabbits (skin absorption) is 16 g/kg.

Wolverton et al. (101) report that the inhalation toxicity is also low with an EC_{50} for motor control loss (mice) for 30 min at 5173 ppm. No significant toxic responses were reported for rats, 500 ppm, 6 h/d, 4 d (102), mice to 1300 ppm, 1 h, rats to 3000 ppm for 0.5–4 h (103) baboons, 1400 ppm 4 h (104).

Inhalation: As an anesthetic, methyl chloroform can cause dealth in excess of 14,000–15,000 ppm (105).

Adams et al. (106) reported on the response of animals to acute inhalation exposure. Maximum time concentrations in air survived by rats were as follows: 6 min at 30,000 ppm, 1.5 h at 15,000 ppm, and 7 h at 8000 ppm. Maximum time concentrations in air with no detectable injury in rats were as follows: 18 min at 18,000 ppm and 5 h at 8000 ppm. It should be noted that the maximum level with no detectable injury is very close to the maximum level survived. This information has been confirmed by Torkelson et al. (95) using inhibited solvent.

Bruckner et al. (107) performed an acute and subacute study in rats. Several parameters were studied in addition to lethality. Single oral doses up to 4 g/kg in corn oil did not cause death or treatment-related effects on serum enzymes organ weights, or histological findings in the livers and kidneys of Sprague–Dawley rats 24 h after gavage. Rats treated with nine doses in 11 d were scheduled for sacrifice on the twelfth day. Doses of 0, 0.5, 5.0, or 10.0 g/kg were administered. Doses of 5 and 10 g/kg/d caused hyperexcitability and protracted narcosis as well as some fatalities, but there was little evidence of toxicity in the survivors or in the 0.5 g/kg/d group. In a 12 wk oral study doses of 0, 0.5, 2,5, or 5.0 g/kg were given 5 d/wk. Reduced body weight and CNS effects were seen only in the 2.5- and 5.0-g/kg groups and 35% of the rats in these groups died, but only the 5.0-g/kg group showed serum enzyme changes. The 0.5-g/kg (500 mg/kg) group developed no alterations in toxicity during the 12 wk study.

Torkelson et al. (95) reported on eyes, skin, and skin absorption: The material caused only minor, transient irritation in the eyes of rabbits, and no reports of human injury have been reported following eye contact. The skin shows only slight reddening and scaliness from contact. The reaction is somewhat increased on repreated exposures. Confinement of the liquid on the skin results in considerable pain and irritation. Applied under a cuff for 24 h, 3.9 g/kg was survived by all rabbits; 15.8 g/kg failed to kill all the rabbits treated with the undiluted liquid. Others have reported similar low hepato- and renal toxicity in rats and other species (47, 108–110).

Gehring (111) determined that at 13,500 ppm the LT_{50} (lethal time, 50%) was 595 min but that liver function as measured by serum glutamic-oxalic-transaminase (SGOT) was virtually unaffected unless exposures approached those causing anesthetic death.

Klaassen and Plaa reported an intraperitoneal LD_{50} of 3.9 g/kg in rats (110) and an LD_{50} of 120 mmol/kg (16 g/kg) in mice (108).

4.4.1.2 Chronic and Subchronic Toxicity The EPA (2) reports that the oral RfD for 1,1,1-trichloroethane had been withdrawn on 08/01/1991 pending further review by the RfD/RfC Work Group and that no reference concentration is available. Please see the section on carcinogenicity for additional information.

Adams et al. (106) exposed animals 7 h/d, 5 d/wk for 1–3 mo. At 10,000 ppm rats showed staggering gait and weakness in 10 min. By 3 h, they showed loss of color, irregular respiration, and semiconsciousness. Survivors had completely recovered by the following morning. For those that succumbed, death seemed to be due to either cardiac or respiratory failure. At 5000 ppm, there was definite but mild narcotic effect within 1 h. There was reduced activity. Rats survived for 31 exposures over 41 d without apparent injury. Rabbits showed slight retardation of growth at 5000 ppm. At 3000 ppm, rabbits and monkeys showed no response over a 2-mo period. Guinea pigs showed a barely significant retardation of growth at 650 ppm.

Torkelson et al. (95) reported results of exposures of female guinea pigs and male rats for 3 mo, exposed for 0.05–3 h/d at 1000–10,000 ppm. Some pathologic changes in the livers and lungs of guinea pigs exposed for 3 or 1.2 h/d at 1000 ppm and for 0.2 or 0.5 h/d at 2000 ppm. The anesthetic effect was paramount. No significant toxic changes were reported for exposures to the vapor at 500 ppm for 7 h/d, 7 days/week, for 6 m in rats, guinea pigs, rabbits, or monkeys.

Prendergrast et al. (112) performed continuous (24 h/d) exposure for 14 wk and showed that it produced little injury to rats, mice, dogs, and monkeys at 1000 ppm and essentially no effect at 250 ppm except minor, apparently reversible cytoplasmic alterations in the livers of mice. After exposure to 1000 ppm dogs and monkeys were considered unaffected by the exposure, but the rats and mice exhibited significant increases in liver weight and liver triglycerides and fatty and necrotic changes visible microscopically in the livers.

Quast et al. (113) repeatedly exposed groups of 96 rats of each sex to 875 or 1750 ppm, 1,1,1-trichloroethane vapor 6 h/d, 5 d/w for 1 yr with no adverse effects (see section on carcinogenicity).

Several other subchronic studies indicated minor and reversible effects (114–116).

The section on carcinogenicity also describes a 2-yr inhalation exposure study of rats and mice with effects only at 1500 ppm in rats, but not at 500 or 150 ppm. There was no effect on mice at any concentration.

4.4.1.3 Pharamacokinetics, Metabolism, and Mechanisms Absorption from the skin of humans and rodents after topical application (#51, 52, 53, 54) (117–120) has been shown.

Both *in vivo* and *in vitro* systems metabolize methyl chloroform by microsomal P-450 to trichloroethanol (121, 122). This metabolite is conjugated with glucuronic acid and the trichloroethanol-glucuronide appears in the urine (96). The trichloroethanol can also be oxidized to trichloroacetic acid. It can account for considerable metabolites in rodent and human urine (115, 123–126).

Pulmonary absorption by humans is from 30 to 60% depending on the duration and concentration of the exposure (123, 127).

Gehring et al. (62) indicated that the low systemic toxicity of methyl chloroform is related to the small amount of metabolism that occurs in animals and humans. Because of its low toxicity, it has been used as a model compound in absorption–excretion studies (95, 128). In one of the first metabolic studies on this compound, Hake et al. (129) reported 97.6% of radioactive methyl chloroform injected intraperitoneally was excreted unchanged by the lungs, and only 0.85% of the radioactivity was found in the urine. This and subsequent studies on humans and animals indicate that only small amounts of trichloroacetic acid and trichloroethanol may be found in the urine after injection or inhalation (115, 126, 130–132), but that most of the dose is expired unchanged no matter what the route of administration.

As reported by Schumann et al. (126), rats and mice eliminated 96% of their body burden within 24 h following 6 h inhalation exposure to 150 or 1500 ppm [^{14}C]1,1,1,-trichloroethane. Exhalation of the parent compound was very high, 87–97% of the body burden in mice and 94–98% in rats at 150 and 1500 ppm, respectively. The remaining ^{14}C activity (2–13%) was recovered either as CO_2 in expired air or as nonvolatile radioactivity in urine, feces, carcass, or cage wash.

Although quantities were small, mice metabolized two to three time more than rats on a body weight basis. Fat contained the highest concentrations of ^{14}C activity. Prior long-term repeated exposure to nonradioactive 1,1,1-trichloroethane did not increase the rate of metabolism of a radioactive dose. Reitz et al. (133) have developed pharmacokinetic models for interspecies, high-dose/low-dose, and dose route extrapolations, as models for regulatory risk analysis (134).

According to VanDyke and Wineman (135) the small amount of metabolism that takes place appears to occur in a saturable process. Enzymatic dechlorination by rat liver microsomes *in vitro* is very low and apparently not enhanced by enzyme inducers. VanDyke (136) reports that the reaction is catalyzed by cytochrome P450 in the presence of oxygen. Kawai et al. (137) reported that only 2% of absorbed 1,1,1-trichloroethane was excreted in the urine of the 48 male printing workers they studied.

Occupational Exposures: Imbriani et al. (138) examined occupationally exposed persons and found intact methyl chloroform in the urine from 33 to 314 mg/L. Nolan et al. (124) exposed six humans at 35 or 350 ppm for 6 h and calculated the urinary elimination of trichloroethanol and trichloroacetic acid at 27 and 76 h, respectively.

4.4.1.4 Reproductive and Developmental Schwetz et al. (139) reported that pregnant female rats and mice were exposed 7 h/d on days 6 to 15 of gestation and the mothers and fetuses examined for effects. The inhaled vapor concentration was 875 ppm of an inhibited formulation containing 5.5% inhibitors. No effects related to exposure were observed on either the mothers or fetuses.

The NTP (NTP 1987 (140, 141)) found no signs of developmental toxicity at doses where maternal intoxication was present when given to male and female CD rats prior to mating and throughout pregnancy in drinking water at 30 ppm. Bogen and Hall (134) used these data to determine a "virtually safe dose" of 14–28 mg/d based on the delivered dose to the rat embryo.

York et al. (142) repeatedly exposed female Long–Evans rats to 2100–2200 ppm of methyl chloroform vapors 2 wk before breeding and until day 20 of gestation without effect on teratogenicity or subsequent neurobehavioral studies of the offspring allowed to be delivered normally.

Riddle et al. (72) modified a multigeneration reproduction study to include screening for dominant lethal and teratogenic effects. Mice were fed water containing methyl chloroform so that daily dosage levels were 0, 99.4, 264, or 852 mg/kg. According to the authors, "There appeared to be no dose-dependent effects on fertility, gestation, viability, or lactation indices. Pup survival and weight gain were not adversely affected. Gross necropsy of male and female F/0 generation mice treated with 1,2-DCE or 1,1,1-TCE failed to reveal compound or dose-related effects."

George et al. (143) reported that when methyl chloroform was fed in drinking water to CD rats at 0, 3, 10, or 30 ppm using 0.05% Tween 80 as an emulsifying agent for 14 d prior to and 13 d after cohabitation, "there was no indication of an increase in the incidence of cardiac or other malformations."

These data as well as all other studies appear to refute adequately an allegation of teratological effect reported by Dapson et al. (144).

4.4.1.5 Carcinogenesis The EPA (IRIS) reports that there are no human carcinogenic data and classifies this material as D, not classifiable as to human carcinogenicity and that the animal carcinogenicity data are "Inadequate." In 1987, IARC reviewed the existing information and concluded that there was inadequate evidence for carcinogenicity in animals (74, p. 73). Three animal studies are relevant an NCI bioassay (gavage) and two inhalation studies by Quast et al., (145, 146), none of which gave clear evidence of carcinogenic activity.

The NCI (147) treated Osborne–Mendel rats (50/sex/dose) with 750 or 1500 mg/kg technical-grade 1,1,1-trichloroethane 5 times/wk for 78 wk by gavage. The rats were observed for an additional 32 wk. Twenty rats of each sex served as untreated controls. Low survival of both male and female treated rats (3%) may have precluded detection of a significant number of tumors late in life. Although a variety of neoplasms was observed in both treated and matched control rats, they were common to aged rats and were not dose related. Similar results were obtained when the NCI (147) treated B6C3F1 hybrid mice with the time-weighted average doses of 2807 or 5615 mg/kg 1,1,1-trichloroethane by gavage 5 d/wk for 78 wk. The mice were observed for an additional 12 wk. The control and treated groups had 20 and 50 animals of each sex, respectively. Only 25–45% of those treated survived until the time of terminal sacrifice. A variety of neoplasms was observed in treated groups, but the incidence not statistically different from matched controls.

Quast et al. (145) exposed 96 Sprague–Dawley rats of both sexes to 875 or 1750 ppm 1,1,1-trichloroethane vapor for 6 h/d, 5 d/wk for 12 m, followed by an additional 19 mo observation period. The only significant sign of toxicity was an increased incidence of focal hepatocellular alterations in female rats at the highest dosage. It was not evident that a maximum tolerated dose (MTD) was used, nor was a range-finding study conducted. No significant dose-related neoplasms were reported, but these dose levels were below those used in the NCI study.

In another study, Quast et al. (146) used an inhibited formulation of 1,1,1-trichloroethane. Fischer 344 rats and B6C3F1 mice of both sexes were exposed to 0, 150, 500, or 1500 ppm 6 h/d, 5 d/wk for 2 yr. The authors indicate that there were no indications of an oncogenic effect in rats or mice following 2 yrs of exposure to the 1,1,1-trichloroethane formulation and a no-observed-adverse-effect-level (NOAEL) of 500 ppm for adverse effect of any kind. The ATSDR reviewed this information (56) and determined that the study adequately demonstrated negative evidence of carcinogenicity in animals by lifetime inhalation up to 1500 ppm.

It should be noted that an isomer of methyl chloroform, namely, 1,1,2-trichloroethane, is

carcinogenic in mice, inducing liver cancer and pheochromocytomas in both sexes. Dichloroethanes, tetrachloroethanes, and hexachloroethanes also produced liver cancer in mice and other types of neoplasms in rats and further that 1,4-dioxane, a known animal carcinogen that causes liver and nasal tumors in more than one strain of rats and hepatocellular carcinomas in mice, is a contaminant of technical-grade 1,1,1-trichlorethane.

4.4.1.6 Genetic and Related Cellular Effects Studies According to the EPA (IRIS), mutagenicity testing of 1,1,1-trichloroethane has produced positive results in *S. typhimurium* strain TA100 (148) as well as some negative results (149).

Methyl chloroform was mutagenic for *S. typhimurium* strain TA1535, both with exogenous metabolic activation (150) and without activation (80). 1,1,1-Tricholoroethane did not result in gene conversion or mitotic recombination in *Saccharomyces cerevisiae* (150), nor was it positive in a host-mediated forward mutation assay using *Schizosaccharomyces pombe* in mice. The chemical also failed to produce chromosomal aberrations in the bone marrow of cats (151), but responded positively in a cell transformation test with rat embryo cells (152).

The extensive summary (98) of genotoxic studies on methyl chloroform concludes that the potential for genetic damage is very small at acceptable exposure conditions.

4.4.2 Human Experience Symptoms of exposure to this compound may include irritation of the eyes, dizziness, incoordination, unconsciousness, and death. Irritation of the mucous membranes and respiratory tract may occur. Fainting may also occur. Other symptoms may include decreased reaction time, impaired manual dexterity, ataxia, lightheadedness, positive Romberg test, diarrhea, respiratory arrest, and nausea. It causes a proarrhythmic activity that sensitizes the heart to epinephrine, resulting in cardiac arrhythmias. This sometimes will cause cardiac arrest, particularly when massive amounts are inhaled. Inhalation can cause euphoria. High concentrations may cause narcosis. Exposure can cause headache, drowsiness, burning sensation on the eyes and skin, irritation of the throat, cardiac sensitization, aspiration of vomitus during anesthesia, blood pressure depression, chemical pneumonitis, and pulomary edema with hemorrhage. It can also cause anesthesia, cardiac fibrillations, slight reddening of the skin, central nervous system impairment, helplessness, loss in equilibrium, and mild eye and nasal discomfort. Other symptoms are hallucinations, distorted perceptions, motor activity changes, irritability, aggression, hypermotility, and other gastrointestinal changes. Impaired judgement has been reported. Increased reaction time has also been reported. Repeated skin contact may result in a dry, scaly, and fissured dermatitis due to its defatting properties. Prolonged skin contact may result in considerable pain and irritation. Other symptoms may include difficult breathing, asphyxiation, slight lacrimation, and slight smarting of the eyes and respiratory system. It may cause impaired psychophysiological functions. It may also cause irregular heart beat, lassitude, and coma. High concentrations cause central nervous system depression. Hemorrhage in the brain may also result from exposure to high concentrations. Eye contact may lead to superficial and transient injury to the eyes. It may also lead to mild conjunctivities. Chronic exposure may result in liver and kidney damage. Exposure to and/or consumption of alcohol may increase its toxic effects.

Findings in laboratory animals is consistent with humans (105). Numerous deaths due to CNS depression or cardiac arrhythmias have been reported from poorly ventilated areas (153–162).

Several authors (163, 164) have evaluated methyl chloroform as a surgical anesthetic, but for several reasons, including lack of potency and effects on cardiac function, it was abandoned from serious consideration. If the subject has been alive when removed from exposure, recovery has generally been rapid and complete.

Table 63.4 on the probable effects of exposure to humans to the vapor of methyl chloroform has been published for establishing emergency exposure limits.

Table 63.4. Probable Result of Single Exposure to the Vapors of 1,1,1-Trichloroethane (210)

Exposure time (min)	Concentration in Air (ppm)	Expected Effect in Humans[a]
5	20,000	Complete incoordination and helplessness (R)
	10,000	Pronounced loss of coordination (R)
	5,000	Definite incoordination (R, M)
	2,000	Disturbance of equilibrium. Odor is unpleasant but tolerable (H)
15	10,000	Pronounced loss of coordination (R)
	2,000	Loss of equilibrium (H)
	1,000	Possible beginning loss of equilibrium (H)
30	10,000	Pronounced loss of coordination (R)
	5,000	Incoordination (R, M)
	2,000	Loss of equilibrium (H)
	1,000	Mild eye and nasal discomfort; possible slight loss of equilibrium (H)
60	20,000	Surgical anesthesia, possible death (R)
	10,000	Pronounced loss of coordination (R)
	5,000	Obvious loss of coordination (R, M)
	2,000	Loss of coordination (H)
	1,000	Very slight loss of equilibrium (H)
	500	No detectable effect, but odor is obvious (R, H)
	100	Apparent odor threshold (H)

Laboratory Studies: Numerous laboratory studies in humans have permitted confirmation of many of the toxicologic data derived in animals. Stewart et al. (92), in a series of papers have evaluated the use of expired air for monitoring employee exposure and have produced a series of graphs based on expired air concentration following known exposures to various concentrations for different periods of time. These studies have also investigated metabolism and urinary excretion and evaluated clinical chemical parameters. Most important, however, are their studies to evaluate equilibrium, coordination, alertness, and other signs of anesthetic action. Based on these studies it has been concluded that, except for possible objections to odor, no untoward responses are observed even after repeated prolonged exposures of human subjects to 350 ppm. A few subjects may respond as concentrations approach 500 ppm, and if allowed to inhale 800–1000 ppm, some subjects show minor CNS impairment.

Other investigators (165) have found similar results, but Gamberale and Hultengren (166) reported effects at lower vapor concentrations. Gamberale and Hultengren, however, used a mask to administer the vapors, and this may have influenced their test results.

Monster (94) has published extensive studies on biologic monitoring of 1,1,1-trichloroethane,

trichloroethylene, and perchloroethylene.

Liquid methyl chloroform has been shown by Stewart and Dodd (167) as well as Fukabori et al. (168) to be absorbed through the intact skin, but Riihimaki and Pfaffli (169) have shown that the vapors are not absorbed in toxicologically significant amounts.

Industrial Experience: Although chronic effects have been shown to be of little consequence in industrial exposure (170), failure to recognize the high vapor pressure of methyl chloroform and to prevent inhalation of high concentrations, has resulted in reports of death. The number of deaths per year (2–3 worldwide) appears to be decreasing relative to consumption, as proper precautions are being taken to avoid exposure. Nonoccupational cases of deliberate sniffing have been reported, but generally a consistent pattern of use of the solvent in a confined space without regard for ventilation is the cause of industrial death.

Stewart (171) discussed the consequencs of overexposure and the treatment of overexposed subjects.

A single report (172) alleging chronic cardiac toxicity following repeated exposure to 1,1,1-trichloroethane is inconsistent with all other reports of rapid recovery as well as epidemiologic evidence (170). Furthermore, there are obvious discrepancies in claiming urinary excretion of 1,1,1- and 1,1,2-trichloroethane long after exposure, suggesting the report is in error. A rather extensive study of an industrial population exposed to methyl chloroform for up to 6 yr confirms the data derived from animals (170). No effect of exposure was found in a matched-pair study of 151 subjects and 151 controls despite particular emphasis placed on hepato- and cardiotoxic effects.

Mattsson et al. (173) conducted an elaborate investigation in which male and female Fischer 344 rats were exposed to 1,1,1-trichloroethane vapors for 6 h/d, 5 d/wk, for 13 wk. Exposure levels were 200, 630, and 2000 ppm. Rats were clinically examined regularly and were given a functional observational battery monthly (FOB, including forelimb and hindlimb grip performance testing). After 13 wk of exposure, the functional integrity of the nervous system was evaluated by FOB and by visual, auditory, somatosensory, and causal nerve evoked potentials. After functional testing, a subgroup of rats had histopathologic examination of brain, spinal cord, peripheral nerves, and limb muscles. No treatment-related findings were discovered in any parameter except for a slightly smaller forelimb grip performance in the 2000-ppm exposure group. A subgroup of rats was examined for grip performance 6 wk postexposure; forelimb grip performance was still smaller in 2000-ppm rats. Forelimb nerves and muscles from these rats then were examined histopathologically, and no treatment-related lesions found. No reason was discovered for this difference in forelimb grip performance. It normally decreases (habituates) over time as a function of experimental conditions, and it is speculated that the daily acute-sedative effect of 2000 ppm 1,1,1-trichloroethane has an interaction with the habituation process. Other than a possible indictor of acute sedation, there was no recognized toxicologic significance to this difference in forelimb grip performance. Furthermore, histopathological examination of rats exposed to 2000 ppm for 13 wk found no effects related to exposure in any organ, including the nervous system.

4.4.2.2.5 Carcinogenesis The EPA (IRIS) classifies methyl chloroform as – D; not classifiable as to human carcinogenicity on the basis that there are no reported human data, and animal studies (one lifetime gavage, one intermediate-term inhalation) have not demonstrated carcinogenicity. Technical-grade 1,1,1-trichloroethane has been shown to be weakly mutagenic, although the contaminant, 1,4-dioxane, a known animal carcinogen, may be responsible for this response.

Carcinogenicity Classification:

EPA	Group D, Not Classifiable as to Human Carcinogenicity
IARC	Group 3, not classifiable as to its carcinogenicity to humans
ACGIH TLV	A4, Not Classifiable as a Human Carcinogen

4.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV, NIOSH REL ceiling and the OSHA PEL are all 350 ppm. The ACGIH STEL/C is 450 ppm. ACGIH has an A4 designation for this chemical.

Other Occupational Exposure Values: Australia: 125 ppm (1990); Federal Republic of Germany: 200 ppm, short-term level 1000 ppm, 30 min, twice per shift, pregnancy group C, no reason to fear a risk of damage to the developing embryo or fetus when MAK and BAT values are observed (1998); Sweden: 50 ppm, 15-min short-term value 90 ppm (1990); United Kingdom: 350 ppm, 10-min STEL 450 ppm (1991).
4.6 Studies on Environmental Impact

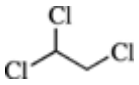
Saturated Halogenated Aliphatic Hydrocarbons Two To Four Carbons
Jon B. Reid, Ph.D., DABT

1,1,2-Trichloroethane
5.0.1 CAS Number:
[*79-00-5*]
5.0.2 Synonyms:
Vinyl trichloride, beta-trichloroethane, 1,2,2-trichloroethane, and ethane trichloride (not recommended because of confusion with 1,1,1-trichloroethane)
5.0.3 Trade Names:
NCI-C04579, RCRA Waste Number U227, RCRA Waste Number U359, beta-T
5.0.4 Molecular Weight:
133.40
5.0.5 Formula:
$C_2H_3Cl_3$, $ClH_2C–CHCl_2$
5.0.6 Molecular Structure:



5.1 Chemical and Physical Properties

Physical state	Colorless liquid
Molecular weight	133.41
Specific gravity	1.4397 at 20°C (20/4°C)
Melting point	36.5°C
Boiling point	113.8°C
Vapor pressure	25 torr (25°C) 19 torr (20°C)
Refractive index	1.4711 (20°C)
Percent in “saturated”air	3.3 (25°C)
Solubility	0.44 g/100 g water at 20°C; soluble in ethanol and ethyl ether; 4.50 g/L at 20°C
Flammability	Not flammable by standard tests in air

5.1.1 General

5.1.2 Odor and Warning Properties Although 1,1,2-trichloroethane is reported to have an odor similar to chloroform, no quantitative data were found concerning odor or warning properties. In view of its high systemic toxicity, odor cannot be used to protect against excessive acute or chronic exposure.

5.2 Production and Use

The use of 1,1,2-trichloroethane is quite restrictive. It is used to a slight extent as a specialty solvent but mostly as a chemical intermediate; a solvent for fats, waxes, natural resins, alkaloids, and various other organic materials; intermediate in production of vinylidene chloride and teflon tubing; component of adhesives. The availability of other less toxic solvents discourages its use. Upwards of 95% of this compound manufactured in the United States is consumed in producing vinylidene chloride. Domestic production is about 410 million pounds. It must not be confused with its much less toxic isomer, 1,1,1-trichloroethane.

5.3 Exposure Assessment

1,1,2-Trichloroethane has been detected in ambient urban air at concentrations up to 0.223 m/m^3 (174). It is degraded in the troposphere by reaction with hydroxyl radicals ($t_{1/2}$ = 24 d) (1) to hydrochloric acid, phosgene, formyl chloride, and chloroacetyl chloride.

5.3.3 Workplace Methods NIOSH Method 1003, for halogenated hydrocarbons is recommended for determining workplace exposures to 1,1,2-trichloroethane.

5.3.5 Biomonitoring/Biomarkers 1,1,2-Trichloroethane is absorbed from the lungs and no doubt also is excreted in the breath. Although no data are available, it seems probable that the low concentrations that could be present in expired air after exposure to levels considered safe for occupational exposure will not be useful for monitoring workers exposure. Qualitative analysis might verify that exposure to 1,1,2-trichloroethane has occurred.

Ikeda and Ohtsuji (130) have shown a positive Fujiwara reaction in the urine of rats and mice treated with 1,1,2-trichloroethane, but the value of this determination in humans does not appear to have been investigated. At the low levels of exposure considered acceptable, it may have limited value.

5.4 Toxic Effects

1,1,2-Trichloroethane is toxic by ingestion or inhalation. It is an irritant of the skin, eyes, mucous membranes, and upper respiratory tract. It may be absorbed through the skin, and in high concentrations, it is narcotic. It is a positive animal carcinogen. When heated to decomposition it emits toxic fumes of carbon monoxide, carbon dioxide, hydrogen chloride gas, and phosgene gas.

The principal physiological responses to 1,1,2-trichloroethane are depression of the central nervous system and liver injury. With regard to the CNS effects, it is considerably more potent than chloroform by inhalation (7, pp. 155–156; 175). At narcotic concentrations, ocular and upper respiratory tract irritation is present.

Similarity in chemical names has resulted in some confusion in older literature that misquoted work by Lazarew (175) and stated that the 1,1,2 compound was less toxic than 1,1,2-trichloroethane. Torkelson et al. (95) have explained the source of the error, which could be serious because 1,1,2-trichloroethane is much more hepatotoxic when given to animals by single or repeated doses. Even current literature occasionally confuses the two substances or fails to distinguish between them. No new published reports of human injury were found.

5.4.1 Experimental Studies 5.4.1.1 Acute Toxicity Concentrations of 13,600 ppm for 2 h exposures produce deep narcosis, respiratory arrest, and death (7, 175). Carpenter et al. (176) indicated that exposure of 2000 ppm for 4 h was lethal to rats. Torkelson and Rowe (105) reported hepatic and

renal necrosis for rats inhaling 250 ppm for 4 h. Smyth et al. (63) and Di Vincenzo and Krasavage (177) reported rat oral LD_{50} values for male and female mice at 378 and 491 mg/kg body weight, respectively. Klaassen and Plaa (109) reported a dog interperitoneal LD_{50} of 648 mg/kg. Wahlberg (178) published that repeated applications of 0.5 mL or more to guinea pig skin caused death in all 20 animals in 3 d.

Wright and Shaffer (179) reported that the oral lethal dose for dogs was 0.5 mL/kg. Irish (180) indicated an LD_{50} for rats of 0.1–0.2 g/kg. Liver and kidney pathology were seen at considerably lower doses. Gehring (111) included 1,1,2-trichloroethane in a series of chlorinated solvents evaluated for hepatotoxicity and considered it less hepatotoxic in the rat than carbon tetrachloride or chloroform, but markedly more toxic than 1,1,1-trichloroethane. Klaassen and Plaa (110) and Plaa et al. (181) have confirmed this in mice as well as rats. Watrous and Plaa (182) have indicated that kidney injury also occurs following oral and subcutaneous treatment of mice.

Inhalation: Pozzani et al. (183) reported that a single 7 h exposure to 500 ppm of the vapor was lethal to about half of the rats so exposed. Carpenter reported the acute lethal concentration for about half of the exposed rats to be 2000 ppm for a 4-h exposure followed by a 14-d observation period (176).

5.4.1.2 Chronic and Subchronic Toxicity The critical effect for oral administration, as determined by the EPA (IRIS), is clinical serum chemistry with a NOAEL of 20 mg/L (drinking water 39 mg/kg/d), giving an oral reference dose (RfD) of 4E-3. This was determined from a mouse subchronic drinking water study with a LOAEL of 200 mg/L (drinking water). References for this study are White et al. (184) and Sanders et al. (185).

The studies by White et al. (184) and Sanders et al. (185) were selected by the EPA as the basis for the derivation of the oral RfD because they are considered adequate studies in which mice of both sexes were exposed to 1,1,2-trichloroethane in drinking water for 90 d. Concentrations provided were 0, 20, 200, or 2000 mg/L, which resulted in intakes of 0, 4.4, 46, and 305 mg/kg/d for males and 0, 3.9, 44, and 384 mg/kg/d for females. Clinical chemistry indications of adverse effects on the liver occurred in both sexes at 2000 mg/L. Effects on the erythrocytes occurred only in females, and depressed humoral immune status occurred in both sexes at 200 and 2000 mg/L. The concentration of 20 mg/L, corresponding to 3.9 mg/kg/d for female rats is the NOAEL at which significant adverse effects were not observed and is chosen as the basis for the derivation of an oral RfD.

The previous oral RfD (2E-1 mg/kg/d) was based on the NCI (186) study in rats. This study's major weakness was its lack of reporting of noncancer effects. Also, doses far below the NCI (186) NOAEL (65.7 mg/kg/d) have been shown to alter levels of clinical serum chemistries, which are indicative of systemic tissue damage.

At present the EPA (IRIS) does not provide a reference concentration (RfC) for inhalation exposure.

5.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Yllner (187) injected ^{14}C-labeled, 1,1,2-trichloroethane intraperitoneally in mice. The site of labeling on the molecule was not stated. When collected over a 3-d period, 73–87% of the activity was recovered in the urine. Less than 2% was in the feces; this may have been the result of contamination by urine. Expired air contained 16–22% of the radioactivity (60% $[^{14}C]CO_2$ and 40% unchanged 1,1,2-trichloroethane).

1–3% of the labeled compound remained in the animal. Metabolism by microsomal cytochrome P450 appeared to proceed through chloroacetic acid (188), indicating oxidative dechlorination or dechlorination followed by oxidation of 1,1,2-trichloroethane at the carbon containing two chlorine atoms.

According to VanDyke (136, 189). This is followed by further oxidation of the chloroacetaldehyde

to the corresponding acid. Cytochrome P450 is probably involved in the dechlorination. MacDonald et al. (190) speculated that glutathione is involved in the metabolism of 1,1,2-trichloroethane.

5.4.1.3.1 Absorption Absorption of the liquid through the skin has shown to occur in guinea pigs (174). Jakobson and other workers also investigated the kinetics of absorption through the guinea pigs' skin as well as the nature of injury to the skin with prolonged contact (174, 191). Wahlberg (178) reported that repeated applications of 0.5 mL or more to the skin killed all the guinea pigs in 3 d, but 0.25 mL killed only 5 of 20 animals treated for a longer period of time. Although absorption does not appear to be a serious problem from acute exposure, prolonged or repeated exposure of the skin may result in manifestations of chronic toxicity.

5.4.1.4 Reproductive and Developmental According to Seidenberg et al. (192) pregnant ICR/SIM mice were intubated on days 8 to 12 of gestation with evaluation of the usual parameter of developmental toxicity. The dose (not stated) was selected to produce minimal toxicity based on weight reduction, mortality, or other signs of toxicity. The test results were reported to be negative. No other details were given.

5.4.1.5 Carcinogenesis According to the NCI (185), 1,1,2-trichloroethane has been included in the NCI bioassay program, in which it was fed by gavage to rats and mice. As in many of these studies with hepatotoxic compounds, hepatocellular carcinomas occurred in mice but not rats fed for 78 wk. Rats were kept an additional 35 wk and mice 13 wk following treatment. Pheochromocytomas were also observed in mice. The doses fed were 92 and 46 mg/kg/d for rats and 390 and 195 mg/kg/d for mice. Mortality was accelerated in female mice but not in the rats or male mice. The NCI report does not indicate the degree of noncarcinogenic histopathology produced by these doses.

In a bioassay conducted by NCI (185), technical-grade (92.7%-pure) 1,1,2-trichloroethane was administered by gavage in corn oil to Osborne–Mendel rats and B6C3F$_1$ mice: (50/species/sex/dose) for each of two doses and 20 animals/species/sex for each of two control groups. Administration was 5 times/wk for 78 wk, during which time doses for rats were increased from 70 and 30 mg/kg/d to 100 and 50 mg/kg/d and doses for mice were increased from 300 and 150 mg/kg/d to 400 and 200 mg/kg/d. By two statistical tests, treatment of mice was found to be associated with increased incidence of hepatocellular carcinomas. A dose-related increase in pheochromocytomas was also confirmed in female mice. Tumors found in treated but not control rats included adrenal cortical carcinomas; transitional-cell carcinomas of kidney; renal tubular adenomas; and hemangiosarcomas of spleen, pancreas, abdomen, and subcutaneous tissue. There was, however, no statistically significant increase in tumor incidence in rats as a function of treatment.

5.4.1.6 Genetic and Related Cellular Effects Studies There are numerous references to mutagenic studies on 1,1,2-trichloroethane. It would appear at most to be weakly positive in some systems but negative in others. Mirsalis et al. (193) show that it did not induce unscheduled DNA synthesis but was positive in an S-phase synthesis. 1,1,2-Trichloroethane was found to be nonmutagenic for *Salmonella typhimurium* (194). In rats and mice acutely exposed to 1,1,2-trichloroethane by inhalation and intraperitoneal injection, trichloroacetic acid, trichloroethanol, chloroacetic acid, and thiodiacetic acid were among the urinary metabolites identified (130, 187).

5.4.2 Human Experience Symptoms of exposure to this compound may include irritation of the skin, eyes, nose, mucous membranes, and upper respiratory tract; eye damage; skin cracking and crythema; central nervous system depression; liver and kidney damage; narcosis; drowsiness; incoordination; unconsciousness; and death. Other symptoms may include headache, tremor, dizziness, peripheral paresthesia, hyposthesia, or anesthesia.

The only human studies found relate to permeability in the skin and distribution in the body after inhalation of a radioactive charge. Morgan et al. (195, 196) calculated a blood–air partition coefficient of 44. They also found that 3% of the inhaled chlorine was recovered in exhaled air,

indicating a relatively slow elimination.

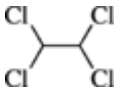
The USEPA (197) determined a permeability coefficient for intact human skin at 8.4×10^{-3} cm/h. Using these data, Tsuruta (198) calculated the dermal uptake of 13.9 mg if both hands were exposed for 1 min.

Wahlenberg (199) determined that a 1.5-mL application to the forearms of adult males for 5 min caused localized hyperemia, transient blanching pain, and burning sensation.

5.4.2.1 General Information 5.4.2.2.5 Carcinogenesis The EPA classifies this compound as - C; possible human carcinogen on the basis of: hepatocellular carcinomas and pheochromocytomas in one strain of mice. Carcinogenicity was not shown in rats. 1,1,2-Trichloroethane is structurally related to 1,2-dichloroethane, a probable human carcinogen. There are no human carcinogenicity data.
5.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV is 10 ppm with an A4 notation. NIOSH considers 1,1,2-trichloroethane as a carcinogen and recommends lowest feasible exposure and an exposure limit of 10 ppm. The OSHA PEL is also 10 ppm with a skin notation.
5.6 Studies on Environmental Impact
None found.

Saturated Halogenated Aliphatic Hydrocarbons Two To Four Carbons
Jon B. Reid, Ph.D., DABT

1,1,2,2-Tetrachloroethane
6.0.1 CAS Number:
[*79-34-5*]
6.0.2 Synonyms:
Acetylene tetrachloride, 1,1-dichloro-2,2-dichloroethane, sym-tetrachloroethane, 1,1,2,2-TCA
6.0.3 Trade Names:
Bonoform, Cellon, Westron, Acetosol
6.0.4 Molecular Weight:
167.86
6.0.5 Molecular Formula:
$CHCl_2CHCl_2$
6.0.6 Molecular Structure:



6.1 Chemical and Physical Properties

Physical state	Colorless liquid
Molecular weight	167.86
Specific gravity	1.586 (25°C)
Melting point	–44°C
Boiling point	146.3°C

Vapor pressure	6 torr (25°C)
Refractive index	1.4918 (25°C)
Percent in “saturated”air	0.79 (25°C)
Solubility	0.32 g/100 mL water at 25°C; soluble in ethanol and ethyl ether
Flammability	Not flammable by standard tests in air

1 mg/L 145.8 ppm and 1 ppm 6.86 mg/m^3 at 25°C, 760 torr.

This compound has the highest solvent power of the chlorinated hydrocarbons.

6.1.1 General An ATSDR toxicological Profile for 1,1,2,2-trichloroethane is available (3).

6.1.2 Odor and Warning Properties 1,1,2,2-Tetrachloroethane has a mild, sweetish odor similar to several other chlorinated hydrocarbons. Lehmann and Schmidt-Kehl (200) reported 3 ppm to have a noticeable odor and 13 ppm to be tolerated for 10 min. Concentrations of 186 ppm inhaled for 30 min, or 335 ppm inhaled for 10 min, have a disagreeable and marked odor, causing upper respiratory irritation and CNS effects. Because the odor is not particularly striking, and because the acceptable level is 1 ppm, odor does not appear to be of value as a warning property. Amoore and Hautala (10) reported 1.5 ppm was detectable by humans.

6.2 Production and Use

1,1,2,2-Tetrachloroethane was formerly used as a solvent for cleaning and extraction processes and is still used to some extent as a chemical intermediate. Present usage is quite limited because less toxic solvents are available.

6.3 Exposure Assessment

6.3.3 Workplace Methods NIOSH Method 1019 is recommended for determining workplace exposures to 1,1,2,2-tetrachloroethane.

6.3.5 Biomonitoring/Biomarkers The apparent high toxicity of 1,1,2,2-tetrachloroethane would suggest that neither breath nor urine analysis would be adequately sensitive for monitoring exposures at the low level considered acceptable for occupational exposures.

6.4 Toxic Effects

According to Sax and Lewis (201), 1,1,2,2-tetrachloroethane is a poison by inhalation, ingestion, and intraperitoneal routes and is moderately toxic by several other routes. It is considered to be the most toxic of the common chlorinated hydrocarbons. It is considered to be a very severe industrial hazard, and its use has been restricted or even forbidden in certain countries. Its narcotic action is stronger than that of chloroform, but because of its low volatility, narcosis is less severe and much less common in industrial poisoning than in the case of other chlorinated hydrocarbons. It is a lacrimator and irritant of the skin, eyes, nose, throat, mucous membranes, and respiratory tract. When heated to decomposition, it emits toxic fumes of carbon monoxide, carbon dioxide, hydrogen chloride gas, and phosgene.

The most significant injury from subacute or chronic exposures has been reported to be in the liver. The first indication may be a greatly enlarged and palpable liver, which may progress to fatty degeneration, jaundice, and cirrhosis. Injury to the kidneys may also be observed.

This compound also causes CNS depression, dizziness, and incoordination, as do many chlorinated hydrocarbons. In very severe acute exposures, unconsciousness and death from respiratory failure may be seen. Central nervous system depression is not a striking part of the response to usual industrial exposure because of low volatility and because other injurious effects predominate at lower levels. Respiratory irritation may be observed and may lead to pulmonary damage. A significant irritation in the gastrointestinal tract is also observed and may result in nausea, vomiting, and gastric pain.

Literature reviews are available (7, 202, 203), but there is a remarkable lack of quantitative data in animals to support the apparent high toxicity in humans. It is possible, however, that inhaled concentrations have been underestimated, that dermal contact has been more significant than realized, or that the purity of industrial 1,1,2,2-tetrachloroethane available at that time was less than later production.

Limited data on the 1,1,1,2 isomer (204) indicate that this isomer may be less toxic than the symmetrical isomer.

6.4.1 Experimental Studies 6.4.1.1 Acute Toxicity Barsoum and Saad (205) reported that an oral dose of 0.7 g/kg body weight in dogs is a toxic dose, but Wright and Schaffer (179) reported that a lethal dose for dogs was 0.3 mL/kg (0.5 g/kg) given orally. Smyth et al. (63) reported an oral LD_{50} of 200 mg/kg in rats, but did not specify which isomer they used, although a prior publication refers to the 1,1,2,2-tetrachloroethane isomer (45). Gohlke et al. (206) reported deaths of rats treated with 250 mg/kg.

Schwander (207) indicated that 1,1,2,2-tetrachloroethane may be absorbed through the intact skin. However, it does not have a high acute toxicity by this route; Smyth (45) reported an acute dermal LD_{50} of 4 g/kg in rabbits. Based on experience, repeated exposure may be of considerable concern. It has a solvent effect on the skin, but no data on eye irritation by the liquid were found.

Although there are a number of animal experiments with this material, a clean-cut quantitative study of animal response from acute exposure has not been reported. Smyth et al. (63) quoted unpublished work by their laboratory indicating that rats were found to survive a 4 h exposure at 500 ppm but would not survive 4 h at 1000 ppm. They also reported three of six rats exposed to 1000 ppm for 4 h died.

In a report that does not appear to be consistent with oral studies, daily doses of 100–800 mg/kg (17–130 mg/kg/d) were injected intraperitoneally for 7 d in male rats with no toxic symptoms. Liver enzymes and possible hematologic changes were reported (208).

1,1,2,2-TCA is moderately irritating to the skin, and vapors appear nonirritating to the eye of the dog (209). Liver damage involving cytochrome P450 and possibly mediated through free radicals interfering with *in vivo* lipid peroxidation has been reported in mice following single 300 or 600 mg/kg doses (210).

The acute inhalation toxicity of 1,1,2,2-TCA has been thoroughly studied and is relatively low. A 4 h LC_{50} of 1000 ppm for rats has been reported (176); a second investigation found lethality beginning at 1000 ppm (211). The corresponding number for the mouse is 655 ppm, with all mice dying at 786 ppm (212). Narcosis is seen in mice inhaling 625 ppm (49) and in cats at 1000 ppm (175) for 1 h.

Guinea pigs show eye irritation when exposed at 576 ppm, narcosis at 5050 ppm, and death at 6310 ppm (213). Reflex reactivity in mice is reduced within 30 min when inhaling 1091 ppm 1,1,2,2-TCA (175). At the lower end of the dose–response curve, a decrease in spontaneous motor activity was seen in rats inhaling 200 ppm for a single 6 h period (214), and no effects were reported following a 30-min exposure at 576 ppm (213).

6.4.1.2 Chronic and Subchronic Toxicity The EPA (IRIS) has not determined a reference dose or reference concentration for this material (2).

Lehmann and Flury (16) reported data from limited vapor experiments on cats and rabbits, which were exposed to a concentration of 100 to 160 ppm for 8–9 h daily for 4 wk. No typical organ

changes were found. These observations are rather surprising when, as is discussed later, industrial experience indicates that injury to humans has occurred at much lower concentrations.

Navrotskii et al. (215) exposed rabbits to tetrachloroethane (presumably the 1,1,2,2 isomer) vapor for 7–11 m. The 3–4-h daily exposures were to 100 mg/m^3 (14.6 ppm). According to the available abstract, only slight effects on the liver were observed. Schmidt et al. (216) also reported only slight effects in rats exposed to 15 mg/m^3 (2 ppm) for 265 d and considered their results somewhat inconclusive. Some toxicologic parameters deviated during the exposure but were not different from the controls at the end. Mortality was not affected, but histological examination appears to have been inadequate to evaluate chronic effects.

Truffert et al. (217) reported exposing rats 6 h/d, 5 d/wk for 15 wk to 260 ppm with no effect on the respiratory or renal toxicity, but increased deposits were found in the liver.

6.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Studies have shown that 1,1,2,2-trichloroethane is readily absorbed via the lungs or gastrointestinal tract. Some authors have indicated absorption by the skin. It is apparently readily excreted by the lungs.

Yllner (218) injected ^{14}C-labeled 1,1,2,2-tetrachloroethane intraperitoneally in female albino mice at doses of 0.21 to 0.32 g/kg and studied the elimination for 3 days. About half the dose, 45 to 61 percent, was exhaled as carbon dioxide with 28 percent excreted in the urine. About 16 percent remained in the animal and only 4 percent was expired unchanged. Several products were found in the urine with half the urinary activity unaccounted for. Both enzymatic and nonezymatic activity was postulated. Enzymatic hydrolytic fission of chlorine-carbon bonds results in dichloroacetic acid and glycolic acid. Nonenzymatic dehydrochlorination results in trichloroethylene and subsequently trichloroethanol and trichloroacetic acid.

When fed to rats and mice, more than 90 percent of the dose was metabolized (219). Although there was incorporation in mouse DNA, it was not by adduct formation. These authors concluded that their data supported a cytotoxic rather than a genetic mechanism of carcinogenesis observed in mice.

Ikeda and Ohtsuji (130) also found trichloro products in the urine of mice and rats exposed for 8 h to 100 ppm of 1,1,2,2-tetrachloroethane vapor.

6.4.1.4 Reproductive and Developmental A very limited reproduction study by Rosenkrantz (220) indicated no gross reproductive or teratological effect in rats exposed daily for 9 mo prior to mating. A second report by Schmidt (221) describes fetotoxic (lethal) effects in two strains of mice given intraperitoneal injections of tetrachloroethane, presumably the 1,1,2,2-isomer. The doses administered, 300, 400, or 700 mg/kg/d were given singly or on several days of pregnancy. According to the author's summary, the compound was fetotoxic and faintly teratogenic.

The reproductive organs have not been target organs in the limited studies in animals.

6.4.1.5 Carcinogenesis The EPA (IRIS) has classified this material as –C, possible human carcinogen on the basis of increased incidence of hepatocellar carcinomas in mice (222).

The National Cancer Institute (222) has included 1,1,2,2-tetrachloroethane in their bioassay series using rats and mice. Their summary states that the time-weighted average doses (by gavage) were 108 and 62 mg/kg/d for male rats, 76 and 43 mg/kg/d for female rats, and 282 and 142 mg/kg/d for all mice. There was a highly significant positive dose-related trend in the incidence of hepatocellular carcinoma in mice of both sexes. No statistically significant incidence of neoplastic lesions was observed in male or female rats. However, 2 hepatocellular carcinomas and 1 neoplastic nodule, which are rare tumors in the male Osborne–Mendel rat, were observed in the high-dose males. Under the conditions of this bioassay, orally administered 1,1,2,2-tetrachloroethane was a liver carcinogen

in B6C3Fl mice of both sexes. The results did not provide conclusive evidence for the carcinogenicity of 1,1,2,2-tetrachloroethane in Osborne–Mendel rats.

6.4.1.6 Genetic and Related Cellular Effects Studies Mixed results have been obtained in mutagenic studies with most results negative (203). Schumann et al. (219) found little binding to DNA of rats and mice due to adduct formation, indicating a low potential for direct mutagenic activity.

6.4.2 Human Experience Symptoms of exposure to this compound may include irritation of the skin, eyes, nose, throat, mucous membranes, and respiratory tract. Lacrimation may occur. Corrosion may also occur. Other symptoms of exposure include drowsiness, headache, jaundice, abdominal pain or distress, tremor, fatigue, constipation, insomnia, irritability, anorexia, loss of appetite, pulmonary edema, nephritis, albumin and casts in the urine, and kidney damage. Giddiness and unconsciousness have occurred. Central nervous system effects include general anesthesia, somnolence, hallucinations, and distorted perceptions. Other effects include narcosis, acute yellow atrophy of the liver, liver cirrhosis, fatty degeneration of the kidneys and heart, brain changes, changes in the peripheral nerves, hemolysis, salivation, restlessness, dizziness, nausea, vomiting, coma, and death. Monocytosis, dermatitis, liver tenderness and damage, delirium, and convulsions may occur. Oliguria, cyanosis, central nervous system depression, uremia, peripheral paresthesia, and hypesthesia may also occur. Exposure may cause prickling sensation and numbness of limbs, loss of kneejerk, sweating, paralysis of the interossei muscles of the hands and feet, disappearance of ocular and pharyngeal reflexes, peripheral neuritis, liver dysfunction, general malaise, an unpleasant taste in the mouth, mental confusion, stupor, hematemesis, purpuric rashes, and blood changes, including an increase in mononuclear leukocytes, progressive anemia, and slight thrombocytosis. Gastrointestinal disturbances may occur. It may also cause liver necrosis, nervousness, incoordination, respiratory failure, and enlargement and fatty degeneration of the liver. Heart damage has been reported. Neurological disturbances have also been reported. It can cause hepatitis, gastric pain, vertigo, and leukopenia. It can also cause a deep dusky coloration of the skin, weight loss, pain over the liver, dark urine, and bilirubinuria. Pulmonary damage, gastrointestinal irritation, barely perceptible pulse, and shallow and rapid respiration may result. Other symptoms that may occur are polyneuritis (inflammation of the nerves), conjunctivitis, extreme exhaustion, hematuria, mental instability, cardiac irregularity, and epigastalgia. Skin contact may result in dryness, scaling, and inflammation. Severe lesions may occur. Eye contact may result in burning and serious eye damage. Inhalation may cause a burning sensation, wheezing, coughing, laryngitis, and shortness of breath. Ingestion may cause diarrhea and severe mucosal injury.

The review by von Oettingen (7) summarizes much of the old data on human experience and based on numerous cases describes the rather severe effects discussed earlier in this section.

Sherman (223) reported on eight humans who were given 3 mL of tetrachloroethane by mistake. It was given with 30 g of magnesium sulfate and water. Within 1.5–2.5 h, all were comatose. Reflexes were absent and the pulse barely perceptible. Respiration was shallow and rapid. The patients all recovered and showed no after-effects.

Gurney (224) reported a number of cases of chronic exposure to 1,1,2,2-tetrachloroethane. He studied 277 individuals of whom 75 had symptoms and 55 had enlarged livers. There were nearly as many with enlarged livers among those who did not show symptoms as there were among those who did. Coyer (225) reported on six cases, one of which was fatal.

It is evident from clinical reports of exposure to 1,1,2,2-tetrachloroethane that the principal effect involves the liver. Symptoms referrable to gastrointestinal injury may also be observed.

A study of mortality of army personnel who treated clothing with impregnite for protection against mustard gas in World War II has been reported (226). Tetrachloroethane was used as a solvent for the impregnite (N,N-dichlorohexachlorodiphenylurea). The exposed group was compared with a control group that used a water-based system and with unexposed personnel from the same unit.

Overall deaths during the 31 yr follow-up period were less than expected, possibly related to the screening process used in selection of military personnel. The investigators, however, considered that some other cancers may have shown an increase.

The adverse health effects of 1,1,2,2-TCA first became apparent at the beginning of World War I with reports of numerous poisonings of workers in the aircraft industries of several European countries (227, 228), Many deaths were reported, and most cases presented a clinical picture characterized by gastrointestinal, hepatic, and nervous system effects. Although none of a large number of clinical cases contains quantitative exposure data, they consistently indicate primary involvement of the liver (229–232). In domestic airplane factories, complaints of headaches, drowsiness, and nausea, without more serious signs, were attributed to a limited production and short exposure time (lesser exposures) (233). From suicide cases that present similar clinical findings, estimates of a human fatal oral dose ranging from 285 (234) to 6000 mg/kg (235) have been made. The lowest adverse effect level has been estimated to be 100 mg/kg.

Seventy-five workers employed at a plant producing and using 1,1,2,2-TCA were studied for their cardiovascular status. Exposure concentrations ranged from 0.37 to 3.20 ppm, with occasional peaks to 40 ppm. The authors concluded that chronic low-level exposure caused no greater occurrence of cardiovascular lesions than that in the general population (236).

In humans, 97% of an inhaled single-breath dose of 1,1,2,2-TCA is absorbed with very little (3.3%) exhaled as unchanged chemical; urinary excretion was 0.015%/min (195). The metabolism and kinetics in humans have not been as well developed as for chlorinated solvents such as trichloro- and tetrachloroethylene (for which biologic exposure indices exist).

Of 380 workers examined in the workplace where 1,1,2,2-TCA was the solvent for cellulose acetate, 192 were in direct contact, and some of the remaining 188 workers were occasionally exposed to its vapors. The signs of poisoning in the workers were most frequently of the nervous system. These symptoms were characterized by tremor and increased with the amount of solvent in the air. Jaundice was not detected in any of the workers (237).

Early work of Lehman suggests that, in humans, a concentration of 3 ppm 1,1,2,2-TCA may be detected by odor, 13 ppm may be tolerated without effect for 10 min, and inhalation of 145 ppm for 30 min or 334 ppm for 10 min will cause irritation of the mucous membranes, pressure in the head, vertigo, and fatigue (200).

6.4.2.3.5 Carcinogenesis Carcinogenic Classification:

EPA	Group 3, possible human carcinogen.
IARC	Group 3, not classifiable as to its carcinogenicity in humans
MAK	Group B, justifiably suspected of having carcinogenic potential
NIOSH	Carcinogen, with no further categorization
TLV	A3, animal carcinogen

6.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV is 1 ppm with an A3 and skin notation. NIOSH considers 1,1,2,2-TCA a carcinogen and recommends the lowest feasible exposure and an REL of 1 ppm. The OSHA PEL is 5 ppm with a skin notation.

Other Nations: Australia: 1 ppm, skin (1993); Federal Republic of Germany: 1 ppm, skin, Group B, justifiably suspected of having carcinogenic potential (1997).

6.6 Studies on Environmental Impact

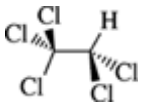
Saturated Halogenated Aliphatic Hydrocarbons Two To Four Carbons
Jon B. Reid, Ph.D., DABT

Pentachloroethane
7.0.1 CAS Number:
[*76-01-7*]
7.0.2 Synonyms:
Ethane pentachloride
7.0.3 Trade Names:
Pentalin
7.0.4 Molecular Weight:
202.29
7.0.5 Molecular Formula:
$CHCl_2CCl_3$
7.0.6 Molecular Structure:



7.1 Chemical and Physical Properties

Physical state	Colorless liquid
Specific gravity	1.6712 (25/4°C)
Melting point	–29°C
Boiling point	162°C
Vapor pressure	3.4 torr (25°C)
Refractive index	1.50250 (24°C)
Percent in “saturated air”	0.45 (25°C)
Solubility	0.05 g/100 mL at 20°C; soluble in ethanol, ethyl ether
Flammability	Not flammable by standard tests in air

7.1.1 General No new information was found since last edition.

7.1.2 Odor and Warning Properties Pentachloroethane has a sweetish odor, not unlike chloroform. The threshold at which the odor is detected has not been determined, and therefore its value as a warning is not known.
7.2 Production and Use
Pentachloroethane has been used as a solvent and chemical intermediate but has had little commercial utilization. Pentachloroethane is used as a solvent for oil and grease in metal cleaning; in the separation of cola from impurities by density difference; as a chemical intermediate, in the manufacture of tetrachloroethylene and dichloroacetic acid; as a solvent for cellulose acetate, certain cellulose ethers, resins, and gums; as a drying agent for timber by immersion at temperatures greater than 100°C; in dry cleaning and soil sterilizing.
7.3 Exposure Assessment
No information found.

7.3.3 Workplace Methods NIOSH Method 2517 is recommended for determining workplace exposures to pentachloroethane.

7.4 Toxic Effects

Sax and Lewis (242) report that pentachloroethane is a poison by inhalation and intravenous routes and is an experimental carcinogen, and moderately toxic by ingestion and subcutaneous routes. It is irritating to the eyes, lungs, corneas, upper respiratory tract, the skin, and mucous membranes. It is very toxic by inhalation, or skin absorption. It has a strong narcotic effect. When heated to decomposition, this compound emits highly toxic fumes of CO, CO_2, and HCl.

Toxicologic data on pentachloroethane are quite limited. Pentachloroethane has a narcotic effect that has been indicated to be even greater than that of chloroform. Exposure to this material may also result in injury to the liver, lungs, and kidneys, but rats and mice have tolerated rather high doses without injury. It has caused liver tumors in mice but not in rats.

7.4.1 Experimental Studies 7.4.1.1 Acute Toxicity Barsoum and Saad (205) reported the lethal oral dose to be 1.75 g/kg of body weight.

Lehmann and Flury (16) indicated that cats inhaled 1 mg/L of air (120 ppm) 8–9 h daily for 23 d without overt symptoms of poisoning. However, they showed significant pathological changes in the liver, lungs, and kidneys. Dogs exposed to the vapor for 3 wk showed fatty degeneration of the liver and injury to the kidneys and lungs.

7.4.1.2 Chronic and Subchronic Toxicity Navrotskii et al. (215) exposed rabbits to 100 or 10 mg pentachloroethane vapor per cubic meter of air 3–4 h daily for 7–11 m. Only limited data are discussed in the available abstract. Antibody titers were reported to be elevated after 1–1.5 m exposure to 100 mg/m^3 (12 ppm). The abstract also states that toxic effects occurred at 10 mg/m^3 but the nature of the toxic effects is not specified.

Pentachloroethane containing 4.2% hexachloroethane was studied by Mennear et al. (243). The material was administered by gavage to rats and mice of both sexes. Prechronic studies of 2 and 13 wk failed to reveal specific target organ toxicity at 10, 50, 100, 500, or 1000 mg/kg. However, all rats fed 1000 mg/kg/d died within 4 d, although the same dose was lethal to only one female mouse. The 500-mg/kg/d dose was lethal to 3/5 rats of each sex between the fourth and tenth day. Decreased motor activity and lethargy were observed but little body weight loss. There were no gross or histological changes.

When fed 5 d/wk for 13 wk at doses of 5, 10, 50, 125, or 250 mg/kg/d to rats or 5, 10, 50, 100, or 500 mg/kg/d to mice, weight loss was the only parameter affected by treatment. All rats survived, and only those fed 250 mg failed to gain weight at the rate of the controls. Only one mouse treated with 500 mg/d died, but weight gain of this group was 29% less than controls. Gross and histopathology were considered normal after 13 wk.

7.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Yllner (244) injected ^{14}C-pentachloroethane subcutaneously in mice at doses of 1.1–1.8 g/kg and determined the excretion over a 3 d period. About 1/3 of the dose (12–51%) was expired unchanged; 16–32% was excreted as 2,2,2-trichloroethanol, and 9–18% as trichloroacetic acid in the urine. The expired air also contained trichloroethylene (3–9% of the dose), indicating both dechlorination and dehydrochlorination.

Town and Leibman (245) reported that a cytochrome P450–dependent monooxygenase system was involved in the dechlorination of pentachloroethane to trichloroethylene and 1,1,2,2-tetrachloroethane. Bronzetti et al. (246) considered P448 to be more important. In a report available only as an abstract, weak covalent binding was reported following intraperitoneal injection (247). Labeled pentachloroethane was reported to be bioactivated by cell-free microsomal and cytosolic enzymes from mouse and rats organs.

The role of a-2m-globulin and protein droplet formation in the male rat kidneys has been studied because it is possibly involved in the production of kidney pathology and cancer in male rats (248).

7.4.1.4 Reproductive and Developmental No information on teratology or reporoduction were found. The reproductive organs were not affected in any of the studies reported previously.

7.4.1.5 Carcinogenesis When fed 5 d/wk to male rats for 104 wk at doses of 75 and 150 mg/kg/d, mortality was excessive and body weight gain was below controls starting at 76 wk. Weight gain was decreased in female rats at both levels starting at 42 wk, but mortality in both sexes was increased only at 150 mg/kg/d. No increase in tumors was found, but there was a dose-related increase in the incidence of chronic renal inflammation of male rats and mineralization of renal papillae.

Survival of mice similarly treated with 250–500 mg/kg/d was significantly shortened, and hepatocellular carcinomas were increased. The only other tumor showing an increase was in female mice, where there was a dose-related increase in hepatocellular adenoma. The cause of death did not appear to be either the renal lesions in male rats or the liver tumors in mice, and no other target organs were found to explain the deaths.

7.4.1.6 Genetic and Related Cellular Effects Studies Mutagenic data are limited and equivocal in yeast (246) and negative in *S. typhimurium* (249).

7.4.2 Human Experience Symptoms of exposure to this compound may include irritation of the eyes, lungs, and upper respiratory tract. It may cause irritation of the skin and mucous membranes. It may also cause drowsiness, giddiness, jaundice, headache, and, in high concentrations, unconsciousness. It may also affect the central nervous system and the blood. Overexposure to this compound may damage the liver and kidneys.
7.5 Standards, Regulations, or Guidelines of Exposure
No standards have been proposed for pentachloroethane. It is probably not possible to set a reliable standard because of the limited toxicologic information and experience reported on this material. It is obvious that a concentration safe for repeated exposure would be well below the 121 ppm that was shown to cause pathological change. The unconfirmed report of Navrotskii suggests that exposures be kept much lower. NIOSH recommends that this substance be handled with caution in the workplace.
7.6 Studies on Environmental Impact

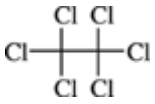
Saturated Halogenated Aliphatic Hydrocarbons Two To Four Carbons
Jon B. Reid, Ph.D., DABT

Hexachloroethane
8.0.1 CAS Number:
[*67-72-1*]
8.0.2 Synonyms:
Carbon hexachloride, ethane hexachloride, hexachloroethylene, 1,1,1,2,2,2-hexachloroethane, HCE, ethylene hexachloride, and perchloroethane
8.0.3 Trade Names:
A Vlothane, Distokal, Distopan, Distopin, Egitol, Falkitol, Fasciolin, Mottenhexe, Phenohep
8.0.4 Molecular Weight:
236.74

8.0.5 Molecular Formula:
C_2Cl_6, Cl_3CCCl_3
8.0.6 Molecular Structure:



8.1 Chemical and Physical Properties

Physical state	Solid <294> rhombic crystals
Specific gravity	2.091 (20°C)
Melting point	Sublimes at 186.8°C
Boiling point	189°C
Solubility	0.005 g/100 mL water at 22°C; soluble in ethanol, ethyle ether
Flammability	Not flammable by standard tests in air

8.1.1 General An ATSDR Toxicological profile for hexachlorethane is available (250). It is found as colorless crystal.

8.1.2 Odor and Warning Properties Hexachloroethane is reported to have a camphorous odor.
8.2 Production and Use
Hexachloroethane has been used as a chemical intermediate, in pyrotechnics, as an insecticide, and as a parasiticide in animals. It is an undesired by-product of certain chlorination processes and is of environmental concern in soil and water.
8.3 Exposure Assessment
HCE has been employed in veterinary practice as an anthelmintic for livestock, but it is doubtful that it is still used for this purpose. While some may be used as an insecticide and in chemical manufacture, large amounts are used by the United States Army in pyrotechnics and smoke devices (251). It is a by-product of certain chlorination processes, sometimes appearing in waste tars. HCE is produced in France, Spain, and the United Kingdom; it is not manufactured in the United States (252). HCE imported for 1985 was reported to be 1,124,000 kg (253).

8.3.3 Workplace Methods NIOSH Method 1003, for halogenated hydrocarbons is recommended for determining workplace exposures to hexachloroethane (10a).

8.3.5 Biomonitoring/Biomarkers Biologic monitoring of exposed workers may determine if exposure has occurred, but at this time available data appear inadequate to quantify exposure.
8.4 Toxic Effects
According to Sax (254), hexachloroethane has high toxicity via intravenous and moderate via oral, intraperitoneal, and dermal routes. It is irritating to the skin, eyes, mucous membranes, and upper respiratory tract. When heated to decomposition, it emits toxic fumes of CO,CO_2, HCl gas, and phosgene. It is absorbed through the skin. It is a positive animal carcinogen.

Much of the experience with this material has come about because of its use as a parasiticide in animals, although more recent articles indicate renewed interest in this chemical because of environmental concerns, and its use in pyrotechnics. Von Oettingen (7) reviewed the literature available in 1955 and Oak Ridge National Laboratory in 1988 (255). It is possible that some of the effects ascribed to hexachloroethane in the older literature may have been due to impurities in the samples tested. It has been shown to produce liver cancer in mice and kidney cancer in male rats.

The kidneys appear to be the target organ, and males are more affected that female laboratory animals.

8.4.1 Experimental Studies 8.4.1.1 Acute Toxicity Hexachloroethane has a low acute oral toxicity. Thorpe (256) reported the LD_{50} for rats to be 5.9 g/kg, a value consistent with Reynolds and Yee (257), who reported rats survived 6.16 g/kg for up to 24 h, and Barsoum and Saad (205), who reported dogs survived 6 g/kg. A dose of 6 g/kg over a 2-d period was lethal to cats (258). Similar figures are given in Table 63.5 taken from Weeks et al. (251).

Table 63.5. Lethal Dosages for Animals Following Single Administration of Hexachloroethane

Animal	Treatment[a]	Diluent	Dosage (mg/kg)
Rabbit, male	Oral ALD	Methylcellulose	>1,000
Rat, male	Intraperitoneal ALD	Corn oil	2,900
Rat, female	Oral LD_{50}	Corn oil	4,460
		Methylcellulose	7,080
Rat, male	Oral LD_{50}	Corn oil	5,160
		Methylcellulose	7,690
Guinea pig, male	Oral LD_{50}	Corn oil	4,970
Rabbit, male	Dermal LD_{50}	Water paste	≥32,000

The toxicity in larger species such as dogs and cattle is consistent with the laboratory animals.

Twelve daily oral doses of 1000 mg/kg to rabbits cause significant reduction in body weight and increased relative liver and kidney weights. Gross and histology injury occurred in the liver and kidneys. Daily doses of 320 mg/kg caused liver injury, but 100 mg/kg caused no significant effect (251). When fed to rats to determine the maximum tolerated dose in the NTP studies discussed subsequently, the following results were reported (259). In the 16-d studies (dose range, 187–3000 mg/kg), all rats that received 1500 or 3000 mg/kg and 1/5 males and 2/5 females that received 750 mg/kg died before the end of the studies. Final mean body weights of rats that received 750 mg/kg were 25% lower than that of vehicle controls for males and 37% lower for females. Compound-related clinical signs seen at 750 mg/kg or more included dyspnea, ataxia, prostration, and excessive lacrimation. Other compound-related effects included hyaline droplet formation in the tubular epithelial cells in all dosed males and tubular cell regeneration and granular casts in the tubules at the corticomedullary junction in the kidney in males receiving 187 and 375 mg/kg.

Weeks et al. (251) reported reversible injury when crystalline hexachloroethane was applied to the cornea of rabbit eyes for a prolonged period. It produced little or no skin irritation and did not appear to be significantly absorbed percutaneously. The dermal LD_{50} was greater than 32 g/kg by this route. The compound did not sensitize the skin of guinea pigs.

Rats exposed to 2.5 mg/L (260 ppm) of the vapors for 8 h showed no adverse effects, but 57 mg/L caused severe injury, including death. The higher concentration was supersaturated and contained particles of hexachloroethane (251).

Barsoum and Saad (205) indicated that an intravenous dose of 325 mg/kg in dogs resulted in death.

A corresponding dose for pentachloroethane was found to be 100 mg, and for chloroform, 90 mg. This would indicate that hexachloroethane is intrinsically less toxic than the other materials, or is absorbed much more slowly. Weeks et al. found the approximate lethal dose (ALD) when injected intraperitoneally in male rats to be 2900 mg/kg, and Baganz et al. (260) determined an LD_{50} for white mice of 4500 mg/kg by this route.

Weeks et al. (251) published the oral lethal dose (approximate) for rabbits as greater than 1000 mg/kg, the oral LD_{50} for rats at 4460 mg/kg (corn oil) Applied to the shaved skin of rabbits, the dermal LD_{50} was 32,000 mg/kg, and it did not sensitize guinea pigs. Rats exposed for 8 h at a calculated 59,000 ppm vapor showed severe toxic signs and death, but no toxic effects were observed for 8 h at 260 ppm.

8.4.1.2 Chronic and Subchronic Toxicity The EPA (IRIS) considers the critical effect for oral exposure is "atrophy and degeneration of the renal tubules, with a NOAEL of 1 mg/kg/d and a LOAEL of 15 mg/kg/d and a reference dose (RfD) of 1E-3. This is based on a rat subchronic dietary study by Gorzinski et al. (261), as summarized here:

Groups of 10 male and 10 female Fischer 344 rats were treated with diets containing hexachloroethane for 16 wk. Dosages were 0, 1, 15, or 62 mg/kg/d, as determined by the investigators. The rats were evaluated for overt signs of toxicity, body weight gain, food consumption; urinalysis, hematological and clinical chemistry parameters; organ weights; and gross pathology. Comprehensive histologic examination was performed on the control and 62 mg/kg/d groups, while histologic examination of the 1- and 15-mg/kg/d groups was limited to the liver and kidney. At 15 and 62 mg/kg/d, male rats had dose-related increased incidences of renal lesions, including renal atrophy, degeneration, hypertrophy, and dilation. At 62 mg/kg/d, males had increased absolute and relative kidney weights and peritubular fibrosis; females had slight renal tubular atrophy and increased liver weights. No other effects were observed. Thus 15 mg/kg/d is the LOAEL and 1 mg/kg/d is the NOAEL.

In a draft report for a subchronic gavage study (262) rats were treated by gavage with 0, 47, 94, 188, 375, or 750 mg/kg/d, 5 d/wk for 13 wk. Body weight gain was reduced at 750 mg/kg/d, behavioral signs of toxicity were seen at 94 mg/kg/d, and increased relative liver and kidney weights occurred at 375 mg/kg/d. Dose-related increased incidences of renal tubular regeneration occurred at 47 mg/kg/d.

In a 6 wk inhalation study, rats, dogs, and guinea pigs were exposed to hexachloroethane 6 h/d, 5 d/wk for 6 wk at 0, 145, 465, or 2520 mg/m^3 (251). Neurobehavioral effects occurred in rats and dogs, and reduced body weights, increased relative liver weights, and deaths occurred in guinea pigs at 2520 mg/m^3. No effects were observed at 465 mg/m^3. Based on this inhalation NOAEL in rats, an RfD of 0.03 mg/kg/d could be calculated using an uncertainty factor of 1000. However, a later 16 wk oral study by Gorzinski et al. (261) is a better basis for the RfD.

When fed for 3 wk at dosages much higher than used by Gorzinski, NTP (259) reported the following results: In the 13 wk studies (dose range, 47–750 mg/kg), 5/10 male rats and 2/10 female rats that received 750 mg/kg died before the end of the studies. The final mean body weight of male rats that received 750 mg/kg was 19% lower than that of vehicle controls. Compound-related clinical signs for both sexes included hyperactivity at doses of 94 mg/kg or higher and convulsions at doses of 375 or 750 mg/kg. The relative weights of liver, heart, and kidney were increased for exposed males and females. Kidney lesions were seen in all dosed male groups, and the severity increased with dose. Papillary necrosis and tubular cell necrosis and degeneration in the kidney and hemorrhagic necrosis in the urinary bladder were observed in the five male rats that received 750 mg/kg and died before the end of the studies; at all lower doses, hyaline droplets, tubular regeneration, and granular casts were present in the kidney. No chemical-related kidney lesions were

observed in females. Foci of hepatocellular necrosis were observed in several male and female rats at doses of 188 mg/kg or higher.

Rats, dogs, guinea pigs, and quail were exposed 6 h/d, 5 d/wk for 6 wk to hexachloroethane vapor (van Haaften (263)). Extensive studies were conducted to determine possible injury including behavioral, reproductive, clinical chemical, hematologic, and histological examinations. Animals exposed to 260 ppm were seriously affected, including death (except for quail). Quail showed no adverse effect at any dosage. There was no evidence of injury of any type in any species at 15 ppm. Exposure to 48 ppm caused minimal injury. The most significant effects appeared to be irritation of the eyes and respiratory tract. Apparently liver and kidney injury were not significant at these levels of exposure.

8.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Jondorf et al. (264) reported that an oral dose of 0.5 g/kg of body weight in a rabbit was slowly metabolized. Approximately 5% appeared in the urine in a period of 3 d and from 14 to 24% in the expired air. These authors used chromatographic and isotopic dilution techniques to determine the nature of the metabolities in the urine. These were reported as percent of the dose given: trichloroethanol, 1.3; dichloroethanol, 0.4; trichloroacetic acid, 1.3; dichloroacetic acid, 0.8; monochloroacetic acid, 0.7; and oxalic acid, 0.1.

Fowler reported different results for sheep and Leghorn cockerels (265, 266), but the differences in the methods used make it impossible to compare the data from these species with those from rats. Interestingly, hexachloroethane is reported to be a metabolite of carbon tetrachloride but not chloroform. For details see the section on metabolism of chloroform.

Gorzinski et al. (261) analyzed liver, kidneys, blood, and adipose tissue from rats fed hexachloroethane in a 110 d dietary feeding study described in a preceding section. After 57 d the authors reported that the “concentration of HCE in the kidneys of male rats was significantly higher at all dose levels when compared to females (mg HCE/g of kidney with increasing dose <294>males: 1.4, 24.3, 95.1; females: 0.4, 0.7, 2.0); this is consistent with the more pronounced renal toxicity noted for male rats. However, the results of the tissue analysis indicated that HCE was cleared in an apparent first-order manner with a half-life estimated to be 2–3 days.”

The metabolism (reductive dechlorination) of hexachloroethane in rats and mice is mediated by microsomal cytochrome P450 with oxidation of NADPH. Dechlorination with loss of two chlorines in a two-step process produces the major metabolite tetrachloroethylene. Much less pentachloroethane and trichloroethylene are produced. Further metabolism results in some of the same substances as tetrachloroethylene itself.

Hexachloroethane, being fat soluble, enters those tissues that are lipoid in nature, but has been shown to be present at higher concentrations in male rat kidneys than in females. This is consistent with greater toxicity in males (261).

Gorzinski (261) fed doses of 0, 1, 15, or 62 mg/kg/d in the diet for 16 wk (see preceding section on oral toxicity for details). Clearance, due to metabolism and elimination, was first order at 62 mg/kg/d, indicating nonsaturation. The half-time was approximately 2.5 d for fat, liver, kidney, and blood. They concluded that elimination from the rat was more rapid than that reported for other species.

Table 63.6 taken from Gorzinski (261), shows the organ concentration after 16 wk on the respective diets.

Table 63.6. Concentration of Hexachloroethane in the Tissues of Rats Fed Hexachloroethane in the Diet for 16 Weeks

Sex	Dose (mg/kg/d)	mg HCE/g Tissue[a]			
		Blood	Liver	Kidney	Fat
M	1	0.079 ± 0.057	0.291 ± 0.213	1.356 ± 0.29	3.15 ± 0.37
	15	0.596 ± 0.653	1.736 ± 1.100	24.33 ± 5.73	37.90 ± 6.10
	62	0.742 ± 0.111	0.713 ± 0.343	95.12 ± 11.56	176.1 ± 14.50
F	1	0.067 ± 0.039 (3)	0.26 ± 0.035 (2)	0.369 ± 0.51	2.59 ± 0.72
	15	0.162 ± 0.049 (3)	0.47 ± 0.204	0.688 ± 0.17	45.27 ± 11.33
	62	0.613 ± 0.231	0.631 ± 0.262	2.01 ± 0.66	162.1 ± 7.10

Mitoma et al. (52) fed a series of chlorinated ethanes and ethenes to rats and mice to determine the amount of metabolism. Rats were given the NCI maximum tolerated dose (MTD) in corn oil for 5 d/wk for 4 wk followed by a corresponding radio-labeled dose. In rats 93% was recovered and in mice 95.5%. Their data for hexachloroethane are given in Table 63.3. They concluded the biochemical parameters they measured including protein binding provided no clue to differentiate the carcinogens from the noncarcinogenic compounds.

Lattanzie et al. (267), however, concluded that hexachloroethane "bound" to DNA and other macromolecules of the rat and mouse. They reported it less reactive than tetrachloroethane and similar to 1,2-dichloroethane.

8.4.1.4 Reproductive and Developmental Weeks et al. (251) carried out teratological studies in pregnant rats fed by gavage or exposed by inhalation. Oral doses of 50, 100, or 500 mg/kg were fed on days 6 through 16 of gestation. Separate groups were also exposed 6 h/d to 15, 48, or 260 ppm of the vapors. Although body weight gain of the dams in the 500-mg/kg oral and 260-ppm inhalation groups was lower than the controls, there appeared to be no teratological effects on the fetuses. There were adverse effects on gestation indexes and on the number of fetuses alive at the highest oral dose. The fetal reabsorption rate was increased in this group.

8.4.1.5 Carcinogenesis The EPA (IRIS) (2) classifies hexachoroethane as C, possible human carcinogen on the basis of observation of carcinomas in one mouse strain after oral exposure. There are no human carcinogenicity data. The EPA considers the animal carcinogenicity data as "limited."

Technical-grade hexachloroethane (98% pure) was administered by gavage to Osborne–Mendel rats and B6C3F1 mice (50 each male and female) (268).

Rats were treated with either 250 or 500 mg hexachloroethane/kg/d, 5 d/wk for 23 wk. After this time animals were rested 1 wk and gavaged for 4 succeeding weeks up to week 78; an observation period of 33–34 wk followed. Final TWA treatment doses were 212 and 432 mg/kg/d. There was no evidence of hexachloroethane-induced neoplastic growth in rats. Mice were administered 500 or 1000 mg/kg/d, 5 d/wk, continuously. At week 9 the doses were increased to 600 and 1200 mg/kg/d, and this dosage was maintained until week 78. Mice were observed for 12–13 wk after cessation of treatment. The TWA doses were 590 and 1179 mg/kg/d. Mice of both sexes showed a significant increase in the incidence of hepatocellular carcinoma.

When hexachloroethane was restudied in F344/N rats at doses of 0, 10, or 20 mg/kg/d 5 d/wk to

male rats and 0, 80, or 160 mg/kg doses to female rats, body weight was only slightly depressed toward the end of the 2 yr gavage period (259). Survival was not affected in any group. The following nonneoplastic and neoplastic effects were reported in the 2 yr studies: Incidences of kidney mineralization (vehicle control, 2/50; low dose, 15/50; high dose, 32/50) and hyperplasia of the pelvic transitional epithelium (0/50; 7/50; 7/50) were increased in dosed male rats. Renal tubule hyperplasia was observed at an increased incidence in high-dose male rats (2/50; 4/50; 11/50). These lesions have been described as characteristic of the hyaline droplet nephropathy that is associated with an accumulation of liver-generated a-globulin in the cytoplasm of tubular epithelial cells. The severity of nephropathy was increased in high-dose male rats (moderate vs. mild), and the incidences and severity of nephropathy were increased in dosed females (22/50; 42/50; 45/50). The incidences of adenomas (1/50; 2/50; 4/50), carcinomas (0./50; 0/50; 3/50), and adenomas or carcinomas (combined) (1/50; 2/50; 7/50) of the renal tubule were also increased in the high-dose male group. One of the carcinomas in the high-dose group metastasized to the lung. No compound-related neoplasms were observed in females. The incidence of pheochromocytomas of the adrenal gland in low-dose male rats was significantly greater than that in vehicle controls (15/50; 28/45; 21/49), and the incidences for both dosed groups were greater than the mean historical control incidence (28–11%). The relationship of hyalin droplet formation to kidney tumors in the rat has been the subject of several investigations, because the phenomenon appears to be more important in male rats than in female rats or humans. This is particularly important because the mutagenic potency of hexachloroethane appears to be low.

8.4.1.6 Genetic and Related Cellular Effects Studies Hexachloroethane was tested against one yeast strain, *Saccharomyces cervisiae*, and five strains of *Salmonella typhimurium* with and without rat liver activation with no evidence of mutagenic effects (263). Hexachloroethane was not mutagenic in *S. typhimurium* strains TA98, TA100, TA1535, or TA1537 when tested with and without exogenous metabolic activation. In Chinese hamster ovary cells, hexachloroethane did no induce chromosomal aberrations with or without metabolic activation but did produce sister chromatid exchanges in the presence of exogenous metabolic activation (259).

8.4.2 Human Experience Symptoms of exposure to this compound include skin, eye, mucous membrane, and upper respiratory tract irritation. Chronic effects include liver damage and nervous system disturbances. High concentrations can cause narcosis.

A report of inhalation exposures to humans describes the effects of a military smoke bomb in a fraternity house (269). However, it is probably not appropriate to ascribe the effects specifically to hexachloroethane because a variety of chemicals would be present in the smoke.

Exposure of workmen to the fumes of hot hexachloroethane has been reported to cause blepharospasm, photophobia lacrimation, and reddening of the conjunctiva but no corneal injury and no permanent damage (270, 271). However, the available citation does not give details of the exposure conditions or duration.

8.4.2.2.5 Carcinogenesis There is no human carcinogenicity data. EPA (IRIS) (2) classifies hexachloroethane as C, possible human carccinogen on the basis of observation of carcinomas in one mouse strain after oral exposure. (See animal section on carcinogenesis.)

Carcinogenic Classification:

IARC	Group 3, agent is not classifiable as to its carcinogenicity in humans
NIOSH	Carcinogoen without further classification
NTP	Reasonably anticipated to be a human carcinogen (RAHC)

ACGIH TLV A3, Confirmed Animal Carcinogen with Unknown Relevance to Humans

8.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV for hexachloroethane is 1 ppm with a notation indicating possible skin absorption.

The NIOSH considers hexachloroethane a potential carcinogen and recommends the lowest possible exposure, and an REL of 1 ppm. The OSHA PEL is also 1 ppm.

Other countries: Australia: 10 ppm, proposed change 1 ppm (1990); The former Federal Republic of Germany: 1 ppm (1998); United Kingdom: vapor 5 ppm (50 mg/m^3), total inhalable dust 10 mg/m^3, respirable dust 5 mg/m^3 (1987).

Saturated Halogenated Aliphatic Hydrocarbons Two To Four Carbons
Jon B. Reid, Ph.D., DABT

1-Propyl Chloride
9.0.1 CAS Number:
[*540-54-5*]
9.0.2 Synonyms:
n-Chloropropane
9.0.3 Trade Names:
NA
9.0.4 Molecular Weight:
78.541
9.0.5 Molecular Formula:
$CH_3CH_2CH_2Cl$, C_3H_7Cl
9.0.6 Molecular Structure:

9.1 Chemical and Physical Properties

Physical state	Colorless liquid
Specific gravity	0.8910 (20/4°C)
Melting point	–122.8°C
Boiling point	46.4°C
Vapor pressure	350 torr (25°C)
Refractive index	1.38838 (20°C)
Percent in “saturated”air	44.5
Solubility	027 g/100 mL water at 20°C; soluble in ethanol, ethyl ether
Flammability	Flash point <–18°C; explosive limits 2.6–11.1% in air

9.1.1 General

9.1.2 Odor and Warning Properties No data were found concerning odor or warning properties.
9.2 Production and Use
No information found.
9.3 Exposure Assessment

No information found.
9.4 Toxic Effects
Very little information is available on *n*-propyl chloride because it has found so little use in industry. Von Oettingen (7) reviewed the data available prior to 1955.

9.4.1 Experimental Studies 9.4.1.1 Acute Toxicity Abreu et al. (272) exposed rats to 1.7 mmol/L (40,000 ppm) 1 h/d for 4 d and then examined the livers and lungs. Slight alveolar hemorrhage and "significant" focal necrosis of the liver were observed. This concentration was reported to be anesthetic in mice.

9.4.1.2 Chronic and Subchronic Toxicity No information found.

9.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Barnsley (273) found 2-hydroxypropylmercapturic acid in the urine of rats injected subcutaneously with a 40% w/v solution of 1-chloropropane in arachis oil. VanDyke and Wineman (135) reported that enzymatic dechlorination occurs *in vitro* using rat liver microsomes. Cytochrome P450 may be involved based on *in vitro* data (274). Hepatic microsomes from phenobarbital-induced rats produced a variety of metabolites: propene, 1,2-epoxypropane, 1,2-propandiol, propienic acid, and an unidentified species bound to protein (275). If glutathione was added, there was conjugation with it.

9.4.1.4 Reproductive and Developmental No information found.

9.4.1.5 Carcinogenesis No information found.

9.4.1.6 Genetic and Related Cellular Effects Studies *n*-Propyl chloride was studied at 1000 mg/kg orally in rats and found not to produce a dominant lethal response (276).

9.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization No information found.

9.4.2 Human Experience No information found.
9.5 Standards, Regulations, or Guidelines of Exposure
None has been established for propyl chloride.
9.6 Studies on Environmental Impact
None found.

Saturated Halogenated Aliphatic Hydrocarbons Two To Four Carbons
Jon B. Reid, Ph.D., DABT

Isopropyl Chloride
10.0.1 CAS Number:
[*75-29-6*]
10.0.2 Synonyms:
2-Chloropropane
10.0.3 Trade Names:
NA
10.0.4 Molecular Weight:
78.541
10.0.5 Molecular Formula:
$CH_3CHClCH_3$, C_3H_7Cl
10.0.6 Molecular Structure:

10.1 Chemical and Physical Properties

Physical state	Colorless liquid
Specific gravity	0.862 (20.°C)
Melting point	–117°C
Boiling point	35.74°C
Vapor pressure	523 torr (25°C)
Percent in “saturated”air	68.7 (25°C)
Solubility	0.31 g/100 mL water at 20°C; soluble in alcohol, diethyl ether
Flammability	Flash point –45°C (tag open cup)

10.1.1 General No new information on this compound was found since the last edition.

10.1.2 Odor and Warning Properties Warning properties may be inadequate to protect against excessive repeated exposure. Several subjects did not detect 500 ppm of the vapors.
10.2 Production and Use
Isopropyl chloride has had minimal use as a solvent and chemical intermediate, and to some extent as an anesthetic. Its flammability has limited its use despite its apparent favorable toxicity.
10.3 Exposure Assessment
No information was found.
10.4 Toxic Effects
Isopropyl chloride has a potent anesthetic action and has been proposed for medical usage.

Von Oettingen in 1955 reviewed the literature on the use of this material as an anesthetic (7). Vomiting and cardiac arrhythmia have been observed. It may also cause histopathological changes in the liver and kidneys but is rather low in potency.

Very little information has been published on this compound.

10.4.1 Experimental Studies 10.4.1.1 Acute Toxicity Twenty 6-h exposures to 1000 ppm in rats caused no evidence of injury during exposure, but extensive vacuolation and necrosis were seen in the liver of male and female rats. Similar exposures to 250 ppm caused no injury (277).

10.4.1.2 Chronic and Subchronic Toxicity No information was found.

10.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms VanDyke and Wineman (135) report that 2-chloropropane was enzymatically dechlorinated *in vitro* by rat liver microsomesed. Cytochrome P450 may be involved based on *in vitro* studies (274).

10.4.1.4 Reproductive and Developmental No information was found.

10.4.1.5 Carcinogenesis No information was found.

10.4.1.6 Genetic and Relatled Cellular Effects Studies Simmon et al. (278) reported that isopropyl chloride was mutagenic in *S. typhimurium* when tested in desiccators.

10.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization No information found.

10.4.2 Human Experience No information on human experience was found.
10.5 Standards, Regulations, or Guidelines of Exposure
No standards have been established for isopropyl chloride. Based on the limited available data from animals, it is suggested that time-weighted average exposures should be controlled below 500 ppm.
10.6 Studies on Environmental Impact
None found.

Saturated Halogenated Aliphatic Hydrocarbons Two To Four Carbons

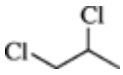
Propylene Dichloride
11.0.1 CAS Number:
[*78-87-5*]
11.0.2 Synonyms:
1,2-Dichloropropane, alpha,beta-dichloropropane, alpha,beta-propylene dichloride, Dichloro-1,2-propane, PDC
11.0.3 Trade Names:
AI3-15406, Caswell No. 324, CCRIS 951, ENT 15,406, HSDB 1102, NCI-C55141
11.0.4 Molecular Weight:
112.99
11.0.5 Molecular Formula:
$C_3H_6Cl_2$
11.0.6 Molecular Structure:



11.1 Chemical and Physical Properties

Physical state	Colorless liquid
Specific gravity	(20/4°C) 1.1558 (1.159 at 25°C)
Melting point	–100°C
Boiling point	95–96°C
Vapor pressure	143 torr (25°C)
Refractive index	1.437 (25°C)
Percent in “saturated” air	3.4 (25°C)
Solubility	0.27 g/100 mL water at 20°C; soluble in alcohol, ethyl ether
Exposure limits	3.4–14.5% in air
Flash point	60°F, 16°C (Closed cup), 21°C (Open cup)

11.1.1 General

11.1.2 Odor and Warning Properties The odor may be adequate to warn against acute injury, but it

appears doubtful if it will prevent excessive repeated exposure. It has a chloroformlike odor.

11.2 Production and Use

Propylene dichloride has been used as a solvent, chemical intermediate, and fumigant. Flammability has significantly limited its use as a solvent.

11.3 Exposure Assessment

No information was found.

11.3.3 Workplace Methods NIOSH Method 1013 is recommended for determining workplace exposures to propylene dichloride (10a).

11.3.5 Biomonitoring/Biomarkers There appears to be inadequate data to determine the feasibility of biologic monitoring of exposure to propylene dichloride following industrial exposure, although Ghittori et al. (279) have presented limited data showing a relationship of urinary metabolites to inhaled exposure concentrations in workers.

11.4 Toxic Effects

Propylene dichloride is toxic by ingestion, inhalation, and skin absorption. It causes CNS depression, injury to the liver and kidney, and possibly hemolytic anemia and disseminated intravascular coagulation. There are indications of adrenal and possibly testicular injury in animals after repeated exposure. At high concentrations the vapors are irritating to the eyes and nose, and irritation of the nasal (olfactory) tissue of animals has been observed. It appears to be weakly mutagenic and carcinogenic, but available data indicate no reproductive effect. When heated to decomposition, it emits toxic fumes of carbon monoxide, carbon dioxide, chlorine, hydrogen chloride gas, and phosgene.

Von Oettingen in 1955 summarized the literature prior to that date (7). A more recent summary published in 1989 contains details of several extensive unpublished toxicologic studies conducted by The Dow Chemical Company, the data from which have been provided to the EPA (60).

11.4.1 Experimental Studies 11.4.1.1 Acute Toxicity The lethal dose of propylene dichloride to guinea pigs is between 2 and 4 g/kg of body weight. Repeated oral feedings of doses as low as 0.2 g/kg of body weight were survived for some period of time, but the animals showed liver injury. An oral LD_{50} for rats of 1.9 g/kg (1.7–2.1 g/kg) has been reported (63).

As part of their procedure for establishing dosage for lifetime studies, NTP conducted 14-d and 13-wk studies in rats and mice (280). All five male and female rats fed 2000 mg/kg/d for 14 d died. On gross necropsy, the renal medullae were red at this dose but not at lower doses. Body weight was depressed 14–15% at 1000 mg/kg in both sexes and at 500 mg/kg in male rats.

Mice were slightly more susceptible because 9/10 mice fed 1000 mg/kg for 14 d died and red renal medullae were observed in 3/5 males at 500 mg/kg and in 1/5 female mice at 125, 250, and 500 mg/kg. Body weight was depressed at 500 mg/kg in male mice and possibly at 250 mg/kg in female mice.

An acute inhalation LD_{50} for 8-h exposures of rats to propylene dichloride was reported by Pozzani et al. (183) as 14 mg/L (3000 ppm).

Mice were exposed to analytically determined concentrations of propylene dichloride vapor in order to study the relationship of lethality to anesthesia and to liver injury (as measured by SGPT in the blood) (111). Based on 10-h exposures, an LC_{50} of 720 ppm was determined. The anesthetic ET_{50} (ET = effective time) at that concentration was 350 min, and the ET_{50} for increased SGPT was 186 min. Based on these data propylene dichloride has much less potency toward causing liver injury than carbon tetrachloride, because its anesthetic, hepatotoxic, and lethal conditions are quite similar. Gehring reported the ratio of ET_{50} anesthesia to ET_{50} for carbon tetrachloride as 136, as compared

to 1.9 for this ratio for propylene dichloride (111). The ratio of LT_{50} to ET_{50} for carbon tetrachloride was 5480 and for propylene dichloride 2.7. It was concluded by the investigator that in mice, respiratory injury, rather than liver injury, was the primary cause of acute death. Anesthetic effects were observed, but they were considered secondary to obstructive respiratory failure.

In limited unpublished study reported to the EPA "male rats and mice were exposed to 0, 500, or 1500 ppm propylene dichloride (PDC) for a single 6-h exposure. Rats exposed to 1500 ppm were lethargic during exposure, lost weight after the exposure, and exhibited pale livers upon gross necropsy. All mice exposed to 1500 ppm died within 24 h postexposure and exhibited nonspecific changes typical of animals which die in acute studies. Several mice exposed to 500 ppm PDC died and exhibited various degrees of liver toxicity upon gross and histological examination" (281).

Early longer-term toxicologic studies on this material were published by Heppel and co-workers (282, 283). These data have been summarized by Von Oettingen (7) for repeated exposure to concentrations of 2200 to 400 ppm. "Exposure for 7 hours daily on 5 days per week to 1,000 ppm (4.4 mg/L) caused in guinea pig no signs, other than drowsiness; rabbits were not affected; and rats showed some incoordination and it appeared that the animals developed some tolerance to the exposure. On the other hand many rats and mice died after a few hours' exposure. Liver function tests performed in dogs showed no definite abnormal values but nevertheless histological examination of their organs gave evidence of liver damage. None of the animals studied gave evidence of injury of the blood or blood-forming organs."

Heppel et al. (283) reported that "repeated exposure to 400 ppm for 7 hours daily on 5 days per week for a total of 128 to 140 (exposures) caused no other ill effects except a decrease in weight gain of rats, whereas mice showed a high incidence of mortality." A group of C3H strain mice exposed to 400 ppm propylene dichloride showed rather high mortality. Hepatomas were observed in some of the animals that survived.

In an incomplete report Shaipak (284) claims impaired spermatogenesis in rats exposed continuously to 9 mg/L (3.6 ppm). The duration of the study was not given in the available abstract but is described as "long periods," possibly 7 d. This report is not consistent with most of the data cited above, or subsequent studies that indicate the testes were not affected by inhalation of higher concentrations. However, Bruckner et al. (285) also reported testicular effects.

Results of repeated inhalation of propylene dichloride were also reported to the EPA (281, 286). Male and female rats and male rabbits were exposed to 0, 100, 300 or 1000 ppm PDC for 6 h/exposure for 9 exposures in 2 wk; male and female mice were exposed to 0, 30, 100, or 300 ppm PDC for the same time period. Body weight gains of rats exposed to PDC (all levels) were decreased from control values. The olfactory mucosa of the nasal turbinates in rats was observed histologically to be affected at all exposure levels. The extent and severity of degeneration of the olfactory mucosa was directly correlated with exposure level. Male and female mice exposed to 300 ppm PDC had increased liver weights and decreased thymic weights. Some mice exposed to 100 or 300 ppm PDC had degenerative changes in the olfactory mucosa, but these changes were not as severe as observed in rats at the same exposure level. Only minor liver changes were observed histologically in mice exposed to 300 ppm PDC. Male rabbits exposed to 1000 ppm PDC had equivocal degenerative changes in the olfactory mucosa. While a no-observable-effect level (NOEL) was not established in rats, a NOEL of 30 ppm for mice and 300 ppm for rabbits was established in a 2 wk study (281).

Skin: Propylene dichloride on the open skin causes only mild irritation. Single short contact will probably be without any effects. The intensity of the reaction is greatly increased when it is held close to the skin by clothing. The LD_{50} for percutaneous absorption has been reported as 8.15 g/kg (63).

Eye: Propylene dichloride causes some pain and irritation when splashed into the eyes of rabbits, but

it would not be expected to cause serious or permanent injury. It should be washed out immediately with water.

11.4.1.2 Chronic and Subchronic Toxicity The EPA (IRIS) provides no oral reference dose but does provide a reference concentration for inhalation, based on the critical effect of hyperplasia of the nasal mucosa with a LOAEL of 69.3 mg/m^3 (15 ppm). This was based on the study by Nitchke et al. (286). Male and female F344 and B5C3F$_1$ mice (10/group) were exposed to 0, 15, 50, or 150 ppm dichloropropane (0, 69.3, 231, or 693 mg/m^3) for 6 h/d, 5 d/wk for 13 wk (duration-adjusted concentrations = 0, 12.4, 41.3, and 124 mg/m^3). New Zealand rabbits (7/sex/group) were exposed to 0, 150, 500, or 1000 ppm dichloropropane (0, 693, 2310, or 4621 mg/m^3) according to the same regimen (duration-adjusted concentrations = 0, 124, 413, and 825 mg/m^3). The animals were observed daily after exposure for overt signs of toxicity as well as changes in behavior pattern and nervous system activity. Body weights were measured weekly. Hematology, clinical chemistry, and urinalysis were done prior to exposure and 2 weeks before study termination. Histopathology was conducted on 52 tissues in the control and high-concentration groups for all three species. The nasal tissues, larynx, trachea, and lungs were evaluated in all concentration groups for all three species. Histopathological examinations were also made on the liver and kidney in mice and on the liver, bone marrow, and spleen in rabbits at all exposure concentrations. The number of sections of the nasal cavity was not stated; it was assumed that four sections were taken as was done in the preliminary 2-wk study in the same lab. No treatment-related deaths were observed in any species. Body weights were statistically significantly reduced in the male rats (90% of control) and female rats (92–94% of control) exposed to 150 ppm, and slightly reduced at 50 ppm dichloropropane. No significant treatment-related effects on any hematological, clinical chemistry, or urinalysis parameters studied were noted in the rats or mice. Histopathological effects were seen in the upper respiratory tract of the rats that were concentration-related in incidence and severity. Very slight to slight hyperplasia of the respiratory epithelium of the nasal cavity was observed (0/10, 2/9, 5/10, and 9/10 in males and 0/10, 3/10, 7/10, and 9/10 in females at 0, 15, 50, and 150 ppm, respectively). This hyperplasia occurred primarily in the anterior regions of the nasal cavity. Very slight to slight degeneration of the olfactory mucosa in the rostral portion of the nasal cavity was noted for all male and female rats exposed to 50 or 150 ppm dichloropropane, but not in the control and 15-ppm groups. Statistical analysis of these results was not reported. Slight inflammation of the larynx was also noted in several male rats exposed to 150 ppm dichloropropane; no other treatment-related effects were observed in the respiratory tract of rats. No effects were observed in the liver, spleen, or bone marrow in rats exposed to 150 ppm.

No treatment-related pathological effects were observed in the mice. Anemia was seen in the rabbits exposed to dichloropropane in a concentration-related manner. Red blood cell counts (RBC), hemoglobin concentration, and percent packed cell volume were statistically significantly decreased in the animals exposed to 150 ppm (red blood cell count only), 500, or 1000 ppm dichloropropane. Animals in the 500- and 1000-ppm groups exhibited evidence of a regenerative response (bone marrow hyperplasia and hemosiderin-laden macrophages). Minimal degeneration of the olfactory epithelium was also observed in the nasal cavity of some rabbits from all exposure groups and the controls, but the incidence and severity were higher in the 1000-ppm male animals. This study demonstrates that respiratory effects are apparently the most sensitive endpoint of dichloropropane-induced toxicity, and that species vary considerably with regard to their susceptibility to these effects. A LOAEL of 15 ppm [LOAEL(HEC) = 1.3 mg/m^3] can be estimated for this study, based on nasal epithelial hyperplasia in female rats. This LOAEL should be considered minimal because of the low incidence and severity of the lesions seen at this concentration. Despite the minimal nature of the effects, they are considered to be adverse because of the increase in incidence and severity with increasing exposure concentration. This relationship is additionally supported by the short-term data (described later). Based on the exposure concentrations used in this study, rats are more than 10 times more sensitive than mice and 100 times more sensitive than rabbits to the nasal effects.

In an NTP (280) 13-week study rats were fed 0, 60, 125, 250, 500, and 1000 mg/kg/d. Five of 10 male and female rats died at 1000 mg/kg and 5/10 males at 500 mg/kg. Body weight was depressed 16% at 500 mg/kg. Centrilobular congestion of the livers occured in 5/10 males and 2/10 females receiving 1000 mg/kg. Hepatic fatty changes and contrilobular necrosis were observed in 2/10 females receiving 1000 mg/kg. Mice were fed 0, 30, 60, 125, 250, and 500 mg/kg. One female mouse fed 500 mg/kg died at 12 wk, and one male fed 60 mg/kg died in the first week. Body weights were little affected, and no compound-related histopathological effects were recorded.

In another study on male rats fed 0, 100, 250, 500, or 1000 mg/kg in corn oil for 1, 5, or 10 doses, a larger number of biochemical parameters were measured in addition to histopathological examination 24 h after treatment (285). There was evidence of development of resistance to propylene dichloride by the tenth dosage. No deaths occured, but a no-observed-effect level was not established because cytochrome P450 levels were incresed in the liver even at 100 mg/kg. However, "doses of 500 and 1000 mg/kg were required to produce significant liver injury."

The same dosage, 100 mg/kg, the lowest dose fed, was found to be an observed effect level in a 13-wk gavage study as well. When fed to male rats for 13 wk at 0, 100, 250, 500, or 750 mg/kg/d, members of the 750-mg/kg group died or were sacrificed, as did 50% of the 500-mg/kg group Bruckner et al. 1989 (285). Although cause of death was not stated and may have been anesthetic, histopathology was only moderate to mild. Hepatitis, hemosiderosis of the spleen, vacuolation of the medulla and lipidosis of the cortex of the adrenals, degenerate spermatogonia, reduction in spermatozoa in the epididymis, and testicular degeneration were observed at 750 mg/kg. At 500 mg/kg testicular and adrenal changes were reported in some of the rats with reduced sperm production and degenerate spermatogonia in the epididymis. There was an increase in fat storage in the adrenal cortex. No such effects were seen in the 100- or 250-mg/kg groups. Dose-dependent depression of weight gain occured at all levels. Nephrotoxicity was not apparent, and liver toxicity as measured by serum enzymes was very limited. Possibly hemolytic anemia occured. All animals in the 500-ppm group were sacrificed the day after exposure, but groups of 100 and 250 mg/kg rats examined 1 wk after treatment stopped had recovered significantly. It is interesting that the testicular changes reported following gavage in this study have not been reported in other studies.

In response to a TSCA section 4(a) test rule, 1,2-dichloropropane (PDC) was evaluated for potential neurotoxic effects in groups of 15 Fischer 344 rats/sex given 0 (corn oil controls), 20, 65, or 200 mg PDC/kg body weight/d, 5 d/wk for 13 wk (287). Specific tests required by the test rule included monthly evaluation of a functional observational battery, hindlimb grip strength, motor activity, and comprehensive neuropathology at the end of the study. Other parameters evaluated included weekly clinical observations, weekly body weights, and body temperatures after 13 wk of treatment.

Transient clinical effects were noted in a dose-responsive manner shortly after gavage for rats receiving all dose levels of PDC. The rats adapted rapidly to PDC such that these effects were no longer noted after the fourth daily dose. Body weights were depressed throughout the study for male rats given 200 mg/kg/d. Males receiving 65 mg/kg/d and females given 200 mg/kg/d had slightly decreased body weights that were also attributed to PDC ingestion. No effects attributable to PDC were noted upon the functional observational battery, hindlimb grip strength, or motor activity at any of the monthly intervals throughout the study. After 13 wk of gavage, the temperature of rats receiving 200 mg/kg/d was slightly lower, particularly females. The body temperature was within the range of normal daily variation and the decrease was not considered toxicologically significant. No gross or histopathologic effects on the nervous system, either central or peripheral, were demonstrated by any of the techniques employed.

All rats not selected for the 13-wk termination were held without further treatment for an additional 9 wk. Parameters noted to be affected in the 13-wk portion were evaluated in these rats. The body weight differences persisted for the 9 wk post-treatment period. Body temperature differences for the female rats, but not male rats, receiving 200 mg/kg/d also remained throughout this period. Female rats previously receiving 65 mg/kg/d also tended to have slightly decreased body temperature during

the recovery period.

In summary, aside from early transient clinical signs and minor body weight and temperature decreases, there were no effects attributable to DCP in the functional observational battery, grip strength, motor activity, and neuropathology.

11.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms It has been shown that rat liver microsomes *in vitro* are capable of metabolizing 1,2-dichloropropane (136). More information on metabolism is discussed on 1,3-dichloropropane (288). Jones and Gibson have proposed a metabolic pathway (289) that has been expanded by Timchalk et al., who studied the disposition and metabolism of [^{14}C]1,2-dichloropropane (propylene dichloride) in Fischer 344 rats following oral and inhalation exposure (290): The objective of this study was to compare the disposition and metabolism of [^{14}C]1,2-dichloropropane ([^{14}C]DCP) following oral and inhalation exposure since these two routes are of interest with regards to occupational and and accidental exposure. [^{14}C]DCP was administered orally to groups of four rats of each sex as a single dose of 1 or 100 mg/kg and as a multiple 1 mg/kg nonradiolabeled dose for 7 d followed by a single 1-mg [^{14}C]DCP/kg dose on day 8. In addition, four rats of each sex were exposed to [^{14}C]DCP vapors for a 6-h period in a head-only inhalation chamber at target concentrations of 5, 50, and 100 ppm. [^{14}C]DCP was readily absorbed, metabolized, and excreted after oral or inhalation exposure. For all treatment groups the principal routes of elimination were via the urine (37–65%) and expired air (18–40%). The tissues, carcass, feces, and cage wash contained <11, 9.7, and 3.8% of the dose, respectively. The major urinary metabolites, as a group, from the oral and inhalation exposures were identified as three, *N*-acetylcysteine conjugates of DCP, *N*-acetyl-*S*-(2-hydroxypropyl)-L-cysteine, *N*-acetyl-*S*-(2-oxopropyl)-L-cystein, and *N*-acetyl-*S* (l-carboxyethyl)-L-cystein. The majority (61–87%) of the expired volatile organic material was found to be parent DCP in all samples analyzed. Increasing the dose/concentration of [^{14}C]DCP resulted in an increase in the amount of exhaled [^{14}C]-volatile organics. The peak DCP blood concentrations (inhalation exposure) were not proportional to dose, indicating a dose dependency in the blood clearance of DCP. Nonetheless, upon termination of exposure, DCP was rapidly eliminated from the blood. In all treatment groups, following oral and inhalation exposure the majority of the radioactivity was eliminated by 24 h postdosing, and no differences were noted between sexes. Therefore, it can be concluded that in the rat the pharmacokinetics and metabolism of [^{14}C]DCP are similar regardless of route of exposure or sex.

These authors proposed a metabolic pathway (Fig. 63.2) quite similar to Jones and Gibson and concluded that incorporation into macromolecules is due to metabolism and not alkylation.

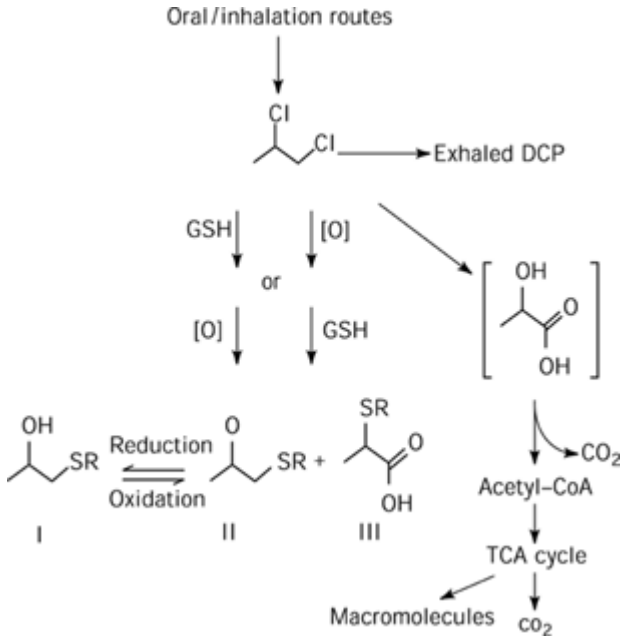


Figure 63.2. Proposed metabolic scheme for 1,2-dichloropropane in the rate (R = *N*-acetylcysteine) [from Timchalk et al. (290)].

11.4.1.4 Reproductive and Developmental Thirty bred female Sprague–Dawley rats were fed propylene dichloride in oil by gavage at dose levels of 0, 10, 30, or 125 mg/kg/d on days 6 to 15 of gestation. The usual teratological parameters were evaluated Kirk et al. (291). Administration of PDC to pregnant rats at a dose level of 125 mg PDC/kg body weight/d produced transient decreases in respiration, movement, muscle tone, and extensor thrust reflex, and increases in salivation and lacrimation within 1 h of dosing on day 6 of gestation. Rapid accomodation to PDC exposure was observed in these animals on the second day of dosing (day 7 of gestation), as evidenced by a decrease in the frequency and severity of clinical observations. Decreased feed consumption and significant decreases in maternal body weight gain resulting in significantly lower maternal body weights were also observed at 125 mg PDC/kg body weight/d. There were, however, no adverse effects on any reproductive parameter measured in any of the dose levels tested. Fetal examination revealed a significant increase in the incidence of delayed ossification of the bones of the skull in the 125 mg PDC/kg body weight/d dose group. This increase was considered to be a reflection of at most slight fetotoxicity, secondary to the reduced maternal growth. There were no adverse effects on any parameter in rats exposed to 10 or 30 mg PDC/kg body weight/d. Based on these results, PDC was not teratogenic at a dose level that produced obvious maternal toxicity (125 mg PDC/kg body weight/d), and 30 mg PDC/kg body weight/d was considered the no-observed-effect level for maternal and fetal effects.

In a similar study 18 inseminated New Zealand white rabbits were administrated 0, 15, 50, or 150 mg/kg/day on days 7 through 9 of gestation (292). Administration of 150 mg PDC/kg/d resulted in anorexia in the majority of animals in this dose group producing significant decreases in maternal body weight gain during the treatment period (days 7–20 of gestation). One maternal death resulting from anorexia was also recorded in the 150-mg/kg/d dose group. Measurement of hematologic parameters revealed anemia (decreased red blood cell counts, hemoglobin concentration, and hematocrit) in rabbits given 150 mg/kg/d, with microscopic examination revealing slight-to-moderate anisocytosis, poikilocytosis, and/or polychromasia, indicative of a regenerative anemia. Despite the obvious maternal effects, there were no adverse effects on any of the reproductive parameters measured in any dose group, nor were there indications of teratogenicity in any of the dose groups. Fetal examination revealed low, but statistically significant, increase in the incidence of delayed ossification of the bones of the skull in the 150-mg/kg/d dose groups. Based on these results, 150 mg/kg/d was considered maternally toxic and produced evidence of slight fetotoxicity.

Therefore, the no-observed-effect level for both maternal and fetal effects was 50 mg/kg/d.

A two-generation reproduction study in rats produced no effect on reproductive parameters, although there was an obvious effect on water consumption and body weight (293). The investigators summarize the study as follows. Groups of 30 male and 30 female Sprague–Dawley rats each were provided with drinking water containing PDC at concentrations of 0 (control), 0.024%, 0.10%, or 0.24% (w/v) over two generations. A concentration of 0.24% PDC in water represented the maximum practicable attainable concentration based on solubility. Adult rats were evaluated for body weights, water and feed consumption, reproductive performance, and gross pathologic and histologic changes. The resultant litters were evaluated for size, neonatal growth, and survival.

Administration of PDC via the drinking water to male and female Sprague–Dawley rats over two generations produced concentration-related palatability effects in adults at 0.24%, 0.10%, and 0.024%. Decreases in water consumption, reflective of a rejection due to palatability, were observed at all levels tested in both the f0 and f1 generations in males and females. These decreases in water consumption at 0.24% PDC (50% below controls) resulted in consistent body weight effects. These differences in water consumption and body weights were also evident among females during gestation and/or lactation. Slight decreases in water consumption 0.024% PDC were associated only with slight decreases in weight gain in females during gestation and had no adverse effects on these animals. There were no treatment-related gross pathologic changes noted in any dose group. Histologic changes related to PDC exposure were limited to increased hepatocellular granularity in males and females of both generations at all dose groups. These histologic changes were considered reflective of a physiologic, adaptive response to PDC and not an indication of toxicity. There were no treatment-related histologic changes in the reproductive tracts of either sex in their generation.

Despite the obvious effects of continuous exposure to PDC on water consumption and body weights, reprodutive function was unaffected in either generation. The substantial decreases in water consumption among females at 0.24% PDC resulted in significantly lower neonatal body weights and slightly increased neonatal mortality in their litters. These neonatal effects were considered secondary to the substantial decreases in maternal water consumption, rather than a direct effect of PDC. There were no neonatal effects at PDC concentrations of 0.10% or 0.024% in either generations.

It should be noted that the concentrations of PDC in the drinking water administered to these animals were at the limit of solubility, and were approximately 100,000-fold higher than levels detected in the environment. Despite the exaggerated levels, neonatal growth and survival were only affected at a PDC concentration of 0.24%, which also resulted in significant reduction in parental water consumption and body weight changes. These effects on the neonates were thus considered secondary to the effects on the adults. Significantly, there were no adverse effects on reproductive performance as measured by fertility and litter sizes at any dose level tested. Thus the no observed adverse effect level for adults was 0.024% PDC, the no observed effect level for neonatal effects was 0.10% PDC, and the reproductive NOEL was 0.24% PDC, the limit of solubility.

It was difficult to calculate with any precision the daily dosage because consumption varied greatly with age of the rats and whether the females were pregnant or lactating. Roughly the lowest level ranged from 20 to 25 mg/kg/d for males and 35 to 45 mg/kg/d for females. The intermediate dose resulted roughly in 65 to 90 mg/kg/d for male rats and 110 to 140 for females. The highest water concentration resulted in roughly 130 to 160 mg/kg/d in males and 190 to 270 mg/kg/d in females.

11.4.1.5 Carcinogenesis The EPA (IRIS) (2) states: “this substance has not undergone a complete evaluation and determination under US EPA’s IRIS program for evidence of human carcinogenicity potential.”

Propylene dichloride was fed by gavage to rats and mice, 5 d/wk for 103 wk. Dosages were 0 (corn oil controls), 125, and 250 mg/kg for mice and 0, 62, and 125 mg/kg for rats (280). Survival was

reduced in high-dose female rats and mice (possibly due to infection in female mice). Body weight was reduced in high-dose rats of both sexes, and clear-cell changes and necrosis of the livers were found in high-dose female rats. The investigators concluded that dose-related increases were observed for adenomas of the liver in both male (control, 7/50; low dose, 10/50; high dose, 17/50) and female (1/50, 5/50, 5/50) mice. The increase in the frequency of liver carcinomas supported the evidence that there was a neoplastic response in the mouse liver for both sexes (males: 11/50, 17/50, 16/50. females: 1/50, 3/50, 4/50). Hepatocytomegaly and hepatic necrosis were increased in male mice, but not in female mice.

A dose-related increase in adenocarcinomas of the mammary gland was observed in female rats (control, 1/50; low dose, 2/50; high dose, 5/50), with the majority of these tumors being found at the end of the study (1/37, 3%; 2/43, 5%; 4/16, 25%). The incidence of mammary adenocarcinomas was increased when compared to the historical controls for this laboratory (3/150, 2.0%) and for all laboratories combined (11/895, 1.2%). Mammary fibroadenomas were decreased in the high-dose treated female rats (15/50, 20/50, 7/50).

Under the conditions of these 2-yr gavage studies, there was no evidence of carcinogenicity for male F344/N rats receiving 62 or 125 mg/kg. For female rats there was equivocal evidence of cacinogenicity in that 250 mg/kg 1,2-dichloropropane caused a marginally increased incidence of adenocarcinomas in the mammary gland; these borderline malignant lesions occurred concurrent with decreased survival and reduced body weight gain. There was some evidence of carcinogenicity for male and female B6C3F1 mice exposed to 1,2-dichloropropane, as indicated by increased incidences of hepatocellular neoplasms, primarily adenomas (280).

11.4.1.6 Genetic and Related Cellular Effects Studies Published mutagenicity tests on microbial systems were summarized by NTP (294). Generally responses were weak to negative in *Drosophila, Salmonella, Streptomyces*, and *Aspergillus*. NTP also conducted studies on *Salmonella* TA100, TA98, TA1537, and TA1535 in the presence or absence of liver S-9 fraction, and no clearly positive responses were obtained. Chromosomal aberration and sister chromatid exchange studies in Chinese hamster ovary cells resulted in an increase with and without S9 activation. ATSDR concluded dichloropropane poses a genotoxic threat to humans ATSDR (60).

A dominant lethal study in Sprague–Dawley rats fed drinking water containing 0, 0.024, 0.10, and 0.24% for 14 wk produced no evidence of mutagenicity (294).

Among PDC-treated males, concentration-related decreases in water consumption were noted at all levels treated, and decreased body weights were noted in males given 0.10% or 0.24% in the water. Mating performance was unaffected in these animals. Evaluation of the resorption rates among these groups revealed that the weekly values for the females mated to PDC-treated males ranged from 2.2% to 8.1%, well within the historical control range expected for this strain. Resorption rates among the concurrent controls were low, ranging from 3.5% to 5.4%. Statistically significant increases from concurrent control values identified during the first week of breeding in the resorption rates in the 0.024% and 0.24% PDC-treated groups were considered a reflection of the normal variability in this strain. In contrast, single oral administration of cyclophosphamide at a dose of 100 mg/kg resulted in a 10-fold increase in the resorption rate, consistent with the acknowledged mutagenic potential of this compound. The concentrations of PDC in the drinking water administered to these animals were at the limit of solubility in water, and were approximately 10,000-fold higher than levels detected in the environment. Despite these exaggerated levels, PDC was not mutagenic in a dominant lethal assay in male Sprague–Dawley rats exposed continuously to concentrations up to 0.24% in the drinking water (136).

11.4.2 Human Experience Symptoms of exposure to this compound may include irritation of the skin, eyes, and respiratory tract. It may also cause irritation of the mucous membranes of the nose, throat, and lungs. Other symptoms may include dermatitis by defatting of the skin and more severe irritation if confined against the skin. Exposure can cause slight smarting of the eyes or respiratory

system and smarting and reddening of the skin. Exposures may also lead to hemolytic anemia, disseminated intravascular coagulation, necrosis and failure of the kidneys, liver failure, and death. Liver and kidney damage occur. Heart damage may also occur. Prolonged exposure may cause nausea, headache, vomiting, and central nervous system depression. High concentrations may cause nacrosis. Drowsiness and lightheadedness have been reported. Cardiac effects have also been reported. Eye contact may cause burning, tearing, reddening, and swelling of the eye and surrounding tissue. Skin contact can cause burning and swelling. Inhalation may lead to coughing, burning sensation, runny nose, sore throat, and dizziness.

Liver, kidney, and hemocytic anemia and disseminated intravascular coagulation appear to be characteristic responses to excessive exposure to propylene dichloride. Pozzi et al. (295) reported finding three publications regarding human exposure to propylene dichloride and discussed three subjects they had examined. All the cases were from Italy, indicating propylene dichloride may have had more usage in that country. One of the three subjects who drank an undisclosed amount of propylene dichloride died of septic shock after developing renal failure and liver damage. Many other changes including hemolytic anemia were observed.

11.4.2.2 Clinical Cases 11.4.2.2.1 Acute Toxicity A young woman who admitted sniffing a cleaning solution containing 98% propylene dichloride complained of vomiting and abdominal pain, widespread ecchymoses, hematuria, and metrorrhagia on first admission. Several months after she was readmitted with oliguria, epistaxis, hematuria, metrorrhagia, and periorbital and conjunctival hemorrhages. She again had vomited and had severe abdominal pain followed by fever, facial edema, and erythemas. She showed evidence of severe renal failure, acute liver damage, and hemolytic anemia. Renal biopsy showed acute tubular necrosis. The patient survived.

The third case, a 55-year-old woman, who had glomerulonephritis and had been on hemodialysis for 3 yr, was admitted with abdominal pain. It was subsequently found she had spent 6 h cleaning her flat with 2 L of solvent (composition not stated) 3 d prior to admission. She developed anorexia, abdominal pain, and nocturnal sweating prior to admission. Severe liver failure, hemolytic anemia, and other blood changes were observed. The patient survived.

Larcan et al. (296) reported an accidental ingestion of 50 mL of a cleaning substance by a 46-year-old man. According to the available abstract, the man was in deep coma within 2 h, with mydriases and hypertonia. Artificial hyperventilation and osmotic diuresis were applied and consciousness was recovered in 24 h. The patient suddenly developed a picture of irreversible shock with cardiac failure, lactic acidosis, and hepatic cytolysis at the thirty-sixth hour. He died after developing acute delirium with tremors. Necropsy evidenced centri- and mediolobular acute hepatic necrosis. The abstract indicated gas chromatography was used to confirm the identity of propylene dichloride, but no details were presented.

A similar response involving a 73-year-old woman has also been reported in a 1992 letter to the editor (297). In addition to the hemolytic anemia, there appeared to be persistent changes in liver enzymes.

A workman was sprayed on one side of his face with propylene dichloride when a pipeline burst (271). There was smarting of the eye on that side that persisted for several hours. The corneal epithelium was damaged in several small areas in the palpebral fissure, but recovery was prompt with no special treatment.

Two interesting cases of dermatitis suggestive of sensitization have been reported in women using a complex (aerosol spray) mixture containing propylene dichloride (298). When tested against the components of the mold-release spray, one women tested strongly positive and the other slightly positive. Few details are given.

In another report of alleged allergies due to Shell DD*f* Fumigant Mixture, which contains about

27% propylene dichloride, two subjects tested negative for the mixture and one subject positive for the mixture but not propylene dichloride alone (299).

The health effects in humans (truck drivers, highway patrol officers, fire fighters, and hospital employees) who were exposed to dichloropropane following the accidental spill of 2000 gallons from a truck were described by Rubin (300). The exposed individuals complained of chest discomfort, dyspnea, and cough, and some had persistent chest pain or discomfort and fatigue. These symptoms indicate that dichloropropane is a respiratory irritant. The level of exposure to dichloropropane was not quantified.

No epidemiologic studies were found in which propylene dichloride was the subject of the study.

11.4.2.3.5 Carcinogenesis Carcinogenicity Classification:

IARC	Group 3, not classifiable as to its carcinogenicity to humans
MAK	Group 3, possible human carcinogen
NIOSH	Carcinogen, with no further categorization
ACGIH TLV	A4, Not Classifiable as a Human Carcinogen

11.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV TWA is 75 ppm with a STEL/C of 110 ppm. NIOSH considers propylene dichloride a carcinogen and recommends the lowest feasible concentration. The OSHA PEL is 75 ppm.

Other Occupational Exposure Values: Australia: 75 ppm, 15-min STEL 110 ppm (1990); Federal Republic of Germany: no MAK, Group 3, possible human carcinogen (1998).

Ethyl Bromide
12.0.1 CAS Number:
[*74-96-4*]
12.0.2 Synonyms:
Monobromoethane, bromic ether, bromoethane, hydrobromic, ether, and monobromoethane
12.0.3 Trade Names:
Halon 2001, Monobromoethane, Bromic ether
12.0.4 Molecular Weight:
108.97
12.0.5 Molecular Formula:
CH_3CH_2Br
12.0.6 Molecular Structure:

12.1 Chemical and Physical Properties
Ethyl bromide is a colorless to yellow, highly volatile, flammable liquid with an ethereal odor. The material turns yellow when exposed to light and air.

Physical state	Colorless liquid
Specific gravity	1.4515 g/mL at 25°C (25/4°C)
Melting point	–119°C
Boiling point	38.4°C
Vapor pressure	475 torr (25°C)
Refractive index	1.42386 (25°C)
Percent in “saturated”air	62.5 (25°C)
Solubility	0.91 g/100 mL water at 20°C; soluble in ethanol, ethyl ether
Flammability limits	6.75–11.25% by volume in air

12.1.1 General

12.1.2 Odor and Warning Properties Ethyl bromide has a definite though not particularly distinctive odor. A threshold of odor response has not been reported. Odor should not be considered a warning property.

12.2 Production and Use

The principal use of ethyl bromide is as a chemical intermediate. Although it has been occasionally proposed as an anesthetic, it has not been used to any extent for that purpose.

12.3 Exposure Assessment

Human exposure has occurred with its use as an anesthetic, but widespread use has ceased.

12.3.3 Workplace Methods NIOSH Method 1011 is recommended for determining workplace exposures to ethyl bromide (10a).

12.3.5 Biomonitoring/Biomarkers Determination of bromide ion in the blood may be of value in determining whether exposure to ethyl bromide has occurred. However, the available data do not permit a quantification of exposure based on blood bromide; nor is it known if measurable concentrations will be present at currently acceptable levels of exposure.

12.4 Toxic Effects

Ethyl bromide may be harmful by ingestion or inhalation. It is an irritant of the skin, eyes, mucous membranes, and upper respiratory tract. It is narcotic in high concentrations. When heated to decomposition, it emits toxic fumes of carbon monoxide, carbon dioxide, bromine, and hydrogen bromide gas.

The primary acute response from exposure to ethyl bromide is CNS depression, as in the case of ethyl chloride. In contrast, however, ethyl bromide causes irritation of the lungs and injury to the liver, muscle, kidneys, and other organs. It has caused cancer in female mice and possibly in male mice and both sexes of rats.

12.4.1 Experimental Studies 12.4.1.1 Acute Toxicity Oral, Skin, and Eyes: The liquid is apparently irritating to the skin and eyes of rabbits and is reported to be absorbed through the skin (301).

Inhalation: Sayers et al. (302) reported acute studies on the response of guinea pigs to ethyl bromide (see Table 63.7).

Table 63.7. Physiological Response of Guinea Pigs to Ethyl Bromide in Air (302)

Concentration (%)	Exposure Time (min)	Response

14	10	Unconscious; death in several days
5	98	Unconscious; died 1 h later
6	10	Survived; lung injury
2.4	90	Died in 18 h
	30	Some delayed death; pathological changes in lungs, liver and spleen
1.2	270	Some deaths; histopathological changes
	90	Survived; histopathological changes
	55	Survived; slight histopathological changes
0.65	270	Some deaths
	180	Survived; histopathological changes
0.07	810	One death and histopathological changes
	540	Survival; normal

Vernot et al. (303) determined 1-h LC_{50}s of 27,000 and 16,200 ppm (120 and 72 mg/L) for rats and mice, respectively.

These data are similar to the results in F344/N rats and B3C3F_1 mice given single 4 h exposure to 625-, 1250-, 2500-, 5000-, or 10000-ppm exposures. All animals exposed to 10,000 ppm died. During the initial part of the exposure, clinical signs included an increased rate of respiration, hyperactivity, and incoordination. By the end of the exposure the rats were dyspneic and comatose. It is not clear what clinical signs were observed at lower concentrations or how long the signs persisted after exposures ceased. Male rats did not die after exposure to 5000 ppm or less, but 2/5 female rats died at 5000 ppm. No rats or mice died at 2500 ppm.

Rats and mice were also given 10 repeated 6-h exposures to 0, 250, 500, 1000, 2000, or 4000 ppm (304). All animals exposed repeatedly to 4000 or 2000 ppm died or were sacrificed in extremis. All animals exposed to 1000 ppm or less survived. Deaths occurred as early as days 2 and 3 at 4000 ppm and as late as day 10 at 2000 ppm. Growth of survivors was not affected by exposure. Prostration, dyspnea, lacrimation, and twitching were observed during exposure. Pulmonary congestion and hemorrhage were observed at 2000 ppm and to a lesser degree at 1000 ppm.

Intraperitoneal: The available abstract of a report by Kosenko (305) gives LD_{50} values of 2850 and 1750 mg/kg for mice and rats given single intraperitoneal injections. The abstract further states the material was rapidly detoxified and not accumulated significantly in mouse tissues.

Waite and Yant (306) studied the microscopic pathology of guinea pigs exposed to ethyl bromide vapor. Ethyl bromide exposure concentrations of 60,000 to 180,000 ppm were used with 5- to 19-min exposure times, and concentrations of 3,200–24,000 ppm were used with exposure times of 90–810 min. The exposed animals that died and those that survived up to 8 d postexposure were autopsied to determine any resulting pathology. The high-concentration exposures mainly produced pulmonary damage in the bronchioles and alveoli. Bronchiolar cells showed swelling, distention, and cytoplasmic vacuolation with an exudate containing erythrocytes, epithelial cells, and leukocytes. Swelling of the alveolar walls was noted. Alveolar spaces were found to contain a sero-fibrinous exudate, endothelial leukocytes, and fine granules. At the lower exposure concentrations, the pulmonary reactions were similar to those at the higher concentrations, but to a lesser degree. In some cases, congestion of the kidneys and liver caused by large numbers of erythrocytes was also observed. At the lower concentrations, kidney effects were the most prominent with apparent

compression of the capillary tufts and tubular damage. There was also central liver lobule necrosis in many cases.

Similar toxicity has been reported in rats (307), dogs (308), cats (309), rabbits (310), and mice (272). Oral doses of 200 mg/kg body weight of ethyl bromide administered in 61 daily doses were reported to cause no apparent toxicity in rabbits (311). Sixty-two daily oral doses administered to rabbits at 300 or 600 mg/kg resulted in paralysis but were not fatal.

12.4.1.2 Chronic and Subchronic Toxicity According to the available abstract, rats were exposed 4 h daily for 6 mo to 2.4 mg/L (about 540 ppm), with some evidence of liver injury and disrupted liver function (312).

More recently, rats and mice were exposed 6 h/d, 5 d/wk for 14 wk (65 exposures) to 0, 100, 200, 400, 800, or 1600 ppm (304). In mice, a single death occurred at 200 ppm but none at 800 ppm. Body weight gains did not appear to be affected except at 1600 ppm, at which concentration ataxia, posterior paresis, dyspnea, and tumors were observed. At autopsy, lesions were observed only at 1600 ppm. Mineralization of granular layer of the cerebellum, degeneration of the spinal cord, hemosiderosis of the spleen, depletion of the hematopoietic cells of bone marrow, atrophy of skeletal muscle, severe atrophy of the testes with complete absence of germinal epitheleum, and minimal atrophy of the uterus were observed in rats. Mice were less affected than rats, but atrophy of the uterus, involution of the ovary, and atrophy of skeletal muscle were reported.

12.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Ethyl bromide, given to rats and mice rapidly detoxified and did not accumulate after repeated administration (313). Cohn et al. (314) suggested that some of the ethyl bromide in anesthetized patients is converted to ethyl sulfide since there is evidence of a lingering garlic odor on the breath for several days postexposure.

Ethyl bromide is enzymatically dehalogenated *in vitro* by rat liver extract (315). Ethyl bromide is a substrate for glutathione *S*-transferase. Female Wistar rats given 1.16 millimoles of ethyl bromide in oil by gavage were sacrificed 2 h later, and livers were assayed for glutathione; ethyl bromide-treated rats showed liver glutathione levels 52% that of controls (316). Ethylmercapturic acid is also an ethyl bromide metabolite as shown by its apperance in the urine of rats administered 1.25 g/kg subcutaneous doses of ethyl bromide. This finding was supported by the presence of *S*-ethyl-cysteine in acid-treated urine (317). Ethyl bromide reduces cytochrome P450 activity by degradation of the enzyme's heme group. Hepatic microsomes from phenobarbital-induced Wistar rats, treated with 44.4 millimolar ethyl bromide, showed a 27% reduction in cytochrome P450 activity. The enzyme binding was by the type I manner. Activities of cytochrome b_5 and cytochrome c were not affected. Speculation suggests that deactivation of the cytochrome P450 by heme degradation could be a mechanism that would trap reactive species that could damage cellular components.

Absorption and excretion through the lungs is rapid, but it may be hydrolyzed to some degree in the body, resulting in the formation of inorganic bromide (318).

12.4.1.4 Reproductive and Developmental No data for teratogenicity were found.

12.4.1.5 Carcinogenesis: ACGIH considers this chemical an animal carcinogen with unknown relevance to humans. There is no EPA (IRIS) file.

In the lifetime carcinogenic/toxicology study (304), groups of rats and mice were exposed 6 h/d, 5 d/wk for 104 wk to 0, 100, 200, or 400 ppm by inhalation. Survival of rats was unaffected or in the case of the 100 ppm female rats was significantly above the control group. Body weights were also unaffected.

Likewise survival of mice was little affected by exposure except for a decrease in survival at

400 ppm in female mice, which also had body weights 6–16% lower than controls after the twenty-ninth week. No clinical signs were apparent in any group, but at autopsy there was evidence of respiratory irritation at 400 ppm. It was concluded there was clear evidence of an increase in neoplasms (endometrial adenomas, adenocarcinomas, and squamous cell carcinomas) in the uteri of female mice. The tumors contributed to the decreased survival of the female mice exposed to 400 ppm. The terminal rats of uterine tumors were 0, 3, 14, and 61% in the 0-, 100-, 200-, and 400-ppm groups.

There was equivocal evidence of carcinogenic activity in the lungs of male mice, and a marginally increased incidence of neoplasms in the brain and lungs of female rats. Male rats were considered to have some evidence of a slightly increased incidence of tumors in the adrenals, brain, and lungs. Although there was a clear dose–response relationship in female mice, the dose response in male mice and rats of both sexes was not as clear.

These results are somewhat similar to the results of the study on ethyl chloride, but obviously ethyl bromide is a more potent uterine carcinogen in female mice, causing uterine cancer at much lower concentrations.

Simmon and Poirier (319) and Poirier et al. (320) gave intraperitoneal doses to strain A mice in three groups of 20 animals each at 1, 1/2, and 1/5 of the MTD once per week for 24 wk. They reported no increased incidence of pulmonary tumors over background (background was ca. 20%). The authors speculated that the inactivity may be due to metabolic inactivation when administered intraperitoneally.

Dipple et al. (321) gave rats single subcutaneous injections and observed over 90 wk for sarcomas at the injection site. Doses were 1.36, 0.46, and 0.14 g/kg and showed no activity. The authors speculated that the inactivity may be due to the slow reaction rate of ethyl bromide for sufficient alkylation of vital cellular components.

12.4.1.6 Genetic and Related Cellular Effects Studies Because of its alkylating properties, ethyl bromide has been tested for mutagenicity in microbial systems. Based on several studies including those at NTP, ethyl bromide appears to be a direct alkylating agent in bacterial systems (304). In cultured Chinese hamster ovary cells it induced increased sister chromatid exchange but did not increase the frequency of chromosomal aberrations (322).

12.4.2 Human Experience Symptoms of exposure to this compound include irritation of the skin, eyes, mucous membranes, and upper respiratory tract. Other symptoms include anesthesia, narcosis, lung irritation, acute congestion and edema, liver damage, and kidney damage. It can cause nausea, dizziness, headache, and nervous system disturbances. Central nervous system depression, cardiac arrhythmias, and cardiac arrest may occur. Loss of balance, slurred speech, unconsciousness, and death can occur. Ingestion can cause burning of the digestive tract, vomiting, and moderate gastrointestinal upset. Skin rash may occur. This compound can affect motor control after repeated exposures. Heart damage has been reported. Persons with pre-existing skin disorders or eye problems, or impaired kidney or respiratory function, may be more susceptible to the effects of this substance.

Ethyl bromide has toxic effects on the skin, pulmonary, hepatic, renal, cardiovascular, and neurological systems of humans. In some instances, the toxic effects can be delayed. Individuals with pre-existing disease of the above organ systems probably would be at increased risk from ethyl bromide exposure. There is a lack of data on the human carcinogenicity of ethyl bromide. Skin absorption may also contribute to the overall exposure to ethyl bromide.

Limited human experience during surgical anesthesia has indicated that, in addition to CNS depression, there is a possibility of lung congestion and degeneration of the liver and kidney tissues.

12.4.2.2 Clinical Cases There are no detailed epidemiological or human toxicological studies concerning ethyl bromide, but there are reports of human exposures. In the late eighteenth century, the use of ethyl bromide as an anesthetic was advocated for a number of medical procedures. Probable ethyl bromide concentrations used during some of these procedures approached 100,000 ppm. Von Oettingen (7, pp. 134–138; 323) and Scherbatscheff (308) have reviewed the adverse effects encountered from the use of ethyl bromide for this purpose. In addition to central nervous system (CNS) depression, narcosis, and anesthesia, ethyl bromide administration causes excitation and an initial increase in pulse rate, followed by a slowed pulse and marked vasodilation. Patients have been reported to experience tinnitus, heart palpitations, muscle rigidity and spasms, abdominal wall cramping, hemorrhaging, and a garlicky odor on their breath. Fatalities have occurred from respiratory or cardiac arrest immediately following anesthesia or up to over 24 h post-treatment. Symptoms in fatal cases include vertigo, weakness, difficult breathing, weak and rapid pulse, and unconsciousness, followed by cardiac failure. The autopsy of one fatal case showed ecchymosis of the pericardium, hyperemia and edema of the lungs, and fatty degeneration of the heart and liver. Blindness and conjunctival hyperemia and hemorrhaging have also been reported as occasional results of ethyl bromide anesthesia.

Sayers et al. (302) found that 12,000 ppm ethyl bromide caused immediate eye irritation in human volunteers, and a 5-min exposure at 6500 ppm lead to eye irritation, headache, and vertigo.

Reznikov (324) related clinical cases of occupational ethyl bromide intoxication observed between 1937 and 1942. The course of ethyl bromide poisoning was described in three stages. The first stage lasted 2–4 d and involved a garlicky odor on the breath, sleepiness, fatigue, sharp pain and paresthesia of the lower legs, and a staggering gate. During the second phase that lasted 2–5 d, the symptoms of the first phase grew more severe. The third phase was characterized by spastic paresthesia of the legs, disturbance of the peripheral nervous system, and atrophy of the lower leg. CNS disturbances can also occur at high ethyl bromide exposures. Prognosis for recovery is good for most patients. Blood bromine concentrations of patients suffering from ethyl bromide poisoning at the time of admission were reported to be 15–53 mg/100 mL. Spinal fluid bromine concentrations were 4–7 mg/100 mL. After 5–10 d without exposure, the patients' blood bromine levels were 5–7 mg/100 mL; however, after 2–3 wk, these returned to background levels of 0.61–1.81 mg/100 mL. No background levels for spinal fluid bromine concentration are reported. Blood bromine levels are suggested as a diagnostic and monitoring tool for ethyl bromide exposure. It was pointed out that the blood bromine levels did vary and not all workers supposedly poisoned by ethyl bromine showed greatly elevated levels.

Watrous (325) reported that a group of workers intermittently exposed to ethyl bromide air concentrations up to 1500 ppm complained of no systematic symptoms over a period of several years, but the possibility of undetected chronic toxicity was not ruled out. The abstract of a study of 262 pregnant workers exposed to ethyl bromide vapor reported a significant number of early and late pregnancy toxemias. These workers were also exposed to toluene, ethyl chloride, butyl alcohol, and orthosilicic ester; therefore, these observations cannot be solely attributed to ethyl bromide.

In addition to irritation, repeated or prolonged contact of ethyl bromide with the skin may also lead to absorption of the compound. The Dow Chemical Company (326) states that a single prolonged skin exposure can lead to the absorption of harmful amounts of ethyl bromide. The National Institute for Occupational Safety and Health (NIOSH) (327) states that ethyl bromide can be absorbed through human skin.

12.4.2.3.5 Carcignogenicity Carcinogenicity Classification:

IARC 3, not classifiable as to carcinogenicity to humans

MAK 2, probably human carcinogen

ACGIH A3, Confirmed Animal Carcinogen with Unknown Relevance to Humans

12.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV TWA is 5 ppm with an A3 and skin notation. NIOSH questions whether the OSHA PEL of 200 ppm is protective enough for workers. The NIOSH IDLH is 2000 ppm.

Other Occupational Exposure Values: Australia: 200 ppm, STEL 250 ppm (1990); Federal Republic of Germany: no MAK, A2, clearly carcinogenic only in animal studies (1997); United Kingdom: 200 ppm, STEL 250 ppm (1995).

Ethylene Dibromide
13.0.1 CAS Number:
[*106-93-4*]
13.0.2 Synonyms:
1,2-Dibromoethane, Sym-dibromoethane, dibromoethane, alpha, beta-dibromoethane, glycol bromide, and glycol dibromide, ethylene bromide
13.0.3 Trade Name:
Bromofume, Celmide, DBE, Dowfume 40, Dowfume EDB, Dowfume W-8, Dowfume W-85, Dowfume W-90, Dowfume W-100, EDB, EDB-85. E-D-BEE, ENT 15,349, Fumo-Gas, Iscobrome D, Kopfume, NCI-C005220, Nephis, Pestmaster, Pestmaster EDB-85, RCRA Waste Number U067, Soilbrom-40, Soilbrom-85, Soilbrom-90, Soilbrom-100, Soilbrome-85, Soilbrome-90EC, Soilfume, UN 1605, and Unifume
13.0.4 Molecular Weight:
187.88
13.0.5 Molecular Formula:
$C_2H_4Br_2$
13.1 Chemical and Physical Properties
Ethylene dibromide is a colorless, nonflammable, heavy liquid with a sweetish odor.

Physical state	Colorless liquid
Specific gravity	2.172 at 25°C (25/4°C)
Melting point	9.97°C
Boiling point	132°C
Vapor pressure	11 torr (25°C)
Refractive index	1.53789 (20°C)
Percent in “saturated” air	1.5 (25°C)
Solubility	0.43 g/100 mL water at 30°C; soluble in ethanol, ethyl ether
Flammability	Essentially nonflammable by standard tests in air; it has been used as a fire extinguisher

13.1.1 General

13.1.2 Odor and Warning Properties The odor of ethylene dibromide is not unpleasant and has been termed “chloroformlike.” The odor is not detectable at a low enough concentration to be considered a good warning of excessive exposure.

13.2 Production and Use
Ethylene dibromide was previously used extensively in leaded antiknock gasoline and in fumigant mixtures, but both of these uses have virtually disappeared in the United States. It is used to some extent as a chemical intermediate, special solvent, and gauge fluid. The most significant human exposure appears to have been the result of its use as a fumigant. The high boiling point, low vapor pressure, and high heat of vaporization greatly reduce the probability of high concentrations accumulating rapidly in the work atmosphere.
13.3 Exposure Assessment
No information found.

13.3.3 Workplace Methods NIOSH Method 1008 is recommended for determining workplace exposures to ethylene dibromide (10a).

13.3.5 Biomonitoring/Biomarkers Increased bromide ions may be found in the blood after exposures but is of limited value in biologic monitoring because of the low concentrations present at acceptable levels of exposure. It is not clear if any of the other metabolites is of use for the same reason.
13.4 Toxic Effects
Ethylene dibromide may be toxic by inhalation, ingestion, or skin absorption. It is irritating to the skin, eyes, mucous membranes, and respiratory tract. It may also cause narcosis. It is absorbed through the skin. When heated to decomposition, it emits toxic fumes of carbon monoxide, carbon dioxide, and hydrogen bromide gas. It may also emit ionic and oxidized halogen.

The toxicity of ethylene dibromide has long been recognized and probably because of its low vapor pressure and control of exposure, a relatively small number of cases of acute human injury have been reported despite rather widespread usage. Exposure to high concentrations of the vapors of ethylene dibromide may result in some CNS depression, although the anesthetic action is weak. Deaths from acute exposure at high concentrations are usually due to pneumonia developed as a result of injury to the lungs. Following acute exposures, injury may be observed in the lungs, liver, and kidneys. Chronic exposure over a long period to levels significantly above the threshold also results in a response very similar to that seen from acute exposure. It should be particularly noted that in experimental animals the difference between the concentration causing severe injury and death and that which is tolerated for long-term exposure is not great. Ethylene dibromide has been shown to be carcinogenic in animals, to be mutagenic in many test systems, and to cause adverse effects on the sperm of laboratory and domestic animals. EPA (IRIS) (2) considers it a probable human carcinogen on the basis of increased incidences of a variety of tumors in rats and mice in both sexes by three routes of administration but that the human data are “inadequate.”

Several reviews are available, one of the more comprehensive by Alexeeff et al. (328). Certainly extreme caution must be used in handling ethylene dibromide, to prevent inhalation, ingestion, and skin contact.

13.4.1 Experimental Studies 13.4.1.1 Acute Toxicity Although there are newer references, the acute and short-term animal data cited in previous editions of this volume remain valid. Alexeeff et al. (328) cites many of the more recent reports. There is new evidence of toxic effects at dosages lower than those causing death.

Rowe et al. (329) reported the single-oral-dose LD_{50} for several species of animals: female mice, 420 mg/kg; male rats, 148 mg/kg; female rats, 117 mg/kg; guinea pigs, 110 mg/kg; unsexed chicks, 79 mg/kg; and female rabbits, 55 mg/kg.

Rowe et al. (330) and McCollister et al. (331) compared ethylene dichloride, carbon tetrachloride, and ethylene dibromide, as components of fumigant mixtures. With regard to oral toxicity, ethylene dibromide was, by far, the most toxic of the three. Also ethylene dibromide was more toxic in inhalation exposures of less than 7 h. The minimum lethal concentration for rats in the 8-h exposure

as 200 ppm. The highest concentration not producing detectable injury for 8 h was 50 ppm.

Eyes: Rowe et al. (329) also reported experiments on the effects of ethylene dibromide in the eyes of rabbits. Undiluted ethylene dibromide caused obvious pain and conjuctival irritation, clearing in 48 h. A slight, superficial necrosis of the cornea was observed. Nevertheless, healing was prompt and complete. A 10% solution in propylene glycol was also tested and produced a more severe reaction than did the undiluted material. However, the eye healed without scarring or apparent injury. It is obvious that, in handling ethylene dibromide, the eye should be protected. If the material gets into the eye, it should be washed out promptly.

Skin: Ethylene dibromide is definitely irritating and injurious to the skin. Rowe et al. (329) reported that a 1% solution of ethylene dibromide in butylcarbitol acetate applied 10 times in 14 d to a rabbit's ear caused slight irritation characterized by erythema and exfoliation. The same repeated application, when bandage on to the shaved abdomen, produced erythema and edema, progressing to necrosis and sloughing of the superficial layer of the skin.

Skin Absorption: Thomas and Yant (330) indicated that ethylene dibromide could be readily absorbed through the skin in toxic amounts. Rowe et al. reported quantitive measurements of the toxic dose absorbed through the skin in rabbits for a contact period of 24 h. A dose of 0.21 g/kg body weight was survived by 14 out of 15 animals; 1.1 g/kg body weight killed five of five animals.

Inhalation: A quantitative expression of acute vapor toxicity of ethylene dibromide is found in the data of Rowe et al. (329). The maximum survival exposures of rats to ethylene dibromide vapor in air were as follows: 3000 ppm for 6 min, 400 ppm for 30 min, and 200 ppm for 2 h. Guinea pigs survive 400 ppm for 2 h and 200 ppm for 7 h. The maximum exposure without adverse effect on female rats are 800 ppm for 6 min, 100 ppm for 2.5 h, and 50 ppm for 7 h. The pathological changes following acute exposure described by Rowe et al. were congestion, edema, hemorrhages, and inflammation of the lungs. The liver showed cloudy swelling and central lobular fatty degeneration and necrosis. The kidneys showed slight interstitial congestion and edema with slight cloudy swelling of the tubular epithelium in some cases.

13.4.1.2 Chronic and Subchronic Toxicity EPA (IRIS) indicates that there is no reference dose available for oral exposure for ethylene dibromide, nor is there a reference concentration for inhalation exposure.

Alexeeff et al. (328) reported finding 20 studies in which cats, chickens, guinea pigs, mice, quail, rabbits, and rats were repeatedly exposed to ethylene dibromide. Generally the results are similar to those found following single exposures.

Oral: Aman et al. (33) gave 3–20 mg/kg dosages fed daily to rats and guinea pigs for 95 d were reported to cause no effect on body weight, nor were clinical signs apparent.

These data are consistent with a study by NCI (73) in which rats and mice were intubated 5 d/wk for 6 wk and then observed for an additional 2 wk. All rats survived 63 mg/kg/d, but one male and one female fed 100 mg/kg/d died. Male mice fed 159 mg/kg/d or less survived, but one female mouse dosed with 100 mg/kg/d and two dosed with 250 mg/kg/d died. Body weight of mice was unaffected at dosages 159 mg/kg/d.

Repeated vapor exposure in animals has been reported by Rowe et al. (329). Animals were exposed 7 h/d, 5 d/wk for periods up to 6 mo. At 100 ppm in air, rats and rabbits were in poor condition, and some deaths occurred within the first week or two of exposure. The rats showed injury to the lungs, liver, and spleen. The rabbits showed definite liver injury. At 50 ppm, the rates showed a fairly high mortality (approximately 50%) due to pneumonia and infection of the upper respiratory tract, which may be related to the effect of ethylene dibromide on the lung. A number of them, however, lived through the full 6-mo period. They had increase in lung, liver, and kidney weight and some

histopathological changes in the lungs. Guinea pigs subjected to 57 7-h exposures in 80 d showed some depression of growth but no increase in mortality. Lung, liver, and kidney weights were increased. There were slight histopathological changes in the liver and kidneys. An exposure of 25 ppm was tolerated by rats, guinea pigs, rabbits, and monkeys. The male rats, however, showed high mortality due to pneumonitis and infections of the upper respiratory tract, which the authors apparently considered the result of the chemical exposures. Testicular pathology was not exceptional in these animals, and testicular weights were not consistently affected. Changes in the testes of certain species are discussed in the next sections.

Plotnick and Conner (332), however, saw adverse effects in Sprague-Dawley rats exposed to 20 ppm of the vapor 7 h/d for their lifetimes. Half the rats that also had 0.5% disulfiram (Antabuse) in their diet were very severely affected by 10 mo of exposure. The section on carcinogenesis contains more details of this study.

NTP (335) exposed rats and mice to 0, 3, 15, or 75 ppm of the vapor 6 h/d, 5 d/wk for 13 wk. No deaths occurred in either male or female rats, but male weight gain was depressed in a dose-related manner at all levels. Female rats failed to gain weight only at 75 ppm. Swelling and/or vacuolization of the adrenal cortical cells of the zona fasiculata was found in 8/10 rats and a slight decrease in the follicular size of the thyroid in 6 of 10 rats at this dosage level. A dose-related depression of weight gain was observed in both sexes of mice at all dosage levels. One death occurred in female mice exposed to 75 ppm, and four deaths occurred in the lowest-exposure group of male mice, although there were none at the two higher levels. There was apparently eye irritation in mice exposed to 75 ppm, and megalocytic cells were found lining the bronchioles at that concentration.

Other short-term repeated studies include Short et al. (336), Rezanick et al. (337), and Nitschke et al. (338), discussed in the following.

Reznick exposed rats and mice 6 h/d for 13 wk to 0, 3, 15, or 75 ppm. Rats exposed to 15 or 75 ppm and mice exposed to 75 ppm had cytomegaly, focal hyperplasis, squamous metaplasia, and loss of cilia in the dorsal region of the nasal cavity.

Short et al. exposed pregnant rats and mice to 0, 20, 38, or 80 ppm ethylene dibromide 23 h/d for 10 d starting on day 6 of pregnancy. There were adverse effects on maternal welfare as measured by lack of weight gain or food consumption in both species at all doses. Mortality occurred in rats exposed to 80 ppm and in mice exposed to 38 and 80 ppm. The fetus was affected but only at exposures causing maternal toxicity, and was not considered tetratological.

Nitschke et al. exposed rats to 0, 3, 10, or 40 ppm 6 h/d, 5 d/wk, with scheduled sacrifices after 1, 6, or 13 wk of exposure and after 88–89 d recovery following exposure.

Exposures to 3 ppm were without “consistent effect in any parameter measured.” Ten ppm caused slight epthelical hyperplasia in the nasal turbinates of 1, 6, and 13 wk but not after 88 d recovery. Rates exposed to 40 ppm exhibited decreased body weight gain throughout the 13-wk exposure period and increased liver and kidney weights after 6 and 13 wk. Hyperplasia and nonkeratinizing squamous metaplasia of the respiratory epithelium of nasal turbinates were also seen after 13 wk exposure with apparent recovery of 19/20 rats during the 88-d recovery period. The authors concluded that 3 ppm was a NOEL.

13.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Alexeeff et al. (328) suggest that the route of metabolism may have a pronounced effect on the site and nature of toxic action. Further, it is speculated by these authors that the rat may not be the best animal model because it uses a mercapturic acid pathway little used in humans. Figure taken from the above reference, is based primarily on rat studies.

It has been shown by Stott and McKenna (339) that rats about 50–60% of inhaled ethylene

dibromide and none of the retained compound was excreted unchanged.

The role of ethylene dibromide versus its metanolites in binding with macromolecules and with toxicity and/or carcinogenicity at sites remote from the site of treatment is not clear, but may be influenced greatly by glutathione. Alexeeff et al. (328) indicate the complexity by stating the following: “Thus, the studies on EDB's potential mechanism of action indicate that GSH may be a major factor for preventing the noncarcinogenic action of EDB. The studies also indicate GSH may be involved in the metabolic activation of EDB producing a genotoxic intermediate. These findings represent a potential paradox. GHS may be important in the prevention of the noncarcinogenic effects of EDB, but the resulting EDB–GSH conjugate may be reponsible for the carcinogenic action of EDB. These conclusions are further complicated by studies indicating that while single doses of EDB deplete GSH, multiple doses increase GSH levels. The conjugation pathway appears secondary in the liver but may be primary in the extrahepatic tissues where most of the carcinogenic action of EDB is observed. Humans differ quantiatively in comparison to rodents in the hepatic production of genotoxic metabolites; human tissue appears to produce more genotoxic metabolites via the oxidative pathway than rodent tissue.

13.4.1.4 Reproductive and Developmental According to Short et al. (336), although it caused maternal toxicity at 20, 38, or 80 ppm when inhaled 23 h/d, ethylene dibromide did not appear to be teratogenic in rats and mice.

According to IRAC (340), it has been shown to have rather marked effects on the reproductive systems of some birds and mammals. Ingestion of ethylene dibromide by chicken hens for a prolonged period reduced the number and size of the eggs.

Alumot et al. (341) showed that male chickens were less affected than hens, and bulls, but not cows, rams, or ewes, were markedly affected by repeated exposure to ethylene dibromide. The number of sperm, their morphology, and their motility were affected in bulls and rams, as shown by examination of testes and ejaculates. Rat spermatogenesis was reversibly impaired by five daily intraperitoneal injections of 10 mg/kg (341).

When Epstein et al. (342) studied a dominant lethal test system using mice, ethylene dibromide was found to be negative. Doses of 50 or 100 mg/kg were given orally and intraperitoneally.

13.4.1.5 Carcinogenesis The EPA (IRIS) classified ethylene dibromide as B2; probale human carcinogen on the basis of increased incidences of a variety of tumors in rats and mice in both sexes by three routes of administration at both the site of application and at distant sites. Ethylene dibromide is mutagenic in various *in vitro* and *in vivo* assays and structurally similar to 1,2-dibromo-3-chloropropane, a probale human carcinogen and to ethylene dichloride, a probale human carcinogen.

The EPA (IRIS) considers the human data, with regard to carcinogenesis, as Inadequate. Mortality studies of workers occupationally exposed to EDB (343) found neither total deaths nor total malignancies of individuals exposed to EDB exceeded the control rate. The studies are inconclusive due to their small cohort size; lack of, or poorly characterized, exposure concentrations; and/or concurrent exposure to other potential or known carcinogens.

The EPA (IRIS) considers the animal carcinogenicity data as sufficient—ethylene dibromide has been tested for carcinogenicity by gavage, inhalation, and dermal adminstration.

Gavage Study: The NCI (344) administered TWA doses of 27 and 29 mg EDB/kg bw/d to male and 26 and 28 mg EDB/kg bw/d to female rats by gavage for 49 and 61 wk for the low- and high-dose groups, respectively. High treatment-related mortality prompted the early termination of the study (planned for 110 wk) and alterations of the dosing regime, regimen, resulting in similar TWA dosage for high- and low-treatment groups. Significant increased incidences of squamous cell carcinomas of

the stomach (both sexes), hepatocellular carcinomas and neoplastic nodules of the liver (females), and hemangiosarcomas of the circulatory system (males) were observed upon histologic examination. The stomach tumors developed after a short latency period and were observed to metastasize to multiples sites. Male and female B6C3F1 mice received TWA doses of 44 or 77 mg EDB/kg bw/d by gavage for 53 wk and were observed for their lifetime (344). The incidence of squamous cell carcinomas and alveolar/brochiolar adenomas of the lung was significantly increased over the controls in all the mice. As in the rat bioassay, no tumors were observed in the controls, and high treatment-related mortality prompted dosing regimen alterations.

Inhalation Study: Fischer 344 rats and B6C3F1 mice of both sexes were exposed to EDB vapors at 0, 10, or 40 ppm, 6 h/d, 5 d/wk for their lifespans (335). The incidence of nasal cavity carcinomas and adenocarcinomas in the rats of both sexes and alveolar/bronchiolar carcinomas in female rats and mice of both sexes was significantly increased over the controls. The chronic inhalation of EDB was also associated with circulatory system hemangiosarcomas in both sexes of rats (high-dose only), mammary gland fibroadenomas of female rats, mammary gland adenocarcinomas of female mice, subcutaneous fibrosarcomas of female mice, and tunica vaginalis mesotheliomas of males rats. Stinson et al. (1981), in a chronic inhalation study of experimental design indentical to the NTP study (with B6C3F1 mice only), reported an elevated incidence of nasal cavity carcinomas in the female mice exposed to 40 ppm EDB. Both sexes had dose-related epithelical hyperplastic lesions of the nasal cavity. Histologic and pathologic exams were conducted only on the nasal cavity.

Inhalation: Wong et al. (345) exposed Sprague–Dawley rats of both sexes by inhalation to 0 or 20 ppm EDB, 7 h/d, 5 d/wk for 18 mo. Splenic hemangiosarcomas and adrenal gland tumors of both sexes, subcutaneous mesenchymal tumors in males, and mammary gland tumors in females were significantly increased over the controls. Histologic examination excluded the nasal cavity.

Dermal: Lifetime dermal application of EDB to female He:ICR Swiss mice caused both skin papillomas at 50 mg and lung papillomas at 25 and 50 mg, a significant increase by comparison to the controls (79). A single dermal application of EDB followed by thrice weekly treatment with phorbol myristate acetate (PMA) did not result in an increased papilloma incidence.

13.4.1.6 Genetic and Related Cellular Effects Studies EDB has been studied for mutagenic potential by a variety of *in vitro* and *in vivo* test systems. Reverse and forward mutations have been consistently produced in bacterial assays and in *in vitro* assays using eukaryotic cells. EDB caused an increase in unscheduled DNA synthesis in cultured mammalian cells (346–348) and single-strand DNA breaks in *in vitro* cultured cells and in *in vivo* rat liver cells (350). Direct evidence of intractions with DNA have been provided by the formation of nonextractable radiolabeled DNA following both *in vivo* and *in vitro* exposure to radiolabeled EDB.

13.4.2 Human Experience Ethylene dibromide may cause skin, eye, mucous membrane, and respiratory tract irritation. It may also cause demage to the lungs, liver, and kideys. Inhalation may result in delayed pulmonary lesions. The vapor may have a narcotic action. Prolonged skin contact with the liquid may cause erythema, blistering, and skin ulcers (may be delayed 24–48 h). Dermal sensitization to the liquid may develop. Inhalation may cause severe acute respiratory injury, central nervous system depression, and severe vomiting. Other symptoms include abdominal pain, nausea, diarrhea, dark and scant urine, anuria, mild icterus, marked agitation, jaundice, moderate anemia, systemic effects, and chemical burns. Pulmonary congestion may result after exposure by inhalation, and ingestion may cause gastrointestinal distress and pulmonary edema. After short exposure to very high concentrations, drowsiness occurs. Other symptoms include tychypnea, diffuse inflammation of the gastric and intestinal mucosa, massive central lobular necrosis of the liver, and patchy necrosis of the tubular epithelium. It may cause vesiculation. It may also cause skin burns. Inhalation may be fatal as a result of spasm, inflammation, and edema of the larynx and bronchi. Other symptoms include chemical pneumonitis and eye damage. High concentrations are extremely destructive to tissue of the mucous membranes, upper respiratory tract, skin, and eyes. Anesthesia, conjunctivitis, pharyngeal and bronchial irritation, severe loss of appetite, headache, and depression have also been

reported. Eye contact may cause a temporary loss of vision. Death may result from respiratory or circulatory failure. Lung injury may result in pneumonia and eventually cause death. Persons with pre-existing skin disorders or eye problems, or impaired liver, kidney, or respiratory function may be more susceptible to the effects of this material.

Von Oettingen (74 p. 152) noted cases of poisening when ethylene dibromide was mistakenly used in place of ethyl bromide as an anesthetic.

Kochman (351), in reporting a subacute poisoning case from accidental inhalation, stated that a concentration of 50 ppm could be dangerous to humans.

Kochmann (351) reported poisoning in a chemical plant worker engaged in manufacturing ethylene dibromide who suffered from conjunctivitis, pharyngeal, and bronchial irritation, severe loss of appetite, headache, and depression. When he was removed from the exposure, his condition improved.

The liver and kidneys are target organs as in animals.

Olmstead (352) reported on a death following ingestion of 4.5 mL or 140 mg/kg by a 43-year-old woman, and Letz et al. (353) on two workers who entered a tank. However, it is not clear from the nature of their response that the two worker were in fact injured by ethylene dibormide or by some other agent such as *Clostridia* (354).

Serious skin injury can occur from clothing (particularly shoes) wet with ethylene dibromide. This is true not only when material is spilled inside the shoe but also when it wets the outside, for it penetrates leather. Pflesser (355) observed a case of prolonged contact with the skin when liquid ethylene dibromide was accidently spilled into the shoes. There was reddening, blistering, and burning pain.

Calingaert and Shapiro (356) have observed that ethylene dibromide can penetrate through serveral types of protective clothing, particularly neoprene rubber and several types of plastic gloves. Nylon was found to be the most resistant material but lacking in good physical characteristics.

Ott et al. (343) performed an epidemiological study of 161 employees who manufactured ethylene dibromide. Concentration in one plant ranged from 1 to 10 ppm in 1950; in 1952, concentrations were from 19 to 31 ppm (area samples) and up to 13 ppm in drum filling. Twenty years later, time-weighted-average concentrations averaging 2 and 3.5 ppm were found for two groups of workers (343). Three episodes of exposure to concentrations of ethylene dibromide vapor believed to be between 100 and 200 ppm were reported. These excursions resulted in gastrointestinal discomfort, vomiting, and respiratory involvement, which apparently were caused by exposures above 100 ppm for an hour or less or by longer exposures at lower concentrations (e.g., 75 ppm). In one plant, 5 malignant neoplasms were reported versus 2.2 expected. In the other plant, there seems to have been no excess over the number expected. The exposure to ethylene dibromide vapor at one of these plants, at least, appears to have been greater than at two other facilities engaged in the manufacture of ethylene dibromide (and in one case, vinyl bromide). Of 68 sample results in these plants during 1975 and 1976, only 1 sample, at 18 ppm, exceeded 5 ppm and only 10 others were above 1 ppm. IARC (74) reviewed this and two other studies of workers but determined that there was inadequate evidence for carcinogenicity to humans.

The reproductive history of 297 male employees manufacturing ethylene dibromide was also summarized by Wong et al. (357). In this limited study, reproduction generally appeared to be unaffected by exposure to ethylene dibromide, although in one of four plants, the subjects had fewer children than predicted, possibly due to a high number of vasectomies.

Other studies, however, suggest the number and quality of sperm from 46 exposed workers may

have been affected by exposure (358). However, there are inconsistencies in the results, such as a lack of a clear relation to extant of exposure.

13.4.2.1 General Information 13.4.2.2.5 Carcinogenesis The EPA(IRIS) considers the human data with regard to carcinogenesis as inadequate (see later section on human experience—carcinogenesis). Mortality studies of workers occupationally exposed to EDB (343) found neither total deaths nor total malignancies of individuals exposed to EDB exceeded the control rate. The studies are inconclusive due to their small cohort size; lack of, or poorly characterized, exposure concentrations; and/or concurrent exposure to other potential or known carcinogens.

13.5 Standards, Regulations, or Guidelines of Exposure

No TLV for ethylene dibromide was recommended by the ACGIH in1992–1993, although it was included in their list of their animal carcinogens. It would appear prudent to limit vapor exposure with careful control to minimize dermal contact as well.

NIOSH REL	Ca TWA 0.045 ppm C 0.13 ppm (15-min)
OSHA PEL	TWA 20 ppm C 30 ppm 50 ppm (5-min maximum peak)
IDLH	Ca (100 ppm)

ACGIH-TLY Recommendation: Ethylene dibromide is a severe mucuous membrane, eye and skin irritant. It causes liver and kidney damage and is carcinogenic in experimental animals.

Evidence of carcinogenicity was reported in animals exposed to ethylene dibromide through several routes of administration. Based on these data and the redefination of the carcinogenicity classifications by the TLV Committee, the A2 classification no longer applies. Therefore, an A3, Confirmed Animal Carcinogen with Unknown Relevance to Humans, is assigned to ethylene dibromide, with no set TLV at this time. Because of the potential for systemic toxicity resulting from skin absorption, a skin notation is also recommended.

Carcinogenic Classification

EPA	Group B2, Probable human carcinogen; sufficient evidence from animal studies; inadequate evidence or no data from epideologic studies
IARC	Group 2A, Probably carcinogenic to human
MAK	Group 2, Probably a human carcinogen
NIOSH	Carcinogen, with no further categorization
NTP	Group 2, resonably anticipated to be a carcinogen
TLV	A3, Confirmed Animal Carcinogen with Unknown Relevance to Humans

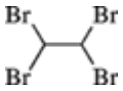
Other Occupational Exposure Values: Australia: no exposure standard, Category 2 carcinogen, probable human carcinogen, skin (1990); Federal Republic of Germany: no MAK, skin, Group 2 carcinogen, probably a human carcinogen (1997); Sweden: Group B carcinogen, may be produced, used, or otherwise handled only after permission has been obtained from the Labour Inspectorate (1984); United Kingdom: 0.5 ppm, skin, carcinogenic substance, R45—may cause cancer (1991); U.S. NIOSH: 0.045 ppm, 15-min ceiling 0.13 ppm, carcinogen, IDLH 100 ppm; U.S. OSHA: 20, STEL 30 ppm, 5-min peak per 8-h shift 50 ppm (113).

13.6 Studies on Environmental Impact

None found.

Saturated Halogenated Aliphatic Hydrocarbons Two To Four Carbons
Jon B. Reid, Ph.D., DABT

1,1,2,2-Tetrabromoethane
14.0.1 CAS Number:
[*79-27-6*]
14.0.2 Synonyms:
Acetylene tetrabromide, tetrabromoacetylene, and 1,1,2,2-tetrabro--moethylene
14.0.3 Trade Names:
Muthmann's liquid, TBE, and UN 2504
14.0.4 Moleculer Weight:
345.65
14.0.5 Molecular Formula:
$CHBr_2CHBR_2$
14.0.6 Molecular Structure:



14.1 Chemical and Physical Properties

Physical state	Colorless to yellow liquid
Molecular weight	345.7
Specific gravity	2.966(20/4°C)
Melting point	–1.0°C
Boiling point	Decomposition 253.5°C
Vapor pressure	0.04 torr (24°C)<0.1 torr at 20°C
Refractive index	1.63795(20°C)
ppm v/v in air “saturated” at 25°C	80(theoretical)
Solubility	0.065 g/00 mL water at 30°C; soluble in ethanol, ethyl ether, chloroform
Flammability	Not flammable by standard tests in air

1mg/L 70.4 ppm and 1 ppm 14mg/m^3at 25°C, 760 torr

14.1.1 General

14.1.2 Odor and Warning Properties The odor of 1,1,2,2-tetrabromomethane is sweetish and has been compared with chloroform or camphor. The odor is not distinctive enough to be considered a good warning property, although it may give sufficient warning to avoid serious acute exposure.
14.2 Production and Use
Because of its high density, this compound is used in separating minerals by specific gravity or density. It is also used as a solvent for fats, oils, and waxes, as solvent in microscopy, and as a fluid inliquid gauges.
14.3 Exposure Assessment
14.3.3 Workplace Methods Si gel; tetrahydrofuran; gas chromatography/flame ionization detection; IV[#2003]: (4), sample workup with silica gel; IV indicates the 4th edition of NIOSH Mannual of Analytical Methods (DHHS) [NIOSH] publication No. 94-113.

14.3.5 Biomonitoring/Biomarkers Few data are available, but some metabolism may occur, since Hoollingsworth et al (359) reported a slight increase in blood bromide of chronically exposed animals.

14.4 Toxic Effects

Virtually no new reports were found of toxicologic studies since the last revised edition of this volume.

According to SAX, this compound is a poison by inhalation and ingestion, an experimental neoplastigen, an eye and skin irritant, and a narcotic. This compound is a very potent mutagen (360).

Acute/chronic hazards: This compound may be fatal if swallowed (361). It is harmful if inhaled or absorbed through the skin. It is an irritant of the skin and respiratory tract (361). When heated to decomposition, it emits highly toxic fumes of carbon oxides, carbonyl bromide, bromine, and hydrogen bromide gas (361, 362).

1,1,2,2-Tetrabromomethane is a CNS depressant and liver and kidney toxicant. If given in sufficiently large doses, it may cause narcosis, coma, and eventually death from respiratory failure. There may be lung irritation, and pathological changes may be observed in the liver and kidneys. Because the vapor pressure is exceedingly low at room temperature, inhalation exposure may be controlled by reasonable precautions and ordinary ventilation. However, contact with the skin should be avided as well.

14.4.1 Experimental Studies 14.4.1.1 Acute Toxicity Gray (363) reported the LD_{50} for rabbits and guinea pigs to be approximately 0.4 g/kg of body weight. Rats survived 0.6 g/kg and succumbed to 1.6 g/kg (359).

Based on studies using rabbits, contact with the open skin does not result in any skin reaction if it is washed off in a resonable period of time. If the material is bandaged onto the skin and allowed to remain there for a period of hours, a slight redness appears. In 24 h there is some edema and blistering. It can be concluded that ordinary contact does not represent a skin problem. However, wet clothing or shoes that may contain the material should be removed and cleaned before reuse.

No data were found on skin absorption, but given the rather high inhalation toxicity, it should be assumed enough can be absorbed on repeated exposure to be toxic.

Arkhangel-Skaya and Yanushkevich (364) reported on the exposure of rats to aerosols of 1,1,2,2-tetrabromomethane. A concentration varying from 3.7 to 4.2 mg/L for a single exposure of 2 h gave only slight and ill-defined symptoms of toxicity. Concentrations varying from 5.9 to 7.2 mg/L caused excitation followed by sleepiness. Repeated daily exposure to aerosol concentrations of 3.7 to 4.2 mg/L resulted in death of the animals. Ingestion due to preening may have increased the exposure.

Merzbach (365) and Glaser and Frisch (309) exposed animals to vapors of 1,1,2,2-tetrabromomethane. It is a bit difficult to determine the significance of their findings, for Gray (363) indicated that the concentrations reported by these authors were, in most instances, well above a saturated atmosphere.

Gray reported exposure of animals to the vapors of 1,1,2,2-tetrabromomethane at near saturation in a static chamber. Rabbits were exposed for up to 2.5 h and rats for up to 3 h with no deaths. Guinea pigs exposed 0.5 h survived. One out of two survived an exposure of 1 h but all exposed succumbed to exposures of 1.5 h or more. In the guinea pigs that died, injury was seen in the liver and kidneys. The guinea pigs recovered consciousness in a period of 5 h but died in periods of from 1 to 5

following exposure.

14.4.1.2 Chronic and Subchronic Toxicity Gray (363) exposed mice, rats, guinea pigs, and rabbits for 15 min daily for 47–92 d to a "saturated atmosphere." One mouse out of 43 died of an unknown cause; the rest survived without adverse effects. Four out of 36 albino rats were ill from lobar pneumonia, a complication that was considered unrelated to the exposure. The rest of the animals survived without injury. The rabbits were observed taking significant amounts of the condensed 1,1,2,2-tetrabromomethane orally by licking it from their bodies. They were therefore not considered significant to the experiment. It should also be recognized that a certain amount of oral intake would have been possible in the case of the other animals as well, but even so, the chronically exposed animals showed no significant pathological change.

Hollingsworth et al. (359) reported that the concentration in air could not be maintained above approximately 14 ppm by analysis. The theoretically saturated concentration should have been about 79 ppm. Rats, guinea pigs, rabbits, and a monkey were exposed 7 h/d, 5 d/wk for periods ranging from 100 to 106 d. The average concentration was 14 ppm by analysis. All animals survived and apperared normal. There was growth depression in guinea pigs. All animals showed an increase in liver weight. Histopathological changes were observed in the liver and lungs. At 4 ppm, some animals showed slight histopathological changes in the liver and some in the lungs. At 1.1 ppm, animals appeared normal.

14.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Few data are available, but some metabolism may occur, since Hollingsworth et al. (359) reported a slight increase in blood bromide of chronically exposed animals.

14.4.1.4 Reproductive and Developmental No reports were found.

14.4.1.5 Carcinogenesis 1,1,2,2-Tetrabromomethane was applied to tumor-prone H2: ICR Swiss mice in a skin application study (79). Doses of 45 mg/application/mouse were applied 3 d/wk as in action solution to the dorsal skin. Apparently no increase in tumors was found at the site of application, but there were a statistically significant greater number of stomach papillomas.

14.4.1.6 Genetic and Related Cellular Effects Studies Brem et al. (366) reported that the compound was not mutagenic to *S. typhimurium* and that it inhibited the growth of *E. coli*.

Rosenkrantz et al. (367) subsequently reported that 1,1,2,2-tetrabromoethane was negative in the standard (Ames) assay but strongly mutagenic against *S. typhimurium* when tested in suspension.

14.4.2 Human Experience Symptoms of exposure to this compound include irritation of the eyes, nose and upper respiratory tract, anorexia, jaundice, central nervous system effects, urobilinuria, bilirubinuria, and monocytosis (368). Other symptoms include nausea, severe headaches, irritation of the mucous membranes and skin, and dizziness (prolonged exposure). It can cause abdominal pains, lung irritation, dermatitis, and kidney damage (361). It can also cause liver damage (369, p.9; 370). Skin contact may result in blisters (370).

Van Haaften (263) describes the only available report of human injury alleged to be due to 1,1,2,2-tetrabromomethane. Although there appears to be little doubt that the chemists involved had exposure to the vapors, skin exposure was very high, and it is impossible to separate the effects. "Near-fatal liver injury" was reported with headaches, anorexia, stomach ache, and heartburn. Although there is no question of a serious response by the liver, the effects were similar to viral hepatitis. Unfortunately no determinations of blood bromide were reported to determine the magnitude of the exposures.

14.5 Standards, Regulations, or Guidelines of Exposure

The TLV for 1,1,2,2-tetrabromomethane recommended by the ACGIH in 1992–1993 is 1 ppm

(14 mg/m^3).

OSHA PEL: TWA 1 ppm (14 mg/m^3)

IDLH 8 ppm
14.6 Studies on Environmental Impact
None found.

Propyl Bromide
15.0.1 CAS Number:
[*106-94-5*]
15.0.2 Synonyms:
n-Propyl bromide, bromopropane, 1-bromopropane
15.0.3 Trade Names:
NA
15.0.4 Molecular Weight:
123
15.0.5 Molecular Formula:
C_3H_7Br
15.0.6 Molecular Structure:

15.1 Chemical and Physical Properties

Physical state	Colorless liquid
Specific gravity	1.3539 (20/4°C)
Melting point	–109.85°C
Boiling point	71.0°C
Vapor pressure	143 torr (25°C)
Refractive index	1.43411 (20°C)
Percent in “saturated” air	19.3 (25°C)
Solubility	0.25 g/100 mL water at 20°C; soluble in alcohol, ethyl ether
Flammability	No data were found

1 mg/L 198.8 ppm and 1 ppm 5.03 mg/m^3 at 25°C, 760 torr

15.1.1 General

15.1.2 Odor and Warning Properties No data were found.
15.2 Production and Use
Propyl bromide has had but minor use in industry. It has been studied as an anesthetic but has not

found significant use.
15.4 Toxic Effects
Propyl bromide has a depressant action on the central nervous system and, for that reason, has been considered as a possible anesthetic. Exposure of animals to anesthetic concentrations may result in injury to the lungs and liver.

15.4.1 Experimental Studies 15.4.1.1 Acute Toxicity The material is reported to be irritating to the skin and eyes of mice (301) and to have intraperitoneal LD_{50}s of 2.5 and 2.9 g/kg for mice and rats, respectively (371). Orally administered 1-bromopropane was excreted in expired air (318). Barnsley et al. (273) report that rats metabolize 1-bromopropane. Another reference (372) also reports excretion by rats of a mercapturic acid metabolite as well as the parent compound. It has been reported to be negative when tested for dominant lethal activity in rats (276) when studied at 400 mg/kg orally.
15.5 Standards, Regulations, or Guidelines of Exposure
None has been established.
15.6 Studies on Environmental Impact
None found.

Ethyl Iodide
16.0.1 CAS Number:
[*75-03-6*]
16.0.2 Synonyms:
Monoiodoethane, 1-iodoethane, ethyl iodide, ethyl iodide, 99% and hydriodic ether, 99%
16.0.3 Trade Names:
NA
16.0.4 Molecular Weight:
155.97
16.0.5 Molecular Formula:
C_2H_5I
16.0.6 Molecular Structure:

16.1 Chemical and Physical Properties

Physical state	Colorless liquid that may become colored with iodine if exposed to the light
Specific gravity	1.9245 (25/4°C)
Melting point	–108.5°C
Boiling point	72.2°C
Vapor pressure	137 torr (25°C)
Refractive index	1.5076 (25°C)
Percent in “saturated” air	18 (25°C)

Solubility	0.4 g/100 mL water at 20°C; soluble in ethanol, ethyl ether, benzene, chloroform
Flammability	No flash point by standard tests in air, but can be made to combust

1 mg/L 156.7 ppm and 1 ppm 6.38 mg/m^3 at 25°C, 760 torr

16.1.1 General Colorless liquid that may become colored with iodine if exposed to the light

16.1.2 Odor and Warning Properties Ethyl iodide has an ethereal odor but may not be an adequate warning of excessive exposure.
16.2 Production and Use
Ethyl iodide is used in small quantities as a chemical intermediate. In the past, it had limited medicinal use.
16.4 Toxic Effects
Most of the information on the toxicity of ethyl iodide has been obtained because of the interest in this material for the treatment of fungus infections and for measurement of cardiac output. No new, relevant data were found since the third revised edition of this volume. It has been administered to humans as a vapor that, when inhaled, is absorbed by the lungs. It can cause CNS depression and may affect the kidneys, thyroid, lungs, and the liver.

16.4.1 Experimental Studies 16.4.1.1 Acute Toxicity Skin Absorption: Von Oettingen (7) cites a 1936 report by Schwander (207) that indicated ethyl iodide was absorbed through the skin, with deaths occurring 7 d after treatment.

Flury and Zernik (373) have reported the physiological effect of various concentrtations on mice. According to Reinhardt et al., who cite data by Herman and Vial, it was not possible to classify ethyl iodide as to its potency as a cardiac sensitizer based on the available data.

16.4.1.6 Genetic and Related Cellular Effects Studies Simmon and Poirier (319) tested ethyl iodide against *S. typhimurium* and *E. Coli* with positive mutagenic results.

Poirier et al. (320) indicate that when injected intraperitonially two to four times in 24 wk at a total dose of 38.4 mmol/kg, ethyl iodide did not result in an increase in lung adenomas in Strain A mice.

16.4.2 Human Experience Discussions of the response of humans to the therapeutic inhalation of the vapors of ethyl iodide are given in the publications of Blumgart et al. and Schwartz. These reports describe skin lesions and peripheral neuritis in patients.
16.5 Standards, Regulations, or Guidelines of Exposure
No standard has been established for ethyl iodide.
16.6 Studies on Environmental Impact
None found.

Saturated Halogenated Aliphatic Hydrocarbons Two To Four Carbons

17.0.4 Molecular Weight:
136.3
17.0.5 Molecular Formula:
$C_3H_5BR_2Cl$
17.0.6 Molecular Structure:
See attachment
17.1 Chemical and Physical Properties

17.1.1 General :

Physical state	Dense yellow or amber liquid. May also appear in granular form.
Specific gravity	209 (20/4°C)
Melting point	5°C
Boiling point	196°C
Vapor pressure	0.8 torr (21°C)
Refractive index	1.5518 (25°C)
Solubility	Less than 0.1 g/100 ml water at 20øC; Soluble in hydrocarbons, alcohols Percent in saturated air is 0.13 at 25°C
Flammability	Not flammable by standard tests in air

17.1.2 Odor and Warning Properties: Pungent odor at high concentrations. Unpublished data indicate the odor is perceptible at 0.01 ppm to 0.03 ppm (374). It appears doubtful that odor will provide significant warning to discourage excessive exposure, since 0.2 ppm was tolerable although disagreeable to a small series of test subjects.
17.2 Production and Use
DBCP is produced by liquid phase addition of bromine to allyl chloride It was first produced commercially in the United States in 1955.

DBCP is a contaminant of the flame retardant tris (2,3-dibromopropyl) phosphate, and was been used primarily as a soil fumigant to control nematodes. Unlike other halogenated nematocides, DBCP could be applied to soil without damaging perennials. Its use in the United States was canceled in 1979. However, it is still used in Hawaii for use on pineapples and in other places in the world.
17.3 Exposure Assessment
17.3.3 Workplace Methods Per the OSHA website, the primary sampling/analytical method is: media-petroleum base charcoal tube (100/50 mg sections, 20/40 mesh); sampling volume-10 liters; sampling rate-0.2 liters/min; analytical method-GC/ECD; Secondary analytical method: PID.

17.3.4 Community Methods A number of methods have been approved for the determination of DBCP in water. These include: AOAC Method 993.15; APHA Methods 6210-C and D, 6230-C and D; CLP Methods 6231-B and LC_VOA; EMSLC Methods 502.2, 504, 504.1, 524,1, 524.2 551 and 608.1 (375).

17.3.5 Biomonitoring/Biomarkers Although an increase in bromide ion in the blood of individuals exposed to DBCP is likely, the small quantities expected at acceptable levels of exposure would not be meaningful for assessing worker exposures (376).
17.4 Toxic Effects

Laboratory studies and human experience have shown DBCP to be a highly toxic material, particularly from chronic exposure. The testes, liver and kidneys appear to be particularly affected. A summary of the toxicity has been published (377). Much of the original data on acute and repeated studies in animals was initially determined by Torkelson et al (378).

17.4.1 Experimental Studies

17.4.2 Acute Toxicity Oral Single dose oral LD_{50s} for male rats have been reported as 170 and 300 mg/kg and for female mice as 260 and 410 mg/kg by two laboratories. Oral LD_{50s} of 210, 180 and 60 mg/kg were reported for male guinea pigs, male rabbits and unsexed chicks. Kidney degeneration and depressed body weight, which took a long time for recovery, were noted after single doses of 126 mg/kg to male rats (379). Slightly higher LD_{50} values were reported by Rakhumatullaev who noted CNS depression and incoordination following acute oral doses. Single oral doses of 100 mg/kg produced inhibition of the CNS system, prolonged weight loss, and decreased spermatogenesis (379).

Eyes Slight pain and irritation of conjuctiva and irises were observed in rabbits treated with a few drops of undiluted DBCP or a 1 percent solution in propylene glycol.

Skin Single applications did not appear to be more than slightly irritating to rabbit skin, but when applied repeatedly there appeared to be extensive necrosis in the dermis although the epidermis showed only slight crustiness.

Skin Absorption When applied to rabbits' skin for 24 hours, LD_{50s} of 1.4 and 0.5 g/kg have been reported for undiluted DBCP and a 10 percent solution in propylene glycol.

Inhalation Values of 368 ppm, 1hr; 323 ppm, 2 hr; 154 ppm, 4 hr; and 103 ppm, 8 hr were reported by one laboratory (378). In this same paper a second laboratory found DBCP to be somewhat more lethal to their strain of rats, with kidney injury and delayed deaths commonly observed. When rats given 15-7 hr exposures to 40 ppm, almost all died. Extensive injury was noted in the kidneys and testes. Six exposures produced poor health, loss of weight, lung congestion, cloudy swelling of the liver, and nephritis in groups of five male or female rats. The testes of one male appeared atrophied.

Intramuscular Injections Rats were reported to have survived two series of intramuscular injections each given 3 consecutive days (total six injections). The daily doses, 25 mg/kg in propylene glycol, did not produce significant alterations in body weight, lymphocyte counts, or in nucleated cells in formoral smears. These data appear somewhat inconsistent with the previously discussed effect of subacute inhalation exposure (378).

17.4.1.2 Chronic and Subchronic Toxicity Oral In a 90 day feeding trials, the lowest dose level causing a decrease in growth rate for female rats was 150 mg/kg and for male rats 450 mg/kg (380).

Daily oral administration of 70 mg/kg body weight to rats was lethal after 3 weeks of dosing. Degenerative effects were noted in the vascular system and in all internal organs. DBCP was given by gavage to 190 rats either in a dose of 10 mg/kg body weight (single dose) or in repeated doses of 10 mg/kg for 5 months. After the single dose, the animals developed nervous system depression and weight loss (381).

In another study by Kodama and Dunlap in which DBCP was fed as part of the diet, chronic toxicity was not as high as in other studies by gavage or inhalation. Rats fed diets containing 1350 ppm by weight of DBCP were injured but rats ingesting diets containing 450 mg DBCP per kilogram of diet showed only slight evidence of injury. A diet containing 150 mg/kg fed for 90 days produced retarded weight gain of female rats but otherwise was reported to have little effect on male and

female rats. The doses in milligrams per kilogram of body weight and the possible loss of DBCP by evaporation from the food prior to eating were not discussed (374).

Inhalation Torkelson et al. reported severe effects following 50 to 66 7-hr exposures of rats, guinea pigs, rabbits, and female monkeys to 12 ppm. Five ppm inhaled 7 hr/day for 70 days (50 exposures) produced severely decreased testicular weights in half the rats, with histological changes in the testes, kidneys, and bronchioles (376).

17.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms When a dose of 20 mg/kg of 1,2-dibromo-3-chloropropane-3-^{14}C was given orally, it was metabolized rather rapidly by male rats (382). Only traces (0.4 percent of the ^{14}C were excreted in the expired air as unchanged DBCP. Essentially all (98.8 percent) was absorbed from the gut and 90 percent of the activity was excreted in 3 days. During the first 24 hr, 49, 14 and 16.5 percent of the activity was excreted in the urine, feces, and expired air, respectively. The radioactivity in expired air was primarily carbon dioxide. The activity in the urine was in the form of an acidic metabolite (8 percent of the activity of the urine) or as a highly polar metabolite(s) (>90 percent of urinary activity). Some accumulation occurred in the body fat in the form of a metabolite.

Single subcutaneous injections of DBCP produced dose-dependent injury to kidney, testis, epididymis and liver in male rats. Pretreatment with enzyme inducer phenobarbital reduced the nephrotoxicity and hepatotoxicity of DBCP and resulting serum creatinine and urea nitrogen concentrations. Cobaltous chloride pretreatment enhanced the necrogenic effect of DBCP on the kidney and potentiated DBCP-induced elevations of serum creatinine and urea nitrogen concentrations. The gonadotoxicity of DBCP was enhanced by cobaltous chloride and reduced by phenobarbital. The modulating effects of cobaltous chloride and phenobarbital could not be ascribed simply to changes in tissue concentration of the protective conjugation substrate glutathione, since cobaltous chloride increased and phenobarbital did not alter renal and hepatic nonprotein sulfhydryl concentrations (383).

Rats treated orally with DBCP excreted a small amount of 2-bromoacrylic acid. Rabbit liver microsomal oxidases also yielded 2-bromoacrylic acid from DBCP. The conversion involves initial enzymic sulfoxidation or hydroxylation at methyl chloride moiety (CH_2Cl) substituents and then facile nonenzymic reaction to liberate 2-haloacroleins which are further oxidized to the 2-haloacrylic acids. 2-Haloacroleins as potent mutagens and intermediary metabolites may contribute to the adverse toxicologic properties of DBCP (384).

Male rats were challenged with a single dose of DBCP showed a significant decrease in cytochrome p450 in microsomes isolated from liver, kidney, testis, lung and small intestine mucosa 48 hr after treatment. Lipid peroxidation was not found in hepatic microsomes. In liver tissue, treatment resulted in decrease in cytochrome p450 in both rough and smooth microsomal fractions and nuclei, but not in mitochondrial fractions. Mixed function oxidase activities in hepatic microsomes decreased parallel with cytochrome p450 content. Thus, treatment with alkyl halides may preferentially affect isozymes of cytochrome p450 (385).

Following intraperitoneal administration of 50 mg/kg of DBCP to rats in propylene glycol, S,S'-(2-hydroxypropane-1,3-diyl) bismercapaturic acid and S-(2,3-dihydroxypropyl)mercapturic acid were found as metabolites in urine. The metabolic pathway for DBCP includes oxidation and hydrolysis to a series of epoxide metabolites and formation of male anti-fertility agents alpha-chlorohydrin and alpha-bromohydrin from epoxides. Subsequent oxidative metabolism of these latter two compounds to oxalic acid presumably causes liver damage (386).

17.4.1.3.1 Adsorption Male Wistar rats were orally given 20-400 mg/kg (387) ^{14}C labeled DBCP. Major sites of radioactivity were found in the liver and kidney. It is suggested by the authors that the macromolecular binding *in vivo* is caused by an activated metabolic intermediate formed on the

microsome (387).

17.4.1.4 Reproductive and Developmental Following repeated treatment by gavage in either doses of 100 mg/kg body weight or repeated doses on 10 mg/kg body weight to rats for 5 months, an effect on spematogenesis was observed in males: the number and viability of spermatozoa were decreased; the estrus was inhibited in females (381).

Male rabbits exposed to 10 ppm DBCP for 8 weeks by inhalation appeared infertile when mated during the 14th week (388).

Male rabbits, about 14 weeks old were exposed continuously to 0.3 to 10 ppm DBCP. Hypertrophy of the adrenals and marked weight reduction of epididymis, testes and seminal vesicles were observed. Reduction in number of spermatozoa in epididymis and reduction in white blood cells also occurred (389).

Although DBCP has a pronounced effect on the male reproductive system, it was not teratogenic when given to female rats at dosages of 0, 12.5, 25, or 50 mg/kg body weight on days 6 through 15 of pregnancy. The investigators reported it was toxic to dams and fetuses at 50 and 25 mg/kg but not at 12.5 mg/kg (390). Reznik and Sprinchan reported that the estrus cycle of female rats was affected by doses of 10 mg/kg fed repeatedly for 4 to 5 months. Morphological changes have not been reported in the ovaries but these authors suggest that decreased hormonal secretion by the ovary produces the altered estrus cycle (391).

The report by Torkelson et al. (378) of severe testicular injury has been confirmed by numerous other investigators (379, 388, 391, 392, 393, 394). The papers by Burek et al (394) and Rao et al (388) indicate significant species differences, with rabbits more sensitive than rats. Male rabbits were exposed 6 hr/day, 5 days/week to 0, 0.1 or 1.0 ppm (14 weeks) or 10 ppm (2 and 8 weeks). Male and female rats were exposed for 14 weeks to 0, 0.1, 1 or 10 ppm DBCP vapor. Two weeks of exposure of rabbits to 10 ppm produced detectable testicular alterations principally on spermatogenesis. Sertoli cells were unaffected in these animals. Six to 8 weeks of exposures to 10 ppm produced nearly complete atrophy of the germinal tissue of rabbits. Rats, on the other hand, showed no detectable changes after similar exposure to 10 ppm for 5 weeks and only moderate alterations after 14 weeks. There was considerable variation between individual animals. At 1 ppm, rats showed no testicular atrophy after 14 weeks but rabbits were moderately affected. At 0.1 ppm, no effect was seen microscopically in either species, but an equivocal, apparently reversible increase in abnormal sperm was seen by electron microscopy of the testes of the rabbits but not of the rats (394). Reproduction was severely impaired at the higher concentrations, as would be expected from the marked effect observed on sperm counts. Furthermore, a dominant lethal effect was observed when male rates exposed to 10 ppm were mated with unexposed females. This effect was reversible since subsequent matings did not show this effect.

17.4.1.5 Carcinogenisis Two groups of 50 male and 50 female B6C3F_1 hybrid mice, 5 to 6 weeks old were fed technical grade DBCP in corn oil by gavage on 5 consecutive days/week. Approximate time weighted average doses were 114 and 219 mg/kg for males and 110 and 209 mg/kg for females. Two groups, each of 20 males and 20 females were used as vehicle controls. Animals were killed at 60 and 78 weeks and high dose animals at 47 weeks because of high mortality related to tumors. In males, 40/50 of the high dose group had died by end of week 47 and 42/50 of the low dose group had died by week 59. In females, 30/50 of the high dose group had died by end of week 47 and 41/50 of the low dose group. By week 60, squamous cell carcinomas of forestomach occurred in 43/46 low dose males, 47/49 high dose males, 50/50 low dose females and 47/48 high dose females. This lesion occurred with frequent metastases to abdominal viscera and lung. No gastric neoplasms occurred in either vehicle or untreated controls (381).

When fed by gavage to male and female rats and mice in a NCI bioassay program, DBCP had been

shown to produce tumors. The high exposure rats were given 24 to 30 mg/kg per day and the low dose rats 12 to 15 mg/kg per day. The dosage to mice was changed during the study so that daily doses ranged from 160 to 260 mg/kg per day as well as half these levels (low dose) in male mice, and 120 to 160 mg/kg per day and half these levels (low dose) in female mice. Treatments were given 5 days/week for 78 weeks. Tumors were present after 10 weeks of treatment. Ultimately 90 percent of the mice and 60 percent of the rats developed squamous cell carcinomas of the forestomach. A high incidence (54 percent) of mammary adenocarcinomas was observed in female rats but not in mice (395). These results have been confirmed in subsequent studies in which DBCP was administered to rats and mice in the diet, by gavage or by inhalation.

17.4.1.6 Genetic and Related Cellular Effects Studies DBCP was evaluated for genotoxicity in the mouse spot test. Male PW mice, homozgous for 5 coat mutation, were mated with C57BL/6 females. On day 10 of the pregnancy, the females received ip injections of 106 mg/kg DBCP dissolved in soybean oil. The offspring were examined for recessive color spots for 14-30 days following birth. Pups from treated animals showed a significantly higher frequency (2.9%) of recessive color spots compared with solvent treated (0.6%) or untreated (0.9%) controls. Most of the spots induced by DBCP were light brown, which suggest that DBCP induced predominately point mutations in the pigment cells. It was, therefore, concluded that DBCP is mutagenic in somatic cells of mice *in vivo*; however, no teratogenic effects were observed (396).

DBCP has been found to be mutagenic in bacterial test systems using S. typhimurium TA 1530 and E. coli but is quite toxic to the latter. The dominant lethal effects reported by Rao et al (388) also suggest mutagenic changes in mammals.

17.4.2 Human Experience

17.4.2.1 General Information In the July 1977, a worker at a chemical plant in California noted and complained of his inability to father a child. During discussions with fellow workers, it was discovered that several other workers were having a similar problem. These workers were tested and found to be sterile. As a result of this testing, the Oil, Chemical and Atomic Workers (OCAW) union requested the National Institute for Safety and Health (NIOSH) to conduct a health hazard evaluation of their plant. Subsequent to, OSHA alerted approximately 80 manufacturers and formulators to the potential hazard of worker exposures to DBCP.

17.4.2.2 Clinical Cases Investigations in the health effects of DBCP began in 1977. Since that time, a number of studies have confirmed the toxic nature of DBCP.

17.4.2.2.1 Acute Toxicity In humans, DBCP produces moderate CNS depression and pulmonary congestion after exposure by inhalation and causes acute gastrointestinal distress and pulmonary edema after ingestion (397).

17.4.2.2.4 Reproductive and Developmental Five to eight years after the initial effects of DBCP exposure were discovered in 1977 and all exposures were terminated, there appeared to be no major changes in testicular function of most of the 44 exposed men as measured by sperm concentration or serum FSH levels. Recovery of sperm production in two of eight originally azoospermic workers was observed and no increase in sperm production could be detected in the other men who had low sperm counts (398).

A group of 22 factory workers who were exposed to DBCP during production were reassessed 8 years after being diagnosed as azoospermic (388) or oligozoospermic (380) when initially evaluated in 1977. A follow-up study after 4 years had indicated that the gonadotoxic effects of DBCP might be reversible. The objective of the eight year reassessment was to confirm this effect as well as to assess the outcome of pregnancies among wives of DBCP exposed workers. It was observed that recovery of spermatogenesis occurred in 4 oligozoospermic and 3 azoospermic men whose plasma FSH hormone concentration was normal during the whole period. A marked increase in this hormone and luteinizing hormone levels above the upper limit of normal was found in azoospermic men who did not recover. No significant changes in FSH hormone levels were detected in both

recovered and non-recovered oligozoospermic workers. It was also concluded that paternal exposure to DBCP was not associated with increased risk of fetal malformations or spontaneous abortions. There were 44 conceptions; 22 occurred during paternal exposure to DBCP and 22 during the recovery period. These 44 conceptions resulted in 36 live births (and one ongoing uncomplicated pregnancy). The spontaneous abortion rate did not differ from the frequency found in the re-exposed or non-exposed pregnancies. The 3 induced abortions were not related to paternal DBCP exposure (399).

Kapp et al (399a) have reported Y-chromosomal nondisjunction in DBCP exposed employees but these data were not confirmed at the time. The Y-chromosome counts were made on ejaculates with extremely low sperm counts; the control sample was from a different location, and the statistical methodology was questioned.

17.4.2.3 Epidemiology Studies The mortality experience of a cohort of 548 workers who had potential exposure to DBCP was updated in 1989. There were 68 total deaths compared with 72.1 expected. There 19 deaths from all malignancies compared to 19.0 expected. There no deaths from stomach, liver, kidney, testes or nasal cavity cancers. There were 7 deaths from cancer of the lung compared with 6.6 expected (400).

A historical prospective mortality study was conducted on 3579 white male workers employed between 1935 and 1976 with potential exposures to brominated compounds, including DBCP. Workers were classified by their work areas or departments to estimate their potential exposures. A significant excess due to diseased of the circulatory system was observed among the workers exposed to DBCP (401).

17.5 Standards, Regulations or Guidelines of Exposure
There is inadequate evidence in humans for the carcinogenicity of DBCP. There is sufficient evidence in experimental animals for its carcinogenicity. According to IARC, the overall evaluation of DBCP is that of a possible carcinogen to humans (Group 2B) (402).

The OSHA permissible exposure limit is 1 ppb DBCP as an 8 hr time weighted average (403). NIOSH recommends that occupational exposures to carcinogens be limited to the lowest feasible concentration (404).

17.6 Studies on Environmental Impact
Since the restrictions on the use of DBCP in 1979 as a nematocide and soil fumigant, little release of DBCP presently occurs. The use of DBCP as a laboartory reactant is not expected to result in large quantities being released to the environment. If released to the atmosphere, DBCP will exist solely in the vapor phase in the ambient atmosphese based on measured vapor pressure of 0.58 mm HG at 20° C. Vapor phase DBCP is degraded in the atmosphere by reactionwith photochemically produced hydroxyl radicals with an estimated half life of 37 days. Products of DBCP are formed during this

process.

DBCP released to soil will likely volatilize or leach. In alkaline, but not neutral or acidic soils, hydrolysis may be significant. Biodegradation is possible but is expected to be slow relative to volatilization and leaching.

In water, DBCP is expected to volatilize. It may also hydrolyze. Esitmated volatilzation half lives for a model river and model lake are 14 hours and 9 days, respectively. In groundwater after DBCP is expected to persist due to its low estimated rate of hydrolysis. In surface waters, biodegradation may occur but is expected to be slow relative to the rate of volatilization. Photodegradation is not expected to be an important fate process for this compound. Sorption to sediments and bioconcentration are not expected to be important fate processes based on measured Koc values of 40-149 and measured BCF values of 3.6-19, respectively. Human exposure is expected to result primarily from ingestion of drinking water, particularly from ground water sources containing DBCP (405).

Unsaturated Halogenated Hydrocarbons
R. A. Lemen, Ph.D., MSPH

1.0 1,3-Dichloropropene
1.0.1 CAS Number:
[*542-75-6*]
1.0.2 Synonyms:
3-Chloroallyl Chloride; 3-chloropropenyl chloride; Telone®; Telone II Soil fumigant; 1,3-dichloropropylene; alpha-chloroallyl chloride; chloroallyl chloride; 1,3-dichloro-1-propene; Telone II; alpha, gamma-dichloropropylene; gamma-chloroallyl chloride; 1,3-dichloropropene (mixed isomers); 1,3-dichloro-1-propylene; 1,3-dichloropropene-1; dorlone ii; Tri-Form; 1,3-D; Telone IIR; chloropropenyl chloride; 1,3-dichloro-2-propene; 1,3-dichloropropene, E-Z-; 1,3-Dichloropropene (mixed)
1.0.3 Trade Names:
cis,*trans*-1,3-Dichloropropene, DD*f* Soil Fumigant (Shell Chemical Company), Telone*f* Soil Fumigants (The Dow Chemical Company), Vorlex*f* Soil Fumigants (Schering, A. G. Berlin/Bergkamen)
1.0.4 Molecular Weight:
110.98
1.0.5 Molecular Formula:
$C_3H_4Cl_2$
1.0.6 Molecular Structure:

1.1 Chemical and Physical Properties

1.1.1 General (1) Although a product that contains primarily *cis* isomer is available, 1,3-dichloropropene isomers are not commonly separated. Commercial products often contain varying amounts of other C_3 compounds and epoxy inhibitors. Hence the following data for a 92% material must be considered only approximate.

Physical State	colorless to light straw-colored liquid
Specific Gravity	1.22
Melting Point	–60°C
Boiling Point	104°C 104.3°C (*cis*) 112°C (*trans*)
Vapor Pressure	5720 Pa at 25°C (*cis*); 4522 Pa at 25°C (*trans*) (2)
Relative Vapor Density	3.83 (air = 1) (2)
Percent in "Saturated" Air	3.7 at 25°C
Solubility	<0.01 g/100 ml in water; soluble in acetone, diethyl ether, benzene, chloroform, octane, and toluene (2, 3).
Flash Point	27°C
Explosive Limits	5 to 14.5% at 80°C

1.1.2 Odor and Warning Properties Rick and McCarty (4) reported that an odor concentration of 4.4 ppm to 3.1 ppm (mean ñ SD) was detected by 22 persons. Concentrations that can cause injury from a single exposure will probably have an odor detected by most people; however, the odor cannot be relied upon to warn against concentrations that can cause injury from prolonged repeated exposure. The odor is sharp, penetrating and irritating (3).

1.2 Production and Use

The *cis* and *trans* isomers of 1,3-dichloropropene are used primarily in soil fumigants. A small amount is used as a chemical intermediate. Exposure occurs principally during manufacture or during bulk handling activities. Because it is generally injected into the soil at depths of 15 to 30 cm, airborne concentrations are generally well below 0.5 ppm, even when measured in the middle of a fumigated field. The material is flammable.

1.3 Exposure Assessment

1.3.1 Air Indoor air in Knoxville, TN contained 52.4 mg/m^3 during the winter and outside the mean was 5.0 mg/m^3 (2).

1.3.2 Background Levels 1,3-Dichloropropene is not a natural product, and its presence in the environment results from industrial use.

1.3.5 Biomonitoring/Biomarkers It seems unlikely that analysis of blood urine or expired air will be of significant value for industrial hygiene monitoring at currently accepted levels of exposure but may help determine if exposure has occurred.

1.4 Toxic Effects

1.4.1 Experimental Studies The subchronic inhalation toxicity data for 1,3-dichloropropene are contradictory. Older data indicate that the commercial product studied at that time (1958–1975) was quite irritating and hepatotoxic, but data developed on currently produced fumigants indicate considerably less hepatotoxicity. Although impurities and inhibitors in the samples used in older toxicity studies may account for part of the discrepancy, different strains of animals, different animals' diets, and different methods of handling the samples used in recent studies may also explain

the difference. It is reasonable to rely more on the more recent data, which has been obtained with improved methods and with samples of better characterized purity. Reviews are available (5, 6).

1.4.1.1 Acute Toxicity A 10% solution of a *cis* and *trans* mixture of 92% purity (8% related compounds) had acute oral LD_{50}s of 710 and 470 mg/kg in male and female rats, respectively. The livers and kidneys of treated animals were grossly affected and there was a suggestion of lung injury in surviving animals (7). Stott et al. (8) reported oral LD_{50}s of 640 mg/kg for male and female mice, 300 to 713 mg/kg for male rats, and 224 to 560 mg/kg for female rats.

Severe to moderate injury occurred in the eyes of rabbits in which a couple of drops of liquid 1,3-dichloropropene had been placed. Prompt washing with water greatly reduced the degree of irritation. The vapors were quite irritating to the eyes and caused lacrimation (7). When a more recent sample was tested, marked conjunctival irritation and discharge were noted and some reddening of the iris. All irritation subsided in 14 days (8).

Necrosis and edema occurred when liquid 1,3-dichloropropene was confined on the skin of rabbits, but if it was allowed to evaporate, the effect was greatly reduced. Positive guinea pig skin sensitization was reported using a 0.1% v/v solution in mineral oil (6), an atypical response for a small chlorinated hydrocarbon.

Absorption through the skin occurred particularly when the liquid was confined or when it was dissolved in propylene glycol, which retarded evaporation. A 24 h LD_{50} for dermal exposures to 333 mg/kg under a cuff was been determined. Higher dermal LD_{50}s of 1000 mg/kg for males and between 1300 and 2000 for females were determined for rats. Fourteen days after treatment, there was congestion of the lungs and congestion of the viscera was apparent in animals that died (6).

According to a 1967 publication by Torkelson and Oyen (7), 2700 ppm was extremely irritating to the respiratory tract and caused liver and kidney injury in rats. Rats survived a 1 h exposure but died from a 2 h exposure to 1000 ppm of the vapor. These rats and others exposed to 700 ppm had a peculiar garlic (or skunk) odor following exposure, indicating probable absorption and possible reaction of the 1,3-dichloropropene with the hair or skin of the rats. Guinea pigs, but not rats, succumbed following a single 7 h exposure to 400 ppm; the rats, however, were severely injured, lost weight, and required 8 days to recover lost weight. Lung injury was still present 8 days after exposure.

When a more recent sample was studied, 4 h inhalation LC_{50}s between 1035 and 855 ppm for male rats and 905 ppm for female rats were determined (8). All rats exposed to 1000 ppm for 4 h died, as well as one female exposed to 850 ppm. Eye and nasal irritation were observed, as well as decreased body weight. Although body weight had not returned to normal at the end of the 2 week observation period, there were no exposure-related observations at gross autopsy. These investigators also reported a strong odor, described as mercaptan-like in rats and mice exposed to 90 or 150 ppm.

In an early subacute study to define the conditions for a subsequent chronic study, Torkelson and Oyen found considerable liver and kidney injury grossly evident in small groups of rats exposed 19 times to 50 ppm, 7 h/day in a 28-day period. Less injury from these early chemical samples was seen at 11 ppm (7).

However, much less toxicity was observed from a later sample tested by Stott et al. (8), according to the authors' abstract.

To provide a comprehensive subchronic inhalation toxicity study of the soil fumigant, technical grade 1,3-dichloropropene (DCPT), male and female Fischer 344 rats and $B6C3F_1$ mice were exposed to 0, 10, 30, 90, or 150 ppm DCPT vapors for 6 h/day, 5 days/week for 13 weeks. The

primary target tissues of inhaled DCPT were identified as the nasal mucosa of both sexes of rats and mice and the urinary bladder of female mice. In addition, depressed growth rates of all animals exposed to 90 or 150 ppm DCPT (up to 20% in rats and 12% in mice) resulted in a variety of alterations in hematologic and clinical chemistry parameters and changes in organ weights relative to controls. Nasal mucosal effects consisted of a slight dose-related degenerative effect on nasal olfactory epithelium or a mild hyperplasia of the respiratory epithelium or both in all animals exposed to 90 or 150 ppm and 2 of 10 male rats exposed to 30 ppm DCPT. Some focal areas of respiratory metaplasia were also noted in high-exposure group mice. Urinary bladder effects consisted of a diffuse, moderate hyperplasia of the transitional epithelium in female mice exposed to 90 or 150 ppm DCPT. No treatment-related effects were observed in rats or mice exposed to 10 ppm DCPT vapors.

Parker et al. (9) also found much less effect than Torkelson and Oyen in CD-1 mice and Fischer 344 rats exposed to 0, 5, 15, or 50 ppm for 6 h/day, 5 days/week for 6 or 12 weeks. Their test material was Shell DD*f* soil fumigant, which contained 55% 1,3-dichloropropene and 30% 1,2-dichloropropane. The balance was related compounds, according to the available abstract.

The following parameters were examined: pharmacotoxic signs; body weights; hematology (HGB, HCT, RBC, WBC, and diff. leukocyte count), serum chemistry (BUN, GLU, ALB, GPT, and ALP); urinalysis; gross pathology; histopathology; organ weights and organ weight/body weight ratios of brain, heart, liver, kidneys, testes or ovaries, and adrenals. The only exposure-related effect observed was increased mean liver weight/body weight ratios of male mice and rats and mean kidney/body weight ratios of female rats at the 50-ppm exposure level. Other statistically significant differences were either inconsistent or not dose-related. Slight to moderate diffuse hepatocytic enlargement in 12/21 of the 50-ppm male mice after 12 weeks exposure was the only compound-related histopathological change.

1.4.1.2 Chronic and Subchronic Toxicity When 1,3-dichloropropene was fed by gavage to groups of rats at 0, 1, 3, 10, or 30 mg/kg body weight for 6 days/week for 13 weeks, it was concluded that 3 to 10 mg/kg was a nontoxic effect level. No gross or microscopic pathological changes related to exposure were observed at any level, nor were general condition, demeanor, survival, hematologic indexes, serum enzyme, activity, or urinalysis affected by exposure. The relative weights of the kidneys increased at 30 mg/kg/day in both sexes and at 10 mg/kg/day in males (10). More recent data by Osterloh and Kiwen (11) suggest that the nephrotoxic effects of 1,3-dichloropropene may be mediated through the mercapturic acid metabolites in the kidney rather than glutathione depletion (2). Haut et al. (12) found a no-observed-adverse-effect of 5 mg/kg body weight for rats and 15 mg/kg body weight per day for mice.

1,3-Dichloropropene is included in the NCI bioassay program discussed under carcinogenesis in the next section, and a lifetime study on a microencapsulated sample is under way.

Four species of animals were exposed for 7 h/day, 5 days/week to either 3 or 1 ppm 1,3-dichloropropene in air for 6 months. This study used a sample available in 1977 (7). There was no effect in rats, rabbits, guinea pigs, or dogs exposed to 1 ppm (0.9 ppm recovered analytically) based on demeanor, general appearance, growth, mortality, hematologic examination, final body and organ weights, and gross and microscopic examination of all major organs. The kidneys of the males rats exposed to 3 ppm showed cloudy swelling, which was attributed to exposure. This effect was also seen in a small group of male rats exposed for 4 h/day, but not in rats exposed 2 or 1 h/day.

1.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms 1,3-Dichloropropene given either orally or via inhalation is absorbed rapidly and eliminated through metabolism (glutathione conjugation) within 24–48 hours (3).

1.4.1.4 Reproductive and Developmental Pregnant Fischer 344 rats and New Zealand white rabbits were repeatedly exposed to 0, 20, 60, or 120 ppm for 6 h/day on days 6 to 15 (rats) or 6 to 18

(rabbits) of gestation (13). There was no evidence of teratological effects despite obvious toxicity the pregnant dams. The authors' abstract states,

Exposure-related decreases in maternal weight gain and feed consumption were observed in rats at all treatment levels. Decreased weight gain was also observed among rabbits at 60 and 120 ppm. A slight, but statistically significant, increase in the incidence of delayed ossification of the vertebral centra in rats exposed in utero to 120 ppm of DCP was considered of little toxicologic significance in light of the maternal toxicity observed at this exposure concentration. No evidence of teratogenic or embryotoxic response was observed in either species at any exposure level tested. Thus, it was concluded that DCP was not teratogenic at exposure levels up to 120 ppm in either rats or rabbits.

A two-generation reproduction study in which rats were routinely given 6 h daily exposure, 5 days/week to 0, 10, 30, or 90 ppm was reported (14). Dams and nonpregnant females were not exposed from day 20 of gestation through day 4 of lactation. Toxic effects were seen only in the parents exposed to 90 ppm and consisted of decreased body weight and histological changes in nasal mucosa. Reproductive parameters, neonatal growth, and survival were unaffected at all levels, including 90 ppm.

When Shell DD fumigant that contained 28% *cis*-1,3-dichloropropene, 25.6% *trans*-1,3-dichloropropene, and 25.6% 1,2-dichloropropane was used in a single-generation study, adverse effects were observed only in the group of rats that inhaled 90 ppm (15).

The effects of inhaled D-D (1,3-dichloropropene/1,2-dichloropropane) on reproduction were studied in rats of both sexes. The rats inhaled nominal concentration of 0, 10, 30, or 90 ppm (v/v) D-D for 6 h/day, 5 days/week for 10 weeks. Treated males of proven fertility were paired with untreated virgin females at intervals during and after exposure. Treated females were paired with untreated males immediately after the 10-week exposure period. Various aspects of reproductive performance and general toxicity were assessed. Exposure to D-D produced no adverse effects on the libido, fertility, or morphology of the reproductive tracts of rats of either sex; no treatment-related dominant lethal effect was observed in male rats. Slight reduction in body weight gains and slight increases in liver and kidney weights were observed in 90 ppm rats of both sexes.

There were no treatment-related effects on testicular weight, sperm count, or sperm morphology in male mice given five injections of 10, 19, 38, 75, 150, 300, or 600 mg/kg intraperitoneally and examined 30 days later (16).

Possibly because of impurities or stabilizers in different samples, contradictory results have been obtained in *in vitro* and *in vivo* test systems. Highly purified 1,3-dichloropropene had no directly acting mutagenicity to *Salmonella typhimurium* TA100 (17). The investigators hypothesized that a minor oxidation product produced in purifying of previous samples was responsible for the direct mutagenic activity seen in some previous studies.

Furthermore glutathione, which is present in much higher concentrations in mammalian cells than in bacteria, has a detoxifying conjugative effect (18). The addition to standard bacteria test systems of a concentration of glutathione, equal to that present in mammalian cells, virtually eliminated mutagenic activity in *S. typhimurium* TA100 (19). In fact, many mammalian systems have produced negative results, including the Chinese hamster ovary HGPRT forward mutation assay, rat hepatocyte unscheduled DNA synthesis, mouse bone marrow micronucleus, and a dominant lethal study in rats (6, 15). It is important to develop a better understanding of the importance of

glutathione and the significance of bacterial test systems that are low in glutathione (18).

1.4.1.5 Carcinogenesis The IARC (2) has concluded that technical grade 1,3-dichloropropene (that contains 1.0% epichlorohydrin) administered by gavage caused urinary bladder, lung, and forestomach tumors in mice and in the liver and forestomach in rats. Further, it concluded that inhalation exposures resulted in bronchioalveolar adenomas in mice, whereas no tumors were seen in rats (2). After injection with the *cis* isomer, malignant tumors occurred at the site of injection (2). These findings led the IARC (2) to conclude that there is sufficient evidence for carcinogenicity in experimental animals, at least when tested with technical grade 1,3-dichloropropene (2).

Van Duuren (20) tested what was reportedly *cis*-1,3-dichloropropene and found it negative in an initiation-potentiation bioassay on mouse skin when tested with 7,12-dimethylbenzanthracene and phorbol myristate. It was not carcinogenic to the backs of Hs:ICR Swiss mice following 3 times/week application of 122 mg/kg for 85 weeks. Subcutaneous injections once a week increased local fibrosarcomas.

NTP (21, 22) tested a 92% commercial product that was stabilized with epichlorohydrin. It is not clear how much epichlorohydrin was present but the concentration may have been as high as 1.8%. Rats were fed 0, 25, or 50 mg/kg/day and mice 0, 50, or 100 mg/kg/day via gavage for 3 days/week for up to 2 years. Ancillary studies were conducted to determine the time-related effects on a group of rats treated for 9 to 27 months, according to the authors' summary.

The primary organs affected were forestomach (rats and mice), urinary bladder (mice), lung (mice), and liver (rats). Compound-related nonneoplastic lesions included basal-cell or epithelial hyperplasia of the forestomach (rats and mice), epithelial hyperplasia of the urinary bladder (mice), and hydronephrosis (mice). Neoplastic lesions associated with administration of Telone II included squamous-cell papillomas of the forestomach (male and female rats, female mice), squamous-cell carcinomas of the forestomach (male rats, female mice), transitional-cell carcinomas of the urinary bladder (female mice), alveolar/bronchiolar adenomas (female mice), and neoplastic nodules of the liver (male rats). Although *cis*- and *trans*-1,3-dichloropropene are the principal components of Telone II, the presence of 1% epichlorohydrin, a direct-acting mutagen and carcinogen added as stabilizer, may have influenced the development of forestomach lesions. The results of the ancillary studies supported the findings of the carcinogenesis studies and demonstrated the time-dependent development of lesions in the forestomach (basal-cell hyperplasia and squamous-cell papilloma).

Perhaps the most pertinent study is that of Lomax et al. (23), who exposed Fischer 344 rats and $B6C3F_1$ mice to 0, 5, 20, or 60 ppm (0, 22.7, 90.8, or 272 mg/m^3) technical grade 1,3-dichloropropene for 6 h/day, 5 days/week for up to 2 years. Ancillary groups were exposed for 6 to 12 months. Exposure resulted in nontumorigenic lesions of the nasal mucosa in both sexes of rats and mice exposed to 60 ppm and female mice exposed to 20 ppm, in the urinary bladder mucosa of both sexes of mice exposed to 60 ppm, and in the forestomach of male mice exposed to 60 ppm. Slight changes in the relative degree of cellular vacuolation in renal and hepatic tissues of male and female mice exposed to 60 ppm, respectively, were also observed following months of exposure. These changes were consistent with changes in the renal lipid and hepatic glycogen content of these mice and were considered related to depression of body weight and did not represent a toxicologically significant effect of exposure. However, in contrast to the results of the oral gavage bioassay, an increased incidence of benign lung tumors in the high-exposure group of male mice was the only tumorigenic response observed. The benign tumors did not progress to malignancy, nor did they have an effect on survival. This apparent difference in results between the lifetime gavage and the lifetime inhalation studies is striking, especially when the total daily dose 5 days/week by inhalation, based on respiratory rates and tidal volumes, would have been considerably more than that from the repeated boluses of oral dose given three times per week. Whether the response in the oral study was due to the administration of boluses or possibly due to some other factor such as the epichlorohydrin that had been added to the sample is not clear. It certainly suggests the need for

caution in extrapolating the results to humans, particularly in the light of the lack of mutagenic activity of 1,3-dichloroprene in mammalian cells. No-effect levels of 5 ppm for mice and 20 ppm for rats were found.

Gehring et al. summarized the available data on metabolism (6). Absorption occurs through the skin, from the gut, or by inhalation. Hutson et al. (24) fed ^{14}C-labeled 1,2-dichloropropane and both isomers of 1,3-dichloropropene to rats and found differences in their metabolism. With all compounds, 80 to 90% of the radioactivity was eliminated in the first 24 h. The major route of excretion of radioactivity was in the urine, where 50.2, 80.7, and 56.5% of the 1,2-dichloropropane, *cis*-1,3-dichloropropene, and *trans*-1,3-dichloropropene activity, respectively, were found. The amount of ^{14}C-carbon dioxide excreted was quite different for the two isomers. The *cis* isomer yielded only 3.9% of the dose and the *trans* isomer 23.6%, and correspondingly less radioactivity was in the urine. As expected with volatile compounds, residual unreacted compounds were not present as significant residues, although metabolites entered the normal metabolic pool. Subsequently Climie et al. (25) showed that 82 to 84% of the radioactivity of the ^{14}C-label at the second carbon was recovered in the urine of rats as *N*-acetyl-*S*-(*cis*-3-chloropropenyl)cysteine.

Both *cis* and *trans* isomers are eliminated rapidly by the rat (half-life less than 30 min) (26). A relatively small amount was found bound to macromolecules in the forestomach and to a lesser degree in the glandular stomach of rats and mice. Macromolecular binding correlated to dose- and time-related depression of nonprotein sulfhydryl of the stomach and liver (27, 28).

Excretion and distribution of 1,3-dichloropropene in rats fed up to 50 mg/kg was independent of dose. More than 80% was excreted in 24 h. Mice had a similar response at doses up to 100 mg/kg. Excretion in rat urine was primarily of the mercapturic acid conjugate and its corresponding sulfoxide, as it was in humans (28).

The *N*-Acetylcysteine conjugate of 1,3-dichloropropene was found in the urine of four men 24 h after field application of Telone II fumigant, consistent with similar findings in animal studies (16).

1.4.2 Human Experience 1.4.2.2.1 Acute Toxicity A brief case report was found in the literature. This article is of dubious value because it contains a significant amount of subjective evidence and presents inadequate control data (29). After accidentally drinking a solution containing a mixture of *cis* and *trans* isomers of 1,3-dichloropropene, a 27-year-old male died 40 hours later after experiencing gastrointestinal distress, adult respiratory distress syndrome, and hematologic and hepatorenal function impairment (30).

A fatality following ingestion reportedly involved abdominal pain and vomiting. The patient became semicomatose, exhibited muscular twitching, and died, despite gastric lavage and therapy for pulmonary edema (31).

1.4.2.2.5 Carcinogenesis In a case report (32) 1,3-dichloropropene and malignant lymphoma were associated in two firemen who died 7 years after a single exposure. A third person, a farmer, was included, but the authors failed to mention that he had been ill for some time before his alleged exposure. The authors correctly drew no conclusions as to cause and effect. IARC (2) concluded that there was no epidemiological data on the carcinogenicity of 1,3-dichloropropene in humans. However, based on the experimental animal data, IARC (2) place classified the technical grade 1,3-dichloropropene as possibly carcinogenic to humans and placed it in its 2B Group. 1,3-Dichloropropene has been classified as may reasonably be anticipated to be a carcinogen (33).
1.5 Standards, Regulations, or Guidelines of Exposure
OSHA has no PEL for 1,3-dichloropropene, whereas NIOSH considers it a carcinogen and recommends a REL of 1 ppm (5 mg/m^3) with a skin notation (34). The ACGIH has recommended 1 ppm as the TLV®, with skin and A4 notations; similar values have been used as guidelines and standards in other countries (35, 36). The WHO has recommended an international drinking water

standard of 20 mg/L (37).

Unsaturated Halogenated Hydrocarbons

2.0.5 Molecular Formula:
$C_2H_2Cl_2$
2.0.6 Molecular Structure:
cis-

; *trans*-

2.1 Chemical and Physical Properties
2.1.1 General (38)

Physical State	colorless liquid
Specific Gravity	1.284 (*cis*); 1.257 (*trans*)
Melting Point	–57°C; –81.5°C (*cis*); –49.4°C (*trans*)
Boiling Point	48–60°C; 60.3°C (*cis*); 48.0–48.5°C (*trans*)
Vapor Pressure	kPa at 20°C: 24.0 (*cis*); 35.3 (*trans*) 180–264°C (*cis*);
Percent in “Saturated” Air	27.4 at 20°C
Relative Vapor Density	3.4 (air = 1)
Solubility	poor in water, 0.50 g/100 mL; 0.08 g/100 mL (*cis*); 0.63 g/100 mL (*trans*); soluble in ethanol, ethyl ether
Explosive Limits	9.7 to 12.8% in air (*cis*)
Autoignition Temperature	460°C
Flash Point	6°C (c.c.); 2.2 to 3.9°C (c.c.) (*cis*); 6°C (*trans*) (c.c.)

2.1.2 Odor and Warning Properties No definitive data are available. The odor has been described as slightly acrid like a chloroform mixture of isomers.
2.2 Production and Use
The *cis* and *trans* isomers of 1,2-dichloroethylene have had only limited use as solvents and chemical intermediates. Neither of the isomers has developed wide industrial usage in the United States partly because of their flammability.
2.3 Exposure Assessment
2.3.3 Workplace Methods NIOSH Method 1003 is recommended for determining workplace exposures to the 1,2-dichloroethylene isomers (80).

2.3.5 Biomonitoring/Biomarkers The metabolisms of *cis*- and *trans*-1,2-dichloroethylene have been reviewed (39). Metabolism is thought to proceed via epoxidation through dichloroacetaldehyde to dichloroethanol and dichloroacetic acid. Cytochrome P450 is involved in the epoxidation (40, 41). There are differences in the rate of metabolism of the two isomers.

There are no data to evaluate biological monitoring in humans.
2.4 Toxic Effects
2.4.1 Experimental Studies Because neither isomer has found wide usage, toxicological data are limited. The compounds were studied as anesthetics, and von Oettingen (42) summarized the old data. However, some of these data must be considered suspect because the purity of the samples and the ratio of the isomers is not always indicated. Even recent data are inconsistent, and there are considerable variations among studies (39).

Unpublished data indicate low to moderate oral toxicity and rather large differences among studies. Unpublished data cited in the third revised edition of this publication reported an oral LD_{50} of more than 2000 mg/kg for a 60:40 *cis:trans* mixture. Fruendt et al. (43) reported an oral LD_{50} of 1275 mg/kg which was surprisingly low compared to an intraperitoneal LD_{50} of 7650 mg/kg reported for female Wistar rats by the same investigators. Fruendt et al. reported considerable pulmonary pathology, suggesting that some of the dosage may have been aspirated. Hayes et al. (44) reported feeding *trans* isomers to Sprague–Dawley rats and determining acute oral LD_{50}s of 7900 and 9900 for males and females, respectively.

Values of 2100 and 2400 mg/kg were determined for fasting mice gavaged with a 10% aqueous solution containing Emulphor (45). Deaths generally appeared to be due to anesthetic effects.

trans-1,2-Dichloroethylene was fed to rats and mice in drinking water studies (44). There was little effect when it was fed to mice for 14 days at daily doses of 21 and 210 mg/kg body weight. When it was fed for 90 days at average doses of 0, 17, 175, and 387 mg/kg to male mice and 0, 23, 224, and 452 mg/kg body weight to female mice, effects were described as minimal based on gross pathological, hematologic, and clinical chemical parameters. Histopathological examinations were not made, but cell-mediated immune status was reportedly unaffected in both sexes. Humoral immune response was not affected in female mice but was suppressed at all three dosages in male mice (46).

Immunotoxicity was evaluated by feeding *trans*-1,2-dichloroethylene (47) to Charles River CD-1 mice. LD_{50}s of 2221 and 2391 mg/kg body weight were determined for males and females, respectively. Deaths due to CNS depression occurred between 4 and 24 h after treatment. When fed by gavage for 14 days at 0.1 and 0.01 of the LD_{50} levels, there was no effect on body weight. Necropsy 24 h after the last dosing showed no changes in liver, spleen, lung, thymus, kidney, or brain weight. Serum lactic dehydrogenase, SGPT, and urea levels were unaffected. There was a nonstatistically significant trend toward reduction in the ratio of humoral IgM antibody forming cells to spleen red blood cells. When evaluated for cell-mediated immune response by using human serum

albumin, the mice showed a slight effect that was not dose-dependent.

Plaa and Larson (48) evaluated kidney toxicity in mice and concluded that both the *cis* and *trans* isomers were, at most, weak nephrotoxins.

When fed in drinking water to Sprague–Dawley rats for 90 days at doses of 402, 1314, and 3114 mg/kg body weight per day (male rats) and 353, 1257, and 2809 mg/kg/day (female rats), there were no compound-related effects on hematological, serological, or urinary parameters. Female rats showed a dose-related increase in kidney weight, but no gross or histological changes were found in either males or females (44).

The available data conflict on whether there is a significant difference between the toxicity of the two isomers. According to Smyth, the *cis* isomer did not kill or anesthetize rats in 4 h at 8000 ppm. At 16,000 ppm, they were anesthetized in 8 min and were killed in 4 h. He also states that the *trans* isomer was twice as toxic and anesthetic as the *cis* isomer (49), and that the important effect of inhalation is narcosis. Lehmann and Flury (50) reported that disturbance of equilibrium and prostration occur in approximately the same length of time from similar concentrations of the *cis* and *trans* isomers. Both slight narcosis and deep narcosis occurred with the *cis* isomer at concentrations of about half of the *trans* isomer.

More recently, Gradiski et al. (51) reported a 6 h LC_{50} of 22,000 ppm for mice exposed to the *trans* isomer, but Fruendt et al. (43) claimed adverse effects in rats that received a single 8 h exposure to 200 ppm of the *trans* isomer. Fruendt et al. reported that five of six rats had livers that appeared normal when stained for fat accumulation, but one showed fat deposition. Apparently, all six rats showed effects in the lungs, whereas only one control rat was similarly affected. These workers reported fibrous swelling in the cardiac muscle of rats exposed for 8 h to 3000 ppm. Fruendt's data are markedly inconsistent with other inhalation studies.

Fruendt and Macholz (52) reported that a single 8-h exposure to 200 ppm of either *cis*- or *trans*-1,2-dichloroethylene inhibited mixed-function oxidases in rats and the *cis* isomer was more active than the *trans* at high concentrations.

The concentration of 1,2-dichloroethylene required to cause anesthesia is not clear. No gross effects were seen in rats at 200 ppm (43), in several species at 1000 ppm (51), or in rats at 3000 ppm. Old data suggest that concentrations approaching 1 to 2% are required to cause surgical anesthesia in mice or other species (42).

Reinhardt et al. (53) concluded there were inadequate data on which to rank the ability of 1,2-dichloroethylene to sensitize the heart to adrenaline.

Intraperitoneal LD_{50}s of 6 mL/kg (7650 mg) (rats) and 3.2 mL/kg (mice) for the *trans* isomer were reported by Fruendt et al. (43), who surprisingly reported a lower oral LD_{50} (1 mL/kg) for rats.

2.4.1.2 Chronic and Subchronic Toxicity Lehmann and Flury (50) reported the results of repeated exposures of cats and rabbits to vapor concentrations of 0.16 to 0.19% in air. Animals exposed to the *cis* isomer at this concentration showed loss of appetite and some respiratory irritation but no histological changes.

Conflicting data exist on the chronic toxicity of 1,2-dichloroethylene. Torkelson, as cited in the Third Revised Edition of Patty's, reported no adverse effect in rats, rabbits, guinea pigs, or dogs exposed to either 500 or 1000 ppm for 7 h/day, 5 days/week for 6 months. The sample consisted of 60% *cis* and 40% *trans* isomers. The parameters studied included growth, mortality, organ and body weights, hematology, clinical chemistry, and gross and microscopic examinations of the major organs. In contrast, Fruendt et al. (43) claimed marked effects in rats exposed for 8 h daily, 5

days/week for 16 weeks to 200 ppm of the vapors of the *trans* isomer. Liver and lungs were affected and the leukocyte count decreased.

2.4.1.4 Reproduction and Developmental When *cis*- and *trans*-dichloroethylene isomers were incubated in the presence of metabolically active mouse liver enzymes, they were not mutagenic to *E. coli* K-12 or *S. typhimurium* (54, 55).

More recent data give mixed results in a variety of *in vitro* and *in vivo* test systems (39), and the *cis* isomer was apparently more active than the *trans* isomer. Chromosomal aberrations in a mouse bone and gene conversion in a mouse host-mediated assay have been reported (39).

No data on teratogenesis or carcinogenesis were found. *cis*- and *trans*- 1,2-Dichloroethylene have been scheduled in the NTP bioassay program, but no data are available.

2.4.2 Human Experience 2.4.2.1 General Information 1,2-Dichloroethylene was studied as an anesthetic in humans, apparently with some success. Only one old report of one fatality was found (56); death was probably due to anesthesia. Routes of exposure can be by inhalation and ingestion. Harmful contamination of the air is reached rapidly by evaporation at 20°C. Irritation of the eyes and respiratory tract can also occur and central nervous system effects, like narcosis (38) may occur at high levels.

2.4.2.2.2 Chronic and Subchronic Toxicity Long-term or repeated exposure can result in defatting of the skin (38).
2.5 Standards, Regulations, or Guidelines of Exposure
The TLV recommended by the ACGIH is 200 ppm (793 mg/m^3) (35). The NIOSH REL/OSHA PEL is also 200 ppm. The NIOSH IDLH is 1000 ppm.

Unsaturated Halogenated Hydrocarbons

3.0 Dichloroacetylene
3.0.1 CAS Number:
[*7572-29-4*]
3.0.2 Synonyms:
1,2-Dichloroacetylene; Dichloroethyne; DCA
3.0.3 Trade Names:
NA
3.0.4 Molecular Weight:
94.93
3.0.5 Molecular Formula:
C_2Cl_2
3.0.6 Molecular Structure:

3.1 Chemical and Physical Properties
3.1.1 General (57–59)
Physical liquid (or colorless gas at elevated temperatures)

State	
Melting Point	–66 to –50°C
Boiling Point	32–33°C
Solubility	insoluble in water; soluble in ethanol, diethyl ether and acetone
Flash Point	Spontaneously combustible; severe explosion hazard; Acetylene is used as a stabilizer; in the presence of trichloroethylene its stability is considerably increased

3.1.2 Odor and Warning Properties Dichloroacetylene has a disagreeable sour-sweet odor. Based on the experience in closed environmental systems, it is doubtful that dichloroacetylene has useful warning properties. No data were found for odor thresholds.

3.2 Production and Use

Dichloroacetylene is not commercially available in large quantities. It is reportedly a by-product of the synthesis of vinylidene chloride and is not known to be used commercially (58, 59).

Dichloroacetylene is a highly toxic, spontaneously combustible, undesired, and noncommercial product of the dehydrochlorination of trichloroethylene. It has resulted from exposure of trichloroethylene vapor to Hopcalite in a closed environmental system (submarine) and soda lime in closed circuit (rebreathing) anesthesia machines and from exposure of trichloroethylene liquid to caustic in degreaser tanks. It may also be an undesired by-product during chemical processes such as production of vinylidine chloride (60).

When dichloroacetylene was decomposed in the presence of oxygen, seven substances were found; phosgene, hexachlorobutadiene, chloroform, carbon tetrachloride, trichloroacetyl chloride, tetrachloroethylene, and trichloroacryloylchloride (60).

3.3 Exposure Assessment

3.3.1 Air Dichloroacetylene does not occur as a natural product (58, 59).

3.3.3 Workplace Methods No workplace measurement method is available (61).

3.3.4 Community Methods Dichloroacetylene has been measured in air over the range of 0.4–40 mg/m^3 using gas chromatography with electrolytic conductivity detection.

3.3.5 Biomonitoring/Biomarkers No data were found but in view of the high toxicity of dichloroacetylene, biological monitoring does not appear reasonable.

3.4 Toxic Effects

3.4.1.1 Acute Toxicity Dichloroacetylene is highly toxic and causes nausea; neurological, liver, and kidney injury; and liver and kidney tumors in rodents.

Reichert et al. (62) reported that the LC_{50}s for 1 and 4 h exposures of mice were 124 and 19 ppm, indicating that the vapor is highly toxic. Deaths were due to kidney injury. Degenerative lesions were found in the brain, a finding the investigators thought consistent with rather pronounced sensory loss and effects in facial muscles of humans. Reichert et al. reported similar injury in rabbits. Neuropathological changes were not found following a 2.25 h exposure of groups of rats to about 300 ppm dichloroacetylene (63). However, trigeminal somatosensory evoked potentials were significantly slower than baseline values or concurrent controls. Trichloroethylene/dichloroacetylene-exposed control animals were unchanged.

Rats were exposed for 6 h/day, 5 days/week for 6 weeks to dichloroacetylene at 2.9, 9.8, or 15.5 ppm in a dichloroacetylene–trichloroethylene mixture and for continuous 90 day exposure to 2.8 ppm dichloroacetylene (64). The trichloroethylene vapor concentrations were 3.2, 50, and 150 ppm during

the repeated exposures and 5.3 ppm during the continuous. Approximately 4 ppm acetaldehyde vapor was also present. Although no deaths were reported, rats exposed repeatedly to 9.8 and 15.5 ppm were unkempt in appearance and showed some respiratory distress. No signs of toxicity were seen during repeated exposure to 2.9 ppm, but rats exposed continuously were emaciated and showed weakness in the hind limbs. One rat appeared to be blind at the end of the exposure period. The most striking observation during microscopic examination was in the kidneys of rats exposed continuously to 2.8 ppm and repeatedly to 15.5 ppm. Effects in the lungs were less consistent and not clearly related to exposure. The course of development of the kidney changes with time has been studied in rats exposed continuously to 4.8 ppm for up to 28 days. In addition to rather marked injury to this organ, weakness in the hind legs, self-inflicted bite wounds, weight loss, and some deaths were observed.

Reichert et al. (65) also reported severe kidney injury and some deaths in rabbits exposed for 1 h to 126, 202, and 307 ppm or for 6 h to 17 to 23 ppm.

3.4.1.2 Chronic and Subchronic Toxicity The rat is mildly to markedly susceptible to dichloroacetylene-induced trigeminal nerve dysfunction, as assessed by trigeminal nerve-stimulated somatosensory evoked potential. The kidney is the likely target organ of exposure to dichloroacetylene (66). Data from longer term studies are reported in the section on carcinogenicity. Patel et al. (67) found that glutathione-dependent bioactivation of dichloroacetylene might be related to neurotoxic effect of dichloroacetylene. Barret et al. (68) found that, although dichloroacetylene had only a slight effect on the fatty acid content of the brain, it did have a higher intensity for inducing trigeminal nerve alterations.

3.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Glutathione conjugation has been shown in rats following inhalation of dichloroacetylene (69). These investigators reported the identification of *S*-(1,2-dichlorovinyl) glutathione (DCVG) as a product of the glutathione (GSH)-dependent metabolism of DCA *in vitro* and the identification of *N*-acetyl-*S*-(1,2-dichlorovinyl)-L-cysteine (N-Ac-DCVC) as a urinary metabolite of DCA in rats.

The product, DCVG, was definitively identified by ^{1}H-NMR spectrometry (400 MHz), mass spectrometry, and UV spectroscopy. N-Ac-DCVC was identified as a urinary metabolite from rats by GC/MS after esterification. Urine (collected for 24 h) from male rats exposed to 36 ñ 5 ppm DCA (100 mmol of DCA introduced into the exposure system) for 1 h contained 10.7 mmol of N-Ac-DCVC as determined by HPLC analysis. Formation of DCVG, renal processing to *S*-(1,2-dichlorovinyl)-L-cysteine, and cleavage of this cysteine S-conjugate by cysteine S-conjugate b-lyase in the kidney and the formation of reactive and mutagenic intermediates may account for DCA nephrotoxicity and nephrocarcinogenicity. N-Ac-CDVC is the end product of DCVG processing by the enzymes of mercapturic acid formation.

Using a nose-only dynamic system, Kanhai et al. (70) gave ^{14}C-dichloroacetylene to rats for 1 h at concentrations of 20 or 40 ppm. Retention rates of 17.6 and 15.6% of the radioactivity were reported for 20 and 40 ppm, respectively. Elimination of radioactivity was almost quantitative in 96 h. Elimination of radioactivity in urine was 67.8% at 20 ppm and 60% at 40 ppm. Elimination in feces was 27.5% at 20 ppm and 27% at 40 ppm. Only 3.4 to 3.5% remained in the carcass.

Metabolites in the urine were identified as *N*-acetyl-*S*-(1,2-dichlorovinyl)-L-cysteine, dichloroethanol, dichloroacetic acid, oxalic acid, and chloracetic acid. Only the cysteine conjugate was found in feces. It was formed in the kidneys because only *S*-(1,2-dichlorovinyl) glutathione was found in the bile. Biliary cannulation did not influence renal excretion of the cysteine conjugate.

They concluded that

the results suggest that two metabolic pathways are operative in dichloroacetylene metabolism *in vivo*. Cytochrome P450-dependent oxidation represents a minor pathway accounting for the formation of 1,1-dichloro compounds after chlorine migration. The major pathway is the biosynthesis of toxic glutathione conjugates. Organ-specific toxicity and carcinogenicity of dichloroethyne (acetylene dichloride) is due most likely to the topographical distribution of gamma-glutamyl transpeptidase which is concentrated mainly in the kidney of rats.

3.4.1.4 Reproduction and Developmental The reproductive organs have not been target organs in available studies.

Only limited data on the mutagenic potential of this very reactive compound were found (71). The investigators summarized their study which they concluded clearly demonstrated the mutagenicity of pure dichloroacetylene, as follows: DCA vapor was streamed under analytical control through the bacterial suspensions. DCA is soluble in aqueous solution and was stable under the experimental steady-state conditions of the bacterial exposure. There is a linear correlation between the supply of DCA vapor and solubilized DCA in the range of 1000 and 16,000 ppm. Mutagenic response was observed with strain TA100 if the bacteria were suspended in Oxoid medium. No mutagenicity was detected with strain TA98. DCA mixtures with acetylene, as used as a stabilizer for animal experiments, were not mutagenic in either bacterial strain with or without S9 mix in the cell suspension. One of the degradation products of DCA, trichloroacryloyl chloride, showed pronounced mutagenic properties with and without drug-metabolized enzymes. Other degradation products of DCA, such as trichloroacetyl chloride and hexachlorobutadiene, were not mutagenic, with or without liver homogenate.

3.4.1.5 Carcinogenesis The IARC (58, 59) concluded that there is limited evidence for the carcinogenicity of dichloroacetylene to experimental animals based on treatment-related increases in the incidence of adenocarcinomas of the kidney in male mice, benign tumors of the liver and kidney, and an increased incidence of lymphomas in rats.

Kidney tumors were the most significant carcinogenic response reported in an inhalation study of rats and mice (72). The investigators summarized their data as follows: Groups of 30 male and 30 female rats and mice were exposed to DCA vapor under the following conditions: mice, group I: 9 ppm for 6 h/day, 1 day/week for 12 months; group II: 2 ppm for 6 h/day, 1 day/week for 18 months; group III: 2 ppm for 6 h/day, 2 days/week for 18 months; rats: 14 ppm for 6 h/day, 2 days/week for 18 months; controls: under identical conditions except for the addition of DCA to breathing air. The most important result is a striking increase in the formation of kidney cystadenomas of the proximal tubuli in all DCA-exposed animals. The median latency time of this tumor varied widely in both mice and rats. Renal cystic adenocarcinomas were found in statistically significant numbers in male mice. In addition to kidney tumors, the development of cystadenomas of the Harderian gland in mice and of liver cholangiomas in rats were highly significant findings. DCA failed to induce liver tumors in mice. Our results confirm that DCA possesses high carcinogenic potential, pronounced organotropic properties, and distinct species differences for the number and nature of the induced tumors. The risk associated with handling chlorinated aliphatic hydrocarbons is essentially increased by the decomposition product, DCA.

The investigators commented on the rapid induction of tumors at low concentrations and in only 1 to 2 days/week of exposure. Cystic adenocarcinomas were found in 42% of the male mice after exposure to 2 ppm for 1 day/week for 18 months.

3.4.2 Human Experience 3.4.2.2.2 Acute Toxicity Deaths possibly due to kidney injury have been reported. Defolgue (73) summarized human experience during anesthesia from trichloroethylene before 1961. IARC (59) has summarized more recent data, most of which has come from Henschler and co-workers in Wurzburg, Germany, who concluded that dichloroacetylene “possesses the

highest carcinogenic potential of all representatives of the class of chlorinated, aliphatic hydrocarbons" and "that it is by far the most toxic compound of this class of xenobiotics" (72).

Deaths ascribed to dichloroacetylene have been reported following use of trichloroethylene with soda lime in closed-circuit anesthesia machines, but the precise inhaled concentrations were not determined (64). Saunders (74) described human experience in an incident in a closed environmental system in which alkaline materials were present in the life support system.

3.4.2.3 Epidemiology Studies 3.4.2.3.1 Acute Toxicity Dichloroacetylene can cause headaches, dizziness, nausea, vomiting, eye irritation, mucous membrane irritation, and neurological disorders such as paresis and neuralgia in several cranial nerves. Nausea has occurred at concentrations as low as 0.5 to 1.0 ppm.

3.4.2.3.2 Chronic and Subchronic Toxicity The toxic effects were mainly neurological and could last from several days to years (58, 59).

3.4.2.3.5 Carcinogenisis The IARC (58) could not find data by which to classify dichloroacetylene for its carcinogenicity to humans.
3.5 Standards, Regulations, or Guidelines of Exposure
OSHA has no PEL for dichloroacetylene, whereas NIOSH recommends treating it as a carcinogen that has a ceiling REL of 0.1 ppm (0.4 mg/m^3) (61). The TLV for dichloroacetylene recommended by the ACGIH is a ceiling of 0.1 ppm (0.39 mg/m^3) with an A3 notation (35). The ILO (75) indicates that the standards and guidelines are similar for other countries, and no international drinking water standard exists (37).

Unsaturated Halogenated Hydrocarbons
R. A. Lemen, Ph.D., MSPH

4.0 Allyl Chloride
4.0.1 CAS Number:
[*107-05-1*]
4.0.2 Synonyms:
3-chloropropene; 3-chloropropene-1; 3-chloro-1-propene; 1-chloro-2-propene; chloroallylene,; chloropropene; 3-chloropropylene; alpha-chloroproplylene; 3-chloroprene; 1-chloro propene-2; 3-chloro-1-propylene; 2-propenyl chloride
4.0.3 Trade Names:
NA
4.0.4 Molecular Weight:
76.526
4.0.5 Molecular Formula:
C_3H_5Cl
4.0.6 Molecular Structure:

4.1 Chemical and Physical Properties (76)

Physical State	colorless yellow, or purple liquid

Specific Gravity	0.9376 at 20/4°C
Melting Point	–134.5°C
Boiling Point	44.6°C
Vapor Pressure	39.3 kPa at 20°C
Relative Vapor Density	2.6 (air = !)
Refractive Index	1.4155 (20°C)
Percent in “Saturated” Air	48 at 25°C
Solubility	0.337 g/100 mL in water at 20°C; miscible with ethanol, ethyl ether, and chloroform
Flash Point	–31.7°C (c.c.)
Explosive Limits	3.3 to 11.1% in air
Autoignition Temperature	390°C

4.1.2 Odor and Warning Properties Allyl chloride can be a yellow or purple liquid that has an unpleasant and pungent odor. Shell Chemical Company published the following information in its bulletin (77). The odor threshold for half of the people was 0.47 ppm in air. The odor threshold for essentially all people was 25 ppm. Eye irritation occurs between 50 and 100 ppm. Nasal irritation and pulmonary discomfort may be observed at levels below 25 ppm.

Another study reports a 50% response to 0.21 ppm and a 100% response to 0.5 ppm. A third study reports that a definite odor was detected by 10 to 13 volunteers exposed to 3 ppm (78).

Odor may be considered a warning of levels hazardous from acute exposure, but allyl chloride is not detected at low enough concentrations to warn of levels hazardous from chronic exposure.

4.2 Production and Use

The major use of allyl chloride is as a chemical intermediate for resins and polymers. About 90% is used to make epichlorohydrin, the basic building block for epoxy resins, and in glycerol synthesis (79). Allyl chloride is flammable. World production in 1989–1990 was estimated at 500–600 thousand tons per year, and production facilities were located in South America, China, Europe, and the United States (79).

4.3 Exposure Assessment

4.3.1 Air Few data are available for allyl chloride in the environment (79).

4.3.3 Workplace Methods Allyl chloride can be measured in the workplace by using a solid sorbent tube (coconut shell charcoal, 100 mg/50 mg) and using the gas chromatography, FID technique. The working range is 0.16 to 3 ppm (0.5 to 10 mg/m^3) for a 100-L sample. The method is applicable to short-term samples taken at 1 L/min (80).

4.3.5 Biomonitoring/Biomarkers No data were found that would indicate the utility of biological monitoring, and it appears doubtful if it would be useful at the exposure level acceptable to workers.

4.4 Toxic Effects

4.4.1 Experimental Studies Although older data indicate that allyl chloride is moderate in acute toxicity and high in chronic toxicity, data recently derived for rats and mice indicate considerably lower liver and kidney toxicity. The effects are primarily due to inhalation, which can produce respiratory irritation, as well as liver and kidney injury. Effects on the pancreas have been alleged, but this has not been confirmed. Skin contact can produce irritation and a deep-seated pain referred to as “deep-bone ache.”

There are reports of polyneuropathies in exposed workers and experimental animals, changes that

have not been seen in laboratory animals exposed to higher concentrations of vapor in other studies. These claims obviously need confirmation.

Literature was reviewed by NIOSH (81) and IARC (79, 82).

4.4.1.1 Acute Toxicity Smyth and Carpenter (83) reported an oral LD_{50} of 700 mg/kg of body weight as determined in rats. Karmazin (84) also reported moderate oral toxicity; LD_{50}s of 450, 500, and 300 mg/kg were determined for rats, mice, and rabbits, respectively. Mild degenerative changes were observed in the myocardium, livers, and kidneys. Lu et al. (85) reported 425 and 460 mg/kg LD_{50}s for mice and rats, respectively.

Unless confined on the skin, allyl chloride is only mildly irritating. It may be absorbed through the skin in amounts sufficient to cause systemic intoxication in animals. Smyth and Carpenter reported an LD_{50} of 2.2 g/kg for 24 h skin absorption on rabbits. The Shell Chemical Corporation's Industrial Hygiene Bulletin (77) states, “The absorption of the liquid through the skin of human beings is attended by deep-seated pain in the contact area.”

Vapor concentrations of 50 or 100 ppm allyl chloride are irritating to the eyes. Higher concentrations of vapor may cause very severe irritation and pain. Liquid splashed in the eyes would be expected to cause severe irritation and should be washed out immediately with water.

There are contradictory reports of the toxicity of allyl chloride vapors in animals. Acute vapor studies of animals were reported by Adams et al. (86). Maximum exposure time–concentrations in air for a single exposure survived by rats were as follows: 3 h at 290 ppm, 1 h at 2900 ppm, and 15 min at 29,300 ppm. Comparable figures for guinea pigs were 8 h at 290 ppm, 3 h at 2900 ppm, and 1/2 h at 29,300 ppm.

The primary lesions were in the kidneys and the lungs. The kidney injury was severe, and there was congestion, hemorrhage, and marked parenchymatous degeneration. The pulmonary injury was also severe, particularly at higher concentrations. It consisted of marked congestion and frequent hemorrhages in the alveolar spaces.

A similar high acute and subacute toxicity has been shown by Shamilov and Abasov (87), who determined 4 h and 2 h LC_{50}s of 2100 and 2600 ppm (6.6 and 8.2 mg/L) for rats and mice. Four hour daily exposures to 0.4 mg/L (130 ppm) for a month affected the central nervous system and kidney function of rats, as shown by increased excretion of chlorides and protein.

However, a later study indicates significantly less acute effects on rats and mice (Dow Chemical Company, Midland, MI, unpublished data). The reason for the difference in response is not clear but may be due to changes in sample purity, the method of handling the sample, the strains of animals, changes in diets, or combinations of these and other factors. Groups of 10 male and female Fischer 344 rats and $B6C3F_1$ mice were exposed to various concentrations (range 200 to 2000 ppm) for 6 h. Parameters monitored included appearance and demeanor, body weights, clinical chemistry values, organ weights, and gross and histopathological examination. Significant findings included mortality, body weight loss, increased blood urea nitrogen and serum glutamic pyruvic transaminase values, and liver and kidney pathology. Although both liver and kidneys were target organs, the primary effect of allyl chloride exposure in both rats and mice was renal toxicity. Rats were more susceptible to allyl chloride vapor than mice on the basis of mortality data, renal pathology, and associated clinical laboratory findings. Female rats were affected to a greater degree than male rats, whereas male mice were affected to a greater degree than female mice. Minimal effect levels for renal toxicity were 300 ppm for rats and 800 ppm for mice. No significant effects were seen in rats or mice exposed to 200 ppm allyl chloride. Previous studies reported mortality in rats at 300 ppm; hence these results are quite different because the first mortality did not occur until rats were exposed to

concentrations of 1000 ppm.

Lu et al. (85) reported 2 h LC_{50}s of 11.5, 11.0, 11.4, and 5.8 mg/L (3680, 3520, 3660, and 1856 ppm) for female mice, male rats, female rats, and male guinea pigs, respectively. They also reported 2 h "lethal concentrations" of 22.5 and 10.5 mg/L for male rabbits and cats. Another report by these investigators (88) describes the exposures as static with gas chromatographic analysis. Lethal concentrations caused signs of irritation, such as closed eyes, pawing and scratching of the nose and mouth, lacrimation, and salivation, which were most prominent in guinea pigs and cats. Diarrhea occurred within 24 h. Initial signs included hypoactivity, unconsciousness, breath holding, and paralysis of rear legs in mice. Later drowsiness, unconsciousness, tremors, convulsions, and death due to apnea occurred in the various species but were most severe in guinea pigs. Unsteady gait and ataxia in cats were also observed following exposure. Marked injury to the lungs and histopathological changes in the kidneys were reported. Injury to the liver and alveolar space were observed at higher levels. Conditioned reflex was reportedly affected in cats by exposure to 745 mg/m^3 but not to 650 mg/m^3. Duration of exposure was not given.

4.4.1.2 Chronic and Subchronic Toxicity Almeev and Karmazin (89) stated that repeated oral doses of 0.015 mg/kg/day in the course of an 8 month study did not lead to morphological changes or other effects in rats. Karmazin (90) reported changes in conditioned reflexes after 6 months at this same dosage, which was the only dose level in these studies.

Data on repeated exposure of animals are also contradictory. The effects of repeated inhalation of allyl chloride vapors by four species were reported by Torkelson et al. (78). They reported that

animals were exposed repeatedly to either eight or three ppm of allyl chloride in air to establish conditions safe for repeated exposure. Rats, guinea pigs and rabbits had definite liver and kidney pathology after one month of repeated seven-hour exposures to eight ppm.

Histopathological examination showed

significant evidence of ill effect of a severe degree in the liver and kidneys of essentially all the animals. These were characterized by dilation of the sinusoids, cloudy swelling and focal necrosis in the liver; and by changes in the glomeruli, necrosis of the epithelium of the convoluted tubules and proliferation of the interstitial tissues in the kidney.

These species and dogs tolerated similar exposures to 3 ppm for 6 months, and only slight reversible liver pathology was seen in female rats.

The report by Torkelson et al. varies considerably from more recent data from the same laboratory. In 90 day studies, rats and mice have shown no effect from repeated 7 h exposures to 100 ppm or less (Dow Chemical Company, Midland, MI, unpublished data). Groups of 25 rats and mice of each sex were exposed to 0, 50, 100, or 250 ppm for 6 h/day, 5 days/week for 3 months. Ten animals of each sex and species from each concentration were sacrificed after 30 days, and the balance was necropsied at the end of the exposure period. The parameters evaluated included in-life observations, body weight, hematology, clinical chemistry, urinalysis, organ weights, gross necropsy, and light microscopic examination of tissues from major organs. The kidneys of male rats exposed to 250 ppm had increased cytoplasmic granularity and eosinophilic staining of the cortical epithelial cells. There was also an increased incidence and degree of focal tubular collagen and atrophy in the kidneys of the 250-ppm rats. No adverse effects were observed in any group of mice or in rats exposed to 100 ppm or lower after 90 days.

Because of outbreaks of polyneuropathy in workers, limited studies were conducted in animals by Lu et al. (85). Six male rabbits and two female cats were reportedly exposed to a nominal concentration of 206 mg/m^3 (66 ppm) for 6 h/day, 6 days/week for 3 months. Muscle weakness in the extremities, lurching motion, and unsteady gait were evident in all rabbits by the second month, but there was considerable difference in the time of onset in individual rabbits. Paralysis and unsteady gait, muscle atrophy, and emaciation were seen in rabbits but only muscle weakness and unsteady gait in rats. EMG changes, degeneration of peripheral nerve fibers only in distal nerves, and liver kidney and lung pathology were observed. Such marked peripheral nerve injury or paralysis has not been observed in other studies at higher concentrations in rats and mice.

Ten male and one female rabbit and 20 male rats were also exposed for 6 h/day, 6 days/week for 5 months to 17.5 mg/m^3 (5.6 ppm) without apparent ill effects. EMG studies showed occasional sharp waves in three rabbits at the end of the exposure, but the investigators did not attach significance to them.

In a follow-up study, He et al. (91) treated 10 albino mice three times per week with gavage doses of 300 or 500 mg/kg for 2 to 17 weeks. They reported that 70% of the animals had focal kidney change and that central-peripheral distal type axonopathy was commonly seen. Tolerance developed from continued dosing.

Omura et al. (92) found that male ICR mice died within 24 hours after a single subcutaneous injection of 496–1037 mg/kg body weight and had severe haemorrhage and edema of the lung and inconsistent, non-dose-related damage to the liver and kidney. When the surviving mice were sacrificed one week later, the only histopathological changes were found in the testes.

4.4.1.4 Reproduction and Developmental Intraperitoneal injections of 80 mg/kg given from day 1 to day 15 of gestation caused severe toxicity in rat fetuses. The sample used may not have been pure, and the route of treatment is most unnatural (93).

Allyl chloride was not teratogenic in rats or rabbits following exposure to 30 or 300 ppm for 7 h/day during the period of major organogenesis (94).

Decreases in body weight gain and increased liver weight were observed among both rats and rabbits exposed to 300 ppm of AC, and an increase in kidney weights was observed in maternal rats. The incidence of fetal resorptions was not significantly increased in either test species.

Ossification of vertebral centra and sternebrae was delayed at 300 ppm.

This slight delay in fetal development may be associated with the observed effects in the maternal animals at this level. Fetal body weights and measurements were not adversely affected in rats, thus the effects on the offspring were minimal and were observed only at an exposure level which also produced effects in the maternal animal. Low incidences of malformed fetuses were observed in all test groups, including controls, for both rats and rabbits and there was no indication of a teratogenic response in either species following inhalation exposure.

Mutagenic data were summarized by the IARC (82), which concluded that allyl chloride was positive in many test systems. Redistilled allyl chloride was studied for mutagenic structure–activity relationships in a large series of compounds (95) and then compared to chemical alkylating capacity using 4-(*p*-nitrobenzyl) pyridine. Mutagenicity in *S. typhimurium* TA 1535, 1537, 1538, 98, and 100

bacteria with and without liver homogenate (S-9) activation was determined. Allyl chloride was mutagenic even without liver homogenate. It was positive in a chemical alkylating test, and the authors considered that it was a direct-acting mutagen, particularly because adding of the S-9 fraction greatly decreased mutagenic activity.

4.4.1.5 Carcinogenesis Allyl chloride was included in the NCI gavage bioassay program and reportedly showed no evidence of carcinogenicity in Osborne–Mendel rats of either sex. There was a higher than background incidence only of squamous cell carcinomas and papillomas in the forestomachs of both sexes of mice and squamous cell papillomas in the forestomachs of female mice. The incidence in other organs did not increase.

The doses fed by gavage were as follows: male rats, 77 and 57; female rats, 73 and 55; male mice, 199 and 172; and female mice, 258 and 129 mg/kg/day. Survival of high-dose male mice, male rats, and female rats was poor. As in many of these old studies, histopathological examinations were inadequate. Gastric irritation was evident.

Groups of 30 Ha:ICR Swiss mice received 31 or 90 mg technical grade allyl chloride in acetone on their skin three times per week for 440 to 594 days without evidence of tumors. Equivocal results were observed in a two-stage mouse-skin assay, that involved a single 94 mg application followed by 3 days/week treatment with phorbol myristyl acetate (20).

Allyl mercapturic acid was isolated from the urine of rats dosed with allyl chloride (96). These investigators also reported that 3-hydroxypropylmercapturic acid was identified as a metabolite. A study of the pharmacokinetics and metabolism following single administration of ^{14}C-allyl chloride to CDF-Fischer 344 rats by oral, inhalation, and intravenous exposure was reported (97).

Following oral and inhalation exposure, the fate was dose- and route-dependent. Most of the radioactivity was excreted as polar metabolites in urine or as CO_2 and parent compound in expired air. Epichlorohydrin was not a major metabolite. A one-compartment bimodal absorption model adequately described the parent compound blood level following oral treatment, and a two-compartment model better described the blood levels following intravenous dosing and inhalation exposure. The terminal half-life in blood depended on the inhaled concentration at high concentrations, but at 100 ppm or less, the half-lives were less than 30 min. A single 6 h exposure to 1000 or 2000 ppm caused marked depletion of nonprotein sulfhydryl (NPSH) in the liver, kidneys, and lungs, but a 100 ppm exposure caused only a slight although statistically significant decrease. NPSH was not changed in kidneys, liver, lung, or blood after a 6 h exposure to 100 ppm. Cytotoxicity was apparent in rats' kidneys 24 h after a 6 h exposure to 1000 or 2000 ppm.

IARC (79) has found inadequate evidence of carcinogenicity in experimental animals.

4.4.2 Human Experience Because of its recognized toxicity, allyl chloride has generally been handled carefully during its manufacture. Eye irritation resulting from overexposure to the vapors has been the most frequent complaint (77, 81). The onset of orbital pain may be delayed several hours after exposure. More intense vapor exposure produces conjunctivitis, reddening of the eyelids, and corneal burn.

One unique feature of dermal exposure is a so-called deep-bone ache, which has been reported following dermal contact.

A report available only as an abstract indicates kidney dysfunction in workers exposed above the 3 mg/m^3 standard. Although kidney injury is consistent with the response in animals, not enough data are given in the abstract to determine the significance of the report in terms of dosage (98).

Another report by Hausler and Lenich (99) also inadequately describes the employees' exposure

levels but indicates many adverse effects in a population of 60 people. An odor of garlic on the breath and body was a common complaint. The skin and respiratory tracts appear normal, but there were alterations in liver function tests. These effects disappeared following better industrial hygiene control measures.

Neurological effects attributed to allyl chloride in the absence of liver and kidney injury have been reported in Chinese workers (91). Although the peripheral neuropathies were ascribed by the investigators to inhaled allyl chloride, absorption through the skin was not considered. Furthermore, their results were not confirmed in other countries. No explanation is readily apparent, and the issue merits further study.

Enterline et al. (100) found limited evidence for elevated heart disease in a Texas plant where workers were exposed to allyl chloride and high, moderate, low, or no exposure to epichlorohydrin. It was suggested by the senior author that further research on this apparent association is needed (101), and Ross (102) suggested that the study lacked data on confounders and adequate exposure data.

Olsen et al. (103) reported on a cohort of 1064 men employed at a Texas plant in epoxy resin, glycerine, and allyl chloride/epichlorohydrin production between 1957 and 1986 and followed-up through 1989. There were 66 total deaths (SMR = 0.8; 95% CI 0.6–1.0) and 10 cancers (SMR = 0.5; CI 0.2–0.9). However, the authors noted that the cohort was limited due to sample size, duration of follow-up, small numbers of deaths both expected and found, and the limited exposure potential.

The IARC found that it could not classify allyl chloride as a human carcinogen on the basis of available data (79).

4.5 Standards, Regulations, or Guidelines of Exposure

The TLV for allyl chloride recommended by the ACGIH is 1 ppm (3 mg/m^3), and the STEL is 2 ppm (6 mg/m^3) with an A3 notation. The OSHA PEL is 1 ppm (3 mg/m^3) as is the NIOSH REL (80). Skin contact must be prevented because allyl chloride may be absorbed (76). The ILO (104) indicates that similar standards or guidelines are used in other countries (104). No international guidelines for drinking water have been suggested (37).

Unsaturated Halogenated Hydrocarbons

R. A. Lemen, Ph.D., MSPH

5.0 Hexachlorobutadiene

5.0.1 CAS Number:

[*87-68-3*]

5.0.2 Synonyms:

HCBD; perchlorobutadiene; hexachloro-1,3-butadiene; 1,1,2,3,4,4-hexachloro-1,3-hexachlorobutadiene; dolen-pur; gp-40-66:120; hexachlorobuta-1,3-diene; hexachlorobutadiene 13-

5.0.3 Trade Names:

NA

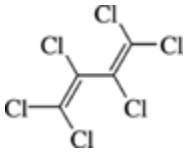
5.0.4 Molecular Weight:

206.76

5.0.5 Molecular Formula:

C_4Cl_6

5.0.6 Molecular Structure:



5.1 Chemical and Physical Properties
5.1.1 General The physical properties listed for hexachlorobutadiene are somewhat uncertain (105, 106).

Physical State	colorless liquid
Specific Gravity	1.68 (25/4°C)
Melting Point	–21°C
Boiling Point	212°C
Vapor Pressure	20 Pa at 20°C
Relative Vapor Density	9.0 (Air = 1)
Refractive Index	1.5535 (25°C)
Percent in "Saturated" Air	0.037 at 25°C
Solubility	insoluble in water at 20°C (0.00032 g/100 mL)
Flammability	not flammable by standard tests in air
Flash Point	90°C

5.1.2 Odor and Warning Properties Old data on an inadequately characterized sample indicate that 1 ppm was detectable by only about half of those who attempted to smell it. The odor of hexachlorobutadiene should be considered inadequate to warn against excessive repeated exposures. It reportedly has a turpentine-like odor.
5.2 Production and Use
Although hexachlorobutadiene (HCBD) has been used as a pesticide in other countries, exposure in the United States has mostly been as an unwanted by-product of certain processes associated with chlorination of hydrocarbons. It is reported to have some use as a chemical intermediate (107). In the United States it was also used for recovering chlorine-containing products and as a fluid for gyroscopes (108).
5.3 Exposure Assessment
5.3.1 Air The air around vineyards where hexachlorobutadiene was used was found contaminated within a radius of ≥100 meters (108). It has also been found near plants that manufacture tetrachloroethylene; trichloroethylene (highest level reported was 463 mg/m^3) at lower levels was found near plants that produce chlorine and triazine herbicide and in landfills where chemical wastes were dumped (109, 110).

5.3.3 Workplace Methods Sampling is done with a solid sorbent tube (XAD-2; 100 mg/50 mg) and then measured by the gas chromatography/ECD technique (NIOSH Method 2543). The working range is 0.01 to 2.0 mg/m^3 for a 100-L sample. The estimated limit of detection (LOD) is 0.02 mg per sample (111).

5.3.4 Community Methods Many methods have been suggested for measuring hexachlorobutadiene in air, water, food and drink, biological tissues, and soil. A good summary can be found in IARC Monograph 71 (108).

5.3.5 Biomonitoring/Biomarkers Currently there are no useful biological monitors for hexachlorobutadiene, particularly at the low levels recommended for occupational exposure. Kociba et al. (112) suggested that urinary excretion of coproporphyrins be included as part of a medical

surveillance program for employees.

5.4 Toxic Effects

5.4.1 Experimental Studies Kociba et al. cite literature values for acute oral LD_{50}s of 90 mg/kg for guinea pigs, 87 to 116 mg/kg for mice, and 200 to 350 mg/kg for rats. They also determined an LD_{50} of 580 mg/kg for adult male rats and a range of 200 to 400 mg/kg for adult female rats. Weanling rats have LD_{50}s of 65 and 46 mg/kg for males and females, respectively. Most deaths occurred 2 to 3 days after treatment but some were delayed as long as 17 days. Short-term dietary studies in which rats were fed 0, 50, 150, and 450 ppm in their diet for 2 weeks resulted in growth depression and kidney injury similar to that seen in acute studies (122).

Kociba et al. also reported that no kidney injury was produced by daily doses of 3 mg/kg body weight but that higher levels in a 30-day study did. At 100 mg/kg body weight/day, minimal liver injury was observed.

When groups of five $B6C3F_1$ mice of each sex were fed 0, 30, 100, 300, 1000, or 3000 ppm in their feed for 15 days, very severe effects and deaths occurred at the highest dosages (123). Apparently no attempt was made to relate dietary level to dose per body weight in the published paper, but estimated daily intake was calculated in the NTP report of this study (121). Estimated intakes by male mice were 3, 12, 40, 19, and 24 mg/kg/day for the 30-, 100-, 300-, 1000-, and 3000-ppm diets and 5, 16, 49, 30, and 36 mg/kg, respectively, for female mice. All mice died or were sacrificed in a moribund condition after 7 days at the two top levels. There was no mortality at the three lowest levels. However, retardation of growth was seen at all levels, and clinical signs were apparent at 300 ppm and higher. Histopathology was observed in several organs, particularly the liver but also the kidneys and spleens. The weights of several organs, including the thymus, lungs, kidney, and testes, were affected.

When hexachlorobutadiene was fed to mice for 13 weeks at dietary levels of 0, 1, 3, 10, 30, or 100 ppm, no clinical signs or mortality were observed (124). These dietary levels corresponded to 0, 0.1, 0.4, 1.5, 4.9, and 16.8 mg/kg/day for hexachlorobutadiene for male mice and 0, 0.2, 0.5, 1.8, 4.5, and 19.2 mg/kg/day for female mice based on food consumption. A marked reduction in body weight gain and in kidney weight was seen in male mice at 30 and 100 ppm and in female mice at 100 ppm. Thymus weights were comparable in all groups in contrast to marked changes in the two-week study. No gross lesions were seen at autopsy, and the only microscopic lesion was tubular regeneration in the renal cortex at 30 and 100 ppm and possibly at 10 ppm in male mice, although female mice kidneys were affected at all dosage levels. The mobility of sperm was reduced in dosed mice, though not in a dose-related manner. Female mice were more susceptible than males, and a NOAEL was not achieved for female mice. The NOAEL for male mice in this 13-week study was considered by the investigators to be 10 ppm in the diet.

According to Kociba, “Dermal application of 126 mg/kg hexachlorobutadiene was lethal to half the rabbits in 7 hours and 4 of 4 after 24 hours. All rabbits survived the dermal application of 120 mg/kg for 4 hours or 63 mg/kg for 24 hr.”

According to an available abstract, a single subcutaneous injection of 20 mg/kg into female rats resulted in the deaths of young born 3 months later to these dams (866). This must be confirmed.

Single 4- to 7-h exposures to 133 to 500 ppm hexachlorobutadiene caused the deaths of some or all exposed rats. Exposure for 0.9 h to 160 ppm or 3.5 h to 35 ppm was survived by all rats. Guinea pigs and cats died from similar exposures to 160 ppm or from 7.5 h exposures to 35 ppm (112).

Gage (125) exposed rats to 250 ppm for 4 h and 100, 25, 10, or 5 ppm for 6 h. Fifteen exposures to 5 or 10 ppm resulted in no observed toxic effects, except for retarded weight gain at 10 ppm. Fifteen exposures to 25 ppm, two exposures to 100 ppm, and two exposures to 250 ppm resulted in

respiratory irritation and injury, as well as rather pronounced effects on the renal tubules. The adrenals showed injury at 100 and 250 ppm.

Limited unpublished data of The Dow Chemical Company also indicate a rather high subacute toxicity for hexachlorobutadiene when inhaled. Small groups of rats and guinea pigs were exposed to about 8 or 30 ppm 7 h/day, 5 days/week. The guinea pigs exposed to 30 ppm died after four exposures, whereas 9 of 10 rats survived. However, severe injury was grossly apparent in the lungs, livers, and kidneys of the survivors. Ten of 10 rats and four of five guinea pigs survived 197 h exposures to 8 ppm, but liver and kidney injuries were grossly apparent on necropsy.

5.4.1.1 Acute Toxicity Hexachlorobutadiene has a rather high chronic toxicity and can cause lung, liver, and particularly renal injury in rats, including renal cancer. Much of the data for this section are taken from Kociba et al. (112), who reviewed the literature and published their own chronic toxicity and reproductive studies in rats.

The proximal tubules of the kidneys were the site of most injury in Kociba's studies. Subsequently, there have been a number of studies of metabolism and mode of toxic action, including a large number of reports from the Central Research Laboratory of Imperial Chemical Industries (113–119).

Yang (120) published a useful review. NTP (121) reviewed some of the data as part of the ongoing studies referred to in subsequent sections, ATSDR (107) has issued a draft for comment, and the IARC (108) reviewed the data in 1979 and 1987 (3).

5.4.1.2 Chronic and Subchronic Toxicity Small groups of rats, rabbits, and guinea pigs exposed for 7 h/day, 100 times to 3 ppm in a 143 day period were adversely affected, but those exposed 129 times in 184 days to 1 ppm were not. The livers and kidneys of the animals exposed to 3 ppm were the organs most affected (Dow Chemical Company, Midland, MI, unpublished data).

An available abstract indicated that mice and rats tolerated 0.024 mg/L (22 ppm) of hexachlorobutadiene in air for 7 months. The details of the number of hours per day and the number of exposures are not available (126).

Kociba et al. (112) presented the most complete study to date. Their summary follows: In the chronic dietary study, as in shorter term studies conducted previously with HCBD, the kidney was the primary target organ. Ingestion of 20 mg/kg-day of HCBD for up to 2 years caused multiple toxicological effects, including decreased body weight gain, increased mortality, increased urinary excretion of coproporphyrin, increased weights of kidneys, increased renal tubular epithelial hyperplasia, and renal tubular adenomas and adenocarcinomas, some of which metastasized to the lungs.

Ingestion of the intermediate dose level of 2 mg/kg-day of HCBD for up to 2 years caused lesser degrees of toxicity, including increased urinary coproporphyrin excretion and increased renal tubular epithelial hyperplasia. The fact that urinary excretion of coprophyrin increased at this dose level, which produced no neoplasms, may indicate the usefulness of this parameter as a biological monitor when included in a medical surveillance program for workers exposed to HCBD. Ingestion of the lowest level doses of 0.2 mg/kg-day of HCBD for up to 2 years caused no effects that could be attributed to treatment. Whereas the intermediate dose level of 2.0 mg/kg-day caused a slight degree of renal toxicity, the highest dose level of 20 mg/kg-day for up to 2 years caused multiple and substantial toxicological effects, including renal tubular neoplasms. Thus, these data indicate a clear-cut dose-response relationship for HCBD-induced toxicity that affects primarily the kidney. HCBD-induced renal neoplasms occurred only at a dose level higher than that causing discernible renal injury.

5.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Because the kidneys are the primary site of toxic action in rodents, they have also been a major subject of metabolic study. However, the liver,

biliary excretion, reabsorption, and metabolism are also involved (113–119).

Yang (120) has proposed a metabolic scheme based on a number of references.

Davis et al. (127) used low intraperitoneal doses of ^{14}C-hexachlorobutadiene with and without nonradioactive 300-mg/kg oral doses. The oral dose reportedly decreased urine osmolality, the glomerular filtration rate, and drug excretion and caused necrosis of the proximal tubular cells of the kidneys. At 48 h following dosing with only the tracer, rats excreted 40% in the feces and 30% in the urine but those that also received the nephrotoxic 300-mg/kg oral dose excreted only 7% in the feces and 6% in the urine. Eighty-seven percent of that in the urine was water soluble and polar, as was all the activity in the bile. Reichert (128) gave oral doses of 1 or 50 mg/kg ^{14}C-hexachlorobutadiene and after 72 h found 45 and 67% in the feces, as well as 26 and 11%, respectively, in the urine at the two dosages. There was not as marked a change in the amount of unchanged hexachlorobutadiene exhaled, but [^{14}C]CO_2 was reduced from 3 to 1.2%, and 8 to 10 times as high a proportion was bound covalently in the kidneys and liver. Of five major metabolites found in urine, one was the glucuronide, whereas in the bile the major metabolite reported by Reichert was the glutathione conjugate.

Biliary excretion of an orally administered dose of hexachlorobutadiene is high in rats compared to fecal excretion. Within two days, 17 to 20% of a 200-mg/kg dose was excreted in bile versus less than 5% in feces (117). Both the glutathione conjugate and the probable conjugate metabolite, cysteinyl glycine conjugate, were identified. A bile cannula completely protected the kidneys indicating that metabolism by the liver was necessary. Yang (120) summarizes work that supports increased toxicity due to glutathione conjugation rather than the more common detoxification associated with glutathione conjugation.

Payan et al. (129) drew similar conclusions from studies in rats given oral or intravenous doses.

5.4.1.4 Reproduction and Developmental Several studies of teratogenicity and reproduction of hexachlorobutadiene were reported. Japanese quail kept on diets that contained 30 ppm (about 5 mg/kg body weight per day) for 90 days had no deleterious effect on reproduction. Male and female rats were fed 20, 2, or 0.2 mg/kg/day for 90 days before mating and during gestation and lactation. Both sexes fed the two higher levels were adversely affected, primarily in the kidneys, but reproductive indexes were not. Only slight changes occurred at 2 mg/kg/day, and no effects were observed at 0.2 mg/kg/day. The only reproductive finding was a slight nonsignificant decrease in neonatal weight at 21 days at the top dosage only. No toxicological effects were observed among the adults at a dose level of 0.2 mg/kg/day or among the neonates at dose levels of 0.2 or 2.0 mg/kg/day.

Harleman and Seiner (122) also reported no effect on fertility or progeny except for decreased body weight at birth and weaning in rats born to mothers fed 150 ppm in their diet. Grossly observable malformations were not seen in their small study.

Rats were exposed to 0, 2, 5, 10, or 15 ppm hexachlorobutadiene for 6 h/day during days 6 to 20 of gestation in an inhalation teratology study. A significant reduction in maternal weight gain and in fetal body weight occurred at 15 ppm. The incidences of external, visceral, and skeletal alterations did not significantly increase in any of the hexachlorobutadiene-exposed groups. It was concluded that hexachlorobutadiene was not teratogenic at concentrations high enough to cause maternal toxicity and slight fetal toxicity.

Yang (120) summarized conflicting data on the mutagenic potential of hexachlorobutadiene. Reichert et al. presented evidence that published positive results may be due to impure samples and that larger than normal quantities of drug metabolizing enzymes (S-9 mix) are needed in the test system. Two putative metabolites, pentachloro-3-butenoic acid chloride and pentachloro-3-butenoic acid, were mutagenic in the absence of S-9 mix and were 50 to 100 times as active as

hexachlorobutadiene.

5.4.1.5 Carcinogenesis Schrenk and Dekant reported that considerably more binding to DNA occurred in the kidney compared to the liver and concluded that a genotoxic mechanism of carcinogenesis was “operative” in initiating hexachlorobutadiene nephrocarcinogenesis. However, there is strong evidence of such severe proximal tubular injury that the relationship of this injury to subsequent cancer is a likely possibility. In rats given oral administration, it produced benign and malignant tumors in the kidneys in both sexes (108). IARC (108) then concluded that there is limited evidence that hexachlorobutadiene is carcinogenic in rats.

Nakagawa et al. (130) reported that hexachlorobutadiene is a potent nephrotoxicant that selectively damaged the straight portion (pars recta) of the proximal tubule in the rat. They also reported administering 0.1% hexachlorobutadiene for 30 weeks to male Wistar rats previously given 0.1% *N*-ethyl-*N*-hydroxyethylnitrosamine (EHEN) in their drinking water for 2 weeks and that the combined treatment resulted in a significantly higher incidence of renal cell tumors than when EHEN was administered alone.

5.4.2 Human Experience In 1979 (108), the IARC cited only one study of human effects. The draft ATSDR profile cited no references to human data. The WHO (105) indicated that hexachlorobutadiene can be absorbed through the skin causing pain, redness, blisters, and skin burns. They also indicated that if it is in the eyes, it can cause pain, redness, severe deep burns, and even loss of vision. If ingested, it can cause a burning sensation, abdominal pain, shock and/or collapse. When inhaled, it can result in a burning sensation, cough, sore throat; the symptoms can be delayed, and coma may occur in severe cases (105). WHO (105) further stated that harmful contamination can be reached in the air rather quickly at 20°C.

5.4.2.2.1 Acute Toxicity Acute or short-term exposures can result in irritation of the eyes, skin, and respiratory tract. The liquid is known to be corrosive and may affect the kidneys (105).

5.4.2.2.2 Chronic and Subchronic Toxicity Chronic, long-term, or repeated exposures can result in skin sensitization and may cause genetic damage in humans (105).

5.4.2.2.5 Carcinogenesis The IARC (108) concluded that there were no data on which to evaluate its human carcinogenicity.

5.4.2.2.6 Genetic and Related Cellular Effects Studies Chronic exposure may cause genetic damage in humans (105).
5.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH recommended TLV is 0.02 ppm (0.21 mg/m^3) and an A3 carcinogen designation (35). OSHA has no PEL and NIOSH recommends treating it as a carcinogen at a REL of 0.02 ppm (0.24 mg/m^3), and both ACGIH and NIOSH note a skin designation (131).

Unsaturated Halogenated Hydrocarbons
R. A. Lemen, Ph.D., MSPH

6.0 b-Chloroprene
6.0.1 CAS Number:
[*126-99-8*]
6.0.2 Synonyms:
Chloroprene, 2-chlorobutadiene; chlorobutadiene; beta-chlorobutadiene; alpha-chloroprene;

neoprene; 2-chloroprene; 2-chlorobutadiene; 2-chlorobuta-1,3-diene; 2-chloro-1,3-butadiene
6.0.3 Trade Names:
NA
6.0.4 Molecular Weight:
88.54
6.0.5 Molecular Formula:
C_4H_5Cl
6.0.6 Molecular Structure:

6.1 Chemical and Physical Properties
6.1.1 General (132)

Physical State	colorless liquid
Specific Gravity	0.9583 (20/20°C)
Boiling Point	59.4°C
Melting Point	–130°C
Vapor Pressure	23.2 kPa at 20°C (188 torr at 20°C)
Relative Vapor Density	3.0 (Air = 1)
Refractive Index	1.4583 (20°C)
Percent in "Saturated" Air	28 (25°C) (25.000 ppm at 20°C)
Solubility	0.21152/100 mL at 20°C in water; soluble in alcohol, diethyl ether
Flash Point	–40°C
Explosive Limits	4 to 20% in air

6.1.2 Odor and Warning Properties b-Chloroprene has a pungent, ether-like odor (133) and is a lacrimator.
6.2 Production and Use
Chloroprene is used as a chemical intermediate, largely as a monomer for manufacturing rubber. At room temperature, it reacts with oxygen to form peroxides and polymerizes to produce cyclic dimers or open-chain, high molecular weight products (134).
6.3 Exposure Assessment
Chloroprene is not found as a natural product (135).

6.3.1 Air Chloroprene emissions into the air have been reported in the United States from 838 tons in 1987 down to 446 tons in 1995 (136).

6.3.2 Background Levels Chloroprene has been found in industrial waste water and nearby groundwater and in waste gas from industrial sources (137–139).

6.3.3 Workplace Methods b-Chloroprene in the workplace is sampled with a solid sorbent tube (coconut shell charcoal, 100 mg/50 mg) and then measured using the gas chromatography, FID technique, NIOSH Method 1002. The working range is 10 to 60 ppm (40 to 200 mg/m^3 for a 3-L air sample and the method is sensitive enough to determine concentrations as low as 12 ppm in 15-min samples taken at 0.2 L/min. The estimated limit of detection (LOD) is 0.03 mg per sample (3.8 mg/m^3) assuming a maximum sampling volume of 8 L (140).

6.3.4 Community Methods Methods have been described for sampling b-chloroprene in water using gas extraction, thermal desorption, and gas chromatography/mass spectrometry and the detection limit is thought to be around 0.02 mg/L (135).

6.4 Toxic Effects

6.4.1 Experimental Studies Old reviews of the toxicity of b-chloroprene are available (141, 142), but surprisingly few new references were found since the Third Revised Edition of this publication. What is available tends to support the conclusions of that edition. At high concentrations b-chloroprene has an anesthetic action, but this is not as important as eye and respiratory tract irritation and liver injury, which result from excessive exposures. Hair loss has also been reported in humans and animals exposed to b-chloroprene.

The available literature is extremely contradictory as to the type of injury that has resulted from exposure to b-chloroprene and to the exposure levels that cause them. Russian literature claims considerably different and/or greater effects than have been observed in studies from other places that have tried to confirm these claims. No clear explanation is available, but at least two possible explanations appear reasonable. b-Chloroprene is a very unstable compound, which, unless handled with extreme care, expoxidizes and polymerizes to toxic compounds (143, 144). This might explain the alleged effects in animals. Alleged effects in humans may be due to this same cause or to the use of different chemical processes that produce different types of impurities. Many other causes can be postulated, but in our opinion more credence must be given to animal studies in which the sample is known to have been handled with extreme care and to the results of experience in U.S. industry where the method of handling has been reported.

6.4.1.1 Acute Toxicity b-Chloroprene is an irritant when intubated into the stomach of laboratory animals. It also produces CNS depression, generalized congestion, and edema. Von Oettingen et al. (145) reported that the LD_{100} for rats is 670 mg/kg of body weight. Death occurred from 5 h to 4 days after administration. LD_{50}s of 251 mg/kg for rats and 260 mg/kg for mice were reported by Asmangulian and Badalian (146).

Conjunctivitis and necrosis of the cornea were reported. Von Oettingen (42) quoted Roubal to this effect. Apparently, nervousness and irritability are typical responses to exposure. A more thorough discussion of the clinical picture can be found in reports by Nystrom (143) and Ritter and Carter (147).

The vapors reportedly cause irritation and evidence of pain in the eyes at 625 ppm but not at 160 or 40 ppm in rats exposed for 6 h/day for 4 weeks (147).

Von Oettingen (145) indicated that some systemic toxicity results from repeated topical application of chloroprene to the skin of rats. Ritter and Carter (147) indicated that systemic poisoning results from the topical application of chloroprene to guinea pigs. It is uncertain how completely the animals were prevented from breathing the vapors when it was applied to the skin.

Perhaps the most surprising effect from topical application is the loss of hair. Because hair grows readily when the individual is removed from contact, the action may be directly on the hair. Apparently, this is observed both in humans in industrial operations and in animals exposed in the laboratory. Ritter and Carter question whether this action is of chloroprene itself or an intermediate in the polymerization of chloroprene, but it is agreed that the depilatory action does occur in workers who handle chloroprene in the polymerization process.

Von Oettingen (145) indicated that a 1 h exposure of mice to chloroprene vapor at a concentration of 3 mg/L of air (829.2 ppm) was fatal to all animals exposed. A concentration of 1 mg/L (277 ppm) did not kill any of the animals. They also reported that the LC_{100} is 7.5 mg/L for an 8 h exposure of rabbits of air and is 2.5 mg/L for cats.

Clary et al. (148), using fresh, purified b-chloroprene, determined an approximate lethal concentration of 2280 ppm (8.42 mg/L) for a 4 h exposure of rats. All six rats exposed to 1690 ppm (6.24 mg/L) survived. Injury to the respiratory tract was apparent in a few rats sacrificed 1 or 2 days after exposure. Some liver changes were reported.

They also exposed rats and hamsters to 625, 160, or 40 ppm for 6 h/day, 5 days/week for 4 weeks. The authors concluded that toxic effects were observed at all levels.

The primary effects seen at the low level were skin and eye irritation and weight loss in rats. At higher levels, tissue damage, especially to the lung and liver, and mortality were observed. Hair loss was observed, primarily at the two highest levels in female rats. The range-finding studies indicate that repeated exposure of rats at approximately 625 ppm resulted in mortality, as well as growth retardation. In hamsters, one exposure at 630 ppm was lethal. Midzonal liver degeneration and necrosis, as well as increased liver and kidney weights in both species, were also noted at both the high exposure and midexposure levels. The lower exposure level (40 ppm) was irritating in both species, and significant growth retardation was also noted in the rats. The alopecia observed in the present studies is consistent with earlier reports (144).

Thirteen-week exposures of rats and mice to chloroprene were conducted by NTP as part of their procedure for selecting doses for lifetime studies (134). The exposure concentrations were 0, 5, 12, 32, 80, and 200 ppm for rats and 0, 5, 12, 32, and 80 ppm for mice. Exposures were for 6 h/day. The Pathology Working Group (PWG) draft report (149) indicates

administration of chloroprene to male and female rats via inhalation 5 days per week for 13 weeks resulted in minimal to moderate lesions of the nasal mucosa in those exposed to 80 and 200 ppm. Degeneration and respiratory metaplasia of the olfactory epithelium and suppurative inflammation of the turbinates were observed in 10/10 males and 8/10 females dosed at 200 ppm and 10/10 males and 9/10 females dosed at 80 ppm. Lesions in the liver considered to be compound-related included randomly distributed necrosis in 2/10 males and 6/10 females; hemosiderosis in 5/10 males and 10/10 female rats; and minimal inflammation in 3/10 male and 8/10 females rats limited to the 200 ppm dose level. The PWG considered the 32 ppm dose as the no-effect level for both male and female rats.

Nasal and occular discharge were observed at 200 ppm, and the feet were bloodstained. Growth and final body weight were not affected. Other data in the consulting laboratory report to NTP indicate an increase in kidney weight in both sexes of rats exposed to 80 and 200 ppm but no effect on male reproductive parameters or on cyclicity or length of estrus in female rats. Neurobehavioral test were unaffected. Moderate coagulopathy was also reported at 200 ppm, and the nonprotein sulfhydryl was reduced in the liver and lungs of rats, suggesting conjugation with glutathione. A possible exposure-related minimal suppurative gastritis was observed in the forestomach submucosa of 2/20 rats exposed to 200 ppm.

The draft PWG report summary states.

Administration of chloroprene to male and female B6C3F_1 mice via inhalation 5 days per week for 13 weeks resulted in a minimal or slight epithelial hyperplasia in the forestomach. The incidence was 3/10 male and 7/10 female mice dosed at 80 ppm. The no-effect level was 32 ppm.

At terminal necropsy, gross lesions of firm white nodules or raised pale foci were observed in a few stomachs of the 80-ppm group. In addition, the consulting laboratory report indicated no clinical signs but a slight reduction in body weight gain at 80 ppm. Neither male nor female mice reproductive parameters were altered. No hematologic or clinical chemical parameters were altered,

but nonprotein sulfhydryl content of liver and lungs was reduced at 80 ppm at week 12.

6.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Bartsch et al. (150) reported isolating a metabolite capable of alkylation when they added human liver enzymes to *S. typhimurium* in their mutagenicity test system, but few data have been added since. The most likely route of metabolism is epoxidation and subsquent glutathione conjagation with mercapturic adic formation (151).

6.4.1.4 Reproduction and Developmental Numerous Soviet reports describe teratological and reproductive effects in animals. These effects may have been due to improper handling of the samples and resulting toxic reaction products.

When the purity of the sample was carefully controlled, repeated exposures to 25 ppm or less of the vapor caused no reproductive, teratological, or embryo toxic effects in rats (152). Despite frank clinical toxicity in exposed pregnant rats, fetuses showed no teratogenic effects at b-chloroprene levels as high as 175 ppm (E. I. du Pont de Nemours & Co., Wilmington, DE, unpublished data). Reproductive parameters were unaffected in the NCI study reported in the previous section.

b-Chloroprene, like many other compounds was mutagenic in some but not all test systems. Several reports summarized by NIOSH (141) indicate mutagenic activity in *Drosophila*, mice, and rats in addition to microorganisms. Whether this is due to impurities in the samples is not clear. Bartsch et al. (150) reported that liver enzymes were needed to produce mutations in *S. typhimurium*. They were able to trap an alkylating metabolite and considered the mutagenic activity as the likely result of an oxirane metabolite. An unpublished study (E. I. du Pont de Nemours & Co., Wilmington, DE, unpublished data) found no dominant lethal effects in rats and mice exposed to 100 ppm.

Using NTP genetic test procedures, negative results were obtained in *S. typhimurium* TA98, TA100, TA535, and TA1537 with and without Arochlor-induced rat and hamster liver S-9 homogenate. Dosages were 0, 3, 10, 33, 100, 333, 1000, or 3330 mg/plate. The top dosage inhibited growth. No effect on cytogenetic end points occurred in bone marrow cells of B6C3F1 mice exposed to 0, 12, 32, 80, or 200 ppm (153). A lack of genetic effect has also been demonstrated in groups of 10 to 15 male B6C3F1 mice exposed for 6 h/day for 10 days to ambient air, or 12, 32, 80, or 200 ppm b-chloroprene (154). Butadiene and isoprene that were run concurrently caused several mutagenic effects correlated with exposure concentration. All mice exposed to 200 ppm b-chloroprene died. At 80 ppm and less, there was

no increase in CA (chromosomal aberrations), SCE (sister chromatid exchange) or micronucleated erythrocytes nor did it significantly alter the rate of erythropoiesis or bone marrow cellular proliferation kinetics. However the MI (mitotic index) in the bone marrow of chloroprene exposed mice was significantly increased.

6.4.1.5 Carcinogenesis The IARC (135) determined that there is sufficient evidence for the carcinogenicity of chloroprene in experimental animals. This evaluation is based on production of tumors of the lung, circulatory system, Harderian gland, mammary gland, liver, kidney, skin, mesentery, forestomach, and the Zymbal gland in mice (135). In rats, the IARC found that tumors of the mammary gland increased only at high-doses and when all types were combined (135). No tumors were reported in the hamster studies (135).

A large number of Soviet studies reportedly produced cancer in animals (141). b-Chloroprene dissolved in corn oil (150 mg/kg) was administered to pregnant rats on the 17th day of gestation, and the offspring were treated from weaning with weekly doses of 50 mg/kg for their life spans (155). According to the abstract of this somewhat unusual experimental design, the total incidence of tumors was similar in treated and controls.

Kumming albino mice inhaled 0, 2, 19, or 189 mg/m^3 (0.5, 5, or 50 ppm) for 4 h/day, 6 days/week for 7 months (156). All survivors were killed at the end of the eighth month or when moribund. No lung tumors were found before the sixth month. The reports indicate an increase in lung papilloadenomas and to a lesser extent adenomas occurred in a dose-related manner but it is not clear at what levels of exposure.

The NTP reported significantly increased incidences of neoplasms of the lung, circulatory system, Harderian gland, and mammary gland (females only) and that tumors of the forestomach, liver (females only), kidney (males only), skin and mesentery (females only), and Zymbal gland (females only) also increased after mice inhaled chloroprene that was more than 99% pure at concentrations of 0, 12.8, 32, and 80 ppm (0, 46, 116, and 290 mg/m^3) (157). The IARC (135) noted that the livers of both exposed and control male mice contained lesions consistent with *Helicobacter hepaticus* infection, but the females did not, which may have compromised the detection of neoplastic effects in this organ among the male mice.

The NTP (157) also found increases in neoplasms of the oral cavity, thyroid gland, kidney, lung (males only), and mammary gland (females only) in rats exposed to chloroprene more than 99% pure at inhalation concentrations of 0, 12.8, 32 and 80 ppm (the same as the mice above). Melnick et al. (158) reported that the cancer potency of chloroprene was greater in mouse lungs than in the lungs of rats whereas it was greater in the rat kidney than in the mouse kidney but nearly equivalent in the mammary gland of both rats and mice.

In another study that exposed rats to inhalation concentrations of 0, 10 or 50 ppm (0, 36 or 180 mg/m^3) chloroprene for 6 hours, five days a week for 24 months, mammary tumors significantly increased in exposed female rats, and if skin tumors in the male had originated from the epidermis, then the total number of squamous-cell carcinomas of the skin (5/100) in high-dosed rats would have been significantly different (p<.05) from the control group (159). In a similar study of hamsters, no increase in tumors was found comparing the control group and those exposed (159).

6.4.2 Human Experience

6.4.2.2 Clinical Cases Even more so than other chemicals, the extreme instability of b-chloroprene and the resulting products make it difficult to ascribe effects in humans to the chemical itself. Numerous reports of injury in production and use of b-chloroprene have been published and presented by NIOSH (141) and WHO (132). Symptoms include hair loss, chest pain, fatigue, nausea, personality changes, conjunctivitis, dermatitis and chemical burns, unconsciousness, decreased spermatogenesis and other reproductive effects, sexual impotency, cough, dizziness, and sore throat.

A group of 336 currently exposed and 227 previously exposed b-chloroprene workers was compared to 283 workers never exposed to b-chloroprene (160). No biochemical or hematologic alterations were indicated or suggested for a wide array of tests, including many that were positive in earlier studies.

6.4.2.2.5 Carcinogenesis NIOSH (141) reported skin cancer, lung cancer, and liver and kidney injury.

Careful study of two U.S. plants (161) did not find lung cancer. In this study, no other cause of death was related to exposure to b-chloroprene, and overall mortality was equal to the experience throughout the rest of the company.

Mortality from cancer that accounted for 16 deaths among 1258 workers was reported in a Chinese study resulting in an SMR of 2.4. A significant excess of liver cancer was reported in employees in the monomer workshop, and the SMR was 4.8 (4 observed when only 0.83 would have been

expected) (162). The IARC (135) reported that the selection criteria were not entirely clear and that a bias could have occurred because only reference rates during a three-year period were used.

In a Russian study of Moscow shoe-manufacturing workers, there was an excess of cancer mortality, and 265 deaths had an SMR of 1.2 (95% CI 1.0–1.3). Overall 10 deaths occurred from liver cancer giving an SMR of 2.4 (95% CI 1.1–4.3); leukemia accounted for 13 deaths giving an SMR of 1.9 (95% CI 1.0–3.3). When workers exposed to chloroprene were compared to those unexposed workers, the relative risk of liver cancer increased to 4.2 (95% CI 0.5–33), accounting for 9 deaths; 9 deaths from kidney cancer were also reported giving a relative risk of 3.8 (95% CI 0.5–31); and a slight increase of nine leukemia deaths occurred at a relative risk of 1.1 (95% CI 0.3–3.7). The authors suggested that the leukemia excess may be due to concomitant exposure with benzene, whereas the liver cancer excesses point to the carcinogenic effect of chloroprene (163). A study of chloroprene workers from Armenia evaluated the cancer risk among 1897 men and 417 women at a production plant in Yerevan between 1940 and 1988 and found that the overall cancer mortality was less than expected, but increased incidence (SMR 3.27; 95% CI 1.47–7.27) and mortality (SMR 3.39; 95% CI 1.09–10.5) from liver cancer was found. This increase, it was suggested, had a dose-response relationship through duration of employment, duration of high exposures, and cumulative exposure (164).

The IARC (135) concluded that there was inadequate evidence for the carcinogenicity of chloroprene in humans but given the sufficient evidence from experimental animal studies, gave its overall evaluation that chloroprene is possibly carcinogenic to humans and placed it in its 2B Group.
6.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV of b-chloroprene is 10 ppm with a skin designation (36 mg/m^3). Thus skin contact should be prevented. OSHA has a 25 ppm PEL (90 mg/m^3) also with a skin designation, and NIOSH considers b-chloroprene a carcinogen and recommends a REL ceiling value of 1 ppm for 15 minutes (3.6 mg/m^3) (165). The exposure limits and guidelines of other countries range from 0 mg/m^3 in Germany, because it is considered a carcinogen, to 50 mg/m^3 in Czechoslovakia (135).

Unsaturated Halogenated Hydrocarbons

7.0 Vinylidene Chloride
7.0.1 CAS Number:
[*75-35-4*]
7.0.2 Synonyms:
1,1-Dichloroethylene, VDC, 1,1-DCE
7.0.3 Trade Names:
NA
7.0.4 Molecular Weight:
96.94
7.0.5 Molecular Formula:
$C_2H_2Cl_2$ or $CH_2{=}CCl_2$
7.0.6 Molecular Structure:

7.1 Physical and Chemical Properties

7.1.1 General (166)

Physical State	volatile, colorless liquid*
Specific Gravity	1.213 (20°C)
Freezing Point	–122.5°C
Boiling Point	31.7°C
Melting Point	–122°C
Vapor Pressure	66.5 kPa at 20°C; (495 torr at 20°C)
Relative Vapor Density	3.3 (air = 1)
Relative Density of the Vapor–Air Mixture at 20°C	2.5 (air = 1)
Refractive Index	1.427 (20°C)
Percent in "Saturated" Air	78
Solubility	0.225 g/100 mL by weight in water at 25°C; soluble in most organic solvents
Flash Point	–19°C (c.c.); –15°C (o.c.)
Autoignition Temperature	570°C
Flammability Limits	5.6 to 16% by volume in air Octanol/water Partition Coefficient as Log P_{OW} 1.32

*In the presence of air or oxygen, and particularly with the inhibitor removed, vinylidene chloride forms a complex peroxide compound at temperatures as low as –40°C. The peroxide is shock-sensitive and explosive. Reaction products formed with ozone may be particularly dangerous.

7.1.2 Odor and Warning Properties Vinylidene chloride has a characteristic sweet smell that resembles carbon tetrachloride or chloroform. Most persons can detect a mild but definite odor at 1000 ppm in air. Some people can detect it at 500 ppm. Vapors that contain decomposition products have a disagreeable odor and can be detected at concentrations considerably less than 500 ppm. Neither the odor nor the irritating properties of vinylidene chloride are adequate to warn of excessive exposure.

7.2 Production and Use

Vinylidene chloride is used as a chemical intermediate, particularly as a copolymer in the production of plastics. Production in 1990 was 290 thousand tons (167).

7.3 Exposure Assessment

7.3.1 Air It is estimated that 2–5% of the vinylidene chloride manufactured is emitted to the air in the United States (168). EPA estimates that the median ambient air level in suburban/urban areas is 20 ng/m^3 (169, 170). The levels found around industrial sources were higher, and the median was 14 mg/m^3.

7.3.2 Workplace Methods Analytical sampling can be done with a solid sorbent tube (coconut shell charcoal, 100 mg/50 mg) and measured by gas chromatography, FID. The working range is 0.5 to 5 ppm (2 to 20 mg/m^3) for a 5-L air sample (NIOSH Method 1015) (171).

7.4 Toxic Effects

Little information is available from studies in humans, and most conclusions are based on animal studies. This may be partly the result of early recognition of the rather high chronic toxicity of vinylidene chloride and the need to control exposures in a manner quantitatively similar to carbon tetrachloride. Exposures to high concentrations result primarily in CNS depression and the associated symptoms of drunkenness, which may proceed to unconsciousness and even death. Liver and kidney injury may result but are more likely the result of repeated exposures. Species, strain,

sex, and nutritional state have a significant impact on the observed responses of laboratory animals to vinylidene chloride. Reviews are available (42, 172–175).

7.4.1 Experimental Studies When VDC was fed in a corn oil solution to male rats, an acute oral LD_{50} of 1500 mg/kg was determined (176). These workers and Jaeger et al. (177) showed that numerous changes in liver and plasma enzymes occur, consistent with the histological changes observed in the livers of treated animals.

Forkert and Reynolds (178) reported unusual histological changes in the Clara cells and ciliated cells of the bronchiolar epithelium of the lungs of rats fed vinylidene chloride at doses of 10 or 200 mg/kg body weight as a solution in mineral oil. Despite serious injury, recovery appeared to be complete 7 days after treatment. Similar changes occurred in mice (179). These investigators examined biochemical changes following 125 mg/kg intraperitoneal doses and noted marked changes in the lung in the absence of liver and kidney effects. Recovery took 3 to 6 weeks. The unusual susceptibility of mice is consistent with data from other studies. As described in the section on carcinogenicity, the mouse kidney is the only organ that shows a positive response in animal studies.

Vinylidene chloride is moderately irritating to the eyes of rabbits. It causes pain, conjunctival irritation, and some transient corneal injury. Permanent damage is not likely. However, a high concentration of the phenolic (MEHQ) inhibitor sometimes used in vinylidene chloride may cause eye injury. Contaminated eyes should be flushed immediately with large quantities of flowing water.

Liquid vinylidene chloride is irritating to the skin of rabbits after direct contact for only a few minutes. The inhibitor content of the vinylidene chloride may be partly responsible for this irritation. Where leaks occur, vinylidene chloride will evaporate and the phenolic (MEHQ) inhibitor may accumulate until it reaches a concentration that can cause local burns and possibly depigmentation of the skin. Particular caution should be used with regard to contamination of clothing, which should be removed immediately and thoroughly cleaned before reuse. The volatility of vinylidene chloride probably prevents absorption of significant quantities through the skin unless it is in solution or confined.

Lethality varies considerably with species, sex, strain, and nutritional status, possibly explained in part by the availability of glutathione, which provides a protective effect. ATSDR (174) reported LCT_{50}s for 4 h exposure of male rats of 6000 to 8000 ppm and for female rats of 10,000 ppm. When rats were non-fasting (sex unspecified), 4 h LCT_{50}s of 10,000 ppm to 15,000 ppm were observed; fasting for 16 h before exposure reduced the LCT_{50} almost 30-fold (177).

Mice were much more susceptible to 4 h LC_{50}s of 100 ppm reported for “fed” male mice and 200 ppm (females) versus 40 and 115 ppm, respectively, for fasting mice (180). When rats received 20 repeated 6 h exposures to 200 ppm, only slight nasal irritation was observed; similar exposure of four male and four female rats to 500 ppm also decreased weight gain and produced liver cell degeneration (125). Rabbits, monkeys, rats, and guinea pigs were exposed for 8 h/day, 5 days/week for 6 weeks to 395 mg/m^3 (100 ppm), and there were no deaths, overt signs of toxicity, or histopathological changes (181).

Seven days of essentially continuous exposure (22 to 23 h/day) to 40 ppm was more toxic to male mice than female mice or male rats in terms of SGOT, SGPT, and lethality (182). Seven of 10 male mice died, whereas no female mice or male rats died. This is consistent with the higher rate of metabolism of vinylidene chloride by mice, the carcinogenic effect in that species, and the higher susceptibility of that species to liver and kidney injury.

Although vinylidene chloride sensitizes the heart of rats to epinephrine, only limited data are available on its potency (183).

7.4.1.2 Chronic and Subchronic Toxicity The results of long-term feeding studies are described in the section on carcinogenicity. Quast et al. reported no effect in dogs fed capsules containing daily doses of 25 mg/kg/day in peanut oil for 90 days (184).

Animals exposed for 5 days/week, 8 h/day for 6 months had liver and kidney injuries at concentrations of 100 and 50 ppm. There was minimal injury to the liver and kidney, even at a concentration as low as 25 ppm (Dow Chemical Company, Midland, MI, unpublished data). In a continuous exposure for 90 days to 189 mg/m^3 (about 47 ppm), considerable mortality occurred in guinea pigs and monkeys (7/15 and 3/9, respectively), but surviving animals exhibited no overt signs of toxicity. Mottled livers were evident on gross examination, and considerable injury was seen microscopically in that organ. Dog livers were most affected, but kidneys, adrenals, and lungs were also injured. Less effect was observed following continuous exposure to 101, 61, and 20 mg/m^3 (181).

Repeated 6 h daily exposures to 25 or 75 ppm for 5 days/week for 90 days resulted in minimal, apparently reversible changes in the livers of rats (185).

7.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Absorption of vinylidene chloride from the lungs or gastrointestinal tract or after intraperitoneal injection is rapid and is dose-dependent and saturable. Furthermore, it is influenced by the state of nutrition of the animal (fasting versus non-fasting rats) and by feeding other substances, including ethyl alcohol. At relatively high dosages, most ingested or injected vinylidene chloride is excreted unchanged in the expired air of rats (199). Mice metabolize a higher proportion of orally administered vinylidene chloride than other species, consistent with the higher toxicity in mice (200).

The metabolism of vinylidene chloride following inhalation and oral administration has been studied (201, 202). Metabolism is dose-dependent. Following a 6 h exposure to 10 ppm, 98% of the acquired body burden was metabolized by the rat to nonvolatile compounds. At 200 ppm, only 92 to 96% was metabolized. Fasting before exposure significantly reduced the detoxifying pathways for vinylidene chloride and enhanced covalent binding of metabolites to liver and kidney tissue. Fasting rats exposed to 200 ppm sustained liver and kidney damage, whereas nonfasting rats did not; fasting had no effect on rats exposed to 10 ppm vapor. The two major urinary metabolites were *N*-acetyl-*S*-(2-hydroxyethyl)cysteine and thiodiglycolic acid, indicating that the major detoxification pathway in the liver is by conjugation with liver glutathione, possibly through an epoxy intermediate. Jones and Hathway (199) found monochloroacetic acid in the urine of rats treated orally with vinylidene chloride. Short et al. (203) also reported that disulfiram reduced the acute lethal and hepatotoxic effects of vinylidene chloride.

Based on published data, Fielder et al. proposed a rather elaborate metabolic map for vinylidene chloride shown in Figure 38.9.

A physiologically based pharmacokinetic model was proposed for the rat. The authors note the extreme sensitivity of their model to vinylidene chloride kinetics and warn that extrapolation to different conditions or to humans must be done very cautiously.

7.4.1.4 Reproductive and Developmental Rats and rabbits were exposed 7 h/day to 20 (rats only), 80, or 160 ppm of vinylidene chloride vapor during organogenesis (186). Pregnant rats were also fed drinking water that contained 200 ppm (w/w) of vinylidene chloride. No teratogenic effects were observed in either species but toxic effects (decreased weight gain, decreased food consumption, increased water consumption, or increased liver weight) were observed in the dams of rats that inhaled 80 or 160 ppm and rabbits that inhaled 160 ppm. Although a teratogenic effect was not observed, embryo toxic and fetotoxic effects were noted in both rats and rabbits. These included delayed ossification, wavy ribs, and resorption (rabbits). The investigators concluded that

at levels causing little or no maternal toxicity (20 ppm in rats and 80 ppm in rabbits), there was no effect on embryonal or fetal development. Among the rats given drinking water that contained 200 ppm vinylidene chloride there was no evidence of toxicity to the dams or their offspring.

On the basis of their inhalation studies, Short et al. (187) claimed that vinylidene chloride is a weak teratogen in rats and mice.

Sprague–Dawley rats were used to evaluate the effects of parental administration of vinylidene chloride in drinking water on reproduction (188). Rats were fed water containing 0, 50, 100, or 200 ppm for three generations, including six litters. Mild dose-related changes of the livers occurred in the dams but not in the offspring. The investigators concluded that reproductive capacity was not affected by the exposure.

Reproductive organs have not been target organs in long- or short-term studies.

Summaries of the available data on mutagenesis are available (173, 174, 189). Vinylidene chloride *per se* is not mutagenic in an *in vitro* test system but positive results have been observed with metabolic activation in several microbial, yeast, and cellular systems. Because glutathione is often present in lower concentrations in *in vitro* systems than it is in mammalian organs, many of these mutagenic tests may not be representative of expected effects in humans.

Vinylidene chloride was inactive in a mouse dominant lethal mutation study (190) after exposure to 40, 120, 200 mg/m^3 (10, 30, or 50 ppm) for 6 h/day for 5 days. Male CD rats exposed to 55 ppm for 6 h/day, 5 days/week were also unaffected when studied for dominant lethal effects (182).

Although reaction with macromolecules occurs following treatment of rats and mice with vinylidene chloride, available data suggest that reaction is the result of metabolic activity and occurs only at concentrations injurious to rodents (191, 192). The weak activity of vinylidene chloride, the protective effect of glutathione, and the lack of direct alkylation are consistent with the low carcinogenic activity seen only in mice, but not in rats and hamsters, and support a nongenotoxic causation of cancer in mice kidneys.

7.4.1.5 Carcinogenesis Varying results have been obtained in carcinogenic studies in animals (193). Although the carcinogenicity of this material has not been observed in several long-term studies in rats (193–195) or in hamsters (195), kidney tumors were reported in a single study in mice (195). The tumors were observed primarily in the kidneys of male mice and were accompanied by significant injury to the kidney tissue (191, 196, 197) considered that the effects were the result of tissue injury and subsequent repair rather than a genetic mechanism that involves alkylation of DNA.

F344 rats were fed 1 or 5 mg/kg body weight and B6C3F$_1$ mice 2 or 10 mg/kg body weight in a corn oil solution by gavage for 104 weeks. The report concludes that “vinylidene chloride was not carcinogenic for F344 rats or B6C3F$_1$ mice of either sex.” Although high-dose male and female rats showed chronic renal inflammation and high-dose male mice showed necrosis of the liver, NTP concluded that maximum tolerated doses had not been fed (198). Vinylidene chloride inhaled for 6 h/day for 12 months caused two hemangiosarcomas (one of the mesenteric nodes and one of the subcutaneous tissue). Although the authors consider the finding significant, the failure to produce this tumor in other long-term studies, together with the fact that vinyl chloride was being used simultaneously in a parallel study, has prompted questions about the significance of the observation.

Van Duuren et al. (20) applied low doses of vinylidene chloride to ICR/Ha Swiss mice skin by several methods. Repeated dermal application of vinylidene chloride by itself produced no tumors, but when a promoter, phorbol myristate acetate, was used, skin tumors resulted. Vinylidene chloride did not produce tumors when injected subcutaneously at weekly intervals at a dose of 2 mg/mouse per injection.

In the largest available study, no increase in tumors was found in rats that ingested up to 19.3 or 25.6 mg/kg/day (male and female rats, respectively) or in rats that inhaled 25 or 75 ppm (v/v) for 6 h/day for 18 months and then kept for their lifetimes (184, 193).

7.4.2 Human Experience 7.4.2.2.1 Acute Toxicity Inhalation can cause dizziness, drowsiness, and even unconsciousness. Skin exposure can cause redness and burns. Exposure of the eyes can result in redness and pain and ingestion can cause abdominal pain and sore throat (166). Ingestion may also cause aspiration into the lungs and a resulting risk of chemical pneumonitis, and it may also affect the central nervous system (166).

7.4.2.2.2 Chronic and Subchronic Toxicity Long-term or repeated exposures that cause dermatitis may result from contact with the skin. Vinylidene chloride may also have long-term effects on the liver and kidneys (166).

7.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms In the Ames bioassay test, vinylidene chloride is activated by human liver S9 supernatant, thus suggesting the presence of cytochrome enzyme P450 (167). The WHO (167) also reported the formation of dichloroacetaldehyde from two human liver microsomal preparations.

7.4.2.3 Epidemiology Studies Studies of industrial populations that handle vinylidene chloride have been published but all are small and of limited value. The first mortality study has limited value because the major interest was vinyl chloride, and only limited exposure to vinylidene chloride occurred. A second study, also by Ott et al., looked at mortality and the findings of health examinations of 138 employees exposed to measured levels of vinylidene chloride where vinyl chloride was not involved. Measured concentrations ranged from 5 to 20 ppm time-weighted average. No effects on mortality or health parameters were found. Studies by Thiess et al. (204) and by Waxweiler et al. (205, 206) were also negative.

The IARC has concluded that there is inadequate evidence in humans and limited evidence in experimental animals for the carcinogenicity of vinylidene chloride and has placed it in its Group 3 category as not classifiable as to its carcinogenicity to humans (207).
7.5 Standards, Regulations, or Guidelines of Exposure
OSHA has no PEL for vinylidene chloride, and NIOSH recommends treating it as a carcinogen based on animal studies (171). The ACGIH recommends a TLV of 5 ppm (20 mg/m^3) with an A4 notation (208). The International Labour Office (209) reports similar values for standards and guidelines in other countries. The World Health Organization has a guideline for drinking water at 30 mg/L (210).

Unsaturated Halogenated Hydrocarbons
R. A. Lemen, Ph.D., MSPH

8.0 Vinyl Chloride
8.0.1 CAS Number:
[*75-01-4*]

8.0.2 Synonyms:
Monochloroethylene; chloroethene; chloroethylene; VC; VCM; Vinyl C monomer
8.0.3 Trade Names:
NA
8.0.4 Molecular Weight:
62.5
8.0.5 Molecular Formula:
C_2H_3Cl
8.0.6 Molecular Structure:

8.1 Chemical and Physical Properties
8.1.1 General

Physical State	colorless gas
Specific Gravity	0.9106 (20/4°C)
Melting Point	–153.8°C
Boiling Point	–13.4°C
Vapor Pressure	2530 torr at 20°C
Solubility	0.11 g/100 mL at 25°C; soluble in ethanol, ethyl ether, carbon tetrachloride, and benzene
Stability	may produce peroxides; on combustion degrades to hydrogen chloride, carbon monoxide, carbon dioxide, and traces of phosgene
Flash Point	–77.8°C (open cup)
Autoignition Temperature	472.22°C
Explosive Limits	4 to 22% by volume in air

8.1.2 Odor and Warning Properties Although vinyl chloride has a faintly sweet odor at high concentrations, the odor is of no value in preventing excessive exposure. The actual vapor concentrations that can be detected have never been adequately determined and vary from one individual to another, in impurities in the sample, and probably in duration of exposure.
8.2 Production and Use
Vinyl chloride was first synthesized around 1935 (211). Vinyl chloride has been used in the United States for more than 65 years. Production of vinyl chloride monomer is based on cracking ethylene dichloride (212). The demand for vinyl chloride was 13.7 billion pounds in 1996, 14.5 billion pounds in 1997, and is expected to be 16.8 billion pounds by 2001 (212). The historical growth of the industry has been around 3.7% per year from 1988–1997 and is expected to continue at around 3% through 2001 (212). Ninety-eight percent is used for polyvinyl chloride (PVC) production and the remaining 2% for polyvinylidene chloride and chlorinated solvents (212). More than 70% of the PVC manufactured is used in construction (212).
8.3 Exposure Assessment
8.3.1 Air The air concentrations of VC around PVC plants averages around 44 mg/m^3 (17 ppb), and some measurements in U.S. cities were from 8 mg/m^3–3.2 mg/m^3 (3.1–1250 ppb) in Houston, Texas, an area where large production facilities are located, and in Delaware City, Delaware, with maximum concentrations were 3.9 mg/m^3 91.5 ppm (213–215).

8.3.3 Workplace Methods NIOSH analytical method 1007, has been a method of choice that uses a solid sorbent tube and then the gas chromatography, FID technique. The working range is 0.4 to

40 mg/m^3 (216).

8.3.5 Biomonitoring/Biomarkers Biological monitoring is of little practical value at exposures considered acceptable by today's standards.
8.4 Toxic Effects
8.4.1.1 Acute Toxicity The primary acute physiological effect of vinyl chloride is depression of the central nervous system, which begins to occur at concentrations of 8000 to 10,000 ppm (217). Early studies as a surgical anesthetic were discouraged by its high flammability and by cardiac and circulatory disturbances noted in animals and patients at the 10 to 20% concentration necessary to produce surgical anesthesia (218–220).

Acute liver toxicity even at these high concentrations appeared to be low, but there have since been suggestions of a delayed carcinogenic response following massive subacute exposures in animals (221).

8.4.1.2 Chronic and Subchronic Toxicity Essentially no investigations were published before 1961 on the response to chronic vapor exposure. Schaumann exposed mice and rats and found that they tolerated a level sufficient for "light narcosis" for periods of 4 h/day for five to eight consecutive days or for 1 h/day for 4 weeks without showing kidney or liver injury [as cited by Lehmann and Flury (50)].

Torkelson et al. (222) reported on repeated exposures of animals for 7 h/day, 5 days/week. At 500 ppm, rats showed increased liver weight and histopathology. At 200 and 100 ppm, rats showed increased liver weight, but no changes could be observed in dogs or guinea pigs. All species tolerated 50 ppm for 6 months without adverse effects. Repeated exposures of rats for 1 h/day at 200 or 100 ppm were tolerated without observable effect. The effects on the liver were mild and apparently reversible, and they were not observed in rats kept 6 to 8 weeks after the 6 month exposures ceased. This was the longest period for which any animals were observed in this study.

Noncarcinogenic effects in the liver were also reported in later onconological studies.

8.4.1.4 Reproductive and Developmental At least two studies have shown no teratological response in laboratory animals that inhaled vinyl chloride during pregnancy; however, fetotoxic effects were observed, particularly when ethanol was administered simultaneously in drinking water.

John et al. (223) evaluated the effects on mice, rats, and rabbits. Groups of pregnant CF-1 mice, Sprague–Dawley rats, and New Zealand white rabbits were exposed to 500 ppm vinyl chloride for 7 h daily during organogenesis. Mice were also exposed to 50 ppm and rats and rabbits to 2500 ppm. Maternal toxicity was observed, most prominently in the mice, but the exposures did not cause significant embryonal or fetal toxicity or teratological effects. Simultaneous administration of 15% ethanol in drinking water produced toxic effects greater than those of vinyl chloride alone. Maternal toxicity was increased more than embryo toxicity.

Ungvary et al. (224) showed that vinyl chloride crosses the placenta and is found in the amniotic fluid and fetal blood, as well as in the maternal blood of rats. Pregnant rats were exposed continuously to 1500 ppm (4000 mg/m^3) during the first, second, or third trimester of pregnancy without teratological effects. No embryo toxicity was noted when vinyl chloride was administered during the second or third trimester, but during the first trimester, it increased fetal mortality and caused other fetotoxic effects. Fetal losses and induction of CNS malformation due to trypan blue administration were not potentiated by a combined exposure of pregnant rats to vinyl chloride and the dye. The reproductive organs were target organs in lifetime animal studies, although Bi et al. claim to have produced testicular injury in male Wistar rats in 12 months at 100 ppm (225).

Numerous references attest to the mutagenic effect of vinyl chloride or its metabolites in *in vitro*

systems using bacteria, yeast, and hamster cells (226, 227). *Drosophila* males treated with 1 to 20% vinyl chloride vapors had an increased frequency of complete and mosaic recessive lethals. Muratov and Guskova (228) reported that continuous exposures of rats to 0.15, 0.4, or 10 mg/m^3 (60, 160, or 3900 ppm) for 3.5 months increased the incidence of chromosomal fragmentation, agglutination, and bridging. The incidence reportedly increased when the rats were housed at 35°C rather than at 22°C. No mutagenic effects were observed at 0.07 mg/m^3 (28 ppm).

Inhalation of 2500 or 5000 ppm for 4 h/day for 5 days or intraperitoneal injection of 300 or 600 mg vinyl chloride/kg/day resulted in chromosomal changes in the marrow cells of Chinese hamsters (229). However, Anderson et al. (230) reported the lack of a dominant lethal effect in a study in which mice were exposed to 3000, 10,000, or 30,000 ppm for 5 days. Similarly Short et al. (231) found no evidence of pre- or postimplantation loss in female rats mated with males that had been exposed for 11 weeks to 0, 250, or 1000 ppm. Exposures were for 6 h/day, 5 days/week.

The available mutagenic data are consistent with a genotoxic causation of cancer.

8.4.2 Human Experience 8.4.2.2 Clinical Cases Because vinyl chloride is a gas, the only significant route of toxic industrial exposure is inhalation. Ingesting low levels for a long period of time has also produced adverse effects, including cancer in animals. If vinyl chloride is confined on the skin in a liquid, some might be expected to be absorbed, but the relative amount is small. The likelihood of acute toxic effects is not nearly as significant as are liver injury, angiosarcoma of the liver, liver and biliary cancer, and possibly acroosteolysis. It appears that metabolism of vinyl chloride is necessary before many of its toxic effects occur. Numerous reviews, bibliographies, and key references are available (42, 232–234), and many regulations apply to handling vinyl chloride.

8.4.2.2.1 Acute Toxicity Limited human studies by Mastromatteo et al. (217) showed that concentrations must approach 1% (10,000 ppm) before humans notice the anesthetic effects of vinyl chloride gas. Surgical anesthesia requires concentrations greater than 10%. Baretta et al. (235) studied the expired air of subjects exposed to 50, 250, or 500 ppm for 7.5 h with a half-hour lunch break. Although they concluded that expired air sampling might have utility in monitoring exposure at the occupational standards then in use, expired air can be expected to be of little value at currently accepted levels of exposure.

8.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms Numerous studies indicate that a reactive metabolite, not vinyl chloride *per se*, is probably responsible for its toxicity. Although most inhaled vinyl chloride is excreted unchanged, depending on the dose, a varying amount is metabolized in a saturable process (235). Vinyl chloride is metabolized by epoxidation and subsequent production of chloroacetaldehyde. Further oxidation and conjugation with glutathione are responsible for the metabolites in urine.

Gehring et al. (234, 236) analyzed the metabolic and carcinogenic data from humans and laboratory animals. Using several models to predict the incidence in humans from animal data, they found that all models overpredicted, unless corrections were made for rates of metabolism and for the surface areas of the different species.

8.4.2.2.5 Carcinogenesis Because it was one of the first large-scale industrial chemicals clearly demonstrated to cause cancer in humans, it has been the subject of much research and regulation. Only a small portion of the available references have been cited.

The early industrial history of vinyl chloride is remarkably free of adverse reports except for problems of fire and explosion. The earliest reports of adverse effect on industrial workers related to vinyl chloride were of anesthesia and anesthetic deaths. Danziger (237) reported two fatal cases, only one of which was definitely ascribed to a massive exposure to vinyl chloride. Other reports indicate that exposures were poorly controlled, and probably amounted to thousands of parts per millions in

many situations before 1974.

Cutaneous lesions (scleroderma), collagen disease, and Raynaud's syndrome were reportedly observed by Suciu et al. (238) in a PVC plant, but contrary to some reports these authors did not ascribe the effects to vinyl chloride *per se*; rather they considered that they were related to other materials used in the factory. Subsequently, numerous authors reported acroosteolysis in PVC workers in Europe and the United States. This was accompanied by scleroderma and Raynaud's syndrome.

The association of vinyl chloride exposure with human cancer occurred when three case reports of angiosarcoma of the liver were discussed in a report of Creech and Johnson in 1974 (239). This finding led to many studies of the effects of exposure to vinyl chloride. There is no question that angiosarcoma of the liver was caused by exposure to vinyl chloride primarily while cleaning reactor vessels. As of February 1991, a total of 153 vinyl chloride-related deaths due to angiosarcoma of the liver were recorded in non-Soviet bloc countries some cases apparently still living (240). The incidence of death reached a maximum of 10 cases per year during 1973–1984 and subsequently decreased to about four per year. Latency since the year of first exposure averages about 24 years worldwide.

Angiosarcoma of the liver and combined liver-biliary tumors in humans are certainly consistent with the results of studies in animals because they have been produced in several epidemiological studies.

Mutagenic effects reported in workmen exposed to vinyl chloride include increased frequency of chromosomal aberrations, sister chromatid exchange, and micronuclei (241). Several of the studies cited by Sinus et al. (241) indicated that there is a dose response and that no-effect levels for mutagenesis may exist.

A U.S. study covering 1942–1982 identified a population of 10,173 men who satisfied the definition of the study cohort (242). A total of 1536 deaths occurred, and the standardized mortality ratio (SMR) was of 90.07. A total of 359 cancer deaths were observed versus 341.73 expected (SMR 105.1) which was not statistically significant. Angiosarcomas of the liver and combined liver-biliary cancers were significantly elevated.

The investigators also claimed an excess of brain and CNS cancers as a result of exposure to vinyl chloride. There were 23 deaths observed and 12.76 expected (SMR, 180.2). The authors stated,

Our analysis did not demonstrate any dependence of brain cancer mortality on latency. Contrary to our observation on liver cancer, a higher brain cancer mortality risk was found among those who were exposed after age 35 and who were exposed during or after 1960 than those who were exposed before 1960 and at a younger age. Based on the limited exposure information available in this mortality study, the implication of this difference in risk profile is not clear at this point.

Pneumonia as a cause of death was significantly low, but in PVC plants, emphysema (including chronic respiratory disease) was elevated (SMR 163). Earlier English studies suggest that the respiratory effects may have been due to PVC dust.

Cancers of the buccal cavity and pharynx, digestive tract, lung cancer, brain cancer, and lymphatic cancers were reported among workers who were employed at least one year in plants that produced and/or polymerized vinyl chloride (243). Brain and liver cancer were observed among 161 workers who died and were employed in two plants that produced and polymerized vinyl chloride. An 11-fold excess of liver and biliary tract cancer and a fourfold excess of brain cancer occurred. Digestive tract and lung cancer were also elevated (244). Cancer mortality among 257 workers exposed to

vinyl chloride for at least 5 years consisted of a 2.3-fold excess in cancer deaths from all sites and three deaths due to hemangiosarcoma of the liver (245).

A report from the United Kingdom reported an increased risk of digestive system cancers among workers who had 15 years of latency or more from exposures to vinyl chloride or poly(vinyl chloride) (246). The National Institute for Occupational Safety and Health (NIOSH) study by Waxweiler et al. (247) found two causes of death in excess: nonneoplastic respiratory disease (6 obs.vs. 3.4 exp.) and all malignant neoplasms combined (35 obs. vs. 23.4 exp., $p = .05$). When specific cancer sites were evaluated, excess cancers were found for CNS, respiratory system, and hepatic systems in workers who had 15 or more years of latency since first exposure. Pathological analysis of the 14 liver cancer cases, showed that 11 were angiosarcoma, and nine of the ten cases of brain cancer were glioblastoma multiforme. All of the lung cancers were large cell undifferentiated or adenocarcinomas. In Sweden, statistically significant excesses of liver-pancreatic and brain cancer were reported among 771 workers of a vinyl chloride/polyvinyl chloride production plant (248). In Germany vinyl chloride-polyvinyl chloride exposed workers had excesses of cancer of the liver, lung, brain, and the lymphatic and hematopoietic systems (249). In the United Kingdom, excess liver cancer mortality was found at all exposure levels (high, medium, or low) among 7561 males employed at one of four plants that produced poly(vinyl chloride) between 1940 and 1974 (250).

A large multicentric study of European experience combined 12,706 subjects from 19 factories in Italy, Norway, Sweden, and the United Kingdom (241). A total of 1438 deaths were observed versus 1636.4 expected (SMR 88.95). The SMR for all malignant neoplasms was 104, for cancer of the liver-biliary 286 (24 versus 8.4), and for cancer from unspecified sites 187 (24 versus 12.9 expected). Three of the cancers of unspecified site were liver cancers; no other site was in excess.

Another area of interest is the question of what, if any association, did vinyl chloride have in the etiology of lymphoma and hemopoietic cancers? In an industry-sponsored study published in 1974, there was a pattern of increased exposure and lymphoma among 8384 men who had worked at least one year with exposures to vinyl chloride before December 31, 1972. Though not statistically significant, the authors indicated that the findings " ... are particularly interesting." They observed 5 cases when 7.54 would have been expected (243). This paper probably suffered from lack of power to really detect a true increase, so this finding was of great interest. At a conference in New York, the next year, another study, this one conducted by the National Institute for Occupational Safety and Health (NIOSH), looked at four plants and 1,294 workers who had at least 5 years of exposure and also reported a nonstatistically significant excess for lymphatic and haematopoietic system cancers (4 obs. vs. 2.5 exp.—SMR 159). The SMR increased with latency to 176 after a 15 year latency period (247).

Additional studies continued and reported increased mortality from lymphoma. One study of nine different countries found nonstatistical increases in malignant lymphomas in conjunction with exposure to vinyl chloride (251). Such increases were also observed in studies in Germany and Russia in the early 1980s (252–254). In a further report from Russia, some of the same authors of the earlier study, found that a significant increase in deaths from malignancies of the lymphatic and hemopoietic tissues in the absence of liver angiosarcomas occurred among workers employed between 1939 and 1977 in producing vinyl chloride and polyvinyl chloride. They suggest that this finding probably reflected the specific carcinogenic action of different doses of vinyl chloride. The risk of cancer was highest among the workers exposed to concentrations of vinyl chloride of 300 mg/m^3 and also greater in those who had worked at the plant for 15 to 19 years (255).

In a mortality study of 88,000 Union Carbide Corporation personnel employed from 1974 to 1983 using a population-based surveillance system, the overall population exhibited a 30% lower mortality and a 10% lower cancer mortality compared to the general United States population. The mortality rates for both lymphosarcoma and reticulosarcoma were significantly elevated, and according to the authors, these higher rates were found among hourly male employees who were

clustered in one company location. They point out that this same location showed an excess of liver cancer associated with vinyl chloride operations (256).

Briefly, another study found chromosomal breaks induced by vinyl chloride and lymphocytosis (257) in which the authors conclude that G-banding showed that sites of chromosomal break points caused by vinyl chloride can be related to lymphatic tissue disorders. The authors also conclude that lymphomas and leukemias can be expected from vinyl chloride exposure at concentrations as low as 1 ppm. Finally, a study of Danish men found that a probable exposure to vinyl chloride was associated with increased risk of myeloma (a tumor composed of cells derived from hematopoietic tissues of the bone marrow) that rose fivefold from longer exposures (258).

There are epidemiological studies that have not shown such associations with exposure to vinyl chloride, but the studies cited above do point to a general pattern that leads to a conclusion that vinyl chloride exposures can result in malignancies of the lymphatic and hematopoietic system. This is also the conclusion of the International Agency for Research on Cancer, and its conclusion was based on fewer studies than are now available (259). Animal bioassay's have also supported these epidemiological findings (260–262).

Almost 30 years since the first reports of angiosarcomas in the liver of animals and humans, it is clear that, in addition to liver angiosarcoma and combined liver-biliary cancer which have consistently increased, brain and lymphatic cancers are also attributable to exposures to vinyl chloride. Mutagenic effects have been found and have reversed as exposures were better controlled. Liver injury has resulted from vinyl chloride *per se*, as have such well established conditions as acroosteolysis, scleroderma, and Raynaud's syndrome, which have been clearly related to the PVC production process. The International Agency for Research on Cancer has concluded that the evidence for cancer in humans shows that exposure to vinyl chloride causes tumors of the liver, brain, lung, and hematolymphopoietic system (259). The IARC has also concluded that evidence for cancer in animals shows that VC produces tumors of the mammary gland, lung, Zymbal gland, and skin and angiosarcomas of the liver. Oral administration of ethanol and inhalation of vinyl chloride resulted in more liver tumors than from vinyl chloride alone (259).

Tamburro (263) has concluded that current clinical, biochemical, and hematologic tests are of limited value in predicting angiosarcoma but may be of value in other hepatotoxic effects.

8.4.2.2.6 Genetic and Related Cellular Effects Studies Despite efforts to corroborate reported reproductive effects in human studies (264), they have not been confirmed in properly conducted epidemiological studies. In fact the early “positive” report (264) has been severely criticized for bias and defective methodology and, according to independent reviews, should not continue to be cited as evidence for reproductive effects in humans (265–267).

8.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH recommends a TLV of 1 ppm (2 mg/m^3) vinyl chloride. The U.S. Department of Labor (OSHA) PEL is 1 ppm and the 15 min ceiling is 5 ppm; standards in other countries vary, but generally require limiting exposures to 5 ppm or less. It appears reasonable to assume that these levels established to protect against angiosarcoma of the liver will prevent other adverse effects as well. NIOSH recommends treating vinyl chloride as a carcinogen.

8.6 Studies on Environmental Impact

Cases of hepatic angiosarcoma have been reported in persons who had no occupational exposure but lived in the area near vinyl chloride polymerizing or fabricating poly(vinyl chloride) facilities in the United States and Great Britain. This indicates an environmental etiology (268–270).

Unsaturated Halogenated Hydrocarbons
R. A. Lemen, Ph.D., MSPH

9.0 Vinyl Bromide
9.0.1 CAS Number:
[*593-60-2*]
9.0.2 Synonyms:
Bromoethylene; bromoethene; monobromoethylene: Vinyl-13C2 bromide (gas)
9.0.3 Trade Names:
NA
9.0.4 Molecular Weight:
106.96
9.0.5 Molecular Formula:
C_2H_3Br
9.0.6 Molecular Structure:

9.1 Chemical and Physical Properties
9.1.1 General

Physical State	colorless gas
Specific Gravity	1.4933
Melting Point	–139.5°C (271)
Boiling Point	15.8°C (271)
Vapor Pressure	119 kPa at 20°C 1033 torr at 20°C
Solubility	soluble in acetone, benzene, diethyl ether, chloroform, and ethanol; insoluble in water (271)
Stability	polymerizes rapidly in sunlight and, can react vigorously in the presence of oxidizing materials (271)
Flash Point	5°C
Explosive Limits	upper, 15%; lower 9% by volume (272)

9.1.2 Odor and Warning Properties Pungent odor. No published data were found but, based on its high chronic toxicity, it can be assumed that vinyl bromide has inadequate warning properties to prevent excessive chronic exposure.
9.2 Production and Use
Vinyl bromide is used as a copolymer primarily in the production of flame resistant acrylic polymers and to a limited extent as a chemical intermediate. Vinyl bromide is produced in Germany, Japan, and the United States (273).
9.3 Exposure Assessment
9.3.1 Air Sampling for vinyl bromide was conducted in two communities in the United States where production facilities were located, but no concentrations were reported in the air. However, the authors did report that vinyl bromide was in the air. More recently, vinyl bromide has been measured in ambient air samples (272).

9.3.2 Background Levels No information on whether vinyl bromide occurs naturally was found. Vinyl bromide may be found in the air as a result of degradation from 1,2-dibromoethane as well as from facilities that use or manufacture it (274).

9.3.3 Workplace Methods NIOSH recommends gas chromatography/flame ionization detection for analysis, Method 1009 a method that is valid over the range of 1.3–56 mg/m^3 (0.3–33 ppm) for a 6-L air sample (80).

9.3.4 Community Methods The method for environmental monitoring using gas chromatography/mass spectrometric has a lower limit of detection of between 10^3–10^5, but no range was given.

9.3.5 Biomonitoring/Biomarkers Vinyl bromide is metabolized and bromide ion is found in the blood of exposed animals. Determination of blood bromide was considered useful for biological monitoring at the then current industrial hygienic levels, but blood bromide is of very limited value at current standards of 1 to 5 ppm.

9.4 Toxic Effects

9.4.1.1 Acute Toxicity Vinyl bromide is a gas and the only significant route of toxic industrial exposure is inhalation. Limited data have been published. According to Leong and Torkelson (275),

Preliminary evaluation of the toxicity of vinyl bromide showed that the compound had an acute oral LD_{50} of approximately 500 mg/kg when a chilled 50% solution in corn oil was fed to male rats. It was found to be slightly to moderately irritating to the eyes, to be essentially nonirritating to the intact or abraded skin or rabbits, and to produce no frostbite from evaporation of the liquid.

Abreu (276) reported that 7 mmol/L (1700 ppm) was the highest tolerable concentration for mice exposed for 10 min and that half that concentration produced pronounced anesthesia. Leong and Torkelson (275) published very limited acute data indicating much lower toxicity than Abreu. They reported that

acute inhalation toxicity studies showed that exposure of rats to a nominal concentration of 100,000 ppm (437,636 mg/m^3) resulted in deep anesthesia and death within 15 minutes, but if the exposure was terminated before death, all animals recovered and survived. Exposure to a nominal concentration of 50,000 ppm (218,818 mg/m^3) resulted in unconsciousness within 25 minutes. All animals survived a 1½-hour exposure, but not a 7-hour exposure. At 25,000 ppm (109,409 mg/m^3) rats were anesthetized, but they recovered rapidly when removed from the atmosphere even after 7 hours of exposure. Necropsy of survivors of the 50,000 ppm groups 2 weeks after exposure revealed slight to moderate liver and kidney damage. However, no abnormality was observed grossly in the survivors of the 25,000-ppm group.

9.4.1.2 Chronic and Subchronic Toxicity Male and female rats, rabbits, and monkeys were repeatedly exposed for 6 h/day to either 250 or 500 ppm for 6 months without apparent effect, except for an increase in blood bromide ion concentration (275). There were no compound-related effects with respect to demeanor, body and organ weights, food consumption, a number of hematologic parameters, or mortality. Gross and microscopic examination of the major organs and tissues at the end of the exposure period revealed no remarkable abnormal changes. This study was not long enough to evaluate carcinogenicity.

9.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Based on bromide release, Gargas and Andersen concluded that vinyl bromide had two distinct saturable components (277). Metabolism is

expected to be similar to that of vinyl chloride, probably proceeding through epoxidation, and subsequent conjugation to macromolecules and other biological compounds (278) Vinyl metabolites to alkylate liver nucleic acids.

9.4.1.3.1 Absorption Vinyl bromide inhaled by rats was readily absorbed by the lung and showed an 11-fold accumulation in the entire organism compared to equilibrium (274).

9.4.1.4 Reproductive and Developmental No data were found, even by the IARC working group (59, 274).

9.4.1.5 Carcinogenesis Sprague–Dawley rats were exposed to nominal concentrations of 10, 50, 250, or 1250 ppm vinyl bromide gas for 6 h/day, 5 days/week (279). Groups were scheduled for sacrifices after 9, 12, 18, or 24 months; however, the 1250-ppm group had to be sacrificed after 72 weeks because of severe effects. In general, the results were quite similar to those seen from exposure to vinyl chloride. The investigators concluded that a decline in body weights was evident among all exposure levels. Microcytic anemia, elevated serum bromide levels, decreased BUN, elevated alkaline phosphatase, elevated LDH, and hematuria were observed. Angiosarcomas, primarily of the liver, were induced in both male and female rats in all four exposure groups. An increase in the number of Zymbal's gland neoplasms was found in both male and female rats at exposure levels of 52, 247, and 1235 ppm. An increased incidence of primary hepatocellular neoplasms was seen in males exposed to 247 ppm and in females exposed to 9.75, 52, and 247 ppm. The increase in primary hepatocellular neoplasms was detected primarily in animals that survived the 24-month exposure or died following 18 months of exposure. No exposure-related pathology was observed in the brains of the rats.

Similarly, results were seen in groups of six rats exposed to 50, 250, or 1250 ppm for 6 months as part of a carcinogenic study and killed as part of an interim sacrifice (279). After 1 year, however, tumors of the liver and Zymbal glands of the ears were observed. Liver angiosarcomas and Zymbal gland tumors that were dose-response related were observed after inhalation by rats (274).

The carcinogenic potency of vinyl bromide compared to vinyl chloride has not been established; however, Bolt et al. (280) studied the formation of preneoplastic hepatocellular foci in newborn rats and concluded that vinyl bromide had only one-tenth the potency of vinyl chloride. The investigators speculated that the lower potency may be associated with the lower rate of metabolism reported for vinyl bromide (281).

9.4.1.6 Genetic and Related Cellular Effects Studies Vinyl bromide vapors were mutagenic in *Salmonella typhimurium* TA1530 and TA100. Addition of rat and human liver enzymes enhanced activity in the *in vitro* test system (282) and also induced somatic mutations in *Drosophila melanogaster* (274). It is thought that vinyl bromide reacts with DNA and form etheno adducts, the same as those formed by vinyl chloride (283).

9.4.2 Human Experience Human experience has been limited, but it should also be assumed that vinyl bromide, like vinyl chloride, can cause certain cancers in humans. Toxicological reviews are available (173, 279).

9.4.2.2.1 Acute Toxicity Vinyl bromide can cause loss of consciousness and is a skin and eye irritant with that results in a frostbite type of burn (173).

9.4.2.2.5 Carcinogenesis No data for the effects of vinyl bromide on humans were available (274). However, the IARC (274) has classified vinyl bromide as probably carcinogenic to humans (2A) based on the consistently parallel response between vinyl bromide and vinyl chloride. Both vinyl chloride and vinyl bromide are activated to their corresponding epoxides via a P450-dependent pathway (274).

9.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH recommends a TLV of 0.5 ppm (2.2 mg/m^3) for vinyl chloride. OSHA has no standard and the standards in other countries require limiting exposures to 5 ppm or less. The National Institute for Occupational Safety and Health (NIOSH) recommends treating vinyl bromide as a carcinogen limited to 0.2 ppm, the limit of quantification (LOQ) (284).
9.6 Studies on Environmental Impact
Vinyl bromide as a degradation product of 1,2-dibromoethane may form in the air (274).

Unsaturated Halogenated Hydrocarbons
R. A. Lemen, Ph.D., MSPH

10.0 Trichloroethylene
10.0.1 CAS Number:
[*79-01-6*]
10.0.2/10.0.3 Synonyms & Trade Names:

Acetylene Trichloride	Fluate	TCE	Tri-Clene
Algylen	Germalgene	Threthylen	Trielene
Anamenth	Lanadin	Threthylene	Trielin
Blacosolv	Lethurin	Tri	Trilene
Chlorilen	Narcogen	Triad	Triline
Chlorylen	Narkosoid	Trial	Trimar
Densinfluat	Nialk	Triasol	Vestrol
Dow-Tri	Perm-A-Clor	Trichloran	Vitran
Ethinyl Trichloride	Petzinol	Trichloren	Westrosol
Fleck-Flip	Philex	Triclene	

(285, 286).

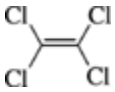
11.0 Tetrachloroethylene
11.0.1 CAS Number:
[*127-18-4*]
11.0.2 Synonyms:
tetrachloroethylene; 1,1,2,2-tetrachloroethylene; tetrachloroethene; PERK;PERC; Dowper; Perclene; Nema; Tetracap; Tetropil; Ankilostin; Didakene; carbon dichloride; perchlor; antisol1; fedal-un; PER; Perawin; Perclene d; Percosolve; perklone; persec; tetlen; tetraleno; tetralex; tetravec; tetrochloroethane; tetroguer; perchloroethylene
11.0.3 Trade Name:
NA
11.0.4 Molecular Weight:
165.83
11.0.5 Molecular Formula:
C_2Cl_4
11.0.6 Molecular Structure:



11.1 Chemical and Physical Properties

Physical State	colorless liquid
Specific Gravity	1.625
Melting Point	–22°C
Boiling Point	121°C
Vapor Pressure	1.9 kPa at 20°C (20 torr at 26.3°C)
Relative Vapor Pressure	5.8 (air = 1)
Solubility	almost insoluble in water (0.015 g/100 mL at 25°C); soluble in ethanol, and ethyl ether, chloroform, and benzene

11.1.2 Odor and Warning Properties Perchloroethylene has a not unpleasant ethereal or aromatic odor. In addition to clinical evaluation of perchloroethylene as an anesthetic, several other studies in human subjects are available. Hake and Stewart (428) summarized their extensive studies on humans. The analysis of expired air and urine were discussed in the preceding section and dermal absorption of perchloroethylene in the section on skin absorption. Based on detailed studies of neurological, psychological, and behavioral effects and the volunteers' subjective response, the authors concluded that 100 ppm of perchloroethylene was probably without effect but the margin of safety is small. Perchloroethylene plus alcohol or Valium (Diazepam) had no more effect on performance than alcohol or Valium alone. At 200 ppm some subjects objected to the odor and eye irritation, and higher concentrations were unacceptable. Light-headedness began at 200 ppm or slightly above.

Carpenter (429) exposed himself and three other subjects to perchloroethylene and determined that the odor was detectable at 50 ppm; that 500 ppm produced salivation, a metallic taste, eye irritation, and other objectionable reactions; and that 1000 and 2000 ppm produced the beginnings of narcosis and discomfort. This is consistent with data by Rowe et al. (430), who found that 280 ppm was

objectionable to test subjects and 216 ppm was marginal.

11.2 Production and Use

Perchloroethylene is used as an industrial solvent, particularly in dry cleaning and degreasing. It has been used as an anti helmintic in humans and animals. It also finds limited use as a chemical intermediate.

11.3 Exposure Assessment

Sampling in the workplace is done by air bag using gas chromatography (portable/photoionization detector (PDI) (431). The working range for this method is from 0.1 to 100 ppm for both air and exhaled breath samples by direct on-site analysis or by collection into inert sampling bags.

11.3.3 Workplace Methods NIOSH Method 1003 is recommended for determining workplace exposures to tetrachloroethylene (80).

11.3.5 Biomonitoring/Biomarkers Hake and Stewart (428) summarized much of their own and others' data on the use of expired air for monitoring industrial exposures. This included the results of an extensive study (432) in which male and female human subjects were exposed singly or repeatedly for various periods of time to several concentrations of perchloroethylene. Graphs are presented that are useful in estimating worker's exposure on the basis of expired air samples. It appears that analysis of expired air is useful for monitoring occupational exposure to perchloroethylene but that analysis of urinary metabolites is of less value (433).

11.4 Toxic Effects

The major response to perchloroethylene at high concentrations is CNS depression. It is not, however, sufficiently effective to be considered a useful anesthetic. Irritation of the eyes, nose, and throat may also be observed at high concentrations. There are some indications of nausea and gastrointestinal upset at high concentrations, and changes in the liver and kidneys may be seen following excessive exposure; however, the effects are not as severe or striking as they are from a material such as carbon tetrachloride. Relatively few incidences of industrial problems due to exposure to perchloroethylene have been reported, probably because of a number of circumstances, including low vapor pressure and toxicity.

Case reports relate a rather consistent set of symptoms. Certainly anesthesia and, in cases of higher exposure, liver injury are related to perchloroethylene. Nausea, headache, anorexia, vertigo, dizziness, and other symptoms may be related to the CNS and hepatic effects. Sensitization of the heart to epinephrine does not occur with this compound. As for many compounds, massive doses of perchloroethylene given by gavage produced liver cancer in mice but not rats. Kidney tumors occurred only in male rats and a possible increase in mononuclear cell leukemia was also observed in both sexes of rats. Numerous reviews are available (6, 42, 142, 434, 435).

11.4.1.1 Acute Toxicity Perchloroethylene has moderate to low toxicity by single-dose ingestion. When fed to laboratory mice, an LD_{50} of 8850 mg/kg was reported. Animals survived at 4000 (dog and cat) and 5000 (rabbit) mg/kg. A dose of 500 mg/kg reportedly does not cause death in humans (436). Pozzani et al. (437) reported an acute oral LD_{50} of 2600 mg/kg for rats, and Hayes et al. (438) reported 3835 and 3005 mg/kg for male and female rats, respectively.

Liquid perchloroethylene may cause pain, lacrimation, and burning; however, permanent injury is unlikely. High concentrations of the vapors are uncomfortable to the eyes.

If perchloroethylene is allowed to evaporate, no significant effect on the skin is likely. However, if it is confined on the skin or if exposures are prolonged and frequently repeated, the solvent causes dermatitis by defatting the skin. Absorption of liquid through the skin is not likely to be a significant route of toxic exposure (439, 440), although some absorption does take place. Riihimaki and Pfaffli (441) determined that absorption of the vapors through the skin of human subjects was not significant at 600 ppm.

The response of rats to single exposures was reported by Rowe et al. (430). They stated that 2000 ppm was tolerated for up to 14 h and 3000 ppm was tolerated for 4 h with no deaths. Unconsciousness was observed in the rats within a few minutes at concentrations of 6000 ppm or more, and after several hours at 3000 ppm, but unconsciousness was not observed at 2000 ppm. At these high-level single exposures, the predominant response was one of depression of the nervous system. Deaths occurred during or immediately after exposure. There were slight changes in the liver, characterized by a slight increase in weight, slight increase in total lipids, and slight cloudy swelling.

Pozzani et al. (437) reported an 8 h LC_{50} of 34.2 mg/L (5040 ppm) for rats.

Several other investigations studied the effect of perchloroethylene on the liver and confirmed the observation of Rowe et al. (430). Kylin et al. (442) exposed mice for 4 h to 200, 400, 800, or 1600 ppm. No liver necrosis was observed, but fatty infiltration consistent with dose was observed at all levels.

Drew et al. (443) exposed rats to 500, 1000, or 2000 ppm perchloroethylene vapors for 4 h and measured serum enzymes. Four liver enzymes (SGOT, SGPT, glucose-6-phosphatase, and ornithine carbamyl transferase) were markedly increased by exposure to 2000 ppm and moderately increased by exposure to 1000 ppm, but were affected very little by exposure to 500 ppm.

Gehring (444) exposed mice to 3700 ppm and determined an anesthetic ED_{50} of about 234 min, a SGPT ED_{50} of 470 min, and an LT_{50} of 730 min. He concluded that liver toxicity was of relatively low importance compared to anesthesia.

The hepatotoxicity and renal toxicity of perchloroethylene were studied following subcutaneous injection. Plaa et al. (445) determined an LD_{50} of 390 mg/kg when perchloroethylene was injected in male mice. The hepatoxicity was low (rated 3 versus 1 for 1,1,1-trichloroethane and 190 for carbon tetrachloride). Plaa and Larson (48) measured nephrotoxicity following intraperitoneal injection and concluded that perchloroethylene was only weakly nephrotoxic.

Other references reported LD_{50} values of 4600 to 5700 mg/kg for mice (444, 446) and 3400 mg/kg for dogs given intraperitoneal injections.

11.4.1.2 Chronic and Subchronic Toxicity The NCI included perchloroethylene in their bioassay program, but unfortunately their experimental design did not call for adequate histological examinations of noncancerous lesions. They did report toxic nephropathy as discussed later under carcinogenesis (447).

When perchloroethylene was administered in drinking water for 90 days, body weight decreased and there were suggestions of liver effects but no clear evidence of injury at 1400 mg/k/day, the highest dosage fed (438).

The first chronic study of tetrachloroethylene vapors was carried out by Carpenter (429). He exposed rats to concentrations of 70, 230, and 470 ppm for 8 h/day, 5 days/week for periods up to 7 months. All of his animals survived and had growth comparable to his controls. No pathological effects were observed at 70 ppm. At 230 ppm, he observed some pathological changes in both the liver and kidneys. At 470 ppm, the pathological indications of injury to the liver and kidneys were more striking.

Rowe et al. (430) reported the results of chronic vapor exposures of several species of animals. At 1600 ppm in air, rats showed a drowsy, depressed condition for the first week and later a definite “irritation.” Enlargement of the liver and kidneys was noticeable. Guinea pigs showed a loss in body

weight, an increase in liver weight, and moderate histological changes. At 400 ppm, after 130 exposures of 7 h/day over a period of 183 days, rats showed no evidence of adverse effect. Guinea pigs showed definite increases in liver and kidney weights and slight fatty degeneration of the liver. Rabbits and monkeys showed no evidence of injury. At 200 ppm, guinea pigs showed an increase in liver weight, an increase in total liver lipids, and slight to moderate histopathological changes in the liver. At 100 ppm, female guinea pigs showed an increase in liver weight. Histologically, the liver appeared normal.

Guinea pigs in these studies displayed a particular susceptibility and showed changes even at 100 ppm. However, because human experience had been favorable, these authors were inclined to accept the previously used maximum allowable concentration of 200 ppm as satisfactory. They suggested, however, that this should be considered a ceiling and fluctuations should be around an average of 100 ppm.

In a similar study, rats, mice, guinea pigs, rabbits, and dogs were exposed to a 4:1 mixture of 1,1,1-trichloroethane and perchloroethylene vapors (448). Animals exposed to 800 ppm 1,1,1-trichloroethane plus 200 ppm perchloroethylene for 7 h/day for 6 months exhibited mild and reversible liver and kidney changes consistent with the effect expected from 200 ppm of perchloroethylene alone. Repeated exposures to 400 ppm 1,1,1-trichloroethane plus 100 ppm perchloroethylene had no effect in all species.

Kylin et al. (449) exposed mice to 200 ppm for 4 h/day, 6 days/week for 1, 2, 4, or 8 weeks. Fatty degeneration was observed, but no liver cell necrosis or effects on the kidneys were observed.

NTP exposed rats and mice for 6 h/day, 5 days/week for 13 weeks to establish a dose for the lifetime study reported in the section on carcinogenesis (450). The targeted concentrations were 0, 100, 200, 400, 800, and 1600 ppm. The highest concentration was lethal to 20 to 70% of the rats and mice. Exposures to 200 to 800 ppm caused minimal to mild hepatic congestion in rats.

In dosed male and female mice, minimal to mild hepatic leukocytic infiltration, centrilobular necrosis, bile stasis (400–1600 ppm) and mitotic alteration (200–1600 ppm) were produced. Tetrachloroethylene exposure also caused minimal renal tubular cell karyomegaly in mice at concentrations as low as 200 ppm.

11.4.1.3 Pharmacokinetics Metabolism, and Mechanisms Perchloroethylene is metabolized by a microsomal cytochrome P450 mixed-function oxidase system. Metabolism is dose-dependent in the rat, first-order at low concentrations and zero-order (metabolic saturation) at higher concentrations (281). Mice metabolize perchloroethylene faster than rats, which do so faster than humans. Mice and probably humans also have saturable metabolisms (464).

When given to rats by gavage or inhalation, much of the administered perchloroethylene was recovered unchanged in expired air (465). These investigators reported that 72 and 90% of the body burden were expired unchanged after oral doses of 1 and 500 mg/kg in rats and 68 and 88% after a 6-h exposure to 10 or 600 ppm vapor. The balance was primarily nonvolatile metabolites.

In mice there was a shift in metabolism at high doses (458), and much more was excreted unchanged above 500 mg/kg given orally.

By far the major urinary metabolite in rats and mice is trichloroacetic acid; more than half appears as the acid and its conjugate. Much smaller amounts of oxalic acid, trichloroethanol, dichloroacetic acid, and *N*- trichloroacetylaminoethanol or its conjugate (466) are excreted. Ethylene glycol,

chlorine, and CO_2 have been reported by others as metabolites. Conjugation with glutathione is not as significant as with some other chlorinated solvents, but at high doses, a mercapturic acid conjugate has been found in bile and urine. More is found in the rat than in the mouse. Gehring et al. (6) commented on the carcinogenic significance of this metabolite, and noted that although it appears to be a "spill-over" metabolite, it has mutagenic activity in bacterial assays (Ames test), suggesting that care be taken to avoid kidney and liver injury by limiting human exposure.

11.4.1.4 Reproduction and Developmental Early studies of reproduction by Carpenter (429) showed no effect at 420 ppm. Schwetz et al. (451) evaluated the teratogenic potential of perchloroethylene in rats and mice. Pregnant rats and mice were exposed to 300 ppm perchloroethylene for 7 h/day on days 6 to 15 of gestation. They reported a significant decrease in the fetal body weight of mice and a slight, but statistically significant, increase in the incidence or resorptions among the rat fetal population. Soft tissue examination of fetuses from exposed mice revealed a significant increase in the incidence of subcutaneous edema. The incidence of skeletal anomalies was not different from the controls, but among litters of mice the incidence of delayed ossification of skull bones and the incidence of split sternebrae increased slightly compared to those of the controls. A teratogenic effect was not observed. Negative teratological studies have also been reported in rats and rabbits by Beliles et al. (452) and John et al. (453).

Perchloroethylene was inactive when tested in *E. coli* and *S. typhimurium*, even when mouse liver enzymes were added (54).

NIOSH (454) and Bartsch et al. (455) also reported no mutagenic effects in tests with *Salmonella* but Cerna and Kyperova (456) claimed that it was positive even without metabolic activation. The available abstract also indicated that perchloroethylene was positive in a host-mediated assay in ICR mice, but the response was at high dosages (LD_{50} and 1/ 2 LD_{50}) and was not dose-related.

Cerna and Kyperova (456) reported no cytogenetic changes in female ICR mice given half the LD_{50} once or one-sixth the LD_{50} five times by intraperitoneal injection.

Rampy et al. (457) reported no mutagenic effects in lymphocytes of rats after 12 months of 6 h daily exposures 5 days/week to either 300 or 600 ppm of the vapor.

NTP conducted its battery of mutagenic tests as part of the cancer bioassay (450). It had negative results in all categories including the *S. typhimurium* Ames test with and without activation, mouse lymphoma with and without activation, sex-linked recessive mutations in Drosophila, and sister chromatid exchange in Chinese hamster ovary cells. Schumann et al. (458) did not find evidence of significant binding to hepatic DNA.

Other references cited by ATSDR (435) in its 1992 review give conflicting results, possibly due to impure samples or samples inhibited with epoxides. It is clear, however, that perchloroethylene is at most a weak mutagen.

11.4.1.5 Carcinogenesis Several studies of different types have been conducted on perchloroethylene, indicating that it has a low carcinogenic potential in mice, but not a definite effect in rats.

When perchloroethylene was fed by gavage at doses of approximately 1000 and 500 mg/kg/day to Osborne-Mendel rats and $B6C3F_1$ mice in the NCI bioassay program, hepatocellular carcinomas increased in mice but not in rats (447, 459). Toxic nephropathy was seen in both rats and mice.

Perchloroethylene was not active when tested for lung adenomas in Strain A cancer-susceptible mice (460). The mice were injected intraperitoneally with 80 mg/kg (14 injections), 200 mg/kg (24

injections), and 400 mg/kg (24 injections).

Van Duuren et al. (20) treated the skin of mice in different manners and did not produce cancer of the skin or of distant sites. Doses of 54 and 18 mg/kg were applied three times per week to the dorsal skin of mice. A dose of 163 mg/kg was applied in conjunction with a promoter (phorbal myristate acetate).

In a toxicological and carcinogenic study in which rats were exposed for 6 h/day for 12 months to 600 or 300 ppm perchloroethylene vapor and then kept for their lifetimes, there was no evidence of a tumorigenic response in either sex (457). Other criteria examined included body weights, mortality, hematologic data, urinalyses, clinical chemistry determinations, lymphocyte cytogenetics, terminal organ weights, and gross and histopathological changes, especially tumor incidence. An increase in mortality from the 5th to the 24th month of the study in male rats exposed to 600 ppm was the only deviation from controls that was considered related to exposure. The mortality increase was associated with an earlier onset of spontaneous advanced chronic renal disease.

Studies have been conducted to explain mechanistically the sensitivity of the $B6C3F_1$ mouse and the resistance of the rat to perchloroethylene-induced hepatocellular carcinoma (458). On the basis of body weight, mice activated perchloroethylene to a greater extent than rats, resulting in a greater degree of hepatic injury in the mouse. The authors suggested that the predominant mechanisms of tumorigenicity of perchloroethylene in the mouse was by recurrent hepatic cytotoxicity which enhanced the spontaneous incidence of hepatocellular carcinoma normally found in $B6C3F_1$ mice and not by direct interaction of perchloroethylene with hepatic DNA. They also suggested that the levels of perchloroethylene that protect against organ toxicity should be effective in preventing any tumorigenic risk of perchloroethylene to humans.

NTP (450) exposed rats to 0, 200, or 400 ppm and mice to 0, 100, or 200 ppm for 6 h/day, 5 days/week for 103 weeks. They concluded that

under the conditions of these 2-year inhalation studies, there was clear evidence of carcinogenicity of tetrachloroethylene for male F344/N rats as shown by an increased incidence of mononuclear cell leukemia. There was clear evidence of carcinogenicity for $B6C3F_1$ mice as shown by increased incidence of both hepatocellular adenomas and carcinomas in males and of hepatocellular carcinomas in females.

Because there was considerable tissue injury in the mouse liver and rat kidney and because the mononuclear cell leukemia is very common in the Fischer rat, there has been a considerable question about the significance of these data. The lack of or weak mutagenic activity in most test systems also supports a nongenetic mechanism for the production of tumors.

When exposed for only 10 consecutive days to 0, 100, 200, or 400 ppm (the same as the NTP study), rats were unaffected, but mice showed considerable evidence of liver injury, including peroxisomal proliferation (461). Likewise, Goldworthy et al. (462, 463) reported hyalin droplet formation in male rat kidneys, a finding often related to specific organ toxicity and carcinogenicity in male rats.

11.4.2 Human Experience Oral doses of about 60 to 86 mg/kg were given when perchloroethylene was used as an anthelmintic (434). Metabolism in humans is consistent with that found in rats and mice, but is slower. Most of the inhaled perchloroethylene is excreted unchanged over a relatively long period of time (432).

The older data on human exposure to perchloroethylene were summarized by von Oettingen (42) and

more recent data by NIOSH (454). As expected, numerous case reports give conflicting data.

Deaths probably due to anesthesia have occurred, but there is little documentation of the concentrations inhaled. In other cases, victims have been unconscious for hours and survived with no sequelae. In general, it appears that the following responses are possible: anesthesia ranging from slight inebriation to death, nausea, although less pronounced than carbon tetrachloride or ethylene dichloride; and headache, anorexia, and eye and nasal irritation. Liver injury following excessive subacute and chronic exposure has been reported in a few but not all subjects.

11.4.2.2.5 Carcinogenesis Perchloroethylene is considered a carcinogen in the latest annual report of the National Toxicology Program (467). The International Agency for Research on Cancer (IARC) considers perchloroethylene *probably carcinogenic to humans*, which they base on *sufficient evidence* in experimental animals and *limited evidence* in humans (286). NIOSH recommends treating perchloroethylene in the workplace as a *potential occupational carcinogen* (323, 397).

Two cohort studies have reported excesses of cancer of the esophagus, and relative risks were 2.1 and 2.6, respectively (409, 411). However, caution should be used in interpreting these results because of the lack of smoking and alcohol histories. Cervical cancers increased in two cohort studies, and relative risks were 1.7 and 3.2, respectively (409, 412). Blair et al. (409), Spirtas et al. (410), and Anttila et al. (412) found excesses of non-Hodgkin's lymphoma, and relative risks were 1.7, 3.2, and 3.8, respectively in three different cohort studies of workers exposed to perchloroethylene. One study found a significant excess of leukemia which appeared to be dose-related whether or not the latent period was considered (468). Hepatocellular adenomas and carcinomas in mice significantly increased in both sexes as did mononuclear-cell leukemia in rats of both sexes (450, 469).

Overall, perchloroethylene causes peripheral nervous system damage, liver injury, defects in memory, various CNS effects, esophageal cancer, non-Hodgkin's lymphoma, leukemia, and cervical cancer in humans. In animals, it has caused kidney and liver injury, as well as liver cancer and leukemia. Toxic effects from animal studies of perchloroethylene have been known since the early 1950s (430, 470), and since the early 1940s the ingestion of PCE by humans has been known to cause psychosis, vertigo, intoxication, giddiness, nausea, sleepiness, and unconsciousness (471–473).
11.5 Standards, Regulations, or Guidelines of Exposure
OSHA has a PEL of 100 ppm and a ceiling of 200 ppm, and a 300 ppm 5-min max peak in any 3 hours (474). NIOSH recommends treating tetrachloroethylene as a carcinogen (474).

The TLV recommended by the ACGIH is 25 ppm (170 mg/m^3). Perchloroethylene is classified as A3 (animal carcinogen).

The Biological Exposure Indices Committee of the ACGIH recommends a limit of 10 ppm perchloroethylene is end-exhaled air (1 ppm = 6-8 mg/m^3 at NTP).

Care should be taken to use these TLVs and BEIs only in the manner recommended by the committees. It is also desirable not to depend only on the BEIs but also to use air monitoring because brief, high exposures may produce unacceptable incoordination and yet result in acceptable BEIs. In view of the carcinogenic response in animals, human exposure should be carefully controlled to prevent possible liver and kidney injury.

Dibenzo-*p*-Dioxins: 2,3,7,8-Tetrachlorodibenzo-*p*-Dioxin

Jon B. Reid, Ph.D., DABT

Introduction

Dibenzo-*p*-dioxins are a class of compounds of which there are 75 possible isomers as shown in the following structure and Table 65.1. A recent IARC Monograph (1) summarizes much of the information on these compounds (Table 65.2) (2–4). By far, the majority of the information is for 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), the most toxic of the isomers. Most of the material in this chapter relates to this compound.

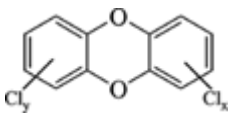


Table 65.1. Isomers of Dibenzo-*p*-Dioxins

Number of Cl Atoms	Number of Isomers
1	2
2	10
3	14
4[a]	22
5	14
6	10
7	2
8	1
Total	75

[a] The most important isomer is 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD).

Dibenzo-*p*-Dioxins: 2,3,7,8-Tetrachlorodibenzo-*p*-Dioxin

Debdas Mukerjee, Ph.D.

1.0 Introduction

Polyhalogenated biphenyls are a family of compounds based on biphenyl as the parent compound. Chlorinated and brominated biphenyls have been manufactured for commercial purposes. There are 209 possible structural congeners of polychlorinated biphenyl (PCB) (1) and for polybrominated biphenyls (PBBs) the same number of congeners (2) can exist.

1.0.1 CAS Numbers

A listing of all PCB congeners is given in Table 66.1 along with their Chemical Abstract Services (CAS) Registry numbers an identifying numbering system (3). Table 66.2 contains synonyms and molecular structures of PCB congeners.

Table 66.1. Numbering of PCB Isomers and their CAS Numbers

Ballschmiter No.[a]	Structure[b]	CAS No.
Monochlorobiphenyls		
Molecular weight: 188.66		
Molecular formula: $C_{12}H_9Cl$		
1	2	[*2051-60-7*]
2	3	[*2051-61-8*]
3	4	[*2051-62-9*]
Dichlorobiphenyls		
Molecular weight: 223.10		
Molecular formula: $C_{12}H_8Cl_2$		
4	2,2'	[*13029-08-8*]
5	2,3	[*16605-91-7*]
6	2,3'	[*25569-80-6*]

Halogenated Benzenes

A. Philip Leber Ph.D., DABT, James S. Bus, Ph.D., DABT

A. Introduction

This group of chemicals is derived through substitutions of chlorine for hydrogen atoms on the benzene ring. The toxicological properties of chlorinated benzenes differ substantially from benzene in that they lack the hematological toxicity and leukemogenic activity that have been associated with benzene. The compounds have an aromatic odor with lower volatilities, higher densities, and lower flammabilities than the parent compound benzene. Some of the settings in which exposures may be encountered are in manufacturing sites, home and public areas where deodorants or disinfectants are present, and in the applications of the materials as fumigants, insecticides, lacquers, paints, and seed disinfection products.

Because a substantial number of studies have focused on comparative evaluations of compounds in this chemical group, the results of these investigations are presented below prior to detailed discussions of individual compounds. In addition, a summary of various regulatory classifications of these compounds is provided.

Comparative Toxicological Properties of Chlorobenzenes

According to a Chemical Manufacturers Association (CMA) Technical Report (1), consistently observed signs of acute intoxication vary with the route of administration and the degree of exposure. Varshavskaya (2) reported the following effects for chlorobenzene and *o*- and *p*-dichlorobenzenes (DCB) in mice, rats, and guinea pigs: hyperemia of the visible mucous membranes, increased salivation and lacrimation, and initial excitation followed by drowsiness, adynamia, ataxia, paraparesis, paraplegia, and dyspnea. Induced mortality, which usually occurs within 3 days, results from respiratory paralysis. Changes revealed by gross postmortem examination may include hypertrophy and necrosis of the liver and submucosal hemorrhages in the stomach. Histologically disclosed changes are edema of the brain and necrosis of the centrobular region of the liver, the proximal convoluted tubules of the kidneys, the bronchial and bronchiolar epithelium of the lungs, and the stomach mucosa. The liver generally showed the most severe damage.

Table 67.1 (3) presents data on the acute oral toxicity of mono- and dichlorobenzenes in rodents. This information suggests greater toxicity for *o*-DCB relative to the other compounds in three of four animal species tested. The basis for this observation may lie within the differences seen for the metabolism of these compounds, and the formation of a more reactive metabolite for the *ortho*-substituted chemical (discussed further below).

Table 67.1. Oral LD_{50} for Chlorobenzenes (3)

	LD_{50} (Mg/kg body weight)		
Species	**Chlorobenzene**	***o*-Dichlorobenzene**	***p*-Dichlorobenzene**
White mice	1145	2000	3220
White rats	2390	2138	2512
Rabbits	2250	1875	2812
Guinea pigs	5060	3375	7595

The acute effects of intraperitoneal dosing of a series of chlorinated benzenes (mono-, di-, tri-, tetra-, and penta-substituted) were assessed in rats (4). Following single doses at levels in excess of 100 mg/kg, animals were monitored for evidence of liver, kidney, and thyroid effects. The 1,2-di-, 1,2,4-tri-, and 1,2,4,5-tetrachlorobenzenes were most toxic in terms of body weight losses over 3 days. Liver function enzyme levels [alanine aminotransferase (ALT)] were significantly elevated, as were microscopic signs of cellular damage following treatments with 225 and 450 mg/kg of the monochloro compound, ≥150 mg/kg of 1,2-dichlorobenzene, and ≥185 mg/kg and above of 1,2,4-trichlorobenzene. Kidney changes included protein droplet nephropathy for the 1,4 dichloro and the more highly substituted compounds. Serum thyroxine (T4) levels were suppressed at the lowest doses administered (1 mmol/kg) for the 1,2-dichloro and the higher-substituted benzenes. The greatest activity was seen for the tri and penta compounds. This activity appears to depend on formation of phenolic metabolites, which were shown to have the capacity to displace T4 from serum binding proteins in the rat. Alternatively, enhanced metabolic deiodination of T4 may result from induction of hepatic enzymes by the chlorinated benzene compounds. The precise mechanism for this phenomenon has not yet been established.

Hepatotoxicity evaluations of the three dichlorobenzene isomers (*ortho*, *meta*, *para*) were made following intraperitoneal injection into Sprague–Dawley and F344 male rats (5). Liver effects were monitored using plasma ALT levels, microscopic observations, liver nonprotein sulfhydryl (NPSH) concentration, and ^{14}C-DCB binding to liver proteins. One day following a dose of 132 mg/kg of each isomer, ALT levels were increased for *o*-DCB only. As dose levels were increased up to 5 times, *p*-DCB exhibited no activity in this assay, whereas *m*-DCB induced a weak response beginning at 264 mg/kg. Test chemical binding to proteins paralleled this liver response. Results for phenobarbital-pretreated rats indicated that liver enzyme induction was associated with the hepatotoxity of the *ortho* and *meta* isomers but not the *para* isomer. Further evidence of enzyme mediation in the hepatotoxic mechanism was found when SKF-525A (a cytochrome P450 enzyme inhibiter) blocked the response of the *ortho* and *meta* isomers. NPSH levels were depressed relative to controls following dosing of *ortho* and *meta* isomer dosing, but the para isomer did not cause any change in this parameter. The authors concluded that the relative hepatotoxicity of dichlorobenzene isomers is *o*- > *m*- ≫ *p*-, and that oxidative biotransformation plays an important role in this activities of these chemicals.

Carcinogenicity of Chlorinated Benzenes

The carcinogenic potentials of many of the chlorobenzenes have been assessed in animal studies. Table 67.2 (6–13) summarizes these findings.

Table 67.2. Results of Carcinogenesis Bioassays in Rodents Following Administration and Chlorinated Benzenes

	Tumors In

Compound	Mice	Rats	Dose (mg/kg)	Ref.
MCB	None	Liver nodules (males)	60, 120 oral 30, 60 (male mice)	6
o-DCB	None	None	60, 120 (gavage)	7
p-DCB	Liver	Males—kidney	150, 300—male rats 300, 600—others oral	8
	None	None	75,500 ppm inhaln. 5 hr/day, 5 days/week, 57 weeks—mice; 78 weeks—rat	9
HCB	Liver	Liver, males—kidney	6–24 mg/kg daily (diet)	10, 11
	Liver, thyroid, angiosarcomas	(Hamsters)	4–16 mg/kg daily	12, 13

The findings for monochlorobenzene (MCB) were negative in mice whereas benign liver tumors were induced in rats. *o*-DCB did not induce rodent tumors in this bioassay. *p*-DCB was shown to be carcinogenic in both rodent species in oral gavage studies, but the results were negative in inhalation tests. Owing to the relatively short periods of exposure in the latter study compared to the conventional 100+ weeks, the results may be considered equivocal. Hexachlorobenzene (HCB) has been demonstrated to induce tumors in multiple species in multiple organs. These results have contributed to the higher suspicion of carcinogenic potential for HCB compared to other chlorinated benzenes (see Table 67.3).

Table 67.3. Cancer Classifications for Chlorobenzenes

Chemical	USEPA (26)	IARC (27)	NTP (28)	ACGIH (29)
Chlorobenzene	D[a]	—	—	—
o-Dichlorobenzene	—	3[a]	—	—
p-Dichlorobenzene	C[b]	2B[d]	+[e]	—
Tri-, tetra-, pentachlorobenzenes	—	—	—	—
Hexachlorobenzene	B2[c]	2B[d]	+[e]	—

[a] Not classifiable as to carcinogenicity in humans.
[b] Possible human carcinogen.
[d] Possibly carcinogenic to humans.
[e] Reasonably anticipated to be carcinogenic to humans.
[c] Probable human carcinogen (no human evidence).

The chlorobenzene class of compounds is devoid of significant evidence of genetic toxicity (14). MCB and *o*-DCB are the two members of the class most likely to form expoxides, which renders

suspect genotoxic activities. However, MCB was negative in bacterial and *Aspergillus* gene mutation tests and in rat hepatic DNA repair assays but weakly positive in a mouse micronucleus assessment (15). The mutagenicity literature for *o*-DCB indicates some activity in higher plants but no effects in *Salmonella*, *Escherichia coli*, or yeast (16). *p*-DCB literature (17) indicates that the compound lacks genotoxic activity in bacteria, hepatic DNA repair assays, mouse lymphoma cells, tests for chromosomal aberrations in lymphocytes, Chinese hamster ovary (CHO) cells, and rat and mouse bone marrow cells. This compound did induce chromosomal changes in various higher plant assays, although human health implications have not been established (see further discussion for *p*-DCB below). HCB has been shown to be devoid of genotoxic activities in *Salmonella* gene mutation and rat dominant lethal testing (18). This lack of genetic activity suggests that alternative mechanisms of action (nongenotoxic) for the tumorigenic members of the class need to be considered.

Because of the induction of kidney tumors by *p*-DCB and HCB, these chemicals as well as other chlorobenzenes were investigated for evidence of a protein-mediated mechanism that is known to operate for numerous chemicals, including unleaded gasoline and *d*-limonene. It was discovered that both *p*-DCB (19) and HCB (20) induced a male rat–specific protein that causes increased kidney cell turnover and necrosis (sometimes referred to as *hyalin droplet nephropathy*) with kidney tumor formation a long-term outcome of this chronic injury. The implication of these findings is that kidney tumors formed in this manner have no relevance to human risk assessments because the protein (a_{2u}-globulin) responsible for the adverse effects in the kidney is unique to male rats. This concept is now recognized in certain regulatory agencies (21). Evaluations of other agents have been performed for this protein-induction activity, and results indicate that the 1,3,5 (22) and 1,2,4 (23) trichlorobenzenes, 1,2,4,5-tetrachlorobenzene (24), and pentachlorobenzene (25) are active. However, the actual carcinogenic potentials of these chemicals have not been determined in long-term bioassays.

The U.S. Environmental Protection Agency (USEPA) and Occupational Safety and Health Administration (OSHA) regulate various chlorobenzenes as pesticides, as potential pollutants of air and water, or as workplace contaminants. These agencies as well as other nonregulatory bodies [International Agency for Research in Cancer (IARC), National Toxicology Program (NTP), American Conference of Governmental Industrial Hygienists (ACGIH)] issue classifications that are intended to indicate the level of evidence for carcinogenic potentials in humans (based on animal data) for each of these chemicals. These classifications are presented in Table 67.3 (26–29).

The precise relevance to human health of tumor findings in animal studies is a topic that continues to be actively debated. Although there is no substantive evidence that any of the chlorobenzenes have induced cancer in humans, positive results in animals indicate a need for awareness that exposure to these materials should be kept to a minimum.

Halogenated Benzenes

B. Halogenated Benzenes

Table 67.4. Excretion and Distribution of Radioactive Metabolites from Orally Administered [^{14}C]-Chlorobenzene in Rabbits[a] (51)

	% of Dose

Urine	19.6
Feces	
Methanol extract	1.05
Dry burn	1.55
Tissues (one animal)	0.053

[a] Combined total urinary, carcass, and fecal ^{14}C collected during 4 days dosing and 3 subsequent days. Total dose = 8.28 g.

Table 67.5. Distribution of RadioactiveMetabolites in Urine of Rabbits Dosed Orally with ^{14}C-Chlorobenzene (51)

Metabolite	% of Total Urinary Radioactivity
3,4-Dihydro-3,4-dihydroxychlorobenzene	0.57
Monophenols	2.84
Diphenols	4.17
Mercapturic acids	23.80
Ethereal sulfates	33.88
Glucuronides	33.57
Total	98.83

Table 67.6. Subchronic Toxicities of Hexachlorobenzene[a]

Species	Dose	Test Duration	Effects Observed
Rats	2 mg/kg/day	13 days	No toxic effects
	6 mg/kg/day	13 days	Skin twitching and nervousness
	20 mg/kg/day	13 days	Neurotoxic symptoms; increase in liver weight
	60, 200 mg/kg/day	13 days	Neurotoxic symptoms; increase in liver and kidney weights
Rats	10 mg/kg/day	30 days	No toxic effects
	30, 65 mg/kg/day	30 days	Increase in feed consumptions/body weight gains; increased urinary coproporphyrin; increase in liver/body weight ratio
	100 mg/kg/day	30 days	Same as at 30 mg/kg/day plus elevated excretion of uroporphyrin
Rats	100 mg/kg/day	51 days	13/33 deaths in 1 months; neurotoxic symptoms; increased liver weight;

			porphyria
Rats	300 mg/kg/day	10 days	30% mortality
	150 mg/kg/day	30 days	60% mortality
	50 mg/kg/day	30 day	30% mortality
Male rats	0.2%	12 weeks	Retardation in weight gain; prophyria; degenerative changes in liver
Rats	0.025 mg/kg/day[b]	4–8 months	No toxic symptoms; possible effect on conditioned reflexes
Guinea pigs	0.5%	8–10 days	Marked neurological symptoms
Mice	0.5%	8–10 days	Marked neurological symptoms
Rabbits	0.5%	6 weeks	Increase in urinary porphyrins
	0.5%	8–12 weeks	Mortalities
Japanese quail	1 ppm	90 days	No toxic effects
	5 ppm	90 days	Slight increase in liver weight; slight porphyria
	20 ppm	90 days	Increased liver weight, decreased egg production; porphyria; liver/kidney pathological changes
	80 ppm	90 days	5/15 deaths (18- to 62-day period); neurotoxic symptoms; porphyria; increased liver weight; decreased egg production and hatchability; liver/kidney pathological changes.
Japanese quail	500, 2500 ppm	30 days	All 12 died in 30 days
	100 ppm	3 months	Mortality (1/12 on 20th day, 10 within 7 weeks 1 in 10 weeks); one surviving cock showed marked loss of weight; necrosis of liver cells and porphyria
Chickens	120–480 ppm	3 months	No toxic effects

[a] This table was prepared by C. E. Mumma and E. W. Lawless for the EPA (119) and is based on information from a 1975 report by the National Academy of Sciences (120). The route is oral (in diet) unless otherwise indicated.
[b] Administered in water.

9.0 Other Halogenated Benzene Compounds

o-, *m*-, and *p*-dibromobenzene
Tri- and tetrabromobenzenes
1,2-, 1,3-, 1,4-bromochlorobenzene
2,4- and 3,5-dibromochlorobenzene
o-, *m*-, and *p*-bromofluorobenzene
2,4- and 3,4-dibromofluorobenzene
o-, *m*-, and *p*-bromotoluene
o-, *m*-, and *p*-bromophenol

9.1 Chemical and Physical Properties
A potential source of information is the Material Safety Data Sheets from the suppliers of these chemicals. Further data may be available from the chemical literature.
9.2 Production and Use
Many halogenated benzene chemicals are manufactured and sold, but only in small amounts (<1 million lb) relative to those for the lower chlorinated benzenes. These materials are sold for the manufacture of specialty products (e.g., pharmaceuticals, agricultural chemicals, high performance polymers).

Virtually no data have been published on the health effects of these chemicals. Producers may have information that is unpublished.

Organic Chlorofluoro Hydrocarbons
George M. Rusch, Ph.D., DABT, FATS

A. Introduction

The chlorofluorocarbons (CFCs) were introduced in the 1930s as “safe” replacements for refrigerants such as sulfur dioxide, ammonia, carbon tetrachloride, and chloroform. In World War II, they were used to produce insecticide aerosols to protect the troops in tropical areas against malaria and other insectborne diseases. During the next 40–50 years, the number and type of applications expanded to include foam blowing, precision cleaning, and propellants for medicinal, cosmetic, and general-purpose aerosols, air conditioning, and refrigeration. These uses eventually resulted in emission of the CFCs into the atmosphere. Because of their low chemical reactivity, they typically

have long atmospheric residence times, and as a consequence, they are distributed globally (Table 68.1) (1–12).

Table 68.1. Ozone-Depletion Potential (ODP), Atmospheric Lifetime, years (AL), and Greenhouse Warming Potential (GWP) for Various Chlorofluorocarbons, Hydrochlorofluorocarbons, and Hydrofluorocarbons

			GWP Relative to		
Substance	ODP	AL years	CFC 11	CO_2 (100 yr)	References
CFC 11		65			1, 2
	1.0	60	1.0	4000 (230 yr)

In 1974 Molina and Rowland (13) hypothesized that, once the CFCs reach the stratosphere, they will undergo breakdown to release chlorine atoms. The chlorine atoms could then react with the stratospheric ozone breaking it down into oxygen (Fig. 68.1). Since the stratospheric ozone absorbed much of the sun's ultraviolet b radiation (UVB), decreased ozone levels would lead to increases in ground-level UVB (14). This could affect crop growth and lead to increases in cataracts and nonmelanoma skin cancers. Following reports of a marked drop in column ozone over Antarctica (the "ozone hole") during the Antarctic winter, in 1987 most of the nations of the world drafted and signed an agreement calling for the phaseout of CFCs. This agreement is known as the *Montreal Protocol*.

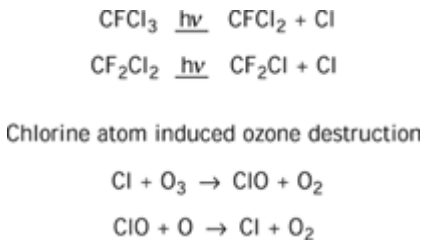

Figure 68.1. Stratospheric breakdown of CFCs 11 and 12.

Development was initiated on two types of "in-kind" replacements (15–17). The first were the hydrochlorofluorocarbons (HCFCs) and the second were the hydrofluorocarbons (HFCs). Both contain hydrogen and are susceptible to attack by hydroxyl radicals present in the atmosphere. Therefore, they have a shorter atmospheric lifetime and either are not transported to the stratosphere or are transported there only in small amounts. The HCFCs contain chlorine and are still capable of causing ozone depletion, although, since their atmospheric lifetimes are short, their ozone-depleting potential (ODP) is lower than those associated with the CFCs. The HFCs do not contain chlorine (or bromine, also associated with ozone depletion). They, therefore, do not cause ozone depletion. A ranking scale has been developed using CFC11 as the reference compound, with an assigned value of 1. These values are also presented in Table 68.1.

A second concern, regarding both CFCs and their replacements, is that they are greenhouse warming gases. They, along with other substances such as carbon dioxide, trap the sun's infrared radiation and convert it to heat. However, they are also good insulating materials, and frequently their use as foam blowing agents in refrigeration equipment can lead to considerable energy savings, reducing carbon dioxide emissions. The greenhouse warming potentials (GWPs) for many of the CFCs, HCFCs, and HFCs are given in Table 68.1.

Many methods have been developed for atmospheric monitoring of these substances. For low level determinations, frequently a preconcentrating step is employed first, then the collected material is eluted into a gas chromatograph using either an electron capture detector or high resolution mass spectrometry (Brunner) (18, 19). Collection materials include cold, activated carbon (20), cold, activated carbon plus Tenax-TA (21), porous glass beads (22), sorption on cold SE-30/glass wool (23), or sorption on cold OV-101 (24, 25) all followed by gas chromatography (GC) with an electron

capture detector. These methods are reported to have a detection level of 1 part per trillion (ppt). Sorption on cold activated charcoal coupled with GC and high resolution mass spectroscopy has a detection limit of 2.6 ppt (26). Sensitivity without precollection is much lower, frequently in the range of 50–100 ppb (27, 28) although with an electron capture detector it reportedly can reach 5–10 ppt (29–31). For higher levels, sorption on silica gel followed by GC with a flame ionization detector has been used (32) or direct chromatography with flame ionization detection (33, 34). Methods have also been developed to measure low levels in water (35).

Because of their widespread use and concerns about their environmental effects and health effects, several reviews have been written on these materials, such as the IPCS monograph on the fully halogenated chlorofluorocarbons (36), the IPCS monograph on the partially hydrogenated chlorofluorocarbons (37), the review of the alternate fluorocarbons by Dekant (15), the detailed discussion on CFC 11 written by Aviado in the last edition of this book (38), and the series of Joint Assessment of Commodity Chemicals monographs published by ECETOC on HCFC 22, HFC 32, HCFC 123, HCFC 124, HFC 125,HCFC 132b, HCFC 133a, HFC 134a, and HCFC 141b.

From the reviews as well as the data presented later in this chapter, it can be seen that many of these chemicals are not highly toxic. Some, in fact, do not show significant signs of toxicity at air exposure levels up to a few percent or even over 5 or 10%. The most typical response seen following overexposure is CNS depression related to the anesthetic properties of many of these chemicals. Also, some have caused hepatotoxicity and occasionally reproductive effects. In the 1960s, it was discovered that inhalation of the vapors of some of the CFCs could produce a “high.” This was a preanesthetic effect associated with central nervous system (CNS) depression. Some individuals, typically teenagers, would spray substances containing CFC propellants into a bag and then take several deep breaths of the vapor. The products associated with this abuse included fry pan vegetable oil sprays, aerosol deodorants and hairsprays, and glass chiller sprays. The propellants most often involved were blends of CFCs 11 and 12, although nonchlorofluorocarbon substances such as toluene, benzene, and gasoline were also implicated (39–41). Occasionally one of the individuals would show a short period of excitement and then collapse and die. Autopsy generally was unremarkable. Death was attributed to cardiac arrhythmia resulting from sensitization of the heart to catechol amines (42). In all, some 65 deaths were attributed to this CFC “sniffing.” Although rare, a few cases of death have been reported for people using metered dose inhalants for asthma (43). In these cases, it could not be determined whether death was due to the propellant or a sympathomimetic agent. It did appear that the inhalant had been overused. Occupationally, there were also reports of a few accidental deaths attributed to overexposure to CFCs, most typically CFC 113. The pattern was similar to that reported in the abusive “sniffing” situations. An individual was working in a confined area where large quantities of CFC 113 were present. In such cases, the individual is overexposed for a fairly short time, collapses, and develops a rapid heartbeat, which can lead to cardiac arrhythmia and possibly death (44). Several approaches using mice (45, 46), monkeys (47), rabbits (48), and dogs (49) have been evaluated; however, the protocol that involves exposure of dogs to test a compound under conditions designed to simulate stress, while monitoring cardiac function, has provided good comparative information. This protocol was developed in the late 1960s and early 1970s (42, 50–52) and has recently been reviewed (399). The protocol involves training a group of dogs to calmly accept the procedure for several days prior to the exposure. On the day of the exposure, each dog is exposed individually. The dog is placed in a sling and the snout-only exposure mask and EKG leads are attached. After 2 min, the dog is given an injection of epinephrine (adrenaline) of 4–12 mg/kg. An amount that has previously been determined to be just below that necessary to produce a spontaneous arrhythmia. The animal is observed for 5 min. If no arrhythmias are produced, the exposure is initiated. After 5 min of exposure, the dog is given a second injection of epinephrine and the exposure is continued for another 5 min with EKG monitoring for ventricular fibrillations or cardiac arrhythmias. The test is concluded at that point. Each dog will receive multiple exposures, each separated by at least one week. The study should be designed to allow for the determination of a no-observed-effect level (NOEL), a threshold, and the EC_{50} as median effect concentration. The two most important values are the NOEL and threshold. The level of epinephrine

used represents approximately 10 times the level seen in people under stress; this makes the test highly sensitive. In fact, the NOEL determined in this test is well below the minimum exposure level required to induce cardiac effects in humans or animals resulting solely from a combination of stress and exposure. This has been demonstrated using CFC 113 as an example. For CFC 113, with injections of epinephrine, the highest NOEL was 2500 ppm and the threshold was 5000 ppm (52). When 12 dogs were exposed to 2000 ppm for 6 h and then given and injection of epinephrine, only one developed an arrhythmia. When dogs were exposed to concentrations of ≤ 12,000 ppm and frightened by electric shock or a loud noise, none developed an arrhythmia. Likewise, when dogs were exercised on a treadmill and exposed to 20,000 ppm of CFC 113, none developed an arrhythmia (50). No arrhythmias were seen in monkeys exposed to 50,000 ppm or in mice exposed to 100,000 ppm of CFC 113 without injections of epinephrine or other stressers (125). All of these studies demonstrate the sensitivity of the protocol design in determining the potential for exposure to a chemical to induce cardiac effect. A comparison of the dogs given an injection of epinephrine to those exercising on the treadmill indicates at least an eightfold difference in thresholds. If the comparison is made to monkeys not under stress, the difference is at least 20-fold. Finally, with HCFC 142b, in conjuction with epinephrine, arrhythmias were seen in all 12 dogs exposed to 100,000 ppm. Without epinephrine, exposures of 800,000 ppm of HCFC 142b caused only a marked response in one of the dogs. When the dogs were exposed to 800,000 ppm of HCFC 142b and startled with a noise, but not given epinephrine, only 42% gave a marked response (42).

On the following pages, each compound is discussed individually. They have been divided into three general areas: chlorofluorocarbons, hydrochlorofluorocarbons, and hydrofluorocarbons.

Organic Chlorofluoro Hydrocarbons
George M. Rusch, Ph.D., DABT, FATS

B. Chlorofluorocarbons
1.0 Trichlorofluoromethane
1.0.1 CAS Number: [*75-69-4*]

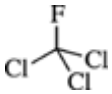
1.0.2 Synonyms: CFC 11, R-11, fluorotrichloromethane, F-11, Halocarbon 11, Fluorocarbon 11, Freon-11, Frigen 11, Fluorocarbon no. 11, FC 11, Halon 11, Propellent 11, Trichlorofluoromethane (Monofluorotrichloromethane)

1.0.3 Trade Names: Algofrene 11, Isceon 11, Forane 11, Arcton 11, AF 11, Genetron 11, Freon® 11, Freon® MF (solvent), Arcton 9, Genetron 11, Isceon 131, Isotron 11, Ledon 11, Aigofrene type 1, Electro-cf 11; Eskimon 11, Kaltron 11, Khaladon 11

1.0.4 Molecular Weight: 137.38

1.0.5 Molecular Formula: CCl_3F

1.0.6 Molecular Structure:



1.1 Chemical and Physical Properties
1.1.1 General (36)

Physical form	Liquid
Color	Colorless
Boiling point at 101.3 kP_a	23.8°C
Freezing point	–111°C
Specific gravity	1.494 @ 17.2°C
Vapor density	5.86 g/L
Vapor pressure	690 torr at 20°C
Solubility in water	0.11 g/L
log P_{ow}	2.53
Limit of flammability	Nonflammable

1.1.2 Odor and Warning Properties CFC 11 has a light ethereal odor with poor warning properties.

Organic Chlorofluoro Hydrocarbons
George M. Rusch, Ph.D., DABT, FATS

C. Hydrochlorofluorocarbons
11.0 Dichlorofluoromethane
11.0.1 CAS Number: [*75-43-4*]

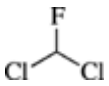
11.0.2 Synonyms: HCFC 21, F-21, R-21, dichloromonofluoromethane, refrigerant R21, freon 21, fluorodichloromethane, R-21

11.0.3 Trade Names: Genetron 21, AF-21, Freon® 21

11.0.4 Molecular Weight: 102.92

11.0.5 Molecular Formula: $CHCl_2F$

11.0.6 Molecular Structure:



11.1 Chemical and Physical Properties
11.1.1 General (7, 117)

Physical form	Gas
Color	Colorless
Boiling point at 101.3 kP_a	8.9°C
Freezing point	–135°C
Specific gravity	1.405 at 9°C
Liquid density at 9°C	1.405
Vapor density (air = 1)	Data not available

Vapor pressure at 25°C	Data not available
Solubility in water at 25°C	9.5 g/L
log P_{ow}	Data not available
Limit of flammability	Not flammable

11.1.2 Odor and Warning Properties Dichlorofluoromethane is almost odorless with poor warning properties.

Organic Chlorofluoro Hydrocarbons
George M. Rusch, Ph.D., DABT, FATS

D. Hydrofluorocarbons
19.0 Difluoromethane
19.0.1 CAS Number: [*75-10-5*]

19.0.2 Synonyms: HFC 32, R-32, HFA 32

19.0.3 Trade Names: Ecoloace 32, Forane 32, Asahiklin 32, Genetron 32; Meforex 32; Klea 32

19.0.4 Molecular Weight: 52.024

19.0.5 Molecular Formula: CH_2F_2

19.0.6 Molecular Structure:

19.1 Chemical and Physical Properties
19.1.1 General (336)

Physical form	Gas
Color	Colorless
Boiling point at 101.3 kP_a	–51.7°C
Freezing point	–136°C
Liquid density at 20°C	1.1 g/mL
Vapor density (air = 1)	1.8
Vapor pressure at 25°C	1670 kP_a
Solubility in water at 25°C	4.4 g/L
log P_{ow}	0.21
Limit of Flammability	lower, % v/v: 13.6
	upper, % v/v: 32.2

19.1.2 Odor and Warning Properties Difluoromethane is odorless or has a light ethereal odor with poor warning properties.

Miscellaneous Chlorinated Hydrocarbon Pesticides
James S. Bus Ph.D., DABT, A. Philip Leber Ph.D., DABT

A. Introduction

This chapter presents information on two structurally and toxicologically different classes of chlorinated pesticides: the organochlorine insecticides and the herbicide 2,4-dichlorophenoxyacetic acid (2,4D). The first group described, the chlorinated hydrocarbon insecticides, belong to a structural class containing only carbon, hydrogen and chlorine. This pesticide group has dramatically decreased in use and fallen into regulatory disfavor because, in general, its structural properties promote both persistence in the environment and bioaccumulation within the food chain. In contrast the herbicide 2,4D contains carbon, hydrogen, chlorine, and oxygen, and is a widely used herbicide with environmental and toxicological properties distinctly different from the organochlorine insecticides.

The organochlorine insecticides represent the first group of synthetic compounds to have a significant impact on the control of infectious diseases transmitted via insect vectors. These insecticides were used extensively in the United States and other Western countries, and are still used in Third World regions as both agricultural insecticides and agents to combat such vectorborne

diseases as malaria, typhus, plague, Chagas' disease, yellow fever, dengue, encephalitis, filariasis, and African trypanosomiasis (sleeping sickness) (1). Of these insecticides, DDT (dichlorodiphenyltrichloroethane) is credited as the primary compound that, for the first time in history, brought epidemics of malaria, typhus, and plague to a complete stop. DDT was introduced in 1943, with related insecticides following shortly thereafter. This chemical is still used extensively in tropical regions to combat malarial mosquitoes, and substitution of this pesticide with others such as malathion would be most expensive.

From 1950 to 1972, the U.S. production of DDT in 1000-kg units equaled 1,204,700. The production of the aldrin–toxaphene group (aldrin, chlordane, dieldrin, endrin, heptachlor, toxaphene) during 1952–1972 totaled $865{,}600 \times 10^3$-kg units; a total of $41{,}500 \times 10^3$-kg units of benzene hexachloride (lindane) was manufactured in the United States from 1950 to 1963. Of these quantities, approximately 50% of the DDT and 80 percent of the aldrin–toxaphene group were used in the United States (2, 3).

One attribute that contributes to the effectiveness of this chemical class is the persistence in the environment, providing not only an immediate impact on insect populations but also a prolonged insecticidal presence extending well beyond the time of application. This persistence is now generally considered an undesirable feature owing to findings suggesting delayed adverse impacts on nontarget populations of insects as well as birds. In addition, increased cancer risks for humans are alleged to result from exposures to these chemicals such as those resulting from pesticide applications and ingestion of contaminated fish and other food species. Although the actual balance of risks versus benefits associated with the use of these insecticides is debated, regulatory action has virtually eliminated their use in the United States and other western countries. Table 69.1 summarizes the regulatory status of these products (4, 5).

Table 69.1. Regulatory Standings of Chlorinated Hydrocarbon Insectides (4, 5)

Chemical	U.S. Registration	Foreign Use
Aldrin/dieldrin	EPA canceled all products	Yes
Chlordane/heptachlor	Voluntarily canceled; use for fire ants in power transformers, existing stocks for termites in homeowners' possession allowed; may reinstate for termite use pending finding of air monitoring tests	Use in termite control, some agricultural applications
DDT	Canceled all products	Yes
Endrin	Voluntary cancellation, all products	Unknown
Kepone	Canceled all products	Unknown
Lindane	Restricted uses (plant nurseries, pet shampoos, livestock sprays, seed treatment, household sprays, flea collars, hardwood logs, etc.); avocados, pecans are only food crop use allowed	Yes
Mirex	Canceled all products; existing stocks used for ants on pineapples in Hawaii	Unknown
Toxaphene	All products canceled; existing stocks use allowed for cattle dip, pineapples	Unknown

	in Puerto Rico, bananas in Virgin Islands, emergency use on corn, cotton, small grains

The persistence of these insecticides in the environment and their prolonged activity against pests following application can be attributed to a combination of their insolubility in water and high solubility in fats, absorption and adsorption onto particulate matter, and resistance to chemical, physical, and microbiological degradation. From target crops and surrounding soil and water, these compounds have entered the food chains of mammals, birds, fishes, and other animal species. DDT in particular was implicated in inducing acute and perhaps chronic insecticide intoxications in fish and birds as a result of bioaccumulation. In 1970, at the height of insecticidal use in the United States, Canada, and European countries, significant decreases in eggshell thickness were found in 15 of 22 species of aquatic birds, particularly in those feeding in fresh and brackish waters near agricultural areas. According to King et al. (6), population declines of the following species were observed, and continued study was proposed: brown pelican, reddish egret, white-faced ibis, laughing gull, and Forster's tern. The acute lethal potencies of these compounds in laboratory rats vary considerably, as shown in Table 69.2 (7).

Table 69.2. Acute Toxicity of Organochlorine Insecticides[a]

Acute Toxicity	Pesticide	CAS Number	Rat Oral LD_{50} (per kg Body Weight) Males and Females Combined (7)
Highly toxic	Endrin	[*72-20-8*]	13 mg
	Dieldrin	[*60-57-1*]	46 mg
	Aldrin	[*309-00-2*]	50 mg
Moderately toxic	Toxaphene	[*8001-35-2*]	85 mg
	Lindane	[*58-89-9*]	90 mg
	Heptachlor	[*76-44-8*]	131 mg
	Kepone	[*143-50-0*]	95 mg
	p,*p*'-DDT	[*50-29-3*]	116 mg
	Chlordane	[*57-74-9*]	283 mg
Slightly toxic	Kelthane	[*115-32-2*]	1.05 g
	p,*p*'-DDE	[*72-55-9*]	1.16 g
	Perthane	[*77-47-4*]	4.0 g
	Hexachloro-pentadiene		(corrosive)

Smith (8) discusses the fact that the primary acute toxicity noted in animals and humans following excessive exposures to chlorinated insecticides is neurological hyperactivity. With DDT and related compounds, the effects progress gradually from mild tremors to convulsions, whereas convulsions are the first sign of intoxication for compounds such as lindane, aldrin, dieldrin, endrin, toxaphene, and related materials. The latter can produce incoordination, weakness, and an ataxic state that is not associated with tremor, discriminating the intoxication induced by these substances from that of DDT. In general, the acute effects have not been shown to pose significant hazards to exposed

populations, and current concern over the toxicities of these compounds is linked primarily to chronic low-level exposures discussed below.

As mentioned above, because of reported environmental effects of these pesticides plus their classifications in the early 1970s as "potential human carcinogens," the use of most organochlorine pesticides was discontinued or markedly curtailed in the United States, Canada, and most European countries (9–11). The alleged human hazard, cancer, was based on observations of tumor induction in laboratory animals, primarily in mice, in which these compounds produced benign and malignant liver cell tumors. Table 69.3 (12–15) lists carcinogenicity classifications by the U.S. Environmental Protection Agency (USEPA), the National Toxicology Program (NTP), and the International Agency for Cancer Research (IARC); these classifications are intended to reflect human cancer risks related to chemical exposures to the chlorinated pesticides listed.

Table 69.3. Carcinogenicity Classification[a] of Chlorinated Insecticides

Chemical	USEPA (12, 13)	NTP (14)	IARC (15)	Basis
Aldrin	B2	—	3	Mouse liver tumors
Chlordane/heptachlor	B2	—	3	Mouse liver tumors
Chlordecone (Kepone)	—	e	2B	Rat, mouse liver tumors
DDT	B2	e	2B	Mouse liver, lung tumors, lymphomas; rat liver tumors; no tumors in three hamster studies
Dieldrin	B2	—	3	Mouse liver tumors
Endrin	—	—	3	No evidence
Lindane	B2/C	e	—	Mouse liver tumors
Mirex	B2	e	2B	Mouse, rat liver, and thyroid tumors
Toxaphene	B2	e	2B	Mouse, rat liver tumors

[a]

B2 Probable human carcinogen (no human evidence).

2B Possibly carcinogenic to humans.

C Possible human carcinogen.

3 Not classifiable as to carcinogenicity in humans.

e Reasonably anticipated to be carcinogenic to humans.

One reason for this debate is that few chemicals that induce rodent tumors appear to induce activity in humans. In 1975, Kraybill (16) wrote "None of the pesticide chemicals thus far have been shown to be carcinogenic to man." Workers (mostly men) who have been engaged in the manufacture, handling, and spraying of DDT, aldrin, dieldrin, toxaphene, chlordane, and heptachlor have been exposed to considerably higher concentrations and quantities of these insecticides than the general population of the United States. Among the exposed groups, only acute effects such as eye, skin, or respiratory irritation were reported, particularly following exposures to dusty formulations of the compound. High worker exposure occurring during the early years of production of some of these compounds was associated with induction of liver microsomal enzymes and the ability of some highly exposed workers to increase their drug-metabolizing capacity.

However, frank and undisputed injury to the liver or other human organs has not been reported in the United States, Canadian, and Western European literature. To the best of our knowledge the organochlorine insecticides (individually and in combination) that have been ingested with home- and restaurant-prepared food and drink by the U.S. population for more than 35 years (DDT was introduced in 1943), followed by a period of greatly reduced intake, have caused no recognized or clearly defined harmful effects. The significance of rodent liver tumors as indicators of human cancer risks continues to be debated in scientific circles (17–19).

Parenthetically, although the organochlorine insecticides are considered potential human carcinogens, it is noted that there has been a significant, almost constant decrease in the incidence of liver cancer deaths (males and females, classified since 1949 as primary, secondary, and not stated whether primary or secondary) in the continental United States, namely, from 8.8 (per 100,000 population) in 1930 to 8.4 in 1944 (when DDT was introduced for use) and to 5.6 in 1972. In the period 1985 to 1987, the liver cancer death rate in the United States was 4.1. According to U.S. vital statistics for the general U.S. population, this almost steady decline in total liver cancer deaths for a 55-year period is even more significant in light of the constantly increasing lifespan of the people of the United States, which, in turn, has resulted in a constant increasing percentage of the population "at risk" for liver cancer (2, 3).

Although liver cancer death rates have declined, the incidence of human breast cancer has increased (20). This increased incidence of breast cancer was largely attributed to more frequent use of mammography and other screening techniques, as well as other changes in other risk factors such as prevalence of certain reproductive variables e.g., age of first child, diet, alcohol consumption, and long-term use of menopausal estrogens. However, because of the weak estrogenic activity of several organochlorine chemicals, several epidemiology studies have evaluated the association between exposure to organochlorine chemicals such as the polychlorinated biphenyls (PCBs) and DDT and an increased incidence of breast cancer (21, 22). A case-control study reported by Wolff and co-workers (23) demonstrated a positive association between blood *p*,*p*'-DDE (the main tissue metabolite of DDT) concentrations and increased incidence of breast cancer. Subsequent larger case-control studies, however, failed to identify a link between DDT exposure and breast cancer (24, 25). The lack of an association between DDT exposure and an increased incidence of breast cancer was further supported by the observation that the *p*,*p*'-DDE metabolite of DDT is not estrogenic, and that the estrogenic activity of DDT was associated only with *o*,*p*'-DDE, a DDT-family member found at low or nondetectable concentrations in most environmental and human samples (26).

Ethers

Myron A. Mehlman, Ph.D.

A. General

1.1 Sources

Naturally occurring ethers may be constituents of essential oils and may be extracted from these sources. Although some ethers may appear naturally, they may be prepared synthetically from other chemicals or other ethers (1).

Symmetrical ethers are produced by the catalytic dehydration of their corresponding alcohols, for example, diethyl ether from ethanol (2). They are also obtained as by-products from the formation of their corresponding esters or alcohols. Ethers may also be made by special synthesis procedures (3, 4). Some ethers are obtained through the destructive distillation of selected hardwoods.

1.2 Uses
Ethers have a wide variety of industrial uses. Their commercial value is recognized in the following industries: rubber, plastics, paints and coatings, refrigeration, medicine, dentistry, petroleum, chemical, perfume, cosmetics, toiletries, and food.

The more volatile ethers have been used as liquid refrigerants, general anesthetics, commercial solvents, primers for gasoline engines, fuel additives (5), and rocket propellants. Other ethers have been used as alkylating agents in chemical syntheses of organic chemicals and in the manufacture of polymers. They are also used to denature alcohol (6). Halogenated ethers are used in the preparation of ion-exchange resin (7), which is a modified polystyrene resin that is chloromethylated and then treated with a tertiary amine or with a polyamine. Ethers have wide use as commercial solvents and extractants for esters, gums, hydrocarbons, alkaloids, oils, resins, dyes, plastics, lacquers, and paints. They are used as dewaxing extractants for lubricating oils. Ethers have had limited use as cleaning and spotting agents. They are used as chemical intermediates in the manufacture of textile aids, such as dyes and resins. In the pharmaceutical industry, ethers are used as solvents, suspending agents, flavorings for oral drugs, and dental products. They are used to increase viscosity, as penetrants and wetting agents, and as antioxidants and stabilizers. Ethers are used in foods as flavorings and in perfumes as fragrances. They are used as solvents for elastomers and for regenerating rubber. They have use as antiskinning agents in surface coatings and as weathering agents for paints and plastics. Ethers are also used in soaps. Ethers appear in heat transfer agents. Several industries use specific ethers for thickening, dispersing, suspending, binding, and film forming.
1.3 Physical and Chemical Properties
A summary of physical and chemical properties of ethers is presented in Table 72.1 (8–15).

Aliphatic Carboxylic Acids, Saturated
Steven T. Cragg, Ph.D., DABT

A. Saturated Aliphatic Monocarboxylic Acids
Industrial Applications
Saturated, aliphatic monocarboxylic acids are used in many varied applications, such as in the production of synthetic fiber materials, resins, plastics, and dyestuffs. A number of the acids and their esters are important chemical intermediates or solvents and are used in cosmetics or food applications.
Health Effects
The major physiological effect of the majority of the monocarboxylic acids is primary irritation of the moist surfaces of the body (eye, skin, or mucous membranes). The degree of irritation usually depends on the strength of the acid (dissociation), its water solubility, and its potential to penetrate the skin or, with the more volatile acids, the potential for exposure through vapor contact. The dissociation constants and aqueous solubilities for these acids are given in Table 70.1. The short-chain acids such as formic, acetic, and propionic acids are relatively strong acids and can produce burns similar to those of mineral acids. Higher molecular weight acids such as lauric and stearic acid are not strong irritants probably due mostly to poor skin penetrability, low volatility, and low water solubility. Their dissociation constants are similar to those of many of the shorter chain acids.

Metabolic Fate

Saturated, straight-chain monocarboxylic acids are incorporated into normal intermediary metabolism and are ultimately broken down by the b-oxidation pathway to produce acetate and an acid with two fewer carbons than the original acid. The process is repeated until the end product is acetate, propionate, or butyrate. Acetate and butyrate are utilized for energy via the citric acid cycle or are converted to acetoacetate and subsequently other ketone bodies. Ketone bodies may be oxidized or excreted in the urine, depending on the nutritional state of the organism. Propionate originates from odd-chain acids and is converted to carbohydrate and, unlike acetate, into lipids.

In some cases, medium-chain acids are partly oxidized by  -oxidation. This produces dicarboxylic acids, which may be broken down by b-oxidation from either end.  -Oxidation does not normally occur with straight-chain acids that have more than 12 carbon atoms; it may occur when the capacity for b-oxidation is exceeded because of a large dose or blocked because of substitution in the a or b position on the molecule. Medium- and long-chain fatty acids also may be metabolized via chain elongation, which occurs by the addition of two-carbon (acetate) units to the carboxyl group of the original acid. Short-chain acids, such as butyric, caproic, and caprylic acids, may be converted to long-chain fatty acids, but this occurs largely by cleaving into two-carbon units, which are used as building units for chain elongation.

In general, a-ethyl-substituted acids are not readily metabolized and are eliminated primarily by conjugation with glucuronic acid and excretion in the urine or by dealkylation.

Aliphatic Carboxylic Acids, Saturated
Steven T. Cragg, Ph.D., DABT

B. Saturated Polycarboxylic Acids
Introduction
Industrial Applications Saturated, aliphatic polycarboxylic acids are used in applications similar to those of monocarboxylic acids.

Health Effects The physiological effects of saturated, aliphatic polycarboxylic acids are similar to those described for monocarboxylic acids.

The acid dissociation constants and water solubilities of aliphatic dicarboxylic acids are presented in Table 70.3. The short-chain acids, in particular oxalic and malonic acids, are relatively strong acids and can cause local irritation, whereas the longer chain acids (e.g., pimelic and sebacic) are not irritants. The presence of the second carboxyl function in oxalic acid greatly increases its acidity, compared with formic acid. The fact that oxalic acid is a solid and has less water solubility may partly counteract the effect of increased ionization.

Table 70.3. Physical Properties of Saturated Aliphatic Polycarboxylic A

slightly soluble; Ins, insoluble.

Metabolic Fate Dicarboxylic acids are less extensively metabolized than monocarboxylic acids. An exception to this is the succinate, which is rapidly metabolized by incorporation into intermediary metabolic pathways to produce glucose and glycogen.

Appreciable quantities of many of the dicarboxylic acids are excreted in urine; the amount depends on the dose and route of administration. Some metabolism of the longer chain acids does occur by b-oxidation, producing a dicarboxylic acid that has two fewer carbons than the original. This process may continue as far as the succinate. Oxalic acid is excreted unchanged, and malonic acid is only partly degraded, apparently by decarboxylation to acetate.

Aliphatic Carboxylic Acids, Unsaturated
Steven T. Cragg, Ph.D., DABT

Unsaturated Monocarboxylic Acids
Introduction
Industrial Applications The alkenoic series of carboxylic acids are obtained from such natural sources as animal tallows and greases, and vegetable, coconut, palm, and marine oils. Several have also been produced synthetically from petroleum sources. They are frequently referred to as fatty acids (C_6 to C_{24}) and have important commercial applications in plastics, coating materials, fungicides, food preservatives, lubricants, and perfumes. They have been used as softening agents for rubber and as pharmaceuticals in medicine and dentistry. Acids of this type are unstable and polymerize readily, hence offering important chemical and physical properties for use in producing esters, acid halides, acid amides, and acid anhydrides.

As a class, the unsaturated carboxylic acids have been subjected to an extensive battery of studies, including acute, short-term, and chronic toxicity and carcinogenicity tests and reproductive and developmental toxicity and genotoxicity tests. Overall, these acids have a low level of mammalian toxicity, although they are strong skin and eye irritants in animal tests and are irritating to mucosal membranes in humans. For those acids for which adequate studies have been conducted, there is no evidence that they are reproductive or developmental toxicants or carcinogens. Mutagenicity and clastogenicity studies suggest that this group of acids is devoid of genotoxic activity. The biochemistry of many of these acids can be found in general textbooks. Rapid metabolism to other fatty acids may explain their general low degree of toxicity. The physical properties and acute toxicity of saturated monocarboxylic acids are provided in Tables 71.1 and 71.2 (1–35) respectively.

Table 71.1. Physical Properties of Unsaturated Aliphatic Monocarboxylic Acid

Acid	Chemical Abstracts Acid Name	CAS Number	Mol. wt.	M.P. (°C)	B.P. (°C)	Solubility[a]			Sp Gr
						H_2O	Alcohol	Other	
Propiolic	2-Propynoic	[*471-25-0*]	70.05	18	144 (dec)	∞	∞	Ether (∞) $CHCl_3$ (∞) Benzene (∞)	1. (2

Aliphatic Carboxylic Acids, Unsaturated
Steven T. Cragg, Ph.D., DABT

Unsaturated Polycarboxylic Acids
Polycarboxylic acids are used to manufacture a wide variety of products such as resins, textiles, medical products, printing inks, and foods. They are also used in organic syntheses and electropolishing applications. Except for fumaric and maleic acids, there is a paucity of information available for these acids. However, similar to that of the monocarboxylic acids, polycarboxylic acids have a low level of mammalian toxicity, although they, too, are strong skin and eye irritants in animal tests. For those acids for which adequate studies have been conducted, there is no evidence that they are genotoxic or carcinogenic. Fumaric, aconitic, and itaconic acids are normal constituents of human metabolism. Information on human exposure is sparse. The physical properties and acute toxicity of saturated monocarboxylic acids are provided in Tables 71.3 and 71.4, (335–341) respectively.

Table 71.3. Physical Properties of Unsaturated Aliphatic Polycarboxylic Acid

Acid	Chemical Abstracts acid name	CAS Number	Mol. Wt.	M.P. (°C)	B.P. (°C)	Solubility[a]		
						H_2O	Alcohol	Other
Maleic	(*Z*)-2-Butenedioic	[*110-16-7*]	116.07	139–140	135°C (dec.)	v	v	Ether (sl s) Acetone (v) $CHCl_3$ (ins) Benzene (ins)
Fumaric	(*E*)-2-Butenedioic	[*110-17-8*]	116.07	300–302 (sealed tube)	290	v sl	sl s	Ether (v sl) Acetone (v sl) $CHCl_3$ (v sl)
Mesaconic	(*E*)-2-Methyl-2-buteneioic	[*498-24-8*]	130.1	204.5	Subl.	v sl	v	Ether (sl s) $CHCl_3$ (v sl) Benzene

								(v sl)
Citraconic	(*Z*)-2-Methyl-2-butenedioic	[*498-23-7*]	130.1	93-93.8 (dec.)		v		Ether (v sl) $CHCl_3$ (ins) Benzene (v sl)
Itaconic	Methylenebutanedioic	[*97-65-4*]	130.1	175	dec.	sl s	sl s	Ether (v sl) Acetone (sl s) $CHCl_3$ (v sl) Benzene (v sl)
Aconitic	1-Propene-1,2,3-tricarboxylic	[*499-12-7*]	174.11	130	198–205 (dec.)	sl s		Ether (v sl)

[a] ∞, soluble in all proportions; v, very soluble; sl s, sightly soluble; v sl, very slightly soluble; ins, insoluble; dec., decomposes; subl, sublimes.

Table 71.4. Acute Toxicity of Unsaturated Polycarboxylic Acids

Acid	Species	Route	LD_{50} (mg/kg)	Ref.
Maleic	Mouse	Oral	2400	3
	Rat	Oral	708	335
	Rat	Inhaln	>0.72 g/m^3 (LC_{50}/1 h)	335
	Guinea pig	Skin	>1000	335
	Rabbit	Skin	1560	335

Ethers
Myron A. Mehlman, Ph.D.

A. General
1.1 Sources
Naturally occurring ethers may be constituents of essential oils and may be extracted from these sources. Although some ethers may appear naturally, they may be prepared synthetically from other chemicals or other ethers (1).

Symmetrical ethers are produced by the catalytic dehydration of their corresponding alcohols, for example, diethyl ether from ethanol (2). They are also obtained as by-products from the formation of their corresponding esters or alcohols. Ethers may also be made by special synthesis procedures (3, 4). Some ethers are obtained through the destructive distillation of selected hardwoods.
1.2 Uses
Ethers have a wide variety of industrial uses. Their commercial value is recognized in the following industries: rubber, plastics, paints and coatings, refrigeration, medicine, dentistry, petroleum, chemical, perfume, cosmetics, toiletries, and food.

The more volatile ethers have been used as liquid refrigerants, general anesthetics, commercial solvents, primers for gasoline engines, fuel additives (5), and rocket propellants. Other ethers have been used as alkylating agents in chemical syntheses of organic chemicals and in the manufacture of polymers. They are also used to denature alcohol (6). Halogenated ethers are used in the preparation of ion-exchange resin (7), which is a modified polystyrene resin that is chloromethylated and then treated with a tertiary amine or with a polyamine. Ethers have wide use as commercial solvents and extractants for esters, gums, hydrocarbons, alkaloids, oils, resins, dyes, plastics, lacquers, and paints. They are used as dewaxing extractants for lubricating oils. Ethers have had limited use as cleaning and spotting agents. They are used as chemical intermediates in the manufacture of textile aids, such as dyes and resins. In the pharmaceutical industry, ethers are used as solvents, suspending agents, flavorings for oral drugs, and dental products. They are used to increase viscosity, as penetrants and wetting agents, and as antioxidants and stabilizers. Ethers are used in foods as flavorings and in perfumes as fragrances. They are used as solvents for elastomers and for regenerating rubber. They

have use as antiskinning agents in surface coatings and as weathering agents for paints and plastics. Ethers are also used in soaps. Ethers appear in heat transfer agents. Several industries use specific ethers for thickening, dispersing, suspending, binding, and film forming.

1.3 Physical and Chemical Properties

A summary of physical and chemical properties of ethers is presented in Table 72.1 (8–15).

B. Alkane Ethers

Physiological data on industrially important saturated, symmetrical and asymmetrical alkyl ethers not specifically discussed in this section are presented in Tables 72.5 and 72.9. Data will be found for dihexyl ether (35), di(2-ethylhexyl) ether (35), methyl isopropyl ether (75), and ethyl butyl ether (37). Physical and chemical properties data are presented in Table 72.1.

Table 72.8. Atmospheric Concentration of Diethyl Ether and Reported Effects

Concentration, ppm	Effect
0.7–1920	Reported range of human odor detection
200	Nasal irritation
19,000 (1.9%)	Lower flammability limit, lowest anesthesia limit
42,000 (4.2%)	LC_{50} in mice
50,000 (5.0%)	Maintenance of surgical anesthesia
64,000 (6.4%)	Lethal concentration for rats
100,000–150,000 (10–15%)	Induction of human anesthesia

Table 72.9. Toxic Effects of Other Saturated Alkyl Ethers

Material and Molecular Formula	Anesthetic, mL/kg: Surgical Anesthesia	Anesthetic, mL/kg: Respiratory Arrest	Odor	Remarks
Methyl propyl ether (73, 74) $CH_3OCH_2CH_2CH_3$	Dog, 0.8	2.1	Ethereal	Caused no deleterious effect in dog, monkey, or rat
Methyl isopropyl ether	Dog, 1.12	2.62	Ethereal	Caused no

(75) $CH_3OCH(CH_3)_2$	deleterious effect in dog, monkey, or rat

Table 72.10. Incidence of Kidney Cancers in Male F344 Rats in Inhalation Study[a] with MTBE

Dose, ppm	Adenomas	Carcinomas	Combined adenomas and carcinomas
0	1/44 (2%)	0/44 (0%)	1/44 (2%)
400	0/46 (0%)	0/46 (0%)	0/46 (0%)
3000[b]	5/44 (11%)	3/44 (7%)	8/44 (18%)
8000[b]	3/39 (8%)	0/39 (0%)	3/39 (8%)

[a] 24-month study (144).
[b] 3000 and 8000 ppm rats were sacrificed at 97 and 82 weeks, respectively, at which point the appearance of cancer would be less likely detected.

Table 72.11. Incidence of Cancers in Sprague–Dawley rats exposed only to MTBE for 2 Years[a]

	Male		Female	
Dose, mg/kg[b]	**Testicular Leydig Cell, %**	**Corrected No., %**	**Lymphomas and Leukemia, %**	**Corrected No., %**
0	3.3	7.7	4.0	3.4
250	3.3	8.0	10.0	11.8
1000	18.3	34.4	20.0	25.5

[a] From Belpoggi et al. (146).
[b] 60 animals per group in each sex. Alive male rats at 96 weeks of age, when the first Leydig cell tumor was observed.

Table 72.12. Regulations and Guidelines Applicable to Methyl tert-Butyl Ether (MTBE)[a]

Agency	Description	Information	Ref.

	International		
WHO		NA	
IARC	Group (cancer ranking)	NA	
	National (Domestic)		
Regulations:			
Air: EPA	CAAA Title III	None	U.S. Congress §112 of CAAA 10/26/90
	Standards of Performance for VOC Emissions from SOCMI, Distillation Operations Chemicals Affected	Yes	40 CFR 60.667
	Standards of Performance for VOC Emissions from SOCIL, Reactor Processes Chemicals Affected	Yes	40 CFR 60.707
	Regulation of Fuels and Fuel Additives—Complex Emission Models	Yes	40 CFR 80.45 (151)
	Measurement of Reformulated Gasoline Fuel Parameters	Yes	40 CFR 80.46 (152)
Water: EPA/OW	Description of Bulk Organic Chemicals Subcategory	Yes	40 CFR 414.70

VT	Drinking Water Standard	40 mg/L

[a] Update of drinking water guidelines and other areas in progress. Units in table reflect values and units of measure designated by each agency in its regulations or advisories. *Abbreviations*: ACGIH = American Conference of Governmental Industrial Hygienists; CAAA = Clean Air Act Amendments; EPA = Environmental Protection Agency; IARC = International Agency for Research on Cancer; NA Not available at the present time; OERR = Office of Emergency and Remedial Response; OSW = Office of Solid Waste; OW = Office of Water; VOC = Volatile Organic Compound; WHO = World Health Organization.

The lifetime health advisory is 0.020 mg/L, otherwise, it is 0.20 mg/L.

[c] C = Possible human carcinogen.

Ethers
Myron A. Mehlman, Ph.D.

C. Alkene Ethers

Physiological data on several symmetrical and asymmetrical alkene ethers are presented in Table 72.5.

Table 72.13. Toxic Effects of Some Alkene Ethers

Material	Species	Anesthetic: Surgical Anesthesia	Anesthetic: Respiratory Arrest	Reference
Ethyl vinyl ether $CH_3CH_2OCH{=}CH_2$	Mouse	6% (v/v)	16% (v/v)	61, 158
	Rat	—	16% (v/v) for 4 hr killed 2, 3, or 4 of 6	159
	Dog	0.56 mL/kg	1.66 mL/kg	
Isopropyl vinyl ether $(CH_3)_2CHOCH{=}CH_2$	Dog	0.50 mL/kg	3.08 mL/kg	160

Ethers
Myron A. Mehlman, Ph.D.

D. Polyoxy Ethers
Physical and chemical data are presented in Table 72.1.

Physiological data of polyoxy ethers are presented in Table 72.5. Acute exposure values are presented for 1-butoxy-2-ethoxyethane, 2-butoxyethyl vinyl ether, 1,2-dibutoxyethane, 2,2'-dibutoxyethyl ether, 2-methoxyethyl vinyl ether, and 1,3-dimethoxybutane.

Ethers
Myron A. Mehlman, Ph.D.

E. Halogenated Alkyl Ethers
The halogenated ethers are more potent anesthetics than the alkane and alkene ethers, and also have higher acute toxicity. Three references that describe the anesthetic potential of halogenated ethers, which are too numerous to report here, are those by Poznak and Artusio (164), Terrell et al. (165), and Speers et al. (166). Some industrially important halogenated ethers have been shown to be carcinogenic in animals and humans. See Section 1.6 for discussion of this characteristic of these alkylating agents.
18.0 Other Haloethers
Table 72.5 contains toxic effects data for the haloethers 2-chloro-1,1,2-trifluoroethyl methyl ether

and 2-chloroethyl vinyl ether. Tables 72.6, 72.7 and 72.14 contain toxic effects data for the haloethers dichloromethyl methyl ether (178, 184), bis(a-chloroethyl) ether (178), and octachlorodi-*n*-propyl ether (178, 184, 185). Table 72.14 contains, in addition, toxic effects data for the haloethers 2-fluoroethyl methyl ether (186), 2,2,2-tri-fluoroethyl methyl ether (183), 2,2-dichloro-1,1-difluoroethyl methyl ether (59, 187–189), 2,2-difluoroethyl ethyl ether (190), 2,2,2-trifluoroethyl ethyl ether (190), 2-fluoro-1',2',2',2',-tetrachloro-diethyl ether (186), bis(2,2,2-trifluoroethyl) ether (191, 192), 2,2,2-trifluoroethyl vinyl ether (71, 193, 194), bis-1,2-(chloromethoxy)ethane (195), 5-fluoroamyl methyl ether (184), bis-1,4-(chloromethoxy)butane (195), perfluoroisobutenyl ethyl ether (196), 6-fluorohexyl methyl ether (186), 4,4'-difluorodibutyl ether (186), bis-1,6-(chloromethoxy) hexane (195), 4-fluoro-4'-chlorodibutyl ether (186), and 2-fluoro-2'-*n*-butoxydiethyl ether (186).

Table 72.14. Toxic Effects of Miscellaneous Haloethers

Material and Molecular Formula	Remarks
Dichloromethyl methyl ether $CHCl_2OCH_3$	See Table 72.6. Data originally from VanDuuren et al. (178) exhibiting weak carcinogenicity in mice. When evaluated as an initiator of carcinogenesis with phorbol ester, 3 mice out of 20 developed papillomas and 1 developed carcinoma (184).
2-Fluoroethyl methyl ether $CH_2FCH_2OCH_3$	Intraperitoneal LD_{50} in mice is 15 mg/kg (186).
2,2,2-Trifluoroethyl methyl ether $CF_3CH_2OCH_3$	Using 10 min for the exposure time Robbins (190) found the anesthetic dose (AD_{50}) to be 8% (v/v); the fatal dose (FD_{50}) to be 16% (v/v) using 20 mice. The time necessary for induction of anesthesia of mice exposed to be LC_{50} is 20 s. The time necessary for recovery of pain sensation after exposure to the LC_{50} for 10 min is 2 min. The time necessary to return to normal gait after 10 min exposure to the LC_{50} is 4 min.
2,2-Dichloro-1,1-difluoroethyl methyl ether $CHCl_2CF_2OCH_3$ (methoxyfluorane)	Artusio et al. (187) evaluated the anesthetic effects in 100 patients. Induction was smooth; no delirium, hypotension, or ventricular arrhythmia was noted. EEG changes, associated with anesthesia were noted. Nausea, vomiting, and the need for analgesics were reduced. Desmond (188) exposed 11 patients to this anesthetic in operations lasting 3–4 h at a concentration of 0.16%. Renal dysfunction lasting for days postoperatively was characterized by a large volume of low osmolality urine produced. Other reports of dramatic renal failure with use of this anesthetic are discussed. Swann et al. (59) found that 6.4% (v/v) produced respiratory arrest in 2 of 4 mice in 5.25 min. Rats exposed (189) to a 0.5% (v/v) atmosphere for 2, 4, or 6 h showed decreased food intake, diuresis, and reduced urinary osmolality.

2,2-Difluoroethyl ethyl ether $CHF_2CH_2OCH_2CH_3$	Using 10 min for the exposure time, Robbins (190) found the anesthetic dose (AD_{50}) to be 4% (v/v) and the fatal dose (FD_{50}) to be 9% (v/v) using 24 mice. The time necessary for induction of anesthesia of mice exposed to the LC_{50} is 1 min. The time necesary for recovery of pain sensation after exposure to the LC_{50} for 10 min is 2 min. The time necessary to return to normal gait after a 10-min exposure to the LC_{50} is 5–20 min.
2,2,2-Trifluoroethyl ethyl ether $CF_3CH_2OCH_2CH_3$	Using 10 min for the exposure time Robbins (190) found the anesthetic dose (AD_{50}) to be 4% (v/v) and the fatal dose (FD_{50}) to be 8% (v/v) using 16 mice. The time necessary for induction of anesthesia of mice exposed to the LC_{50} is 30 s. The time necessary for recovery of pain sensation after exposure to the LC_{50} for 10 min is 20 s. The time necessay to return to normal gait after 10 min exposure to the LC_{50} is 1 min.
1-Chloroethyl ether $CH_3CHClOCHClCH_3$	See Table 72.6. Data originally from VanDuuren et al. (178) exhibiting moderate carcinogenicity in mice. When injected subcutaneously at a dose of 300 mg in mice, slight carcinogenicity was noted as sarcomas in 4 of 30 mice. When evaluated as an initiator of carcinogenesis with phorbol myristate acetate 7 out of 9 mice developed papillomas.
2-Fluro-1',2',2',2',-tetrachlorodiethyl ether $CH_2FCH_2OCHClCCl_3$	Pattison et al. (186) reported the intraperitoneal LD_{50} in mice to be 48 mg/kg.
Bis(2,2,2-trifluoroethyl) ether $CF_3CH_2OCH_2CF_3$	The clonic convulsion dose (CD_{50}) reported by Truitt and Ebersberger (191) as intravenous in 30 mice is 26 mg/kg. The intravenous LD_{50} is 46 mg/kg. The intraperitoneal clonic convulsion dose (CD_{50}) in 88 rats is 600 mg/kg. The intraperitoneal LD_{50} is 1260 mg/kg in rats. The mouse clonic convulsion dose (CD_{50}) in an inhalation jar is 0.26 mL as volume of product. The tonic convulsion dose (TD_{50}) as volume in an inhalation jar in mice is 0.9 mL and 0.8 mL observed 30 s and 10 min after onset of convulsion, respectively. The mouse inhalation LD_{50} is 2.75 mL and 0.68 mL of product in a jar for the same time intervals. Krantz et al. (192) found the convulsive threshold in rats to be between 29 ppm and 41 ppm for a 90-s exposure time.

2,2,2-Trifluoroethyl vinyl ether $CF_3CH_2OCH{=}CH_2$ (Fluoromar)	Krantz et al. (193) reported the anesthetic properties. Krantz and Carr (71) later reported it to be an excellent analgesic. It does not produce liver damage or sensitize the myocardium to exogenous catecholamines. It produces minimal cardiovascular and respiratory depression. An anonymous report (194) states that animals metabolize this compound to be more toxic trifluoroethanol, which appears only as a trace in humans.
Bis-1,2-(chloromethyoxy) ethane $ClCH_2OCH_2CH_2OCH_2Cl$	VanDuuren et al. (195) demonstrated that 1 mg/0.1 ml of solvent applied to mouse skin 3 times a week produced a statistically elevated incidence of squamous carcinoma. Subcutaneous injections once weekly of 0.3 mg/0.05 mL vehicle produced a statistically elevated incidence of sarcomas. Intraperitoneal injections once weekly of 0.3 mg/0.05 mL vehicle produced a statistically elevated incidence of sarcomas.
5-Fluoroamyl methyl ether $CH_2F(CH_2)_4OCH_3$	Pattison et al. (186) reported that the intraperitoneal LD_{50} for mice is 90 mg/kg.
Octachloro-di-*n*-propyl ether $CCl_3CH(Cl)CH_2OCH_2CHClCCl_3$	VanDuuren et al. (178, 184) reported that skin application in 20 mice as an initiator evaluation with phorbol ester produced 3 papillomas and 1 carcinoma. Evaluated alone it was noncarcinogenic. VanDuuren (185) reported mouse skin tests were negative for carcinogenicity.
Bis-1,4-(chloromethoxy) butane $CH_2ClO(CH_2)_4OCH_2Cl$	VanDuuren et al. (195) demonstrated that 1.0 mg/0.1 mL of vehicle applied to mouse skin 3 times weekly did not produce a statistically elevated incidence of cancer. Subcutaneous injections once weekly of 0.3 mL/0.05 mL of vehicle produced no evidence of cancer. Intraperitoneal injections once weekly at a dose of 0.1 mg/0.05 mL of vehicle produced no evidence of cancer.
Perfluoroisobutenyl ethyl ether $(CF_3)_2C{=}CFOCF{=}C(CF_3)_2$	Schwartzman (196) presented data identifying the olfactory threshold as a level of 2.8 mg/L. Its LD_{50} in mice is 164 mg/kg. A dose of 6 mg/kg in chronic studies in rats and rabbits produced toxic action. A dose of 0.15 mg/kg produced disturbances and minor reversible morphological changes of the nervous system and internal organs. A dose of 0.015 mg/kg produced no changes in 7 months.
6-Fluorohexyl methyl ether $CH_2F(CH_2)_5OCH_3$	Intraperitoneal LD_{50} in mice is 4.0 mg/kg (186).
4,4'-Difluorodibutyl ether $CH_2F(CH_2)_3O(CH_2)_3CH_2F$	Intraperitoneal LD_{50} in mice is 0.82 mg/kg (186).
Bis-1,6-(chloromethyloxy)	VanDuuren et al. (195) demonstrated that

hexane $CH_2ClO(CH_2)_6OCH_2Cl$	1.0 mg/0.1 mL of vehicle applied to mouse skin 3 times a week produced no evidence of cancer. Subcutaneous injections once weekly of 0.3 mg/0.05 mL of vehicle produced a single sarcoma in 50 mice. Intraperitoneal injections once weekly at a level of 0.3 mg/0.05 mL of vehicle produced no evidence of cancer.
4-Fluoro-4'-chlorodibutyl ether $CH_2F(CH_2)_3O(CH_2)_3CH_2Cl$	Intraperitoneal LD_{50} in mice is 1.32 mg/kg (186).
2-Fluoro-2'-*n*-butoxydiethyl ether $CH_2FCH_2OCH_2CH_2O(CH_2)_3CH_3$	Intraperitoneal LD_{50} in mice is 43 mg/kg (186).

The compounds in Table 72.14 are arranged predominantly by increasing chain length and by increases in halogen substituents. Increased fluorination of diethyl ether progressively diminishes its anesthetic potency so that perfluoroethyl ether is devoid of anesthetic properties. On the other hand, a partially fluorinated compound, bis(2,2,2-trifluoroethyl) ether, in addition to some anesthetic action, is a powerful convulsant (192). This chemical is included in Table 72.14. Buckle and Saunders (197) believe that the toxicity of these compounds can be explained by b-oxidation. Pattison et al. (186) propose that the ether link is ruptured *in vivo*. This latter concept is reinforced by work of Johnston et al. (198), who found that animals biotransform trifluoroethyl vinyl ether to its alcohol, trifluoroethanol.

G. Hydroquinone Ethers
Repeated exposure to these chemicals may result in depigmentation of skin. Excessive skin contact may cause dermatitis.

Trapping the dust of hydroquinone ethers with filter devices and their vapors with organic solvents and subsequent analysis by chromatography, spectroscopy, or other method suitable for the detection of the aromatic ring should be adequate for an accurate atmospheric analysis. Physical and chemical properties are presented in Table 72.1.

Table 72.16. Toxic Effects of Butylated Monochlorodiphenyl Oxide Mixtures and Related Compounds in Experimental Studies

Compound	Species	Test	Results	Reference
		Acute Exposure		
Butylated monochlorodiphenyl oxide mixture	Rat	Oral LD_{50}	>10 g/kg	305
	Rat	Inhalation at 25°	No observable	

		C, 50°C	effect	
	Rabbit	Eye irritation	No observable effect	
	Rabbit	Skin irritation	No observable effect	
	Rabbit	Ear acneigenicity	No observable effect	
	Guinea pig	Skin sensitization	No observable effect	
	Fathead minnow	96-h static LC_{50}	15.4 mg/L	
		Flow-through threshold	1.81 mg/L	
	Daphnia magna	48-h static LC_{50}	0.24 mg/L	
	Rat	Pharmacokinetic profile, gavage	Radio-labeled compound is 90% absorbed from the gut. The elimination is biphasic and 75% excreted in feces within 3 days. Monobutylated component half-life is 65 hr. Dibutylated component half-life is 71 h.	306
	Monkey	Pharmacokinetic profile, gavage	Radiolabeled compound was 90% recovered. Major route of excretion was urine. Animal was constipated.	306
Monochlorodiphenyl oxide	Fathead minnow	96 h static LC_{50}	1.75 mg/L	307
		Flow-through threshold	0.090 mg/L	
	Daphnia magna	48 h static LC_{50}	0.39 mg/L	
		Subacute Exposure		
Butylated monochlorodiphenyl oxide mixture	Rabbit	Skin irritation	Very slight effect	307
	Rat	Diet feeding	At levels of 5 to 90 mg/(kg)(day) for 90 or 156 days, no treatment effect noted for demeanor, hematology, urinalysis, clinical	307

			chemistry, porphyrin excretion, or ophthalmology. Body weight reduction noted. Reversible liver and kidney changes noted at 45 and 90 mg/(kg)(day). Test material stored in fat.	
	Rat	Teratology	At levels of 500-1000 mg/(kg)(day), no teratogenic response was noted.	308
	Rabbit	Teratology	At levels of 1 to 10 mg/(kg)(day), no teratogenic response was noted.	308

Table 72.17. Chlorinated Phenyl Ethers Survey of Single-Dose Oral Feeding Studies on Guinea Pigs

H. Cyclic Ethers
General Information
38.0 Cellulose Ethers
General Physical and Chemical Properties
The cellulose ethers—methylcellulose, hydroxypropyl methylcellulose, carboxymethylcellulose sodium salt, ethylcellulose, and hydroxyethylcellulose—are all formed by reacting alkali-cellulose of predetermined average molecular weight with various materials to form the respective ether.

Each anhydroglucose unit of the cellulose polymer has three free hydroxyl groups that can be etherified. The degree to which this is effected and the nature of the substituent group influence markedly the physical properties, particularly solubility, of the product. The molecular weight of the alkali-cellulose markedly affects the viscosity of the final product. All the ethers are odorless, tasteless, and very stable chemically (304).
Exposure Assessment
All the cellulose ethers may be trapped from the air by filtration through a membrane filter. The water-soluble ethers can also be trapped in cold water. Ethylcellulose can be trapped in organic solvents.

The determination of methylcellulose and ethylcellulose can be accomplished in various media for methoxyl and ethoxyl groups. ASTM methods D1347-56 for methylcellulose and D914-50 for ethylcellulose should be consulted. The colorimetric methods of Samsel and DeLap (313) and of Kanzaki and Berger (314) for methylcellulose and of Samsel and Aldrich (315) for ethylcellulose also are very useful.

The method of Morgan (316) is generally the basis for determining the hydroxyalkyl ethers of cellulose. It is based on the hydrolysis of the ether with hydriodic acid, which yields the alkyl iodide and the corresponding olefin. Measurement of the olefin formed can be accomplished by absorbing in Wijs solution with subsequent determination of the iodine number (174).

Hydroxypropyl methylcellulose may be determined by employing the method of Samsel and McHard (317) to determine the methoxyl content, and the method of Lemieux and Purves (318) as modified (319) for determining hydroxypropyl content.

Carboxymethylcellulose can be determined by the anthrone colorimetric method described by Black (320). It can also be estimated by hydrolyzing and determining the resulting glycolic acid by the method of Calkins (321). ASTM method D1439-58T may also be adaptable.

Toxic Effects

The cellulose ethers are all very low in toxicity when administered by normal routes. They are not irritating to the skin or other delicate membranes of the body. When swallowed, they are not absorbed to any appreciable degree and appear unchanged in the feces. No inhalation studies have been conducted, but exposure of humans to the dust in manufacturing operations over many years has not led to any known adverse effects. Parenteral administration of the water-soluble ethers has led to serious adverse effects in animals and it would seem unwise to administer them by such routes to human subjects (304).

I. Crown Ethers

44.0a 6-Crown-2-Ether

44.0b 12-Crown-4-Ether

44.0c 15-Crown-5-Ether

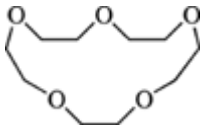
44.0d 18-Crown-6-Ether

44.0e Dicyclohexyl-18-Crown Ether

44.1 Chemical and Physical Properties

44.2 Production and Use

Very little information exists in the literature on the physical and chemical properties of the crown ethers. The name “crown” was first used in 1967 (322) and derives from the stereochemical structure, which for 15-crown-5 may be drawn as follows:



Available chemical and physical properties are presented in Table 72.19. During distillation 18-crown-6-ethers may convert to *p*-dioxane and present an explosion hazard due to clogging of traps (323–325).

Table 72.19. Chemical and Physical Properties of the Crown Ethers

Compound		CAS Number	Molecular Formula
6-Crown-2-Ether 12-Crown-24-Ether		[*294-93-9*]	$C_8H_{16}O_4$
15-Crown-25-Ether		[*33100-27-5*]	$C_{10}H_{20}O_5$
18-Crown-26-Ether		[*17455-13-9*]	$C_{12}H_{24}O_6$
Dicyclohexyl-18-Crown-6		[*16069-36-6*]	$C_{20}H_{36}O_6$

These compounds may be liquid or solid at room temperature. No satisfactory procedure has been developed for analyzing these materials in the atmosphere (326).

44.4 Toxic Effects

44.4.1 Experimental Studies 44.4.1.1 Acute Toxicity The oral LD_{50} for the following crown ethers has been determined to be as follows:

Ether	Mice (327) Oral LD_{50}, g/kg	Time to Death	Rats (328) Oral LD_{50}, mL/kg
6-Crown-2	6.0		
12-Crown-4	3.15	<15 min	2.83
15-Crown-5	1.02	1 hr	1.41
18-Crown-6	0.705	>1 day	1.39

Oral administration of 18-crown-6 to healthy dogs produced transitory signs of tremulous movement and paralysis of the hind limbs 2–12 h after administration (329). Leong (330) reported that a single

oral dose of 12-crown-4 at a level of approximately 100 mg/kg in rats produced central nervous system (CNS) effects and testicular atrophy. The dosages of higher aliphatic crowns, which were capable of producing CNS effects, were 1–10 times higher. This author also reported that skin absorption of 12-crown-4 in rabbits could produce CNS effects, but larger macrocyclic crowns only produced slight skin redness.

Pedersen (322) reported the approximate lethal dose of 300 mg/kg for dicyclohexyl-18-crown-6 by ingestion in rats. Death occurred within 11 min. No deaths occurred at 200 mg/kg. Skin absorption in experimental animals was fatal at a dose level of 130 mg/kg for dicyclohexyl-18-crown-6. This material was irritating to the skin and eyes. It was reported that permanent eye damage may result if the eye is not washed with water after exposure.

44.4.1.2 Chronic Toxicity Leong et al. (326) exposed rats to 0.5 and 1.0 ppm of 12-crown-4 vapors 7 h/day, 5 days/week, for 3 weeks. Both levels produced marked testicular atrophy that was associated with degeneration of the germinal epithelium. This effect persisted up to 4 months postexposure. Atrophy of the prostate and seminal vesicles was also noted. Exposure to 1 ppm of 12-crown-4 vapors produced prominent degradation of conditioned behavioral performances, depression of food and water intake, retardation of growth, and body tremors. These effects were reversible.

44.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms It is believed that the crown ethers complex with electrolytes, thus changing the permeability of Na^+ and K^+ across cell membranes (326, 331–334). Investigations thus far indicate the nerve conduction changes are fully reversible.

44.4.1.7 Neurological Gad et al. exposed three species to 18-crown-6 with a repeated dose regimen that involved ever-increasing dose levels in each animal over the exposure time period (328). Rabbits were exposed intravenously 5 days/week at dose levels increasing from 6 mg/kg to 12.5 mg/kg for 3 weeks. Rats were dosed intraperitoneally to ever-increasing dose levels of 20 mg/kg through 80 mg/kg for more than 1 month. Mice were intraperitoneally dosed from 20 mg/kg to 160 mg/kg. Signs of nervous system effects included tremors, hyperactivity, loss of limb strength, muscle twitching, and decreased awareness of light stimuli. Exposure levels were increased in each species because of accommodation to each dose level in a few hours to 3 days. No clinical or histopathological changes were observed. These authors claim to have observed increasing behavior changes, which are completely reversible, with increasing molecular size of crown ethers.

44.5 Standards, Regulations, or Guidelines of Exposure

No hygienic standards for occupational exposure have been established for the crown ethers.

Aldehydes and Acetals
Maria T. Morandi, Ph.D., CIH, Silvia Maberti, MS

A. Saturated Aliphatic Aldehydes

Aldehydes and Acetals
Maria T. Morandi, Ph.D., CIH, Silvia Maberti, MS

B. Unsaturated Aliphatic Aldehydes

Alpha and beta unsaturated carbonyl compounds (enals) are ubiquitous in the human environment. They are used in the manufacture of chemicals for the production of plastics, pharmaceutical drugs, and cosmetics, and in the rubber industry. They are also formed endogenously, for example, during lipid peroxidation or after oxidative stress. These compounds are highly reactive and are suspected genotoxic mutagens or carcinogens (204, 205). Unsaturated carbonyl compounds are mutagenic toward *S. typhimurium* in the absence of an activating system (206–208) but not in some strains (209, 210).

Table 73.3 shows the effect of unsaturation on the inhalation toxicity of aldehydes.

Table 73.3. Effect of Unsaturation on the Inhalation Toxicity of Aldehydes

Compound	Formula	LC_{50} (ppm) in Rats	Time of exposure (min)
Acetaldehyde	CH_3CHO	20,000	30
Ketene	$CH_2{=}CHO$	130	30
Proionaldehyde	CH_3CH_2CHO	26,000	30
Acrolein	$CH_2{=}CHCHO$	130	30
Isobutyraldehyde	$(CH_3)_2CHCHO$	> 8,000	4 h
Methacrolein	$CH_2{=}C(CH_3)CHO$	250	4 h
n-Butyraldehyde	$CH_3(CH_2)_2CHO$	60,000	30
Crotonaldehyde	$CH_3CH{=}CHCHO$	1,400	30

Table 73.4. Physical and Chemical Properties of Unsaturated Aliphatic Aldehydes

Compound	CAS Number	Molecular Formula	Mol. Wt.	Boiling Point (°C)	Melting Point (°C)	Specific Gravity	Sol. in Water at 68°F	Vap press (mm
Acrolein	[*107-02-8*]	CH_2═CHCHO	56.06	52.6	–87.7	0.84	4	21(
Citronellal	[*106-23-0*]	CH_3═CHCHO	152.23	229.0		0.8898	2	5
Crotonaldehyde	[*4170-30-3*]	CH_3CH═CHCHO	70.10	104.0		0.87		19
2-Ethyl-3-propylacrolein	[*26266-68-2*]	C_4H_9CH═$C(CH_3)$CHO	126.22					
Ketene	[*463-51-4*]	CH_2═CO	42.02	–49.8	–151.0	Gas		> 76
Methacrylaldehyde	[*78-85-3*]	CH_2═$C(CH_3)$CHO	70.09	68.4		0.84	5	
Methyl-b-ethylacrolein	[*623-36-9*]	$C_6H_{10}O$	98.14	136.5		0.8581	1	
Mucochline	[*87-56-9*]	CHOCCl═CClCOOH	168.97		125.0			
Propionaldehyde	[*624-67-9*]	CH═C═CHO	54.05	60.0		0.9152	5	
trans-2-Hexenal	[*6728-26-3*]	C_3H_7CH═CHCHO	98.14	146.5		0.8491		

Table 73.5. Toxic Effects of Unsaturated Aliphatic Aldehydes

Chemical Name	Species	Exposure Route	Approximate Dose	Treatment Regimen	Ob
Ketene	Mouse	Inh	23 ppm/30 m	LC_{Lo}	Conv effec thres
	Monkey	Inh	200 ppm/10 m	LC_{Lo}	Ptosi pulm
	Cat	Inh	750 ppm/10 m	LC_{Lo}	Acut edem struc of sa

C. Halogenated and Other Substituted Aldehydes
Halogenation tends to increase the local irritating action and general toxicity of the aldehyde.
31.0 Chloroacetaldehyde
31.0.1 CAS Number: [*107-20-0*]

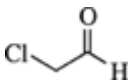
31.0.2 Synonyms: 2-Chloro-1-ethanal; 2-chloroacetaldehyde; monochloroacetaldehyde; 2-chloroethanal; chloroethanal; alpha-chloroacetaldehyde; chloroacetaldehyde, 45% aqueous solution (CAA)

31.0.3 Trade Names: NA

31.0.4 Molecular Weight: 78.50

31.0.5 Molecular Formula: C_2H_3ClO

31.0.6 Molecular Structure:



31.1 Chemical and Physical Properties
See Table 73.6.

Table 73.6. Physical and Chemical Properties of Halogenated Aldehydes

Compound	CAS Number	Molecular Formula	Mol. Wt.	Boiling Point (°C)	Melting Point (°C)	Specific Gravity	Sol. in Water (at 68°F)	Vapor Pressure (mmHg)	Lel Uel (%)
Chloral hydrate	[*302-17-0*]	$CCl_3CH{=}O \cdot H_2O$	165.40	98.0	62.0	1.9081	4		
Chloroacetaldehyde	[*107-20-0*]	$ClCH_2CHO$	78.50	85.5	–16.3			100	
Fluoroacetaldehyde	[*1544-46-3*]	$FCH_3CH{=}O$	62.05						
Trichloroacetaldehyde	[*75-87-6*]	$CCl_3CH{=}O$	147.39	97.8	–57.5	1.512	4	35	
Trifluoroacetaldehyde	[*421-53-4*]	$C_2{-}H_3{-}F_3O_2$	116.05						

31.2 Production and Use
Chloroacetaldehyde is used in the manufacture of 2-aminothiazole and other compounds. It is also used to facilitate bark removal from tree trunks and as a fungicide.
31.3 Exposure Assessment
31.3.2 Background Levels Chloroacetaldehyde has been identified as a chlorination by-product in drinking water supplies and is also a metabolite of vinyl chloride (287).

31.3.3 Workplace Methods NIOSH Method 2015 is recomended for determining workplace exposures to chloroacetaldehyde (141).
31.4 Toxic Effects
31.4.1 Experimental Studies 31.4.1.1 Acute Toxicity The LD_{50}, for chloroacetaldehyde in four species via three routes of entry were rat: 23.0 mg/kg oral and 2.0 mg/kg intraperitoneal; mouse: 21.0 mg/kg oral and 2.0 mg/kg intraperitoneal; rabbit: 1.39 mg/kg intraperitoneal and 67.0 mg/kg skin; and guinea pig: 0.636 mg/kg intraperitoneal (288). Chloroacetaldehyde is acutely toxic to mice via inhalation (289).

31.4.1.2 Chronic and Subchronic Toxicity At doses less than the acute LD_{50}, rats that succumbed after 30 days of injections of chloroacetaldehyde exhibited hematological disturbances, but the most obvious effects were bronchitits and pneumonitis (289).

31.4.1.6 Genetic and Related Cellular Effects Studies Chloroacetaldehyde was mutagenic in the *S. typhimurium* reversion test, the forward mutation system of the *Aspergillus nidulans* and the forward and backward mutation system of *Streptomyces coelicor* (288). Chlroacetaldehyde is a potent toxicant and has DNA reactivity (287). It is an effective inhibitor of DNA synthesis, forms interstrand linkage with DNA *in vitro*, modifies DNA conformation (292), and reacts with nucleotide bases (292a).

For additional information on the toxic effects of chloroacetaldehyde, see Table 73.7.

Table 73.7. Toxic Effects of Halogenated Aldehydes

Chemical Name	Species	Exposure Route	Approximate Dose	Treatment Regimen	Observ Effec
Chloroacetaldehyde	Rat	Oral	89 mg/kg	LD_{50}	
	Rat	Inh	650 mg/m^3/1 h	LC_{50}	BP elevati not characteriz autonomic section; respiratory obstructior

	Mouse	I.v.	660 mg/kg	LD_{50}	Change in motor activ

31.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH ceiling/STEL for chloroacetaldehyde is 1 ppm. The OSHA PEL and the NIOSH REL are also 1 ppm.
32.0 Trichloroacetaldehyde
32.0.1 CAS Number: [*75-87-6*]

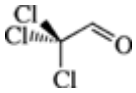
32.0.2 Synonyms: Chloral; grasex; 2,2,2-trichloroacetaldehyde; trichloroethanal; chloral, anhydrous, inhibited

32.0.3 Trade Names: NA

32.0.4 Molecular Weight: 147.39

32.0.5 Molecular Formula: C_2HCl_3O

32.0.6 Molecular Structure:



32.1 Chemical and Physical Properties
See Table 73.6.
32.4 Toxic Effects
For information on the toxic effects of trichloroacetaldehyde, see Table 73.7.
33.0 Chloral Hydrate
33.0.1 CAS Number: [*302-17-0*]

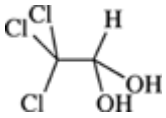
33.0.2 Synonyms: Trichloroacetaldehyde monohydrate; 1,1,1-trichloro-2,2-ethanediol; nycton; rectules; somnos; nortec; kessodrate; hydral; trichloroacetaldehyde hydrate; bi 3411; sk-chloral hydrate; trawotox; Escre; 2,2,2-trichloro-1,1-ethanediol

33.0.3 Trade Names: Noctec; Aquachloral; Chloraldurat; Dormal; 1,1-Ethanediol, 2,2,2-trichloro- (9CI); Felsules; Hydral; Lorinal; Nycoton; Phaldrone; Somni SED; Somnos; Sontec

33.0.4 Molecular Weight: 165.40

33.0.5 Molecular Formula: $C_2H_3Cl_3O_2$

33.0.6 Molecular Structure:



33.1 Chemical and Physical Properties
See Table 73.6.
33.2 Production and Use
Chloral hydrate is made by adding water to trichloroacetaldehyde. The major use of chloral hydrate is in medicinals.

Chloral hydrate is used before some surgeries or procedures to help relieve anxiety and to induce sleep. It is widely used to sedate children undergoing dental and medical procedures and imaging studies (294). Chloral hydrate is available as a suppository, syrup, or capsule.
33.4 Toxic Effects
33.4.1.2 Chronic and Subchronic Toxicity Sanders et al. (295) dissolved chloral in water to form chloral hydrate. Groups of 140 male and 140 female CD-1 mice were maintained on the aqueous solution at concentrations of 0.07 or 0.7 mg/mL as chloral, for 90 days starting at 4 weeks of age; 260 mice/sex received deionized water and served as controls. Low and high TWA dosages based on

measured water intake were reportedly 15.7 and 159.8 mg/kg/day for the males and 18.2 and 173.4 mg/kg/day for females, respectively. Growth, hematology, and serum chemistry parameters, liver enzyme activities and microsomal parameters, organ (liver, lungs, spleen, thymus, kidneys, testes and brain) weights, and gross pathology were evaluated. Significant effects included dose-related increased final body weights in males, increased final body weights in high-dose females, dose-related increased relative liver weights in males, increased serum LDH and SGOT in high-dose males, and increased microsomal cytochrome b5 content and aminopyrine *N*-demethylase and aniline hydroxylase activities in high- and low- dose males. Therefore, the liver appears to be a target organ for chloral toxicity, and the dose of 15.7 mg/kg/day in males is the LOAEL. Because this was the lowest dose tested, this study does not define a NOAEL or NOEL. Dividing the LOAEL of 15.7 mg/kg/day by an uncertainty factor of 10,000 yields an RfD of 0.002 mg/kg/day, or 0.1 mg/day for a 70-kg person.

In female mice, the immune system, particularly the ability to produce IgM antibody to a T-dependent antigen, is the most sensitive indicator (296). In male mice, the liver is the most sensitive organ. Both effects occurred at the lowest concentration tested, 0.07 mg/mL or 15.7 mg/kg (295). The adverse effects on the immune system observed at the 15.7-mg dosage level support the LOAEL used to derive the RfD.

Offspring from mice that were exposed throughout pregnancy to 204 mg/kg/day but not 21.3 mg/kg/day chloral in the drinking water had a behavioral impairment (impaired learning retention of a passive avoidance task) (293). Gross malformations or effects on maternal reproductive parameters were not noted.

33.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Some concern regarding the potential carcinogenicity of chloral hydrate is based on the assumption that it is a reactive metabolite of trichloroethylene and is responsible for the carcinogenicity of this compound (295). Nevertheless, it has been proven that the carcinogenicity of trichloroethylene is due to a reactive epoxide metabolite, rather than chloral hydrate (297).

33.4.1.4 Reproductive and Developmental Intratesticular injection of 300 mg/kg chloral hydrate produced decreased spermatogenesis in mice (298).

33.4.1.5 Carcinogenesis Chloral hydrate has not been adequately tested for teratogenicity, reproductive effects, or chronic toxicity. Similarly, no histological evaluations have been conducted.

33.4.1.6 Genetic and Related Cellular Effects Studies Administration of 40 ml/plate of chloral hydrate to *S. coloericolor* induces mutagenic activity and death in the cell. No effect is noted with a dose of 10 mg/plate of *A. nidulans* (288).

33.4.2 Human Experience Chloral hydrate acts on the central nervous system to induce sleep. At normal doses, this sleep induction does not affect breathing, blood pressure, or reflexes. When used in combination with analgesics, it can be used to manage pain.

33.4.2.2.1 Acute Toxicity Acute overdoses may cause cardiorespiratory depression (298). On rare occasions excessive or repetitive doses have been associated with cardiac arrythmias (299).

Side effects in adults include drowsiness, low body temperature, slurred speech, weakness, difficulty breathing, shortness of breath, nausea, vomiting, confusion, convulsions, and hallucination.

33.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms Chloral hydrate is metabolized to trichloroethanol and trichloroacetic acid, both of which are pharmacologically active and may contribute to the acute toxicity of chloral hydrate. The half-life of trichloroethanol ranges from 9 to 40 hours, depending on the age of the subject (300). The younger the patient, the longer the half-life. This induces the accumulation of active metabolites during repetitive doses (300). In fact, toxicity

characterized by respiratory depression and hypotonia associated with a trichloroethanol plasma concentration seven times that associated with sedation in adults was reported in an infant who received multiple doses of chloral hydrate while on mechanical ventilation (294). There is evidence that chloral hydrate and/or trichloroethanol may increase the risk of both direct and indirect hyperbilirubinemia in newborns (301).

34.0 Fluoroacetaldehyde

34.0.1 CAS Number: [*1544-46-3*]

34.0.2 Synonyms: NA

34.0.3 Trade Names: NA

34.0.4 Molecular Weight: 62.05

34.0.5 Molecular Formula: C_2H_4FO

34.1 Chemical and Physical Properties

See Table 73.6.

35.0 Trifluoroacetaldehyde Monohydrate

35.0.1 CAS Number: [*421-53-4*]

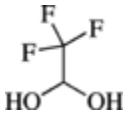
35.0.2 Synonyms: Trifluoroacetaldehyde monohydrate; trifluoroacetaldehyde hydrate; trifluoroacetaldehyde monohydrate, tech.

35.0.3 Trade Names: NA

35.0.4 Molecular Weight: 116.05

35.0.5 Molecular Formula: $C_2H_3F_3O_2$

35.0.6 Molecular Structure:



35.1 Chemical and Physical Properties

See Table 73.6.

35.2 Production and Use

Trifluoroacetaldehyde monohydrate is used as an agricultural chemical, a drug and therapeutic agent, a fungicide, bactericide, and wood preservative.

35.5 Standards, Regulations or Guidelines

Russia has a STEL of 5 mg/m^3 for trifluoroacetaldehyde monohydrate.

Aldehydes and Acetals

Maria T. Morandi, Ph.D., CIH, Silvia Maberti, MS

D. Aliphatic Dialdehydes

A number of dialdehydes have become available commercially and although not all of their properties are completely known, some toxicological data have become available. These materials

have many of the same properties as the monoaldehydes but because of their bifunctionality, may provide different types of useful cross-linking reactions. They tend to polymerize readily and are sometimes available only in an aqueous solution in the presence of polymerization inhibitors.

Table 73.8. Physical and Chemical Properties of Aliphatic Dialdehydes

Compound	CAS Number	Molecular Formula	Mol. Wt.	Boiling Point (°C)	Melting Point (°C)	Specific Gravity	Sol. in Water (at 68°F)	Vapo pressu (mmH

A number of these aldehydes occur naturally as components of essential oils or plant products. They are widely used in perfumes and as flavoring agents.

There has been a limited number of studies of their toxicity, but a considerable amount of work devoted to studying their metabolic fate was summarized initially by Williams in 1959 (313). Recent information is provided when available for a specific chemical.

The metabolism of these aromatic aldehydes follows the pattern established for aromatic acids. In general, the aldehyde grouping in compounds such as benzaldehyde is converted to the acid, probably by liver aldehyde dehydrogenases. This may occur at a relatively slow rate, but it is usually complete. If the aromatic ring contains phenolic groups, as in the case of *p*-hydroxybenzaldehyde, the compound may be excreted partially as the glucuronide and partially as the free acid or as the conjugated acid. Reduction of the aromatic aldehyde group to an alcohol has not been observed. Benzaldehyde itself is not excreted in any such appreciable amounts as an ester glucuronide, but some substituted aldehydes such as 3,4-dimethoxybenzaldehyde are oxidized to the corresponding acid and excreted as ester glucuronides. Nitrobenzaldehydes are oxidized to nitrobenzoic acids which are either excreted as such or in conjugation with hippuric acid or as acetamidobenzoic acids. *p*-Dimethylaminobenzaldehyde may undergo partial demethylation.

The literature references to the aromatic aldehydes did not give many details of the type of toxic reactions found in the past (314). Dr. Fassett did mention, however, the following observations noted in the course of screening tests:

p-Acetamidobenzaldehyde:	the only symptoms noted were moderate weakness in rats that received up to 3200 mg/kg orally.
p-Dimethylaminobenzaldehyde:	weakness, ataxia, unconsciousness, and tremors were noted in mice that received up to 1600 mg/kg orally or up to 400 mg/kg intraperitoneally. Repeated intraperitoneal injection in mice at levels of 100 to 200 mg/kg caused weakness and ataxia, but there was no significant reduction of hemoglobin during such treatment. No difference was found between the pure and technical grade samples.
p-Nitrobenzaldehyde:	in doses of 50 or 400 mg/kg orally in the rat, the symptoms were prostration and cyanosis.
2,4-Dihydroxybenzaldehyde:	rats that received 50 to 3200 mg/kg orally showed weakness, tremors, and violent convulsions.
2-Hydroxyl-5-chlorobenzaldehyde:	the symptoms in mice (either orally or intraperitoneally) were weakness, ataxia, gasping respirations, and unconsciousness. Skin irritation was more marked with this compound than with the corresponding 5-bromo compound.
2-Hydroxy-5-bromobenzaldehyde:	oral or intraperitoneal admnistration in mice or rats caused weakness, ataxia, and unconsciousness.

Aldehydes and Acetals
Maria T. Morandi, Ph.D., CIH, Silvia Maberti, MS

F. Acetals

Since 1963, when D. W. Fassett provided information about the physical properties and toxicity of acetals, the published literature about their toxicity changed very little. Much of the information

provided in the 2nd edition of *Patty's Industrial Hygiene and Toxicology* is reprinted here for the use and convenience of the reader (314).

Any additional information, such as the CAS number, the molecular structure, synonyms and trade names, etc., is provided as currently available in the information from the previous edition.

Acetals or ketals are produced by reactions of aldehydes with alcohols. Their industrial use is increasing, and they may be used as solvents, chemical intermediates, plasticizers, or they may be used to generate aldehydes in the presence of acid. These materials have some of the properties of ethers and are stable under neutral or slightly alkaline conditions but hydrolyze readily in the presence of acids to generate aldehydes (see Table 73.12). This latter reaction makes them capable of hardening natural adhesives, such as glue or casein (333).

Table 73.12. Physical and Chemical Properties of Acetals

Compound	CAS Number	Molecular Formula	Mol. Wt.	Boiling Point (°C)	Melting point (°C)	Specific Gravity	Sol. in Water (at 68°F)	Vapor Pressure (mmHg)	Lel-Uel (%)
Acetal	[*105-57-7*]	$CH_3CH(OC_2H_5)_2$	118.18	102.2	–100.0	1.3834	3		
Chloroacetal	[*621-62-5*]	$CH_2ClCH(OC_2H_5)_2$	152.60	157.0		1.026		20	
Dibutylacetal	[*871-22-7*]	$CH_3CH(OC_4H_9)_2$	174.28	203.3	–69.1	0.8319			
Dichloroethylformal	[*111-91-1*]	$C_5H_{10}Cl_2O_2$							
Dimethylacetal	[*534-15-6*]	$CH_3CH(OCH_3)_2$	90.12	64.5	–113.2	0.8501	3		
Ethylal	[*462-95-3*]	$CH_2(OC_2H_5)_2$	104.20	89.0	–67.0	0.824	2	60	
Ketoacetal	[*5436-21-5*]	$C_8H_{18}N_2O_2$	132.16						
Methylal	[*109-87-5*]	$CH_2(OCH_3)_2$	76.10	42.0	–104.8	0.8593			

The hazards of using acetals in industry are not known with certainty, but a number of them have received a certain amount of experimental study, some of which is summarized in Table 73.13. The physiological properties of the simple unsubstituted acetals are characterized by an etherlike anesthetic action and by a relatively low degree of primary irritation compared to the parent aldehyde. A number of them have been studied for their anesthetic properties, although at present they are not used for this purpose. Bacq and Dallemagne (334–335) and Knoefel (336–338) have investigated methylal, acetal, and a number of other similar materials. The toxicity of methylal has

recently been investigated by Weaver et al. (339). These authors reviewed some of the older literature and pointed out that a number of attempts have been made to use methylal as an anesthetic and that Bacq and Dallemagne (334–335) had investigated this intensively in both dogs and humans. Apparently, anesthesia could be produced in humans, but the onset was slower than with ether and the effect more transitory.

Table 73.13. Toxic Effects of Acetals

Chemical Name	Species	Exposure Route	Approximate Dose	Treatment Regimen	Observed Effect	Reference
Methylal	Rat	Inh	15,000 ppm	LC_{50}		482
	Rat	I.p.	5 gm/kg	LD_{Lo}		483
	Rabit	Skin	> 16 mL/kg	LD	Iritis	484
	Mouse	Inh	35,100 mg/m^3/7 h/22D-I	TCLo	Ataxia	485
Ethylal	Rabbit	Oral	2604 mg/kg	LD_{50}		486
Dimethylacetal	Rabbit	Dermal	20 g/kg	LD_{50}		487
	Rat	Inh	3000 ppm/4 h	LC_{50}	Anesthetic	488
Acetal	Rabbit	Skin	500 mg/24 h	Acute toxicity	Mild	489
	Rabbit	Oral	3545 mg/kg	LD_{50}		486
	Rat	I.p.	900 mg/kg	LD_{50}		490

The experiments of Weaver et al. (339) were concerned principally with the effects on guinea pigs and mice of inhaling various concentrations. At extremely high levels, 153,000 ppm, anesthesia occurred in 20 minutes, and death occurred in about 2 hours. At these levels, definite evidence of irritation was noted in the guinea pig, including squinting, lacrimation, sneezing, and nasal discharge. Other pronounced signs of eye and respiratory-tract irritation were also noted at lower levels, and the LC_{50} in mice for a 7-hour exposure was about 18,000 ppm. Most of the deaths occurred during exposure.

Experiments were also carried out with repeated inhalations in the case of mice. A group of fifty mice received fifteen 7-hour exposures at concentrations of approximately 11,000 ppm. Only minor irritation was noted at this level, although lack of coordination appeared after about 3 or 4 hours of exposure. Recovery was usually complete in 1 hour after removal from the chamber. Six deaths occurred in the fifty animals during the 22-day exposure period. Repetition of these experiments at 14,000 ppm showed more evidence of irritation a greater degree of anesthesia. About 30% of the group of mice succumbed during a 17-day exposure.

Attempts were made to determine the metabolism of methylal in these animals by testing for formaldehyde and formic acid in vitreous humor and urine. No evidences of these metabolic products were found. However, in view of the rather marked irritation that occurred during inhalation and the necrosis following subcutaneous injections in guinea pigs, it seems possible that hydrolysis to formaldehyde takes place. This is readily metabolized so that it would be difficult to

detect under these conditions.

Histopathological studies were made on the guinea pigs and mice exposed by inhalation. Guinea pigs exposed to very high levels and sacrificed 16 to 74 hours after the beginning of exposure showed moderate to severe fatty degeneration of the liver and kidney and extensive bronchopneumonia. Other guinea pigs sacrificed 23 hours after three successive 7-hour exposures showed similar changes in the lungs, liver, and kidneys. However, guinea pigs exposed to five daily 7-hour inhalations at levels of about 45,000 ppm showed no significant changes. Mice that had about 15 seven-hour exposures at levels up to 14,000 ppm showed occasional evidence of pulmonary edema and slight fatty changes in the kidney.

No changes were found in the optic nerves or retinas of mice that could be attributed to methylal. Occasionally some corneal blebs were seen, but these could not be attributed with certainty to the methylal exposure.

These authors conclude that the threshold for producing toxic effects in guinea pigs and mice is of the order of 11,000 ppm. They extrapolate from this to the conclusion that 1000 ppm might be safe for an 8-hour working day. The present threshold limit is 1000 ppm (27). No studies of workers exposed to such concentrations over long periods of time have been reported, and the validity of this level is uncertain now.

Safe handling precautions should include the use of adequate ventilation to be certain that the average concentrations are well below 1000 ppm and avoidance of excessive or prolonged skin contact. Methylal should be handled with due regard for its flammable properties.

Ethylal produced only minor symptoms of weakness in the rat; even at high dose levels, no typical anesthesia was noted (37). It is of interest that the halogenated compound, dichloroethyl formal, possesses a high degree of toxicity in the rat orally or in the guinea pig by skin contact. It was also highly potent by inhalation in the rat, giving 100% fatalities at levels as low as 120 ppm. It was only a slight skin or eye irritant in the rabbit (340). It is obvious that this halogenated material should be handled with considerable care.

Dimethylacetal in animal experiments is somewhat similar to methylal. The pathological effects have not been reported, however (21, 341).

Acetal also has anesthetic properties (342). Knoefel (336) believes that it is probably rapidly hydrolyzed in the stomach. Hydrolysis would give rise to either a hemiacetal or to acetaldehyde and ethyl alcohol.

The introduction of a halogen, as in chloroacetal, also greatly increased toxic properties upon oral administration in rats. (Note the similarity to the toxicity increase in the case of dichloroethylformal.) This suggests that the hydrolysis of this compound gives rise to chloracetaldehyde and ethanol (37). The influence of unsaturation on an acetal is indicated by the high degree of intraperitoneal toxicity in the mouse for crotonaldehyde acetal (340).

Ketoacetal is interesting in that the presence of the keto group in the beta position to the acetal grouping did not enhance the toxicity (37). Not enough compounds have been studied to predict the effect of unsaturation on aldehyde groups adjacent to acetal groups, but from the fragmentary data available, the same principles would apply as mentioned for aldehydes.

In the view of the lack of specific information, it is well to regard substituted acetals as capable of hydrolysis to the component alcohols and aldehydes and to take precautions to avoid excessive skin contact or inhalation.

Acetone
David A. Morgott, Ph.D., DABT, CIH

1.0 Acetone
1.0.1 CAS Number:
[*67-64-1*]
1.0.2 Synonyms:
2-Propanone; b-ketopropane; dimethyl ketone; dimethyl formaldehyde; methyl ketone; propanone; pyroacetic acid; pyroacetic ether; allylic alcohol; dimethylketal; ketone propane; and acetone oil
1.0.3 Trade Names:
NA
1.0.4 Molecular Weight:
58.08
1.0.5 Molecular Formula:
$(CH_3)_2CO$
1.0.6 Molecular Structure:

1.1 Chemical and Physical Properties
The commercial grade of acetone is generally 99.5% pure and contains less than 0.4% water and 0.1% organic matter (1). Other important chemical and physical properties of the material are listed in Table 74.1 (2–8).

Table 74.1. Important Chemical and Physical Properties of Acetone

Property	Value	Reference
Empirical formula	C_3H_6O	
Freezing point	–94.7°C	2
Boiling point	56.2°C at 760 mmHg	2
Density	0.790 g/cm^3 at 20°C	1
	0.784 g/cm^3 at 25°C	
	0.780 g/cm^3 at 30°C	
Vapor pressure	70 mmHg at 0°C	3
	185 mmHg at 20°C	
	410 mmHg at 40°C	
Partition coefficient	–0.24 (log $K_{octanol/water}$)	4
	–0.50 (log $K_{oil/water}$)	5
	–2.82 (log $K_{air/water}$)	6
	–2.34 (log $K_{air/saline}$)	5
	–2.44 (log $K_{air/blood}$)	7
Henry's law constant	2.05 atm	6
Water solubility	Infinite	1
Vapor density	2.0 (air = 1.0)	8
Flash point	Cleveland open cup: –9°C	1
	Tag closed cup: –17°C	
Autoignition temperature	465°C	8

Flammability	Lower limit: 2.5% (v/v) at 25°C Upper limit: 13.0% (v/v) at 25°C	8
Hazard identification code	Health: 1 (slight) Flammability: 3 (high) Reactivity: 0 (stable)	8

Acetone

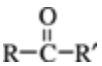
Ketones of Four Or Five Carbons
David A. Morgott, Ph.D., DABT, CIH, Douglas C. Topping, Ph.D., DABT, John L. O'Donoghue, VMD, Ph.D., DABT

Introduction
A ketone is an organic compound containing a carbonyl group (C═O) attached to two carbon atoms and can be represented by the general formula



Several billion pounds of ketones are produced annually for industrial use in the United States. Those with the highest production volumes include acetone, methyl ethyl ketone, methyl isobutyl ketone, cyclohexanone, 4-hydroxy-4-methyl-2-pentanone, isophorone, mesityl oxide, and acetophenone. Common methods used to manufacture ketones include aliphatic hydrocarbon oxidation, alcohol dehydration with subsequent oxidation, dehydrogenation of phenol, alkyl aromatic hydrocarbon oxidation, and condensation reactions.

Ketones are used because of their ease of production, low manufacturing cost, excellent solvent properties, and desirable physical properties such as low viscosity, moderate vapor pressure, low to moderate boiling points, high evaporation rates, and a wide range of miscibility with other liquids. The low-molecular-weight aliphatic ketones are miscible with water and organic solvents, whereas the high-molecular-weight aliphatic and aromatic ketones are generally immiscible with water. Most ketones are chemically stable. The exceptions are mesityl oxide, which can form peroxides, and methyl isopropenyl ketone, which polymerizes. Most ketones are generally of low flammability.

Ketones are commonly used in industry as solvents, extractants, chemical intermediates, and to a lesser extent, flavor and fragrance ingredients. Ketones have also been reported in the ambient air, in wastewater treatment plants (1), and in oil field brine discharges (2).

Ketones of Four Or Five Carbons

Occupational Exposures
In an occupational setting, the primary routes of exposure to ketones are inhalation and skin contact. Ingestion is rare. Since most ketones have a significant vapor pressure at room temperature, exposure by inhalation in the workplace is likely to occur. The principal hazard associated with exposure to ketone vapors is irritation of the eyes, nose, and throat. Many ketones have excellent warning properties and can be easily detected by their odor. Accidental overexposure should be relatively rare provided warning properties are not ignored and olfactory fatigue does not occur. The classic symptoms produced by an overexposure to ketones include, progressively, irritation of the eyes, nose, and throat, headache, nausea, vertigo, uncoordination, central nervous system depression, narcosis, and cardiorespiratory failure. Recovery is usually rapid and without residual toxic effects. In the case of accidental spills, personnel should wear protective clothing including respiratory protection. Contaminated clothing should be removed promptly, and the exposed areas of the body should be thoroughly flushed with water. Many ketones are absorbed through the skin; therefore,

caution should be exercised to avoid repeated or prolonged skin contact. The vapors produced by accidental spills may present a fire or explosion hazard.

Toxic Effects

Although the relative toxicity of most ketones is low and the effects of acute exposures are well recognized, the effects of chronic exposure have received less study. In some cases, metabolic studies have helped to elucidate the toxic effects of several ketones. Generally, when ketones are absorbed into the bloodstream, they may be eliminated unchanged in the expired air, or metabolized by a variety of metabolic pathways to secondary alcohols, hydroxyketones, diketones, and carbon dioxide. Recent studies indicate that carbonyl reduction, a and  –l oxidation, decarboxylation, and transamination play important roles in the metabolism of aliphatic ketones. Aromatic ketones and ketones such as cyclohexanone and isophorone may undergo oxidative metabolism by dehydrogenation, ring hydroxylation, or substituent group oxidation. In addition, aromatic and aliphatic ketones may be conjugated with glucuronic acid, sulfuric acid, or glutathione prior to excretion in the urine. Glucuronic and sulfuric acid conjugation usually occur after a ketone is reduced to a secondary alcohol or oxidized to a carboxylic acid. Of the various conjugation mechanisms that occur, glucuronic acid conjugation appears to be the predominant pathway.

Ketone exposure may alter the toxicity of other chemicals, including other ketones that are metabolized by cytochrome P450 enzymes. Under certain circumstances non-neurotoxic ketones may potentiate the neurotoxicity of other ketones or organophosphates or the hepatotoxicity and renal toxicity of haloalkanes. Data on these interactions are referred to in sections on specific ketyones in Chapters 74, 75, and 76.

Table 75.1. Physical–Chemical Properties

Compound	Molecular Formula	Mol. Wt.	Boiling Point (°C)	Melting Point (°C)	Specific Gravity[ab]	Refractive Index (20° C)	Vapor Pressure (mmHg)	Vapour Density (Air = 1)	M V Co (p 2(
Acetone	C_3H_6O	58.08	56.2	–95.4	0.791	1.3588	180	2.0	23

Introduction

Ketones of carbon number 6–13 are important commercial and industrial materials. Their primary use is as solvents that find use in numerous products and industrial applications. Due to their volatility, environmental regulations have been directed at restricting emissions, particularly to the atmosphere. A number of the ketones discussed in this chapter can undergo photochemical transformations that contribute to their abiotic degradation but may also contribute to the formation of smog. Regulations limiting or prohibiting release of materials that may contribute to smog formation are leading to reductions in the use of some of these materials.

Ketones of Six To Thirteen Carbons

Occupational Exposures

As for the short-chain ketones discussed in Chapter 75, the ketones covered in this chapter are mainly of concern due to inhalation and dermal exposure routes. Acute exposure to high vapor concentrations of these materials may result in narcosis; however, such exposures are rare except in cases of accidents.

Low levels of exposure to many of these ketones can be expected in the environment and through endogenous exposure because ketones are common substrates for many of the enzymes associated with intermediary metabolism in organisms from bacteria to man.

Toxic Effects
Acute exposures to ketone vapors may result in irritation to the eyes and throat. Repeated dermal exposures may result in defatting of the skin, resulting in dryness, cracking, peeling, and inflammation of the epidermis.

The more serious effect of exposure to some of the ketones covered in this chapter is peripheral neuropathy, which has been reported to occur in occupational environments. Other effects including hematologic effects and altered activity levels of various enzyme systems have been reported in experimental animal systems but not in human clinical cases.

Structure–Activity Relationships
Alkanes, primary and secondary alcohols, carboxylic acids, glycols, diketones, epoxides, hydroxy acids, and ketones are metabolically related in many biologic systems. Thus a knowledge of the structure–activity relationships of these various compounds adds to our understanding of their individual and/or combined toxicities. Much of our present knowledge about the structure–activity relationships of ketones has been developed in response to an occupationally related outbreak of neurotoxicity. Since this incident, the emphasis on ketone toxicity has been directed primarily toward neurotoxicity. It must be realized, however, that these same ketones produce effects other than neurotoxicity.

Table 76.1 lists ketones and related compounds that have been examined for neurotoxicity (1–18). Those indicated as positive are substances that showed a specific anatomic and morphologic types of nerve degeneration characterized by large multifocal axonal swellings, often referred to as “giant axonal” neuropathy. These swellings are filled with masses of disorganized neurofilaments and other organelles. Myelin damage also occurs but is generally considered to be a secondary effect. Clinical symptomatology in man includes bilaterally symmetrical paresthesia, best described as a “pins and needles” feeling, and muscle weakness, primarily in the legs and arms.

Table 76.1. Neurotoxicity of Ketones and Related Substances

Chemical	Structure	Neurotoxicity[a]	Ref.
	Six-Carbon Structures		
n-Hexane	$CH_3(CH_2)_4CH_3$	+	1
Practical-grade hexanes	Mixed hexanes	+	1
1-Hexanol	$HOCH_2(CH_2)_4CH_3$	–	1, 2
2-Hexanol	$CH_3CHOH(CH_2)_3CH_3$	+	1, 2
6-Amino-1-hexanol	$HOCH_2(CH_2)_5NH_2$	–	3

Methyl *n*-butyl ketone	$CH_3CO(CH_2)_3CH_3$	+	1, 3–7
Methyl isobutyl ketone	$CH_3COCH_2CH(CH_3)_2$	–	3, 6, 7
2,5-Hexanediol	$CH_3CHOH(CH_2)_2CHOHCH_3$	+	1, 8
1,6-Hexanediol	$HOCH_2(CH_2)_4CH_2OH$	–	8
5-Hydroxy-2-hexanone	$CH_3CO(CH_2)_2CHOHCH_3$	+	1
2,3-Hexanedione	$CH_3COCO(CH_2)_2CH_3$	–	3, 8, 9
2,4-Hexanedione	$CH_3COCH_2COCH_2CH_3$	–	3, 8, 9
2,5-Hexanedione	$CH_3CO(CH_2)_2COCH_3$	+	1, 3, 8–10
	Seven-Carbon Structures		
n-Heptane	$CH_3(CH_2)_5CH_3$	–	3
Methyl *n*-amyl ketone	$CH_3CO(CH_2)_4CH_3$	–	11
Methyl isoamyl ketone	$CH_3CO(CH_2)_2CH(CH_3)_2$	–	3
Ethyl *n*-butyl ketone[b]	$CH_3CH_2CO(CH_2)_3CH_3$	+	3
Di-*n*-propyl ketone	$CH_3(CH_2)_2CO(CH_2)_2CH_3$	–	3
2,5-Heptanedione	$CH_3CO(CH_2)_2COCH_2CH_3$	+	3, 9
2,6-Heptanedione	$CH_3CO(CH_2)_3COCH_3$	–	3, 9
3,5-Heptanedione	$CH_3CH_2COCH_2COCH_2CH_3$	–	8
3-Methyl-2,5-hexanedione	$CH_3COCHCH_3CH_2COCH_3$	+	12
	Eight-Carbon Structures		
3,6-Octanedione	$CH_3CH_2CO(CH_2)_2COCH_2CH_3$	+	3, 9
5-Methyl-3-heptanone	$CH_3CH_2COCH_2CHCH_3CH_2CH_3$	+	13
3-Acetyl-2,5-hexanedione	$CH_3COC(CH_3CO)CH_2COCH_3$	–	14
3,4-Dimethyl-2,5-hexanedione	$CH_3COCHCH_3CHCH_3COCH_3$	+	14–17
3,3-Dimethyl-2,5-hexanedione	$CH_3COC(CH_3)_2CH_2COCH_3$	–	15
	Nine-Carbon Structures		
5-Nonanone	$CH_3(CH_2)_3CO(CH_2)_3CH_3$	+	3
5-Methyl-2-	$CH_3CO(CH_2)_2CHCH_3(CH_2)_2CH_3$	[c]	3

octanone			
Diisobutyl ketone	$(CH_3)_2CHCH_2COCH_2CH(CH_3)_2$	–	3
	Ten-Carbon Structure		
3,4-Diethyl-2,5-hexanedione	$CH_3COCH(CH_3CH_2)CH(CH_3CH_2)$-COCH	–	16
	Eleven-Carbon Structures		
Diisoamyl ketone	$(CH_3)_2CH(CH_2)_2CO(CH_2)_2CH$-$(CH_3)_2$	–	3
	Twelve-Carbon Structure		
3,4-Diisopropyl-2,5-hexanedione	$CH_3COCH(CH_3CH_3CH_2)CH$-$(CH_3CH_3CH_2)COCH_3$	–	18

[a] – Indicates that the material was tested experimentally and found not to be neurotoxic; + indicates the material may produce giant axonal neuropathy.
[b] Ethyl *n*-butyl ketone is metabolized to 2,5-heptanedione, which is neurotoxic.
[c] Commercial samples of 5-methyl-2-octanone may contain 5-nonanone, which is neurotoxic. 5-Methyl-2-octanone enhances 5-nonanone neurotoxicity.

The metabolic interrelationships of some of these neurotoxins are shown in Figure 76.1. Initially, studies of *n*-hexane and methyl *n*-butyl ketone neurotoxicity revealed that the g-diketone 2,5-hexanedione was a neurotoxin. Subsequently, a series of diketones were examined for their ability to produce "giant axonal" neuropathy in rats. Table 76.2 lists these compounds and further emphasizes the necessity of the g-diketone spacing for the production of neuropathy. These findings have led to the theory that neurotoxicity is related to a common metabolic pathway leading to the formation of a g-diketone, which is the toxic metabolite that produces the neuropathy. Except for 2,5-heptanedione and 3,6-octanedione, all metabolic interconversions are oxidation of the  -1 carbon(s), first to an alcohol or diol, then to a g-diketone. In the case of *n*-heptane, where  -1 oxidation may occur, the ketone formed would be a d-diketone such as 2,6-heptanedione, which is not neurotoxic. When the  carbon is oxidized in preference to the  -1 carbon, as when *n*-hexane is converted to 1-hexanol, no g-diketone is formed.

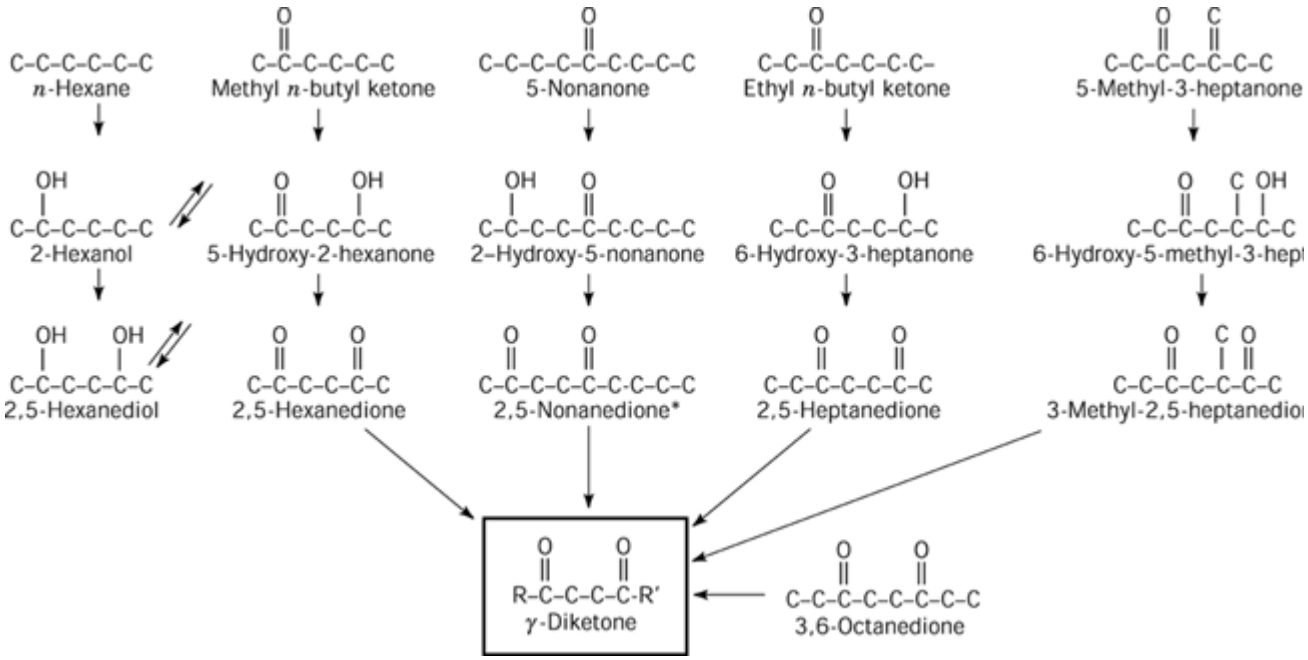

Figure 76.1. Relationships of alkanes, alcohols, and ketones that produce "giant axonal" neuropathy. Hydrogen atoms are included only when present as hydroxyl ions. * Further oxidative and decarboxylative pathways lead to the formation of methyl *n*-butyl ketone and 2,5-hexanedione (see Fig. 76.2). **The 5-methyl-3-heptanone metabolic scheme is an hypothesized pathway that is consistent with the observed neurotoxicity of this material.

Table 76.2. Structure–Activity Relationships of Diketones

Ketone Structure	Spacing	Ketone Neuropathy	Giant Axonal
2,4-Pentanedione	$CH_3COCH_2COCH_3$	b	–[a]
2,3-Hexanedione	$CH_3COCO(CH_2)_2CH_3$	a	–
2,4-Hexanedione	$CH_3COCH_2COCH_2CH_3$	b	–
2,5-Hexanedione	$CH_3CO(CH_2)_2COCH_3$	g	+
3-Methyl-2,5-hexanedione	$CH_3COCHCH_3CH_2COCH_3$	g	+
3,4-Dimethyl-2,5-hexanedione	$CH_3COCHCH_3CHCH_3COCH_3$	g	+
3,3-Dimethyl-2,5-hexanedione	$CH_3COC(CH_3)_2CH_2COCH_3$	g	–
2,3-Heptanedione	$CH_3CH_2COCH_2COCH_2CH_3$	b	–
2,5-Heptanedione	$CH_3CO(CH_2)_2COCH_2CH_3$	g	+
2,6-Heptanedione	$CH_3CO(CH_2)_3COCH_3$	d	–
3,6-Octanedione	$CH_3CH_2CO(CH_2)_2COCH_2CH_3$	g	+

3-Acetyl-2,5-hexanedione	$CH_3COC(CH_3CO)CH_2COCH_3$	g	–
3,4-Diethyl-2,5-hexanedione	$CH_3COCH(CH_3CH_2)CH(CH_3CH_2)COCH_3$	g	–
3,4-diisopropyl-2,5-hexanedione	$CH_3COCH(CH_3CH_3CH_2)CH(CH_3CH_3CH_2)COCH_3$	g	–

[a] 2,4-Pentanedione produces central nervous system damage, which is clinically, anatomically, and morphologically distinguishable from "giant" axonal neuropathy.

These data also suggest that, as chain length increases, the neurotoxicity of the diketone decreases, possibly owing to steric hindrance. However, chain length may not be as important for some materials such as 5-nonanone. The neurotoxicity of 5-nonanone appears to involve two metabolic pathways, one to 2,5-nonanedione, a mechanism similar to that of the other compounds shown in Figure 76.1, and the other to methyl *n*-butyl ketone via a series of oxidative and decarboxylative pathways (Fig. 76.2).

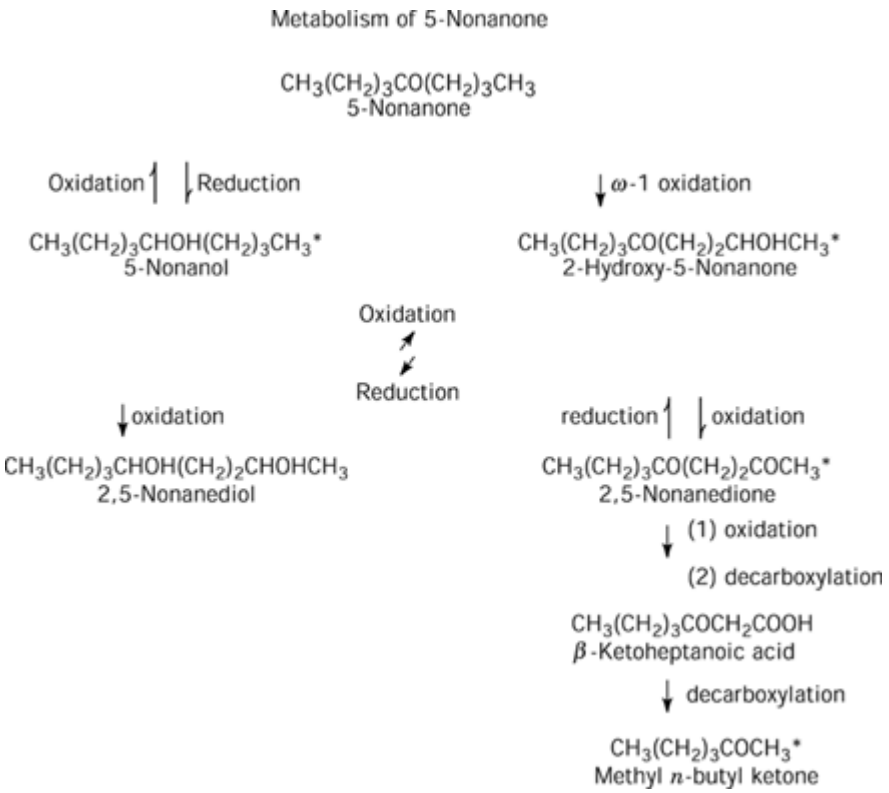

Figure 76.2. Metabolism of 5-Nonanone. *Designates actual metabolites found in blood or urine.

A third modifying factor affecting the neurotoxic potential of these substances is the number and size of substituent groups located between the g-spaced carbonyls. Single methyl groups on the carbons located between the carbonyl groups increase the potential neurotoxicity of the g-diketone (i.e., 3-methyl-2,5-hexanedione or 3,4-dimethyl-2,5-hexanedione, Table 76.1). Two methyl groups positioned on one of the methyl groups between the carbonyls (i.e., 3,3-dimethyl-2,5-hexanedione) eliminate neurotoxicity. Metabolism to a substituted g-diketone may play a role in the neurotoxicity of 5-methyl-3-heptanone (Fig. 76.1).

Summary

A summary of the acute toxicologic properties of the ketones is presented in Table 76.3. During the past 30 years, a significant amount of data has been accumulated on the biologic and toxicologic effects of ketones in experimental animals and man. With the exception of certain studies that have shown that ketones with a particular structure produce a toxic polyneuropathy, these findings support the existing concepts of the relatively innocuous biologic effects of most ketones. The most widely and extensively used ketones appear to be the least toxic.

Table 76.3. Toxicologic Properties of Ketones

Compound	Approximate Oral Rat LD_{50} (mL/kg)	Lowest Reported Lethal Air Conc. Rat (ppm/h)	Skin Irritation[a]	Ocular Injury[a]
Methyl *n*-butyl ketone	3	8000/4	Sl	Sl

Monohydric Alcohols—C_1 to C_6

C. Bevan, Ph.D., DABT

Chemical and Physical Properties

The physical and chemical properties for the C_1 to C_6 monohydric alcohols are listed in Table 77.1. At ambient temperature, the vapor pressure decreases with increasing carbon number as shown in Table 77.1. The water solubility also decreases with an increasing carbon number. The National Fire Protection Association (NFPA) has prepared a rating system to assess the physical and chemical hazards of chemicals with respect to flammability, health, and reactivity (1, 2). The C_1 to C_6 monohydric alcohols are flammable, but not reactive.

Table 77.1. Chemical and Physical Properties of C_1 to C

Compound	CAS #	Mol. formula	Mol. wt.	Boiling point (°C)	Melting point (° C)	Sp. gr.	Refractive index (20° C)	Vapor pressure (mmHg) (°C)	Maxin vap concn (°C

Production and Use

The C_1 to C_6 alcohols represent an important class of industrial chemicals with a wide number of uses. Based on production volume, the monohydric alcohols represent the most important group of the alcohol family (3). Methanol was in the top 50 chemicals produced in the United States in 1995 with a production volume of 11.3 billion pounds (4). In general, the alcohols of commercial significance are produced synthetically, although some alcohols are made from natural products or by fermentation. The most important industrial processes are the methanol process and the oxo process. The oxo process can be used to produce alcohols in the C_3 to C_{20} range by using alkenes as starting materials (3).

The uses of alcohols are numerous and can vary depending on their chemical and physical properties. In general, alcohols are used as solvents, cosolvents, and chemical intermediates. Among the higher alcohols, those containing six carbons or more, the C_6 to C_{11} alcohols are used in the manufacture of plasticizers. Some of the alcohols exist as pure chemicals, but higher monohydric alcohols (C_6 to C_{18}) can also exist as complex isomeric mixtures (3, 5, 6). The major routes of industrial or occupational exposure to alcohols is by dermal contact and/or inhalation. The extent of the exposure pathways depends on the use of the chemical and physical properties of the alcohol.

Metabolism and Disposition

A comparative uptake study has been conducted using human abdominal skin *in vitro* for the C_1 to C_{10} linear alcohols (7). The rate of dermal uptake for the neat material decreases with increasing carbon number.

Williams wrote an early general review on the metabolism and disposition of alcohols (8). Primary alcohols are readily oxidized to the corresponding aldehydes, which are further converted to the corresponding acids. Secondary alcohols are converted to ketones. Alcohols can be conjugated either directly or as a metabolite with glucuronic acid, sulfuric acid, or glycine, and excreted. Tertiary alcohols are more resistant to metabolism and are generally conjugated more readily than secondary or primary alcohols. Biomonitoring methods exist for several of the alcohols, including methanol, ethanol, isopropanol, and *n*-butanol (9). It is important to note that there are endogenous sources for some low molecular weight alcohols that must be considered in evaluating biomonitoring data for those alcohols.

Health Effects in Animals

The acute toxicity data for the monohydric alcohols indicate a low order of acute toxicity by oral, dermal, or inhalation routes of exposure. The C_1 to C_6 monohydric alcohols produce central nervous system depression. Based on the inhalation data, the secondary and tertiary alcohols are more biologically active than the primary alcohols. The C_1 to C_6 linear alcohols have been studied for their aspiration hazard (10). Except for methanol, the linear alcohols are aspiration hazards. Although not studied, the branched isomeric alcohols may be aspiration hazards. Sensory irritation increases with increasing carbon number (11).

Nelson et al. (12) investigated the developmental toxicity of aliphatic alcohols (C_1 to C_{10}) administered by inhalation to rats. Several of the alcohols (methanol, 1-propanol, isopropanol, 1-butanol) produced developmental toxicity but at concentrations that are at least an order of magnitude higher than existing occupational exposure standards and generally in the presence of maternal toxicity. Developmental toxicity did not, as predicted, increase as the carbon chain length was increased from six to eight carbons, after which toxicity would expected to decrease, although sufficiently high vapor concentrations of the longer chain alcohols could not be generated to produce maternal or fetal toxicity. Furthermore, behavioral teratogenic effects were not observed at concentrations lower than those that produced embryo toxicity (e.g., malformations) as revealed by traditional assessment. Although sporadic deviations in behavioral and neurochemical end points were observed with the alcohols, no pattern of effect was seen with any of the alcohols examined. The C_1 to C_6 monohydric alcohols are typically inactive in genotoxicity assays, but on occasion, some weak activity has been noted for methanol and ethanol.

Health Effects in Humans

This review discusses primarily dermal and inhalation routes of exposure, which are the major routes of occupational exposure to alcohols. Many of the high-production alcohols such as methanol, ethanol, propanols, and butanols cause adverse effects when ingested; ingestion, however, is not a major route of occupational exposure. There are some alcohols that have produced adverse effects in humans, including death, in an occupational environment. Nevertheless, alcohols have been used extensively in the workplace generally with few or minor problems. Occasionally, methanol, ethanol, and the propanols produce a skin sensitizing response in humans. In some, but not all, cases the sensitization response was considered to be due to contaminants and not to the alcohol itself.

A common property of some of the alcohols is to produce local irritation to the skin, eyes, and respiratory tract, and the effect or potency varies for the type of alcohol. Many alcohols produce minimal or no adverse effects in humans, possibly because of low exposure combined with the low toxicity potential of the alcohol.

Few alcohols produce neuropathic effects in humans. Abuse of products containing methanol and ethanol has produced some indications of neurotoxicity in humans, but nothing has been reported in an occupational environment. 2-Hexanol produces neurotoxicity by the oral and intraperitoneal routes in animals, but there is no evidence of such an effect having occurred in the workplace.

There is no clear evidence that occupational exposures to alcohols represent a carcinogenic risk to humans. Based on epidemiological data, there is an association between the manufacture of ethanol and isopropanol by the strong acid process (a process no longer used in the United States) and an excess of upper respiratory tract cancer in humans (13). The effect has been attributed to by-products such as dialkyl sulfates (14) and sulfuric acid (15), not the alcohols themselves.

Some of these alcohols such as ethanol and isopropanol can enhance the toxic effects of various chemicals, particularly hepatotoxins. It is thought that the effects may be due largely to an inductive effect of the alcohol on microsomal enzymes, particularly the cytochrome P450 system, which may allow a greater metabolic conversion of the hepatotoxin to its toxic metabolite.

A. C_1 to C_3 Alcohols

The low molecular weight alcohols, including methanol, ethanol, 1-propanol, and isopropanol are used extensively in industry (16). These alcohols exist as volatile liquids at ambient temperatures, and exposure can occur in both industrial and nonindustrial environments.

The best studied monohydric alcohol is ethanol, although an extensive database exists for methanol and isopropanol. These alcohols have a low order of acute toxicity in animals, and the principal effects from inhalation exposure are local irritation and central nervous system depression. Inhalation studies in animals indicate a high no-observed-adverse-effect-level for developmental effects (12).

Table 77.2. Single-Dose Oral Toxicity Values for Methanol in Animals[a]

Species	LD_{50} values (g/kg)	Ref.
Rat	6.2	32
	9.1	32a
	12.9	33
	13.0	34
Rabbit	14.4	35
Monkey	2–3[b]	36
	7.0[b]

Monohydric Alcohols—C_1 to C_6

C. Bevan, Ph.D., DABT

B. Butanols

Butanols consist of four structural isomers of the molecular formula $C_4H_{10}O$: two primary, one secondary, and one tertiary alcohol. There are two stereoisomers of 2-butanol due to an asymmetric carbon atom in the secondary alcohol. All the butanols exist as liquids at room temperature, except *tert*-butanol (melting point 25°C). A relatively good toxicity data base exists for these alcohols. Occupational exposure standards exist for all four butanols.

Monohydric Alcohols—C_1 to C_6

C. Bevan, Ph.D., DABT

C. Amyl Alcohols

This group consists of saturated aliphatic alcohols that contain five carbons. It includes three pentanols, four substituted butanols, and a disubstituted propanol, eight structural isomers that have the empirical formula $C_5H_{12}O$. There are four primary, three secondary, and one tertiary alcohol (347). In addition, 2-pentanol, 2-methyl-1-butanol, and 3-methyl-2-butanol are optically active.

The odd-numbered carbon structure and the extent of branching provide amyl alcohols with unique physical and solubility properties and often offer ideal characteristics for solvent, surfactant, extraction, gasoline additive, and fragrance applications. The original source of amyl alcohols was fusel oil, which is a by-product of the ethanol fermentation industry. Refined amyl alcohol from this source contained 85% 3-methyl-1-butanol and about 15% 2-methyl-1-butanol (347). Amyl alcohols were first produced synthetically from pentane by chlorination and hydrolysis (347). Today the most important industrial process for producing amyl alcohol is the oxo process based on butenes (347). Mixtures of isomeric amyl alcohols such as 1-pentanol and 2-methyl-1-butanol are often preferred because the different degree of branching imparts a more desirable combination of properties (347).

Inhalation of amyl alcohol vapors by humans have been reviewed by Rowe and McCollister (18). The vapors cause marked irritation of the eyes and respiratory tract, headache, vertigo, dyspnea and cough, nausea, vomiting, and diarrhea. Double vision, deafness, delirium, and occasionally fetal poisoning, preceded by severe nervous symptoms, have been attributed to the absorption of amyl alcohol. Coma, glycosuria, and sometimes methemoglobinemia have been reported as characteristic of amyl alcohol intoxication. A few cases of industrial poisoning were caused by amyl alcohol, although the presence of other solvents confounded the issue (18). Workers engaged in producing

smokeless powder reported cough, eye irritation, colic, diarrhea, vomiting, heart palpitation, nervous symptoms, headache, vertigo, vision disturbances, forgetfulness, insomnia, somnolence, weakness, and one fatality. Although other alcohols and ether were employed, the signs increased as the use of amyl alcohol (probably fusel oil) increased (348). Nonindustrial cases of poisoning from drinking fusel oil were characterized by coma, glycosuria, and methemoglobinuria (349). An occupational exposure standard exists only for 3-methyl-1-butanol.

Table 77.6. Pattern of Excretion of Secondary Amyl Alcohols by Rats after Intraperitoneal Injection (135)[a]

	Percent of administered dose				
	Expired air		Urine		
Isomer	Alcohol	Ketone	Alcohol	Ketone	Total Excreted
2-Pentanol	5.4	36.8	1.2	2.0	45.4
3-Pentanol	0.3	50.0	0.1	4.6	55.0
3-Methyl-2-butanol	8.1	48.0	2.9	2.4	61.4

[a] Taken from Rowe and McCollister (18).

Monohydric Alcohols—C_1 to C_6

C. Bevan, Ph.D., DABT

D. Hexanols

The C_6 alcohols consist of a number of primary, secondary, and tertiary structural isomers. Enantiomers can exist for 2-hexanol. The most important commercial members are 1-hexanol, 2-ethyl-1-butanol, and isohexyl alcohols (a mixture of branched C_6 alcohols). The most important member of the secondary alcohols, is methyl isobutyl carbinol. The major use of these alcohols is in the production of esters, such as plasticizers. No occupational exposure standards exist for the hexanols except for methyl isobutyl carbinol.

There is toxicological interest in 2-hexanol because it is a metabolite of *n*-hexane and methyl-*n*-butyl ketone, which are known neuropathic agents in humans and animals.

Monohydric Alcohols—C_7 to C_{18}, Aromatic, and Other Alcohols

C. Bevan Ph.D., DABT

Chemical and Physical Properties

The physical and chemical properties for these alcohols are listed in Table 78.1. The National Fire Protection Association (NFPA) has prepared a rating system to assess the physical and chemical hazards of chemicals with respect to flammability, health, and reactivity (1, 2). In general, these alcohols are not reactive chemicals, except for the unsaturated alcohols.

Compound	CAS Number	Mol. Formula	Mol. Wt.	Boiling Point (°C)	Melting Point (° C)	Sp. Gr.	Refractive Index (20° C)	Va Pres (mn (°

Monohydric Alcohols—C_7 to C_{18}, Aromatic, and Other Alcohols

C. Bevan Ph.D., DABT

Production and Use

Alcohols represent an important class of industrial chemicals with a wide number of uses. Based on production volume, monohydric alcohols represent the most important group of the alcohol family (3). The most important alcohols in this chapter are the plasticizer alcohols (C_7 to C_{11}) and the detergent range alcohols (C_{12} to C_{18}). In 1997, the production volume of 2-ethylhexanol reached 7.68 billion pounds in the United States (4). In general, alcohols of commercial significance are produced synthetically, although some alcohols are made from natural products of fermentation. The most significant industrial process is the oxo process that can be used to produce alcohols in the C_3 to C_{20} range by using alkenes as starting materials (3).

The uses of alcohols are numerous and can vary depending on their chemical and physical properties. In general, alcohols are used as solvents, cosolvents, and chemical intermediates. Among the higher alcohols, defined as containing six carbons or more, the C_6 to C_{11} alcohols are used to manufacture plasticizers. Some of the alcohols are pure chemicals, but higher monohydric alcohols (C_6 to C_{18}) are also complex isomeric mixtures (3, 5, 6). The major routes of industrial or

occupational exposure to alcohols is by dermal contact and/or inhalation. The extent of the exposure pathways depends on the use of the chemical and the physical properties of the alcohol.

Monohydric Alcohols—C_7 to C_{18}, Aromatic, and Other Alcohols

C. Bevan Ph.D., DABT

Metabolism and Disposition
A comparative uptake study has been conducted using human abdominal skin *in vitro* for C_1 to C_{10} linear alcohols (7). The rate of dermal uptake for the neat material decreases with increasing carbon number.

Williams prepared an early general review on the metabolism and disposition of alcohols (8). Primary alcohols are readily oxidized to the corresponding aldehydes, which are further converted to the corresponding acids. Secondary alcohols are converted to ketones. Alcohols can be conjugated either directly or as a metabolite with glucuronic acid, sulfuric acid, or glycine, and excreted. Tertiary alcohols are more resistant to metabolism and are generally conjugated more readily than secondary or primary alcohols.

Monohydric Alcohols—C_7 to C_{18}, Aromatic, and Other Alcohols

C. Bevan Ph.D., DABT

Health Effects
A common property of some of the alcohols is to produce local irritation to the skin, eyes, and respiratory tract, and the effect or potency varies with the type of alcohol. Many alcohols produce minimal or no adverse effects in humans, possibly because of low exposure combined with the low toxicity potential of the alcohol.

Monohydric Alcohols—C_7 to C_{18}, Aromatic, and Other Alcohols

C. Bevan Ph.D., DABT

A. Heptanols
The most important commercial member of this group is isoheptyl alcohol, which is a mixture of branched C_7 alcohols. This alcohol is used for the manufacture of esters such as phthalate plasticizers. 1-Heptanol has little commercial value. Other C_7 alcohols are 2,3-dimethyl-1-pentanol and the secondary alcohols, 2-heptanol, 3-heptanol, 4-heptanol, and 2,4-dimethyl-3-pentanol. 2-Heptanol and 3-heptanol can exist as enantiomers.

The available toxicity data indicate that heptanols have a low order of acute toxicity and no occupational exposure standards exist for them.

Monohydric Alcohols—C_7 to C_{18}, Aromatic, and Other Alcohols

C. Bevan Ph.D., DABT

B. Octanols

The most important commercial C_8 alcohols are 2-ethylhexanol and a mixture of branched C_8 alcohols referred to as isooctyl alcohol. Other octanols of lesser commercial interest are 2-octanol, 1-octanol, 3,5-dimethyl-1-hexanol, 2,2,4-trimethyl-1-pentanol, and 2-ethyl-4-methyl-1-pentanol. These alcohols are liquids at ambient temperature and are used primarily in producing esters, such as plasticizers. No occupational exposure standards exist for octanols except for isooctyl alcohol.

Monohydric Alcohols—C_7 to C_{18}, Aromatic, and Other Alcohols

C. Bevan Ph.D., DABT

C. Nonanols

The most important commercial members of this subgroup of alcohols are the C_9 oxo alcohols, which are a mixture of predominantly C_9 branched alcohols, diisobutyl carbinol, and 2,6-dimethyl-4-heptanol. Two C_9 alcohols of lesser commercial importance are 1-nonanol and 3,5,5-trimethyl-1-hexanol. All of these alcohols are liquids at ambient temperatures.

Acute studies in animals indicate a low order of toxicity. These alcohols are irritating to the skin, eyes, and respiratory tract. They are also aspirations hazard. No serious adverse effects from industrial exposure were reported in humans. Prolonged or excessive exposure to the alcohols can produce local irritation and narcosis. No occupational exposure standards have been established for any of the nonanols.

Monohydric Alcohols—C_7 to C_{18}, Aromatic, and Other Alcohols

C. Bevan Ph.D., DABT

D. Decanols

The decanols consist of more than 20 structural isomers, including a number of enantiomers. The most important commercial members are the C_{10} oxo alcohols, which exist as a mixture of C_{10} branched alcohols. Many of these alcohols are liquids. Unlike the lower alcohols, the decanols are less volatile and flammable (Table 78.1). Toxicity studies indicate that these alcohols have a low order of acute toxicity but they are irritating to both the skin and eyes. No serious industrial intoxication has been reported for the decanols. No occupational exposure standards exist for the decanols.

Monohydric Alcohols—C_7 to C_{18}, Aromatic, and Other Alcohols

C. Bevan Ph.D., DABT

E. Dodecanols

These alcohols consist of more than 20 structural isomers, including a number of enantiomers. The two most prominent members of this group of alcohols are 1-dodecanol and isodecyl alcohol, a mixture of predominantly C_{12} branched alcohols. Toxicity studies indicate that dodecanols have a low order of acute toxicity. 1-Dodecanol is the most studied C_{12} alcohol and is a tumor promoter in mice. There have been no reports of adverse effects in humans. No occupational exposure standards have been established for any of the decanols.

Monohydric Alcohols—C_7 to C_{18}, Aromatic, and Other Alcohols

C. Bevan Ph.D., DABT

F. Tridecanols

19.0 Isotridecyl Alcohol

19.0.1 CAS Number:

19.0.2 Synonym: C_{13} oxo alcohols

19.0.3 Trade Names: NA

19.0.4 Molecular Weight: 200.3

19.0.5 Molecular Formula: $C_{13}H_{28}O$

19.1 Chemical and Physical Properties

Isotridecyl alcohols are liquids or solids.

19.2 Production and Use

Isotridecyl alcohol is produced by the oxo process in which dodecenes are reacted with carbon monoxide and hydrogen in the presence of a catalyst, followed by hydrogenation (3). A major isomer of a commercial-grade product is tetramethyl-1-nonanol. Because of their low volatility these alcohols are used to produce plasticizers, they are also used as surfactant raw materials, as lubricant intermediates, and as solvents (3).

19.4 Toxic Effects

19.4.1 Experimental Studies 19.4.1.1 Acute Toxicity The acute oral LD_{50} is 4.75 g/kg in rats (42), and the dermal LD_{50} in rabbits is greater than 2.6 g/kg (42). No deaths were observed in rats, mice, or guinea pigs exposed to saturated vapors (12 ppm) for 6 h (42). Animals exhibited slight irritation to the eyes, nose, and throat.

These alcohols are reportedly moderately irritating to rabbit skin when applied for 24-h under an occlusive wrap, but slightly irritating when applied under 4-h semiocclusive conditions (17). Isotridecyl alcohol was moderately irritating to eyes of rabbits (42).

19.4.2 Human Experience 19.4.2.1 General Information No adverse effects in humans were reported from exposure to these alcohols.

Monohydric Alcohols—C_7 to C_{18}, Aromatic, and Other Alcohols

C. Bevan Ph.D., DABT

G. Higher Alcohols

Most of the toxicity data on the higher alcohols exist on the C_{16} and the C_{18} alcohols. Limited data exist for 1-tetradecanol and eicosnol (see Table 78.4). No occupational exposure standards have been established for the higher alcohols.

Monohydric Alcohols—C_7 to C_{18}, Aromatic, and Other Alcohols

C. Bevan Ph.D., DABT

H. Aromatic Alcohols

There are at least five aromatic alcohols of commercial interest; three primary alcohols (benzyl alcohol, 2-phenylethanol, and *p*-tolyl alcohol) and two secondary alcohols (1-phenylethanol and 2-phenyl-2-propanol). All of these alcohols are liquids at ambient temperatures. No valid NIOSH methods exist to measure these alcohols in air.

The toxicities of benzyl alcohol and 2-phenylethanol are the most studied of the aromatic alcohols. As a group, these alcohols have a low to moderate order of acute toxicity and have been both active and inactive in genotoxicity assays. No occupational exposure standards have been set for these alcohols.

Monohydric Alcohols—C_7 to C_{18}, Aromatic, and Other Alcohols

C. Bevan Ph.D., DABT

M. Alicyclic Alcohols

There are at least four alicyclic alcohols of commercial interest, two from the cyclohexyl family (cyclohexanol, methylcyclohexanols) and two from the furan family (furfuryl alcohol and tetrahydrofuran methanol). These alcohols are liquids. Cyclohexanol and furfuryl alcohol are the best studied alcohols of this group. Occupational exposure standards exist for these alcohols, except for tetrahydrofuran methanol.

Monohydric Alcohols—C_7 to C_{18}, Aromatic, and Other Alcohols

C. Bevan Ph.D., DABT

N. Unsaturated Alcohols

Unsaturated alcohols can be divided into olefinic (double-bond) and acetylenic (triple-bond) alcohols. Allyl alcohol is the most important olefinic alcohol as well as the most studied in this subset; propargyl alcohol and hexynol alcohol are the most commercially important acetylenic

alcohols. There are also a number of other olefinic alcohols (C_5) and acetylenic alcohols (C_4 to C_{10}) with toxicity data (see Table 78.4). In general, these alcohols are liquids and are quite reactive. Occupational exposure standards exist for allyl alcohol and propargyl alcohol.

Table 78.2. Results of Single or Short-term Exposures of Animals to Vapors of Allyl Alcohol[a]

Concentration (ppm)	Animal	Duration of Exposure (h)	Outcome	Ref.
1000	Monkey	4	Death	199
1000	Rabbit	4	100% lethal	199
200	Rabbit	18 × 7	100% lethal	199
1000	Rat	4	100% lethal	199
1060	Rat	1	LC_{50}	200
1000	Rat	1	LC_{67}	198
500	Rat	1	Survived	201
250	Rat	4	Some deaths	201
165	Rat	4	LC_{50}	200
76	Rat	8	LC_{50}	200
200	Rat	2 × 7	100% lethal	199

[a] Taken from Ref. 34.

Monohydric Alcohols—C_7 to C_{18}, Aromatic, and Other Alcohols

C. Bevan Ph.D., DABT

O. Halogenated Alcohols

The most important commercial members of the halogenated alcohol series are 2-chloroethanol, or ethylene chlorohydrin, and chloropropanols, which are two isomers. These three alcohols exist as volatile liquids. Some of the other halogenated alcohols not covered in this chapter have been reviewed by Rowe and McCollister (34).

Table 78.3. Results of Single Exposures of Animals to the Vapors of 2-Chloroethanol[a]

	Dose			
Animal	(mg/L)	(ppm)	Duration of Exposure (h)	Outcome	Ref.

Guinea pig	18.0	5468	0.25	Death	235
	5.0	1544	0.9	Survived	227
	3.6	1094	1.0	Death	235
	3.0	911	1.8	Death	227
	3.0	911	0.5	Survived	227
Mouse	7.0	2430	2.0	Death	227
	4.5	1367	0.5	Death	227
	4.0	1215	0.25	LC_{67}	227
	3.0	911	1.0	Death	227
	1.2	365	2	LC_{17}	232
	1.0	304	2	Survived	227
	0.38	115	?	LC_{50}	230
Rat	4.0	1215	0.5	Death	227
	3.4	1033	0.25 × 3, 6, or 11	Death	227
	3.0	911	0.25	Survived	227
	0.29	88	?	LC_{50}	230
	0.11	33	4	LC_{50}	233

Monohydric Alcohols—C_7 to C_{18}, Aromatic, and Other Alcohols

C. Bevan Ph.D., DABT

P. Miscellaneous Alcohols

Limited toxicity data exist on a number of alcohols of lesser industrial importance, which are listed in Table 78.4. These alcohols include six monohydric alcohols, one alicyclic alcohol, and four acetylenic alcohols. It should be noted that a number of these alcohols exist as stereoisomers with different CAS registry numbers. The CAS registry numbers listed in Table 78.4 represent the mixed product. It is not known whether biological differences exist among the different isomers.

Table 78.4. Toxicity Data on Miscellaneous Alcohols

Alcohol	Acute Oral Rat LD_{50}	Acute Dermal Rabbit LD_{50}	Acute Inhalation Rat LC_{50}	Skin Irritation	Eye Irritation	Skin Sensitization	Ref.
2-Heptanol (CAS *#543-47-7*)	2.58 g/kg	1.78 mL/kg	No deaths, 8 hr satd. vapor	Slight	Severe	—	273

3-Heptanol (CAS *#3913-02-8*)	1.87 g/kg	4.36 mL/kg	No deaths, 4 hr satd. vapor	Slight	Moderate	—	105
1-Undecanol (CAS *#112-42-5*)	3 g/kg	>5 g/kg	—	Moderate	—	—	274
1-Tetradecanol (CAS *#112-72-1*)	>5 g/kg	>5 g/kg	—	No	Slight	—	275
Eicosanol (mixed isomers) (CAS *#629-96-9*)	>64 mL/kg	>20 mL/kg	No deaths, 8 hr satd. vapor	Slight	Slight	—	43
3,5,5-Trimethyl cyclohexanol (CAS *#116-02-9*)	3.45 g/kg	2.8 mL/kg	—	Moderate	Very severe	—	102
3-Butyn-2-ol (CAS *#2028-69-9*)	34 mg/kg	32–36 mg/kg	1 hr LC_{50}; std. vapor 6 min exposure, 100% lethal	—	Very severe	—	216
Methyl butynol (CAS *#115-9-5*)	1.9 g/kg	>5 g/kg	1 hr LC_{50}; >20 mg/L[a]	None	Severe (10% in H_2O not irritating)	Possibly	216
Methyl pentynol (CAS *#77-75-8*)	0.8 g/kg	>1 g/kg	1 hr LC_{50}; >20 mg/L[b]	Slight	Severe	Possibly	216
Ethyl octynol (CAS # [*5877-42-9*])	2.1 g/kg	0.2–1.0 g/kg	—	—	—	Possibly	34
3,7-Dimethyl-1-octonol (CAS *#106-21-8*)	>5 g/kg	2.4 g/kg	—	Yes. unspec.	—	—	106

[a] A single 4-hr exposure of rats to 3000 ppm methyl butynol caused death, but a 7-hr exposure to 2000 ppm did not. Both exposures caused liver and kidney injury. A single 7-hr exposure to 1000 ppm did not cause grossly apparent injury. Rats that received 81 7-hr exposures to 76 ppm for 115 day exhibited no adverse effects.

[b] A single 4-hr or 7-hr exposure of rats to 4600 ppm methyl pentynol caused anesthesia, considerable injury to the lungs, liver, and kidney, and death. A 2-hr exposure did not cause death but did cause kidney injury and weight loss. A few deaths occurred after 4- and 7-hr exposures to 2000 ppm, whereas all survived a 7-hr exposure to 1000 ppm, although kidney

injury was noted. Groups of rats tolerated 67 7-hr exposures to 100 ppm for 98 days without adverse effects.

Esters of Mono- and Alkenyl Carboxylic Acids and Mono- and Polyalcohols
Michael S. Bisesi, Ph.D., CIH

A. Introduction

Overview

This volume contains three chapters reviewing 12 classes of the organic compounds called *esters*. Chapter 79, this chapter, reviews (*1*) esters of monocarboxylic acids and mono- and polyalcohols and (*2*) esters of alkenyl carboxylic acids and monoalcohols; Chapter 80 reviews (*3*) esters of aromatic monocarboxylic acids and monoalcohols, (*4*) esters of monocarboxylic acids and di-, tri-, and polyalcohol; (*5*) dicarboxylic acid esters; (*6*) alkenyl dicarboxylic esters; (*7*) esters of aromatic diacids; (*8*) tricarboxylic acid esters; and, Chapter 81 covers (*9*) esters of carbonic and orthocarbonic acid; (*10*) esters of organic phosphorous compounds; (*11*) esters of monocarboxylic halogenated acids, alkanols, or haloalcohols; and (*12*) organic silicon esters.

The sequence of the compounds has been organized according to the chemical structure of the major functional metabolites. This involves the ester hydrolyzates, primarily the acid and secondarily the alcohol. The reason for this sequence was the general observation that the degree of toxic effect, in addition to that of the original material, more often was the result of the toxicity of the acid rather than the response of the alcohol.

Esters are important from an industrial hygiene perspective since exposure can occur during the process of manufacturing esters, the process of manufacturing materials containing or composed of esters, handling and use of products containing or composed of esters, and treatment of wastes containing esters. In turn, exposure to esters is important from a toxicological perspective because of the correlated observations of adverse physiological responses exhibited by laboratory animals and humans.

Overviews of the physical, chemical and toxicologic (*i.e.*, physiologic responses) properties of many subclasses of esters and/or of specific compounds are provided. In addition, summaries of relative manufacturing and use information are also included for many compounds.

General Properties of Some Esters

Chemically, esters are organic compounds commonly formed via the combination of an acid, typically an organic (—COOH) mono- or polyacid, plus a hydroxyl (—OH) group of a mono-or polyalcohol or phenol; water (H—OH) is generated as a by-product of the reaction. For example, the reaction (esterfication) of acetic acid (CH_3COOH) with methyl alcohol (CH_3OH) to form methyl acetate proceeds [$CH_3(C{=}O)OCH_3$] as follows:

$$CH_3COOH + CH_3OH \leftrightarrow CH_3(C=O)OCH_3 + H_2O$$

The forward reaction (right; k_1) is known as *esterification*; the reverse (left; k_2) as *hydrolysis*. The occurrence of esterification or hydrolysis reactions depends on the differential reaction rates k_1 *versus* k_2 and the physical properties of the respective final products. The ratio of the concentrations of products [*C*] of k_1 divided by k_2 will give a reaction constant K_s indicative of the stability of the final product:

$$K_s = \frac{[C_{ester}] \times [C_{H_2O}]}{[C_{alcohol}] \times [C_{acid}]}$$

The esters are widely used in industry and commerce. They can be prepared by the reactions of acids with alcohols, by reacting metal salts of acids with alkyl halides, acid halides with alcohols, or acid anhydrides with alcohols by the interchange of radicals between esters. Most esters exist in liquid form at ambient temperatures, but some possess lower boiling points than their original starting

materials. They are relatively water-insoluble, except for the lower molecular weight members. Their flash points are in the flammable range. The monocarboxylic acid esters have high volatility and pleasant odors, whereas the di- and polyacid esters are relatively nonvolatile and exhibit essentially no odor. The monocarboxylic esters occur frequently in natural products, as, for example, in fruits, to which they lend their pleasant odor and taste. Because of the different properties of esters from the original acids and alcohols, esterification can be used for their isolation or to chemically protect specific carboxy or hydroxy functions.

General Toxicity of Some Esters

Absorbed esters and/or metabolites derived from biotransformed esters can initiate toxic effects in some mammalian systems, including humans, and cause adverse physiological responses. Indeed, the underlying causes of physiological responses are due to initial interactions biochemically within a system. Within these chapters, a summary of reviewed literature will reveal that, in general, toxic effects associated with exposure to various esters include primary irritation to ocular, upper and lower respiratory, and dermal systems; depression of the central nervous system (CNS) (*e.g.*, anesthesia, narcosis); dermal hypersensitization; impact to the gastrointestinal (GI), hepatic, and renal systems; abnormal cardiac rhythm; and carcinogenesis. Indeed, these and some additional effects, are based predominantly on rodent studies. A review of the literature reported here, however, indicates that the most commonly reported effects in animals and humans are irritation and, to some extent, CNS depression. Data are reported in this chapter for several classes of esters, including formates (1), acetates (2), acrylates and methacrylates (3), propionates (4), and lactates (5).

Ocular, dermal, respiratory, and even GI irritation is reportedly associated with both the parent ester compounds and the corresponding acid metabolites produced via hydrolytic cleavage reactions (1). Some compounds, such as the aliphatic esters used as lacquer solvents, may cause CNS depression when inhaled in sufficiently high concentrations (6). As expected from Overton theories substantiated by Munch (7) in experiments using rabbits and tadpoles, the more highly water-soluble, lower molecular weight derivatives, such as the methyl and ethyl formates and acetates, are less potent than butyl and amyl acetates. Thus, when Munch used tadpoles to evaluate the potency of aliphatic alcohols and their alkyl esters, he observed a direct relationship between CNS depression and increase in homologous series (7). He concluded that the intact ester was the primary causative agent.

Their anesthetic potency is weaker than that of lower chlorinated hydrocarbons and usually less than that of ethyl ether, but greater than that of ethanol, acetone or pentane. When inhaled, aliphatic esters readily pass through the alveoli, owing to their relatively high solubility in plasma fluid. Those materials with higher water solubility have higher blood–air distribution coefficients and thus presumably reach saturation more slowly. This group of esters appears to be readily hydrolyzed and the resulting alcohols and acids rapidly metabolized.

Most of the aliphatic esters possess some degree of irritation on exposed surfaces. The formates are especially irritating to the eyes and respiratory tract. Ethyl acetates may be irritating at concentrations of 400–800 ppm, whereas ethanol is devoid of effects up to 1000 ppm. The irritant range of butyl acetate, however, coincides with that of its corresponding alcohol. The irritant effect of the higher homolog is a function of the esterified rather than the hydrolyzed material. The local skin effects resemble those of other solvents; namely, defatting and cracking may occur.

Practically all the common aliphatic and aromatic esters, except for some phosphates used as plasticizers, are inert. At the most, minor degrees of irritation may follow inhalation of heated vapors or prolonged skin exposure. Some of the literature also suggests that reported skin sensitization appears more likely in the presence of impurities or side products. Many of the materials are so inert that any LD_{50} value is impractical to determine. Specific pathology is usually absent, even when the materials is fed in massive quantities to the point of nutritional deprivation. Oily or watery excretion products, sometimes observed at high feeding levels, indicate lack of absorption. The apparent nontoxicity may also be a sign of rapid hydrolysis, metabolism, and excretion. The resins are

completely inert, unabsorbed in the gastrointestinal tract, and nonirritant at the surface of the skin and pulmonary system.

Industrial Hygiene Evaluation

One part of industrial hygiene evaluation of esters involves collecting and analyzing air samples to determine their airborne concentrations. To date, published industrial hygiene air sampling and analytical methods are available for relatively few esters compared to the number of ester compounds. In addition, although methods for biological monitoring of laboratory animals and exposed humans can be conducted to determine levels of absorbed esters and metabolites that originate from biotransformed esters, there are few established limits for comparing biological monitoring data.

Contemporary air sampling methods most commonly involve the use of solid absorbents, such as charcoal, carbosieve, and XAD (8, 9). Following desorption of the solid adsorbents using a specified solvent, samples are typically analyzed using gas chromatography with flame ionization detection (GC-FID). The concentration of a given sample is determined by dividing the mass of the ester detected and measured using GC-FID by the volume of air sampled. Concentrations of air samples may be subsequently used to calculate time-weighted averages (TWAs) for comparison to applicable occupational exposure limits (OELs).

Presently, there also are relatively few OELs compared to the number of ester compounds. There are threshold limit values (TLVs) and permissible exposure limits (PELs) established by the American Conference of Governmental Industrial Hygienists (ACGIH) and the Occupational Safety and Health Administration (OSHA), respectively, for some of the ester compounds discussed in this chapter (9–11). In addition, other applicable agencies, such as the National Institute for Occupational Safety and Health (NIOSH), provide published recommendations concerning limits for occupational exposure to some esters (9).

Industrial hygiene sampling and analytical methods for some ester compounds are presented in Table 79.1 along with their respective OELs. Since sampling and analytical methods and occupational exposure limits are subject to periodic revision; however, the reader is encouraged to refer to current publications of ACGIH, OSHA, and NIOSH.

Esters of Mono- and Alkenyl Carboxylic Acids and Mono- and Polyalcohols
Michael S. Bisesi, Ph.D., CIH

B. Esters of Monocarboxylic Acids and Mono- and Polyalcohols
Grouped into this category are the naturally occurring fatty acid esters of C1–C24 acids and C1–C30 alcohols.

Esters of Mono- and Alkenyl Carboxylic Acids and Mono- and Polyalcohols
Michael S. Bisesi, Ph.D., CIH

Formates
The esters called *formates* are alkyl or aryl derivatives of formic acid HCOOH. These esters have various uses ranging from flavoring agents to industrial solvents. As is the case for most esters of toxicological significance, ocular, respiratory, and dermal irritation, and, at higher concentrations, CNS depression, are the major effects associated with exposure. The inhalation hazard decreases with increased molecular weight due to an observed progressive decrease in vapor pressure. There also is an observed decrease in water solubility with increasing molecular weight. von Oettingen reports that the decreased water solubility is associated with increased resistance to acid hydrolysis of the higher homologues. Accordingly, the lowest homologe, methyl formate, may pose a higher hazard potential because of its high vapor pressure and water solubility, but the higher homologs exhibit higher potency as central nervous system depressants (1). A summary of physical and chemical properties is found in Table 79.2 (12) and summaries of toxicologic data are shown in Tables 79.3 (13–16) and 79.4 (17).

Esters of Mono- and Alkenyl Carboxylic Acids and Mono- and Polyalcohols
Michael S. Bisesi, Ph.D., CIH

Acetates
The saturated aliphatic acetates, especially the ethyl and butyl acetates, serve as important solvents in the lacquer industry. The aromatic and cyclic acetates are used as flavoring agents for food and scenting of perfumes, soap, and similar articles.

Physiological effects of some are relatively low, since some acetates are, resemble, or convert into natural body metabolites. In both humans and experimental animals, however, administration of excessive quantities produce effects that consist of eye, throat, and nose irritation, followed by gradual onset of narcosis and slow recovery after termination of the exposure (2, 6)). Orally administered high concentrations of acetates to rabbits appeared to cause loss of coordination in decreasing order: ethyl = isopropyl > butyl > methyl = isoamyl acetate (30). This may be due to the rapid hydrolysis into acetic acid and the corresponding alcohols, causing a simultaneous decrease of the blood P_{CO2} and P_{O2} (30). There is a tendency to acidosis, especially with high concentrations of methyl acetate (30).

No anesthetic symptoms developed in men exposed to 400–600 ppm of ethyl or butyl acetate for 2–3 hrs. Eye irritation has been reported with 200–300 ppm exposure concentrations, but not the characteristic temporary corneal edema, which is caused by the corresponding alcohol (31). An eye injury healed promptly with the C4 but more slowly with the C3 acetate (32). No skin sensitization or dryness has been reported to date. The alkyl acetates possess increased narcotic potential (7), and the C3 and C8 members may have neurotoxic tendencies (33). The cyclic and aromatic acetates produce narcosis and death more readily than do the aliphatic esters. This may be due to the resulting hydrolytic products, which, however, are normally rapidly hydroxylated and excreted (2). For example, phenylacetyglutamine has been found to be excreted daily in 250–500-mg quantities in human urine (34).

A study indicated that thresholds for nasal pungency, odor, and eye irritation decreased logarithmically with the length of carbon chains for acetates, as observed for homologous series of alcohols, and also as seen with narcotic and other toxic responses (35). Data from another study that rated ocular irritation based on corneal thickness suggest that the rating potential for irritation is alcohols >acetates or ketones >aromatics (36).

Physical and chemical properties are summarized in Table 79.5, and toxicologic data are summarized in Tables 79.6 (37–43) and 79.7 (44, 45).

Esters of Mono- and Alkenyl Carboxylic Acids and Mono- and Polyalcohols
Michael S. Bisesi, Ph.D., CIH

C. Esters of Alkenylcarboxylic Acids and Monoalcohols

Esters of Mono- and Alkenyl Carboxylic Acids and Mono- and Polyalcohols
Michael S. Bisesi, Ph.D., CIH

Acrylates, Methacrylates, and Crotonates
Acrylates are esters of propenoic acids and mono- or polyalcohols. Chemically, the acrylic monomers are substituted 2-propene carboxylic acid esters of the type CH_2: CHCOOR. They polymerize readily, with heat or even on standing;the latter reaction is catalyzed by light or oxygen, unless an inhibitor has been added. Uncontrolled polymerization is exothermic and may proceed with explosive force. Methacrylic esters are 2-methyl derivatives of acrylic esters. Chemically, they are of the general structure CH_2: $C(CH_3)COOR$. The higher molecular weight derivatives polymerize to gels or highly viscous liquids. Crotonates are 3-methyl isomers of methacrylates or

butanoic acid esters and bear the general structure CH_3CH: CHCOOR. Lower molecular weight acrylic monomers are liquids having relatively higher vapor pressures. The characteristic odors of the monomers can be unpleasant. See Table 79.10 for a summary of physical and chemical properties.

[a] Solubility in water: v = very soluble; s = soluble; d = slightly soluble; i = insoluble.

Some acrylates occur naturally in several organisms as intermediates in lipid biosynthesis and degradation. The alkyl monomers exist primarily in liquid form, whereas the formed polymers range from clear, glass-like, brittle masses to highly flexible films, solids, or emulsions. They are widely used in commerce and industry as vinyl, acrylic, or higher molecular weight alkene resins. The acrylic monomers are highly important base components in the manufacture of thermoplastics, acrylic resins, and emulsion polymers. They are also used as solvents, plasticizers, latex coatings, adhesives, fibers, floor finishes, and lubricant additives and serve in medical and dental technology as surgical cement for medical devices and prostheses. The methacrylates sometimes serve as bases for acrylic resins with multifunctional effects. These materials find use in surgical organ repair, in compositing contact lenses, for adhesive dental pretreatment, and for a variety of other applications.

The acrylates can be manufactured by a number of procedures. These include dehydration of the corresponding hydroxyalkanoic acid, saponification of the alkene nitrile, catalytic hydration of acetylene and carbon monoxide, or the reaction of acetone with hydrocyanic acid. The methacrylates can be synthesized by catalytic oxidation of isobutylene and subsequent esterification with the appropriate alcohol, or by reacting acetone with hydrocyanic acid and subsequent esterification in sulfuric acid with the appropriate alcohol.

The low molecular weight monomers are lacrimators and irritants to the eyes, skin, and mucous membranes (3). The main potential for human exposure is by the dermal and respiratory routes;however, the irritating properties of these chemicals may serve as a deterrent to repeated exposures. Nonetheless, chronic inhalation of acrylic acid esters can lead to tissue changes or lesions due to local irritant or inflammatory reactions from acrylic acid or its esters that hydrolyze to form the acid. The acute toxicity of acrylates decreases with increasing molecular weight. For example, results from animal studies indicated that the acute lethal toxicity of methyl acrylate was twice that of ethyl acrylate based on inhalation exposure. Another study, based on 24-h LC_{50} concentrations using rats, indicated that the order of acute toxicity was methyl acrylate > ethyl acrylate > *n*-butyl acrylate > butyl methacrylate > methyl methacrylate. In the same study, rat inhalation exposures to 110 ppm 4 h/day, 5 days/week for 32 days did not cause significant changes in body weight, tissue weight, blood chemistry, gross metabolic performance, or small-intestine motor activities when compared to a control group (134). Structure-toxicity relationships of acrylates, including methacrylates, were analyzed in mice and found to be dependent on the log of the partition coefficient and log of rate order constant (135). In general, the toxicity is theorized to mechanistically involve alkylation of cellular nucelophies via Michael is addition (136).

The introduction of unsaturation into a fatty acid, as, for example, comparing the methyl or ethyl esters of propionic acid with the equivalent propenoic or acrylic acid derivatives, shows a tenfold increase in acute toxicity. Comparing acute toxicity of straight with branched-chain acrylates, ethyl acrylate by the oral route may be only half as toxic as methyl acrylate, but 8 times as toxic as methyl methacrylate, and 13 times as toxic as ethyl methacrylate (137). Acute inhalation of higher concentrations may cause narcosis, salivation, and pronounced nasal, occular, and pulmonary irritation or edema. Prolonged skin or eye contact may result in severe tissue damage. The pathology from single exposure is not particularly characteristic, contrary to repeated exposure effects, which include pulmonary congestion or hemorrhage and cloudy swelling and organ weight changes of the liver and kidney, reported following subchronic exposures to excessive concentrations. Acrylic acid and a series of methacrylates were shown to produce hemangiomas and increase resorptions following intraperitoneal injection of pregnant rats (138). Some compounds, such as the methyl-, ethyl-, *n*-propyl-, or butyl methacrylates, can produce inhibition of barium chloride–induced contraction of the isolated guinea pig ileum (139). Animal studies using rats revealed that some acrylates and methacrylates are embryotoxic. The doses of monomers used in the animal studies, however, were much higher than concentrations likely encountered by workers (3).

Allergic reactions have been reported for some acrylates. Although methyl, ethyl, and butyl methacrylates are potent skin sensitizers, experimental simulation proved rather difficult, owing to the rapid evaporation of the materials tested (140). Despite this, causes of human sensitization may occur. Methyl acrylate, methyl methacrylate, ethyl methacrylate, and butyl methacrylate caused allergic contact dermatitis due to working with artificial nail-bonding chemicals (141). Indeed, a study reviewing 10 y of patch testing data showed that 48 of 275 patients exhibited dermal allergic reactions to at least one acrylate. The most common acrylates that caused allergic reactions were 2-hydroxyenthyl acrylate (12.1%), 2-hydroxypropyl acrylate (12%), and 2-hydroxyethyl methacrylate (11.4%). No allergic response were recorded for 2-ethylhexyl acrylate (141).

Acrylates and methacrylates are detoxified predominantly via conjugation with glutathione via the Michaelis addition reaction or glutathoine-*S*-transferase. They are also likely to be hydrolyzed via

carboxylesterases (142). The lower molecular weight esters are rapidly metabolized and eliminated, therefore, will not likely cause cumulative toxicity (3).

The literature revealed much more data regarding methylacrylates than the crotonates. Although the irritant and lacrimatory effects of the crotonates are known, no low level exposure effects in humans have been reported so far. Physiologically, they are somewhat less reactive than the acrylates. They appear to be rapidly metabolized and excreted, possibly because crotonyl and methacrylyl groups are also formed during the normal metabolism of butyryl and isobutyryl derivatives (111). General toxicological data for acrylates, methacrylates, and crotonates are summarized in Tables 79.11 (143, 144) and 79.12 (145–150).

[a] Solubility in water: v = very soluble; s = soluble; d = slightly soluble; i = insoluble.

Table 79.14. Summary of Acute Oral and Inhalation Toxicity of Some Lactates (202)

Compound	Parameter	Species	Dose	Observed Effects
Methyl	Oral LD_{50}	Rat	>2000 mg/kg	Pilorection ≤ 24 h; absence of gross necroscopy changes
	Inhalation $LC_{50/4\ h}$		>5030 mg/m^3	During exposure decreased breathing rates and wet nares; postexposure wet fur; gross necropsy showed 7/10 with grayish lungs and two lungs with irregular surfaces
Ethyl	Oral LD_{50}	Rat	>2000 mg/kg	Pilorection up to 24 h; absence of gross necropsy changes
	Inhalation $LC_{50/4\ h}$		>5400 mg/m^3	During exposure decreased breathing rates, pilorection, lachrymation, and wet nares; gross necropsy showed pale lungs with spots
Propyl	Oral LD_{50}	Rat	>2000 mg/kg	Sluggishness ≤4 h; absence of gross necropsy changes
Isoprophyl	Oral LD_{50}	Rat	>2000 mg/kg	Pilorection ≤24 h; absence of gross necropsy changes
Butyl	Oral LD_{50}	Rat	>2000 mg/kg	Pilorection ≤24 h and diarrhea; absence of gross necropsy changes
	Inhalation $LC_{50/4\ h}$		>5140 mg/m^3	During exposure decreased breathing rates and wet head and fur. absence of necropsy changes
Isobutyl	Inhalation $LC_{50/4\ h}$	Rat	>6160 mg/m^3	During exposure decreased breathing rates, pilorection, and hunched appearance; postexposure apnea; absence of gross necropsy changes

Esters of Mono- and Alkenyl Carboxylic Acids and Mono- and Polyalcohols

Esters of Carbonic and Orthocarbonic Acid, Organic Phosphorous, Monocarboxylic Halogenated Acids, Haloalcohols, and Organic Silicon
Michael S. Bisesi, Ph.D., CIH

I. Introduction

Esters of Carbonic and Orthocarbonic Acid, Organic Phosphorous, Monocarboxylic Halogenated Acids, Haloalcohols, and Organic Silicon
Michael S. Bisesi, Ph.D., CIH

A. Overview

This chapter covers (*1*) esters of carbonic and orthocarbonic acid, (*2*) esters of organic phosphorous compounds, (*3*) esters of monocarboxylic halogenated acids, alkanols, or haloalcohols, and (*4*) organic silicon esters. Other classes of esters are summarized in Chapters 79 and 80. Refer to the Introduction in Chapter 79 for a more detailed overview of general properties of esters.

Unfortunately, as shown in the two prior chapters, mainly fragmented toxicological evaluations are available for esters. Most of these esters are characterized by low toxicity. Indeed, as expressed in Chapter 79, lethal dose (e.g., LD_{50}) values are frequently difficult or impractical to measure.

Localized dermal irritation is one common effect characteristic of exposures to most organic solvents. Few esters are readily absorbed, but there are exceptions, such as tri-*o*-cresyl phosphate (TOCP). Several of the halogenated derivatives, such as ethylchloro- and ethylbromo-, are potent lacrimators. Ethyl fluoroacetate and fluoroacetic acid exhibit about the same mode of action, which may indicate that the acetate is rapidly hydrolyzed and metabolized in the mammalian system. The unsaturated carbonates are also associated with high lacrimatory activity.

TOCP is an example of an ester that can cause neuropathy in a variety of animal species. The initial weakness and paralysis are normally reversible in early stages, but repeated or massive assaults result in demyelination of the nerve fibers. The mechanism of action is not yet certain, but it appears to involve phosphorylation of proteins. Only selected phosphates exhibit neuropathic effects, including diisopropyl fluorophosphorate and *N*,*N*'-diisopropyl phosphorodiamidic fluoride.

Esters of Carbonic and Orthocarbonic Acid, Organic Phosphorous, Monocarboxylic Halogenated Acids, Haloalcohols, and Organic Silicon
Michael S. Bisesi, Ph.D., CIH

B. Industrial Hygiene Evalution

As was expressed in Chapter 79, industrial hygiene evaluation of esters involves collecting and analyzing air samples to determine their airborne concentrations. Published industrial hygiene air sampling and analytical methods, however, are unavailable for most esters. In relation, there are few occupational exposure and biological limits. A list of ester compounds covered in this chapter that have industrial hygiene sampling and analytical methods are presented here in Table 81.1 along with their respective occupational exposure limits, established by the American Conference of Governmental Industrial Hygienists (ACGIH), the Occupational Safety and Health Administration (OSHA), and the National Institute for Occupational Safety and Health (NIOSH) (1–4). As stated in

Chapter 79, since sampling and analytical methods and occupational exposure limits are subject to periodic revision, the reader is encouraged to refer to current publications of ACGIH, OSHA, and NIOSH.

Table 81.1. Summary of Occupational Exposure Limits (OELs) and Monitoring Methods for Some Esters (1–4)

	OSHA		ACGIH			NIOSH

II Esters of Carbonic and Orthocarbonic Acid

Esters of Carbonic and Orthocarbonic Acid, Organic Phosphorous, Monocarboxylic Halogenated Acids, Haloalcohols, and Organic Silicon
Michael S. Bisesi, Ph.D., CIH

A. Overview

The hypothetical hydration of carbon dioxide produces two compounds, carbonic acid, $C(O)(OH)_2$, and orthocarbonic acid, $C(OH)_4$. These acids have never been isolated, although they may be formed and exist in aqueous solution. However, numerous esterified derivatives have been prepared chemically. Only very few of them have been toxicologically investigated in great detail. The majority of toxicological data reported is limited range-finding studies. Organic carbonates are chemically RO(CO)OR, the ortho esters, $RC(OR')_3$, whereby R may equal R' or consist of alkyl, alkenyl, cyclane, or aromatic moieties. These di- and triortho esters have similar physical properties; however, the latter resemble acetals more than carboxylates. The general toxicological impacts are also expected to be similar but nonsignificant, owing to the esters' low stability in acid solutions and their resemblance to normal mammalian metabolites. A summary of physical and chemical properties is found in Table 81.2 (5), and a summary of toxicological data is shown in Table 81.3 (6, 7).

Table 81.2. Chemical and Physical Properties of Representative Esters of Carbonic and Ortho (5)

Compound	CAS No.	Molecular Formula	MW	Boiling Point (° C) (mmHg)	Melting Point (° C)	Density	Solubility[a] in Water	Refractive Index (20° C)	Vapor density (Air=1)
Dimethyl carbonate	[*616-38-6*]	$C_3H_6O_3$	90.08	89.7	3	1.0694	i/s/s	1.3687

B. Carbonates
1.0a Dimethyl Carbonate
1.0.1a CAS Number: [*616-38-6*]

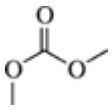
1.0.2a Synonyms: Carbonic acid dimethyl ester

1.0.3a Trade Names: NA

1.0.4a Molecular Weight: 90.08

1.0.5a Molecular Formula: $C_3H_6O_3$

1.0.6a Molecular Structure:



1.0b Diethyl Carbonate
1.0.1b CAS Number: [*105-58-8*]

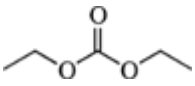
1.0.2b Synonyms: Carbonic acid diethyl ester

1.0.3b Trade Names: NA

1.0.4b Molecular Weight: 118.13

1.0.5b Molecular Formula: $C_5H_{10}O_3$

1.0.6b Molecular Structure:



1.1 Chemical and Physical Properties
1.1.1 General Dimethyl carbonate is miscible with most acids and alkalis, soluble in most organic solvents, but insoluble in water.

Diethyl carbonate is miscible with aromatic hydrocarbons, most organic solvents, and castor oil, but not with water.

1.1.2 Odor and Warning Properties Dimethyl carbonate has a pleasant odor. Diethyl carbonate has a weak odor resembling that of ethyl oxybutyrate.
1.2 Production and Use
The compound diethyl carbonate is manufactured via a reaction of phosgene and ethanol to produce ethyl chlorocarbonate, followed by reaction with anhydrous ethanol. It is used as a solvent for nitrocellulose, in the manufacture of radio tubes, and for fixing elements to cathodes.
1.3 Exposure Assessment
1.3.3 Workplace Methods: NA
1.4 Toxic Effects
1.4.1 Experimental Studies 1.4.1.1 Acute Toxicity The undiluted dimethyl carbonate liquid has an oral LD_{50} in the rat and the mouse between 6.4 and 12.8 g/kg and an intraperitoneal LD_{50} in the range of 800 to 1600 mg/kg (6). Symptoms were weakness, ataxia with gasping, and unconsciousness. A dermal LD_{50} in the guinea pig was found to be greater than 10 mL/kg. Some weight loss was noted, and minimal skin absorption was suspected. However, the degree of irritation was relatively slight (6). Exposure by inhalation appeared relatively hazardous, since 8000 ppm

caused rapid onset of gasping, loss of coordination, frothing from the mouth and nose, and pulmonary edema with death of all rats in a period of 2 h.

Diethyl carbonate is estimated to be moderately toxic via ingestion, dermal, and ocular contact. Intraperitoneally injected diethyl carbonate showed a slight neoplastic effect on the skin at the injection site in the mouse at about 11.4 mg, but not when administered orally at 12.5 mg (8).

1.4.1.2 Chronic and Subchronic Toxicity: NA

1.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Metabolically, the dimethyl and diethyl carbonates may possess alkylating properties similar to those of dimethyl and ethyl sulfate.

1.4.1.4 Reproductive and Developmental A teratogenic effect in 7.6–16.6% of 8-d pregnant hamsters was observed at a diethyl carbonate doses of 0.5–1.0 g/kg when injected intraperitoneally (9).

1.4.1.5 Carcinogenesis A study using male and female mice treated with 0, 50, 250, or 1000 ppm (0–140 mg/kg/d) diethyl carbonate in drinking water indicated no carcinogenic effects (10).

Esters of Carbonic and Orthocarbonic Acid, Organic Phosphorous, Monocarboxylic Halogenated Acids, Haloalcohols, and Organic Silicon
Michael S. Bisesi, Ph.D., CIH

C. Cyclic Carbonates
2.0a Ethylene Carbonate
2.0.1a CAS Number: [*96-49-1*]

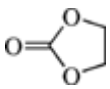
2.0.2a Synonyms: Ethylene carbonate, ethylene glycol carbonate, and 1,3-dioxolan- 2-one

2.0.3a Trade Names: NA

2.0.4a Molecular Weight: 88.06

2.0.5a Molecular Formula: $C_3H_4O_3$

2.0.6a Molecular Structure:



2.0b Propylene Carbonate
2.0.1b CAS Number: [*108-32-7*]

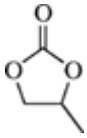
2.0.2b Synonyms: Propylene carbonate and 4-methyl-1,3-dioxolan-2-one

2.0.3b Trade Names: NA

2.0.4b Molecular Weight: 102.09

2.0.5b Molecular Formula: $C_4H_6O_3$

2.0.6b Molecular Structure:



2.2 Production and Use
Used as intermediates in plastic industry.
2.3 Exposure Assessment
2.3.3 Workplace Methods: NA
2.4 Toxic Effects
2.4.1 Experimental Studies 2.4.1.1 Acute Toxicity A range-finding study using ethylene carbonate by Smyth et al. (7) has recorded an oral LD_{50} value of 10.4 g/kg in the rat and a dermal LD_{50} of .20 mL/kg for the rabbit. Inhalation of the concentrated vapor for 8 h caused no deaths in rats. It proved to be a very low irritant to the skin, but moderately irritating to the eye of the rabbit. From a range-finding study using propylene carbonate, an oral LD_{50} in the rabbit above 20 mL/kg was determined. Inhalation of the concentrated vapor for 8 h was not lethal to rats. The undiluted material was a slight irritant to the skin and a moderate irritant to the rabbit eye.

2.4.1.2 Chronic and Subchronic Toxicity: NA

2.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms The mechanistic toxicity of ethylene carbonate was determined to be similar to the toxicity of ethylene glycol (11). Ethylene carbonate is enzymatically metabolized to ethylene glycol, and an enzyme has recently been isolated (12).

2.4.2 Human Experience 2.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms A dermal absorption study using living skin from human donors indicated that propylene carbonate had permeability constants of 0.7 > 0.4 $g/m^2/h$ and 0.6 > 0.3 $cm^3/m^2/h$ (13).

D. Ortho Acid Esters

3.1 Chemical and Physical Properties
3.1.1 General Triethyl orthoformate is a stable liquid, even in sunlight.

Triethyl orthoacetate is liquid at ambient temperature.

Triethyl orthopropionate is a highly soluble liquid.
3.3 Exposure Assessment
3.3.3 Workplace Methods: NA
3.4 Toxic Effects
3.4.1 Experimental Studies 3.4.1.1 Acute Toxicity Oral LD_{50} values in the rat between 3.2 and 6.4 mg/kg of triethyl orthoformate have been recorded (6). Symptoms of toxicity included dyspnea

and weakness. Conversely, a dermal LD_{50} in the guinea pig was found to be above 10 mL/kg, indicating that the material was practically not absorbed. No skin irritation was noted.

The oral LD_{50} for triethyl orthoacetate has been documented (6) between 6.4 and 12.8 g/kg for the rat, the intraperitoneal LD_{50} even higher, as 12.8 to 25.6 g/kg. It is not absorbed through guinea pig skin, and a dermal LD_{50} was found to be above 10 mL/kg. A very low dermal irritation was observed.

Similar to triethyl orthoacetate, the LD_{50} for triethyl orthopropionate ranges in the rat and rabbit are 6.4 to 12.8 g/kg by oral and intraperitoneal administration, and >10 mL/kg in the rabbit when tested dermally (6).

Esters of Carbonic and Orthocarbonic Acid, Organic Phosphorous, Monocarboxylic Halogenated Acids, Haloalcohols, and Organic Silicon

III Esters of Organic Phosphorus Compounds

Esters of Carbonic and Orthocarbonic Acid, Organic Phosphorous, Monocarboxylic Halogenated Acids, Haloalcohols, and Organic Silicon
Michael S. Bisesi, Ph.D., CIH

A. Overview

This class of esters includes phosphines, phosphinates, phosphonates, phosphites, and phosphates. The basic compound of the series is phosphine, PH_3, which then is successively alkylated, oxygenated, and esterified. The progressive series then contains phosphines, R_2PH or R_3P, phosphine oxide, $R_2P(O)H$ or $R_3P(O)$, phosphinic acid esters, phosphinates, $R_2P(O)OR$, phosphites, $(RO)_3P_7$, phosphonic acid esters, $RP(O)(OR')_2$, and phosphites $(RO)_3P(O)$, where R and R' can comprise alkyl or aryl groups for any of these compounds. Some physical and chemical properties and characteristics are listed in Table 81.4 and toxicological information in Tables 81.5 (14–45) and 81.6.

Table 81.4. Chemical and Physical Poperties of Selected Organic Phosphorous

Compound	CAS No.	Molecular Formula	MW	Boiling Point (° C) (mmHg)	Melting Point (° C)	Density	Solubility[a] in Water	Refractive Index (20° C)	(
Tributyl phosphine	[*998-40-3*]	$C_{12}H_{27}P$	202.32	240~242		0.812
