Industrial Toxicology: Origins and Trends
Eula Bingham, Ph.D., John Zapp, Ph.D., (deceased)

1 Introduction

Industrial toxicology is a comparatively recent discipline, but its roots are shadowed in the mists of time. The beginnings of toxicology, the knowledge or science of poisons, are prehistoric. Earliest human beings found themselves in environments that were at the same time helpful and hostile to their survival. They found their food among the plants, trees, animals, and fish in their immediate surroundings, their clothing in the skins of animals, and their shelter mainly in caves. Their earliest tools and weapons were of wood and stone.

It was in the very early period of prehistory that humans must have become aware of the phenomenon of toxicity. Some fruits, berries, and vegetation could be eaten with safety and to their benefit, whereas others caused illness or even death. The bite of the asp or adder could be fatal, whereas the bite of many other snakes was not. Humans learned from experience to classify things into categories of safe and harmful. Personal survival depended on recognition and avoidance, so far as possible, of the dangerous categories.

In a unique difference from other animals, humans learned to construct tools and weapons that facilitated their survival. Stone and wood gave way in time to bronze and then to iron as materials for constructing these tools and weapons. The invention of the bow and arrow was a giant step forward in weaponry, for it gave humans a chance to kill animals or other people from a safe distance. And humans soon used their knowledge of the poisonous materials they found in their natural environment to enhance the lethality of their weapons.

One of the earliest examples of the deliberate use of poisons in weaponry was smearing arrowheads and spear points with poisons to improve their lethal effectiveness. In the *Old Testament* we find at Job 6:4, “The arrows of the Almighty find their mark in me, and their poison soaks into my spirit” (*The New English Bible* version). *The Book of Job* is generally dated at about 400 B. C.

L. G. Stevenson (1) cites the Presidential Address of F. H. Edgeworth before the Bristol Medico-Chirurgical Society in 1916, to the effect that Odysseus is credited in Homer's *Odyssey* with obtaining a man-killing poison from Anchialos, king of the Taphians, to smear on his bronze-tipped arrows. This particular passage does not occur in modern translations of the *Odyssey* and, according to Edgeworth, was probably expurgated from the text when Greece came under the domination of Athens, at which time the use of poisons on weapons was considered barbaric and not worthy of such a hero as Odysseus.

Because the earliest literature reference to Homer is dated at 660 B. C., well before the Pan-Athenian period, an early origin of the use of poisoned arrows can be assumed. Indeed, the word “toxic” derives from the early Greek use of poisoned arrows.

The Greek word for the bow was toxon and for a drug was pharmakon. Therefore, an arrow poison was called toxikon pharmakon, or drug pertaining to the bow. Many Latin words are derived from the Greek, but the Romans took only the first of the two Greek works as their equivalent of “poison,” that is, toxicum. Other Latin words for poison were venenum and virus. In the transition to English, toxicum became “toxin,” and the knowledge or science of toxins becomes “toxicology.”

There were practicing toxicologists in Greece and Rome. Stevenson (1) refers to a book by Sir T. C. Albutt (2) according to which the professional toxicologists of Greece and Rome were purveyors of poisons and dealt in three kinds: those that acted quickly, those that caused a lingering illness, and those that had to be given repeatedly to produce a cumulative effect. These poisons were of vegetable or animal origin, except for arsenic. Although the toxicity of lead was described by Hippocrates, and of mercury by Pliny the Elder, these metals were apparently not deliberately employed as poisons before the Renaissance.

There is little doubt that the customers of the early toxicologists were interested in assassination or suicide. Poisons offered a safer means for the assassin of disposing of an enemy than the more visible alternatives that posed the risk of premature discovery and possibly effective retaliation. As a means of suicide, poison often seemed more acceptable than other available means of self-destruction. Although poisons have continued to be used for both homicide and suicide, their popularity for these purposes has decreased as the popularity of firearms has increased.

The use of poisons as adjuncts to other weapons such as the spear or arrow ceased in Western Europe long before the discovery of firearms. It has persisted to this day in primitive civilizations such as those of the African pygmies and certain tribes of South American Indians. The use of poison on a large scale as a primary weapon of war occurred during World War I, when both sides employed poison gases. In the interval between World War I and World War II, the potential of chemical and biological agents as a means of coercion was thoroughly studied by most of the powers, and both sides were prepared to use them, if necessary, in World War II. Although their use in future wars has apparently been renounced, it should not be forgotten that the chemical and biological toxins remain viable means of coercion that could be utilized under appropriate circumstances in future conflicts. It would not be prudent to forget this in thinking about national defense.

The early and sinister uses of poisons did result in contributions to toxicology. Furthermore, the knowledge obtained did not require extrapolation to the human species, for humans were the subjects in early experimentation.

As mentioned earlier, the professional toxicologists of Greece and Rome had recognized and dealt with poisons that produced acute effects, those that produced lingering effects, and those that produced cumulative effects. We recognize these categories today. The “dose-effects” relationship was also recognized. In Plato's well-known description of the execution of Socrates, Socrates is required to drink a cup of hemlock, an extract of a parsley-like plant that bears a high concentration of the alkaloid coniine. When Socrates asks whether it is permissible to pour out a libation first to any god, the jailer replies, “We only prepare, Socrates, just as much as we deem enough.”

The ancients also had some concept of the development of tolerance to poisons. There have come down through the ages the poison damsel stories. In one of these, related by Stevenson (1), a king of India sent a beautiful damsel to Alexander the Great because he guessed rightly that Alexander was about to invade his kingdom. The damsel had been reared among poisonous snakes and had become so saturated with their venom that all of her secretions were deadly. It is said that Aristotle dissuaded Alexander from doing what seemed natural under the circumstances until Aristotle performed a certain test. The test consisted in painting a circle on the floor around the girl with an extract of dittany, believed to be a powerful snake poison. When the circle was completed, the girl is said to have collapsed and died. The poison damsel stories continued to appear from time to time, and even Nathaniel Hawthorne wrote a short story about one entitled “Rappaccini's Daughter.”

Kings and other important personages, fearing assassinations, sometimes tried to protect themselves from this hazard by attempting to build up an immunity to specific poisons by taking gradually increasing doses until able to tolerate lethal doses, sometimes—it is said—with results disastrous to the queen. Other kings took the precaution of having slaves taste their food before they ate. When slaves became too scarce or expensive, they substituted dogs as the official tasters and found that it worked about as well. Perhaps we have here the birth of experimental toxicology in which a nonhuman species was deliberately used to predict human toxicity.

Little of importance to the science of toxicology developed during the Middle Ages. Such research as was done was largely empirical and involved the search for such things as the Philosopher's Stone, the Universal Solvent, the Elixir of Life, and the Universal Remedy. The search for the Universal Remedy is rumored to have been abandoned in the twelfth century when the alchemists learned how

to make a 60% solution of ethyl alcohol through improved techniques of distillation and found that it had some remarkable restorative properties.

Although modern science is generally held to have had its beginnings in the seventeenth century with the work of Galileo, Descartes, and Francis Bacon, there was a precursor in the sixteenth century of some importance to toxicology. This was the physician-alchemist Phillipus Aureolus Theophrastus Bombastus von Hohenheim, known as Paracelsus. Born in 1490, the son of a physician, Paracelsus studied medicine with his father and alchemy at various universities. He was not impressed with the way that either medicine or alchemy was being taught or practiced and decided that more could be learned from the study of nature than from studying books by ancient authorities.

Through travel and observation, Paracelsus learned more than his contemporaries about the natural history of diseases, to whose cure he applied his knowledge of both medicine and alchemy. He advocated that the natural substances then used as remedies be purified and concentrated by alchemical methods to enhance their potency and efficacy. He also attempted to find specific therapeutic agents for specific diseases and became highly successful as a practicing physician; in 1526 he was appointed Town Physician to the city of Basel, Switzerland, and a lecturer in the university. Being of an egotistical and quarrelsome disposition, Paracelsus quickly antagonized the medical and academic establishment.

In the sixteenth century, syphilis was a more lethal disease than it was to become later, and the medical profession had no interest in it or cures for it. Paracelsus introduced and advocated the use of mercury for treating syphilis, and it worked. The establishment, however, was outraged and denounced Paracelsus for using a poison to treat a disease. Paracelsus loved an argument and responded to this and other accusations with a series of "Defenses," of which the Third Defense (3) contained this statement with respect to his advocacy of the use of mercury or any other poison for therapeutic purposes: "What is it that is not poison? All things are poison and none without poison. Only the dose determines that a thing is not poison." Paracelsus lectured and wrote in German, which was also contrary to prevailing academic tradition. When his works were eventually translated into Latin, the last sentence of the above quotation was usually rendered, "Dosis sola facit venenum" or "The dose alone makes a poison." This principle is the keystone of industrial hygiene and is a basic concept in toxicology.

Mercury soon became and remained the therapy of choice for syphilis for the next 300 years until Ehrlich discovered on his 606th trial an arsphenamine, Salvarsan, which was superior. Antimony was widely used as a therapeutic agent from the seventeenth to the nineteenth century, and with the medical profession was sharply divided as to whether it was more poison than remedy or more remedy than poison.

The period from the seventeenth to the nineteenth century witnessed little decline in the use of human subjects for the initial evaluation of remedies. In 1604, a book said to have been written by a monk named Basile Valentine, but more probably by an anonymous alchemist, was published under the title *The Triumphant Chariot of Antimony*. The book states that the author had observed that some pigs fed food containing antimony had become fat. Therefore, he gave antimony to some monks who had lost considerable weight through fasting, to see if it would help them to regain weight faster. Unfortunately, they all died. Up to this time, the accepted name for the element had been stibium (from which we retain the symbol Sb), but it was renamed antimony from the words auti-moine meaning "monk's bane." The *Oxford English Dictionary* agrees that this might be the popular etymology of the word. This anecdote can be credited to H. W. Haggard (4).

Industrial Toxicology: Origins and Trends

2 Experimental Toxicology

Experimental toxicology, as we know, it followed the rise of organic chemistry, which is usually dated at around 1800. The rise was very rapid, and it is estimated that by 1880 some 12,000 compounds had been synthesized, and of these some turned out to be very toxic, in some cases proving fatal to the chemists who prepared them. Two of the war gases employed on a large scale in World War I, that is, phosgene ($COCl_2$) and mustard gas, bis(b-chloroethyl) sulfide, had been prepared in 1812 and 1822, respectively.

Early organic chemists were not deliberately looking for poisons, but for dyes, solvents, or pharmaceuticals. For example, toxicity was an unwanted side effect, but if it was there, it had to be recognized. The sheer number of new organic compounds synthesized in the laboratory, along with a growing public disapproval of the practice of letting toxicity be discovered by its effects on people, led to a more extensive use of convenient and available animals such as dogs, cats, or rabbits as surrogates for human beings, much as some of the ancient kings used dogs instead of slaves to test their food before they dined.

Loomis (5) credits M. J. B. Orfila (6) with being the father of modern toxicology. A Spaniard by birth, Orfila studied medicine in Paris. According to Loomis:

He is said to be the father of modern toxicology because his interests centered on the harmful effects of chemicals as well as therapy of chemical effects, and because he introduced quantitative methodology into the study of the action of chemicals on animals. He was the author of the first book devoted entirely to studies of the harmful effects of chemicals (6). He was the first to point out the valuable use of chemical analyses for proof that existing symptomatology was related to the presence of the chemical in the body. He criticized and demonstrated the inefficiency of many of the antidotes that were recommended for therapy in those days. Many of his concepts regarding the treatment of poisoning by chemicals remain valid today, for he recognized the value of such procedures as artificial respiration, and he understood some of the principles involved in the elimination of the drug or chemical from the body. Like many of his immediate followers, he was concerned primarily with naturally occurring substances for which considerable folklore existed with respect to the harmfulness of such compounds.

A reading of some of the earlier nineteenth century reports indicates a lack of recognition of and concern with either intraspecies or interspecies variation. Sometimes it is not possible to determine from the report which species of animal was tested. Some reports were based on dosage of only one animal, it being assumed that all others would react similarly. In reports of inhalation toxicity, a lethal concentration might be identified without designating the length of the exposure time.

The initial recognition of biological variability comes from the study of the action of drugs rather than from the study of the action of chemicals as such. The increased interest in the action of drugs resulted from the availability of so many new organic compounds that could be explored for possible therapeutic activity.

In the second half of the nineteenth century, the phenomenon of biological variability was recognized by pharmacologists, as was also the necessity for establishing the margin of safety between a therapeutically effective dose and a toxic dose of a drug. Clinical trials of new drugs with adequate controls began to be accepted as good science. The traditional wisdom and beliefs about therapeutic practice were reexamined by pharmacologists.

Early European efforts are credited by Warren Cook to Gruber (7) who used animals and himself in 1883 to set the boundaries for carbon monoxide poisoning. Lehmann and his colleagues (8) performed toxicity testing on numerous compounds using animals, and these provided the basis for establishing many exposure limits. Korbert (9) provided dose response data on acute exposures for twenty substances that gave information on levels that produced minimal symptoms after several hours, ½ to 1 hour exposures without serious disturbances, and ½ to 1 hour exposures that range from dangerous to rapidly fatal to man and animals. Many of these evaluations are still valid today.

Industrial Toxicology: Origins and Trends

3 Industrial Toxicology
Concerns for the safety of the workplace drove the development of industrial toxicology. The British physician, C.T. Thackrah, noted that, "Most persons who reflect on the subject will be inclined to admit that our employments are to a considerable degree injurious to health ... " and "Evils are suffered to exist, even when the means of correction are known and easily applied. Thoughtlessness or apathy is the only obstacle to success" (10).

In the United States, the first recognition of occupational disease by Benjamin McCready appeared (11) in an essay published by the Medical Society of New York. Illnesses including dermatoses were noted as well as long hours, poor ventilation, and child labor. Certainly, some of the illnesses were from chemical exposures and dust, but it should be noted that ergonomic and human performance concepts are raised in these early writings. Working conditions became a cause for concern among social movements mainly because of child labor. More than a century and a half later we still are concerned about child labor.

Recognition of the relationship between chemical agents and disease (industrial toxicology) moved rapidly in Europe during the last decade of the nineteenth century. This activity may have been stimulated in Germany by the passage during Bismarck's rule of the Workingmen's Insurance Law, which set up an insurance fund into which both employers and employees contributed that amounted to about 6% of total wages paid out. For this, the workers obtained free medical care, as well as some compensation during periods of disability.

Industrial toxicology in the United States grew out of work in occupational and industrial health by such investigators as Hamilton and Hardy (12), the Drinkers at Harvard (13, 14), Hatch at Pittsburgh (15), and Kehoe (16) and Heyroth (17) at Cincinnati. Government and industry provided financial support for these efforts.

There had been no organic chemical industry in the United States before World War I. It was born just after the war, because during the war, the United States felt the lack of useful products such as aniline dyes (used for printing our stamps and currency, among other things) and pharmaceuticals (e.g., aspirin), which had been imported from Germany. Manpower and facilities used during the war for manufacturing munitions became available after 1918, and several companies decided to use them to get into the organic chemical business. Because neither employers nor workers had any previous experience in making and handling organic chemicals, the effects of unanticipated toxicity began to be encountered. That toxicity was not wanted because it was counterproductive and, along with other problems, had to be managed if the industry was to survive.

To manage a problem, it must be anticipated, the causes must be identified and analyzed, and practical means of overcoming the problem must be available. As a means to this end, industrial preventive medicine, industrial toxicology, and industrial hygiene became valuable tools. By the mid-1930s, several large chemical companies in the United States had established in-house

laboratories of industrial toxicology, e.g., DuPont, Dow, and Union Carbide. The purpose of these laboratories was to provide management with sufficient information about the toxicity of new chemicals to enable prudent business decisions.

Another important source of experimental toxicological data that was used to inform the workplace was from work by Hueper at one time, a pathologist at DuPont and chemists who were interested in chemical carcinogenesis and mechanistic research, e.g., the Millers (18) at Wisconsin and Ray (19) at Cincinnati. Early experimental data captured in Hartwell (20) "Survey of Compounds Which Have Been Tested for Carcinogenic Activity, Federal Security Agency, U.S. Public Health Service" eventually provided the bases for the first early lists of carcinogenic chemicals prepared by the American Standards Association and the American Conference of Governmental and Industrial Hygienists in the 1940s.

It should be emphasized that although these beginning efforts in industrial toxicology were occurring in the United States, in Europe experimental toxicology and studies in occupational disease were well underway. For example, early work of the British on coal tars, mineral oils, and other carcinogens (aromatic amines) were widely available (22–25).

It is important to recognize that by the 1930s the data from experimental studies in animals, human case reports, and early epidemiological studies reported the causes of many occupationally induced cancers. Table 1.1 (26–36) presents data and references from several of these early studies, and although more investigations have added to the knowledge regarding these carcinogens, these early observations remain valid.

Table 1.1. Early Studies in Chemical Carcinogenesis

Year	First Reported by	Reported Agent or Process	Site
1775	Pott (26)	Soot	Scrotum
1822	Paris (27)	Arsenic	Skin
1873	Volkmann (28)	Crude wax from coal	Skin
1876	Bell (29)	Shale oil	Skin
1879	Härting and Hesse (30)	Ionizing radiation	Lung
1894	Unna (31)	Ultraviolet radiation	Skin
1895	Rehn (32)	Aromatic amines	Bladder
1898	Mackenzie (33)	Creosote	Skin
1935	Pfeil (34)	Chromate production	Lung
1917	Leymann (35)	Crude anthracene (coal tar?)	Skin
1929	Martland (36)	Radium	Bone

In the United States, a dramatic change occurred in 1935 with the passage of the Social Security Act. Financial and technical support from the Federal Government were given to the States, mostly to Health Departments, to develop health programs to protect workers. New York and Massachusetts maintained their programs in the Labor Department. This effort was very important in industrial toxicology because all of these programs performed investigations into chemical and physical agents in the workplace and the development of disease.

It is important to mention the work of the National Safety Council, which began a series of articles in the 1920s that described the toxicology of certain chemicals in the workplace and provided

recommendations for medical and industrial hygiene monitoring. Recognized leaders in the field wrote these guidelines, usually as a committee document. One example is the classic document on benzol toxicity (37).

Although not called “industrial toxicology,” the emergence of industrial medicine and industrial hygiene as significant public health disciplines became embedded in the basic principles of industrial toxicology, that is, connecting chemical exposures with development of disease through measuring exposures, developing dose-response relationships for adverse health effects, and recommending interventions to reduce exposures and disease. From these early beginnings, guidelines to prevent illness (and injuries) were developed as part of recommendations issued by the National Safety Council, American National Standards Institute in the 1920s, and later by the American Conference of Government Industrial Hygiene (TLVs).

By 1938, there were enough government-affiliated personnel engaged in the practice of industrial hygiene at the federal, state, and local levels to make possible the formation of the American Conference of Governmental Industrial Hygienists (ACGIH). In 1939, the American Industrial Hygiene Association (AIHA) was founded. These societies sought to bring collective knowledge regarding the toxicology of workplace hazards, mainly chemicals, and the necessary skills to reduce exposures. In the early period, industrial toxicologists were involved in recognizing, evaluating, and controlling hazards of the workplace that cause occupational illness and disability. Eventually, as investigators working in industrial toxicology became more specialized, they formed their own society in the 1960s, the Society of Toxicology, and eventually began to meet separately from the American Industrial Hygiene Association.

At the turn of the twentieth century, most industrial toxicological information was gleaned from observations of workers employed in various industries. By the 1930s, experimental industrial toxicology was expanding rapidly with the introduction of studies using animals. Most early studies focused either on cancer or acute toxic responses such as asphyxiation and acute lung injury or neurological symptoms such as dizziness, tremors, convulsions, etc., and death. Probably the development of certain chronic lung diseases resulting from industrial exposures over several years, such as silicosis, coal workers' pneumoconiosis, asbestosis, beryllioses, and the recognition of lead poisoning as a chronic disease, led to the development and use of experimental chronic toxicity studies.

Between 1920 and 1970 (i.e., before most environmental and occupational health laws), industrial toxicology was performed mainly by industry in its own laboratories, e.g., DuPont's Haskell Laboratory where one of the authors of this chapter worked, at Dow Chemical Company where V. K. Rowe was a pioneer investigator, and at various university laboratories, such as Harvard, University of Pittsburgh, New York University, University of Cincinnati, and Johns Hopkins University, where the work was supported by industry. The arrangements at these laboratories ranged from contracts to grant relationships and although the interpretation of the results may have involved some controversy, by and large, the experimental results have stood the test of time. A great deal of toxicological data came from industries where physicians, industrial hygienists, or toxicologists reported adverse health responses in certain occupations where a specific chemical was used. It was this collection of industrial toxicological data that was brought together and formed the basis of the first two editions of Patty's. For example, it is common over the years to see the names of industry leaders in health and safety provide “personal communication” as the source of certain toxicological data (e.g., Dr. D. Fassett, Eastman Kodak) in this volume.

Often these early references are to industry data or observations and were not published in the peer-reviewed literature but remain in files as unpublished reports. Fortunately, some of the reports of early studies are filed in libraries and are public documents (38).

3.1 Acute and Chronic Tests

It is interesting to note the role that World War I played in early toxicology. World War I stimulated a great many studies of acute inhalation toxicity for chemical warfare purposes. The number of

compounds examined during World War I as possible chemical warfare agents is estimated to have been between 3,000 and 4,000, and of these, 54 were used in the field at one time or another. During World War I, chemical warfare agents were selected for their irritancy to skin or eyes, rather than for systemic toxicity, and both the techniques developed for their study, as well as the information gained, were useful to postwar industrial toxicology.

Although chronic, or cumulative, toxicity had been recognized for centuries, it received much less attention than acute toxicity until more recent times, possibly because acute toxic effects were more likely to be recognized than chronic effects. Chronic toxicity could, however, be investigated by any relevant route of exposure, provided that the dosages used were small enough to permit the chronic damage to appear. The most perplexing question was, “How long should a prolonged exposure be to gain all the necessary information?” Opinions differed, but the majority of toxicologists seemed to feel that 90 days of repeated exposure would be sufficient to elicit all of the important manifestations of chronic toxicity in the rat or mouse, provided that the daily doses were sufficiently high but still consistent with survival. This effort was given impetus by the Food and Drug Administration as it began to require such tests for food additives and pesticides. It should be recalled that until 1970 FDA not EPA prescribed the testing requirements for pesticides.

In 1938, as a consequence of the elixir of sulfanilamide tragedy, in which a number of persons died from taking a solution of sulfanilamide in diethylene glycol for therapeutic purposes, the U.S. Food and Drug Administration undertook a comprehensive investigation of the toxicity of the glycols. This investigation culminated in a “lifetime” feeding study with diethylene glycol in rats. In 1945, Nelson et al. (39) reported the results at a meeting of the Federation of American Societies for Experimental Biology. A surprising result of the study was the finding that some of the rats fed a diet containing 4% diethylene glycol had developed bladder stones and that some of those with bladder stones had also developed fibropapillomatous tumors of the bladder. Because neither bladder stones nor tumors had been found in tests of shorter duration, it became obvious that, for some lesions, 90 days was not a sufficient time of exposure. By 1950, the FDA had begun recommending lifetime studies, for which they considered two years in the rat as proper, as part of proof of safety of proposed new intentional and unintentional food additives and pesticides. As a guide to the perplexed, members of the FDA staff prepared an article entitled “Procedures for the Appraisal of the Toxicity of Chemicals in Foods, Drugs, and Cosmetics,” which was published in the September, 1949, issue of Food Drug cosmetic Law Journal (40). It contained a section on how to do long-term chronic toxicity studies and recommended a period of two years for the rat, plus one year for a nonrodent species such as the dog.

Although not an official regulation, the article advised every one of the FDA's expectations with respect to data submitted to it as proof of safety of the proposed new food additive or pesticide. A revision of the article appeared in 1955 (41), and a third revision was published in 1959 as a monograph by the Association of Food and Drug Officials of the United States (42).

During the same period, the Food Protection committee of the National Academy of Science/National Research Council was publishing and revising “Principles and Procedures for Evaluating the Safety of Food Additives” (43) which were, in general, consistent with the FDA staff's guidelines. One common thread ran through both sets of recommendations. With each revision, the complexity of the tests increased and so did the cost.

The FDA's recommended protocol in 1959 (42) for a “lifetime” test with rats called for four groups of a minimum of 25 males and 25 females each. There would be a control group, a low-dose group (a no-effect level, it was hoped), a high-dose group (chosen to be an effect level), and a mid-dose group. All animals would be necropsied for gross pathology. Selected organs would be weighed, and selected organs would be preserved for histopathology. During the course of the experiment, food consumption and weight gains would be measured, blood and urine would be monitored for deviations from normality, and nay-behavioral changes would be noted. A three-generation reproduction study would be carried out at all dose levels. A similar experiment would also be

carried out with four groups of six to eight dogs each for an exposure period of two years to determine whether a nonrodent species responded differently from the rat. Dog reproduction studies were not required. The lifetime of the rat was considered to be two years for the purposes of the test.

Industrial Toxicology: Origins and Trends

4 Trends
4.1 Toxicological Testing
Concerns raised 20 years ago about the costs and validity of toxicological information that may be used for making risk assessments to protect workers and for business decisions on product development are still valid today.

When John Zapp wrote the first part of this chapter, it was the late 1970s and the other author, Eula Bingham, Assistant Secretary of Labor for Occupational Safety and Health, was grappling with the need for toxicological data on which to base occupational health and safety standards. It was during this period (1978) that the National Toxicology Program (NTP) began. This effort was intended to expand the carcinogen testing program of the National Cancer Institute that began during the 1960s.

Today, the National Toxicology Program (44) provides a significant portion of all new data on industrial chemicals used in the United State and in other countries. At present, 80,000 chemicals are used in the United States and an estimated 2,000 new ones are introduced annually to be used in products such as foods, personal care products, prescription drugs, household cleaners, and lawn care products. The effects of many of these chemicals on human health are unknown, yet people may be exposed to them during their manufacture, distribution, use, and disposal or as pollutants in our air, water, or soil.

The National Toxicology Program (NTP) was established by the Department of Health and Human Services (DHHS) in 1978 and charged with coordinating toxicological testing programs within the Public Health Service of the Department; strengthening the science base in toxicology; and providing information about potentially toxic chemicals to health regulatory and research agencies, scientific and medical communities, and the public (See Fig. 1.1). The NTP is an interagency program whose mission is to evaluate agents of public health concern by developing and applying the tools of modern toxicology and molecular biology. In carrying out its mission, the NTP has several goals:

- to provide toxicological evaluations of substances of public health concern;
- to develop and validate improved (sensitive, specific, rapid) testing methods;
- to develop approaches and generate data to strengthen the science base for risk assessment; and
- to communicate with all stakeholders, including government, industry, academia, the environmental community, and the public.

Nationally, the NTP rodent bioassay is recognized as the standard for identifying carcinogenic agents. However, the NTP has expanded its scope beyond cancer to include examining the impact of chemicals on noncancer toxicities such as those affecting reproduction and development, inhalation, and the immune, respiratory, and nervous systems. Recently a Center for Evaluation of Risks to Human Reproduction and a Center for the Evaluation of Alternative Toxicological Methods were created.

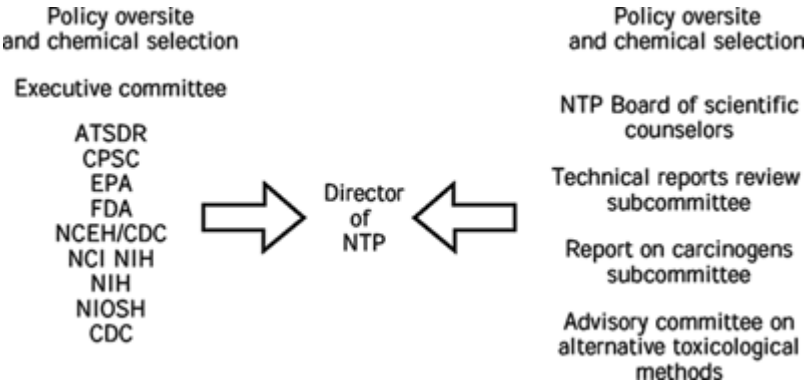

Figure 1.1. National Toxicology Program. The National Toxicology Program (NTP) is headquartered at the NIEHS/NIH, and its director serves as director of the NTP. The Executive Committee composed of the heads of key research and regulatory Federal agencies provides oversight for policy issues. Science oversight and peer review are provided through a mix of Federal, academic, industrial, and public interest science experts.

NTP's testing program seeks to use mechanism-based toxicology studies to enhance the traditional approaches. Molecular biology tools are used to characterize interactions of chemicals with critical target genes. Examples of mechanism-based toxicology include identification of receptor-mediated toxicants, molecular screening strategies, use of transgenic animal models, and the development of alternative or complementary *in vivo* tests to use with rodent bioassays. Inclusion of such strategies can provide insight into the molecular and biological events associated with a chemical's toxic effect and provide mechanistic information that is useful in assessing human risk. Such information can also lead to the development of more specific and sensitive (and often less expensive) tests for use in risk assessment. There is a strong linkage between mechanism-based toxicology and the development of more biologically based risk assessment models. Such models are useful in clarifying dose–response relationships, making species comparisons, and identifying sources of interindividual variability.

Genetically altered or “transgenic” mouse models carry activated oncogenes or inactivated tumor suppressor genes involved in neoplastic processes in both humans and rodents. This trait may allow them to respond to carcinogens more quickly than conventional rodent strains. The advantage provided by such an approach compared with standard rodent models is that in addition to chemicals undergoing metabolism, distribution, and relevant pharmacokinetics, the neoplastic effects of agents can be observed in the transgenic models within a time frame in which few if any spontaneous tumors would arise.

During the past few years, the NIEHS/NTP has evaluated transgenic strains in toxicological testing strategies. The response for 38 chemicals was compared in two genetically altered mouse strains ($p53^{def}$: p53+/– heterozygous and Tg.AC: n-*Ha-ras* transgene) with that of wild-type mice tested in chronic two-year bioassays. Findings from these studies were evaluated by the NTP Board of Scientific Counselors for their suitability in NTP toxicological evaluations. Based upon the NIEHS/NTP review, the transgenic models performed largely according to predictions; they identified all known human carcinogens and most of the multisite/multispecies rodent carcinogens but failed to identify completely rodent carcinogens that produced tumors in selected organs in two-year studies.

The use of these genetically altered mouse models holds promise in carcinogenesis research and testing and clearly is more rapid and less expensive than traditional NTP two-year bioassay studies. The challenge still facing the NTP is to design studies that address remaining questions and concerns and to explore how these models can be used in risk assessment.

The NIEHS Environmental Genome Project is a multicenter effort to identify systematically the alleles of 200 or more environmental disease susceptibility genes in the U.S. population. Information from this human exposure assessment initiative together with the environmental genome project will provide the science base essential for future, meaningful studies of gene/environment interactions in disease etiology.

As a part of an interagency human exposure assessment initiative, the NTP and the NCEH/CDC are collaborating on a pilot project to quantify approximately 70 chemicals in either human blood or urine that are considered endocrine disrupters. Biological samples from the National Health and Nutrition Examination Surveys (NHANES) are being tested. These data will be used to estimate human exposure to endocrine disrupting agents within the U.S. population and to identify those of greatest public health concern. This information can be used in prioritizing chemicals for study and in developing biologically based models for estimating human risks.

4.2 Human Genome

The revolution in genetics and specifically in mapping the human genome, as well as the development of transgenic animals, will radically change the way we evaluate chemical and physical agents. See chapter 7 by Dan Nebert in this volume.

The need to keep toxicologists apprised of the current thinking regarding many new advances in certain toxicological fields has led us to include a special chapter on genetics. Although human variability was recognized as a phenomenon during the last half of the nineteenth century, pharmacogenetics has now become a significant and critical element in understanding dose-response curves in every aspect of toxicology from predicting who can metabolize a chemical to a carcinogen to determining which patient may be at risk of death from a prescribed doses of an anticancer drug. This area will probably bring about the greatest changes in our understanding of worker responses to occupational exposures.

4.3 Global Workplaces

The workplaces of concern in early editions of Patty's were mainly those in U.S. factories where chemicals and certain processes occurred. Today, many of those activities and chemicals have moved overseas, and the scene is dynamic and changing as we write. Hopefully, the toxicological information contained in these volumes will be useful in global workplaces. We have welcomed authors from outside the United States, many of whom are outstanding toxicologists in their own countries and are known internationally. It is the hope of the editors that this trend will continue for Patty's in future editions. Without modern telecommunications and E-mail, we would not have the courage to propose such authors.

4.4 Mixtures

Mixtures have reemerged as a special concern in toxicology. Mainly during the period (1930–1970) when complex mixtures, particularly those derived from fossil fuels (petroleum fractions, coal tar) were being actively investigated, the issues revolved around finding the critical chemical in the complex mix that was responsible for its toxicology. Chemicals in these mixtures enhanced or inhibited the critical chemical. When chemical exposures occurred either together or in sequence as in chemical carcinogenesis, the concepts of initiation and promotion became part of understanding mixtures. Recognition that contributions from several chemicals affecting the same target organ could be at least additive and perhaps of concern in the workplace led the ACGIH to develop a methodology for simple mixtures.

As more information has been produced during the last 10 years regarding the content of hazardous waste sites, once again there are efforts to develop methodologies to account for multiple chemical exposures in attempting to assess risk. One of the most notable is the dioxins and the use of "equivalency factors." However, the way to determine any potential for interactions among a mixture of chemical exposures remains a problem in toxicology and will continue to require investigation in the future.

4.5 Training and Personnel

Current training programs in toxicology place heavy emphasis on genetics. Courses in genetics and molecular biology have largely replaced other fundamental medical disciplines such as biochemistry,

physiology, and pharmacology. Sometimes, aspects of these elements are covered to a small extent in a toxicology course. Courses in risk assessment are usually elective. Most graduate programs in toxicology today provide little background for individuals seeking to work in industrial toxicology. On the other hand, the practical elements that remain as staples in industrial hygiene programs provide much that is useful in industrial toxicology. The deficiency in these programs is the lack of training in the biological sciences, since most industrial hygiene graduates have little or no toxicology unless they take it as an elective. The result is that industry today must be prepared to provide current graduates with on-the-job training equivalent to 2–3 years of a postdoctoral fellowship if they are to work in industrial toxicology.

Pathways and Measuring Exposure To Toxic Substances
Morton Lippmann, Ph.D., CIH

1 Introduction

For toxic substances in the environment to exert adverse effects on humans, they must deposit on and/or penetrate through a body surface and reach target sites where they can alter normal functions and/or structures. The critical pathways and target sites can vary greatly from substance to substance and, for a given substance, can vary with its chemical and physical form. A further complication arises from the fact that chemical and/or metabolic transformations can take place between deposition on a body surface and the eventual arrival of a toxic substance or metabolite of that substance at a critical target site. A critical target site is where the toxic effect of first or greatest concern takes place.

This chapter reviews and summarizes current knowledge concerning the generic aspects of the environmental pathways and processes leading to (1) deposition of toxicants on body surfaces (skin, respiratory tract, gastrointestinal tract); (2) uptake of toxicants by epithelial cells from environmental media (air, waste, food); (3) translocation and clearance pathways within the body for toxicants that penetrate a surface epithelium; and (4) the influence of chemical and physical form of the toxicant on the metabolism and pathways of the chemical of concern. Where the physical attributes of the toxicant such as the length and biopersistence of airborne fibers are of generic concern, these are also discussed in this chapter. Other aspects of the pathways and the fates of toxicants that are specific to the chemical species that are the subject of the following chapters of this volume are discussed, as appropriate, in those chapters.

This chapter also summarizes and discusses techniques for measuring personal and population exposures to environmental toxicants and their temporal and spatial distributions. Quantitative exposure assessment, as a component of risk assessment, involves consideration of (*1*) the nature and properties of chemicals in environmental media, (*2*) the presence in environmental media of the specific chemicals that are expected to exert toxic effects, (*3*) the temporal and spatial distributions of the exposures of interest, and (*4*) the ways that ambient or workplace exposure measurements or models can be used to draw exposure inferences. In this context, the knowledge of deposition, fate, pathways, and rates of metabolism and transport within the body, to be reviewed later in this chapter, provide appropriate rationales for size-selective aerosol sampling approaches and/or usage of biomarkers of exposure. Finally, this chapter discusses the choices of sampling times, intervals, rates, durations, and schedules most appropriate for exposure measurements and/or modeling that are most relevant to risk assessment strategies that reflect data needs for (*1*) documenting compliance with exposure standards; (*2*) performing epidemiological studies of exposure–response relationships; (*3*) developing improved exposure models; and (*4*) facilitating secondary uses of exposure data for epidemiological research, studies of the efficacy of exposure controls, and analyses of trends.

Pathways and Measuring Exposure To Toxic Substances
Morton Lippmann, Ph.D., CIH

2 Nature of Toxic Substances

2.1 Physical Properties of Toxic Air Contaminants

Chemicals can be dispersed in air at normal ambient temperatures and pressures in gaseous, liquid, and solid forms. The latter two represent suspensions of particles in air and were given the generic term “aerosols” by Gibbs (1) by analogy with the term “hydrosol,” used to describe dispersed systems in water. Although hydrosols generally have uniformly sized particles, aerosols do not.

Gases and vapors, which are present as discrete molecules, form true solutions in air. Particles composed of moderate- to high-vapor-pressure materials evaporate rapidly because those small enough to remain suspended in air for more than a few minutes (i.e., those smaller than about 10 mm) have large surface to volume ratios. Some materials with relatively low vapor pressures can have appreciable fractions in both vapor and aerosol forms simultaneously.

Once dispersed in air, contaminant gases and vapors generally form mixtures so dilute that their physical properties, such as density, viscosity, and enthalpy, are indistinguishable from those of clean air. Such mixtures follow ideal gas law relationships. There is no practical difference between a gas and a vapor except that the latter is generally the gaseous phase of a substance that can exist as a solid or liquid at room temperature. While dispersed in the air, all molecules of a given compound are essentially equivalent in their size and capture probabilities by ambient surfaces, respiratory tract surfaces, and contaminant collectors or samplers.

Aerosols are dispersions of solid or liquid particles in air and have the very significant additional variable of particle size. Size affects particle motion and, hence, the probabilities of physical phenomena such as coagulation, dispersion, sedimentation, impaction onto surfaces, interfacial phenomena, and light-scattering. It is not possible to characterize a given particle by a single size parameter. For example, a particle's aerodynamic properties depend on density and shape, as well as linear dimensions, and the effective size for light scattering depends on refractive index and shape.

In some special cases, all of the particles are essentially the same size. Such aerosols are considered *monodisperse*. Examples are natural pollens and some laboratory-generated aerosols. More typically, aerosols are composed of particles of many different sizes and hence are called *heterodisperse* or *polydisperse*. Different aerosols have different degrees of size dispersion. Therefore, it is necessary to specify at least two parameters in characterizing aerosol size: a measure of central tendency, such as a mean or median, and a measure of dispersion, such as an arithmetic or geometric standard deviation.

Particles generated by a single source or process generally have diameters that follow a log-normal distribution, i.e., the logarithms of their individual diameters have a Gaussian distribution. In this case, the measure of dispersion is the geometric standard deviation, which is the ratio of the 84.16th percentile size to the 50th percentile size. When more than one source of particles is significant, the resulting mixed aerosol will usually not follow a single log-normal distribution, and it may be necessary to describe it by the sum of several distributions.

2.1.1 Particle and Aerosol Properties Many properties of particles, other than their linear size, can greatly influence their airborne behavior and their effects on the environment and health. These include

Surface: For spherical particles, the surface varies as the square of the diameter. However, for an aerosol of given mass concentration, the total aerosol surface increases with decreasing particle size. For nonspherical or aggregate particles, the particles may have internal cracks or pores, and the ratio of surface to volume can be much greater than for spheres.

Volume: Particle volume varies as the cube of diameter; therefore, the few largest particles in an aerosol dominate its volume (or mass) concentration.

Shape: A particle's shape affects its aerodynamic drag, as well as its surface area, and therefore its motion and deposition probabilities.

Density: A particle's velocity in response to gravitational or inertial forces increases as the square root of its density.

Aerodynamic diameter: The diameter of a unit-density sphere that has the same terminal settling velocity as the particle under consideration is equal to its aerodynamic diameter. Terminal settling velocity is the equilibrium velocity of a particle that is falling under the influence of gravity and

fluid resistance. Aerodynamic diameter is determined by the actual particle size, the particle density, and an aerodynamic shape factor.

2.1.2 Types of Aerosols Aerosols are generally classified in terms of their processes of formation. Although the following classification is neither precise nor comprehensive, it is commonly used and accepted in the industrial hygiene and air pollution fields.

Dust: An aerosol formed by mechanical subdivision of bulk material into airborne fines that have the same chemical composition. Dust particles are generally solid and irregular in shape and have diameters greater than 1 mm.

Fume: An aerosol of solid particles formed by condensation of vapors formed at elevated temperatures by combustion or sublimation. The primary particles are generally very small (less than 0.1 mm) and have spherical or characteristic crystalline shapes. They may be chemically identical to the parent material, or they may be composed of an oxidation product such as a metal oxide. Because they may be formed in high concentrations, they often coagulate rapidly and form aggregate clusters of low overall density.

Smoke: An aerosol formed by condensation of combustion products, generally of organic materials. The particles are generally liquid droplets whose diameters are less than 0.5 mm.

Mist: A droplet aerosol formed by mechanical shearing of a bulk liquid, for example, by atomization, nebulization, bubbling, or spraying. The droplet size can cover a very large range, usually from about 2 to greater than 50 mm.

Fog: An aqueous aerosol formed by condensation of water vapor on atmospheric nuclei at high relative humidities. The droplet sizes are generally larger than 1 mm.

Smog: A popular term for a pollution aerosol derived from a combination of smoke and fog. The term is commonly used now for any atmospheric pollution mixture.

Haze: A submicrometer-sized aerosol of hydroscopic particles that take up water vapor at relatively low relative humidities.

Aitken or condensation nuclei (CN): Very small atmospheric particles (mostly smaller than 0.05 mm) formed by combustion processes and by chemical conversion from gaseous precursors.

Accumulation mode: A term given to the particles in the ambient atmosphere ranging in diameter from 0.1 to about 1.0 mm. These particles generally are spherical, have liquid surfaces, and form by coagulation and condensation of smaller particles that derive from gaseous precursors. Too large for rapid coagulation and too small for effective sedimentation, they accumulate in the ambient air.

Coarse particle mode: Ambient air particles larger than about 2.5 mm in aerodynamic diameter and generally formed by mechanical processes and surface dust resuspension.

2.1.3 Physical Properties of Toxic Liquid and Solid Components For liquids and solids deposited on human skin or taken into the gastrointestinal (GI) tract by ingestion, penetration to and through the surface epithelium depends upon their physical form, their solubility in the fluids on the surface, and the structure and nature of the epithelial barrier. Dissolved chemicals can penetrate by diffusion, whereas chemicals present as particles or droplets must find access via pores or defects in the barrier associated with injury caused by trauma or corrosive chemicals or by dissolution in solvents that alter the barrier function.

Pathways and Measuring Exposure To Toxic Substances
Morton Lippmann, Ph.D., CIH

3 Human Exposure Pathways and Dosimetry

People can be exposed to chemicals in the environment in numerous ways. The chemicals can be inhaled, ingested, or taken up by and through the skin. Effects of concern can take place at the initial epithelial barrier, i.e., the respiratory tract, the gastrointestinal (GI) tract, or the skin, or can occur in other organ systems after penetration and translocation by diffusion or transport by blood, lymph, etc. As illustrated in Fig. 2.1, exposure and dose factors are intermediate steps in a larger continuum ranging from the release of chemicals into an environmental medium to an ultimate health effect in an exposed individual. There are, of course, uncertainties of varying magnitude at each stage. The diagram could also be applied to populations as well as to individuals. In that case, each stage of the figure would include additional variance for the interindividual variability within a population associated with age, sex, ethnicity, size, activity patterns, dietary influences, use of tobacco, drugs, alcohol, etc.

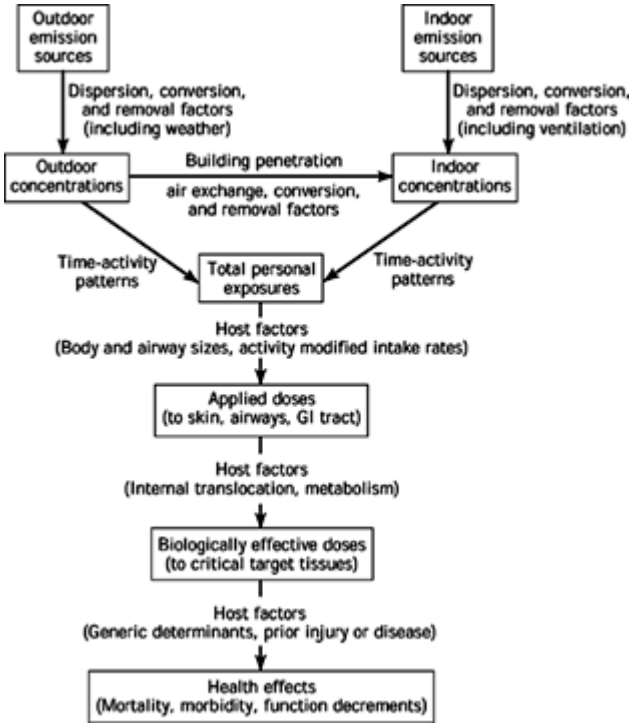

Figure 2.1. Framework for personal exposure assessment and exposure-response (modified from Ref. 1a).

Exposure is a key and complex step in this continuum. The concept of total human exposure developed in recent years is essential to the appreciation of the nature and extent of environmental health hazards associated with ubiquitous chemicals at low levels. It provides a framework for considering and evaluating the contribution to the total insult from dermal uptake, ingestion of food and drinking water, and inhaled doses from potentially important microenvironments such as workplace, home, transportation, recreational sites, etc. More thorough discussions of this key concept have been prepared by Sexton and Ryan (2), Lioy (3), and the National Research Council (4). Guidelines for Exposure Assessment have been formalized by the U.S. Environmental Protection Agency (5).

Figure 2.2 outlines possible approaches for estimating contaminant exposures of populations, as well as individuals, in a conceptual sense, and Fig. 2.3 indicates terminologies used by EPA to describe exposures and their distributions within a population.

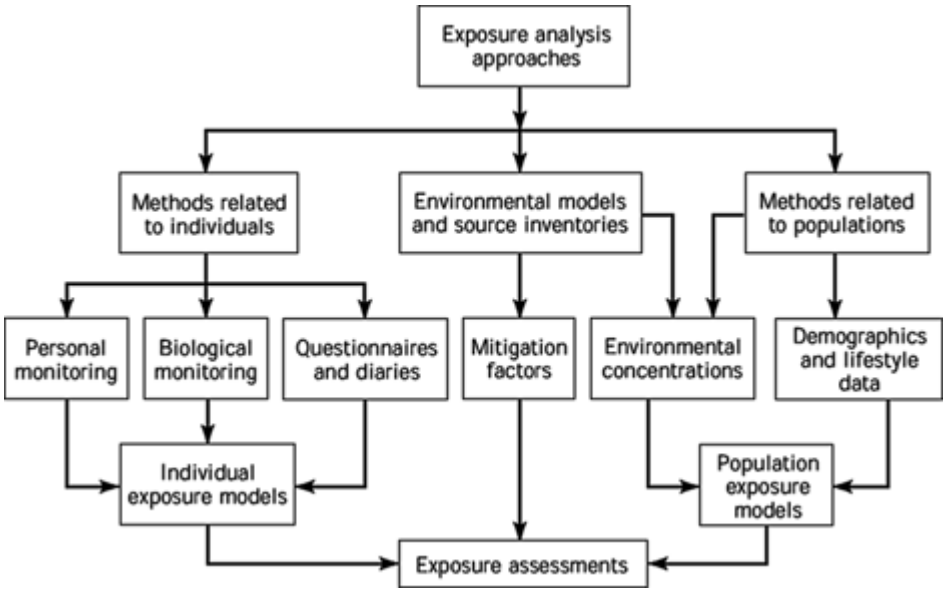

Figure 2.2. Possible approaches for analyzing contaminant exposures.

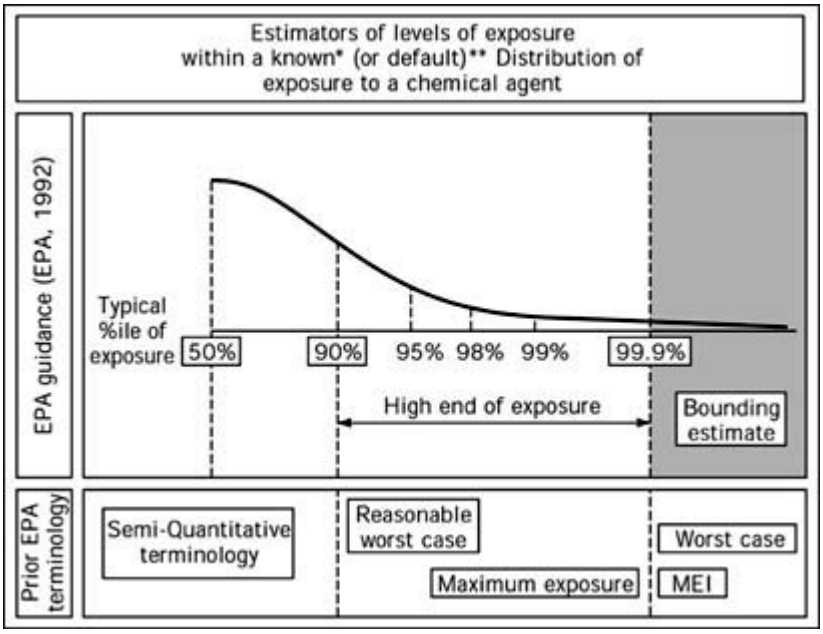

Figure 2.3. EPA guidance on terminology for exposures in the general population.

Toxic chemicals in the environment that reach sensitive tissues in the human body can cause discomfort, loss of function, and changes in structure leading to disease. This section addresses the pathways and transport rates of chemicals from environmental media to critical tissue sites, as well as retention times at those sites. It is designed to provide a conceptual framework as well as brief discussions of (*1*) the mechanisms for—and some quantitative data on—uptake from the environment; (*2*) translocation within the body, retention at target sites, and the influence of the physicochemical properties of the chemicals on these factors; (*3*) the patterns and pathways for exposure of humans to chemicals in environmental media; and (*4*) the influence of age, sex, size, habits, health status, etc.

3.1 Terminology

An agreed on terminology is critically important when discussing the relationships among toxic chemicals in the environment, exposures to individuals and populations, and human health. Key terms used in this chapter are defined as follows:

Exposure: Contact with external environmental media containing the chemical of interest. For fluid media in contact with the skin or respiratory tract, both concentration and contact time are critical. For ingested material, concentration and amount consumed are important.

Microenvironments: Well-defined locations that can be treated as homogeneous (or well characterized) in the concentrations of a chemical or other stressor.

Deposition: Capture of the chemical at a body surface site on the skin, the respiratory tract, or the GI tract.

Clearance: Translocation from a deposition site to a storage site or depot within the body or elimination from the body.

Retention: Presence of residual material at a deposition site or along a clearance pathway.

Dose: The amount of chemical deposited on (applied dose) or translocated to a site on or within the body where toxic effects can take place (delivered dose).

Target tissue: A site within the body where toxic effects lead to damage or disease. Depending on the toxic effects of concern, a target tissue can extend from whole organs to specific cells and to subcellular constituents within cells.

Exposure surrogates or indices: Indirect measures of exposure, such as: (*1*) concentrations in environmental media at times or places other than those directly encountered; (*2*) concentrations of the chemical of interest, a metabolite of the chemical, or an enzyme induced by the chemical in circulating or excreted body fluids, generally referred to as a biomarker of exposure; and (*3*) elevations in body burden measured by external probes.

Pathways and Measuring Exposure To Toxic Substances
Morton Lippmann, Ph.D., CIH

4 Pathways

4.1 Respiratory Tract

The respiratory system extends from the breathing zone just outside of the nose and mouth through the conductive airways in the head and thorax to the alveoli, where respiratory gas exchange takes place between alveoli and the capillary blood flowing around them. The prime function of the respiratory system is to deliver oxygen (O_2) to the gas-exchange region of the lung, where it can diffuse to and through the walls of the alveoli to oxygenate the blood passing through the alveolar capillaries, as needed over a wide range of work or activity levels. In addition, the system must also: (*1*) remove an equal volume of carbon dioxide (CO_2) that enters the lungs from the alveolar capillaries; (*2*) maintain body temperature and water vapor saturation within the lung airways (to maintain the viability and functional capacities of the surface fluids and cells); (*3*) maintain sterility (to prevent infections and their adverse consequences); and (*4*) eliminate excess surface fluids and debris, such as inhaled particles and senescent phagocytic and epithelial cells. It must accomplish all of these demanding tasks continuously during a lifetime and do so with highly efficient performance and energy utilization. The system can be abused and overwhelmed by severe insults, such as high concentrations of cigarette smoke and industrial dust, or by low concentrations of specific pathogens that attack or destroy its defense mechanisms or cause them to malfunction. Its ability to overcome and/or compensate for such insults as competently as it usually does is a testament to its elegant combination of structure and function.

4.2 Mass Transfer

The complex structure and numerous functions of the human respiratory tract have been summarized concisely by a Task Group of the International Commission on Radiological Protection (6), as shown in Fig. 2.4. The conductive airways, also known as the respiratory dead space, occupy about 0.2 liter

(L). They condition the inhaled air and distribute it by convective (bulk) flow to approximately 65,000 respiratory acini that lead off the terminal bronchioles. As tidal volumes increase, convective flow dominates gas exchange deeper into the respiratory bronchioles. In any case, within the respiratory acinus, the distance from the convective tidal front to alveolar surfaces is short enough so that efficient CO_2–O_2 exchange takes place by molecular diffusion. By contrast, submicrometer sized airborne particles whose diffusion coefficients are smaller by orders of magnitude than those for gases, remain suspended in the tidal air and can be exhaled without deposition.

Functions	Cytology (epithelium)	Histology (walls)	Generation number	Anatomy
Air conditioning; temperature and humidily, and cleaning; fast particle clearance; air conduction	Respiratory epithelium with goblet cells: cell types: – Ciliated cells – Nonciliated cells: • Goblet cells • Mucous (secretoey) cells • Serous cells • Brush cells • Endocrine cells • Basal cells • Intermediate cells	Mucous membrane, respiratory epithelium (pseudostratified, ciliated, mucous), glands Mucous membrane, respiratory or stratified epithelium, glands		Anterior nasal passages Nose mouth Pharynx posteric Larynx Esophagu
		Mucous membrane, respiratory epithelium, cartilage rings, glands	0 1	Trachea main bronchi
		Mucous membrane, respiratory epithelium, cartilage plates, smooth muscle layer, glands	2 - 8	Bronchi
	Respiratory epithelium with clara cells (no goblet cells) cell types: – Ciliated cells – Nonciliated cells • Clara (secretory) cells	Mucous membrane, respiratory epithelium, no cartilage, no glands, smooth muscle layer	9 - 14	Bronchioles
		Mucous membrane, single-layer respiratory epithelium, less ciliated, smooth muscle layer	15	Terminal bronchioles
Air conduction; gas exchange; slow particle clearance	Respiratory epithelium consisting mainly of clara cells (secretory) and few ciliated cells	Mucous membrane, single-layer respiratory epithelium of cubodial cells, smooth muscle layers	16 - 18	Respiratory bronchioles
Gas exchange; very slow particle clearance	Squamous alveolar epithelium cells (type I), covering 93% of alveolar surface areas	Wall consists of alveolar entrance rings, squamous epithelium layer, surfactant	**	Alveolar ducts
	Cuboidal alveolar epithelial cells (type II. Surfactant-producing), covering 7% of alveolar surface area Alveolar macrophages	Interalveolar septa covered by squamous epithelium, containing capillaries, surfactant	**	Alveolar ducts

** Unnumbered because of imprecise information
† Lymph nodes are located only in BB region but drain the bronchial and alveolar interstitial regions as well as the bronchial region.

Figure 2.4. Structure and function of the human respiratory tract.

A significant fraction of the inhaled particles do deposit within the respiratory tract. The mechanisms that account for particle deposition in the lung airways during the inspiratory phase of a tidal breath are summarized in Fig. 2.5. Particles larger than about 2 mm in aerodynamic diameter (the diameter of a unit density sphere that has the same terminal settling (Stokes) velocity) can have significant momentum and deposit by impaction at the relatively high velocities present in the larger conductive airways. Particles larger than about 1 mm can deposit by sedimentation in the smaller conductive airways and gas-exchange airways where flow velocities are very low. Particles smaller than 0.1 mm are in Brownian motion, and their random walk while in small airways causes them to diffuse to and deposit on small airway walls at a rate that increases with decreasing size. Finally, particles whose diameters are between 0.1 and 1 mm, which have a very low probability of depositing during a

single tidal breath, can be retained within the approximately 15% of the inspired tidal air that is exchanged with residual lung air during each tidal cycle. This volumetric exchange occurs because of the variable time constants for airflow in the different segments of the lungs. Because of the much longer residence times of residual air in the lungs, the low intrinsic particle displacements of 0.1 to 1 mm particles within such trapped volumes of inhaled tidal air become sufficient to cause their deposition by sedimentation and/or diffusion over the course of successive breaths.

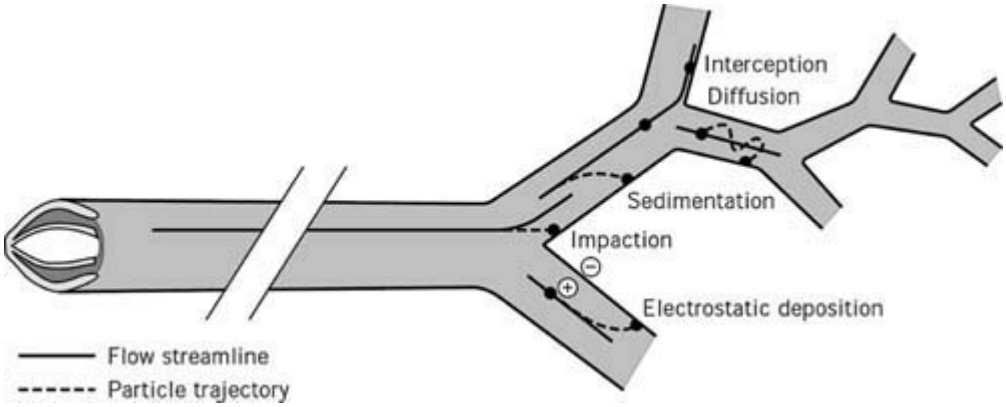

Figure 2.5. Mechanism for particle deposition in lung airways.

The essentially particle-free residual lung air that accounts for about 15% of the expiratory tidal flow acts like a clean-air sheath around the axial core of distally moving tidal air, so that particle deposition in the respiratory acinus is concentrated on interior surfaces such as airway bifurcations, whereas interbranch airway walls have relatively little particle deposition.

The number of particles deposited and their distribution along the respiratory tract surfaces, along with the toxic properties of the material deposited, are the critical determinants of pathogenic potential. The deposited particles can damage the epithelial and/or the mobile phagocytic cells at or near the deposition site or can stimulate the secretion of fluids and cell-derived mediators that have secondary effects on the system. Soluble materials deposited as, on, or within particles can diffuse into and through surface fluids and cells and be rapidly transported throughout the body by the bloodstream.

The aqueous solubility of bulk materials is a poor guide to particle solubility in the respiratory tract. Generally solubility is greatly enhanced by the very large surface to volume ratio of particles small enough to enter the lungs. Furthermore, the ionic and lipid contents of surface fluids within the airways are complex and highly variable and can lead to enhanced solubility or to rapid precipitation of aqueous solutes. In addition the clearance pathways and residence times for particles on airway surfaces are very different in the different functional parts of the respiratory tract.

The ICRP (6) Task Group's clearance model identifies the principal clearance pathways within the respiratory tract that are important in determining the retention of various radioactive materials and thus the radiation doses received by respiratory tissues and/or other organs after translocation. The ICRP deposition model is used to estimate the amount of inhaled material that enters each clearance pathway. These discrete pathways are represented by the compartment model shown in Fig. 2.6. They correspond to the anatomic compartments illustrated in Figure 2.4 and are summarized in Table 2.1, along with those of other groups that provide guidance on the dosimetry of inhaled particles.

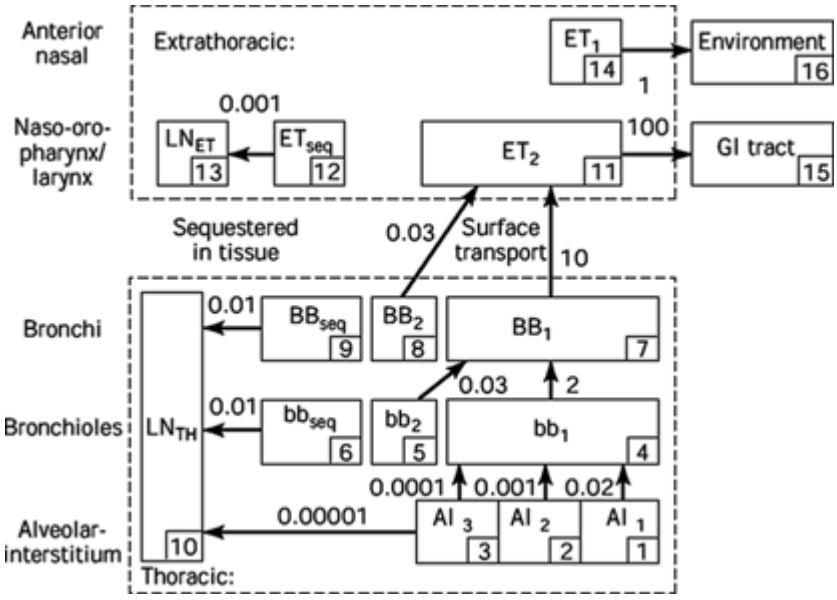

Figure 2.6. Compartment model.

Table 2.1. Respiratory Tract Regions as Defined in Particle Deposition Models

Anatomic Structures Included	ACGIH Region	ISO and CEN Regions	1966 ICRP Task Group Region	1994 ICRP Task Group Region
Nose, nasopharynx	Head airways (HAR)	Extrathoracic (E)	Nasopharynx (NP)	Anterior nasal passages (ET_1)
Mouth, oropharynx, laryngopharynx				All other extrathoracic (ET_2)
Trachea, bronchi, and conductive bronchioles (to terminal bronchioles)	Tracheobronchial (TBR)	Tracheobronchial (B)	Tracheobronchial (TB)	Trachea and large bronchi (BB) Bronchioles (bb)
Respiratory bronchioles, alveolar ducts, alveolar sacs, alveoli	Gas exchange (GER)	Alveolar (A)	Pulmonary (P)	Alveolar-interstitial (Al)

4.3 Extrathoracic Airways

As shown in Figure 2.4, the extrathoracic airways were partitioned by ICRP (6) into two distinct clearance and dosimetric regions: the anterior nasal passages (ET_1) and all other extrathoracic

airways (ET_2), i.e., the posterior nasal passages, the naso- and oropharynx, and the larynx. Particles deposited on the surface of the skin that lines the anterior nasal passages (ET_1) are assumed to be subject only to removal by extrinsic means (nose blowing, wiping, etc.). The bulk of material deposited in the naso-oropharynx or larynx (ET_2) is subject to fast clearance in the layer of fluid that covers these airways. The 1994 ICRP model recognizes that diffusional deposition of ultrafine particles in the extrathoracic airways can be substantial, whereas earlier ICRP models did not (7–9).

4.4 Thoracic Airways

Radioactive material deposited in the thorax is generally divided between the tracheobronchial (TB) region, where deposited particles are subject to relatively fast mucociliary clearance (duration in hours to 1 or 2 days), and the alveolar-interstitial (AI) region, where macrophage-mediated particle clearance is much slower (duration up to several weeks), and dissolution rates for insoluble particles not cleared by macrophages can have half-times measured in months or years.

For purposes of dosimetry, the ICRP (6) divided the deposition of inhaled material in the TB region between the trachea and bronchi (BB) and in the more distal, small conductive airways, known as bronchioles (bb). However, the subsequent efficiency with which mucociliary transport in either type of airway can clear deposited particles is controversial. To be certain that doses to bronchial and bronchiolar epithelia would not be underestimated, the ICRP Task Group assumed that as much as half the number of particles deposited in these airways is subject to relatively "slow" mucociliary clearance that lasts up to about 1 week. The likelihood that an insoluble particle is cleared relatively slowly by the mucociliary system depends on its size.

4.5 Gas-Exchange Airways and Alveoli

The ICRP (6) model also assumed that material deposited in the AI region is subdivided among three compartments (AI_1, AI_2, and AI_3) each of which is cleared more slowly than TB deposition, and the subregions clear at different characteristic rates.

4.6 Regional Deposition Estimates

Figure 2.7 depicts the predictions of the ICRP (6) Task Group Model in terms of the fractional deposition in each region as a function of the size of the inhaled particles. It reflects the minimal lung deposition between 0.1 and 1 mm, where deposition is determined largely by the exchange in the deep lung between tidal and residual lung air. Deposition increases below 0.1 mm as diffusion becomes more efficient with decreasing particle size. Deposition increases with increasing particle size above 1 mm as sedimentation and impaction become increasingly effective.

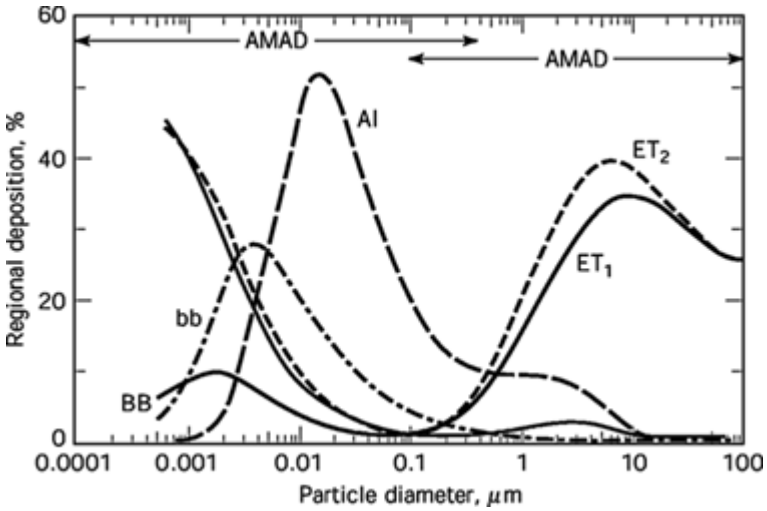

Figure 2.7. Fractional deposition in each region of the respiratory tract for a reference light worker (normal nose breather) in the 1994 ICRP model.

Although aerodynamic diameter is an excellent index of particle behavior for relatively compact

particles that differ greatly in shape and density, it is inadequate for fibers that deposit by interception, as well as by inertia, gravitational displacement, or diffusion. The aerodynamic diameter of mineral or vitreous fibers whose aspect ratio (length/width) is greater than 10 is about three times their physical diameter. Fibers whose diameters are less than 3 mm can penetrate into bronchioles whose diameters are less than 500 mm. For thin fibers longer than 10 or 20 mm, interception, whereby an end of the fiber touches a surface and is collected, accounts for a significant enhancement of deposition (10).

Less complex models for size-selective regional particle deposition have been adopted by occupational health and community air pollution professionals and agencies, and these have been used to develop inhalation exposure limits within specific particle size ranges. Distinctions are made between: (*1*) those particles that are not aspirated into the nose or mouth and therefore represent no inhalation hazard; (*2*) the inhalable (aka inspirable) particulate mass (IPM), i.e., those that are inhaled and are hazardous when deposited anywhere within the respiratory tract; (*3*) the thoracic particulate mass (TPM), i.e., those that penetrate the larynx and are hazardous when deposited anywhere within the thorax; and (*4*) the respirable particulate mass (RPM), i.e., those particles that penetrate through the terminal bronchioles and are hazardous when deposited within the gas-exchange region of the lungs. These criteria are described in more detail later in this chapter in the sections devoted to exposure assessment.

4.7 Translocation and Retention

Particles that do not dissolve at deposition sites can be translocated to remote retention sites by passive and active clearance processes. Passive transport depends on movement on or in surface fluids that line the airways. There is a continual proximal flow of surfactant to and onto the mucociliary escalator, which begins at the terminal bronchioles, where it mixes with secretions from Clara and goblet cells. Within midsized and larger airways are additional secretions from goblet cells and mucus glands that produce a thicker mucous layer that has a serous subphase and an overlying more viscous gel layer. The gel layer that lies above the tips of the synchronously beating cilia is found in discrete plaques in smaller airways and becomes more of a continuous layer in the larger airways. The mucus that reaches the larynx and the particles carried by it are swallowed and enter the GI tract.

The total transit time for particles cleared during the relatively rapid mucociliary clearance phase varies from ~2 to 24 hours in healthy humans (11). Macrophage-mediated particle clearance via the bronchial tree takes place during a period of several weeks. Compact particles that deposit in alveolar zone airways are ingested by alveolar macrophages within about 6 hours, but the movement of the particle-laden macrophages depends on the several weeks that it takes for the normal turnover of the resident macrophage population. At the end of several weeks, the particles not cleared to the bronchial tree via macrophages have been incorporated into epithelial and interstitial cells, from which they are slowly cleared by dissolution and/or as particles via lymphatic drainage pathways, passing through pleural and eventually hilar and tracheal lymph nodes. Clearance times for these later phases depend strongly on the chemical nature of the particles and their sizes, and half-times range from about 30 to 1,000 days or more.

All of the characteristic clearance times cited refer to inert, nontoxic particles in healthy lungs. Toxicants can drastically alter clearance times. Inhaled materials that affect mucociliary clearance rates include cigarette smoke (12, 13), sulfuric acid (14, 15), ozone (16, 17), sulfur dioxide (17a), and formaldehyde (18). Macrophage-mediated alveolar clearance is affected by sulfur dioxide (19), nitrogen dioxide and sulfuric acid (20), ozone (16, 20), silica dust (21), and long mineral and vitreous fibers (22, 23). Cigarette smoke affects the later phases of alveolar zone clearance in a dose-dependent manner (24). Clearance pathways and rates that affect the distribution of retained particles and their dosimetry can be altered by these toxicants.

Long mineral and manufactured vitreous fibers cannot be fully ingested by macrophages or epithelial cells and can clear only by dissolution. Most glass and slag wool fibers dissolve relatively rapidly within the lung and/or break up into shorter length segments. Chrysotile asbestos is more

biopersistent than most vitreous fibers and can subdivide longitudinally, creating a larger number of long fibers. The amphibole asbestos varieties (e.g., amosite, crocidolite, and tremolite) dissolve much more slowly than chrysotile. The close association between the biopersistence of inhaled long fibers and their carcinogenicity and fibrogenicity has been described by Eastes and Hadly (25), and additional data on the influence of fiber length on the biopersistence of vitreous fibers following inhalation was described by Bernstein et al. (26).

4.8 Ingestion Exposures and Gastrointestinal (GI) Tract Exposures

Chemical contaminants in drinking water or food reach human tissues via the GI tract. Ingestion may also contribute to the uptake of chemicals that were initially inhaled, because material deposited on or dissolved in the bronchial mucous blanket is eventually swallowed.

The GI tract may be considered a tube running through the body, whose contents are actually external to the body. Unless the ingested material affects the tract itself, any systemic response depends on absorption through the mucosal cells that line the lumen. Although absorption may occur anywhere along the length of the GI tract, the main region for effective translocation is the small intestine. The enormous absorptive capacity of this organ results from the presence in the intestinal mucosa of projections, termed *villi*, each of which contains a network of capillaries; the villi have a large effective total surface area for absorption.

Although passive diffusion is the main absorptive process, active transport systems also allow essential lipid-insoluble nutrients and inorganic ions to cross the intestinal epithelium and are responsible for the uptake of some contaminants. For example, lead may be absorbed via the system that normally transports calcium ions (27). Small quantities of particulate material and certain large macromolecules such as intact proteins may be absorbed directly by the intestinal epithelium.

Materials absorbed from the GI tract enter either the lymphatic system or the portal blood circulation; the latter carries material to the liver, from which it may be actively excreted into the bile or diffuse into the bile from the blood. The bile is subsequently secreted into the intestines. Thus, a cycle of translocation of a chemical from the intestine to the liver to bile and back to the intestines, known as the *enterohepatic circulation*, may be established. Enterohepatic circulation usually involves contaminants that undergo metabolic degradation in the liver. For example, DDT undergoes enterohepatic circulation; a product of its metabolism in the liver is excreted into the bile, at least in experimental animals (28).

Various factors modify absorption from the GI tract and enhance or depress its barrier function. A decrease in gastrointestinal mobility generally favors increased absorption. Specific stomach contents and secretions may react with the contaminant and possibly change it to a form with different physicochemical properties (e.g., solubility), or they may absorb it, alter the available chemical, and change the translocation rates. The size of ingested particulates also affects absorption. Because the rate of dissolution is inversely proportional to particle size, large particles are absorbed to a lesser degree, especially if they are fairly insoluble in the first place. Certain chemicals, e.g., chelating agents such as EDTA, also cause a nonspecific increase in the absorption of many materials.

As a defense, spastic contractions in the stomach and intestine may eliminate noxious agents via vomiting or by accelerating the transit of feces through the GI tract.

4.9 Skin Exposure and Dermal Absorption

The skin is generally an effective barrier against the entry of environmental chemicals. To be absorbed via this route (*percutaneous absorption*), an agent must traverse a number of cellular layers before gaining access to the general circulation (Fig. 2.8) (29). The skin consists of two structural regions, the epidermis and the dermis, which rest on connective tissue. The epidermis consists of a number of layers of cells and varies in thickness depending on the region of the body; the outermost layer is composed of keratinized cells. The dermis contains blood vessels, hair follicles, sebaceous and sweat glands, and nerve endings. The epidermis represents the primary barrier to percutaneous absorption, the dermis is freely permeable to many materials. Passage through the epidermis occurs

by passive diffusion.

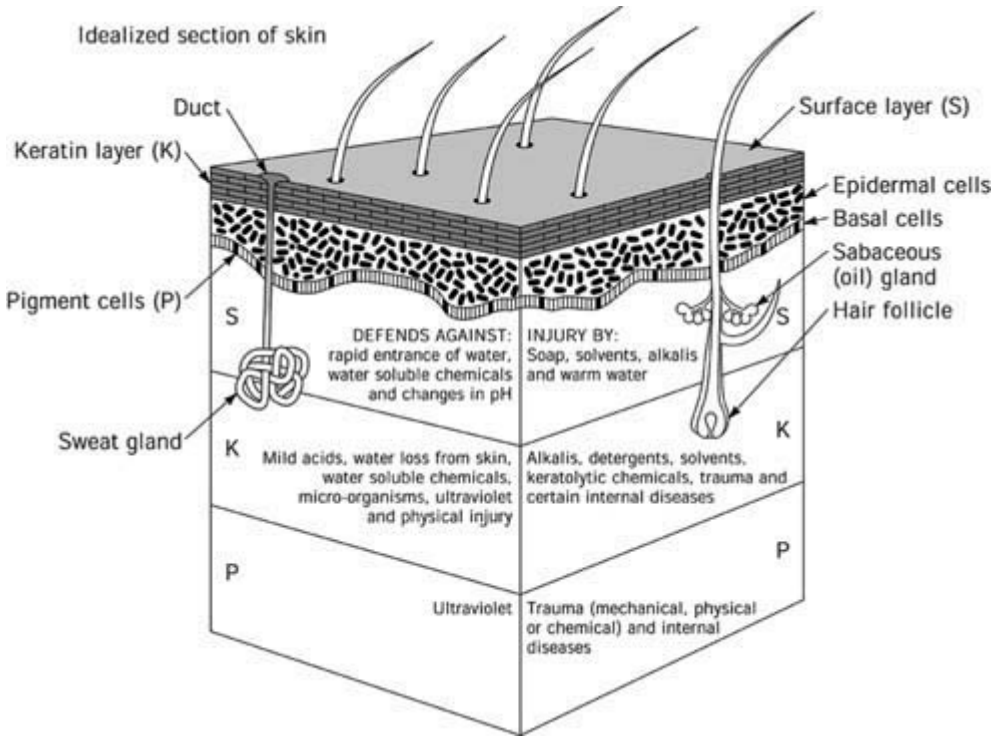

Figure 2.8. Idealized section of skin. The horny layer is also known as the stratum corneum. From Birmingham (29).

The main factors that affect percutaneous absorption are the degree of lipid solubility of the chemicals, the site on the body, the local blood flow, and the skin temperature. Some environmental chemicals that are readily absorbed through the skin are phenol, carbon tetrachloride, tetraethyl lead, and organophosphate pesticides. Certain chemicals, e.g., dimethyl sulfoxide (DMSO) and formic acid, alter the integrity of skin and facilitate penetration of other materials by increasing the permeability of the stratum corneum. Moderate changes in permeability may also result following topical applications of acetone, methyl alcohol, and ethyl alcohol. In addition, cutaneous injury may enhance percutaneous absorption.

Interspecies differences in percutaneous absorption are responsible for the selective toxicity of many insecticides. For example, DDT is about equally hazardous to insects and mammals if ingested but is much less hazardous to mammals when applied to the skin. This results from its poor absorption through mammalian skin compared to its ready passage through the insect exoskeleton. Although the main route of percutaneous absorption is through the epidermal cells, some chemicals may follow an *appendageal* route, i.e., entering through hair follicles, sweat glands, or sebaceous glands. Cuts and abrasions of the skin can provide additional pathways for penetration.

4.10 Absorption Through Membranes and Systemic Circulation

Depending upon its specific nature, a chemical contaminant may exert its toxic action at various sites in the body. At a portal of entry—the respiratory tract, GI tract, or skin—the chemical may have a topical effect. However, for actions at sites other than the portal, the agent must be absorbed through one or more body membranes and enter the general circulation, from which it may become available to affect internal tissues (including the blood itself). Therefore, the ultimate distribution of any chemical contaminant in the body is highly dependent on its ability to traverse biological membranes. There are two main types of processes by which this occurs: passive transport and active transport.

Passive transport is absorption according to purely physical processes, such as osmosis; the cell has

no active role in transfer across the membrane. Because biological membranes contain lipids, they are highly permeable to lipid-soluble, nonpolar, or nonionized agents and less so to lipid-insoluble, polar, or ionized materials. Many chemicals may exist in both lipid-soluble and lipid-insoluble forms; the former is the prime determinant of the passive permeability properties of the specific agent.

Active transport involves specialized mechanisms, and cells actively participate in transfer across membranes. These mechanisms include carrier systems within the membrane and active processes of cellular ingestion, phagocytosis and pinocytosis. Phagocytosis is the ingestion of solid particles, whereas pinocytosis refers to the ingestion of fluid containing no visible solid material. Lipid-insoluble materials are often taken up by active-transport processes. Although some of these mechanisms are highly specific, if the chemical structure of a contaminant is similar to that of an endogeneous substrate, the former may also be transported.

In addition to its lipid-solubility, the distribution of a chemical contaminant also depends on its affinity for specific tissues or tissue components. Internal distribution may vary with time after exposure. For example, immediately following absorption into the blood, inorganic lead localizes in the liver, the kidney, and in red blood cells. Two hours later, about 50% is in the liver. A month later, approximately 90% of the remaining lead is localized in bone (30).

Once in the general circulation, a contaminant may be translocated throughout the body. In this process it may (*1*) become bound to macromolecules, (*2*) undergo metabolic transformation (biotransformation), (*3*) be deposited for storage in depots that may or may not be the sites of its toxic action, or (*4*) be excreted. Toxic effects may occur at any of several sites.

The biological action of a contaminant may be terminated by storage, metabolic transformation, or excretion; the latter is the most permanent form of removal.

4.11 Accumulation in Target Tissues and Dosimetric Models

Some chemicals concentrate in specific tissues because of physicochemial properties such as selective solubility or selective absorption on or combined with macromolecules such as proteins. Storage of a chemical often occurs when the rate of exposure is greater than the rate of metabolism and/or excretion. Storage or binding sites may not be the sites of toxic action. For example, carbon monoxide produces its effects by binding with hemoglobin in red blood cells; on the other hand, inorganic lead is stored primarily in bone but exerts its toxic effects mainly on the soft tissues of the body.

If the storage site is not the site of toxic action, selective sequestration may be a protective mechanism because only the freely circulating form of the contaminant produces harmful effects. Until the storage sites are saturated, a buildup of free chemical may be prevented. On the other hand, selective storage limits the amount of contaminant that is excreted. Because bound or stored toxicants are in equilibrium with their free form, as the contaminant is excreted or metabolized, it is released from the storage site. Contaminants that are stored (e.g., DDT in lipids and lead in bone) may remain in the body for years without effect. However, upon weight loss and mobilization of body reserves, the stored chemicals can enter the circulation and produce toxic effects. For example, pregnant women who had prior excessive exposure to lead can increase their own blood lead levels and also create high and possibly damaging levels of lead exposures to their fetus. Accumulating chemicals may also produce illnesses that develop slowly, as occurs in chronic cadmium poisoning.

A number of descriptive and mathematical models have been developed to permit estimation of toxic effects from knowledge of exposure and one or more of the following factors: translocation, metabolism, and effects at the site of toxic action.

More complex models that require data on translocation and metabolism have been developed for inhaled and ingested radionuclides by the International Commission on Radiological Protection (6–9).

Pathways and Measuring Exposure To Toxic Substances
Morton Lippmann, Ph.D., CIH

5 Measuring and Modeling Human Exposures
Direct measurement data on personal exposures to environmental toxicants would be ideal for risk assessments for individuals, and personal exposure data on large numbers of representative individuals would be ideal for performing population-based risk assessments. However, considerations of technical feasibility, willingness and ability to participate in extensive measurement studies among individuals of interest, and cost almost invariably preclude this option. Instead, more indirect measures of exposure and/or exposure models are relied on that combine a limited number of direct measurements with general background knowledge, historic measurement data believed to be relevant to the particular situation, and some reasonable assumptions based on first principles and/or expert judgements.

When monitoring exposures, it is highly desirable to have benchmarks (exposure limits) as references. There are well-established occupational exposure limits for hundreds of air contaminants, including legal limits such as the Permissible Exposure Limits (PELs) established by the U.S. Occupational Safety and Health Administration (OSHA), as well as a larger number of Threshold Limit Values (TLVs) recommended by the American Conference of Governmental Industrial Hygienists (ACGIH) as professional practice guidelines.

For ingested chemicals, there are acceptable daily intake values (ADIs), such as those adopted by the Food and Drug Administration (FDA) and the U.S. Department of Agriculture.

Until now, comparable exposure limits have not been available for dermal exposure. However, Bos et al. (31) recently proposed a procedure for deriving such limits, and Brouwer et al. (32) performed a feasibility study following the Bos et al. proposal. Table 2.2 from Bos et al. (31) summarizes the nature and applications of such dermal exposure limits.

Table 2.2. Some Characteristics of Available Exposure Limits[a]

	Route of Entry			
	Respiratory Tract	**Gastrointestinal Tract**	**Skin**	**Miscellaneous or Combined**
Name	Maximum accepted concentration (MAC) Threshold limit value (TLV)	Acceptable daily intake (ADI)	Skin denotation	Biological limit value; (BEI, BAT-Werte, biological monitoring guidance value)
Qualitative or quantitative	Quantitative	Quantitative	Qualitative	Quantitative

Target population	Working population	General population	Working population	Working population or general population
Dimensions	mg/m^3	mk/kg/food	Not applicable; however	(a) mg/L blood, mg/L urine, mg/m^3 exhaled air
	parts per million (ppm)	mg/kg body weight	likely to be assessed as mg	(b) cholinesterase inhibition, zinc protoporphyrin, DNA adducts,
	fibres n/m^3		(mg/cm^2)	mutations, etc.
Monitoring methods	Environmental monitoring (EM)	Food residues or contaminants in combination with food intake data	For example, environmental surface wipe-off; patches, gloves, coveralls; tracer methods; skin	Biological media: blood, urine, exhaled air, feces, hair
	Personal air sampling (PAS)	No specific worker monitoring method	washings; or skin stripping	

[a] From Bos et al. (31).

In routine monitoring of occupational exposures, it is quite common to collect shift-long (~ 8 hour) integrated breathing zone samples using passive diffusion samplers (for gases and vapors) or battery-powered personal samplers that draw a continuous low flow rate stream of air from the breathing zone through a filter or cartridge located in the breathing zone that captures essentially all of the air contaminants of interest for subsequent laboratory analyses. Such sampling is typically performed on only a single worker or at most on a small fraction of the workforce on the basis that the exposures of the sentinel worker(s) represent the exposures of other, unmonitored workers in the same works environment. In this case, the modeling of the other worker's exposures is relatively simple.

Shift-long sampling can provide essential information for cumulative toxicants, but that information may be inadequate when peak exposure levels are important (as for upper respiratory irritants or asphyxiants). Continuous readout monitors would be ideal for evaluating such exposures, but may be impractical because of their size and/or cost. Spot or grab samples can be informative for evaluating of such exposures but require prior knowledge of the timing and locations of peak exposures. In such situations, peak exposures can be estimated using fixed-site continuous monitors in the general vicinity and supplementary information or experience-based models that relate breathing zone levels to general air levels in the room. Time-activity pattern data on each worker can be combined with measured or estimated concentrations at each work site or with specific work activities to construct a time-weighted average exposure (TWAE) for that worker to supplement estimates of peak exposures. The characteristics of equipment used for air sampling in industry are described in detail in *Air Sampling Instruments* (33).

In constructing exposure estimates or models for community air or indoor air exposures for the general population, this time-weighted averaging approach is generally known as

microenvironmental exposure assessment. For community air pollutants of outdoor origin, data are often available on the concentrations measured at central monitoring sites, and population exposures to these pollutants are based on models incorporating time-activity patterns (indoors and outdoors), as well as factors representing the infiltration and persistence of the pollutants indoors. Such models should recognize the substantial variability of time-activity patterns among and between subsegments of the population (children, working adults, elderly and/or disabled adults, etc.).

5.1 Biomonitoring

An alternate approach to measuring exposures directly is the use of biomarkers of exposures, determined from analyses of samples of blood, urine, feces, hair, nails, or exhaled air. The levels of the contaminant, its metabolites, changes in induced enzyme or protein levels, or characteristic alterations in DNA may be indicative of recent peak or past cumulative exposures. Exposure biomarkers may be complementary to and, in some cases, preferable to direct measures of environmental exposures. In any case, they are more biologically informative than indirect measures based on models and knowledge of sources or qualitative measures of exposure such as questionnaires about work and/or residential histories. There are diverse types of biomarkers that range from simple to complex in measurement requirements, and they are diverse in their relationships to either remote or recent exposures. There is also a range of biological relevance among exposure biomarkers: some provide indices that are directly biologically relevant, e.g., the level of carbon monoxide in end-tidal air samples and the risk of myocardial ischemia, whereas others, although broadly related, may not cover the temporally appropriate exposure window, e.g., nicotine levels in biological fluids and lung cancer risk from smoke exposure.

For the near term, extensive development of new molecular level biomarkers relevant to malignant and nonmalignant diseases can be anticipated. However, most of these new exposure biomarkers remain to be validated, and few will be ready for translation to the population in the short term. Anticipated applications include epidemiological studies of responses to low-level exposures to environmental agents. Biomarkers will also be used to validate other exposure assessment methods and to provide more proximate estimates of dose.

Exposure biomarkers may be applied to groups that have unique exposure or susceptibility patterns, to monitor the population in general, and to document the consequences of exposure assessment strategies designed to reduce population exposures.

Exposure biomarkers validated against the end point of disease risk and used in conjunction with other measurements and metrics of exposure should prove particularly effective in risk assessment. However, biomarkers of exposure may pose new and unanticipated ethical dilemmas. Information gained from biomolecular markers of exposure may provide an early warning of high risk or preclinical disease; capability for early warning will require a high level of, and an accepted social-regulatory framework for follow-up actions. They may also cause false alarms and needless stress for individuals warned about the presence of uncertain signals.

In summary, exposure represents contact between a concentration of an agent in air, water, food, or other material and the person or population of interest. The agent is the source of an internal dose to a critical organ or tissue. The magnitude of the dose depends on a number of factors: (1) the volumes inhaled or ingested; (2) the fractions of the inhaled or ingested material transferred across epithelial membranes of the skin, the respiratory tract, and the GI tract; (3) the fractions transported via circulating fluids to target tissues; and (4) the fractional uptake by the target tissues. Each of these factors can have considerable intersubject variability. Sources of variability include activity level, age, sex, and health status, as well as such inherent variabilities as race and size.

With chronic or repetitive exposures, other factors affect the dose of interest. When the retention at, or effects on, the target tissues are cumulative and clearance or recovery is slow, the dose of interest can be represented by cumulative uptake. However, when the agent is rapidly eliminated or when its effects are rapidly and completely reversible on removal from exposure, the rate of delivery may be the dose parameter of primary interest.

5.2 Determining Concentrations of Toxic Chemicals in Human Microenvironments

The technology for sampling air, water, and food is relatively well developed, as are the technologies for sample separation from copollutants, media, and interferences and for quantitative analyses of the components of interest. However, knowing when, where, how long, and at which rate and frequency to sample to collect data relevant to the exposures of interest is difficult and requires knowledge of the temporal and spatial variability of exposure concentrations. Unfortunately, we seldom have enough information of these kinds to guide our sample collections. Many of these factors that affect occupational exposures are discussed in detail in the chapters of Patty's *Industrial Hygiene*, 5th ed. (33) The following represents a very brief summary of some general considerations.

5.3 Water and Foods

Concentrations of environmental chemicals in food and drinking water are extremely variable, and there are further variations in the amounts consumed because of the extreme variability in dietary preferences and food sources. The number of foods for which up-to-date concentration data for specific chemicals are available is extremely limited. Relevant human dietary exposure data are sometimes available in terms of market basket survey analyses. In this approach, food for a mixed diet is purchased, cleaned, processed, and prepared as for consumption, and one set of specific chemical analyses is done for the composite mixture.

The concentrations of chemicals in potable piped water supplies depend greatly on the source of the water, its treatment history, and its pathway from the treatment facility to the tap. Surface waters from protected watersheds generally have low concentrations of dissolved minerals and environmental chemicals. Well waters usually have low concentrations of bacteria and environmental chemicals but often have high mineral concentrations. Poor waste disposal practices may contribute to groundwater contamination, especially in areas of high population density and/or industrial sources of wastes. Treated surface waters from lakes and rivers in densely populated and/or industrialized areas usually contain a wide variety of dissolved organics and trace metals, whose concentrations vary greatly with the season (because of variable surface runoff), with proximity to pollutant sources, with upstream usage, and with treatment efficacy.

The uptake of environmental chemicals in bathing waters across intact skin is usually minimal compared to uptake via inhalation or ingestion. It depends on both the concentration in the fluid surrounding the skin surface and the polarity of the chemical; more polar chemicals have less ability to penetrate intact skin. Uptake via skin can be significant for occupational exposures to concentrated liquids or solids.

5.4 Air

Although chemical uptake through ingestion and the skin surface is generally intermittent, inhalation provides a continuous means of exposure. The important variables that affect the uptake of inhaled chemicals are the depth and frequency of inhalation and the concentration and physicochemical properties of the chemicals in the air.

Exposure to airborne chemicals varies widely among inhalation microenvironments, whose categories include workplace, residence, outdoor ambient air, transportation, recreation, and public spaces. There are also wide variations in exposure within each category, depending on the number and strength of the sources of the airborne chemicals, the volume and mixing characteristics of the air within the defined microenvironment, the rate of air exchange with the outdoor air, and the rate of loss to surfaces within the microenvironment.

For community air pollutants that have national ambient air quality standards, particulate matter (PM), sulfur dioxide (SO_2), carbon monoxide (CO), nitrogen dioxide (NO_2), ozone (O_3), and lead (Pb), there is an extensive network of fixed-site monitors, generally on rooftops. Although the use of these monitors generates large volumes of data, the concentrations at these sites may differ substantially from the concentrations that people breathe, especially for tailpipe pollutants such as CO. Data for other toxic pollutants in the outdoor ambient air are not generally collected routinely.

5.5 Workplace

Exposures to airborne chemicals at work are extremely variable in composition and concentration and depend on the materials being handled, the process design and operation, the kinds and degree of engineering controls applied to minimize release to the air, the work practices followed, and the personal protection provided.

5.6 Residential

Airborne chemicals in residential microenvironments are attributable to air infiltrating from out of doors and to the release from indoor sources. The latter include unvented cooking stoves and space heaters, cigarettes, consumer products, and volatile emissions from wallboard, textiles, carpets, etc. Indoor sources can release enough nitrogen dioxide (NO_2), fine particle mass (FPM), and formaldehyde (HCHO) that indoor concentrations for these chemicals can be much higher than those in ambient outdoor air. Furthermore, their contributions to the total human exposure are usually even greater because people usually spend much more time at home than outdoors.

5.7 Conventions for Size-Selective Inhalation Hazard Sampling for Particles

In recent years, quantitative definitions of Inhalable particulate matter (IPM), Thoracic particulate matter (TPM), and Respirable particulate matter (RPM) have been internationally harmonized. The size-selective inlet specifications for air samplers that meet the criteria of ACGIH (34), ISO (35), and CEN (36) are enumerated in Table 2.3 and illustrated in Figure 2.9. They differ from the deposition fractions of ICRP (6), especially for larger particles, because they take the conservative position that protection should be provided for those engaged in oral inhalation and thereby bypass the more efficient filtration efficiency of the nasal passages.

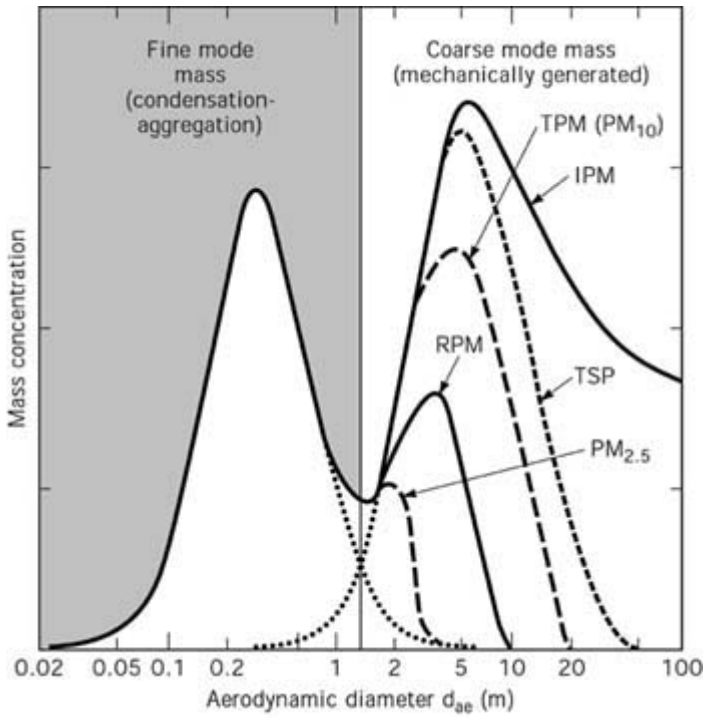

Figure 2.9. Effect of size-selective inlet characteristic on the aerosol mass collected by a downstream filter. IPM = inhalable particulate matter; TSP = total suspended particulate; TPM = thoracic particulate matter; (aka PM_{10}); RPM = respirable particulate matter; and $PM_{2.5}$ = fine particulate matter in ambient air.

Table 2.3. Inhalable, Thoracic and Respirable Dust Criteria of ACGIH, ISO and CEN, and Criteria of U.S. EPA

Inhalable		Thoracic		Respirable		PM_{10}	
Particle Aerodynamic Diameter (mm)	Inhalable Particulate Mass (IPM) (%)	Particle Aerodynamic Diameter (mm)	Thoracic Particulate Mass (TPM) (%)	Particle Aerodynamic Diameter (mm)	Respirable Particulate Mass (RPM) (%)	Particle Aerodynamic Diameter (mm)	T Pa Ma (T
0	100	0	100	0	100		0
1	97	2	94	1	97		2
2	94	4	89	2	91		4
5	87	6	80.5	3	74		6
10	77	8	67	4	50		8
20	65	10	50	5	30		10
30	58	12	35	6	17		12
40	54.5	14	23	7	9		14
50	52.5	16	15	8	5	16	
100	50	18	9.5	10	1		
		20	6				
		25	2				

The U.S. Environmental Protection Agency (36a) set a standard for ambient air particle concentration known as PM_{10}, i.e., for particulate matter less than 10 mm in aerodynamic diameter. It replaced a poorly defined size-selective criterion known as total suspended particulate matter (TSP), whose actual inlet cut varied with wind speed and direction. PM_{10} has a sampler inlet criterion that is similar (functionally equivalent) to TPM but, as shown in Table 2.3, has somewhat different numerical specifications.

In 1997, following its most recent thorough review of the literature on the health effects of ambient PM, the EPA concluded that most of the health effects attributable to PM in ambient air were more closely associated with the fine particles in the fine particle accumulation mode (extending from about 0.1 to 2.5 mm) than with the coarse mode particles within PM_{10} and promulgated new National Ambient Air Quality Standard (NAAQS) based on fine particles, defined as particles whose aerodynamic diameters (d_{ae}) are less than 2.5 mm ($PM_{2.5}$), to supplement the PM_{10} NAAQS that was retained (37). The selection of d_{ae} = 2.5 mm as the criterion for defining the upper bound of fine particles in a regulatory sense was, inevitably, an arbitrary selection made from a range of possible options. It was arrived at using the following rationales:

- Fine particles produce adverse health effects more because of their chemical composition than their size (see Table 2.4) and need to be regulated using an index that is responsive to control measures applied to direct and indirect sources of such particles.

Table 2.4. Comparisons of Ambient Fine and Coarse Mode Particles[a]

	Fine Mode	Coarse Mode

Formed from	Gases	Large solids/droplets
Formed by	Chemical reaction; nucleation; condensation; coagulation; evaporation of fog and cloud droplets in which gases have dissolved and reacted	Mechanical disruption (e.g., crushing, grinding, abrasion of surfaces); evaporation of sprays; suspension of dusts
Composed of	Sulfate, SO_4^{2-}; nitrate, NO_3^-; ammonium, NH_4^+; hydrogen ion, H^+; elemental carbon; organic compounds (e.g., PAHs, PNAs); metals (e.g., Pb, Cd, V, Ni, Cu, Zn, Mn, Fe); particle-bound water	Resuspended dusts (e.g., soil dust, street dust); coal and oil fly ash; metal oxides of crustal elements (Si, Al, Ti, Fe); $CaCO_3$, NaCl, sea salt; pollen, mold spores; plant/animal fragments; tire wear debris
Solubility	Largely soluble, hygroscopic, and deliquescent	Largely insoluble and non hygroscopic.
Sources	Combustion of coal, oil, gasoline, diesel, wood; atmospheric transformation products of NO_x, SO_2, and organic compounds including biogenic species (e.g., terpenes); high temperature processes, smelters, steel mills, etc.	Resuspension of industrial dust and soil tracked onto roads; suspension from disturbed soil (e.g., farming, mining, unpaved roads); biological sources; construction and demolition; coal and oil combustion; ocean spray
Lifetimes	Days to weeks	Minutes to hours
Travel distance	100s to 1000s of kilometers	<1 to 10s of kilometers

[a] Source: USEPA (36).

- Any separation by aerodynamic particle size that attempts to separate fine mode from coarse mode particles cannot include all fine mode particles and exclude all coarse mode particles because the modes overlap (see Figure 2.9).
- The position of the "saddle point" between the fine mode and coarse mode peaks varies with aerosol composition and climate. Data from Michigan indicates a volumetric saddle point at d_{ae} ~2 mm. If the data were corrected for particle density, it might be somewhat higher. Data from Arizona have a lower saddle point at d_{ae} ~1.5 mm.
- Evidence of a need for a fine particle NAAQS came from studies based on $PM_{2.5}$ or $PM_{2.1}$. If $PM_{2.5}$ errs, it also does so on the conservative side with respect to health protection. Further, it was deemed to be impractical to have different cut sizes in different parts of the United States.
- The intrusion of coarse mode mass into $PM_{2.5}$ can be minimized by specifying a relatively sharp cut characteristic for the $PM_{2.5}$ reference sampler (i.e., s_g=1.5).

5.8 Indirect Measures of Past Exposures

Documented effects of environmental chemicals on humans seldom contain quantitative exposure data and only occasionally include more than crude exposure rankings based on known contact with or proximity to the materials believed to have caused the effects. Reasonable interpretation of the

available human experience requires some appreciation of the uses and limitations of the data used to estimate the exposure side of the exposure–response relationship. The discussion that follows is an attempt to provide background for interpreting data and for specifying the kinds of data needed for various analyses.

Both direct and indirect exposure data can be used to rank exposed individuals by exposure intensity. External exposure can be measured directly by collecting and analyzing environmental media. Internal exposure can be estimated from analyses of biological fluids and *in vivo* retention. Indirect measures generally rely on work or residential histories based on some knowledge of exposure intensity at each exposure site and/or some enumeration of the frequency of process upsets and/or effluent discharges that result in high-intensity, short-term exposures.

5.9 Concentrations in Air, Water, Food, and Biological Samples

Historic data may occasionally be available for the concentrations of materials of interest in environmental media. However, they may or may not relate to the exposures of interest. Among the more important questions to be addressed in attempts to use such data are,

1. How accurate and reliable were the sampling and analytical techniques used in collecting the data? Were they subjected to any quality assurance protocols? Were standardized and/or reliable techniques used?
2. When and where were the samples collected, and how did they relate to exposures at other sites? Air concentrations measured at fixed (area) sites in industry may be much lower than those that occur in the breathing zone of workers close to the contaminant sources. Air concentrations at fixed (generally elevated) community air-sampling sites can be either much higher or much lower than those at street level and indoors as a result of strong gradients in source and sink strengths in indoor and outdoor air.
3. What is known or assumed about the ingestion of food and/or water containing the measured concentrations of the contaminants of interest? Time at home and dietary patterns are highly variable among populations at risk.

Many of the same questions that apply to the interpretation of environmental media concentration data also apply to biological samples, especially quality assurance. The time of sampling is especially critical in relation to the times of the exposures and to the metabolic rates and pathways. In most cases, it is quite difficult to separate the contributions to the concentrations in circulating fluids of levels from recent exposures and those from long-term reservoirs.

5.10 Exposure Histories

Exposure histories per se are generally unavailable, except in the sense that job or work histories, routine compliance data on air concentrations, and/or residential histories can be interpreted in terms of exposure histories. Job histories are often available in company and/or union records and can be converted into relative rankings of exposure groups with the aid of long-term employees and managers familiar with the work processes, history of process changes, material handled, tasks performed, and the engineering controls of exposure.

5.11 Occupational Exposure Data in the Information Age

There are increasing opportunities for obtaining technical information that can inform our exposure and risk assessments that arise from the development of: (*1*) sensitive passive monitors for time-weighted average analyses; (*2*) miniature direct-reading sensors for collecting time-resolved, as well as average personal and area concentration data; (*3*) long-path sensors for area monitoring; (*4*) computerized tomography techniques for developing concentration maps from long-path monitoring data; (*5*) biomarkers of exposure; (*6*) technical means of determining worker presence at workstations; and (*7*) an ever-growing toxicological and epidemiological database for relating exposure to risk.

5.12 Exposure Measurements

In the area of chemical sensors, there are multiple possibilities for developing automated and, in some cases, relatively inexpensive real-time microsensors for measuring gaseous and particulate pollutants in personal and microenvironmental measurements (see Table 2.5) (38). New materials

and coating technologies can provide the chemical specificity and selectivity needed for such sensors. These new technologies offer the means to do near real-time measurements to understand the variability of exposures over short and long time periods. Such sensors could also be used to directly reduce exposures by providing immediate exposure information to monitored populations or through linkages to control systems, e.g., air quality monitoring coupled with ventilation controls.

Table 2.5. A Few Examples of New Sensor Technologies with Potential Applications to Occupational and Air Pollutant Exposure Assessment[a]

Ultrasonic Flexural Plate Wave (FPW) Devices for Chemical Multiarray Microsensors. Highly sensitive flexural plate wave devices are being developed for *in situ*, real time analyses of particles and volatile organic compounds in indoor and outdoor air and clean rooms and in emissions sources. FPW sensors can be batch fabricated using well-developed and inexpensive silicon technology and interfaced with microprocessors that record and analyze the sensed measurements.
Computer Tomography/Fourier-Transform Infrared Spectrometry. This emerging technology will provide the means to characterize spatial distributions and movements of air pollutants in three dimensions in indoor and outdoor environments. Recent breakthroughs in computer algorithms for computer tomography have made it possible for this technology to be commercially available within three to five years.

[a] (From USEPA-SAB-IAQC) (38).

Sensor data from field measurements can be transmitted over telecommunications lines directly to computer systems for analysis. Such direct transmission reduces chances for errors in recording data.

Many different kinds of exposure-related models that take advantage of computer capabilities and large databases of information have already been developed and are currently available. These include exposure models that combine concentration data with time-activity patterns to estimate exposures, physiologically based pharmacokinetic models that describe the distribution and metabolism of toxic chemicals (including biomarkers) in the body, and health effects models (e.g., cancer risk models). Such models are typically developed as single models without considering linkages to other models and are often written in different computer languages and have system designs that are not readily compatible with other models. For more fully integrated exposure analysis, from sources to health effects, integrating frameworks must be developed that more readily allow the output from one model to serve easily as input into other models.

In the near future, new insights will inevitably come from combining measurements of the personal environment with measurements of the individual's capacity to interact with that environment. For example, it is technically possible to record simultaneous real-time measurements of specific airborne compounds in an individual's breathing zone, an individual's breathing and exercise rates, and geographic location. Such advanced technology is already being used in some large industries. For example, some combine location in a work area (accessible by coded badges) and continuous work area air monitoring outputs to automatically compute daily time-weighted average exposures of worker cohorts.

5.13 Expanded Applications of Occupational Exposure Databases

Hygienists tend to be compulsive about the quality of the data they collect when assessing occupational exposures and the influence of exposure determinants. They are likely to be careful and consistent in collecting data according to a rational sampling strategy that aids them in interpreting the data and the preparation of recommendations for remedial actions as needed. They also often use

a cumulative data set to document progress in reducing exposures and/or to identify evidence for actual or potential increases. However, they may not recognize additional ways that their carefully acquired data resources can be used by them or others for other important purposes.

Perhaps the single most important need to use such data more broadly is to collect and enter more data on exposure determinants into the databases. Another critical need is to devise means for censoring the data, so that specific individuals and companies do not incur legal or public relations problems because their data become available to others in a traceable form. There will need to be a long period of gradual development and experience with such systems before widespread donations of data can be expected. No matter how long it takes, it is important that the harmonization of the data elements to be entered into company-specific databases take place as soon as possible, so that it is at least feasible for disparate data to be used in a combined analysis. These could be used in corporatewide or industrywide analyses whose results end up in peer-reviewed scientific literature that can benefit all interested parties.

There are now opportunities for harmonizing data elements in occupational exposure databases that, when combined with the capabilities of our state-of-the-art hardware and software, will enable us to collect, assemble, and store very large amounts of data. If such consolidated databases are properly assembled and quality-assured, they could be used by individuals and companies that contributed data, by trade associations, and by research investigators to learn more about the distributions and determinants of occupational exposures, the efficacy of technical means of exposure controls, and the adequacy of current exposure limits for preventing health effects. A Workshop on Occupational Exposure Databases (39) reviewed the various activities that were underway. This was followed by the active development of Guidelines for the Development of Occupational Exposure Databases by both a Joint Ad Hoc Committee of the American Conference of Governmental Industrial Hygienists (ACGIH) and the American Industrial Hygiene Association (AIHA) and by a Task Group appointed by the European Commission. Fortunately, both groups tried to harmonize their recommendations before they were completed. The final report of the ACGIH-AIHA Ad Hoc Committee appeared in *Applied Occupational and Environmental Hygiene* (40), along with a progress report from the European Community Task Group (41).

Important issues remain to be resolved before suitable arrangements can be made to establish a central exposure data repository or for other means of sharing proprietary data that are collected and stored using a common format. It is clear that, for at least some secondary uses of compatible data from different sources, means must be provided to ensure that the data elements cannot be traced back to individual workers, individual work sites, or even to employers.

5.14 Applications and Environmental Exposure and Effects Databases

The environmental health field has learned a great deal about some of the more subtle effects of environmental toxicants on human populations by studying the statistical associations between mortality and morbidity indices, on the one hand, and environmental exposure indices, on the other. Small, but statistically significant increases in population relative risks (RRs) have been demonstrated that link

- blood lead to blood pressure in U.S. adults (based on data from the second National Health and Nutrition Examination Survey (NHANES II) (42).
- blood lead and hearing acuity to neurobehavioral development in children, also based on NHANES II (43).
- blood lead to stature in children, also based on NHANES II (44).
- both ozone and sulfate particles to hospital admissions for respiratory diseases in various U.S. and Canadian communities (45–47).
- fine particles to hospital admissions for cardiovascular diseases in various U.S. and Canadian communities (48, 49).
- fine particles to daily mortality rates in various communities in the Americas and Europe (45, 50).

- fine particles and sulfate particles to annual mortality rates in various U.S. communities (45, 47, 51, 52).
- environmental tobacco smoke (ETS) to lung cancer mortality among spouses in various communities in the U.S., Asia, and Europe (53).
- ETS to 150,000 to 300,000 cases/year of lower respiratory tract infections in U.S. children (53).
- ETS to 200,000 to 1,000,000 additional asthma episodes/year in U.S. children (53).
- ETS to increased prevalence of fluid in the middle ear, symptoms of upper respiratory tract, irritation, reduced lung function in children, and as a risk factor for new cases of asthma in children (53).

In each of these cases, the risks are relatively low (≤1.3), and the biological mechanisms that may account for the associations are either only suggestive or unknown. However, the strength and consistency of the observations are compelling, and attempts to find confounding factors that can account for the associations have been unsuccessful. The U.S. Environmental Protection Agency (USEPA) (44, 45, 53) has used these findings for public health guidance and to set environmental standards. In some cases, detecting such small relative risks was possible only because of the large sizes of the populations studied, sometimes including the total populations of large cities, as for the daily mortality and hospital admissions studies (45). In other cases, stratified random samples of the whole U.S. population have been used, as in the NHANES studies (42–44). Another approach has been to obtain individual risk factor data on large cohorts of individuals. For example, the American Cancer Society study of the relationship between annual mortality and sulfate particle concentrations used data on more than a half million people in 151 U.S. communities (52).

For occupational health studies, the opportunities to study large populations in definable exposure groupings have been quite rare, and few epidemiological studies have had the statistical power to detect relative risks below about 2.

In the future, opportunities for access to data sets that have individual exposure data on relatively large numbers of workers for the study of exposure–response relationships characterized by small relative risks may eventually emerge if the Guidelines and Recommendations on Data Elements for Occupational Exposure Databases, recently endorsed by the Boards of ACGIH and AIHA, discussed previously, are adopted by industries, trade associations, and governmental agencies.

Reproductive and Developmental Toxicology

Carole A. Kimmel, Ph.D., Judy Buelke-Sam

1.0 Introduction

Reproductive toxicology encompasses the study of a wide variety of chemical and physical agents and their effects on the structure and function of the male and female reproductive systems, the ability to conceive and reproduce, the nurture of the young during pregnancy and lactation, and the development of offspring to grow, mature, and reproduce (Fig. 3.1). Developmental toxicology involves the study of the effects of preconceptional, prenatal, and/or postnatal exposures up to the time of sexual maturity on developmental processes. Developmental toxicology is a subset of reproductive toxicology, although the subsequent effects of direct postnatal exposure of young animals or children traditionally have notx been considered part of reproductive toxicology. Reproductive dysfunction and developmental disorders are major public health issues that affect significant proportions of the population. Infertility in humans, defined as the inability to conceive after one year of unprotected intercourse, has been estimated to affect approximately 8% of all married couples in the United States (1). Billions of dollars are spent each year on fertility

treatments, including fertility drugs and the increased use of assisted reproductive techniques (e.g., *in vitro* fertilization). Although many of these technologies can improve fertility, some can also result in multiple births that put small and premature babies at risk. The causes of infertility are varied, and the impact of chemical and physical agents on the reproductive system is unclear. However, several reports in the 1990s of declining human sperm concentration, an increased incidence of cryptorchidism, hypospadias, and testicular cancer, as well as reports that some chemicals may act by disrupting endocrine function (2–5), have raised concerns that environmental chemicals might be causing some of these problems. These concerns have led to requirements, as part of the Food Quality Protection Act of 1996, for testing pesticides and industrial chemicals for their potential to cause endocrine disruption.

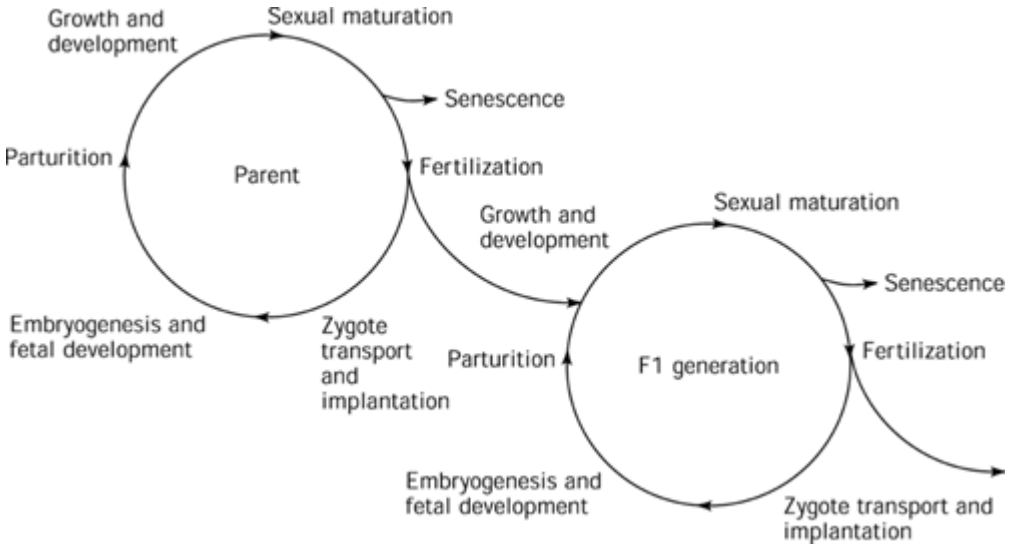

Figure 3.1. Reproductive life cycle of the parental and F1 generations showing the major stages in development, reproduction, and aging.

The incidence of spontaneous abortions in the population has been estimated to be as high as 50% of all conceptions (6, 7). Many of these occur before implantation in the uterus, are not detected, and cannot be distinguished from subfertility or infertility. Tests sensitive to the production of human chorionic gonadotropin as early as eight days after conception (before a woman may know she is pregnant) have shown a rate of 32–34% spontaneous abortions for postimplantation pregnancies (8, 9). The incidence of major birth defects in live-born children is 3–4%, and developmental disorders at school age affect approximately 12–14% of all children. The lifetime cost of caring for children born each year with the 17 most common birth defects and cerebral palsy has been estimated to be more than $8 billion. (10). This is a conservative estimate because these birth defects affect only 22% of children born with birth defects in a year and lost wages of caregivers were not considered. Developmental disorders also include the full gamut of functional effects such as neurobehavioral deficits, altered cardiovascular, pulmonary, renal, and other organ system dysfunction that result from prenatal or postnatal exposures.

The contribution of chemical and physical agents to the cases of reproductive dysfunction in humans is unknown, but there are some outstanding examples of environmental chemicals, pharmaceuticals, and other agents that can affect reproduction, development, and function; these include, for example, lead, methylmercury, polychlorinated biphenyls, diethylstilbestrol, thalidomide, cigarette smoking, and alcohol.

1.1 Definitions

Reproductive toxicology is the study of the occurrence of biologically adverse effects on the reproductive systems of females or males that may result from exposure to chemical or physical agents. The toxicity may be expressed as alterations to the female or male reproductive organs, the related endocrine system, or pregnancy outcomes. The manifestations of such toxicity may include,

but are not limited to, adverse effects on the onset of puberty, gamete production and transport, reproductive cycle normality, sexual behavior, fertility, gestation, parturition, lactation, developmental toxicity, premature reproductive senescence, or modifications in other functions that depend on the integrity of the reproductive systems.

Fertility is defined as the capacity to conceive or induce conception.

Fecundity is the ability to produce offspring within a given time period. For litter-bearing species, the ability to produce large litters is also a component of fecundity.

Developmental toxicity is the occurrence of adverse effects on the developing organism that may result from exposure before conception (either parent), during prenatal development, or postnatally to the time of sexual maturation. Adverse developmental effects may be detected at any point in the life span of the organism. The major manifestations of developmental toxicity include (1) death of the developing organism, (2) structural abnormality, (3) altered growth, and (4) functional deficiency.

Reproductive and Developmental Toxicology

2.0 Overview of Normal Reproduction and Development Relevant to Toxicology
An appreciation of normal reproductive biology and development is important for understanding and evaluating the toxic effects of chemical and physical agents. This section provides an overview of these processes and a discussion of issues that are important in toxicology. Reference texts on reproductive and developmental biology and toxicology should be consulted for more detail (11–19).
2.1 Gametogenesis
The process by which germ cells (ova and sperm) are produced in both the male and female mammal is termed *gametogenesis* (Fig. 3.2) (20). The germ cells originate in both sexes from cells lining the embryonic yolk sac and, during the sixth week of gestation in humans, migrate into the gonadal ridges and become spermatogonia or oogonia, residing in the testis or ovary, respectively. Although many of the processes are similar in males and females, several differences are important for reproductive and developmental toxicology.

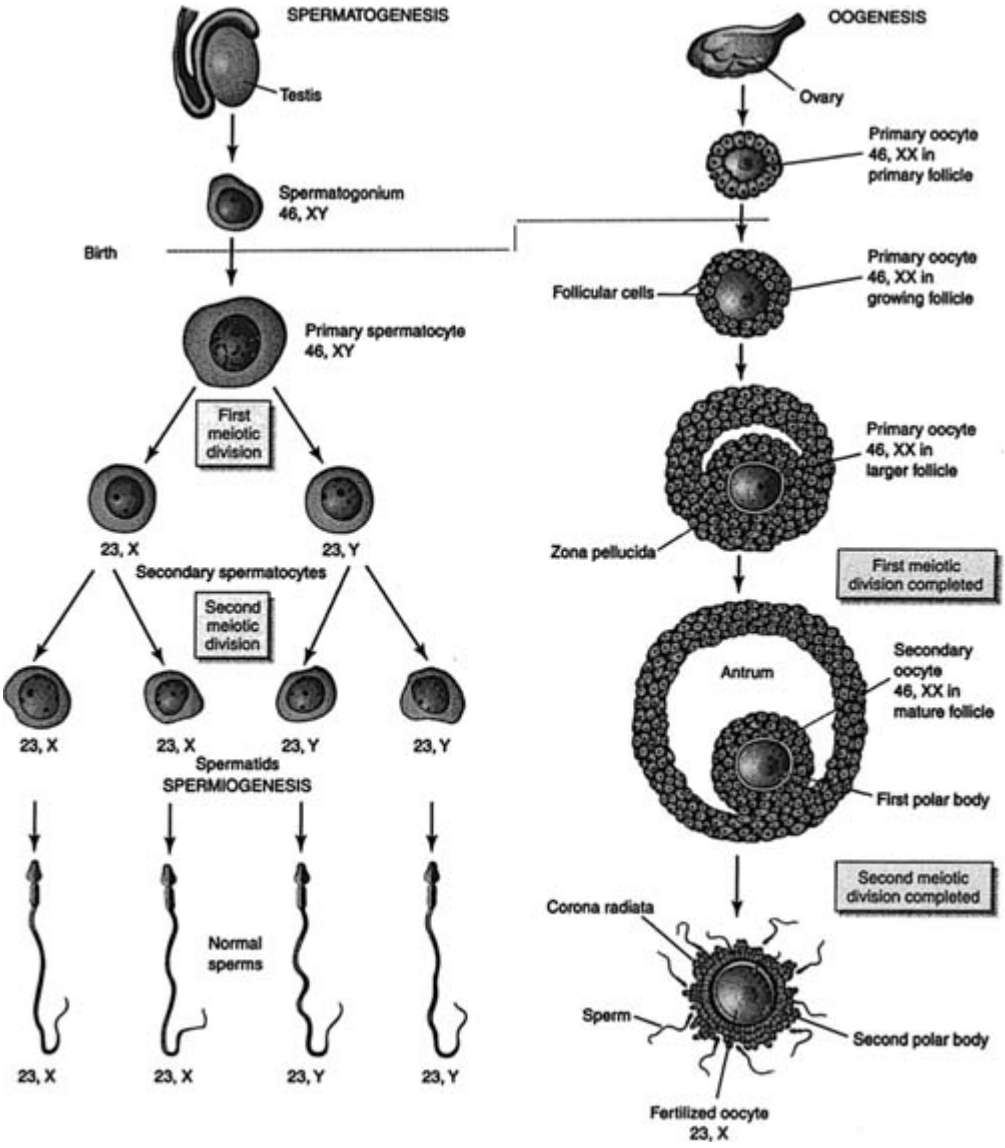

Figure 3.2. Gametogenesis in the male and female (used with permission of W. B. Saunders Co., and modified from Ref. 20).

Spermatogonia are dormant until after birth and up to the time of puberty when they begin to increase in number through mitosis and produce primary spermatocytes. These further divide by a process called *meiosis* to form two haploid (half the chromosome number) secondary spermatocytes, that further divide to form four spermatids. The process by which spermatids are transformed into mature sperm is called *spermiogenesis*. Mature sperm are released into the lumen of the seminiferous tubule of the testis. This transformation from spermatogonia to mature sperm, called *spermatogenesis*, lasts for 60 days in rats or 80 days in humans and continues throughout the life of the male, as long as undifferentiated A-type spermatogonia are present (21). Agents that affect spermatogonia are the most devastating because the effects may be permanent, whereas effects on later stages of spermatogenesis are more likely to be transient. For example, agents that affect DNA synthesis and cell division, such as the chemotherapeutic agents cyclophosphamide and cytosine arabinoside, affect spermatogonia and early spermatocytes (22, 23), whereas brief exposure to heat affects spermatocytes and early spermatids (24) and temporarily results in reduced fertility which is restored as later spermatocytes mature.

Oogenesis is the process of the development of mature ova in the female mammal. Before birth, the oogonia proliferate by mitotic division and form primary oocytes surrounded by follicular cells. The oocyte and its follicle cells are called a *primary follicle*. The first phase (Prophase I) of meiosis in the

oocyte begins before birth, and cells are then arrested until around puberty. At the onset of each estrous cycle, a pool of primordial follicles is recruited into a growing pool of primary follicles, one or more of which go on to form the large Graafian follicle and become an ovulatory follicle. In rodents and other polytocous species, several primary follicles become ovulatory follicles. No more primary oocytes are formed after birth. There is a normal process of atresia of oocytes throughout the prenatal and postnatal periods decreasing from approximately 7 million at 5 months of gestation to approximately 2.8 million at birth, with approximately 300,000 remaining at puberty (25). These continue to decrease so that no more follicles are present by around age 50. Damage to oogonia or primary oocytes before or after birth may be permanent, and an agent that increases atresia of primary oocytes reduces the complement of total ova available for ovulation and possibly decreases the time to onset of reproductive senescence (see later).

2.2 Fertilization

Fertilization involves the penetration of the ovum, its surrounding layers of granulosa cells, and the acellular zona pellucida by the mature sperm in the upper reaches of the oviducts (Fig. 3.3) (26). Fertilization requires a mature sperm that has undergone *capacitation* during its traverse of the female reproductive tract. The events required in capacitation are not well understood, but require plasma membrane modifications, decreases in net negative surface charge, changes in lipid components, alterations in fluidity/mobility of membranes, increased ion permeability, and other internal modifications. In addition, the *acrosome reaction*, which may facilitate penetration of the granulosa cells, and *activated motility*, to allow penetration of the zona pellucida, occur. Factors that can alter capacitation, the acrosome reaction, or activated motility may all play a role in preventing normal fertilization (27).

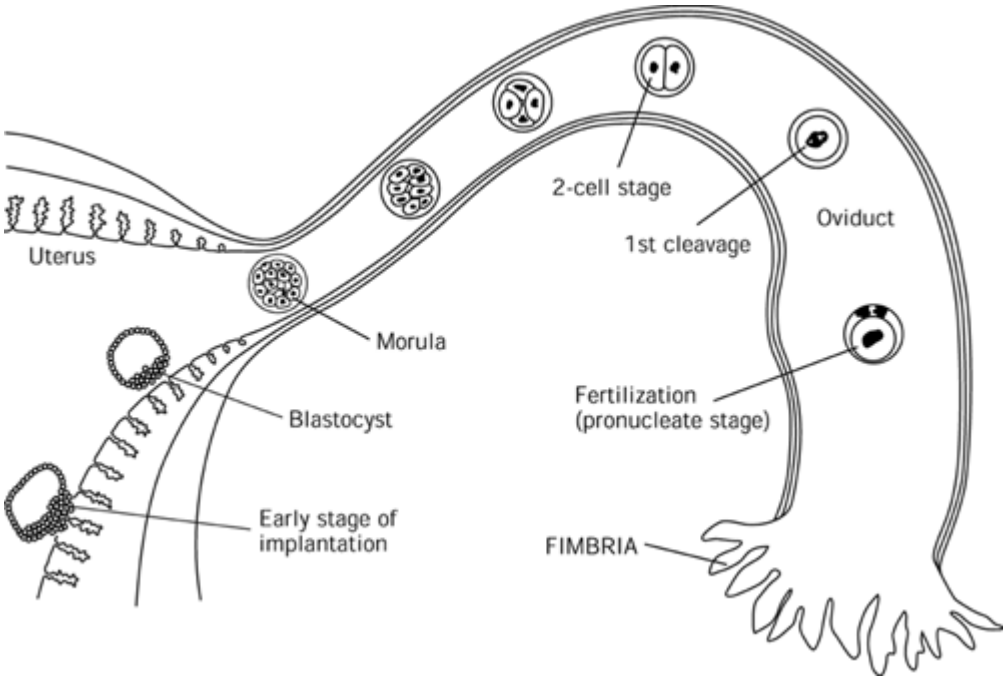

Figure 3.3. Development of the human embryo in the reproductive tract from fertilization to implantation (used with permission of Raven Press from Ref. 26, p. 47).

Several genetic aspects are determined at fertilization. First, the diploid number of chromosomes is restored when the male and female pronuclei fuse and chromosomes from the two become the chromosomal complement of the embyro. Second, by gaining genetic material from two different individuals, genetic diversity is maintained. Third, sex is determined at fertilization, in that a sperm bearing a Y chromosome results in a genetically male individual (XY zygote), whereas an X-bearing sperm results in a genetic female (XX zygote). Finally, fertilization stimulates rapid cell division or cleavage to form the embryo.

2.3 Female Reproduction

The female reproductive system involves the *ovaries, uterus, oviducts, cervix, vagina*, and *mammary glands*. The function of these is controlled by a carefully regulated interaction between the *hypothalmus*, the *anterior pituitary*, and the ovary. The hypothalmus secretes gonadotropin-releasing hormone (GnRH) which results in follicle stimulating hormone (FSH) and luteinizing hormone (LH) release from the anterior pituitary. A preovulatory surge of FSH and LH from the anterior pituitary stimulates differentiation of the granulosa cells and further meiotic division of the primary oocytes to a pre-ovulatory state (Fig. 3.4) (25).

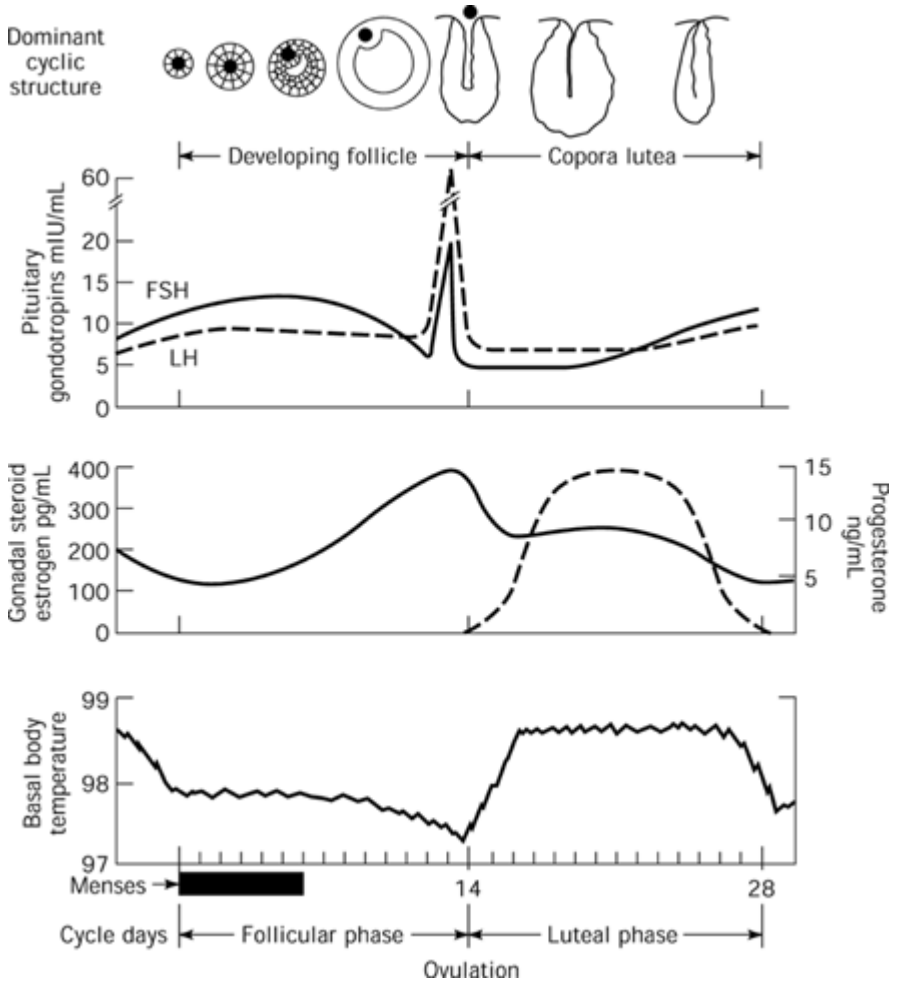

Figure 3.4. Endocrinology of the reproductive cycle in normal women. The dominant cycle structure, pituitary gonadotropins, gonadal steroids, and basal body temperature throughout the menstrual cycle are depicted. Note that in the follicular phase, the follicle enlarges as the serum estrogen rises. A midcycle gonadotropin surge heralds follicular rupture and release of the oocyte. Immediately after ovulation, the corpus luteum develops and secretes large amounts of progesterone with a resultant elevation in basal body temperature. In the absence of the conceptus, the luteal phase is 14 days long, and declining progesterone coincides with the onset of menses (used with permission of Raven Press from Ref. 25, p. 182).

The ovary is comprised of an outer cortex, which includes the *follicles*, and an inner medulla. The granulosa and thecal cells of the follicle secrete estrogen in a modulated fashion during the cycle and control secretion of FSH and LH through a negative feedback mechanism. As the estradiol level rises, it stimulates the release of LH and FSH, and possibly has direct effects on the LH releasing hormone (LHRH) which is released in a pulsatile fashion from the mediobasal hypothalamus. Once ovulation occurs, the follicle forms the corpus luteum, and progesterone is secreted, which stimulates the development of a secretory endometrium in the uterus in preparation for implantation. Progesterone secretion also causes an increase in basal body temperature. If fertilization occurs,

progesterone levels continue to rise. In humans, chorionic gonadotropin (hCG) secreted by the embryonic membranes is necessary to maintain the corpus luteum during early pregnancy. If fertilization does not occur, the ovum degenerates, and menses ensues.

Agents that interfere with the development of the reproductive system and the normal hormonal patterns necessary to regulate development may alter the intricate processes involved in a number of different ways. For example, the normal structure of the ovaries, uterus, oviducts, cervix, and vagina can be altered during development, resulting in interference with fertility and pregnancy. This was the case with the drug diethylstilbestrol (DES), a potent synthetic estrogen used in the 1950s and 1960s to prevent spontaneous abortion. Unfortunately, the drug was not effective in preventing labor but had profound effects on the development of the reproductive system in both boys and girls exposed before birth and produced a rare form of cancer (vaginal adenocarcinoma) in females not detected until after puberty (28). Synthetic androgens and antiandrogens also alter the structure of reproductive organs by interfering with the normal hormonal milieu during development. For example, ethinyl testosterone given to prevent spontaneous abortion resulted in masculinization (pseudohermaphrodism) of female offspring (29), and other androgenic compounds (e.g., danazole, methadriol, and methyltestosterone) prescribed for endometriosis, alopecia, hypotension, and other indications have shown similar effects. Because the endocrine activity of agents may be useful for their therapeutic value, it is sometimes difficult to separate pharmacological efficacy from toxicity. For example, raloxifene, a nonsteroidal selective estrogen receptor modulator (SERM) developed for treatment of postmenopausal osteoporosis acts as an estrogen in bone but functions in uterine tissue as a complete estrogen antagonist. Because estrogen is important in preparing for implantation, raloxifene was found, not unexpectedly, to cause delays in implantation (30); such effects have been seen with other compounds that are estrogen antagonists (reviewed in Ref. 30).

Mammary gland tissue is highly dependent on endocrine function. The mammary gland changes dramatically around the time of parturition as a result of a number of gonadal and extragonadal hormones. Milk letdown depends on suckling by the offspring, release of oxytocin from the posterior pituitary, and secretion of prolactin by the anterior pituitary. Agents that affect hormonal status, mammary gland development, and/or function may cause difficulties with milk production, milk quality, and indirectly result in adverse effects on offspring growth and development. Two neurotransmitters, dopamine and serotonin, play critical roles in the neuroendocrine modulation of prolactin secretion (31, 32), and prolactin is known to be mammotrophic and lactogenic, as well as luteotrophic and endometriotrophic (33, 34). Acute pharmacological doses of serotonin agonists stimulate prolactin release and enhance neonatal mouthing behavior, whereas acute doses of antagonists decrease these responses (35). It has long been known that bromocriptine, a preferential dopamine D_2 agonist, prevents postpartum onset of lactation in humans (36), inhibits established lactation in several species including rats (37), dogs (38), and humans (36, 39), and suppresses the suckling-induced secretion of prolactin in rats (40, 41).

Reproductive senescence occurs with advancing age, depletion of oocytes, and loss of normal ovarian cycling. As indicated earlier, agents that enhance atresia of oocytes may produce early depletion and untimely reproductive senescence. The long-term consequence of early menopause is an increased risk of a number of associated diseases, including heart disease and osteoporosis. Cigarette smoking has been shown to reduce the age at onset of menopause by as much as 2 years (42). In addition, Mattison and Thorgeirsson (43) showed that benzo[a]pyrene, which occurs in tobacco smoke, can kill oocytes in mice.

2.4 Male Reproduction

The male reproductive system is comprised of the *testis, accessory sex glands* (seminal vesicles, prostate, and bulbourethral or Cowper's glands), and the *duct system*. In rodents, there are two additional accessory sex glands, the coagulating glands and the preputial glands. The duct system is comprised of the *efferent ducts, epididymis* (consisting of three parts: head or caput epididymis, body or corpus epididymis, and tail or cauda epididymis), *ductus deferens*, and *ejaculatory duct*. A balanced interplay among the hypothalamus, anterior pituitary, and testis regulates the function of

the male reproductive system (Fig. 3.5) (44). As in the female, GnRH production by the hypothalmus permits release of FSH and LH by the anterior pituitary, which permits release of testosterone from the *Leydig cells*, and in turn is negatively regulated by increased levels of testosterone and dihydrotestosterone, the more active form of the androgen. Several important proteins are secreted by the *Sertoli cells*, including androgen-binding protein, activin which stimulates LH and FSH production by the pituitary, and inhibin and follistatin which have an inhibitory influence on the pituitary gonadotropins. Undernutrition, particularly a low protein diet (8% versus 27% in controls) started at weaning, can have a major impact on the development of the anterior pituitary–testicular axis and the feedback mechanism that controls gonadotropin secretion (45). Several antiandrogenic agents have been shown to interfere with normal development of the male reproductive system. For example, finasteride, a 5-alpha-reductase inhibitor, causes hypospadias in male offspring of rats exposed during pregnancy (46), and the most sensitive period for exposure was gestational days 16 and 17 in the rat (47). Several pesticides (e.g., vinclozolin and procymidone) are antiandrogenic and also cause hypospadias in male offspring (48–50).

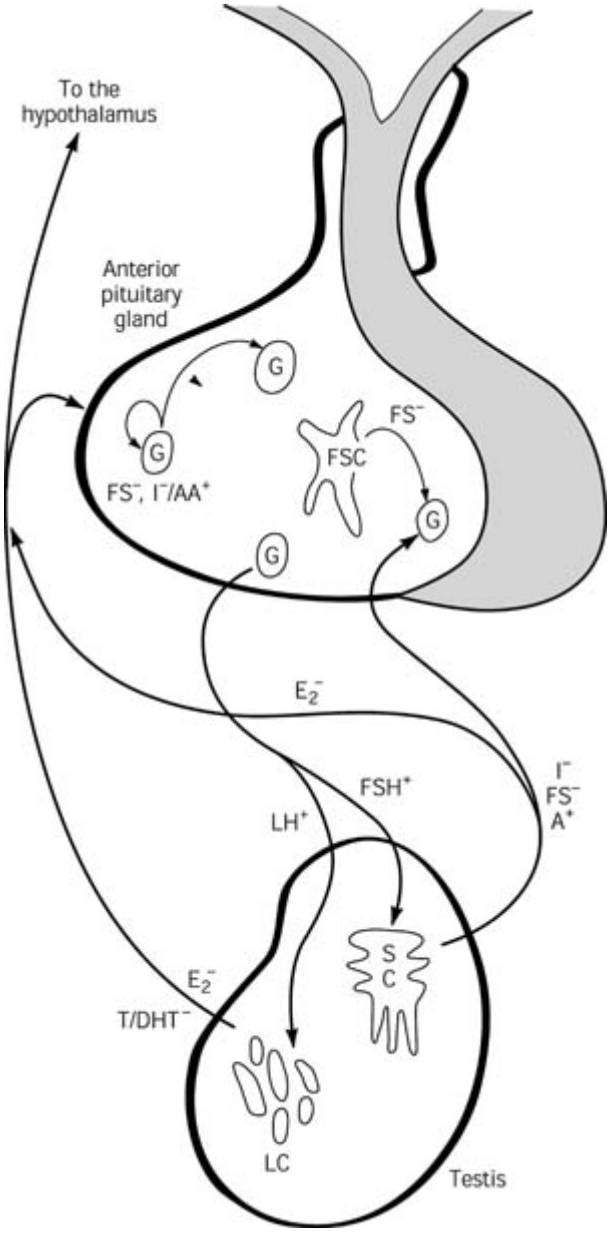

Figure 3.5. Diagram summarizing the anterior pituitary-testicular axis. LH and FSH are secreted by the gonadotrophs (G) to stimulate (+) either the Sertoli cells (SC) or Leydig cells (LC). These cells subsequently produce peptides [inhibin (I), follistatin (FS), and activin (A)] or sex steroid hormones [estradiol (E2), testosterone (T), or dihydrotestosterone (DHT)], which feed back principally at the

level of the anterior pituitary gland to regulate gonadotropin secretion. The modulatory role of these compounds is primarily inhibitory (–), although activin is known to stimulate FSH secretion. Autocrine/paracrine control over LH and FSH occurs at the level of the anterior pituitary gland via the peptides inhibin, follistatin, and activin, which are produced by the gonadotrophs and folliculostellate cells (FSC) (used with permission of Raven Press from Ref. 44, p. 6).

Approximately 90% of the testis is comprised of the *seminiferous tubules*, which are folded and refolded within the testis and contain the developing spermatozoa and Sertoli cells. The Sertoli cells extend from the basement membrane to the lumen of the seminiferous tubules and surround and support the developing germ cells. Tight junctions between the Sertoli cells near the basement membrane form the *blood-testis barrier*, which blocks access to the adluminal comparment. The interstitial tissue contains the Leydig cells (the primary source of testosterone), the vascular supply to the testis, and other cells. Testosterone is converted to dihydrotestosterone, the more active form of the androgen. Spermatogenesis takes place along the tubules in a wave form, so that cross sections of several tubules would reveal sperm in different stages of development. There are 14 distinct stages of development that have been identified in rats (51) (Fig. 3.6) (52), and six distinct stages have been described in humans (53). These stages can be used as a basis for determining the effect of an exogenous agent. A serial mating design can be used to identify site-specific lesions; this type of protocol involves mating males that have been exposed for a short time (5–7 days) with unexposed females for 4–5 day periods over several weeks. Cytosine arabinoside, a chemotherapeutic agent, caused reduced fertility 31 to 41 days post-exposure, indicating an effect on spermatogonia and early spermatocytes (22).

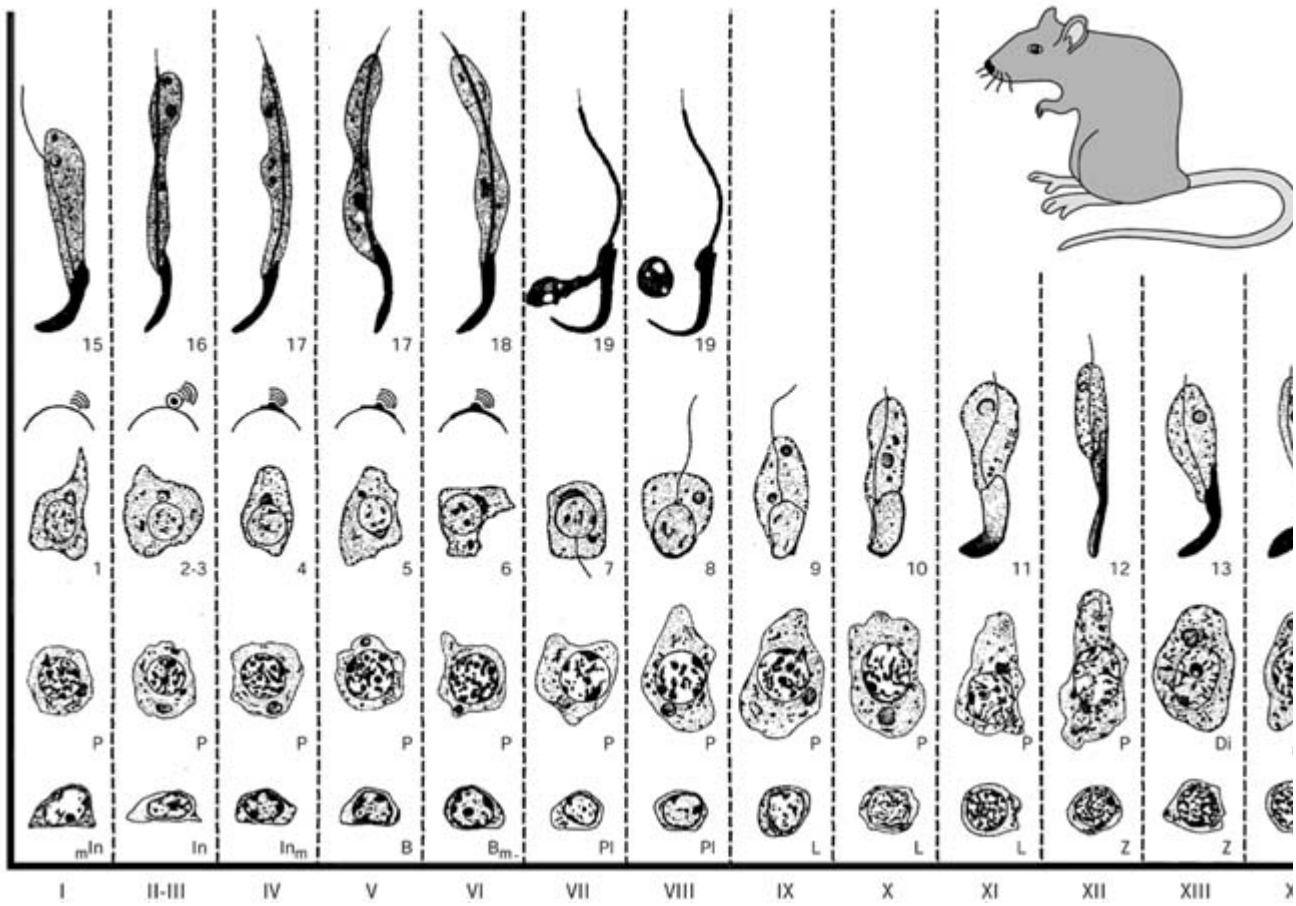

Figure 3.6. Cycle map of spermatogenesis for the rat. The vertical columns, designated by Roman numerals, depict cells associated with various stages. A cycle is a complete series of stages. The developmental progression of a cell is followed horizontally until the right hand border of the cycle map is reached and continues from left to right up the map, ending with spermiation (used with

permission of Cache River Press from Ref. 52, p. 43).

After sperm are released from the Sertoli cells into the lumen, they pass from the seminiferous tubules through the rete testis and efferent ducts into the epididymis, then through the ductus deferens and ejaculatory duct. The sperm undergo maturation in the epididymis and are stored there until ejaculation. The accessory sex glands contribute most of the volume to the semen, and their secretions may be involved in effective transport, survival, and function of the sperm through the female reproductive tract after ejaculation. The duct system and the accessory sex glands are androgen-dependent, and can be affected by agents that alter androgen levels (54).

2.5 Development

Development can be divided into the *prenatal* and *postnatal* periods. Prenatal development includes the *preimplantation* and *postimplantation* periods, and the latter encompasses the *embryonic* and *fetal* periods. Preimplantation is characterized by transport of the zygote from the upper ends of the oviduct into the uterine cavity during a period of 7–8 days in humans, or 5–6 days in rats or mice (Figure 3.3). Rapid cell division of the single-cell *zygote* (fertilized ovum) proceeds through the *morula* stage, a solid ball of approximately 16 cells, and further division results in a multicellular *blastocyst* that contains a cavity. The blastocyst implants in the uterine wall and develops into the definitive embryo. The embryo itself develops from a small group of cells in the blastocyst, the *inner cell mass.* The rest of the cells, the *extraembryonic cells*, form the *placenta* and surrounding membranes. Implantation occurs around gestational day (gd) 7 in humans, gd 5–6 in mice and rats, and gd 7 in rabbits. Agents that interfere with implantation result in apparent subfertility or infertility in humans. The type of effect produced on fertility can be determined in rodents by counting the number of corpora lutea (i.e., ovulated eggs) and the number of implantation sites in the uterine wall if there are enough viable implants to maintain active corpora lutea during pregnancy or if done early in gestation when there are no viable implants.

Placentation is a complex series of events that provides an intimate relationship between the embryonic and maternal tissues for the purpose of nutrition of the embryo and removal of wastes. Early on, before vascularization of the extraembryonic membranes and formation of the *chorioallantoic placenta*, the *yolk sac placenta* provides histiotrophic nutrition (breakdown and transfer of maternal macromolecules). The yolk sac placenta is the primary placenta in rodents through the early part of embryogenesis (when the early neural tube and limb buds are forming), and a gradual switchover to the chorioallantoic placenta occurs around gestation days 11–12 in the rat. In humans, the chorioallantoic placenta becomes functional around gestation day 21 when the neural tube is just beginning to form, an earlier embryonic stage than in rodents. Chorioallantoic placentation involves hemotrophic nutrition (transfer of nutrients via the circulation) and is somewhat different in different species, in that the number of maternal and embryonic layers differs. Although much has been made of these differences in terms of their role in placental transfer of toxicants, there is little evidence that these differences are important factors compared to maternal blood flow, plasma protein binding, molecular size and charge, placental metabolism, and the fetal elimination pathway. A more complete discussion of the morphology and function of the placenta can be found in embryology textbooks and excellent descriptions related to developmental toxicology are given by Beck (55), and Slikker and Miller (56).

Exposure to certain toxic agents during pregnancy may adversely affect placental function, which can in turn affect the developing embryo/fetus. Effects on the placenta may include alterations in blood flow and perfusion, metabolism, placental transfer of essential nutrients or compounds, and in extreme cases, may cause necrosis and separation from the uterine wall. Cadmium is an environmental contaminant associated with refineries, fossil fuel plants, and tobacco smoke and is a demonstrated placental toxicant in both rodents and humans (56). Although cadmium may cross the rodent yolk sac placenta very early in development and cause fetal malformations, it does not cross but accumulates in the chorioallantoic placenta. Adverse developmental effects, ranging from growth retardation to fetal death, observed following such accumulation result from placental dysfunction rather than direct actions on the embryo/fetus.

The embryonic inner cell mass forms a two-layered embryonic disc, consisting of *ectoderm* and *endoderm*. Around gestation day 17 in humans or gestation day 9 in rats, invagination of ectodermal cells occurs through a midline *primitive streak* to form the third intermediate layer of cells, the *mesoderm*. Figure 3.7 shows the major derivatives of each layer. The mesoderm cells form the viscera, blood vessels and cells, muscles, tendons, and bone. The endoderm forms the lining of the gut, respiratory system, thyroid, and pharynx. The ectoderm forms the surface layers of the body, including the skin, hair, and nails, enamel of the teeth, and the lens; a specialized portion of the ectoderm that forms along the edges of the primitive streak is the *neuroepithelium* consisting of the *neural tube* and the *neural crest cells*. The neural tube forms the brain and spinal cord, and the neural crest cells form the cranial and spinal ganglia and nerves, several components of the face and neck, the adrenal medulla, and contribute to the endocardial cushions that separate the chambers of the heart. Agents that interfere with the development and closure of the neural tube may result in anencephaly or spina bifida, and those that interfere with migration of neural crest cells to their ultimate site may result in craniofacial defects, cranial or spinal nerve defects, and/or cardiac septal defects. Retinoids, including excessive supplements of vitamin A or the drug Accutane (used in treating dermatologic disorders), interfere with neural crest cell migration, and both animals and children exposed during early development exhibit a number of these defects (57, 58). In addition, central nervous system malformations and a continuum of neurobehavioral disorders have been identified in animal fetuses and offspring and in children exposed early in pregnancy (59–64). Postnatal death, profound mental retardation, alterations in general learning ability, and other subtle behavioral alterations have been documented. These effects in animals and humans all depend on the dose and developmental stage at exposure, as well as the relative teratogenic potency of the individual retinoid (64).

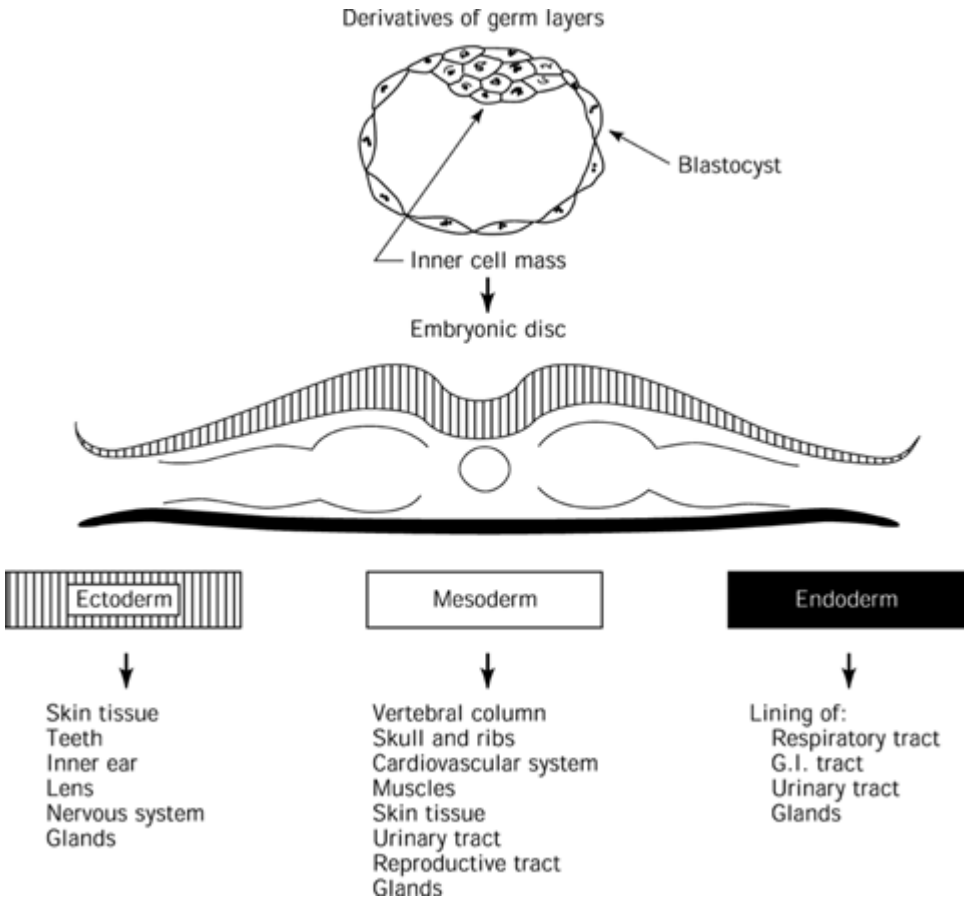

Figure 3.7. Derivatives of the germ layers in the mammalian embryo. Cells of the inner cell mass form the embryonic disc consisting initially of ectoderm and endoderm. During gastrulation, a mesodermal layer is formed in between the ectoderm and endoderm. The primary derivatives of the three germ layers are shown.

The period during which the major conformation of organ systems occurs, called *organogenesis*, encompasses the period from the primitive streak stage until palate closure (gestation days 6–15 in rats and mice, gestation days 17–57 in humans). The *fetal period* consists of the time after major organogenesis until birth, during which organization continues at the histological level in most organ systems.

There are a number of *critical periods* when cells or organ systems are particularly sensitive to exposure to toxic agents. Because of this, the manifestations of developmental toxicity vary depending on the timing of exposure. As examples, exposure before conception may cause chromosomal or DNA changes in germ cells that result in heritable effects, including death, malformations, growth retardation, functional deficits, or cancer in the offspring. During very early embryogenesis when cells are multiplying at a rapid rate and are relatively undifferentiated, exposure tends to result in death or compensation and continued normal development. For several genotoxic agents (e.g., ethylene oxide, ethylnitrosourea, ethyl methanesulfonate) (65–71), exposure during this period also results in malformations and growth retardation. As organogenesis begins, cells become more and more differentiated and the major structure of organs is formed, although not all organs develop at the same time or rate. Exposure during this period may cause major structural defects, as well as death, growth retardation, or postnatal functional changes. As major organ structure is completed, organization and differentiation at the histological, physiological, and biochemical levels proceed; in most mammals, these processes occur to varying extents during pre- and postnatal development. However, there are important differences at birth among experimental animal species and humans in the staging of developmental events that must be recognized in designing studies and interpreting experimental outcome data for potential human risk. Exposure during this late gestational or fetal period may result in alterations that are detected as histopathology, growth retardation, functional changes, or cancer. Subsequent stages of development include further growth and functional maturation of organs/systems, some of which are not completed until after puberty. Exposure during this period may affect the same target organs as in adults but have different consequences because of the immaturity of the target organ itself. Additionally, other immature organ systems may be targets, and relative sensitivities may be greater or lesser due to immaturity of processes responsible for metabolism and excretion of the chemical.

Less work has been done to discern the critical timing for exposure during the postnatal period, but there are examples of neonatal exposures and effects on the developing reproductive system (72–74), and developing nervous system (75). This is an area of current interest to provide adequate guidance for pediatric use of pharmaceuticals and also for environmental exposures that may affect children where they live and play. One area that has received attention recently is the significant increase in childhood asthma (76, 77). As a result, a number of studies are being pursued to discern genetic and/or environmental factors that may be involved or responsible both prenatally and postnatally.

Reproductive and Developmental Toxicology

3.0 Testing Procedures and Guidelines

Standard testing procedures have been used to identify reproductive toxicity since the mid-1950s. However, the first testing guidelines in the United States were not written until 1966 by the U.S. Food and Drug Administration (FDA) for testing the developmental effects (with particular emphasis on teratogenicity) of potential new pharmaceutical agents (78). In 1982, the FDA published testing guidelines (Redbook I) for food additives (79). The Organization for Economic Cooperation and Development (OECD) issued international testing guidelines in the early 1980s for reproductive and developmental toxicity of industrial chemicals (80, 81). In 1982, EPA published its first guidelines

for testing pesticides (82) and in 1985 for industrial chemicals (83).

During the last several years, many of these guidelines have been updated. The FDA participated as a member of the International Committee on Harmonization (ICH), which finalized a revised set of global testing guidelines for preclinical assessment of pharmaceuticals (84, 85). In 1993, the FDA published the draft Redbook II (86) and in 1997 clarified the approach to toxicity testing that had been outlined in Redbook I (79) based on level of concern. The 1997 publication is available at www.vcm.cfsan.fda.gov/~dms/opa-tg1.html. (site currently unavailable) The EPA has recently updated and expanded testing guidelines to include a more comprehensive evaluation of the reproductive toxicity of pesticides and industrial chemicals (87–89). The OECD guidelines are currently being revised. The most recent testing guidelines for pharmaceuticals and for pesticides and industrial chemicals are briefly described here.

3.1 Testing Pharmaceutical Agents for Reproductive Toxicity

Testing of potential new pharmaceuticals is conducted for three reasons: (1) to provide scientifically and ethically appropriate support for clinical trials, (2) to provide data used to establish exposure guidelines for worker safety, and (3) to provide information relevant to risk:benefit assessments in the product label for use by prescribing physicians. Before international acceptance of the ICH testing guidelines (84), preclinical testing for reproductive and developmental toxicity was conducted following different guidelines for U.S., European, or Japanese registration of a new pharmaceutical (90, 91). Harmonization has not altered the overall requirements to evaluate reproductive and developmental outcomes following parental exposure before mating and during pregnancy and lactation, and assessment of effects on the entire parental reproductive process. However, it has reduced testing redundancy and provided the flexibility necessary to design studies most appropriate for assessing the toxicity of individual compounds. Exposure periods, dose selection, and end points evaluated within these studies are chosen based on the following: (1) pharmacology of the compound; (2) the plan for clinical trials, including duration of treatment; (3) known or expected toxicity of the therapeutic class; and (4) the target medical condition and therapeutic population(s).

Preclinical reproductive and developmental studies traditionally have been designated as Segment I, Segment II, and/or Segment III studies based on timing of initiation and duration of parental exposure (Fig. 3.8). These studies are routinely conducted in rodents, although a second Segment II study in a nonrodent species, most often the rabbit, usually is required. Segment I studies are intended to evaluate estrous cycling, mating, testicular and sperm parameters, fertility parameters, and early embryonic development; parental treatment begins before mating (generally 2 weeks for females, 4 weeks for males) and continues in females through implantation (gd 5 or 6). Segment II studies are intended to evaluate embryo and organ development; maternal treatment is initiated once implantation has occurred (gd 6 in rodents, gd 7 in rabbits) and continues throughout the period of major organogenesis (to gd 15 in mice, gd 15–17 in rats, and gd 18–19 in rabbits). Segment III studies are intended to evaluate maternal processes of parturition and lactation, as well as fetal and offspring development through sexual maturity; maternal treatment begins at the end of organogenesis and continues through to weaning of the offspring (usually postpartum day 21 in rodents).

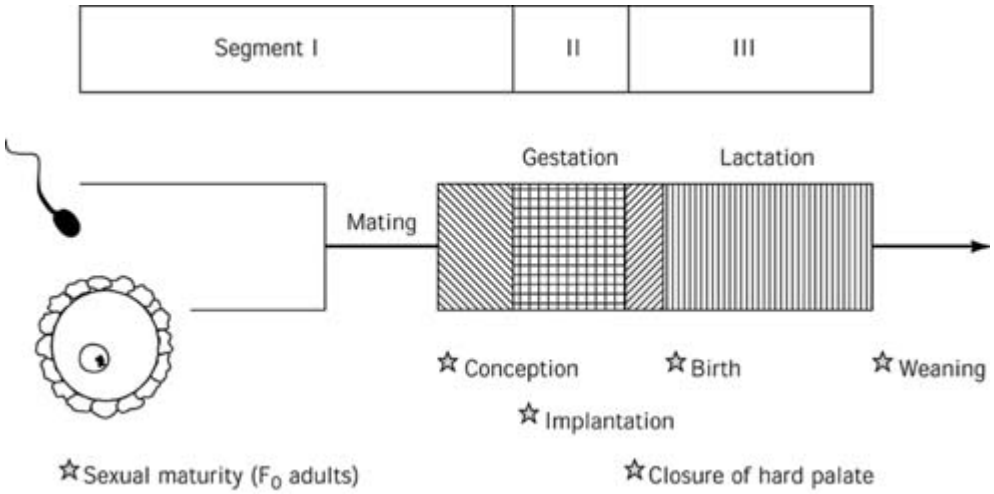

Figure 3.8. Exposure conventions for reproductive and developmental toxicity testing of pharmaceuticals. The Segment I, II, and III designations for these studies refer primarily to the reproductive and developmental events that occur during the discrete parental treatment period. The parameters monitored in any single-Segment or combined-Segment study may include relevant end points which are measured during and/or following the treatment period (diagram developed by J. A. Hoyt and J. Buelke-Sam, included with permission).

Currently, four studies are usually conducted for the majority of potential new pharmaceuticals: a Segment I study in treated male and female rodents; Segment II studies in rodents and rabbits; and a combined Segment II/III study in rodents which includes postnatal assessments of growth, physical development, and behavioral and reproductive performance of the offspring.

However, alternative exposure periods may be more appropriate to assess individual agents. These alternatives may include additional exposure period combinations (e.g., a combined Segment I/II study in rodents for compounds with no anticipated effects on mating and fertility and a single rodent combined Segment I/II/III study for compounds with no expected reproductive or developmental toxicity and anticipated long-term clinical exposures) (92). Other alternatives include more discrete exposure periods (e.g., gd 0–5 of pregnancy for agents that have anticipated adverse effects on implantation processes) (30). The standard reproductive and developmental assessments in these studies may be supplemented with any additional outcome parameters deemed appropriate for individual agents, based on considerations listed before (e.g., progressive histopathological evaluations or functional assessments of suspected target organs or systems) (93).

An additional component of these studies involves determining maternal blood levels and/or toxicokinetic parameters. Most often, such determinations are made within the Segment II exposure period but also may be applicable to other segments. These data allow a more direct comparison of maternal animal and human exposures and may also aid in interpreting reproductive outcome. Maternal blood level data are particularly valuable in verifying that maternal exposure did occur for studies in which no adverse maternal or developmental findings were seen. Placental transfer studies or milk excretion studies also may be conducted to determine embryo/fetal or neonatal exposures more directly.

Another aspect of testing is providing adequate preclinical support for pediatric testing and guidance in the product label for using many pharmaceuticals in the pediatric population (94, 95). Only 20% of the pharmaceutical products currently marketed in the United States include labeling information on safety and effectiveness in infants or children. The ICH guidelines (84) indicate that additional studies involving direct treatment of neonatal and young animals may be necessary to support pediatric clinical trials, in addition to appropriate repeated-dose toxicity studies, standard genotoxicity studies, a complete reproductive and developmental toxicity package (Segments I, II

and III studies), as well as safety data from previous adult human trials. The FDA (95) has defined four human age categories of concern: infant, neonate, child, and adolescent. Table 3.1 provides a general comparison for these categories in humans and several test species, although the comparable age ranges in these species vary depending on the developmental schedules of individual organs or systems. The need for preclinical juvenile studies, the test species for such studies, age categories to be covered, duration of exposure(s), as well as the parameters and ages for assessment of effects within any particular study, are currently being determined compound by compound.

Table 3.1. Comparative Age Categories

Category	Rat (days)	Mini-Pig (weeks)	Dog (weeks)	Primate (months)	Human (years)
Neonate	<10	<2	<3	<0.5	<1 month
Infant	10–21	2–4	3–6	0.5–6	1–2 months
Child	21–30	4–14	6–20	6–36	2–12
Adolescent	30–60	14–26	20–28	36–48	12–18

3.2 Testing Pesticides and Industrial Chemicals for Reproductive Toxicity

Several testing protocols are used to evaluate the reproductive toxicity of pesticides and industrial chemicals. The EPA testing guidelines published in 1998 were harmonized for pesticides and industrial chemicals, so that there are no differences in the testing protocols themselves. The requirements for pesticide testing specifically defined in 40 CFR Part 158. 340 Subpart F include reproductive and developmental toxicity testing for all food-use pesticides or those for which a reference dose (RfD) will be set. For industrial chemicals regulated under the Toxic Substances Control Act, the process involves defining the appropriate tests to be done according to the testing guidelines in test rules for specific chemicals, or testing approaches may be developed under consent agreements with industry for specific chemicals.

In general, the testing guidelines for pesticides and industrial chemicals are more specifically defined than those for pharmaceuticals in terms of number of animals, days of treatment, outcomes, and the methods for measuring them, and reporting of data. There are three major protocols used for pesticide and industrial chemical testing of reproductive and developmental toxicity. These include the prenatal developmental toxicity study, the two-generation reproduction study, and the developmental neurotoxicity study (87–89). These guidelines are available at http://www.epa.gov/docs/OPPTS_Harmonized_870_Health_Effects_Test_Guidelines/Series/. The developmental neurotoxicity study has not been routinely required for most pesticides and industrial chemicals, as discussed futher later. Data from adult toxicity studies are reviewed to determine which target organs might be of concern and whether additional testing of other organ systems may be appropriate, for example, immunotoxicity evaluations in developing animals or perinatal carcinogenic testing.

The prenatal developmental toxicity study (Fig. 3.9) (87) involves exposure of time-mated animals (usually rats and rabbits) to an agent throughout pregnancy or at least from implantation (around gd 6) to the day before parturition (gd 20 in rats, 28–29 in rabbits). Clinical signs and body weights throughout the dosing period are recorded for maternal animals, which are then killed on the day before parturition and examined for gross pathology. Fetuses are harvested from the pregnant uterus, weighed, and examined for external, visceral, and skeletal defects. In addition, the number of implantations and incidence of resorptions or fetal deaths are recorded.

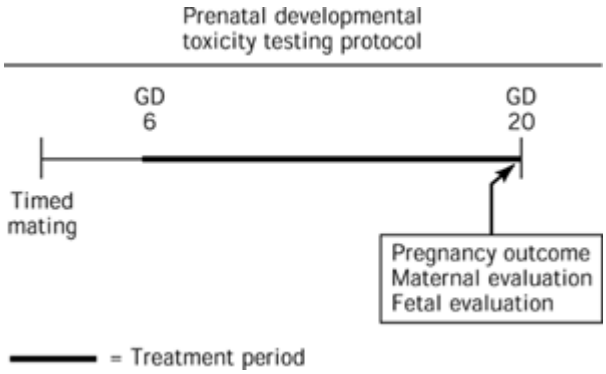

Figure 3.9. Schematic of the prenatal developmental toxicity testing protocol (87). The treatment period is shown by the heavy black line. GD = gestation day; the numbers shown refer to the days of gestation in the rat. Treatment begins on GD 6 around the time of implantation or can be started as soon as animals are mated. The protocol can be conducted in other species with appropriate adjustment of treatment times.

The developmental neurotoxicity study (Fig. 3.10) (89) is currently triggered based on observing malformations of the central nervous system in the prenatal developmental toxicity study, adult neurotoxicity/neuropathology, alterations in brain weight in the two-generation study, or other indicators of potential developmental neurotoxicity, for example, evidence that an agent may cause hormonal effects. A recent evaluation of the literature on developmental neurotoxicity concluded that this study should be conducted as a standard part of reproductive toxicity testing because such triggers may not be inclusive enough to indicate all chemicals that may cause such effects (96). This study can be done as a separate study, in conjunction with the prenatal developmental toxicity study, or preferably with the two-generation reproduction study in the second generation. As a stand-alone study, time-mated pregnant animals (usually rats) are dosed from gd 6 at least through postnatal day (PND) 10 or to weaning. Pups are weighed at various postnatal ages and examined for clinical signs, and several developmental landmarks (e.g., vaginal opening, preputial separation), as well as several behaviors, are evaluated. These include motor activity at PND 13, 17, 21, and 60, auditory startle habituation at weaning and at PND 60, and learning and memory at weaning and around PND 60. Brain weights are recorded from pups killed on PND 11 and at termination of the study neuropathology including a simple morphometric analysis is done.

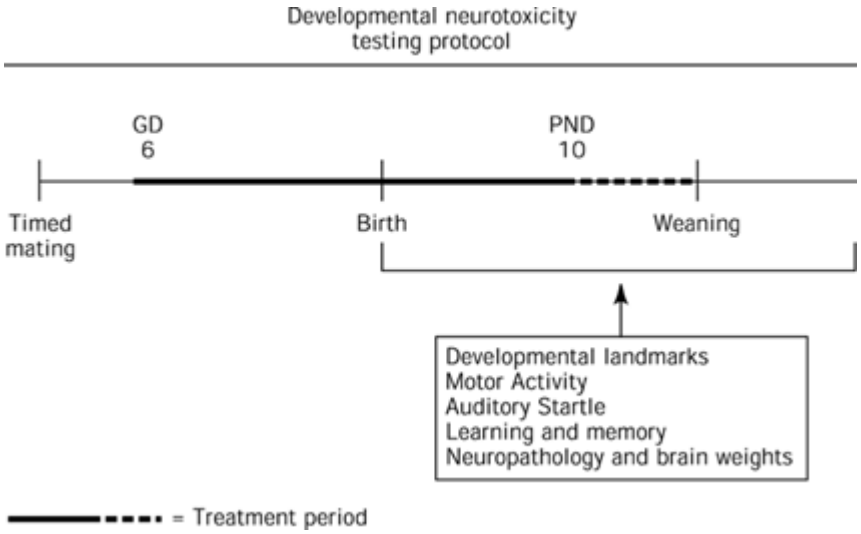

Figure 3.10. Schematic of the developmental neurotoxicity testing protocol (89). The treatment period is shown by the heavy black line, although treatment is currently being extended to weaning in some cases (dashed line). GD = gestational day, PND = postnatal day. This study is typically done in rats but can be conducted in other species. The study can be conducted as a stand-alone protocol

or can be done in conjunction with a prenatal developmental toxicity study or a two-generation reproductive study.

The two-generation reproduction study (Fig. 3.11) (88) involves exposing the parental (P) male and female animals (usually rats) for 10 weeks before mating, through the mating period, and to females during pregnancy. Exposure continues to the lactating females postpartum and to selected F1 males and females for 10 weeks after weaning. F1 males and females are mated and exposure continues to the F1 females during pregnancy and lactation. A second litter may be obtained in each generation for additional studies; for example, a standard fetal examination similar to that done in the prenatal developmental toxicity study may be conducted or the developmental neurotoxicity study may be conducted on a second F2 litter. A number of end points of reproductive toxicity are evaluated in this study. For example, estrous cyclicity is evaluated for three weeks in the P and F1 females before and throughout mating, and semen quality (sperm number, motility, and morphology) is evaluated in the P and F1 males before mating. Reproductive development is evaluated in the F1 and F2 offspring by observing the age at vaginal opening and preputial separation. If there is a treatment-related effect in the F1 sex ratio or sexual maturation, the anogenital distance is measured in F2 pups at birth. Reproductive organs, as well as other potential target organs, from animals in each generation are weighed and examined histologically. In addition, brain, spleen, and thymus weights are recorded for F1 and F2 pups terminated at weaning.

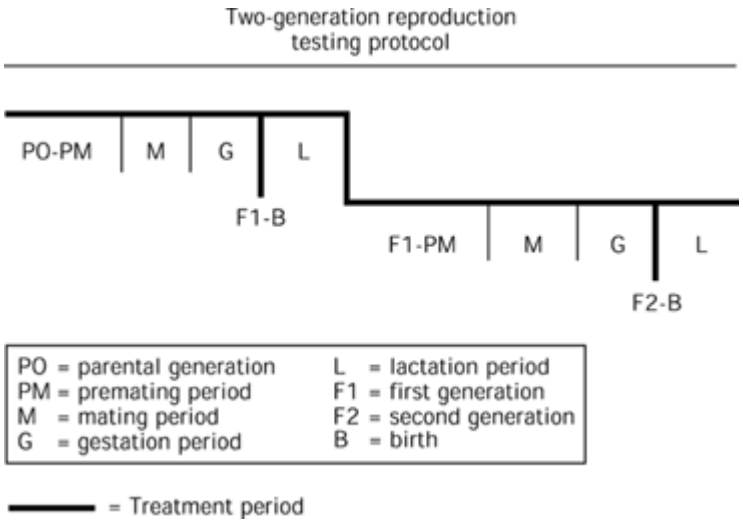

Figure 3.11. Schematic of the two-generation reproduction testing protocol (88). The treatment period is shown by the heavy black line. Males and females are exposed for 10 weeks before mating, and females are continued through gestation and lactation. F1 offspring continue treatment until they are old enough to be mated, and treatment continues through gestation and lactation.

3.3 Other Reproductive Toxicity Testing Procedures

Additional studies may also be used to determine the potential for reproductive toxicity of a drug or chemical. For example, Chapin (97) and Morrissey et al. (98) described the addition of improved testicular histopathology and assessment of estrous cyclicity and sperm quality to standard subchronic testing studies. Such data can provide valuable information on reproductive effects that can then be followed up in further reproductive toxicity testing studies.

The single mating trial, modified from the original FDA two-litter test (90), provides a basic test of fertility and reproductive function. In this type of study, a single mating occurs after a 60–70 day exposure period for males and a 14-day exposure period for females. The longer period of exposure in males is to ensure exposure to all stages of the spermatogenic cycle. If the only effects seen are those on fertility or pregnancy outcome, the contribution of male- or female-specific effects cannot be determined. If estrous cyclicity and ovarian/reproductive tract histopathology are included in

females and sperm measures and reproductive tract histopathology in males, the contribution of an effect of an agent on either gender may be characterized. However, there may still be questions as to which sex is affected. For this reason, some laboratories run separate studies in which only one gender is treated to characterize any gender-specific effects.

The continuous breeding protocol, also known as the Fertility (or Reproductive) Assessment by Continuous Breeding (FACB or RACB), was developed by the National Toxicology Program (99). This protocol was based on an older protocol used to determine full reproductive capacity in which females were mated repeatedly to determine how many litters and offspring they could produce. The RACB, as currently designed, can be conducted in mice or rats and involves dosing before mating and through several pregnancies over a 14-week period. Offspring are removed shortly after birth, counted and examined for viability, litter and/or pup weight, sex, and external abnormalities, and then discarded. Up to five litters can be produced during a 14-week period, and the number of litters, pups, and spacing of litters are recorded. The last litter may remain with the dam until weaning to study the effects of prenatal, as well as postnatal exposures, and to raise for production of an F2 litter. If effects are observed in the parental and F1 animals, crossover matings may be conducted between the treated and control animals (treated females with control males, treated males with control females), to define the affected gender and the site of toxicity. In addition, sperm measures (number, motility, and morphology) and vaginal smear cytology to detect changes in estrous cyclicity can be added at the end of the mating trial and used to detect changes (100, 101). This testing approach allows observing the timing of the onset of effects on fertility, as well as the ability to detect subfertility with measures of number of litters, litter spacing, and litter size.

Gray et al. (102) also proposed a test protocol (the Alternate Reproductive Test—ART) that includes many of the advantages of the RACB, but in addition monitors morphological and physiological changes associated with puberty in the F1 animals, making it useful for detecting compounds that have hormonally mediated effects on reproductive function. Chapin et al. (103) developed a protocol for evaluating several adult functional outcomes following perinatal and juvenile exposures.

Other protocols have been developed to screen and set priorities for further testing. In particular, the Reproductive/Developmental Toxicity Screening Test, which is part of the Screening Information Data Set (SIDS) protocol developed by the Organization for Economic Cooperation and Development (104), was developed to screen a large number of commercial industrial chemicals that have not been tested for potential toxicity. This protocol involves exposing a small number of males and females (8/dose group) during the premating, pregnancy, and lactation periods and then determining any effects on fertility, pregnancy outcome, and sperm measures. This protocol may be combined with the repeated dose toxicity study (105). An effect in this protocol raises concerns about the toxicity of a chemical, but lack of an effect cannot be interpreted as no effect because of the relative insensitivity of the testing protocol.

3.4 Tests of Germ Cell Toxicity

Tests of germ cell toxicity are important for assessing reproductive toxicity, because effects on fertility and pregnancy outcome are often the result. Two types of assays are generally used: measurements of heritable damage (e.g, the dominant lethal test, the specific locus test, and the heritable translocation assay) and measurements of effects in germ cells that may be related to alteration of DNA but may not actually represent heritable damage (e.g., DNA damage and/or repair, chromosomal abnormalities, and abnormal sperm morphology).

The male dominant lethal test was designed to detect the mutagenic effects of agents on the spermatogenic process that are lethal to offspring. It may be conducted in one of two ways: (1) exposure of males for a few days to one week, then mating with one or more females per week for the duration of the spermatogenic cycle; or (2) exposure of males for 10 weeks, then mating to one or more females immediately after exposure. In either case, a decrease in the number of implantation sites, the number of live fetuses, and/or an increase in the number of resorptions at necropsy 15–18 days later indicate a genotoxic effect. This type of testing paradigm can be expanded to follow animals to term and postnatally for longer term effects of male germ cell toxicity. For example,

Anderson et al. (106, 107) conducted dominant lethal studies of 1,3-butadiene in which one-half the pregnant animals were killed on gestation day 17, the other half were allowed to litter, and the pups were followed for 75 weeks to determine viability, growth, and tumorigenicity. A similar exposure and mating protocol was used to characterize male-mediated alterations in the postnatal function of surviving offspring after paternal treatment with drugs and chemical agents (108).

4.0 Risk Assessment

Risk assessment for reproductive and developmental toxicity has developed during the past 20 years and is currently a focus for a number of efforts in research and development, as well as in the regulatory setting. The focus by several regulatory and funding agencies on children's environmental health issues in the 1990s has heightened the awareness of special concerns involving pre- and postnatal exposures and effects. For example, the Food Quality Protection Act (FQPA) of 1996 which updated the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA) for regulating pesticides focused much greater attention on children's exposures to and the potential health effects of pesticides. Also in 1996, a Presidential Executive Order (No. 13045) was issued that requires Federal agencies to make it a high priority to identify and assess environmental health risks and safety risks that may disproportionately affect children and ensure that agency policies, programs, activities and standards address disproportionate risk to children. Another major law affecting children was the Food and Drug Administration Modernization Act of 1997, requiring the FDA to provide a list of approved drugs for which additional pediatric information may produce health benefits in the pediatric population and, for certain new products, requires sufficient data and information to support directions for pediatric use for the claimed indications.

The U.S. Environmental Protection Agency published Guidelines for Developmental Toxicity Risk Assessment in 1991 (109), Reproductive Toxicity Risk Assessment in 1996 (110), and Neurotoxicity Risk Assessment in 1998 (111). These detailed guidelines describe a process for evaluating data and setting reference values for reproductive and developmental effects resulting from environmental exposures. No other similar risk assessment guidelines have been published by U.S. federal regulatory agencies. Recently, the Food and Drug Administration's Center for Drug Evaluation and Research made available for public comment two draft documents that discuss the evaluation of human pregnancy outcome data (available at http://www.fda.gov/cder/guidance/2377dft.pdf) and the evaluation of animal data for reproductive toxicity (available at http://www.fda.gov/cder/meeting/advcomm/paper.pdf). All of these guidance documents include many of the same principles as those in the EPA guidelines but are written for the specific regulatory mandate of each agency.

The EPA guidelines were based on the risk assessment paradigm outlined by the National Research Council (112). The process described by the NRC is comprised of four components, the first two are *hazard identification* and *dose–response assessment*. These two parts of the process constitute the toxicological evaluation that is aimed at characterizing the sufficiency and strength of the available toxicity data and may indicate a level of confidence in the data. Dose–response modeling may be included, if data are sufficient. Another component, *exposure assessment*, derives estimates of potential human exposure based on various environmental and/or occupational scenarios. The integration of human and animal data with the exposure assessment is termed *risk characterization* and constitutes the final step in the risk assessment process. Risk characterization is used along with social, economic, engineering and other factors in weighing alternative regulatory options and in making regulatory and public health decisions. This latter process, called risk management, is purposely separated from the scientific evaluation (i.e., risk assessment) to allow full evaluation of the scientific data without bias from other nonscientific influences.

5.0 Summary

This chapter provides a brief overview of normal reproduction and development, as well as examples of how toxic agents may impact these processes. It summarizes the types of studies conducted and data collected as part of routine toxicity testing. Assumptions that must be made in the risk assessment process and an evaluation of data from both animal and human studies used in this process are discussed. The integration of hazard data (both animal and human) and dose–response information is described, and exposure estimates in the final characterization of risk are summarized. Advances have been made in our understanding of reproductive and developmental toxicity, particularly as the integration of molecular biology and toxicology has grown. However, there are still many gaps in our knowledge of both normal and abnormal reproductive and developmental processes. Further research will continue to fill these gaps and enhance our ability to identify more specific susceptible events in these processes and ultimately reduce adverse reproductive and developmental outcomes due to chemical exposures.

The views expressed in this chapter are those of the authors and do not necessarily reflect the views or policies of the U.S. Environmental Protection Agency. Mention of trade names of commercial products does not constitute endorsement or recommendation for use.

Occupational Chemical Carcinogenesis
Ronald L. Melnick, Ph.D.

1.0 Introduction

1.1 General Concepts of Multistage Carcinogenesis

Cancer is not a single disease, but rather is a general term applied to a multitude of diseases and stages of disease, each of clonal origin, that elicit uncontrollable tissue growth. There are more than 100 different types of cancer. In normal tissue the balance between cell reproduction and cell death determines the ultimate size of an organ. This balance is clearly represented after partial hepatectomy where, following removal of as much as two-thirds of the liver, regeneration results in restoration of the liver to its original size. If a normal cell incurs a defect in its growth regulating processes and acquires a growth advantage over other cells in a particular tissue or organ, it may multiply out of control producing a mass of altered cells; this abnormal overgrowth of new tissue is called a tumor or neoplasm.

The multistep process of carcinogenesis is thought to involve at least four stages (1): (1) initiation—the induction of a heritable change in a cell resulting from DNA damage (from endogenous processes or by a DNA reactive environmental agent or its metabolites) that can lead to point mutations, insertions, deletions, or chromosomal aberrations; (2) promotion—the clonal expansion of the initiated cell population; (3) progression—the process whereby benign neoplasms become malignant, as a consequence of increased genomic instability in neoplastic cells that gives rise to additional genetic alterations (i.e., mutations, chromosomal deletions, and/or rearrangements), and (4) metastasis—the spread of cancerous cells to other parts of the body. With increasing knowledge of the number of genes altered in human cancers, it is evident that even a four-stage model is not adequate to describe the carcinogenic process (2).

Two groups of genes control normal tissue growth; protooncogenes promote growth while suppressor genes halt growth. Normal protooncogenes of which there are 300–400 within the human genome regulate cell division and differentiation (3). If a protooncogene is mutated it may become an activated oncogene that causes the normal regulated cycling pattern of the affected cell to proceed out of control. Similarly a mutation in a suppressor gene may damage the growth-halting program of the cell and thereby allow unabated cell division. *p53* is the most commonly found mutated tumor suppressor gene in human cancers. The proliferating mass of altered cells may undergo additional changes during the progression stage that allow these cells to metastasize, that is, escape from their site of origin and invade surrounding tissues or remote organs of the body. The abnormal cells of a benign tumor become malignant (i.e., cancerous) when they acquire additional genetic changes that enable them to invade and destroy adjacent normal tissue or to metastasize to distant sites. Thus, the cancer cell is one that has lost the ability to respond to signals to differentiate into specialized cells, stop dividing, or even die. Carcinogenesis is the multistep process that leads to the production of cancers or malignant neoplasms that elicit uncontrollable growth and dissemination.

Most tumors are defined by their cell of origin and their behavior or appearance. Benign neoplasms of epithelial origin are referred to as adenomas or papillomas, and benign neoplasms of mesenchymal origin are referred to as fibromas, osteoma, gliomas, etc. Malignant tumors of epithelial cells are carcinomas, and malignant tumors of mesenchymal tissues are sarcomas.

Environmental insults, including ionizing or UV radiation, certain viruses, or various chemical agents can cause genetic damage that converts protooncogenes to oncogenes or inactivates tumor suppressor genes. Genes involved in regulating cell division, differentiation, adaptive responses, signal transduction, and programmed cell death could be adversely affected by exposure to certain chemicals. Thus, environmental pollutants can pose a persistent cancer risk, especially to workers who may be exposed to higher levels of these agents than the general population. The simplest definition of a carcinogen is an agent that can cause cancer. However, identifying an agent as a human carcinogen and assessing human risk associated with environmental or occupational exposure is complicated because of the multitude of factors that must be considered: the induction of benign or malignant neoplasms, animal-to-human extrapolations, the influence of mechanistic information on low-dose risk, and the variability in susceptibility among individuals in an exposed population.

Tumor induction by occupational chemicals is a multistep process that may involve activation of the compound to a DNA reactive form, binding of the active metabolite (or parent compound, e.g., ethylene oxide) to DNA forming a DNA adduct, faulty repair of the adduct leading to a gene mutation, replication of the altered cell to fix the mutation in the genome, and further genetic alterations (including gene mutations, gene rearrangements and gene or chromosome deletions) that lead to progression to a metastatic cancer. Alternatively, some chemicals or their metabolites may act by “nongenotoxic” mechanisms whereby normal cell cycling patterns are disregulated as a consequence of altered gene expression, perhaps through receptor mediated processes (4). In this case, changes in cellular function occur without the chemical producing a direct effect on the normal DNA base sequence. Impacting on these considerations is the recognition that humans are exposed to a multitude of chemicals that have mixed mechanisms of action, and humans vary considerably more than inbred or outbred laboratory animals with respect to genetic factors that influence cancer

susceptibility. Thus, the predicted effect of a single agent may be affected by the mechanism of tumor induction, genetic differences among individuals, health status, and other exposure circumstances.

The first issue in cancer hazard identification is to determine whether exposure to a particular agent can cause a carcinogenic response. Hueper and Conway (5) defined carcinogens as "chemical, physical and parasitic agents of natural and man-made origin which are capable under proper conditions of exposure, of producing cancers in animals, including man, in one or several organs and tissues, regardless of the route of exposure and the dose and physical state of the agent used." Similarly, an Interdisciplinary Panel on Carcinogenicity (6) stated that "the carcinogenicity of a substance in animals is established when administration in adequately designed and conducted experiments results in an increase in the incidence of one or more types of malignant (or, where appropriate, a combination of benign and malignant) neoplasms in treated animals as compared to untreated animals maintained under identical conditions except for exposure to the test compound." In addition to causing an increase in incidence of tumors in treated animals versus controls, a chemical may be considered carcinogenic if it causes tumors earlier in treated animals than in controls or if it causes an increase in the number of tumors per organ (i.e., tumor multiplicity).

Concerning the issue of whether benign neoplasms are indicators of human risk, the National Cancer Advisory Board (7) stated that "benign neoplasms may endanger the life of the host by a variety of mechanisms including hemorrhage, encroachment on a vital organ, or unregulated hormone production" and that "benign neoplasms may represent a stage in the evolution of a malignant neoplasm and in other cases may be 'end points' which do not undergo transition to malignant neoplasms." A similar view was given by an Interdisciplinary Panel on Carcinogenicity (6) and by the Office of Science and Technology Policy (8) which reported that "truly benign tumors in rodents are rare and that most tumors diagnosed as benign really represent a stage in the progression to malignancy." Furthermore, it is not yet known whether benign neoplasms in rodents correspond to benign or malignant neoplasms in other species, including humans. Accordingly, chemically induced benign neoplasms in rodents should be considered important indicators of a chemical's carcinogenic activity, and they should continue to be made an integral part of the overall weight-of-the-evidence evaluation process for identifying potential human carcinogens (9).

The identification of an agent as a carcinogen is based on information from epidemiological studies, experimental animal studies, *in vitro* evaluations, and assessments of mechanistic data and structure–activity relationships. Data from these sources have shown that carcinogens may act by very different mechanisms (e.g., direct acting or requiring metabolic activation; genotoxic or nongenotoxic) and that carcinogens are not equal in their potential to cause human cancer. In addition, most carcinogens operate by a combination of mechanisms that may vary in different target tissues (2). Consequently, there has been much debate on the identification of human carcinogens and in particular on the characterization of human risk associated with exposure to such agents. The term "risk" is used in this chapter to indicate the probability of developing cancer from a particular exposure. Because most known human carcinogens are also carcinogenic in animals when adequately tested, the International Agency for Research on Cancer (10) considers that unless there is convincing data in humans to the contrary, "it is biologically plausible and prudent to regard agents and mixtures for which there is sufficient evidence of carcinogenicity in experimental animals as if they presented a carcinogenic risk to humans."

Individuals may respond differently to similar exposures to a particular carcinogen. The likelihood of an individual developing cancer in an exposed population depends on extrinsic factors including the intensity, route, frequency, and duration of exposure, as well as on host factors including age, sex, health, nutritional status, and inherited characteristics. Hence, this chapter reviews issues related to the identification of carcinogens and factors that influence human risk. We also provide an update on agents that have been identified as "known" human carcinogens or "probable/reasonably anticipated" human carcinogens by IARC and the National Toxicology Program (NTP), as well as exposure standards developed by the Occupational Safety and Health Administration (OSHA) to

reduce worker exposure to these agents.

1.2 U.S. Occupational Safety and Health Laws Related to Risks from Exposures to Hazardous Substances

During the past 30 years, several laws have been promulgated to protect workers from the harmful effects of hazardous agents in the workplace (11). The Occupational Safety and Health Act of 1970, administered by OSHA, includes the following: (1) requires employers to provide safe working conditions for their employees, (2) prescribes mandatory occupational safety and health standards including exposure limits for toxic chemicals, (3) requires assessment of chemical hazards and notification to workers of their exposure to such hazards, and (4) establishes the National Institute for Occupational Safety and Health (NIOSH) "to develop and establish recommended safety and health standards." The Act authorized OSHA to promulgate occupational safety and health standards for toxic materials that ensure "to the extent feasible, on the basis of the best available evidence, that no employee will suffer material impairment of health or functional capacity even if such employee has regular exposure to the hazard dealt with by such standard for the period of his working life."

Based on the belief that any exposure to a carcinogen is not safe, OSHA interpreted the Congressional mandate to mean that carcinogens should be regulated to the lowest level feasible. However, in the 1980 benzene decision (448 US 607, 1980), the U.S. Supreme Court ruled that before OSHA "can promulgate any health or safety standard, the Secretary (of Labor) is required to make a threshold finding that a place of employment is unsafe—in the sense that significant risks are present and can be lessened by a change in practices." The Supreme Court did not define "significant risks" but wrote "if the odds are one in a billion that a person will die from cancer by taking a drink of chlorinated water, the risk clearly could not be considered significant. On the other hand, if the odds are 1 in a 1000 that regular inhalation of gasoline vapors that are 2% benzene will be fatal, a reasonable person might well consider the risk significant and take appropriate steps to decrease or eliminate it." Noting that significant risk can exist in the face of scientific uncertainty, the Court maintained that OSHA is "free to use conservative assumptions interpreting data with respect to carcinogenicity risking error on the side of overprotection rather than underprotection." Thus, OSHA performs quantitative risk assessments using human and/or animal data to determine if an occupational exposure poses a significant risk to workers; risks greater than 1 extra cancer death per 1000 are considered significant (12). The OSHA risk assessments and proposals for revised standards are published in the Federal Register and are open for evaluation and comment by scientists and interested parties (e.g., industry, labor groups, consumers). Informal hearings follow this process.

In contrast to OSHA, the U.S.EPA regulates excess cancer risks in the general population in the range of one per million. Though a significant risk may be clearly indicated in an occupational setting, the promulgation of a new or revised occupational standard requires demonstration that achieving such an exposure standard is both economically and technologically feasible. Hence, improving control technology will reduce worker exposures to carcinogenic agents (13).

The Toxic Substances Control Act (TSCA) created by the U.S. Congress in 1976 is administered by the U.S.EPA for the purpose of (1) regulating the production, processing, importation, and use of chemical substances that present unreasonable risk to human health or the environment; (2) requiring notification of production of new chemicals or significant new use of existing chemicals; (3) requiring toxicity testing for chemicals listed in the TSCA Inventory (generally high production volume/high exposure chemicals or chemicals that U.S.EPA believes may present an unreasonable risk to human health or the environment); and (4) requiring record keeping and reporting of any hazardous effects of any chemical to human health or the environment (11). The main source of recommendations for toxicity studies is the Interagency Testing Committee, an advisory committee that sets testing priorities for TSCA-regulatable substances.

Occupational Chemical Carcinogenesis
Ronald L. Melnick, Ph.D.

2.0 Carcinogen Identification
2.1 Human Studies
2.1.1 Historical Perspective In the early 1700s, Bernardino Ramazzini, the father of occupational medicine, wrote about diseases that occurred in more than 60 occupations and recommended that doctors ask their patients "What is your occupation?" This practice proved to be an extremely useful way of obtaining valuable information on associations between workplace exposures and various disease etiologies. Another early account of occupational cancer was made by a British physician, Sir Percival Pott, in the late eighteenth century when he reported that chimney sweeps developed scrotal cancer as a result of their exposure to soot (14). Subsequent research showed that agents such as soot, coal tars and coal-tar pitches, creosotes, and shale oils are carcinogenic to humans (15). Approximately a century after Pott's discovery, the German physician Rehn reported a high incidence of bladder tumors in aniline dye workers (14). Thus, the initial discovery that aromatic amines were carcinogenic was based on the detection of cancer in exposed humans; subsequent studies in laboratory animals have confirmed these findings. With the more recent advent of animal studies to evaluate the potential carcinogenicity of environmental and occupational agents, evidence of carcinogenicity for several chemicals that are now classified as known human carcinogens was first obtained in experimental animals (16). The alert clinician who recognizes an excessive number of patients who have similar tumors and traces that cluster to a particular exposure provides an enormous public health benefit that can lead to strategies to reduce risks and minimize or prevent specific occupational and environmental causes of disease. The combination of clinical, epidemiological, and experimental findings can greatly advance our understanding of mechanisms of carcinogenesis and provide data necessary to estimate risks and to reduce or eliminate occupationally induced cancers.

Several exposure–disease associations were discovered as the result of observations of high disease rates in specific populations (i.e., clusters) (17). Clusters generally appear as an unusually high occurrences of a disease in a relatively small number of people, most often occupationally or geographically based. Occupational clusters, for example, the finding of angiosarcoma of the liver in workers exposed to vinyl chloride (18) or kidney cancers in workers exposed to trichloroethylene (19), may lead to the discovery of a disease etiology because the exposures are better characterized than in an environmental cluster and there may be opportunities to confirm the association in other workplaces with similar exposure.

Occupational Chemical Carcinogenesis
Ronald L. Melnick, Ph.D.

3.0 Risk Assessment and the Development of Occupational Exposure Standards
3.1 General Background
Section 2.0 focused on methods to identify carcinogens and criteria used to evaluate the strength of evidence on whether an agent poses a human cancer risk. Hazard identification is the first step of the risk assessment process and is concerned with whether an agent can cause an adverse health outcome. Sources of information for this determination include epidemiological studies, animal studies, short-term assays, and evaluations of structure–activity relationships. Thus, even in the absence of epidemiological data, a potential occupational carcinogen may be identified from animal data and/or mechanistic studies.

Risk assessment provides a systematic approach for characterizing the nature and probability of adverse effects (i.e., health risks) in individuals or populations exposed to hazardous agents and often serves as the basis for risk management decisions as to whether and to what extent worker

exposure should be controlled. The National Academy of Sciences/National Research Council developed guidelines for the conduct of risk assessment in the U.S. Federal Government (80). The risk assessment paradigm developed by the NAS consists of four parts: hazard identification, dose–response assessment, exposure assessment, and risk characterization. The risk management decision-making process involves assessing and developing regulatory actions and evaluating the consequences of these actions or of alternative actions.

The evaluation of risk relies on information obtained from all relevant studies, including evidence from exposed humans, animal studies, *in vitro* studies, exposure information, and analyses of structure–activity relationships and dose–response. Uncertainties in estimating low-dose cancer risk exist because mechanisms of chemical carcinogenesis are not well enough understood and because information on the distribution of risk factors in exposed populations is generally not available. In spite of uncertainties and data gaps in the sources of information used to estimate human risk, risk management decisions can and should be made when a potentially hazardous condition is identified. To deal with uncertainties, various assumptions are made in extrapolating effects seen in animals to predictions of human risk (i.e., animals and humans are similarly susceptible to specific chemical carcinogens) and in extrapolating from the exposure range of experimental studies to a range more typical of past and present occupational exposures (i.e., low-dose effects can be estimated from observations made at higher doses). Because the estimates of risk in the low exposure range generally guide policy decisions, statistical models are needed to estimate excess risks that are not readily discernible from observational data (i.e., risks in the range of one per thousand to one per million).

The contribution of various sources of uncertainty in quantitative models of population exposure and low-dose risk can be assessed by analyzing the consequences of varying model assumptions (i.e., sensitivity analysis). A sensitivity analysis can provide information on the variability of model predictions, such as absorption or tissue dosimetry, consequent to variations in values of the model parameters. From such an analysis, the impact of uncertainty on health outcome versus containment/cleanup costs can be factored into regulatory decisions that address the consequences of human exposure to hazardous agents. Incomplete knowledge should not impede health-based decisions that would promote avoidance or reduction of human exposure to agents that are known human carcinogens or have a reasonable likelihood of causing human cancer. Specifying and characterizing uncertainties is important for enhancing the transparency and credibility of regulatory decisions and actions.

Quantitative risk assessment provides a means for incorporating basic and applied research findings into public health policy decisions. As science progresses and we gain further knowledge relevant to the extrapolation issues noted above, assumptions in risk models may be replaced with validated data. In this way, scientific knowledge can strengthen the basis for risk assessments that are used in the regulatory decision-making process. In recent years, there has been increased emphasis on shifting from default assumptions to a more science-based strategy for assessing risk. However, until the processes linking exposure to cancer outcome are better understood, much of this effort may simply reflect a shift to a new set of assumptions that are less health protective.

With respect to chemical carcinogens, the categorizations formulated by authoritative bodies (IARC, NTP, U.S. EPA) serve as the initial basis for regulatory actions. In the past, standards of permissible exposure to occupational agents were generally based on observations of acute or short-term effects in humans or toxic effects in animals. Many of the Threshold Limit Values (TLVs) set by the American Conference of Governmental Industrial Hygienists (ACGIH) (81) were based on the assumption that a threshold exposure must be exceeded before an adverse effect could occur.

Determinations of safe exposure levels have been obtained by dividing no-observed-effect levels (NOELs) or no-observed-adverse-effect levels (NOAELs) by safety factors that were intended to account for differences in susceptibility between animals and humans and variability in susceptibility among individuals. An additional safety factor would be included if the lowest dose used in the

toxicity study did not achieve a NOEL, that is, the lowest dose produced an effect that was assumed to represent the lowest-observed-effect level (LOEL). The NOAEL approach is problematic for evaluating low-dose cancer risk for several reasons. First, this approach assumes a threshold-type reponse regardless of the shape of the dose–response curve or the mechanism of disease induction. Second, the selection of "safety factors" is not based on experimental data demonstrating the validity of the selected values. Third, the dose identified as the NOAEL depends on the size of the dose groups used in the experimental study. The NOAEL is defined as the exposure level that does not produce a significant increase in an adverse effect compared to controls. Thus, if the size of the dose groups is 10, then for the following response [2 of 10 controls, 3 of 10 low dose, and 7 of the 10 high dose], the low-dose group would be labeled as a NOAEL because 3 of 10 is not statistically different from 2 of 10. However, if the group size were expanded to 1000 and the same ratio of response was observed (i.e., control: 200/1000, low dose: 300/1000, high dose 700/1000), then the low-dose group would be labeled the LOEL because 300/1000 is significantly greater than 200/1000. This point is made to demonstrate how methodological issues may impact estimations of low-dose risk.

Most of the original OSHA PELs were based on the ACGIH TLVs for specific chemicals. For example, before 1997, the OSHA 8-hour TWA occupational exposure standard for 1,3-butadiene was 1000 ppm based on early studies showing that it caused irritation to mucous membranes, skin, and eyes, or narcosis at very high concentrations (82). The carcignoenicity of 1,3-butadiene in laboratory animals at exposure concentrations less than 1000 ppm was demonstrated as early as 1984 (83, 84), and less than 7 ppm in 1990 (65); however, the reduction in the occupational exposure standard to 1 ppm was not promulgated until 13 years after the initial report on the multiple organ carcinogenicity of this chemical. There is no obvious explanation why such delays occur in enacting occupational exposure standards for carcinogenic agents. The fact that many occupational carcinogens listed in Table 4.5 lack cancer-based exposure standards indicates that much more effort is needed to protect workers from exposure to carcinogens in the workplace.

The U.S. Supreme Court's 1980 ruling on benzene (described in Section 1.2) was interpreted by OSHA to mean that the Agency must perform quantitative risk assessments, when possible, to determine whether occupational exposure to toxic or carcinogenic agents poses significant risk to workers. If a significant risk exists, then OSHA must quantify risks associated with alternative standards and determine an exposure level that poses no significant risk. Based on the benzene decision, OSHA considers a lifetime occupational risk of one extra cancer per thousand workers to be significant; this is in contrast to environmental cancer risk which is considered significant when lifetime exposure is expected to result in one or more cancer deaths per 100,000 or more than one per million in the general population. In addition, several occupational health standards are limited by economic and technological feasibility. In these cases, occupational lifetime excess cancer risks can be greater than one per thousand. For example, even after regulation the occupational lifetime excess leukemia risk for exposure to 1 ppm benzene is 10 per 1000 (1%), the excess lung cancer risk of occupational lifetime exposure to 10 mg/m^3 inorganic arsenic is 8 to 12 per 1000, and the excess lung cancer risk for occupational lifetime exposure to 5 mg/m^3 cadmium is 4 to 9 per 1000 (13). The determination of what is an accptable level of risk is made from political, social, technological, and economic considerations. Unfortunately, this can result in significant excess cancer risks for exposed workers.

Previous sections of this chapter focused on identifying cancer-causing agents, the first step of risk assessment; issues related to the other three components of the risk assessment paradigm are discussed next.

3.2 Exposure Assessment

Exposure assessment involves determining or estimating the magnitude, duration, frequency, and route(s) of human exposure to the particular carcinogenic agent(s). Thus, the exposure assessment focuses on identifying exposed populations and characterizing the routes and degrees of exposure. If exposure data are collected on an individual basis in the exposed subpopulation (e.g., workers in a specific industry), it would be possible to use that information to characterize the distribution of

exposure in relation to cancer risk. Because epidemiological studies generally lack data on exposure, especially during the time that the disease may have been initiated, retrospective estimates of exposure from incomplete data sets may introduce biases or inaccuracies in characterizing dose–response relationships. In some studies, only semiquantitative relationships between exposure and response can be determined, for example, ever/never exposed or separation into categories of relatively high, medium, or low exposure.

In some animal studies, exposures were similar to those in occupational settings. For example, 1,3-butadiene was shown to be carcinogenic in mice at exposures as low as 6.25 ppm (65), and occupational exposures to this gas ranged from less than 1 ppm to 374 ppm (85).

Model-based approaches for estimating occupational and environmental exposures need to include statistical distributions of model parameters to yield realistic estimates of exposure distribution. Otherwise, reasonable "worst-case" exposure scenatrios are estimated to reflect the upper limits of risk. This issue is particularly important for assessing occupational cancer risk because exposures in various job categories in the past compared to the present are likely to have differed substantially. A single estimate of average workplace exposure does not provide adequate information to assess risk in highly exposed individuals. Ideally, exposure assessments should be based on data from work area and personal (breathing zone) exposure monitoring; however, industrial hygiene surveys and personal monitoring have been reasonably credible only during the past 20 years. Because of changes in industrial processes and improvements in occupational health and safety practices, exposure data collected during the past two decades may have limited use in addressing previous exposures. This issue is particularly pertinent in cancer assessments because of the long latency period for the clinical manifestation of this disease. Current exposure measurements will have greatest value for future occupational epidemiological studies and prospective evaluations of the effectiveness of regulatory actions.

Most occupational exposure assessments used in evaluating human cancer risk have relied on the recall of industrial hygienists and workers and reviews of employment history. One of the most extensive characterizations of occupational exposure in relation to cancer outcome was the study by Macaluso et al. (20) of the styrene-butadiene rubber industry. The retrospective quantitative estimates of exposure included information on individual work histories, plant records relevant to exposure (e.g., industrial hygiene monitoring surveys), and interviews with plant managers, engineers, and other long-term employees to provide insight on manufacturing operations and potential exposure sources (i.e., release into the work area during sampling, loading/unloading, maintenance and cleaning, or from equipment leaks). This information was used to characterize exposure potential in work areas within each manufacturing process, while accounting for historical changes in processes that may have affected exposure, and to characterize exposure potential associated with specific tasks. Mathematical models were developed to estimate job-specific and time-period-specific average exposures. These estimates were linked with individual work histories to obtain individual cumulative exposure estimates expressed as cumulative ppm-years. Interestingly, this analysis showed that exposure to 1,3-butadiene was associated with a dose-related increase in the occurrence of leukemia among exposed workers (20).

Measurements of biomarkers (parent chemical and/or metabolites) in blood, urine, or exhaled breath can provide direct estimates of worker exposure. Other biomarkers of exposure include measurements of DNA adducts, mutations in the *hprt* gene, sister chromatid exchanges, micronuclei, and chromosomal aberrations in peripheral blood lymphocytes. The latter markers reflect interactions of the agent or its metabolite(s) with DNA and induced genotoxic effects associated with exposure.

3.3 Dose–Response Assessment

The dose response assessment for carcinogens involves the process of quantifying the dose and evaluating its relationship to the probability of tumor occurrence. Estimations of human cancer risk from exposure to chemicals identified as carcinogens in animal studies require information and methodologies for extrapolating across species (animal to human), as well as dose (experimental

exposures to workplace exposures).

3.3.1 Allometric Scaling of Animal Dose to Human Dose The first issue in the dose–response assessment, after a hazard has been identified, is defining dose. The dose received or internalized by experimental animals or exposed humans is not necessarily identical to the amount of applied agent or that encountered in the environment. The applied dose may be the concentration of the agent in water or food multiplied by the amount of food or water consumed, or the atmospheric concentration of the agent multiplied by the inhaled volume, or the amount applied to the skin, or the amount injected into the stomach (gavage). The delivered dose is the quantify of material internalized consequent to one of these exposures.

In the absence of specific information on the absorption and metabolism of the agent in animals and humans, risk assessments for airborne agents are based on the conversion of animal inhalation doses to human doses by adjusting for differences in minute volume and normalizing to body weight. If the route of animal exposure is different than that for humans, additional adjustments (e.g., differential rates of absorption from inhalation, dermal, and/or oral exposures) are made to extrapolate animal findings to humans. For example, an equivalent oral dose (EOD) from an inhalation exposure in a given species is calculated from the following equation:

$$\mathrm{EOD} = \frac{\mathrm{EC} \cdot \mathrm{ED} \cdot \mathrm{MV} \cdot \mathrm{AF} \cdot 10^{-3}}{\mathrm{BW}}$$

where

EC is the exposure concentration in air expressed as mg/L
ED is the exposure duration in minutes
MV is the minute volume expressed as mL/min
AF is the fraction of inhaled substance that is absorbed
10^{-3} is the conversion factor for L to mL
BW is body weight in kg

Power functions of 0.67 and 0.75 on body weight have been used to scale animal doses to human doses on a body surface area basis. The following example shows that a dose of 10 mg in a 300 gram (0.3 kg) rat scaled by body weight$^{0.7}$ is equivalent to a dose of 454 mg in a 70 kg human:

$$\frac{\text{rat dose (mg)}}{(\text{rat body weight})^{0.7}} = \frac{\text{human equivalent dose (mg)}}{(\text{human body weight})^{0.7}}$$

$$\text{human equivalent dose} = \text{rat dose} \cdot (\text{human body weight}/\text{rat body weight})^{0.7}$$

$$\text{human equivalent dose} = 10\,\text{mg} \cdot (70/0.3)^{0.7} = 454\,mg$$

On a body weight basis, the rat dose in this example is 33.3 mg/kg (10 mg/0.3 kg), and the human dose is 6.5 mg/kg (454 mg/70 kg). The human equivalent dose (HED) expressed as mg/kg can also be determined from the following equation:

$$\mathrm{HED} = \text{animal dose (in mg/kg)} \cdot \frac{(\text{animal body weight})^{0.3}}{(\text{human body weight})^{0.3}}$$

$$\text{HED} = 33.3\,\text{mg/kg} \cdot (0.3/70)^{0.3} = 6.5\,\text{mg/kg}$$

Several default assumptions are implicit in these calculations. Most important is the assumption that physiological and biochemical processes (e.g., absorption, metabolism) differ between laboratory animals and humans by body surface area (body weight$^{0.7}$). Although physiological processes such as ventilation rate or cardiac output may scale reasonably well with body surface area, there is no reason to assume that metabolic activities differ among species according to body surface area.

If blood or plasma time-course data for the agent are available for animals and exposed humans, then the integrated area under the plasma concentrations curve (AUC) can serve as a surrogate of internal dose for species comparisons of body burden. However, AUC data is limited to the specific exposure conditions. In addition, if the active toxic/carcinogenic agent is a metabolic intermediate, then the AUC for that metabolite would provide a better measure of potential risk.

3.3.2 Estimating Tissue Dose by Physiologically Based Toxicokinetic Modeling Tissue dosimetry becomes even more complex when multiple metabolites are involved in the carcinogenic process and their effects are interactive. A more scientifically rational approach than allometric scaling for estimating tissue dosimetry consequent to a particular exposure is to characterize the biological activities that influence the behavior of the agent in animals and in humans. Such evaluations should include determinations of the range of activities that exist in human subpopulations. Mathematical models that account for the physiological and biochemical processes that affect the absorption, distribution, metabolism, and elimination of the chemical can provide a biologically based approach for characterizing the tissue dosimetry of the parent compound and metabolites resulting from variable exposure conditions, including multiple exposure routes. Further, by using biochemical and physiological parameters that include the range of measured human values, it may be possible to address genetic variability and other factors that contribute to differential sensitivities among subpopulations. Physiologically based pharmacokinetic (PBPK) models have been developed to describe the behavior of drugs in animals and humans; similarly, physiologically based toxicokinetic (PBTK) models can characterize relationships between exposure to toxic agents and tissue concentrations of the parent compound and its metabolites.

PBTK models are designed to characterize the absorption, distribution, metabolism, and elimination of a toxic agent as a function of time. These models are being used increasingly to extrapolate animal doses to human doses because they allow consideration of species differences in physiological, biochemical, and anatomical characteristics and because they can address differences in route, frequency, and level of exposure. Kohn (86) has emphasized the importance of providing realistic representations of anatomical details in PBTK models; for example, including individual tissue capillary spaces, including an alveolar space, and separating the GI tract to allow liver perfusion via the hepatic artery (~ 20%) and via the portal vein (~ 80%) which drains the GI tract capillaries. PBTK models consist of a series of mass balance differential equations that are formulated to represent quantitatively the physiological and biochemical processes that affect the behavior of the agent in the intact animal, including the uptake of the parent compound resulting from an exposure, transport of the chemical to all tissues in the body, metabolism of the chemical, and elimination of the parent compound and metabolites. A PBTK model for 1,3-butadiene (BD) is shown in Figure 4.1 (87). In this figure, the animal is represented as divided into separate tissue compartments, including the site where the gas enters the body from inhalation exposure and the sites where it is subsequently stored or metabolized. The tissue compartments in the model are connected by arterial and venous blood flow. The kinetic behavior of the agent in an organism is determined by species–specific attributes, inlcuding physiological (ventilation rate, cardiac output, organ compartment volumes, and organ blood perfusion rates), physicochemical (tissue partition coefficients for parent compound and metabolites), and biochemical (metabolic kinetic constants) parameters. In the BD model, metabolism is represented in the liver, lung, and kidney of exposed animals. BD undergoes cytochrome P450-mediated oxidation to mutagenic epoxide intermediates, epoxybutene (EB) and diepoxybutane. Both of these epoxides are detoxified by hydrolysis via epoxide hydrolysis (EH) or

by conjugation with glutathione via glutathione-*S*-transferase (GST). By solving the equations in the model simultaneously, estimates of the tissue concentration time-courses of the parent compound and its metabolites are generated for any simulated exposure.

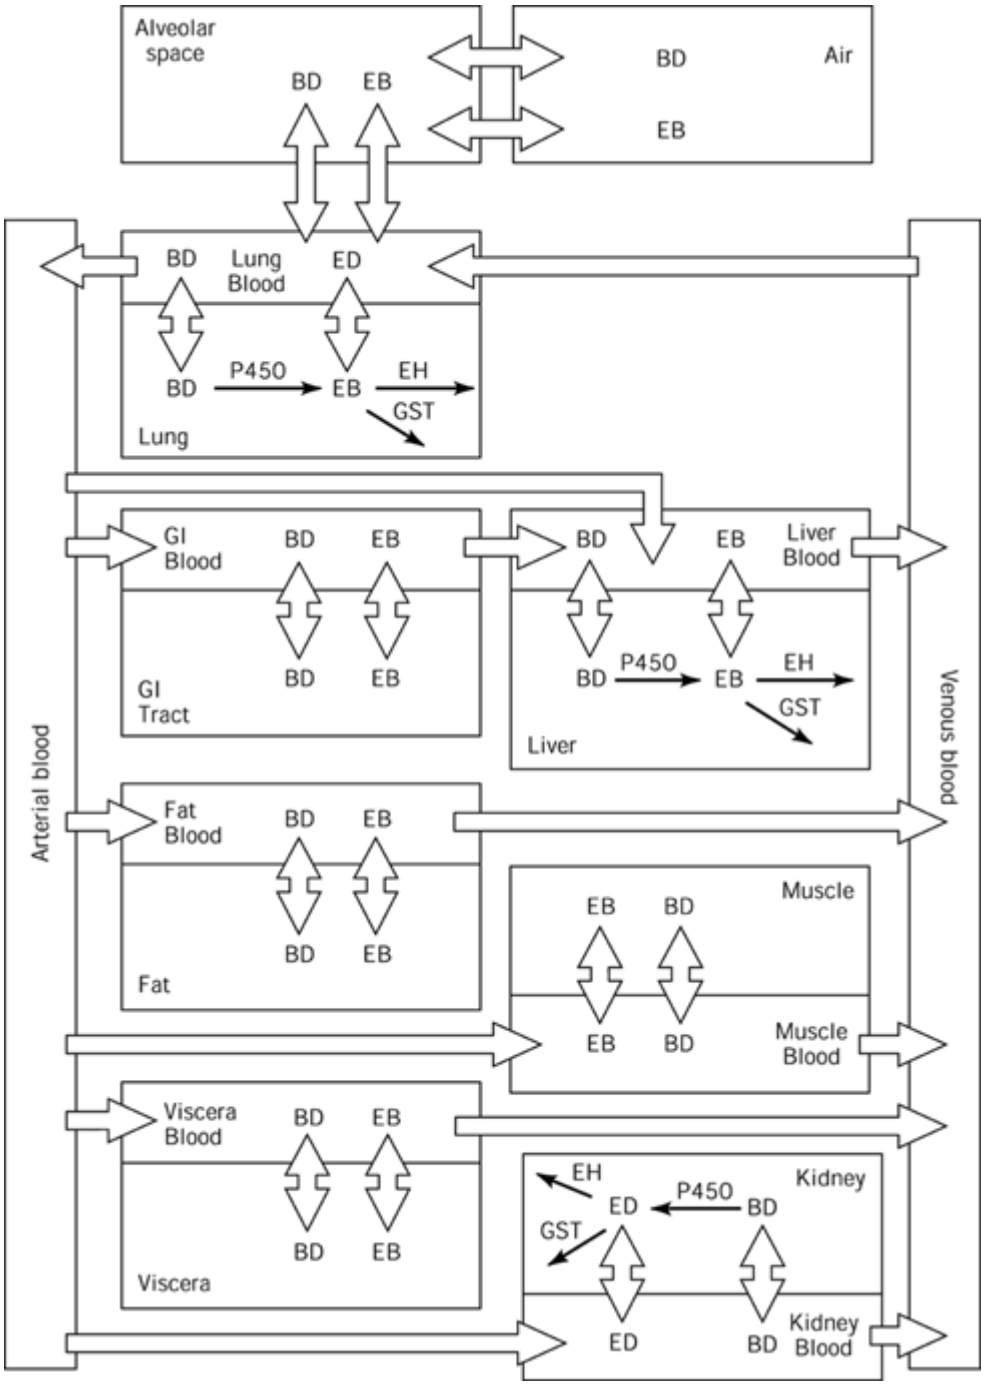

Figure 4.1. Schematic of a physiologically based toxicokinetic model for inhalation uptake, distribution, metabolism, and elimination of 1,3-butadiene (BD). The model includes cytochrome P450 mediated oxidation of BD to epoxybutene (EB), hydrolysis of EB catalyzed by epoxide hydrolase (EH), and conjugation of EB with GSH catalyzed by glutathione-*S*-transferase (GST).

Substitution of human physiological and biochemical parameters for those of laboratory animals can provide a scientifically sound basis to account for species differences in tissue dosimetry; this substitution is possible because of the high interspecies correspondence in physiological structure and function. If adequately validated, such models can serve as a powerful tool for generating biologically based estimates of tissue dose even under conditions that differ from the experimental

range (e.g., human exposure levels) and with different routes of exposure. Validation requires that the model accurately predict *in vivo* behavior of the agent in animals and humans under conditions different from those that were used to establish any adjustable parameter values. Because PBTK models can accommodate parameter values that cover the range of values in human populations, they can be used to evaluate the impact of interindividual variability on tissue dosimetry.

The utility of PBTK models depends on the extent to which testable predictions have been measured and validated. If the true carcinogenic agent arising from a particular exposure is known (parent compound or metabolite), then the model can be used to evaluate relationships between time-dependent tissue concentrations of that agent and tumor outcome. The identification of the appropriate dose surrogate derived from a PBTK model for use in a dose-response analysis is not always obvious because our understanding of the multiple mechanisms of chemical carcinogenesis is limited and because the agent may be metabolized by multiple pathways or to several intermediates that may influence the tumor response.

A validated PBTK model can be used to quantify response as a function of the dose of the toxic agent in the affected tissue site and can be used to predict the likelihood of toxic effects of the chemical at low exposures. Because PBTK models incorporate information on all of the biological processes that affect the disposition of the agent in animals and humans, they offer the opportunity to replace default assumptions associated with allometric scaling with biologically based estimates of tissue dose.

3.3.3 Dose–Response Analysis Tumor response data for the dose–response analysis may come from epidemiological studies or animals studies. Epidemiological data include the cause-specific relative risk or SMR values (the incidence of disease or cohort mortality rates in the exposed population divided by the incidence or mortality rate in the unexposed or general population) or the odds ratios (see Sectoin 2.1.2). From animal studies, the response is the tumor incidence values in the control and treated groups. As noted earlier, if survival patterns differ among dosed and control groups, then survival-adjusted incidence rates should be used in the dose–response analysis.

Several different statistical models have been applied to cancer dose–response data to characterize the shape of the dose–response curve, to identify specific doses associated with specified levels of increased cancer risk (e.g., ED10 is the estimated exposure concentration associated with an increased cancer risk of 10%), and to estimate slopes of the resultant curves. The linearized multistage (LMS) model has been the primary default dose–response model used by federal agencies to estimate human cancer potency and low-dose cancer risk. It is a statistical dose–response model used to estimate extra or additional cancer risk at a specific dose. Additional risk is the probability of a response at a particular dose, $p(d)$, minus the probability of the response at zero dose, $p(0)$. Extra risk includes an adjustment in the denominator of $1\text{-}p(0)$ for any background rate of cancer. For example, if 60 of 100 animals develop a tumor at dose d and the rate for that tumor in controls is 20 of 100, then the additional risk is $p(d)–p(0) = 40\%$ whereas the extra risk is $p(d)–p(0)/1–p(0) = 50\%$.

The LMS model can generate linear and nonlinear dose–response patterns and has been used mostly to generate a maximum likelihood estimate and an upper confidence limit on the slope of the linear low-dose term of the dose–response curve (88). It was adopted by regulatory agencies as a public health protective default approach; however, the use of this model for estimating human cancer risk has been criticized because the parameters of the model do not represent specific rates in the multistep carcinogenic process and it may overestimate the bounds of human cancer risk if the true dose–response is nonlinear.

Empirical dose–response models do not perform extrapolations from animals to humans; rather they assume that at equivalent doses the risk of developing a tumor is similar in humans and rodents. This assumption would lead to an overestimation of risk if rodents are more susceptible than humans and an underestimation of risk if humans are more susceptible than rodents. From parameter values that provide a best fit of the data to these models, estimates of the intercept, shape, and slope of the curve

can be obtained by maximum likelihood estimation. As shown in Figure 4.2, the curve shape may indicate a supralinear response (curve 1), a linear response (curve 2), a sublinear response (curve 3), a saturable reponse (curve 4), or a threshold response (curve 5). A true threshold response indicates that below a certain dose there is no increase in response compared to controls. A saturable response may arise if the metabolic pathway that produces the active intermediate becomes rate-limiting above a particular dose. The sublinear response may arise if cooperative interactions among components involved in the response promote an enhanced effect as dose is increased, or this type of response may occur if detoxification or repair pathways become saturated. The slope of the linear dose–response curve indicates that the response increases proportionally with dose. A Weibull model fit to tumor incidence data for chloroprene and 1,3-butadiene showed that the potency for induction of lung tumors in mice was the same for these two chemicals (89).

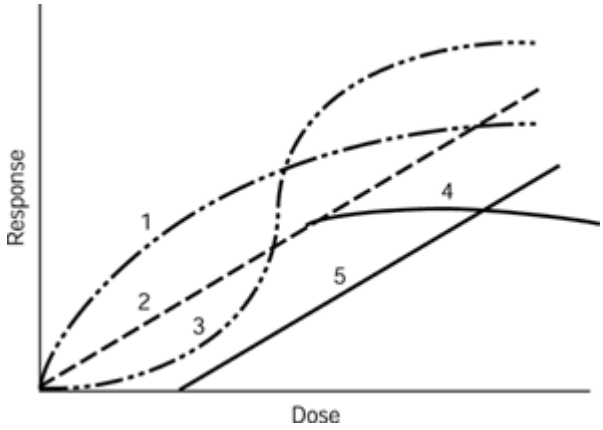

Figure 4.2. Theoretical dose–response curves. Curve 1 is a supralinear response, curve 2 is a linear response, curve 3 is a sublinear response, curve 4 is a saturable response, and curve 5 is a threshold response.

As events in the carcinogenic process become better understood and biomarkers of effect become identified, it may be possible to replace empirical dose–response models with biologically based models for estimating human risk. Mechanistic-based dose–response models link toxicokinetic activities (time course on the distribution of an agent or its metabolites in target tissues) with toxicodynamic activities (critical interactions between metabolites and target tissues). The conceptual framework for the development of such a model is shown in Figure 4.3. Dosimetry models require chemical-specific information on parameters such as tissue partitioning, metabolic activation, detoxification, protein binding, and elimination of the agent, and toxicodynamic models require information on DNA and chromosomal interactions, DNA repair, mutagenesis, altered gene expression, and effects on cell cycling. The toxicokinetic model provides the input of dose for the toxicodynamic model. Tissue time-course data and information on the elimination of parent compound, metabolites, or other biomarkers of exposure are essential for creating and validating dosimetry models, whereas measurements of DNA damage and repair, mutagenesis, mRNA levels, protooncogene activation, suppressor gene inactivation, cell replication and cell death, or other biomarkers linked to the carcinogenic process collected over a wide range of exposure are essential for creating and validating toxicodynamic models. The linking of toxicokinetic models with tissue response models through critical biochemical steps (e.g., DNA binding or receptor-based interactions) can lead to the development of biologically based dose-response models that quantify the sequence of events starting with exposure and resulting in tumor induction.

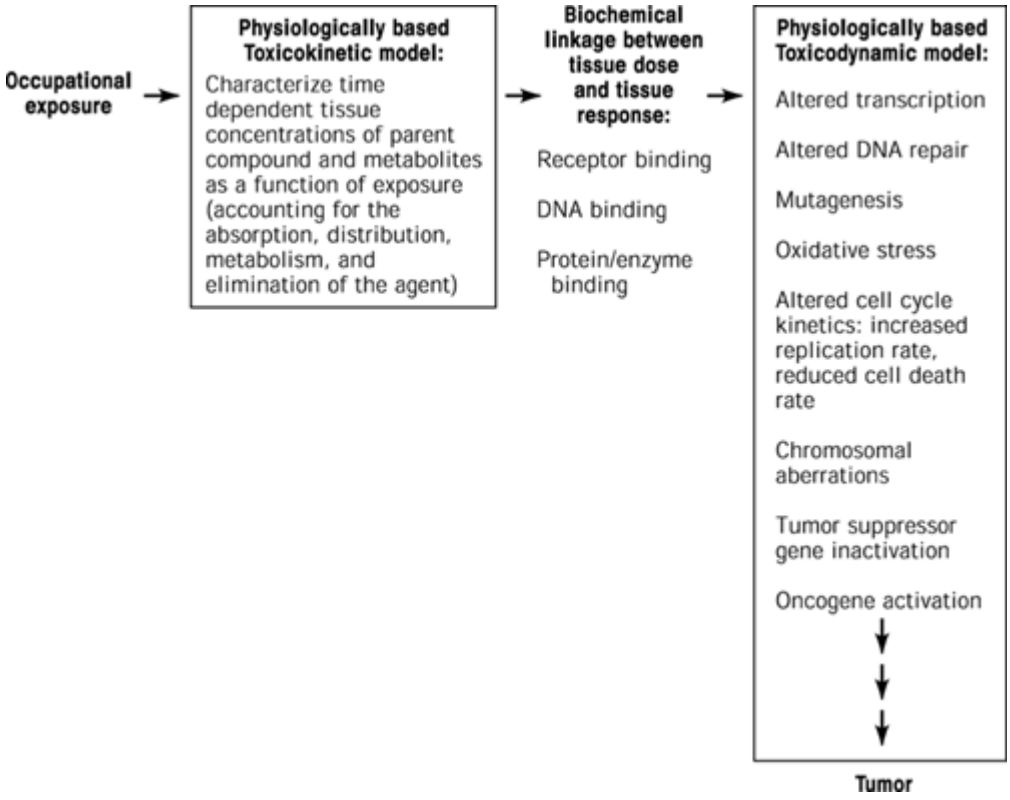

Figure 4.3. Schematic for the conceptual development of biologically based dose–response models of chemical carcinogenesis. This schematic addresses the sequence of events between exposure and tumor induction. Critical biochemical steps link tissue dose derived from the toxicokinetic model with tissue response characterized in the toxicodynamic model.

Portier and Kohn (90) developed a biologically based dose–response model for liver carcinogenesis induced by 2,3,7,8-TCDD in female arts. A PBPK model that characterized tissue dosimetry of TCDD was linked with a two-stage model of carcinogenesis. Parameter values for the carcinogenesis model (birth and death rates of intermediate cells and mutational rates of normal and intermediate cells) were obtained from estimates of changes in concentrations of biomarker proteins consequent to dosing with TCDD. Mutational effects were quantified from data on the induction of CYP1A2 (suggested to increase metabolism of estrogen to catechol estrogens, which lead to oxidative DNA damage) and birth rate/death rate effects were estimated from data on activation of the EGF-receptor. Although the model gave a reasonable fit to the experimental data and predicted a linear dose–response in the low-dose range, the authors cautioned on the use of such model for estimating low-dose risk because the mechanistic links among TCDD-mediated changes in gene expression and mutational effects and birth rate effects are not completely known.

With continued rapid growth of mechanistic information in molecular biology and carcinogenesis, especially in molecular signaling and cellular control processes, it should be possible to create scientifically credible mathematical models that accurately represent the biological processes involved in tumor induction at low doses. However, at present there is no evidence demonstrating that biologically based dose–response models are any more accurate than the LMS model for estimating low dose human risk (91).

3.4 Risk Characterization

Risk characterization provides an integrative summary of the information on the hazard identification, the exposure assessment, and the dose–response assessment that were used to estimate potential human cancer risk under various exposure circumstances. Data on the extent of human exposure to an identified cancer-causing agent are combined with the dose(exposure)–response analysis to generate estimates of potential risk (i.e., the probability or likelihood of cancer) in exposed populations and susceptible subpopulations in relation to the actual exposure circumstances.

The risk characterization should (1) evaluate the strengths and weaknesses of the data that serve as the basis for the quantitative estimates of risk, (2) explain the rationale for selecting a particular extrapolative approach to estimate low-dose risk or explain the basis for determining safe exposure levels, and (3) identify underlying assumptions and analyze uncertainties used to estimate risk. Additional issues such as the potential influence of mixed exposures and factors that contribute to individual differences in susceptibility should also be addressed. The information brought forward in risk characterization provides the basis for developing and evaluating alternative regulatory strategies. Final risk management decisions are often based on estimates of risk, as well as cost and technological feasibility.

OSHA's risk assessments are based on potential occupational lifetime exposure, i.e., working lifetime exposure is assumed to be 8 hours per day, 40 hours per week, 48 weeks per year, for 45 years. Animal inhalation cancer studies with exposure of 6 hours/day, 5 days per week, for 2 years are designed to mimic occupational exposures. Both the experimental protocol and the OSHA assessment cover approximately 15% of the expected lifetime (in hours) for humans and rodents.

Because all human carcinogens have been shown to be carcinogenic in animals when adequately tested (92, 93), most public health agencies regard animal carcinogens as potential human carcinogens. However, because many agents that have been shown to be carcinogenic in animals have not been evaluated in humans, mechanistic research in industry-sponsored laboratories has been styled to support hypotheses that suggest that animal positive findings do not reliably predict human risk. If a critical step in the carcinogenesis process occurs in animals but not in humans, then it might be appropriate to discount the animal tumor data for assessing human risk. For example, if the metabolic pathway causal for tumor induction occurs in animals but does not occur in humans, then the animal response may not be suitably informative of human risk. However, to date, no metabolic pathway causal for tumor induction has been demonstrated to be unique to the animal models used in cancer bioassays. Furthermore, other mechanisms may be operating in humans.

Differences in rates of activation or rates of detoxification between humans and animals should be accounted for in dosimetry models used to extrapolate animal findings to humans. Quantitative differences in toxicocokinetics do not indicate zero risk to humans. Furthermore, because of interindividual differences among humans, some segments of the population may be more sensitive than animals. Polymorphisms and differences in the degree of induction of inducible metabolic enzymes can result in substantial interindividual variability in risk associated with exposure to carcinogenic agents. In some instances, humans may be more susceptible to carcinogenic agents (e.g., arsenic) than animals.

Because of our limited understanding of the mechanisms of chemical carcinogenicity, the demonstration that a particular activity of a chemical is the critical step in the cancer process and that that effect or a similar effect could not occur in exposed people often relies on assumptions or unproven hypotheses (79). Although mechanistic research has increased our understanding of the carcinogenic process, it should be recognized that the exact mechanism of tumor induction has not been elucidated for any chemical that causes cancer in animals or in humans. Decisions to discount the relevance of positive animal findings for evaluations of human risk when based on acceptance of unproved hypotheses could lead to workplace exposure circumstances that pose avoidable cancer risks.

3.4.1 Extrapolation from Animals to Humans The evaluation of human risk from epidemiological data avoids uncertainties of animal to human extrapolations. However, obtaining this information requires a long follow-up period between the initial exposure and the assessment of disease incidence. The warnings from positive animal studies must be heeded to prevent disease occurrence that could have been avoided. Extrapolation models of animal findings to human risk at occupational exposures contain various inherent assumptions because mechanisms of chemical carcinogenicity are not fully understood. The advancement of scientific knowledge of critical steps involved in chemical

carcinogenesis in laboratory animals and humans may eventually obviate the need for many default assumptions used in low-dose extrapolation models, for example, the need to scale tissue dosimetry across species by allometric procedures may be replaced by models that are based on physiological and biochemical parameters specific for laboratory animals and humans.

In characterizing human risk based on tumor induction in laboratory animals, sources of uncertainty need to be identified and analyzed. Uncertainties may concern the reliability of the low-dose extrapolation model, the appropriate dose metric that is used in the tumor dose–response model (e.g., the occupational lifetime cumulative tissue dose, the time-weighted average lifetime dose, the maximum daily tissue concentration), as well as issues related to species and interindividual differences in pharmacokinetics and pharmacodynamics. Models that are validated against measured biomarkers of exposure and effect can strengthen the scientific basis for animal to human extrapolations. Pharmacokinetic issues involving estimates of internal dose or tissue dose include uncertainties in the accuracy of parameter estimates, interdependence of parameters, validity of scaling methods, variability of parameters among individuals, and effects of coexposure to other agents that may alter metabolic processes.

Additional data and models are needed to adequately account for interspecies, intraspecies, and sex differences in susceptibility. The risk characterization should address issues such as, are laboratory animals and humans similarly susceptible to the carcinogenic effects of a particular agent at equivalent doses, has the correct causative agent or intermediate(s) been specified for low-dose extrapolation, and do responses in animals reflect the range of responses that might occur in exposed workers?

Species-specific mechanistic information at the cellular and molecular levels is critical for developing biologically based dose–response models that are applicable for extrapolating animal effects to humans. Quantitative differences between species can be incorporated into mechanistic based dosimetry models used to extrapolate tumor responses observed in animals to humans. In the absence of detailed quantative information on species differences in response, it is prudent to assume that the risk of developing a tumor at equivalent doses is similar in humans and rodents. This assumptions may lead to overestimates or underestimates of human risk because of the numerous factors that can influence the disease outcome such as duration of exposure, age, race, tumor latency, exposure to other agents, route(s) of exposure, health status, lifestyle, and the multitude of hormonal and genetic factors that contribute to interspecies and intraspecies differences in susceptibility. Point estimates of risk such as the maximum likelihood estimate obtained from low-dose extrapolation models do not account for these sources of variability; upper 95% bounds on excess cancer risk address sampling variability, but not the sources of variability listed above.

3.4.2 Estimation of Low–Dose Risk Statistical models, in particular the LMS model, have been used to extrapolate animal findings to estimate risk at occupational exposures. Low-dose estimates of risk are obtained by extending the dose–response curve to the exposure level(s) of concern. However, because these extensions may go beyond the experimental exposure range, the USEPA (66) proposed using a defined value near the range of experimental data as a point of departure for estimating low-dose risk. The draft EPA guidelines for cancer risk assessment call for the use of biologically based models for low-dose extrapolations; these are defined as models in which parameter values are calculated independently of curve-fititing of tumor data. If no acceptable biologically based model is available then a statistical model is fit to the tumor dose–response data to estimate the human equivalent dose for an increased cancer risk of 10% (ED_{10}) and the lower 95% confidence limit on that dose (LED_{10}). Rather than extrapolating to low doses by the default LMS model, low-dose risk is estimated by extending a straight line from the LED_{10} to zero response for agents that indicate a linear mode of action (e.g., DNA reactive genotoxic chemicals or situations in which added human exposure is on the linear part of a dose–response curve) or for agents for which there is insufficient evidence (uncertainty) to support a nonlinear mode of action. For agents that demonstrate a nonlinear mode of action, the EPA will employ a margin of exposure analysis (i.e., the

LED_{10} divided by uncertainty or safety factors) that is intended to signify a human exposure that is considered unlikely to induce disease. By this analysis, no estimates are made of potential risk or likelihood of cancer occurrence. The uncertainty factors are intended to address interspecies and intraspecies differences in pharmacokinetics and pharmacodynamics and the adequacy of the database. The magnitude of the applied uncertainty factors must be analyzed to validate the level of protection that they are assumed to provide.

For a nonlinear dose–response, the margin of exposure approach projects that the response at low doses falls faster than that of a linear dose–response. Hence a higher level of exposure would be considered reasonably safe compared to that estimated from linear extrapolation. The margin of exposure approach is favored by those who have criticized the LMS model as overly health conservative; however, caution is needed to ensure that public and worker health is not compromised when a low-dose model with one set of assumptions is replaced with an alternative approach that is based on unproven hypotheses and less health protective assumptions.

1 Introduction

The approach to assessing the risks of noncancer toxicity generally differs from that used to assess the potential risks of carcinogenicity. Assessment of risks of carcinogenicity most often assumes that a small number of molecular events can evoke mutagenic changes in a single cell, ultimately leading to self-replicating damage and carcinogenicity. Generally, this is considered a nonthreshold effect because presumably no level of exposure does not pose a small, but finite, probability of generating a response. In contrast, it is most often assumed that noncarcinogenic changes have a threshold, a dose level below which a response is unlikely, because homeostatic, compensating, and adaptive mechanisms in the cell protect against toxic effects. For example,

Two paracetamol [Tylenol] tablets will relieve the minor aches and pains ... Twenty-two tablets [are fatal] ... So why is not all paracetamol a danger ... ? The answer to the paracetamol puzzle is that there are two pathways down which our bodies dispose of this drug. Most is removed by converting it to a sulphate and this works fine provided there is no sudden excess that uses up our supply of sulphate enzymes. If this happens the body has another way of removing paracetamol, by oxidizing it. Unfortunately, this produces a toxic chemical that requires glutathione to detoxify it. It is only when the supply of glutathione is exhausted that the [toxin is fatal] (1).

This threshold concept is important in many regulatory contexts. The individual threshold hypothesis holds that some exposures can be tolerated by an organism that has essentially no chance of expressing a toxic effect. Further, risk management decisions frequently focus on protecting the more sensitive members of a population. In these cases efforts are made to keep exposures below the more sensitive subpopulation threshold, although it is recognized that hypersensitivity and chemical idiosyncrasy may exist at yet lower doses.

Quantitative assessment of the noncancer toxic effects of environmental exposures has traditionally been evaluated in terms of concepts such as acceptable daily intake (ADI) and margin of safety. Scientists familiar with such concepts have identified certain limits and difficulties with their use. Based on recommendations of the National Academy of Sciences (NAS) (2), scientists now are better articulating the use of experimental and epidemiological data in making and explaining risk assessment and risk management decisions. As a result, several newer quantitative procedures that augment the traditional concepts have been developed and are presented here.

The basic concepts of risk assessment are also an integral part of evaluating the health risks associated with occupational exposures. Activities such as the identification of hazards, evaluation of the supportive data for determining occupational exposure values, and conducting exposure estimates all fit well into the risk assessment paradigm described in the NAS publication (2). Although one can argue that risk assessment is common in the workplace, the application of many specific risk assessment methodologies is relatively new. Historically, occupational risk assessment decisions relied heavily on professional judgment. A more recent event is the integration of quantitative noncancer risk assessment approaches into the occupational arena. Examples of the increasing focus on the application of quantitative risk assessment are apparent from the activities of organizations that derive occupational exposure values.

Groups such as the United States Occupational Safety and Health Administration (OSHA) are increasingly relying on risk assessment tools to promulgate new or revised occupational levels such as Permissible Exposure Limits (PELs). The need to integrate risk assessment into the standard setting process was demonstrated by the court rulings in response to challenges to OSHA standards. The benzene standard and air contaminant standard were both vacated on the basis that there was an

insufficient demonstration that a significant risk existed and that adoption of the standard would reduce that risk. After addressing the risk assessment issues, OSHA promulgated its benzene standard in 1987. Importantly, in the proposed rulemaking for the update of the PELs (3–5), OSHA made clear its intention to use state-of-the-art risk assessment methods to derive new air contaminant standards. Thus it is clear that risk assessment will play an increasing role in establishing occupational health values promulgated by OSHA.

Other organizations that develop occupational exposure limits (OELs) are also moving from heavy reliance on professional judgment to consistent risk assessment approaches. The National Institute for Occupational Safety and Health (NIOSH), the American Conference of Governmental Industrial Hygienists (ACGIH), and the American Industrial Hygiene Association (AIHA) have also increased their interest and application of risk assessment techniques in the occupational setting. ACGIH has included risk assessment as an issue under study by the Chemical Substances TLV Committee (6). Similarly, AIHA recently published an issue paper on this subject (7). Documentation of risk assessment methodologies for application to occupational settings has also increased in the recent literature (8–11).

This chapter describes the general framework for noncancer risk assessment and some salient principles for evaluating the quality of data and formulating judgments about the nature and magnitude of the noncancer hazard. Highlights of noncancer risk assessment methods used by a variety of agencies and organizations, and examples of how occupational risk assessment is moving toward a more systematic use of risk assessment principles are presented.

This chapter also has several specific aims. The first is to provide scientifically supportable quantitative risk assessment procedures to meet the risk assessment goals listed following. A second aim is to provide a scientific rationale that may be used to deter-mine whether new quantitative risk assessment procedures not specifically examined in this chapter are scientifically supportable. The final aim of this chapter is to provide a basis for developing new or improved quantitative risk assessment procedures.

The quantitative risk assessment procedures described in this chapter have been developed to meet some of the risk assessment goals for various purposes. Although the protection of the public and occupational health is a common theme that runs through these separate risk assessment goals, they are sufficiently different to warrant separate and distinct procedures. Examples of such goals are

- to rank chemicals as to possible hazard
- to determine and/or estimate a level of daily exposure that is likely to be without an appreciable risk of deleterious effects during a lifetime
- to determine and/or estimate the likely human response to exposure to various levels of a particular chemical

Moreover, differing amounts of toxicity data are needed for various quantitative procedures. Thus, the amount of data available affects the choice of procedure, as shown in Table 5.1.

Table 5.1. Some Risk Assessment Goals and Required Data Availability

Goal	Amount of Data	Approach/End Result
Rank chemicals	Limited, moderate or great	Structure-activity relationships (SAR), toxicity equivalency factors (TEFs) for ranking

Get to a "safe" level	Moderate or great	Development of acceptable daily intake (ADI), reference dose (RfD), reference concentration (RfC), permissible exposure limit (PEL); use of dose–response modeling such as benchmark dose/concentration (BMD/BMC), categorical regression
Characterize the full dose–response behavior	Great	Physiologically based toxicokinetic (PBPK) model, biologically based dose–response (BBDR) model (both of which can be used in developing any of the values above)

Noncancer Risk Assessment: Principles and Practice In Environmental and Occupational Settings

Lynne T. Haber, Ph.D., Joan S. Dollarhide, MS, MTSC, JD, Andrew Maier, MS, CIH, Michael L. Dourson, Ph.D., DABT

2 Hazard Identification

Hazard identification is a necessary first step in the risk assessment of a chemical. Hazard identification involves evaluating the appropriateness, nature, quality, and relevance of scientific data on the specific chemical; the characteristics, magnitude, and relevance of the experimental routes of exposure; and the nature and significance to human health of the observed effects. Groups such as the U.S. Environmental Protection Agency (USEPA) have developed guideline documents that explain the process of hazard identification for developmental toxicity (12), reproductive toxicity (13), and neurotoxicity (14). The reader is referred to these more extensive documents for specific details.

2.1 General Principles

Many dose–response processes for noncancer toxicity depend in part on professional judgment whether an effect or collection of effects observed at any given dose of a chemical constitutes an adverse response. Such judgment may not be easily rendered and requires experts trained in the area. For example, Fig. 5.1 shows individual disability as a function of organ system impairment and the overlapping areas of adverse and nonadverse effects. Table 5.2 more clearly describes some of the terms shown in Fig. 5.1, as well as some other key terms for hazard identification.

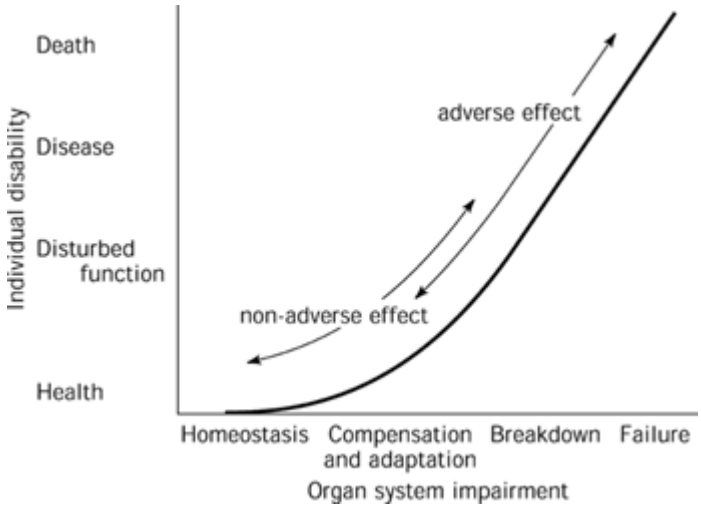

Figure 5.1. Individual disability as a function of organ system impairment.

Table 5.2. Some Key Definitions for Hazard Identification

ADAPTIVE EFFECT enhances an organism's performance as a whole and/or its ability to withstand a challenge. An increase in liver weight due to an increase in hepatic smooth endoplasmic reticulum is an example of an adaptive effect, if hepatic metabolism reduces the chemical's toxicity.
COMPENSATORY EFFECT maintains overall function without enhancement or significant cost. Increased respiration due to metabolic acidosis is an example of a compensatory effect.
CRITICAL EFFECT is the first adverse effect, or its known precursor, that occurs as dose rate or exposure level increases. One or more effects may be critical.
ADVERSE EFFECT is a biochemical change, functional impairment, or pathological lesion that impairs performance and reduces the ability of an organism to respond to additional challenge. The determination of such effects may require special tests or observation, such as preparation of slides for histological analysis.
FRANK EFFECT is an unmistakable adverse effect, such as convulsions or mortality. The determination of such effects can be done by clinical observation and normally does not require special tests.
SEVERITY connotes the toxicological significance attached to the continuum of effects, including adaptive, compensatory, critical, adverse, and frank effects, potentially associated with exposure of xenobiotics.

Although this figure and table are useful tools for showing the broad concept of adversity, the analysis of adversity for a given chemical or situation is strictly a case by case analysis by experts. For example, a chemical often elicits more than one toxic effect, even in one species or in tests of the same or different duration. After assessing the quality of each study, identifying the biological and statistical significance of observed effects (discussed later), and distinguishing between reversible and irreversible end points (discussed later), risk assessment scientists often identify the critical effect(s). The critical effect(s) is the first adverse effect(s) or its known precursor that occurs as the dose rate increases in a study. When several studies are compared, the critical effect is generally the lowest one that occurs collectively. Current dose–response methods described in this text and elsewhere use the critical effects as a basis for the dose–response assessment. The critical effects may change among toxicity studies of different durations, may be influenced by toxicity in other organs, and may differ depending on the availability of data on the shape of the dose–response curve.

Where specific guidance on hazard identification is not available, some general considerations regarding the types of toxicity evidence and adversity of effect are needed. Toward this end, risk assessment scientists look at the available data in several different ways, as outlined here. The following considerations illustrate some broad concepts of hazard identification applicable to all organ systems.

2.2 Evaluation of Human and Animal Data

In general, hazard identification should include considerations of factors affecting study quality, such as study hypothesis, design, and execution. An ideal study addresses a clearly delineated hypothesis, follows a carefully prescribed protocol, and includes sufficient subjects, observations, and statistical

analysis.

In the experience of risk assessment scientists around the world, properly conducted and ethical human studies are most useful in qualitatively establishing a link between exposure to an agent and manifestation of an adverse effect. When there is adequate information on the exposure level associated with a particular end point, controlled human exposure to levels that are not overtly toxic and/or epidemiological studies can also provide the basis for a hazard identification and dose–response assessment. The use of adequate human data to define the hazard and the dose–response relationship avoids the problem of interspecies extrapolation. Animal toxicity studies serve as supporting evidence when adequate human data are available.

Criteria for judging the adequacy of epidemiological studies are well recognized (15). They include factors such as the proper selection and characterization of exposed and control cohorts, the adequacy of duration and quality of follow-up, the proper identification and characterization of confounding factors and bias, the appropriate consideration of latent effects, the valid ascertainment of the causes of morbidity and death, the ability to detect specific effects, and the determination of exposure and/or doses. If possible, the statistical power to detect an effect should be included in the assessment. The strength of the epidemiological evidence, as judged by experts for specific health effects, depends on, among other things, the type of analysis and the magnitude and specificity of the response. For example, the weight of evidence increases rapidly with the number of adequate studies that show comparable results for populations exposed to the same agent under different conditions. As with judging the adequacy of studies, expert judgment is necessary to determine the weight of evidence for or against a specific effect.

In the absence of adequate human data, risk assessment scientists rely primarily on studies of animals for hazard identification. Adequate animal studies offer the benefit of controlled chemical exposures and definitive toxicological analysis. Experimental observations of animals are usually conducted in mammals, and the species most often studied are the rat, mouse, rabbit, guinea pig, hamster, dog, and monkey. Even when there are adequate animal studies, it is often useful to reconsider inadequate human data to evaluate whether the risk assessment based on animal data appears reasonable based on the general understanding from the human data.

Criteria for the adequacy of experimental animal studies include chemical characterization of the test compound(s), the number of individuals in the study groups and whether both sexes are used, the number of study groups, the spacing and choice of dosing levels so as to determine an adequate dose–response relationship, the types of observations and methods of analysis, the nature of pathological changes, the consideration of toxicokinetics, and whether the route and duration of exposure were relevant to environmental exposures. Criteria for the technical adequacy and evaluation of animal studies have been published (16, 17), and should be used to judge the acceptability of individual studies.

However, professional judgment regarding the adequacy of a study is not based solely on the degree to which it fits a prescribed recipe. It is also based on how well it enables one to identify potential adverse effects. Recent end-point-specific risk assessment guidelines published by the USEPA, for example, discuss such professional judgments on developmental toxicity (12) and male and female reproductive effects (13).

Supporting evidence from a wide variety of sources provides additional information for hazard identification. For example, metabolic and other toxicokinetic studies can provide insights into mechanisms of action. Comparison of the metabolism of the compound that exhibits the toxic effect in the animal with its metabolism in humans may strengthen or weaken the dose–response assessment. Toxicodynamic data may also be useful for estimating the dose to humans that would result in the same toxicity as observed in the animal study (i.e., the “equitoxic human dose”) and/or as part of the calculation of the delivered dose to the target organ or site. Evaluation of toxicokinetic differences between animals and humans has allowed the development of generalized dosimetric

adjustments of exposure levels across species (18–21). Risk assessment scientists encourage the development of comparative toxicokinetic and toxicodynamic parameters because such information increases the fundamental understanding of xenobiotic processes and reduces the uncertainties of interspecies extrapolation.

Animal and human studies that are deemed inadequate for quantitative risk assessment (e.g., due to insufficient doses, study duration, number of animals, etc.) nevertheless may provide supporting evidence regarding the target organ(s) and the critical effect. Similarly, *in vitro* studies can often provide insight, but seldom definitive conclusions, on the compound's mode of action and potential for human toxicity. However, it is possible that development of reliable and relevant *in vitro* tests may increase the usefulness of such data for assessing human risk in the future and minimize the need for live animal testing.

2.3 Route, Source, and Duration of Exposure

Because human exposure to a chemical pollutant is often route-specific (e.g., inhaled but not ingested) or source-specific (e.g., water versus food), risk assessment scientists often approach the investigation of a chemical with a particular route, source, and/or duration of exposure in mind. For example, within the oral route of exposure, the bioavailability of a chemical ingested in one source (i.e., food) may differ from that manifested when it is ingested in another source (i.e., water). Usually, the toxicity database on the compound does not provide data on all possible routes, sources, and/or durations of administration.

Toxic effects observed via one route or source of exposure are often relevant to other routes, although expert judgment should be applied in making such extrapolations. For example, if a chemical exhibits developmental effects at low doses via the oral route and it is absorbed from the respiratory tract, there is reason to suspect that it is also a developmental toxicant via the inhalation route. Consideration is given to potential differences in absorption or metabolism resulting from different routes and/or sources of exposure, such as the potential for first-pass metabolism in the case of oral exposure. Consideration is also given to the potential for portal of entry effects (e.g., gastrointestinal effects from oral exposure and respiratory effects from inhalation exposure). Whenever appropriate data are available, these factors are taken into account in the dose–response assessment. (As a specific example, the Reference Dose for hydrogen cyanide employs a fivefold modifying factor to account for the expected pharmacokinetic differences for this compound in water vs. food (2).) For example, guidance has recently been developed for extrapolating oral data to inhalation scenarios (18).

Toxic effects can also vary with magnitude, frequency, and duration of exposure. Studies differ in exposure duration (acute, subchronic, and chronic) and in dosing schedules (single, intermittent, or continuous). Information from all these studies is useful in the dose–response assessment. For example, overt neurological problems identified in a short-term, relatively high-dose study would reinforce the observation of subtle neurological changes noted in a low-dose, chronic study. Low-dose, chronic exposure, however, might also elicit effects either absent or not detected in higher dose, shorter duration exposures (and vice versa). For example, acute exposure to benzene causes central nervous system effects, whereas the critical effect for chronic exposure is hematological effects.

It is frequently necessary to extrapolate from exposures that differ in magnitude, frequency, and duration to those of interest to a specific human situation. For example, one may need to use subchronic experimental data to assess the potential hazard resulting from chronic ambient exposure. Consideration is given to potential differences in absorption or metabolism from different exposures. When appropriate data are available, the quantitative impacts of these differences on the risk assessment are delineated. The procedures outlined in this chapter are generally applicable, with proper judgment, to exposures of differing magnitude, frequency, and duration.

2.4 Evaluation of Toxicological Effects

2.4.1 Severity Defined Severity connotes the toxicological significance attached to the continuum of effects (including adaptive, compensatory, critical, adverse, and frank effects) potentially associated

with exposure to xenobiotics. In general, this continuum starts with adaptive effects, where the organism's ability to withstand a challenge is enhanced. As doses increase, compensatory effects occur and then are often seen as a way for the organism to maintain overall function without further enhancement or significant cost. At some point as dose increases, the critical effect is reached. This is the first adverse effect, or its known precursor, that occurs as dose increases. The critical effect is often the focus of the dose–response assessment based on the assumption that if the critical effect is prevented, then all subsequent adverse effects are prevented. As dose increases, the dose that causes the critical effect is exceeded, and additional adverse effects are manifested as biochemical changes, functional impairments, or pathological lesions. These progressively more severe effects generally impair the performance of the organism and/or reduce its ability to respond to additional challenges. At some point, these adverse effects become manifestly overt, and frank disease ensues.

2.4.2 Assessing the Biological Significance of Statistical Change The general approach that risk assessment scientists take in evaluating whether a change is adverse is consistent with that outlined in Ref. 22. An adverse effect is defined as a biochemical change, functional impairment, or pathological lesion that impairs performance and reduces the ability of an organism to respond to additional challenge. The presence of change alone does not necessarily indicate an adverse effect. The determination of adversity should consider the toxicological and statistical significance of the observed effect(s).

As discussed in part by Gaylor (23), the toxicological and statistical significance of an observed effect must not be equated and in fact toxicological and statistical considerations are often regarded sequentially. The determination of adversity should, instead, involve careful toxicological evaluation where statistics are used only as a tool for clarifying the implications of the data. The actual decision whether an effect is adverse should be based solely on biological grounds. Any animal that is in a state of physiological compromise should be judged as exhibiting an adverse effect. If difficulties exist in interpreting the importance of the effects, these difficulties are often related to whether the effect was statistically significant.

Apparent conflicts between statistics and toxicology can arise when toxicologically insignificant effects are statistically significant or vice versa. For example, the observation in a chronic study of a 5% decrease in net body weight in an experimental group compared to the control group may be statistically significant but may not be considered toxicologically important if both groups are fed ad libitum because such a decrease is often associated with increased longevity. Instead of a real conflict, however, the statistical significance suggests that the effect is real, but the biological reasoning indicates that the effect is not adverse. A special case in this situation is where the toxicological relevance of the statistically significant effect is uncertain. In this case, it is incumbent upon the professionals to judge whether the effect is toxicologically significant.

Evaluating changes that are not statistically significant is more difficult because the observed effects are then only weakly linked to the exposure. The problem is compounded when statistical methods are inappropriately applied. For example, consider the case when the exposed group shows a rare type of lesion. If the observed frequency in the exposed group is small, then the effect is unlikely to be statistically significant, compared with the experimental control group. The risk assessment scientist, however, often evaluates the nature and frequency of the observation in the context of previous experience or data in historical controls (i.e., knowledge of the spontaneous occurrence of the observation in the species) and concludes that the effect is worth further study. Again, this does not imply a conflict but instead illustrates the different types of data analysis that may be performed. If the statistical analysis also included historical controls, the same conclusion might have been reached. Similarly, an effect may exhibit a clear dose–response relationship, but not be statistically significant in pairwise comparisons. In this case, a trend test, or a NOSTASOT test (a method for determining a no observed adverse effect level by doing successive trend tests and removing the highest dose) may support a toxicologist's conclusion that an adverse effect is occurring.

The evaluation of rare effects is not as confusing when the goal is to estimate a dose–response curve,

rather than to determine whether a particular dose level leads to toxicologically significant changes. In the former case, the rarity of the lesion would be used as part of the dose–response relationship.

2.4.3 Assessing the Toxicological Significance of Observed Effects In some instances, the risk assessor must evaluate the toxicological significance of the observed effects, for example when the effect is reversible. A reversible change is often an adaptive or compensatory response to stress or may be an overt adverse response that the body can repair. Reversible changes return to normal or within normal limits either during the course of or following exposure. An irreversible change persists or may progress even after exposure ceases (22). It must be recognized that although a change may be reversible when exposure is terminated, it still may be adverse to an organism. In fact, depending upon the changes observed at the various dose levels tested, a potentially reversible change may well be selected as the critical effect in the dose-response assessment because reversibility often depends on the magnitude of the dose and the duration of exposure. The longer the test species receives the chemical exposure and/or the larger the amount of chemical administered, the greater is the likelihood that the reversible change in the early stages will progress to a permanent irreversible state. For example, the early stages of alcohol intoxication result in fatty infiltration of the liver, which is most often reversible upon cessation of exposure. However, when the exposure becomes chronic and the dose administered is sufficiently high, a permanent cirrhotic condition develops. Both effects are adverse, because the fatty changes, although reversible, result from functional impairment and are a precursor state that can progress to irreversible toxicity; however, liver cirrhosis is considered more serious in nature because reversibility is no longer possible (24).

Certain effects are irreversible (e.g., certain chronic neurological diseases, liver cirrhosis, and emphysema). The description of such effects has a useful role in the hazard evaluation of the chemical in conjunction with more subtle end points because the chemical's full dose–response behavior is described. However, the descriptions of irreversible effects by themselves are seldom considered useful in dose–response assessment because such effects often appear well above the experimental threshold range.

When identifying a hazard, irreversible effects can usually be distinguished from less serious but still adverse changes. However, difficulty arises when trying to determine the toxicological significance of more subtle and/or reversible changes. For example, transient hypertrophy or hyperplasia can be an adaptive change resulting from exposure to a xenobiotic or can be a precursor effect to the production of more severe toxicity, such as the disruption of normal organ function. The toxicological significance of such manifestations is established by carefully analyzing the biochemical, morphological, and physiological changes that occur at other doses and available supporting data and by combining the data analysis with professional scientific judgment to reach an overall determination.

In some cases, it must be ascertained whether an adverse effect that is observed is truly treatment related. For example, if a respiratory tract infection is present in the animal colony, this may predispose the exposed animals to the development of adverse respiratory effects in response to chemical exposure, whereas such effects may not occur in healthy animals. However, if the effects noted demonstrate a clear concentration–response relationship, despite the presence of infection, then the effect may be considered treatment related. For example, mild irritant effects induced by chemical exposure may allow mycoplasma to become established in the extrathoracic region, leading to pneumonia. In this case, the incidence of pneumonia may not be a direct effect of chemical exposure but is secondary to irritation induced by exposure to the chemical and therefore can be considered treatment related.

2.5 Essential Elements and Bioavailability

Special consideration is required for developing oral risk values, such as RfDs, for essential elements, primarily metals. In such cases, particular attention is paid to the available human data for both toxicity and essentiality. Where available, World Health Organization (WHO) and U.S. National Academy of Sciences (NAS) values for minimal requirements and the recommended dietary allowance (RDA) or the estimated safe and adequate daily dietary intake (ESADDI) are

carefully considered in the development of an RfD. For example, consideration of uncertainty factors used in deriving an RfD should take into account that the RfD should generally not be lower than the ESADDI or RDA. Conversely, a risk manager may need to take into account normal dietary exposure to the chemical of interest in calculating acceptable environmental exposure levels. These issues were taken into account, for example, in the RfD for manganese (25).

It is also important to take bioavailability into account in developing risk values, such as PELs and RfDs. The absorption of some chemicals, particularly metals, may depend on the route and form of administration. For example, the inhalation absorption, bioavailability, and subsequent toxicity of nickel compounds is thought to vary by nickel species (6, 26). Gastrointestinal uptake of nickel also varies depending on whether it is in water or in food: human subjects who fasted absorbed 27% of a dose of soluble nickel salts when administered in water but 0.7% when administered in food (27). To account in part for potential differences in the bioavailability of manganese in food compared to water and soil, the USEPA adopted a modifying factor of 3 for the manganese RfD when exposure is via drinking water or soil.

A full consensus has not been reached on accounting for essentiality and differences in bioavailability. An alternative to using a modifying factor is to specify that the risk value is for the dose above that normally ingested in food. Another, more complex approach is to note the degree of absorption via different routes and for risk assessors to take that into account when calculating the total dose. Recent work in this area includes the effort by the National Academy of Sciences to determine the upper intake level for nutrients as part of its overall effort to establish dietary reference intakes (28).

2.6 Weight of the Overall Evidence

Evaluation of the overall weight of evidence is a key step in identifying the critical effect for a noncancer assessment. Evaluation of the overall weight of evidence includes characterization of (1) the quality of the evidence from human studies, (2) the quality of evidence from animal studies, and (3) other supportive information, which is assessed to determine whether the overall weight of evidence should be modified. The other supportive information can be used in evaluating the relevance to humans of the experimental animal model or the observed effect and in identifying the appropriate gas category for conducting dosimetric adjustments (see Section 3.1.2). Hill (15) provided criteria for evaluating whether a causal relationship has been established in an epidemiological study and in the overall epidemiological database. As noted by the USEPA (18), these same criteria apply in evaluating the weight of evidence for the entire database (Table 5.3).

Table 5.3. Criteria for Establishing Causal Significance

The strength of the association is enhanced when
▪ Consistent results are obtained by different investigators under a variety of circumstances.
▪ The association is stronger (larger relative risk or odds ratio).
▪ The association is specific, the exposure is associated with a specific effect, and that effect is specific to the exposure.
▪ Exposure occurs prior to the development of the effect (temporality).
▪ The association is consistent with what is known about the chemical's effects and mechanism based on clinical or animal studies (coherence and biological plausibility).
▪ A dose–response relationship is observed.

Similar criteria apply in evaluating animal data. Ideally, the database should include studies of several species in which a variety of end points are evaluated. For noncancer assessments, this

evaluation should include systemic toxicity following acute, intermediate, or chronic exposure by several routes of exposure, as well as developmental and reproductive effects. If these general tests or analogy to other chemicals suggests a concern, it may also be necessary to conduct specialized testing, such as evaluations of immunotoxicity or neurotoxicity. These studies are used to characterize the chemical's spectrum of potential human toxicity by identifying target organs and the dose ranges associated with adverse effects in animals. *In vitro* data can be used to elucidate potential mechanisms of biological activity, to evaluate the relevance of the end point to humans, and to improve the extrapolation from animals to humans, or to characterize within-human variability. The assessment of the animal database should include an evaluation of the reliability of the experimental design and toxicological interpretation of the results, as described before. In addition, consideration should be given to studies designed to evaluate the metabolism and toxicokinetics of the chemical and to data from other studies that may elucidate its mechanism(s) of action.

Once the data have been critically reviewed, all of the results from the various studies should be examined collectively to determine if a causal relationship exists between chemical exposure and the observed effects. In addition to the general criteria described in Table 5.3, the strength of the overall evidence is enhanced if (1) similar effects are observed in structurally similar compounds and (2) there is some evidence that the chemical also causes the particular effects in humans.

Species-specific differences in sensitivity to a chemical should also be considered. These differences may result from differences in metabolizing the chemical, from other physiological differences such as differences in the anatomy of the respiratory system, or from differences in the sensitivity of the target tissue. These differences can result in apparently inconsistent data that can be explained by considering the chemical's dosimetry, toxicokinetics, and toxicodynamics. Thus, evaluation of toxicokinetics and toxicodynamics can play an important role in evaluating the weight of evidence. For inhalation studies, consideration of particle size is an important part of evaluating the weight of evidence and may explain apparently conflicting results among studies. It is also important to distinguish differences that result from study limitations and experimental design from those that are related to species-specific differences in respiratory function.

3 Dose–Response Assessment

Dose–response assessment is generally the next step in the risk assessment process. It uses the results of the hazard identification as a starting point for determining the likely quantitative outcome in humans. The results of the dose–response assessment generally follow the methods described in Table 5.1. Additional details on the “safe” dose model and improvements to this model follow here.

3.1 General Principles

“Safe” or subthreshold doses are defined by a number of health agencies worldwide. Different names are used for these values, such as Health Canada's Tolerable Daily Intake or Concentration (TDI or TDC) (29); International Programme on Chemical Safety's Tolerable Intake (TI) (30); U.S. Agency for Toxic Substances and Disease Registry's (ATSDR's) Minimal Risk Level (MRL) (31); USEPA's Reference Dose (RfD) (32, 33) or Reference Concentration (RfC) (18, 20); or the World Health Organization's Acceptable Daily Intake (ADI) (34, 35). Many of the underlying assumptions, judgments of critical effect, and choices of uncertainty factors (or safety factors) are similar among health agencies in estimating these subthreshold doses. Approaches used to derive these different subthreshold doses are addressed in more detail in Section 3.3.

We describe here the method for estimating “safe” doses of the USEPA as a way of showcasing some general principles about this scientific area.

3.1.1 USEPA's Method for Developing Reference Doses (RfDs) and Reference Concentrations (RfCs) USEPA defines the RfD (or RfC) as “an estimate (uncertainty spans perhaps an order of magnitude) of a daily (or continuous) exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime” (18, 32). The RfD/RfC is composed of the no observed adverse effect level (NOAEL), lowest observed adverse effect level (LOAEL) or NOAEL surrogate, such as a benchmark dose/concentration (BMD/BMC) for the critical effect, divided by the composite uncertainty factor (UF) and modifying factor (MF). The following equation is used:

$$\text{RfD/RfC} = (\text{NOAEL, LOAEL or BMD/BMC})(\text{UF} \times \text{MF}).$$

The phrase “with uncertainty spanning perhaps an order of magnitude” is intended to reflect the overall precision of the estimate, generally an order of magnitude $\log_{10}$. This does not preclude less precise estimates, however, or the occasional estimate that may be precise to one arithmetic digit. The phrase “including sensitive subgroups” suggests that the estimate is intended for sensitive individuals, leading to the common interpretation that the RfD/RfC is a NOAEL for sensitive individuals. An additional implication of this phrase is that the average individual can be safely exposed to doses somewhat higher than the RfD/RfC. However, the estimate is not intended to protect hypersusceptible individuals, if they exist for particular chemicals. Thus, for example, the RfD/RfC is intended to protect against sensitization (see the RfC for beryllium and compounds, Ref. 25). Once an individual is sensitized, however, that individual may react to exposures much lower than those that caused sensitization, and the RfD/RfC may not protect against such a reaction. The phrase “likely to be without an appreciable risk” means that the estimate is thought to be without the risk of adverse effects for most, if not all chemicals, based on the available toxicity data and the use of uncertainty factors to account for data gaps. The complete absence of risk cannot, however, be guaranteed, in the light of the (small) potential for data gaps that have not been taken into account and the known variability in response among individuals.

4 Risk Characterization

Risk characterization, the final step in the risk assessment process, integrates the results of the hazard identification and dose–response assessment (toxicity assessment) and the exposure assessment. In essence, risk characterization is the “product” of risk assessment because it evaluates and synthesizes the data collected and the decisions made in the risk assessment. The outcome of risk characterization is a summary of the risks posed to individuals and populations, as well as the strengths and weaknesses of the risk assessment. Risk characterization is also a communication tool that provides the risk manager with sufficient information to make effective risk management policies. According to the USEPA (130), an effective risk characterization must have the following qualities:

- Transparency. The risk characterization must clearly describe where scientific data were used and where science policy judgments were used in the risk assessment. Default assumptions should also be clearly explained. Transparency ensures clear separation between science and policy decisions, allows for an assessment of the applicability of the risk estimate by the risk manager, and

facilitates the comparison of different risk estimates.

- Clarity. The risk characterization should present a summary of the key issues and conclusions from each section of the risk assessment, and it should discuss the overall strengths and weaknesses of the assessment.
- Consistency. All risk characterizations should be consistent in general format, while accounting for the unique nature of each specific risk assessment.
- Reasonableness. For the risk assessment to be credible and therefore a useful tool for the risk manager, the risk characterization must be accurate and well balanced. Appropriate conclusions should be drawn without overstretching the data; alternative conclusions should be presented.

The USEPA (130) recommends that each risk characterization include three components: a qualitative summary of each section of the risk assessment, a numerical risk estimate, and a description of uncertainties. This section describes each of these components separately and then discusses how these apply to risk assessment in the occupational setting.

4.1 Developing a Qualitative Summary

In evaluating the use of risk assessment in the federal government, the Commission on Risk Assessment and Risk Management (131) noted that risk characterizations that rely primarily on quantitative estimates "often convey an unwarranted source of precision while failing to convey the range of scientific opinion." As a result of this finding, the Commission recommended that risk assessments should include qualitative information on the nature of the adverse effects and on the risk assessment itself, so that risk managers have information on the range of scientific views and the evidence to support them.

A full discussion of the uncertainty within each analysis and that related to the overall assessment is critical to a complete risk characterization. Uncertainty discussions are important because they form the basis for the overall judgment as to the adequacy of the data and conclusions drawn from it. In addition, highlighting of uncertainties can identify areas where the collection of additional data may reduce the uncertainty and strengthen the risk assessment. An uncertainty discussion includes the quality and quantity of available data (toxicity and exposure), identification of data gaps, the use of default assumptions and parameter values, and the uncertainties in the models used.

The USEPA (130) has prepared an excellent guide for risk assessors to follow when developing the qualitative summary for a risk characterization. The guide is presented in two parts. By asking a series of questions, the guide first directs risk assessors to bring together the major conclusions of the risk assessment and then provides an outline for drawing together all of the information to characterize risk. A summary of the USEPA (130) guidance is presented in Table 5.7.

Table 5.7. Summary of EPA (130) Guidelines on Risk Characterization

Characterize Hazard
▪ Describe key studies, studies that support the key studies, and other valid studies with conflicting results.
▪ Describe what is known about the mechanism of chemical action.
▪ Comment on nonpositive data and whether these data were considered in the hazard characterization.
▪ Summarize the hazard identification including the confidence in the conclusions, alternative conclusions, significant data gaps, highlights of major assumptions.
Characterize Dose
▪ Describe the data used to develop the dose–response curve.
▪ Describe the model used to develop the dose–response curve.

- Discuss the route and level of exposure compared to expected human exposure.

Characterize Exposure

- Discuss significant sources of exposure.
- Describe the populations exposed.
- Describe any modeling used to generate exposure estimates.
- Describe the key descriptors of exposure.
- Evaluate cumulative or multiple exposures.
- Summarize the exposure assessment conclusions, including results of different approaches, limitations of approaches, range of exposure values, confidence in the results.

Risk Conclusions

- Overall picture of risk.
- Major conclusions and strengths.
- Major limitations.
- Science policy options and defaults used.
- Reasons for choices made.

Although application of the principles described in the USEPA risk characterization guidance represents good industrial hygiene practice, there are no specific guidelines for risk characterization in the occupational setting. Typically the "risk characterization document" resulting from an occupational survey is in the form of a survey report. Such a survey report typically describes the rationale for the survey (hazard recognition), the exposure assessment strategies used, the results of the exposure analysis, comparison of the results to occupational standards (hazard evaluation), and recommendations for control of any hazards (hazard control). An important difference in the qualitative description of the risk assessment is the lesser emphasis on the strengths and weaknesses of the reference level and greater emphasis on the exposure estimates. Another major difference is the overlap between risk characterization and risk management. The risk manager for the occupational risk characterization is often not trained in the appropriate evaluation of exposure control options. For this reason, the recommended hierarchy of controls is commonly outlined in the occupational risk characterization document.

4.2 Presenting the Risk Estimate

Once the risk characterization has summarized the qualitative aspects of the risk assessment, it should then present the quantitative aspects of the risk assessment, including calculating risk estimates and discussing the risk in context of other similar risks. For noncancer risk assessment, developing a quantitative risk estimate involves comparing the measure of exposure to a criterion level that has been determined from the toxicity estimate. Based on the traditional approach, the result allows determining whether the exposure (dose) exceeds the allowable dose level. For cancer assessment, a probabilistic measure of risk (e.g. 1:1000 likelihood of excess cancer) is calculated and compared with some risk management standard of "acceptable risk." By contrast, for noncancer risk assessment, the exposure is described only as being larger than, equal to, or less than the RfD, RfC, or other risk value. For example, the exposure may be divided by the RfD or RfC (resulting in the hazard quotient) in an analysis of a Superfund site, the oral intake of a pesticide may be compared to the RfD, or a worker's TWA exposure may be compared to an occupational exposure limit.

In both the environmental and occupational evaluations of risk, it often necessary to evaluate risk in response to a combination of exposures or to exposures through multiple routes. One approach that is used in assessing risk from multiple substances at Superfund sites is determining the hazard index. This involves summing the hazard quotient for each of the substances of concern. In the occupational setting, similar approaches have been adopted by OSHA (5) and ACGIH (6). In the case of the

ACGIH, for exposure to multiple substances with similar effects, the summation of the individual exposure/TLV ratios are compared to a value of 1. If the substances have differing effects, however, then each exposure/TLV ratio is compared to a value of 1 independently.

The approaches for assessing the risk from multiple routes of exposure differ substantially between environmental and occupational settings. In the Superfund paradigm, the total dose can be calculated for the combined inhalation, dermal, and oral exposure before comparison to the appropriate criterion level. In the occupational setting, exposure though inhalation is typically measured as the predominant exposure route. Methods are available to measure dermal exposure; however, this is not often done. As a result, for substances that are absorbed through the skin, comparison of the air concentration to the exposure threshold may not adequately estimate potential risk. To address this problem qualitatively, many organizations that establish occupational exposure limits (OELs) add a notation for substances for which dermal absorption can contribute meaningfully to the total dose. Another approach in occupational assessment to account for the contribution of multiple exposure routes is the use of biological markers of exposure. Several OSHA substance-specific standards include requirements for biological measures of exposure. In addition, biological exposure indices (BEIs) are published by the ACGIH (6).

A single risk estimate is not sufficient to provide risk managers with a clear understanding of risks. Rather, the USEPA (130) suggests that a range of risk descriptors be used to "allow managers to identify populations at greater and lesser risk and to shape regulatory decisions accordingly." The risk descriptors suggested by the USEPA (130) include

- individual risk at both the "central tendency" (50^{th} percentile) and "high end" ($90–95^{th}$ percentile) of the risk distribution.
- population risk: For noncancer risk assessment, this is an estimate of the portion of the population whose exposure exceeds the reference level.
- risk to important subgroups of the population.

It is important to note that, because risk is estimated as a function of exposure, the characteristics that distinguish these different risk descriptors will be related primarily to differing exposure. In addition, the Commission on Risk Assessment and Risk Management (131) suggests comparing the distribution of a population's exposure to the reference level, so that the relationship between exposure and the potential for harmful effects is clearer.

In the occupational setting, the presentation of the variability in the exposure estimates often receives more weight than the uncertainty surrounding the derivation of the OEL. Issues surrounding exposure variability in occupational settings differ from those in environmental risk assessment, in that the exposure estimate is often based directly on measured exposures. The presentation of the data depends on the underlying purpose for the measurements, but it is common for compliance purposes to measure workers expected to have the greatest exposure for a representative exposure group. Thus, an upper bound estimate of exposure is compared to the appropriate occupational exposure limit, whereas comparison of the distribution of the exposures to the OEL would be less common.

Once the range of potential risks has been estimated, it is important that the risk characterization place the risk into the context of other similar risks. Issues to address in completing this part of the risk characterization include evaluating alternatives to the hazard and making risk comparisons. The Commission on Risk Assessment and Risk Management (131) recommends that the following risk comparisons are useful in placing risk in context:

- risks associated with chemically-related agents
- risks with the same agent from different exposure sources

• risks with different agents from the same exposure pathway
• risks of different agents that produce similar effects

4.3 Evaluating the Uncertainty Associated with the Risk Estimates

Another component in risk characterization is the discussion of the sources of both variability and uncertainty in the risk assessment and the evaluation of uncertainty associated with the risk assessment. The USEPA distinguishes between variability and uncertainty in its risk characterization guidance (130). Variability describes interindividual, spatial, or temporal differences within an animal or human population or within monitoring data. It reflects the inherent heterogeneity of the population and cannot be reduced by gathering additional data. Uncertainty, on the other hand, reflects areas for which data are unknown. By contrast, uncertainty can be reduced by eliminating data gaps. Uncertainties are associated with both dose–response models and with fate and transport models; an uncertainty analysis would evaluate the basis for and validation of the model. There are also uncertainties associated with dose–response evaluation that do not use mathematical models. As described in Section 3.3, a number of organizations use uncertainty factors to address such data gaps. Uncertainty is also inherent in estimating the best choice of uncertainty factor.

The field of risk assessment is increasingly utilizing uncertainty and sensitivity analyses to better quantify uncertainty in evaluating risks to human health. Probabilistic methods, such as Monte Carlo modeling, can be used to quantitatively describe uncertainty and parameter sensitivity. In this approach, each of the parameters in a model or calculation is represented by a distribution of possible values. The probability distribution for each parameter is randomly sampled, and the model is run using the chosen set of parameter values. This process is repeated a large number of times until the probability distribution for the desired model output is determined. Using this approach, a "high-end" value (e.g., 95^{th}or 99^{th} percentile) for the overall model can be estimated more accurately than by simply using the "high-end" estimates for each of the inputs. Monte Carlo methods have been used in evaluating exposure for site assessments and for characterizing uncertainty in PBPK models. Such approaches can also be used for quantitative sensitivity analyses by determining how the overall model output varies as one parameter is varied.

An analysis of the uncertainty in noncancer risk values is one area that has received little attention to date. Noncancer risk assessment has traditionally calculated reference values to be protective of human health, rather than predictive of actual toxicity. Each reference value is based on numerous assumptions and uncertainties, which contribute to the lack of precision in these values.

Noncancer risk values are not precise. USEPA's definition for RfDs and RfCs addresses this lack of precision, as " ... an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily or continuous exposure ... " (18, 32) Similarly, IPCS defines Tolerable Intakes (TIs) as "an estimate of the intake of a substance over a lifetime that is considered to be without appreciable health risk" (30). Such lack of precision is specifically mentioned in IPCS (30), which indicates that the precision of the tolerable intake depends upon the validity and reliability of the data and also on the magnitude of the uncertainty factor. The precision of a RfD or TI is to one significant figure at best, and an order of magnitude is the most usual case. As the uncertainty factor increases beyond 1,000, however, the precision becomes even less.

However, as discussed more fully by Felter and Dourson (36), the concept that risk estimates are inherently imprecise seems to have been lost somewhere between calculating risk values and making risk management decisions. There may be several reasons for this, including the desire by risk managers and the public to know with certainty what the risks to public health might be, or alternatively, what dose is safe. The underlying science can seldom determine such "bright lines." Making decisions with imprecise and uncertain data is much more difficult.

Unlike EPA's RfDs and RfCs, which have a stated uncertainty spanning an order of magnitude, explicit quantitative estimates of the range of uncertainty in occupational exposure values are less

clearly outlined. The OSHA PEL does not state the underlying uncertainty associated with its use, and it is enforced so that a single 8-hour TWA above the PEL on any day would be viewed as noncompliance (5). In contrast, the ACGIH TLV-TWA is "an exposure level to which it is " ... believed that nearly all workers may be repeatedly exposed, day after day, without adverse effect." The TLV documentation addresses the underlying uncertainty by indicating that the database used in deriving the value varies from substance to substance, and thus the precision of the estimated TLV is subject to variation. Furthermore, the TLV is not to be considered a fine line between safe and dangerous concentrations.

Even when the lack of precision is acknowledged in the definition of the RfD/RfC, the lack of scientific data upon which the order of magnitude definition is based has led to widely varying interpretations of the inherent range. A recent informal survey of risk assessors and managers at the USEPA found that there were several interpretations of the "order of magnitude" in the definition of the RfD (36). As described in that publication, these interpretations can be described as

"range = x to 10x (where the point estimate of RfD = x). This view is supported by those who believe that the risk assessment process is so inherently conservative that the RfD should be considered the lowest estimate and the range of imprecision all rests above this point estimate.
range = 0.3x to 3x. This is the view held by many of USEPA's former RfD/RfC Work Group members, wherein the RfD is associated with uncertainty on either side. The order of magnitude is divided into half-logs.
range = 0.1x to x. This is the view held by many risk managers, that is, regulatory decisions (e.g., setting of standards or cleanup levels) are based on the assumption that we are "OK" as long as we do not exceed the level of the RfD.
range = 0.1x to 10x. This range could be envisioned if one were to assume that the order of magnitude range could be on either side of the point estimate x."

As discussed by Felter and Dourson (36), even if there were agreement among risk assessors how this "order of magnitude" uncertainty should be interpreted, it may not be appropriate to apply this range of precision equally to all risk values. A number of factors contribute to the precision in a given noncancer risk value. These include the dose spacing, the quality of the study, the degree to which the experimental animal species predicts effects in humans, the severity of the critical effect and the slope of the dose–response curve (both of which are related to the precision with which the threshold is estimated), and the size of the composite uncertainty factor. Thus, the "true" range of the resulting risk value is specific to a given chemical and database. To some degree, the statements that the USEPA includes about the confidence in the study, database, and overall confidence in the RfD/RfC are meant to address the precision in the resulting value, but risk managers may find it difficult to quantitatively apply such qualitative statements. A more formal description of uncertainty in risk assessments can help risk managers move beyond "bright line" values and incorporate uncertainty in risk management decisions.

Felter and Dourson (36) suggested that the expression of risk values as a range has several advantages. Expressing these values as a range makes explicit to risk managers that these values are not "bright lines." Presentation of a range may help with prioritizing hazards and resulting decisions (for example, if two chemicals have similar hazard quotients, but differ in the associated precision.) International harmonization efforts may be assisted by making the range explicit, as risk managers are made aware that the values for a given chemical from different organizations might differ somewhat, but may still fall within the same range. The establishment of ranges, however, would necessitate the development of consistent guidance for interpreting and using these ranges.

A recent invited commentary was held on the imprecision of risk numbers (132). Papers from Health Canada, IPCS, Toxicology Excellence for Risk Assessment (TERA), and the USEPA, USFDA, and

USATSDR set forth various views on this subject. One conclusion from this effort was that risk assessors should be careful to convey a measure of confidence in their results and quantify this when possible. Allowing risk managers and the public to believe that risk estimates are more precise than appropriate may lead to inappropriate risk management decisions and less trust in the science and practice of risk assessment.

4.4 Margin of Safety and Margin of Exposure Approach

Margin of safety (MOS) has traditionally been used in the field of toxicology as a tool to compare dose–response data between a drug's desirable effective dose (ED) and its lethal dose (LD) or minimum toxic dose. For example, the ED_{99} can be divided by the LD_{01} to calculate the margin of safety, or therapeutic index, as it is sometimes called. The larger the MOS, the greater the presumed safety in using the drug.

The MOS concept is useful and has also been carried over to the field of environmental health. In this case, a NOAEL from a toxicity study is divided by a measured exposure to the human population to calculate a MOS. Again, the larger the MOS, the greater the presumed safety. MOS addresses both dose/response (NOAEL) and exposure and therefore, falls within risk characterization as defined by the NAS (2). The MOS must be interpreted by experts depending, in part, on the completeness of the toxicity database from which the NOAEL of the critical effect is derived (129). An analogous term, the margin of exposure (MOE), is also used, as discussed in Barnes and Dourson (32).

The MOS method, as practiced by the EU (129, 133) begins with the same evaluation of toxicity data to determine the NOAEL or LOAEL in the hazard identification step of the risk assessment process. It is after the hazard identification step that the MOS/MOE approach diverges from the estimation of a “safe” dose. The MOS compares this NOAEL or LOAEL to the exposure estimate(s) for the exposed human population(s), whereas in the “safe” dose approaches, uncertainty factors are used to estimate a “safe” dose. If it is not possible to derive a N(L)OAEL/exposure ratio, a qualitative comparison of effects with exposure data should be made. Where it is not possible to determine a N(L)OAEL (e.g. irritation, corrosivity, sometimes sensitization, mutagenicity, genotoxic carcinogenicity), the likelihood that the effect will occur is evaluated on the basis of exposure information. The comparison is in the form of a dimensionless ratio where the NOAEL or LOAEL is in the numerator, the measured or estimated exposure is in the denominator, and both are in the same units. Exposure estimates higher than or equal to the NOAEL or LOAEL indicate concern. Those exposures lower than the NOAEL or LOAEL are evaluated on the basis of expert judgment of the uncertainties related to the following parameters, as outlined in Ref. 129:

- the uncertainty arising, among other factors, from the variability in the experimental data and intra- and interspecies variation;
- the nature and severity of the effect;
- the human population to which the quantitative and/or qualitative information on exposure applies;
- the differences in exposure (route, duration, frequency and pattern);
- the dose–response relationship observed; and,
- the overall confidence in the database.

These assessment factors are similar to those covered by the uncertainty factors of the tolerable intake approach. However, in contrast to the TI approach where expert judgments about the appropriate factors are considered in determining a “safe” dose, which is then used to estimate a guidance value, the MOS approach relies on expert judgments to reach conclusions about given exposures on a case by case basis.

Because the MOS/MOE is a risk characterization technique (i.e., it combines both dose–response and exposure assessment), the results should be compared to other established risk characterization techniques, such as the development of criteria or guideline values. (A good discussion of the

development of guideline values can be found in Ref. 30). One advantage of deriving a guidance value from a TI when compared to the MOS is that exposures at or less than the guidance value can generally be interpreted as without risk. However, when exposures exceed the guidance value, then expert judgment is needed to interpret the significance in health terms of the exceedence. One advantage of the MOS when compared to the guidance values (from a TI) is that not all toxicity databases are strong enough to develop a TI, yet generally these databases can be used to determine a MOS. However, additional care is needed in interpreting of this MOS because the database is correspondingly weaker.

Overlap often exists between the derivation of a guidance value (from a TI) and MOS. This is not unexpected nor necessarily undesirable. However, in such situations, an analysis of these techniques in relationship to each other should be conducted.

Although this type of approach has been used for a number of years in noncancer risk assessment, its use in cancer risk assessment is also becoming more prevalent. Some of the issues and concerns raised with these approaches are pertinent to noncancer risk assessment as well. For example, Health Canada utilizes an Exposure/Potency Index (EPI) (29) to characterize risk from "nonthreshold toxicants" and provide guidance for determining further action under the Canadian Environmental Protection Act. The EPI approach compares quantitative estimates of carcinogenic and mutagenic potency to the estimated daily intake of the substance by the general population (or high-exposure subgroups) or to concentrations in specific media. A margin of exposure (MOE) analysis is recommended by the USEPA in its proposed cancer guidelines (134) as the default approach when there is no evidence for linearity and there is sufficient evidence to support an assumption of nonlinearity.

Each of these approaches (i.e., MOS, MOE, or EPI) is similar in that they compare an experimental dose or potency to an exposure to determine the ratio; the larger the ratio, the "safer" the presumed exposure. Although the ratios may be based on scientific data, the interpretation of these ratios is more of a management judgment. Health Canada (29) clearly identifies the EPI as a tool to characterize risk and provide guidance in setting priorities. Under the CEPA mandate, this is the extent of decision making that needs to be addressed, and guidance is provided as to what ranges of EPIs would indicate priority for further action. USEPA (134) discusses MOE in the dose–response section of cancer assessments, even though it is clearly a risk characterization concept, because it compares dose–response information and exposure data. The proposed USEPA cancer guidelines include a general discussion of some factors that may be considered guidance for the risk manager in determining the appropriate MOE. These are based upon the traditional uncertainty factors utilized in the tolerable intake approaches. However, no definitive suggestions are made for applying these or other factors.

Although developing a MOS, MOE, or EPI is useful in evaluating safety, alternatives exist to characterize the risk when a predetermined exposure level does not exist. One approach is to develop a guidance value, or criterion. How should the estimate of these guidance values fit with approaches such as the MOE or EPI? Specifically, for the MOE, the risk manager must determine a priori which factors need to be included in extrapolating from, for example, an LED_{10} from animal bioassay data to a "safe" intake level for humans. This is best handled by the using uncertainty factors, in a manner similar to that currently used in the tolerable intake approaches for noncarcinogens and the subsequent development of guidance values. Because not all LED_{10}s are created equally—some will be based on increased incidences of severe lesions; others will be based on precursor lesions with no immediate health impact—a comparable strategy of uncertainty factors based on scientific data is needed.

Noncancer Risk Assessment: Principles and Practice In Environmental and Occupational Settings
Lynne T. Haber, Ph.D., Joan S. Dollarhide, MS, MTSC, JD, Andrew Maier, MS, CIH, Michael L. Dourson, Ph.D., DABT

5 Summary
The field of noncancer risk assessment is changing. Improvements based on research and analysis during the last 20 years have yielded newer, more quantitative methods for determining health risks associated with chemical exposures—whether such exposures are from the workplace or the environment. These methods can answer more questions asked of the existing data and allow better risk management decisions. These methods also have broader use and may integrate this area of risk assessment with those that focus more on cancer toxicity and chemical mixtures.

Environmental Exposures

We live in a chemical world, and exposure to xenobiotics is a fact of life. Humans are exposed daily to a variety of chemicals including but not limited to large categories of pesticides, pharmaceuticals, household products, and food additives. Chemical exposures can be intentional or unintentional, to a single chemical or to a mixture of chemicals. Exposures to environmental chemicals occur in populations living in inner cities near chemical manufacturing plants (1, 2) hazardous waste sites, and in the near field runoffs from fields and fertilizers (3). An overturned cargo train or transportation truck can spill chemicals in a pristine environment and become a source of pollution, contamination, and exposure, and eventually lead to an emergency response event. Exposures to environmental chemicals can affect humans, animals, and plants. Thus people of various interests and backgrounds are concerned about environmental exposures. Everyone carries a body burden of chemicals that range from primary elements and radioactive materials to synthetic, persistent chemicals such as dioxins, polychlorinated biphenyls (PCBs), and certain chlorinated pesticides. The major issue is not whether we are being exposed to mixtures of chemicals, but whether these exposure levels exceed the body's ability to detoxify, adapt, or otherwise compensate.

Following a chemical exposure, the body exhibits a spectrum of biologic responses (Fig. 6.1) (1). For many chemicals, low-level human exposures do not produce observable health effects. Physiologically, the body adjusts to the presence of chemicals at this level through adaptive mechanisms. As chemical exposure increases, effects such as enzyme induction and certain biochemical and subcellular changes of uncertain significance may result. The body may have compensatory mechanisms at this level of chemical exposure (3). However, as chemical exposures continue to increase, observable adverse effects may ensue as the body exhausts its adaptive and compensatory mechanisms. Such adverse effects could lead to biochemical, pathophysiologic, histopathologic changes resulting in organ dysfunction. Exposure to higher levels of pollutants could lead to morbidity and mortality. Exposures from multiple sources or pathways may lower the threshold for adverse health effects along this continuum. Considering that humans generally lack homogeneity in biochemical characteristics, some groups within the population will be more susceptible to chemical exposures than others.

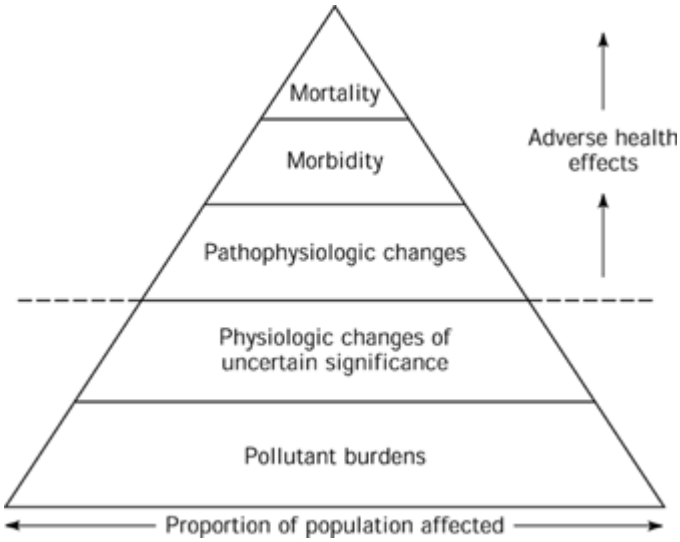

Figure 6.1. Spectrum of biological response to environmental pollutant exposure.

Thus it is important that exposure to environmental chemicals be viewed in the context of overall chemical exposures. Concurrent exposures to chemicals such as welding fumes, indoor air pollutants, tobacco smoke, alcohol, and prescription and nonprescription drugs complicate the health risk assessment of low-level, involuntary, environmental exposure such as may occur at hazardous waste sites. Voluntary exposures to some chemicals frequently entail exposures to relatively high chemical concentrations and are usually well defined and quantifiable, whereas involuntary exposures from waste sites may be at low concentrations and difficult to characterize and quantify. Individual control over exposure varies across personal, occupational, and environmental chemical exposure pathways (Fig. 6.2). Personal exposures such as firsthand tobacco smoke or alcohol are voluntary. Occupational exposure is voluntary, but the individual generally has less control over these exposures. On the other hand, individuals usually have few options for controlling environmental exposures under ordinary circumstances. In most cases, other than relocation, there are no clear options for individual control over hazardous waste exposures. Often an individual may not even be aware of the site, the exposure pathways, or the nature of the exposure. In terms of concentrations, for general populations, personal exposures are usually at higher levels than hazardous waste exposures. Such combined exposures may produce obvious adverse health effects or compromise physiologic defenses that are necessary for maintaining homeostasis.

Figure 6.2. Human exposures to chemicals in the environment.

The potential for combined chemical exposures to compromise physiologic systems may be greater in susceptible populations that include children, elderly persons, women of childbearing age, fetuses, persons with certain genetic disorders, and persons with preexisting infirmities (3). In such populations, pollutant burdens can initiate pathophysiologic changes at lower levels in comparison to the general population. For example, human infants and children differ from adults in size, immaturity of biochemical and physiologic functions in major body systems, and body composition

in terms of proportions of water, fat, protein, mineral mass, and chemical constituents (4, 5). During the first 2 months of life, rapid development occurs in the brain (cell migration, neuron myelination, and creation of neuron synapses), lungs (developing alveoli), and bones (rapid growth). Development of the brain and lungs continues until age 12, at which time gonad maturation, ova and sperm maturations, and breast development occur (6). Depending on the chemical, the stage of growth and development may be a critical factor in determining toxicity (7). Finally, the contribution of hazardous waste to exposures of populations living near hazardous waste sites may constitute a significant contribution to overall body burdens when concurrent with occupational and personal exposures.

Historically, health concerns from exposure to single chemicals drive criteria derivation procedures. Usually, the target chemical, or group of chemicals, is identified by a government agency, international organization, or an advisory body based on legislative mandate, evidence or potential for human risk, or community concerns. For each chemical, exposure and health effects data are reviewed, and a single route-specific index of "acceptable" exposure is derived for the chemical. This approach is taken by several organizations such as the American Conference of Governmental Industrial Hygienists (ACGIH), the Agency for Toxic Substances and Disease Registry (ATSDR), the National Institute for Occupational Safety and Health (NIOSH), the U.S. Environmental Protection Agency (EPA), and the World Health Organization (WHO) (Table 6.1). However, most exposures are not to single chemicals, but to complex mixtures of chemicals that can affect public health through multiple routes of exposure. The Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, or Superfund) of 1980, the Clean Air Act of 1990, and the Food Quality and Protection Act of 1996 all mandate organizations and agencies to consider multiple chemical exposures, sequentially or simultaneously, while setting the criteria to protect public health from potential health effects of chemicals. Thus one has to consider comprehensive risk to populations that are exposed not only to a specific mixture but also to additional environmental agents and naturally occurring compounds that may enhance, inhibit, or contribute to the health risks posed by that mixture. In very few cases, the available information on a mixture and its components is reviewed and a criteria for the mixture are derived. The purpose of this chapter is to highlight issues relevant to the joint toxicity assessment of chemical mixtures through the use of representative published studies, to present the alternative experimental testing approaches for mixtures, and to promote the use of innovative techniques to advance joint toxicity assessment methods.

Table 6.1. Examples of Agencies and Their Derived Criteria

Agency or Organization	Acronym	Criteria Derived
American Conference of Governmental Industrial Hygienists	ACGIH	Threshold limit value (TLV)
Agency for Toxic Substances and Disease Registry	ATSDR	Minimal risk level (MRL)
National Institute for Occupational Safety and Health	NIOSH	Recommended exposure level (REL)
Occupational Safety and Health Administration	OSHA	Permissible exposure level (PEL)
U.S. Environmental Protection Agency	U.S. EPA	Reference dose (RfD); reference concentration (RfC)
U.S. Food and Drug Administration	U.S. FDA	Acceptable daily intake (ADI)
World Health Organization	WHO	Environmental health criteria

(EHC)

Types of Mixtures

Simple Mixtures Human populations are exposed to a range of chemical mixtures that can be simple or complex, partially or completely characterized, and of stable or varying composition. This can be illustrated through a continuum of mixtures as illustrated in Table 6.2. In the field of anesthesiology, combinations of well-defined anesthetics under completely controlled exposure regimens have been used for a long time. For example, morphine in combination with other epidural anesthetics has been used effectively to provide improved overall pain relief following surgery (8). This is an example of a simple mixture that is completely characterized, and the route and duration of exposure are completely controlled.

Table 6.2. Continuum of Chemical Mixtures to Which Humans Can Be Potentially Exposed

	Mogensen et al. (8)	Institute of Medicine (9)
Exposure and conditions	Well-defined, controlled	III-defined, uncontrolled
Causative agents	Bupivacaine, morphine, and Clonidine	Unknown chemical/biological petroleum combustion products
Route of exposure	Inhalation and epidural	Mixed; inhalation, oral or dermal
Monitoring data	Complete	Very limited
Hypothesis testing	Yes	No

Complex Mixtures At the opposite end of the spectrum is exposure to complex mixtures, which can be intentional or unintentional. During the Gulf War, military personnel were intentionally exposed to vaccines and preventive agents including anthrax vaccine and the chemical warfare antidote pyridostigmines (9). Unintentional exposures included chemical/biologic agents and smoke and petroleum combustion products. Potential exposures could have been through a combination of inhalation, oral, and dermal routes. Such mixed exposures were associated with symptoms such as fatigue, abdominal pain, diarrhea, headache, memory loss, skin rashes, and hair loss. Also, the exposure occurred under varying environmental conditions of temperature, humidity, and high winds. These types of complex mixture exposures pose a formidable challenge for health risk assessors. In general, the availability of information on chemical mixtures encountered in the real world varies greatly between simple and completely characterized, and the highly complex and poorly characterized mixtures.

NIOSH estimates that more than one-half of the U.S. workforce is employed indoors, and that this trend will continue to expand (10). This trend is paralleled by the increase in reports of symptoms and signs related to indoor air environments. These effects range from nonspecific symptoms of headaches and eye irritations to signs of allergic and infectious diseases. Although the majority of health problems reported in indoor workers cannot be attributed to specific exposures, evidence suggests that multiple factors are involved including microbiologic, chemical, physical, and

psychologic/social stressors. In addition, voluntary exposures to tobacco, prescription and nonprescription drugs, alcohol, herbal remedies, vitamins, and cosmetics add to the complexity.

Some of the most complex and hard to characterize mixtures are those found at hazardous waste sites because hundreds of chemicals have been identified at such sites (11–13). Attempts have been made to rank them singly (14–16) and in combination (15, 17) based on the threat they pose to the environment and to public health. Parameters influencing exposure, such as transportation of chemicals from waste sites to receptor populations, have also been examined (18, 19). Environmental laws such as CERCLA (or Superfund) section 104, as amended by the Superfund Amendments and Reauthorization Act (SARA) (USC 9604) [i][2]), have helped to focus efforts on the fundamental issue of assessing the impact of chemicals and chemical mixtures. Through this legislation, ATSDR has been specifically mandated to identify individual substances and combinations of substances that pose the greatest public health hazard at hazardous waste sites. The information thus obtained allows the agency to pursue activities such as developing toxicological profiles, identifying substance-specific data needs, and establishing research agendas.

Until recently, basic and critical information necessary for identifying the mixtures most commonly found at hazardous waste sites was not available. ATSDR's Hazardous Substance Release/Health Effects Database (HazDat) is a searchable database that captures pertinent information from public health assessments performed by the agency for hazardous waste sites on the National Priorities List (NPL). HazDat contains environmental contamination and other data from more than 3500 hazardous waste sites or events for which ATSDR has conducted public health assessments, prepared consultations, or provided responses to emergencies involving releases of substances into community environments (20). Using HazDat, the agency produced a list of the top 275 single substances of public health concern at U.S. hazardous waste sites (12). The algorithm used to rank these single chemicals is driven by empirical data and consists of three components: frequency of occurrence, inherent toxicity, and potential for human exposure. Scores from each of the three components are added, and the chemicals ranked according to their overall score. This single-substance list is unparalleled in the public health arena since it is based on the most comprehensive data readily available regarding contaminants at hazardous waste sites. A trend analysis was performed, employing HazDat, to identify the substances and mixtures that occur most frequently in three environmental media: water, soil, and air. This analysis revealed that water, soil, and air were contaminated at 1067 (90%), 894 (75%), and 222 (19%) sites, respectively. Within these subsets of sites, 965 (90%) 770 (86%), and 139 (62%), respectively, exhibited two or more contaminants. The results for the highest occurring single substances and binary and trinary combinations are given for the three media in Table 6.3.

Table 6.3. Priority Substances Found in the Environment: Frequencies of Occurrences of Sir Substances and Their Combinations at 1188 Hazardous Waste Sites[a]

No.	% of Sites	Single Substance	% of Sites	Binary Pairs		% of Sites	Trinary (Tertiary) Combinati

Completed Exposure Pathways

The mere presence of single chemicals or chemical mixtures in the environment does not indicate that a health threat exists. A four-step process is proposed to identify the chemicals that present an actual risk to human health or wildlife (Fig. 6.3). This process allows chemicals and chemical mixtures of concern at waste sites to be identified in a systematic manner by combining the hazard assessment and exposure assessment information of the chemicals (19). In the first step, an all-inclusive list of chemicals is identified. Second, a list is prepared of those chemicals found off-site in environmental media. This takes into account the uneven movement of the chemicals through various environmental pathways from the source of disposal to other areas in the vicinity of the site. The third step involves compiling a list of chemicals with completed exposure pathways. This is a list of chemicals for which all data are available to establish the link between the source of contamination, the mechanism of transport through environmental media, routes of exposure, and a receptor population. Populations have been exposed to such chemicals in the past, are being exposed at present, or will be exposed in the future unless remedial actions are taken. Finally, the chemicals of actual public health concern are selected by comparing the concentrations found with medium-specific, health-based comparison values (and indicating those chemicals) that exceed the established

safe levels. If the concentration of a chemical in a given medium exceeds the appropriate comparison value, the chemical is retained as a contaminant of concern for further evaluation. The most often used comparison values are: environmental media evaluation guides (EMEGs), reference doses (RfDs), cancer slope factors, health advisories (HAs), water quality criteria (WQCs), and permissible exposure limits (PELs).

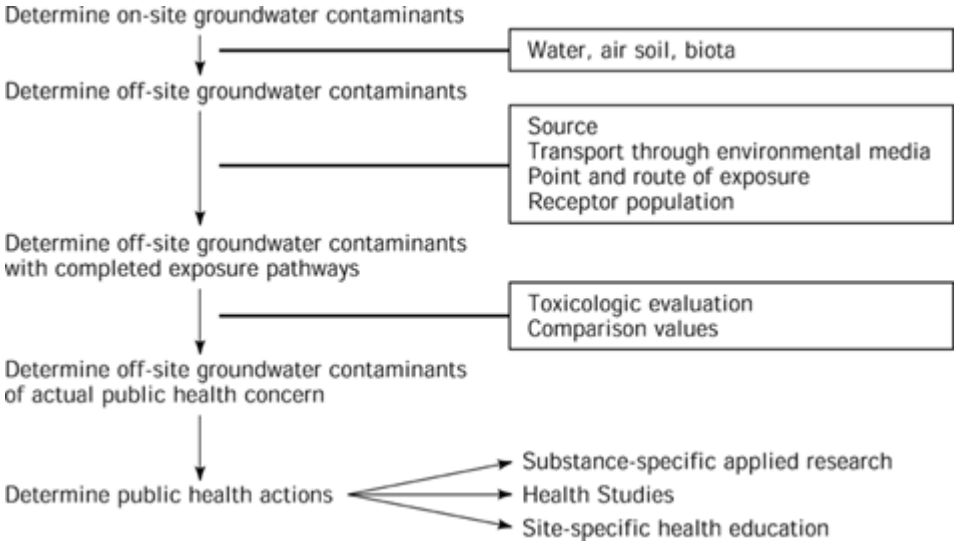

Figure 6.3. The identification of chemicals/chemical mixtures found in completed exposure pathways.

Thus environmental chemical mixtures are characterized through the identification of individual chemical components in completed exposure pathways and joint toxicity assessments are carried out on such mixtures that pose a potential threat to human health and/or the environment.

Approaches for Assessment of Joint Toxic Action

Historical Background

Toxicity assessments for chemical mixtures are based on the following major concepts of "joint action" as defined by Bliss (21).

Similar joint action: The chemicals produce identical effects but have different potencies, so that one component can be substituted for a constant proportion of the other. The toxicity of a mixture is predictable directly from that of the constituents if their relative proportions are known. Thus components of a mixture behave as concentrations or dilutions of one another, differing only in their potencies. This type of joint action is commonly referred to as *dose addition*.

Independent joint action: The chemicals act independently and have different modes of toxic action; that is, the toxicity of the first component may or may not be correlated with the toxicity of a second component. Thus the toxicity of the mixture can be predicted from the dosage–mortality curve for each constituent applied alone and based on the correlation in toxicity between the two chemicals. The observed toxicity can be computed on this basis irrespective of their relative proportions. This type of joint action is commonly referred to as *response addition*.

The mixture of concern, similar mixture, and component-based approaches are used to perform joint

toxicity evaluations of chemical mixtures (22, 23). These three approaches parallel the differences in the categories of chemical mixtures that are encountered in day-to-day life. These categories are based, for the most part, on the nature and number of components in the mixture. The health risk assessors utilize all the plausible approaches that can be applied, compare the results, and decide to use the approach that best suits a given exposure scenario. The results of such multiple analyses may be useful in describing the uncertainty in the joint toxicity assessment. In practice, the use of all three approaches may not be possible for every mixture because of lack of data, time, and other resources.

The "mixture of concern" approach is the most direct and simple method and entails the fewest uncertainties. Hence, it can be called the preferred approach. This approach, however, is the one that can be least frequently applied because it requires that toxicity data be available on the specific mixture of concern and that these data be adequate for deriving an integrated allowable level, such as a minimal risk level (MRL), for the mixture. An MRL is defined as an estimate of daily human exposure to a mixture that is likely to be without an appreciable risk of adverse effects (noncarcinogenic) over a specified duration of exposure. In real life, mixtures with adequate toxicity data are very few. An MRL was derived for fuel oils, a mixture that may vary to a small degree in its composition, but is reasonably consistent from sample to sample. The study used in the MRL derivation represented the actual controlled exposure to a well-defined mixture (24). Often it is not possible to derive a single assessment value that can be used directly in every exposure scenario because some mixtures, such as gasoline, are generally substantially variable in composition depending on the source of the crude oil or differences in the fractionation process. Furthermore, limitations of the mixture of concern approach include uncertainties regarding the extent to which the mixture from the exposure assessment matches the mixture that is the basis for the MRL, due to changes in its composition with time and distance from the release, and/or differences in the original mixture.

Approaches for Experimental Studies of Mixtures

Many approaches can be used for experimental studies of mixtures, depending on the desired goals (31). Problem definition and the formulation of specific questions are important steps that need to be addressed before selecting a specific approach. If toxic effects and risks posed by a mixture are to be determined, then the toxicologic evaluation of the mixture is carried out by testing the whole mixture through the tier or screening approach. If a causative agent(s) is to be determined to mitigate exposures to the active ingredient of a mixture or to identify the source of pollution, bioassay-directed fractionation is carried out. Finally, if the tools for predictive values are being developed, then toxicologic evaluation of individual components, in various combinations, is carried out to gain toxicologic knowledge about the mechanism and mode of action as well as mechanisms of interactions between the components and within the mixture.

Ideally, all the components of the mixture need to be identified, and their toxicity experimentally determined or obtained from the literature. Several testing protocols can be used to obtain appropriate information, but the actual experimental design depends on the number of chemical components of the mixture and if it is desirable to assess possible existing interactions between chemicals in a mixture. The mixture should be tested both at high effective concentrations and at low realistic concentrations.

Once the data are generated, it is necessary to analyze and interpret them. Many descriptive terms and mathematical, graphical, and statistical models have been used to evaluate the joint toxicity of mixtures. Interactive effects of compounds in mixtures with more than three compounds can be best ascertained with the help of statistical designs such as (fractionated) factorial designs or ray design.

In view of the importance of joint toxicity assessment of human exposure to multiple toxicants, appropriate experimental designs and methods of analysis must be used to support conclusions of additivity, synergy, and antagonism.

Whole Mixtures

Whole mixture studies involve exposing test systems to the intact mixture and conducting exposure–response studies to evaluate the nature and magnitude of the hazard associated with exposure. The design of these studies is usually chosen to reflect the net effect of all compounds in the mixture. This approach is applied to study real-life mixtures, such as tobacco smoke, jet fuels, or specially designed mixtures (88).

JP-5 is U.S. Navy's primary jet fuel. It is made up of a collection of hydrocarbons such as paraffins, monocycloparaffins, bicycloparaffins, olefins, alkylbenzenes, and others. The whole mixture of jet fuel JP-5 was administered to groups of 37–50 female C57BL/6 mice at 0, 150, or 750 mg/m^3 by inhalation continuously for 90 d (89). The endpoints evaluated were clinical signs, hematology, blood chemistry, body weight, and histopathological examination of major tissues. No effect on body weight gain was noted. The only remarkable finding in mice was hepatocellular fatty changes and vacuolization at 150 and 750 mg/m^3. This study was used to derive an MRL value of 3 mg/kg/d (25).

The whole mixture approach is recommended for situations where the mixtures are not well characterized and for mixtures with reasonably stable concentrations. In many cases, a whole mixture approach is advised because it can provide a real-life situation exposure scenario. However, caution should be exercised since in many cases these mixtures do vary in composition from time to time and from one exposure to the next. Without knowledge of the individual effects of each of the components to the response given by the whole mixture, no unique single estimate for risk to exposed populations can be estimated.

Formulated Mixtures

A systemic toxicity testing of n components in a chemical mixture would involve 2^n-1 experiments to address all possible combinations at one dose level for each component. To include several doses, one must use a more focused design such as a full-factorial design, which involves k^n experiments when a range of k doses is applied for each of the n components. In most cases, such mechanistically oriented experiments involve separating the mixture into several components that are studied together in formulated mixtures.

A classical design in the statistical literature for studying toxicologic interaction is a factorial design where each of the chemicals in the mixture is studied at all levels of the other chemicals. Generally, the levels of each factor are evenly spaced so as to cover systematically the dose region of interest. The logic of a factorial design is to support efficiently the estimation of a response surface that includes interaction model parameters (90).

A 5 × 5 × 5 factorial design was utilized to identify nonadditive effects on developmental toxicity in Fischer 344 rats caused by combinations of trichloroethylene (TCE), di(2-ethylhexyl)phthalate (DEHP), and heptachlor (HEPT) (78). The 5 × 5 × 5 full-factorial design was selected to detect binary and tertiary interactions among the chemicals in the mixture. The chemicals were administered by gavage to Fischer 344 rats on gestation days 6–15. Dose levels were 0, 10.1, 32, 101, and 320 mg/kg/d for TCE; 0, 24.7, 78, 247, and 780 mg/kg/d for DEHP; and 0, 0.25, 0.8, 2.5, and 8 mg/kg/d for HEPT. The dams were allowed to deliver, and their pups were weighed and examined postnatally. Of the nine endpoints that were analyzed statistically, six had significant binary interactions. Both synergistic and antagonistic interactions were detected among the three components. Maternal death showed no main effects, but DEHP and HEPT were synergistic. For maternal weight gain on gestation days 6–8, main effects for all three agents were observed, as well as TCE–HEPT synergism and DEHP–HEPT antagonism. Maternal weight gain on gestational days 6–20, adjusted for litter weight, showed main effects for TCE and HEPT, but no interactions. Main effects for all three chemicals were evident for full-litter resorptions and prenatal loss. For full-litter

loss, the TCE–HEPT and DEHP–HEPT interactions were antagonistic. Postnatal loss showed DEHP and HEPT main effects but no interactions. Analysis of pup weights on day 1 revealed TCE and DEHP main effects and DEHP–HEPT antagonism; on day 6, DEHP and HEPT main effects, DEHP–HEPT antagonism, and TCE–DEHP synergism were evident. Microphthalmia and anophthalmia incidences revealed TCE and DEHP main effects but no interactions. This extensive examination of a full-factorial design elucidates the complexities of studying and interpreting mixture toxicity. Although the Narotsky study illustrates the utility of full-factorial design to investigate binary and tertiary interaction, the study also used the large number of 2000 pregnant rats experimentally.

The feasibility of carrying a full-factorial design with many chemicals rapidly decreases (90). To overcome the usually costly full-factorial designs, statistically less-than-full designs are used. These designs are referred to as fractionated factorial designs. A fractionated two-level factorial study was designed for a combination of nine chemicals in a subacute rat study (91). In the study, an efficient fractionated design for 16 different groups was used as a subset of the full design, which would have required 2^9 (512) experiments. The combination experiments (satellite part) were composed of a fraction of 1/32 subsets (of the full 512 experiments). The study was intended to find out whether simultaneous administration of nine chemicals at a concentration equal to the "no-observed-adverse-effect level" for each of the chemicals would result in a NOAEL for the combination. A 4-wk oral/inhalation study in male Wistar rats was performed in which the toxicity (clinical chemistry, hematology, biochemistry, and pathology) of combinations of nine chemicals was examined. The study consisted of 20 groups, 4 groups in the main part (n = 8) and 16 groups in the satellite part (n = 5). In the main study, the rats were simultaneously exposed to various combinations of all nine chemicals (dichloromethane, formaldehyde, aspirin, di-(2-ethylhexyl)phthalate, cadmium chloride, stannous chloride, butyl hydroxyanisol, loperamide, and spermine) at concentrations equal to "minimum-observed adverse-effect level" (MOAEL), NOAEL, or $\frac{1}{3}$NOAEL. In the satellite study, the rats were simultaneously exposed to combinations of maximally nine factors (= 9 chemicals) in 16 experimental groups (1/32 fraction of a complete study). In the main part, many effects on hematology and clinical chemistry were observed at the MOAEL. In addition, rats of the MOAEL group showed hyperplasia of the transitional epithelium and/or squamous metaplasia of the respiratory epithelium in the nose. Only very few adverse effects were observed in the NOAEL group. For most of the endpoints chosen, the factorial design revealed main effects of the individual compounds and interactions (cases of nonadditivity) between the compounds.

Other fractionated designs include ray designs in which mixtures of chemicals under study are evaluated along rays of fixed ratios. In a ray design, for example, for a mixture of three chemicals with fixed ratios, represented by chemicals A, B, and C, a 1:0:0 ratio represents a ray of chemical A alone, while a 1:1:1 ratio represents a ray of equal levels of the three chemicals. A ray design for a small number of chemicals and many mixture rays can support the estimation of a response surface. However, the advantage of a ray design is that it can also be used with a mixture of many chemicals and a few mixture rays (90). The ray design was employed to estimate a response surface of developmental toxicity in rats using data from an earlier study in which a full-factorial design was used (78, 90). Similar to the ray designs, other fractional procedures such as the central composite and Box–Behnken designs use specific regions of the dose–response surface to optimize combinational experimental procedures.

Mathematical/Statistical Procedures

Once the data are generated, they need to be analyzed and interpreted. Many descriptive terms and mathematical, graphical, and statistical models have been used to evaluate the joint toxicity of mixtures. In general terms, the purpose of these models is to help interpret data for the entire range of the dose–response surface based on a mathematical/statistical description of the interaction criteria. Thus validated models can also be used to extrapolate from one region to other regions of the dose–response space. The models can also be used for the development of efficient experimental design by considering the cycle of model-experiment procedures to optimize the use of resources and time. The following discussions explain three mathematical and statistical procedures frequently used by scientists interested in combinational toxicology.

Isobolographic Methods An isobole is a contour line that represents equal effects of two agents or more in a mixture. Thus, when the joint effects of various dosages of two agents are plotted, each point of equal response (e.g., ED_{50}, percent lethality, ... , etc.) corresponding to varying doses of both chemicals form the isobole. Isoboles can be used to characterize the nature of the toxicologic interaction. This is done by comparing the isoboles to the line of additivity as shown in Fig. 6.9. The graphical representation of the interactions criteria can also be depicted mathematically as follows: For additivity:

$$\frac{A_c}{A_e} + \frac{B_c}{B_e} + \cdots + \frac{N_c}{N_e} = 1 \tag{7}$$

For synergism:

[TEXnical Error] (8)

For antagonism:

[TEXnical Error] (9)

where A_e, B_e, and N_e are the doses of chemical components A, B, and N that produce the measured response of each chemical as if it were the only component of the mixture. A_c, B_c, and N_c are the doses of each chemical that produce a similar response when the chemicals are all combined together.

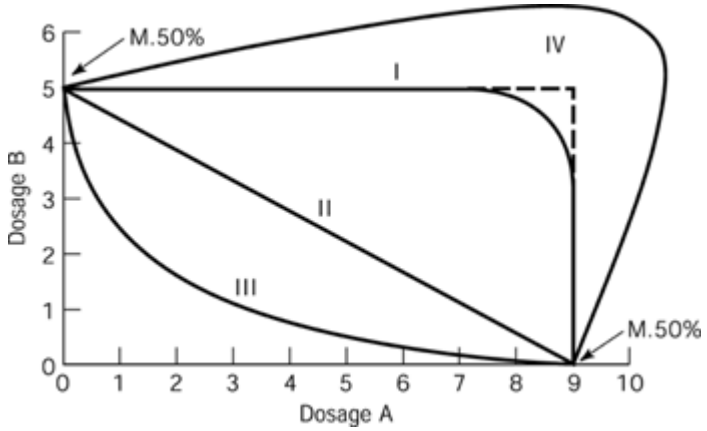

Figure 6.9. Four types of isoboles for a binary mixture of chemical A and B. Curve I describes no-interaction effect, curve II is the line of additivity, and curves III and IV depict synergism and antagonism effects, respectively. M.50% is the dose at which 50% of the tested animals died.

The preceding equations represent the criteria for assessing interaction modes among the different agents in a mixture (92). However, for these equations to be used, individual chemicals in the mixture should have a nonzero response at the given doses (i.e., $A_e \neq 0$, $B_e \neq 0$, ... , $N_e \neq 0$). The major disadvantage of the isobolographic methods is the requirement for a large number of experiments to produce the individual isoboles. For example, one can start with doses of chemicals A and B for a binary mixture, if the response is not equal to the one chosen for the isobole, then doses of A and/or B have to change up or down until the fixed response is obtained. This highly iterative procedure is very resources extensive. With a conventional experimental approach, the isobolographic method is tedious and requires extremely large data sets. For instance, 2000–3000 animals were used to generate an isobole to study the interaction between ethanol and chloral

hydrate effect on the righting reflex of mice (93). Furthermore, the isobolographic methods can only be applied to chemicals that share similar mechanisms and induce the same endpoint of toxicity.

For chemicals that do not share similar mechanisms, a more general mathematical procedure than isobolographic methods is employed. One such procedure is the median-effect principle (MEP). This method is based on the assumption that dose–response relationships of many physical, chemical, and biological processes, specifically related to ligand–enzyme receptor-site interactions, can be described by a general formula:

$$\frac{f_a}{f_u} = \left(\frac{D}{D_m}\right)^h \tag{10}$$

where f_a and f_u are the fractions of the system affected and unaffected, respectively, by the dose (D). D_m is the dose required to produce the median effect (similar to the more familiar ED_{50}), and h is a Hill-type coefficient signifying the sigmoidicity of the dose–response curve. Expansions of this equation to include criteria for the different modes of toxicologic interactions have been published (94).

The MEP method was used for the analyzing of the interactions effect of combined administration of immunosuppressive drugs with cyclosporine (95). Cyclosporine is widely used in organ transplantation. However, its renal, hepatic, and nervous system toxicities limit its therapeutic potential. This problem was addressed using MEP to find other immunosuppressive drugs that can interact synergistically with lower (non-toxic) concentrations of cyclosporine.

Response Surface Methodology The response surface methodology (RSM) allows the study of the mathematical relationship (model) that exists between the chemicals in the mixture and the endpoint of toxicity. RSM was successfully applied to study the interaction between trichloroethylene, carbon tetrachloride, and chloroform using the levels of plasma enzyme activities of ALT, AST, and SDH as endpoints of toxicity in rats (96). This application of RSM showed that carbon tetrachloride/chloroform and carbon tetrachloride/trichloroethylene both displayed a synergistic response for each plasma enzyme activity.

The application of the method relies on statistical regression methods efficiently to design experiments that yield adequate and reliable measurements of the response of interest. The mathematical model is then developed that best fits the collected data. This is accomplished by conducting appropriate statistical tests of hypotheses regarding the model parameters.

Isobolographic, median-effect principle, and response surface methods can quantitatively characterize interaction among components of a chemical mixture. However, these methods cannot provide mechanistic information for the presence of interactions because they are not based on biological mechanisms. This shortcoming can be avoided by employing more mechanistically oriented models such as physiologically based pharmacokinetic/pharmacodynamic (PBPK/PD) models.

Physiologically Based Pharmacokinetic/Pharmacodynamic Models PBPK/PD models mathematically describe the processes of absorption, distribution, storage, metabolism, and excretion; the pharmacodynamic aspects cover the toxic response of the chemical at the target tissue. Fig. 6.10 is a schematic of a compartmental PBPK model.

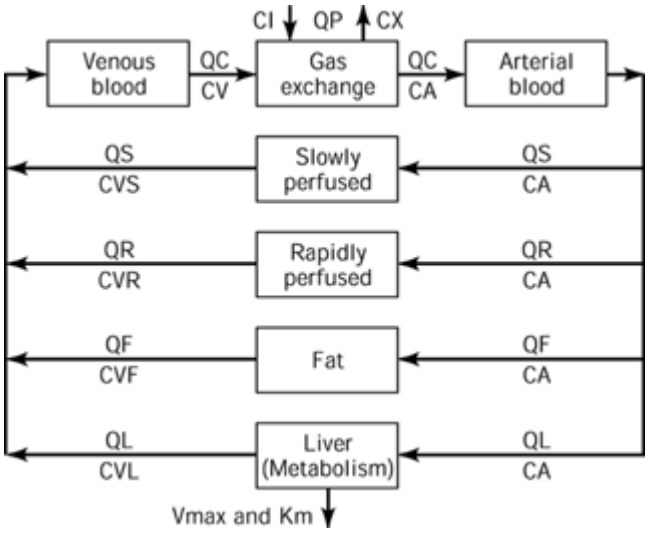

Figure 6.10. Compartments of a typical inhalation exposure PBPK model. Each compartment is characterized by physiological and biochemical parameters. In this specific example, the chemical under study is highly lipophilic, which causes its disposition to be blood flow limited. Thus tissues are selected based on their blood perfusion rates (slowly and rapidly perfused), the chemical's affinity to the tissues (fat), and metabolism sites (liver). The Qs are blood flows into each compartment. CVS, CVR, CVF and CVL, are the venous blood concentration of the chemical leaving the slowly perfused, rapidly perfused, fat, and liver compartments, respectively. CI is the inhaled concentration, CX is the exhaled concentration, and CA is the arterial concentration of the chemical in question.

Pharmacokinetic interaction mechanics can be introduced into PBPK models and verified experimentally. A PBPK model was used to quantitatively distinguish between different types of enzyme inhibition (competitive, uncompetitive, and noncompetitive) (97). A validated PBPK model can also be used to investigate the interaction presence at varying levels of exposure to the different components in a mixture. The PBPK model for the interaction between trichloroethylene and 1,1-dichloroethylene was expanded to include description of the chemicals interactions at the available enzyme sites (98). The investigators' efforts showed the presence of an interaction threshold, absence of interaction, at levels of 100 ppm or less for both chemicals. Expansion of PBPK interaction modeling to investigate a ternary mixture of alkyl benzene in rats and humans was accomplished (99). Few examples in the literature illustrate the application of pharmacodynamic models for analyzing toxicologic interactions. One study was able to investigate quantitatively the interaction mechanism between Kepone and carbon tetrachloride by the use of PBPD models that described the rates of injury and death of hepatocytes as they are affected by this highly synergistic interaction (100). The PBPK/PD model was coupled with Monte Carlo simulations to estimate mortality results for any given combination of the chemicals. To predict the response surface, mortality results are applied to the following logistic regression equation:

$$y = \beta_0 + \beta_1(kep - \overline{\text{kep}}) + \beta_2(CCl_4 - \overline{\text{CCl}_4}) + \beta_3(kep - \overline{\text{kep}})(CCl_4 - \overline{\text{CCl}_4}) \qquad (11)$$

where b_0 is the background rate of lethality rate, b_1 is the slope of the dose–response relationship for Kepone (kep) alone, b_2 is the slope of the dose–response relationship for carbon tetrachloride (CCl_4) alone, and b_3 is the interaction parameter between Kepone and carbon tetrachloride. The overlined kep and CCl_4 are the average estimates of the range of simulated or applied doses of each chemical. The outcome of Eq. (11) can then be introduced into the following equation to calculate the lethality percentage:

$$\% \text{ lethality} = \left(\frac{e^{y}}{e^{y}+1}\right) \times 100 \qquad (12)$$

Subsequently, the model simulations are compared to the experimentally determined lethalities to estimate the values for all the bs; specifically, b_3 was significantly different from zero at a value of 0.01 for the interaction between carbon tetrachloride and Kepone. This positive value is indicative of a synergistic interaction. The regression equations with the model-estimated parameters were then used to derive the isoboles for the interaction between Kepone and carbon tetrachloride at different responses (Fig. 6.11) (101).

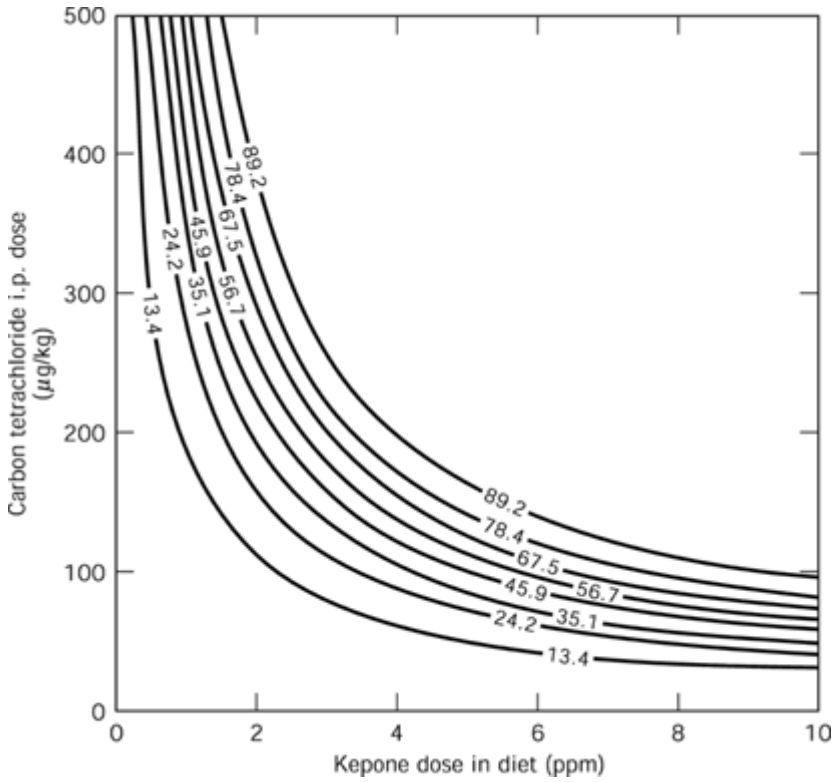

Figure 6.11. An illustration of the contour lines (isoboles) of percent lethality of rats exposed to varying concentrations of Kepone in diet (*x* axis) and intraperitoneal (IP) injections of $CC1_4$ (*y* axis). The lines were generated by PBPK/PD model simulations and a regression equation.

In addition to the complexity of the problem of aggregate toxicity, several problems impair the proper selection, implementation, and application of these approaches to risk assessment. Because of this, for example, the occupational hygienist or toxicologist shopping for an appropriate experimental approach is frequently confounded by the lack of direct comparisons between approaches. Fundamentally, the characterization of chemical interactions consists of the rejection or acceptance of a single model or the selection of a particular model from among competing models. These decisions are based on statistical and/or graphical information involving regression equations, each with underlying implicit and explicit mathematical, statistical, and data structure assumptions (102). It is no easy task to distinguish clearly the intrinsic differences, distinctions, and limitations of these models when applied to characterizing the potential interactive toxicities in the workplace. Adverse health effects are diverse and include parametric and nonparametric responses for cancers, and signs and symptoms of organ dysfunction. As such, the choice of model, criteria for goodness of fit, data transformation, and method of parameter estimation are important to support a mathematically and biologically sound decision.

Future Directions and Conclusions
Given the different types of mixtures for which joint toxicity assessment are performed as well as the many factors that effect the overall toxicity of such mixtures, no single approach is suitable to conduct such assessment for every exposure scenario. However, developing joint toxicity assessment procedures and models is a complex data-intensive task because paucity of data is frequently the bottleneck. For these reasons it is imperative that research to develop appropriate methods continue.

Data gaps can be filled through experimental research to generate key data needed to elucidate toxicologic mechanisms and decipher the mechanisms of interaction so as to incorporate the principles of molecular toxicology in predictable mechanistic models. With reference to chemical mixtures, from the outset, such research should identify elements that could contribute to the joint toxic action of chemicals such as (1) determination of internal doses through toxicokinetics (absorption, distribution, metabolism, receptor binding, and elimination), (2) evaluation of mechanisms of interactions and their significance, (3) identification of multiple target organs that are affected, and (4) assessment of biomarkers, adducts, and metabolites that can be used to biomonitor exposures.

This type of integrated systematic research is possible only when the laboratory investigators, the model developers, and the health assessors work in a collaborative relationship to ensure parallel research in various areas of this multidiscipline research. Special attention is needed to ensure that the animals or test system, doses and dosing regimen, and other variables of the experimental procedure have been selected based on existing data and efficient experimental design to address existing data gaps in the interlinked areas of research. This type of balanced and pragmatic approach has been recommended to meet short-term and long-term needs for screening, prioritizing, and predicting the health effects of chemical mixtures by international panels of scientists educators and administrators (103, 104).

The limitations of available resources make it unlikely that experimental toxicology will yield direct information about all the possible mixtures to which humans or other species may be exposed. Indeed, the information needed to assess hazards from individual chemical exposures may never be obtained. In the current environment of austere resource allocations and heightened awareness of animal use in toxicologic research, more pragmatic experimental testing methods must be used without compromising the sensitivity or specificity obtained through classical methods. Efforts should take into consideration all options available, including recently developed innovative techniques. Several innovative approaches can be implemented for the assessment of joint toxic action of chemicals. To this extent significant advances have been made in alternative toxicologic testing methods, such as *in vitro* testing, PBPK modeling, and biologically based dose–response modeling. Also, correlations have been established between *in vitro* and *in vivo* potencies of chemicals. Hence, several *in vitro* assays validated with *in vivo* studies are available to conduct toxicant interaction studies. Even though most of these tests are still in various investigatory phases, they have been studied enough to obtain initial estimates of dose–response relationships for mixtures of chemicals. Using these types of assays, for specific endpoints, it may be feasible to develop a screen of tests to study interactions. The underlying assumption in such screens is that if biologic activity in these tests is well correlated with *in vivo* toxic potency, interaction coefficients measured using such screening tests may be similarly correlated. The plausibility of such theoretical assumptions must be further established by highly focused *in vivo* studies.

An example of such studies is collaborative research between ATSDR and TNO Nutrition and Food Research Institute to evaluate the role of chemical interactions in the expression of toxicity from low-level exposure to combinations of chemicals (105). The goal of this project was to compare the

estimated toxicity with experimentally determined toxicity of the mixtures so as to determine the accuracy and the predictive capability of the assessment method. The procedure used for the joint toxicity estimates was adopted from the detailed published WOE method (74). Briefly, in the first step, qualitative weight-of-evidence statements for binary pairs of chemicals were prepared for various combinations of chemicals such as (1) the effect of butylhydroxyanisole (BHA) on di(2-ethylhexyl)phthalate (DEHP), (2) the effect of stannous chloride ($SnCl_2$) on cadmium chloride ($CdCl_2$), and (3) the effect of cadmium chloride ($CdCl_2$) on loperamide (Lop). In the second step, these qualitative evaluations were converted to numerical scores, which were then combined to obtain the estimate of toxicity of the four-component mixture. The estimations were made through integration of the component chemical dose–response assessment with computative algorithms that incorporate potential chemical interactions. The estimates thus obtained were compared with results from experimental animal studies using the dose addition, the response addition, and the WOE models. These comparisons indicate that the WOE approach can be used to estimate qualitatively the joint toxicity of these mixtures. Additionally, the results from the WOE method provided the best fit to the experimental results of the mixture of similarly acting nephrotoxicants—namely, trichloroethylene, tetrachloroethylene, hexachloro-1,3-butadiene (HCBD), and 1,1,2-trichloro-3,3,3-trifloropropene (TCTFP). However, this was not true for the mixture of dissimilarly acting nephrotoxicants—namely, mercuric chloride, lysinolalanine, *d*-limonene, and HCBD. This could have been anticipated because the WOE method is based on the concept of dose additivity, which in turn is practiced only when the mechanisms are similar. Thus these results indicated that the WOE-approach evaluations, based on consideration of common mechanisms, can lead to better estimates of joint toxic action than the default assumption of dose additivity. These results also confirmed earlier suggestions (74) that the WOE evaluations should be effect and target-organ specific because none of the models tested could approximate the observed responses in organs other than the target organs. Thus, to verify the role of chemical interactions and the overall toxicity of a mixture, these kinds of specially designed focused experimental studies need to be conducted to help advance the methods for the toxicity assessments of chemical mixtures.

Screening a selection of mixtures in *in vitro* assays can identify a broal range of interaction relationships that could be beneficial to the ultimate goal of predicting interactions. Consequently, *in vivo* measurements could be made to confirm the previously determined *in vitro* relationships covering comparable concentrations. The linkage between the *in vitro* and *in vivo* assay correlations needs to be strengthened by testing chemical mixtures for various effects such as nephrotoxicity, neurotoxicity, and hepatotoxicity in target-organ-specific assays.

An experimental parallelogram design has been used to conduct such carefully planned and goal-oriented research (Fig. 6.12). This design allows multispecies comparisons as well as extrapolation to humans. As a first step, *in vitro* rodent species bioassays (rats, mice, or hamsters) are conducted to test the toxic effects of chemicals. Results from such studies are validated in *in vivo* rodent studies. These studies are then followed with *in vitro* studies with human systems (e.g., human cell lines) to evaluate the findings of the animal studies. Thus the *in vitro* rodent studies are used to confirm the initial *in vivo* rodent findings, and these results are subsequently confirmed *in vitro* in human systems. The information thus generated is used to extrapolate the potential effects of the chemicals to humans. With this design, humans and rats have been shown to have comparable metabolism of 1,3-butadiene which differed from metabolism in mice (106). These comparative data suggested that because the concentration of butadiene epoxide, the active moiety, will be low in humans, the human cancer risk following exposure to butadiene will be similarly low. However, if this assessment was based only on mouse data, the risk would have been incorrectly estimated. This experimental design can be employed for the study of toxicity of chemical mixtures. Eventually, the transformation of *in vitro* findings to *in vivo* observations can be met using computational tools such as PBPK modeling and biologically based dose–response modeling.

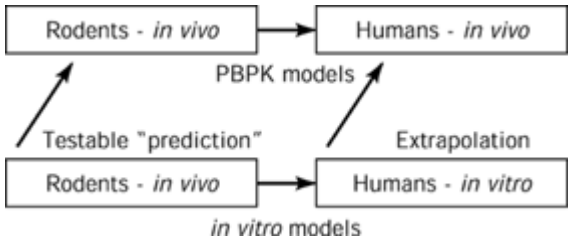

Figure 6.12. *In vitro–in vivo* extrapolation between animals and humans.

In general, computational methodologies provide insights and focus for strategic research. Such methods have to be used to formulate specific hypotheses, based on available data. Then appropriate hypotheses that support public health assessments have to be subjected to experimental testing through collaborative research with partners using *in vitro* or limited *in vivo* studies. The results of such investigations may lead to further testing, revisions in hypotheses, and/or the formulation of new hypotheses. When verified, such hypotheses would allow the development of generalizable rules that can be applied to mixtures of interest that have not been subjected to testing, cannot be subjected to testing, or cannot be used until testing data become available. ATSDR has established a computational toxicology laboratory with capabilities to conduct PBPK extrapolations and quantitative structure–activity relationship (QSAR) studies that allow extrapolations of toxicity within and across chemical classes. Such studies are being supported through collaboration among governmental bodies, the private sector, and academic institutions.

Through cooperative agreements with research institutions, alternative mixtures toxicity testing methods are being developed. Cell culture systems and *in vivo* animal studies are being employed to generate mechanistic and pharmacokinetic information. Following is a brief description of some studies that are ongoing:

1. Human keratinocytes have been used to test the departure from additivity in chemical mixtures of frequently co-occurring metals using cytotoxicity as an index (107). When individual dose–response curves of arsenic, cadmium, chromium, and lead were used in conjunction with the mixtures of these four metals at seven different concentrations, six of these concentrations were found to follow additivity while one of these concentrations showed a highly significant antagonistic effect. In a series of *in vivo* animal studies, the role of individual chemicals in producing liver foci by a mixture containing arsenic, 1,2-dichloroethane, trichloroethylene, and vinyl chloride was studied. Preliminary results show that arsenic is the main component responsible for the antagonistic interactions observed for this mixture.
2. Cultured Rhesus monkey renal cortical cells have been used to investigate the interactions between cadmium and mercury (108). The release of lactate dehydrogenase (LDH) was measured for selected concentrations of 0–50 mM $HgCl_2$, $CdCl_2$, or binary mixtures of both metals in varying ratios of 20:1, 10:1, 5:1, or 2:1. To characterize the interaction, the data were analyzed graphically and mathematically using statistical isobologram, linear, and nonlinear models. The isobolographic and response surface analysis suggested antagonism, while nonlinear models concluded no interaction. Most models supported an overall synergistic interaction when data from all mixing ratios were modeled together. However, individual data set analyses revealed that as the ratio decreased from 20:1 to 2:1, the nature of the interaction gradually changed from synergism to additivity. The relationship was consistent among all the models used, but was most clearly revealed by the linear models.
3. With a goal to develop a PBPK/PD model to integrate tissue injury and repair, an *in vivo* study has been designed to evaluate the toxicologic interactions between trichloroethylene, thioacetamide, allyl alcohol, and chloroform. Liver injury was measured by monitoring plasma enzymes, ALT and SDH, and histopathology. The tissue generation was measured by [H^3]-thymidine incorporation into hepatic nuclear DNA. Preliminary results indicate that the mixture of four hepatotoxicants caused

additive toxicity. The model will be used to quantify liver injury, repair, and the overall joint toxic action as a function of mixture dose.

4. Polycyclic aromatic hydrocarbons (PAHs) and halogenated aromatic hydrocarbons (HAHs) were tested utilizing a battery of cell culture assays (genotoxicity, immunotoxicity, etc.) to investigate the toxicity of several classes of environmentally important chemical mixtures. Results from a genotoxicity assay using binary and tertiary mixtures of PAHs revealed a dose–response gradient with B(*a*)P–chrysene mixture, suggesting an interaction. Similar studies with complex mixtures and isolated fractions indicate that the B(*a*)P content of the PAH mixture cannot be used to predict the genotoxicity. The results from assays of an extract of a manufactured gas plant residue separated into four fractions revealed that genotoxicity varied from fraction to fraction (109). Analyses are being performed to determine the role of high-molecular-weight PAHs or possibly alkyl-substituted PAHs.

The above examples of collaborative research investigations were based on HazDat analyses and observations that several simple mixtures could be identified that would lend themselves to the design of experiments and a systematic way to obtain data. They follow the general hypothesis that research conducted on a small group of chemicals or simple chemical mixtures could benefit communities being exposed to multiple chemicals, such as those living in the vicinity of hazardous waste sites. Additionally, the insights attained from such experimental and computational studies develop professional judgment as a substitute until generalizable rules for joint toxic actions are formulated.

Parallel progress in experimentation, quantitative modeling, and assessment are important to devising generalizable rules through in-depth analysis of data (Fig. 6.13). In the meantime, continued focused experimental/computational research is needed for conducting joint toxicity assessments to ensure adequate public health protection. This assessment process will benefit by using a team approach wherein experimental scientists, model developers, and health risk assessors work to develop consensus on those issues key to protecting the public's health.

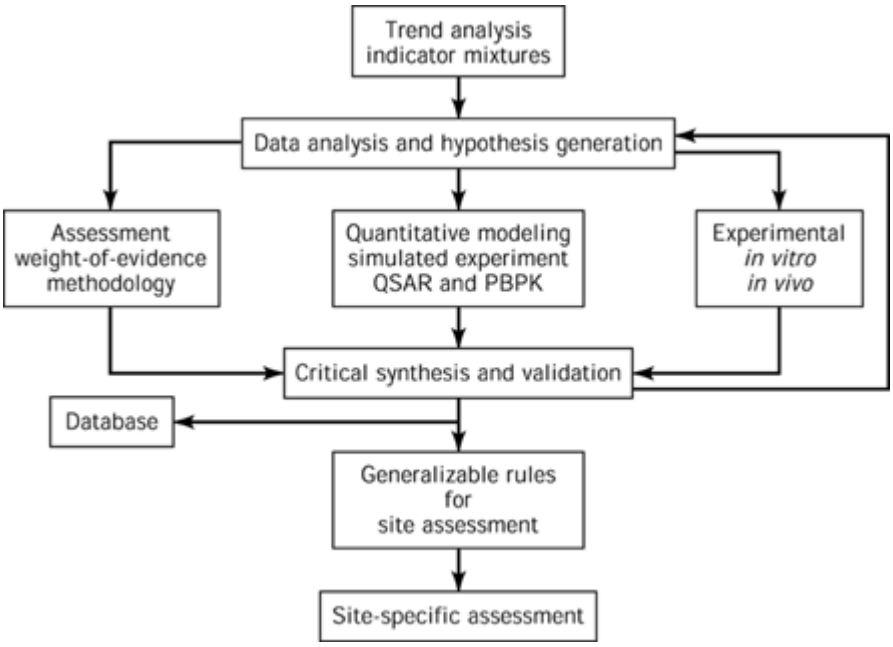

Figure 6.13. A strategic mixtures research program that allows parallel progress between experimental assessment, and computational techniques.

In conclusion, the carcinogenic and noncarcinogenic toxicities associated with chemicals found in the environment do not necessarily translate into actual adverse human health or environmental

effects. One must ascertain the extent of actual exposure experienced by populations at risk and the susceptibility of members of such populations (13). Thus the risk-assessment process must be considered as one component of risk analysis, which also includes biomedical judgment and peer review as recommended by the NRC (110) as well as risk communication and risk management (111). Fig. 6.14 is an illustration of the multiple components of the overall decision-making process of risk analysis. Importantly, this process should reflect a rigorous identification of attendant uncertainties associated with the components of risk assessment as part of risk analysis (112). This procedure would allow the types and the extent of uncertainties to be highlighted, thus promoting the appropriate interpretation of numerical risk estimates in decision making. Although the utility of numerical risk estimates in risk analysis is recognized, these estimates should be considered in the context of the variables and assumptions involved in their derivation and in the broader context of biomedical opinion, host factors, and actual exposure conditions. Thus the actual parameters of environmental exposures must be given careful consideration in evaluating the assumptions and variables relating to both toxicity and exposure.

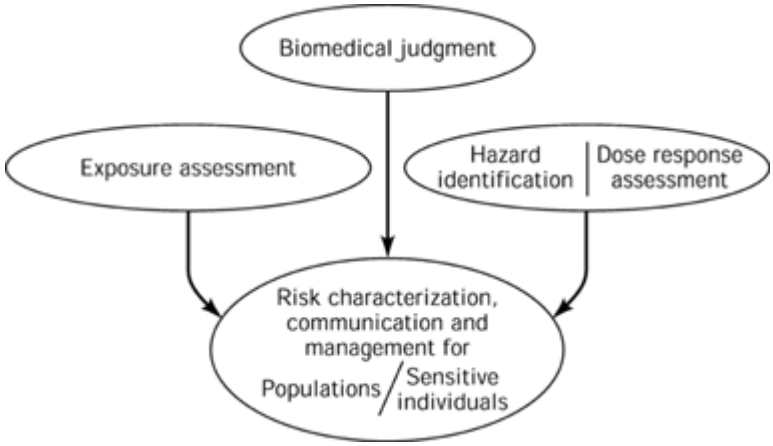

Figure 6.14. The elements of risk analysis with emphasis on biomedical judgment, including molecular epidemiology.

Lack of knowledge and understanding of data make it virtually impossible at this time to determine whether current approaches to protecting public health from the adverse effects of chemical mixtures are adequate. However, from the perspective of protecting public health a high priority needs to be given to identify and conduct research on specific mixtures. Through advances in focused experimental and computational methods it is possible to develop simulation programs that allow modeling of chemical mixtures behavior in biological systems and predict their toxicologic response. Hence, it is important to continue developing suitable new methods and improving old ones for mixture-related research. These types of efforts will help us understand the characteristics of hazard/risk (113) and allow us better to identify, quantify, and express uncertainties in mixture-related risk assessments (103).

Ecogenetics: The Study of Gene–Environment Interactions
Daniel W. Nebert, Amy L. Roe, Ph.D

1 Introduction

What is "an environmental disease?" Why are some individuals and some families affected more easily than others? Indeed, even within families, why are some members affected whereas others are not? When taking the same dose of a prescribed medication, why do some patients—but not others—experience side effects? Why do only 7 out of every 100 cigarette smokers die of lung cancer? The answer to each of these questions involves *interindividual genetic variation* and *the environment*.

We begin this chapter with brief descriptions of the reasons for environmental illnesses. Next, genetic terminology and a definition of "susceptibility genes" are covered—followed by our current understanding of the drug-metabolizing enzymes (DMEs) and the receptors that regulate DME genes. Subsequently, we provide a number of examples and brief summaries of the present-day knowledge of many of these polymorphisms. Last, we speculate as to why these human polymorphisms might exist in the first place. Many of the references cited include reviews in which the reader will find numerous additional studies cited and details described.

Ecogenetics: The Study of Gene–Environment Interactions

2 Exposure and Genetic Predisposition

What is "an environmental disease?" Table 7.1 is not intended to be inclusive, but lists more than a dozen examples of environmentally caused diseases. As will become clear, the two most important determinants in one's risk of developing an environmental disease are (*1*) exposure and (*2*) one's unique genetic makeup.

Table 7.1. Examples of Environmentally Caused Diseases

Bronchogenic carcinoma in cigarette smokers
Chronic bronchitis, emphysema, and heavy wrinkles in cigarette smokers
Liver fibrosis and cirrhosis in alcoholics
Drug-related lupus syndrome in patients taking procainamide
Dangerously lowered blood pressure in patients taking debrisoquine or sparteine
Lung cancer in people exposed to radon
Malignant melanoma, other skin cancers, heat stroke, sunburn in persons exposed to excessive sunlight
Lung cancer in uranium mine workers
Chloracne, porphyria cutanea tarda in workers exposed to dioxin and other halogenated hydrocarbons
Ataxia, lowered mentality in persons exposed to high levels of lead
Increased risk of chronic myelogenous leukemia in workers exposed to benzene, and of urinary bladder cancer in chemical dye workers
Asthma in children and adults exposed to indoor or outdoor air pollution

The first six examples in Table 7.1 represent large doses of an environmental agent that can be quite easily documented by a good medical history [e.g., pack-years of smoking (number of cigarette packs smoked per year multiplied by number of years that the person has smoked), quantity of alcohol consumed, length of time and the dose of drug taken, length of time living in a radon-exposed house]. The next three examples represent exposures to sun and the outdoors and to chemicals in the workplace; quantitation in these cases is generally more difficult than the first six examples (e.g., "What is the actual number of days worked? Was the exposure identical for all these days? Are we dealing with a single chemical or a mixture of multiple chemicals?"). The last four examples in Table 7.1 depict even fuzzier cases in which a cause–effect correlation can be inferred only by an epidemiological study of large human populations, but such a correlation in a particular individual is often difficult to prove—medically, or in a court of law (e.g., ataxia might occur in one patient whose blood Pb^{2+} level is more than 3 times lower than that of another who is asymptomatic. "Is the malignancy diagnosed in a worker caused by his/her occupational exposure, or was he/she going to develop it, anyway?" "Is this particular bout of asthma caused by urban pollution, or is it caused by house dust or cockroach dander in the home?").

Not listed in Table 7.1 are the even more ambiguous situations. For example, how often can an environmental disease be caused by minuscule and intermittent exposures—over decades or a lifetime—to "everyday" chemicals (e.g., eating fruit that had been treated with a fungicide, playing on a golf course that had been sprayed with insecticides or herbicides, ingesting canned food having "detectable" amounts of an endocrine disruptor). Toxicity or cancer occurring in individuals with these kinds of exposure are the most problematic for scientists to quantitate and interpret.

In addition to the *exposure* component, why is it increasingly difficult for a scientist or clinician to be certain of the cause of environmental disease, as one moves down the list in Table 7.1? The answer to this question resides in our *genes*. It is now clear that, just as we each have a distinctive set of fingerprints, each of us has a novel combination of genes that enable us to be resistant or sensitive to various types of chemical and physical insults. This leads to our own unique underlying genetic predisposition to toxicity or cancer. This field of study was termed *ecogenetics* by Brewer in the mid-1970s, and a subset of this field (interaction between genes and response to drugs) had been named *pharmacogenetics* in 1959 by Vogel (1–4). Before examining "gene–environment interactions" in more detail, we will review briefly the essentials of genetics and the fundamentals of exposure and risk estimation.

Ecogenetics: The Study of Gene–Environment Interactions
Daniel W. Nebert, Amy L. Roe, Ph.D

3 Introduction to Genetics
Healthy humans have 23 pairs of chromosomes, 22 autosomal pairs plus the sex chromosomal pair (XX or XY). A gene denotes a location (stretch of DNA) on each of a chromosome pair that encodes a gene product (enzyme, or other protein). A *locus* indicates the location of a stretch of DNA on each of a pair of chromosomes that need not necessarily code for a gene product. *Diploid* refers to a eukaryote having chromosome pairs; *haploid* refers to one active chromosome of each pair (e.g., as found in the sperm and egg). Each gene is made up of two *alleles*, one from the father and one from the mother; the combination of these two alleles, as well as one's genetic makeup, is called the *genotype*. An allele can transmit a dominantly inherited trait (e.g., pigmented skin) or a recessive trait (e.g., blue eyes). Another term for "trait" is *phenotype*. *Homozygotes* are individuals having two

identical alleles; *heterozygotes* are individuals having two different alleles.

3.1 Simple Mendelian Traits

Consider a *single-gene trait* such as the alleles *colored* (*C*) and *noncolored* (*c*) in Mendel's original studies of the garden pea. Allele *C* (red phenotype) is dominant to allele *c* (white phenotype). The Hardy–Weinberg distribution [$(p + q)^2 = p^2 + 2pq + q^2$] states that, if the *allelic frequencies* of *C* (= *p*) and *c* (= *q*) in the population are 0.4 and 0.6, respectively, this would mean that 36% of the population would have the white trait, that is, homozygous for the *cc* genotype (Fig. 7.1). Crossing two *Cc* heterozygotes (which have the red phenotype) would give a 1 : 2 : 1 ratio of the *CC* : *Cc* : *cc* genotypes and a 3 : 1 ratio of the red and white *phenotypes*.

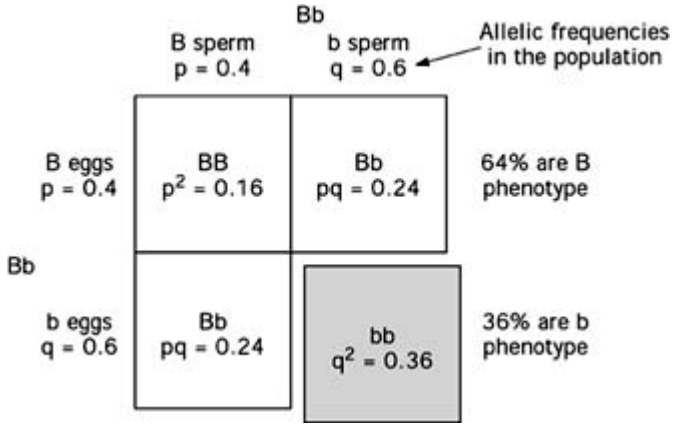

Figure 7.1. Diagram of the Hardy–Weinberg distribution ($p^2 + 2pq + q^2$), showing genotype frequency as a function of allelic frequency.

3.2 Polygenic Traits

A phenotype that is dependent on two or more genes is called *polygenic*, *multifactorial*, or a *multiplex phenotype* (e.g., blood pressure, height, weight). The 1 : 2 : 1 ratio (Fig. 7.2) is the most complicated that a (Mendelian) single-gene, two-allele trait can exhibit. If one considers a trait expressed by two alleles from each of two genes, or from each of three genes (Fig. 7.2), we can readily appreciate how quickly and complex the genotypes and corresponding phenotypes will become. Obviously, the outliers, or individuals at the extreme ends of the spectrum of phenotype, are the most valuable patients to scientists for dissecting the genes involved in producing the phenotype. Virtually 100% of all diseases, including environmental diseases, should be regarded as multiplex phenotypes—usually caused by two or more major genes and perhaps several dozen modifier genes. For example, an abnormal *BRCA1* "tumor suppressor gene" can be regarded as a *major* gene for increasing risk of breast cancer, in probably at least 5% of women, and being homozygous for *NAT2* slow acetylator alleles can be regarded as a *modifier* for enhancing one's risk of breast cancer (see discussion below).

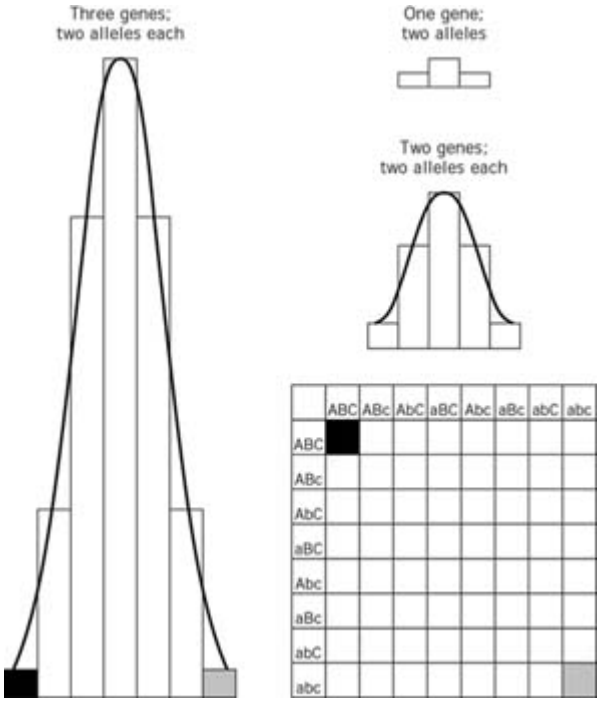

Figure 7.2. Illustration of the distribution of phenotypes, or genetic variation, for one, two or three genes (but having only two alleles each).

3.3 Polymorphism

In a population, there are always more than two alleles for any given gene. Dozens of alleles at a single locus give rise, for example, to the highly variable phenotypes of wing color in butterflies, moths, and ladybugs. A genetic polymorphism exists when a subset (second allele, locus or phenotype) is found in a population. Typically, the allelic frequency is considered by epidemiologists to be "zero," or negligible, or insignificant in its effects on the population structure, if less than 1% of homozygous individuals are affected. However, this is a completely arbitrary choice, and "a polymorphism" exists ipso facto—even if only one case is seen in an entire population.

Others commonly regard a polymorphism as any time a particular phenotype in a population occurs at frequencies of 1 in 1000 or 1 in 10,000. *Mutations* are defined as one or more altered bases (adenine, thymine, cytosine, guanine) in the DNA; mutations require one round of new DNA synthesis to become "fixed." For every one fixed mutation, there are between 1000 and 10,000 "oxidative hits" or other forms of DNA damage that get repaired without turning into a mutation. *Spontaneous* mutation rates (e.g., by background ionizing radiation) occur at frequencies between 1 in 10^6 and 1 in 10^8. Geneticists therefore regard any allele that persists in a population at a frequency of <1 in 10^6 as "having a reason for existing in that population that we might not yet understand." Possible mechanisms for why a particular allelic variant would persist at greater than spontaneous frequencies in a population might include (*1*) *balanced polymorphisms* (in which presence of the mutant allele confers some advantage to the heterozygote; e.g., sickle cell anemia), (*2*) genetic *bottlenecks* (enhanced interbreeding due to low numbers of individuals available, or due to geography), and (*3*) *founder effects* (spread of a mutant allele, originally by one reproductively vigorous individual). We will return to this topic at the end of this chapter.

3.4 Biomarkers

Because of confusion in the field of epidemiology, we believe that the term *biomarkers* needs to be clarified. A *biomarker* refers to some type of evidence that environmental agents have altered cellular macromolecules. Environmental exposure might be *genotoxic* (causing DNA damage) or *nongenotoxic* (disrupting endogenous signal transduction pathways independent of DNA damage) in the cell or organism. Thus, biomarkers would include damaged, or chemically altered, DNA bases or

protein (e.g., oxidized guanine, aflatoxin B_1-DNA adducts, aniline–hemoglobin adducts) or elevated components in the cell or organism (e.g., a-fetoprotein, metallothionein)—as the result of the metabolism of endogenous or exogenous substrates, and/or oxidative stress. Biomarkers are often used as an assessment of exposure to a particular chemical, especially in occupational medicine. The activation of a protooncogene (e.g., *RAS*, *TRP53*), or the inactivation of a tumor suppressor gene (e.g., *RB1*, *WT1*)—leading to cancer—can be the result of mutations caused by abnormally toxic levels of endogenous or foreign chemical metabolites (e.g., benzo[*a*]pyrene, aflatoxin B_1); as such, these mutations represent biomarkers. On the other hand, "variant, or mutant, alleles" (i.e., one's genetic predisposition, inherited from one's parents) have sometimes been regarded by epidemiologists as "biomarkers"; this terminology is strongly discouraged.

3.5 The Human Genome Project

The human genome is estimated to contain approximately 120,000 ± 20,000 genes distributed within the 3.5 billion base pairs of DNA, which constitute the haploid genome. About 5% of the genome represents genes, and the rest represents intergenic spacer regions. Current predictions are that all genes will be identified (but most not yet characterized) by the end of 2001. Currently, McKusick's catalogue (OMIM, "On-line database of Mendelian Inheritance in Man," August 1999) lists more than 10,000 loci, of which about 75% are associated with a disease phenotype. These data would suggest that at least 80,000 genes might have mutant alleles that adversely affect human health and/or cause human disease. It is also possible that mutations in *every* gene, under the right conditions, might contribute to human disease.

3.6 Reverse Genetics

The "candidate gene approach" means that, if gene *XYZ* had already been cloned and characterized and was known to encode, for example, an enzyme that metabolizes a particular environmental chemical to an ultimate toxic or carcinogenic intermediate, one might ask whether *XYZ* allelic differences can be shown statistically to be significantly correlated to the toxicity or cancer phenotype caused by that particular environmental chemical. Hence, *reverse genetics* is the methodology of going from the gene to epidemiological studies in an attempt to explain the etiology of an environmental disease.

3.7 Forward Genetics

As mentioned above, virtually all environmental diseases are now believed to reflect multiplex phenotypes. For example, toxicity caused by a particular environmental chemical (or chemical mixture) might be manifested by the actions of five genes contributing, say, 40, 30, 15, 10, and 5% to the phenotype; three "modifier" genes might influence the action of two "major" genes. How can such complexity be dissected and understood? The recent advances in the genetic dissection of complex traits via forward genetics (or, the "positional cloning approach") promise to be very exciting indeed during the next few years—not only in human genetics—but particularly in environmental genetics.

The challenge of genetic dissection of complex traits has become highly successful through four major approaches: linkage analysis, allele sharing (nonparametric) methods, association studies, and polygenic dissection of experimental laboratory animal crosses. The key breakthrough was the recognition in the mid 1980s (5) that naturally occurring DNA sequence variation provides a virtually unlimited supply of *genetic markers* (as opposed to *biomarkers*).

The first "useful" genetic marker, described in the late 1970s, was *restriction fragment length polymorphisms* (RFLPs)—due to restriction endonuclease "sites" in the DNA usually 4–8 bases in length. A second class of RFLPs, in which the restriction fragment length variability is caused by a *variable number of tandem repeats* (VNTRs, also called *minisatellites*), was described in the mid-1980s. A more useful subclass of VNTR polymorphisms, in which the repeat unit consists of only two base pairs (called dinucleotide repeats, or microsatellites), was discovered in the late-1980s and shown to be easily scored by the *polymerase chain reaction* (PCR). These microsatellites show a large variability in length per DNA locus, are distributed randomly throughout the genome, and are present as several thousand copies per genome. During the 'nineties, DNA microsatellite marker methodology was the most common and most successfully used technique for linkage analysis. This

technology is being rapidly replaced by *single-nucleotide polymorphisms* (SNPs) methodologies. There are an estimated 6–30 million SNPs throughout the 3.5 billion bases in the human genome; this means the possibility of genetic markers every 200 to 1,000 base pairs (bp) throughout the human (or mouse) genome. Within the next 2 years, it is anticipated that informative SNPs every 10 kb (kilo–base pairs) to every 50 kb throughout the entire 3.5 billion base pairs of the human genome will be identified.

With the availability of so many useful SNPs as markers throughout the entire genome, a new type of analysis is rapidly emerging as perhaps the most exciting advance in the field of genetics since our understanding of mendelian inheritance in the mid nineteenth century. This type of approach has been called *quantitative trait loci* (QTL) analysis, which is the method for determining the chromosomal locations of two or more unlinked genes that contribute to a multiplex phenotype (Fig. 7.3). Interestingly, the method of genetic mapping, by which one compares the inheritance patterns of chromosomal regions, allows one to find where a gene is located without knowing what the gene is. Hence, this positional cloning approach (forward genetics) is just the opposite of the above-described candidate gene approach (reverse genetics), which has been the predominantly used method during the past two decades.

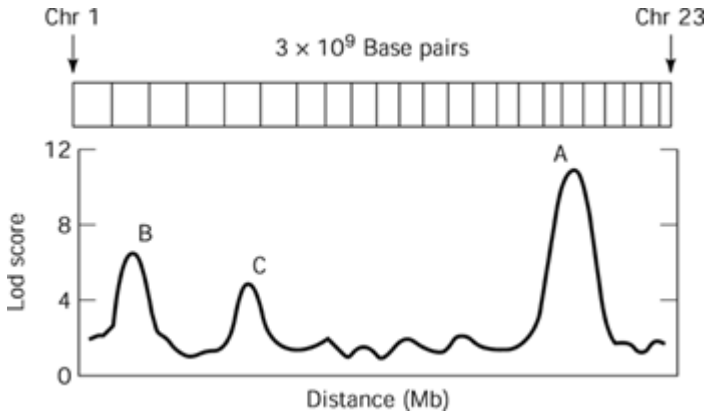

Figure 7.3. How to correlate phenotype with genotype by QTL mapping analysis. Human (or any other species) chromosomes are placed end to end, making the 3.5 billion bases (of human DNA) as if it were a straight line. Following a "genomic screen," lod scores of a trait (phenotype) are computed as a function of points along this straight line (genotype). In this imaginary example, primary gene A has a lod score of about 11, secondary gene B about 6, and secondary gene C about 4 (localized to chromosomes 18, 3, and 7, respectively) [Chr, chromosome; Mb, megabases (linear distance of 1 million base pairs of DNA)].

3.8 Lod Scores

Linkage analysis is a means of correlating phenotype with genotype (Fig. 7.3) via lod scores (6). Screening a human population for a correlation between a trait (e.g., red hair) and each of (e.g.) 2600 DNA markers, we can ask "What is the likelihood that the trait will correctly match one or more DNA markers, versus the likelihood of a random match by chance alone?" This is what is computed in a "log odds" (*lod*) score, which can establish whether a randomly chosen DNA marker is actually linked to that particular trait. The likelihood of two (or more) loci remaining together when chromosomes are recombined (following union of the sperm and ovum) is represented by the recombination fraction, q; this is written $L(q)$. The closer the two loci are to one another, the smaller q is. The likelihood ratio, $L(q)/L$ (½) measures whether the recombination fraction is equal to q (< ½ denotes linkage), as opposed to being equal to ½ (i.e., no linkage). Hence, the equation

$$\text{Lod score} = \log_{10} \frac{L(\theta)L}{L(\frac{1}{2})} = \frac{\text{likelihood of "true" linkage}}{\text{likelihood of chance alone}}$$

If the likelihood of true linkage is 1000 times greater than that by chance alone, the $\log_{10}$ of the ratio

1000 is 3.0, and this is considered in human genetics as a “significant” lod score. Numerous software programs are now available to compute lod scores, “set” the baseline, and suggest the chromosomal locations of many “significant” major and modifier genes that might be found correlated with a phenotype (Fig. 7.3).

It should be emphasized, however, that having a significant lod score with a particular gene does not necessarily implicate a correlation between phenotype and genotype; in other words, ultimately experiments that carry out *functional genomics* are absolutely mandatory. The true gene responsible for the trait might be tens of thousands of base pairs away in linkage disequilibrium (i.e., two loci segregating together from one generation to the next, due to being closely linked on a chromosome and therefore unlikely to be separated via recombination events during meiosis). It is only after *functional studies* are completed (e.g., demonstrating that an amino acid change leads to alteration in function of the gene product in the mutant allele but not wild-type allele) that one has proven an association between phenotype and genotype.

Experimental proof of a lowered enzyme activity or greater receptor affinity are examples of functional studies. A recent example of an erroneous relationship was the molecular epidemiological report on a purported association between risk of prostate cancer and the vitamin D_3 receptor (VD3R) gene (7). After the cDNA-expressed VD3R protein was demonstrated to have no alterations in function [i.e., no differences in receptor affinity (7), it was concluded that another gene—in linkage disequilibrium—must be responsible for the increased risk in prostate cancer. The same appears to be the case for nonfunctional mutations in the coding region (I462V), or Msp I site 3'-ward of the last exon, of the human *CYP1A1* structural gene and its association with increased risk of lung cancer in Japanese populations (3, 4).

Ecogenetics: The Study of Gene–Environment Interactions
Daniel W. Nebert, Amy L. Roe, Ph.D

4 Environmental Genetics
Genes that encode the DMEs involved in metabolism of environmental chemicals, and genes that code for the DME receptors with which environmental chemicals or physical agents interact as either agonists or antagonists, might influence a toxic or carcinogenic outcome (Fig. 7.4). There continues to be an increasing understanding of the mechanisms by which differences in these genes or loci (*genotype*) and the degree of resistance or sensitivity to a toxic or carcinogenic chemical (*phenotype*) lead to environmental disease in some individuals but not others. Foreign chemicals and physical agents (e.g., exposure or dosage), as well as the effects by other modifier genes, are all able to influence one's genotype—leading ultimately to the toxic effect or malignancy (phenotype) (Fig. 7.4).

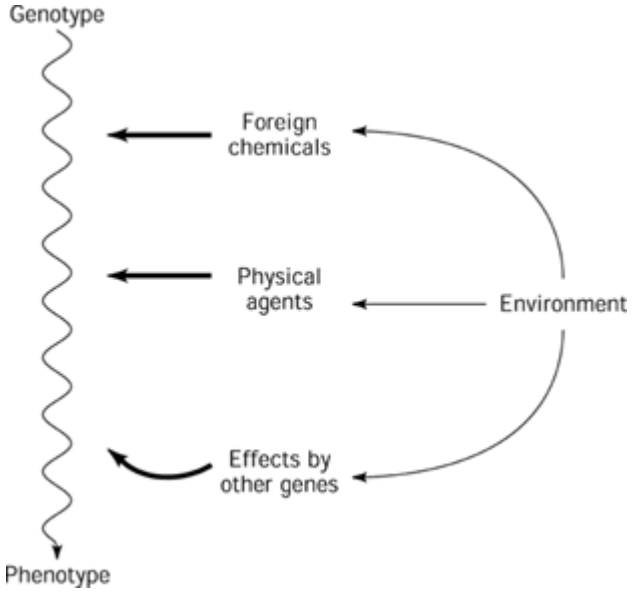

Figure 7.4. Illustration of the effects of the environment on an organism's genotype, by which the phenotype can be changed.

Ecogenetics: The Study of Gene–Environment Interactions
Daniel W. Nebert, Amy L. Roe, Ph.D

5 Susceptibility Genes
Of the 120,000 genes in the human genome, what genes might be involved in causing environmental toxicity and cancer? As described earlier in this chapter, it is likely that at least 75% of these 120,000 genes might contribute to human diseases including environmental diseases. The 120,000 genes can be divided roughly into three broad categories: metabolism genes, the signal transduction genes, and the infrastructure genes.

Metabolism genes code for enzymes. Enzymes "act as a catalyst to induce chemical changes, altering a substrate to form an intermediate or product." Benzo[*a*]pyrene hydroxylase, mediated by CYP1A1, is an example of an enzyme characterized because of its capacity to metabolize the environmental agent benzo[*a*]pyrene; although the enzyme must have an endogenous substrate for evolutionary reasons, and is known (e.g.) to metabolize arachidonic acid metabolites, the true endogenous substrate has not yet been established. Adenine deaminase is generally regarded as an endogenous enzyme, metabolizing the known endogenous substrate adenine; however, any adenine analog used as a chemotherapeutic agent would be regarded as a drug, or environmental agent—thus demonstrating that virtually any "housekeeping gene" encoding an enzyme critical to endogenous pathways in the cell still might contribute to environmental disease under a particular circumstance. Any allelic differences in the genes (e.g., low enzymatic activity), encoding either benzo[*a*]pyrene hydroxylase or adenine deaminase, combined with the proper environmental exposure (or dose of drug), could therefore be responsible for interindividual susceptibility to environmental toxicity or cancer. The genes and enzymes involved in metabolism of virtually all endogenous as well as environmental chemicals have also been termed *drug-metabolizing enzymes* and *DME genes*, respectively, and the receptors that up- and down-regulate many of these enzymes have been called *DME receptors* (4, 8). DME genes (e.g., *CYP1A2*, *CYP26*, *GSTP1*, *ALDH2*, *UGT1A6*, *NQO1*, *HYL1*, *SULT1*, *FMO3*) represent the majority of the metabolism genes.

Signal transduction genes encode proteins (including kinases, phosphatases, transcription factors, cell-surface receptors, DME receptors, drug transporters, binding proteins, tumor suppressors) that participate in signal transduction cascades (e.g., *TP53*, *RB1*, *APC*, *WT1*, *BRCA1*, *PMS2*, *MSH6*, *PPA2*, *MDM2*, *AHR*, *RAR*, *RXR*, *PPARA*). Genes encoding proteins involved in the nuclear matrix, histones, chromatin, or nucleosomes (anything involved in the transcriptional response to endogenous or exogenous signaling) are also included in this category.

Infrastructure genes code for proteins involved in the assembly of all cellular and subcellular structures (e.g., spindle formation, kinesins, adhesion proteins, Golgi apparatus, ribosomes, peroxisomes, nucleolar membranes).

A *susceptibility gene* is defined as any gene that encodes a *gene product* (enzyme, or other protein) that an environmental agent might interfere with (either as an agonist or an antagonist), causing perturbation of normal cellular functions and critical life processes of the cell—leading ultimately to toxicity or malignancy. Susceptibility genes presumably constitute subsets of metabolism genes, signal transduction genes, and infrastructure genes. Allelic differences in any susceptibility gene would therefore produce differences in risk of environmental toxicity or cancer. It seems feasible that allelic variants in metabolism genes would be less likely lethal, compared with that in signal transduction genes or infrastructure genes; studies with "knockout" mouse lines have repeatedly demonstrated, however, that disruption of a gene considered to be "essential" did not lead to morbidity or mortality in the mouse line. It is therefore increasingly appreciated that signal transduction cascades exhibit a great deal of redundancy; hence, we anticipate that human allelic variants in such signal transduction genes will exist at rates similar to that in metabolism genes.

Interindividual differences in DME activities have been shown to be particularly substantial (e.g., 10 to >40-fold), whereas differences in receptor affinity and other signal transduction function are seldom so striking (2- to perhaps 20-fold). Such dramatic increases or decreases in DME activity can lead to large differences in toxicity or cancer risk—in response to the same amount of exposure to an environmental pollutant (or chemical mixture) or to a physical agent such as sunlight or ionizing radiation.

Ecogenetics: The Study of Gene–Environment Interactions

6 Drug-Metabolizing Enzymes
Around 1930–1970, DMEs were considered as a "liver detoxification system" responsible for breaking down drugs and other hydrophobic environmental chemicals for excretion. It is now clear that (*1*) at least some of these DMEs are located in every eukaryotic cell, (*2*) almost all DMEs have endogenous compounds as their natural substrates, and (*3*) many of these DMEs have existed in evolution prior to the divergence of bacteria from eukaryotes, indicating that these DMEs have been responsible for critical life functions long before animal–plant divergence (8, 9).

Since the late 1940s, it has been taught that drug and carcinogen metabolism is carried out by phase I (functionalization) and phase II (conjugation) reactions (Fig. 7.5). Originally, these two coupled reactions were regarded simply as a "liver detoxification system." In the 1960s, some of these activities were then discovered in nonhepatic tissues such as lung, kidney, and gastrointestinal tract—indicating that the activities were not confined only to liver. Then, by the late 1960s, it was realized that some inert chemicals can actually be activated, or metabolically potentiated, to the toxic or carcinogenic intermediate (10). Phase I DMEs, many of which are in the cytochrome P450 superfamily, introduce a functional group, usually a hydroxyl, into their endogenous and exogenous substrates. Thus, a procarcinogen such as benzo[*a*]pyrene, found in cigarette smoke, becomes

metabolically activated to reactive intermediates such as benzo[*a*]pyrene 7,8-oxide and 4,5-oxide. There are >1000 other polycyclic aromatic hydrocarbons in cigarette smoke. Phase II DMEs—such as glutathione transferases, UDP glucuronosyltransferases and *N*-acetyltransferases—take the P450-mediated oxygenated product (or any other endogenous or exogenous compound already having functional groups) and use the functional group for conjugation with such moieties as glutathione, glucuronic acid, sulfate, cysteine, or acetate—yielding a very hydrophilic product that can easily be excreted. Table 7.2 lists many of the prototypic phase I and phase II enzymes.

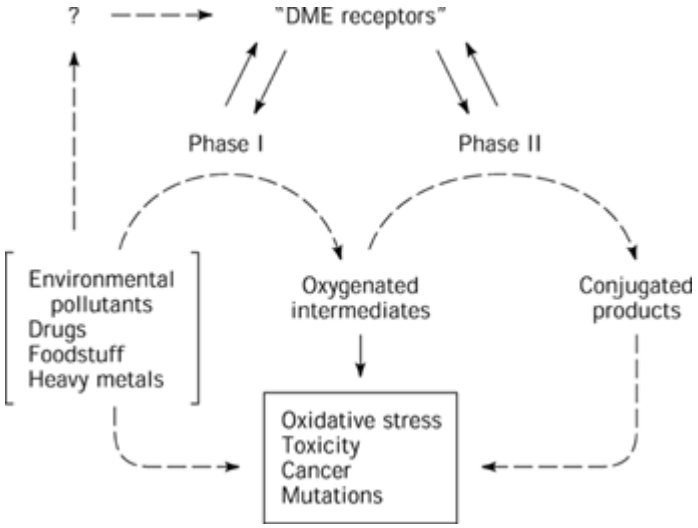

Figure 7.5. Diagram of the fate of drugs (R) entering the cell. The fate of other environmental chemicals is essentially the same. Chemicals can enter the cell by either passive diffusion or active transporters. Either the parent nonmetabolized drug or metabolite reaches its clinical target (efficacy), or the foreign chemical or metabolite can cause toxicity via perturbation of the cell cycle or covalent binding. Reception mechanisms are able to detect the environmental chemical as a "signal" and sometimes can up- or down-regulate phase I and phase II DMEs (9). Transporter proteins can also assist in moving the parent foreign chemical and metabolites out of the cell. Reproduced with permission from Nebert et al. (4).

Table 7.2. List of Enzymes that are Often Included as Drug-metabolizing Enzymes

Phase I
P450s, flavin-containing monooxygenases (FMOs), hydroxylases, lipoxygenases, cyclooxygenases, peroxidases, oxidases, monoamine oxidases (MAOs), dioxygenases, reductases, quinone reductases, aldoketoreductases, carboxylesterases, NAD- and NADP-dependent alcohol (and steroid) dehydrogenases
Phase II
UDP glucuronosyl-, glutathione-, and sulfotransferases
Transaminases, acetyltransferases, methyltransferases, acyltransferases
Glycosylases, glucuronidases, various hydrolases and esterases

These phase I and phase II reactions can be very complex (11). For example, it is possible for benzo[*a*]pyrene to be metabolized to more than 700 intermediates and products, if one counts all the stereoisomers. Benzo[*a*]pyrene 7,8-oxide can be converted (by epoxide hydrolase) to the *trans*-7,8-

dihydrodiol, which can then be activated by a phase I P450 to the ultimate carcinogen benzo[*a*] pyrene *trans*-7,8-dihydrodiol-9,10-epoxide (BPDE). Although the combined effect of phase I and phase II DME activities is usually the detoxification of the drug or environmental chemical, metabolic intermediates, (e.g., BPDE) readily form protein and DNA adducts and are strong toxicants, mutagens and carcinogens, by virtue of their highly reactive electrophilic groups. BPDE is genotoxic because it produces DNA damage. Moreover, it is worth noting that incoming chemicals can be toxic and carcinogenic without requiring metabolism. Also, so-called detoxified conjugated products can even be cleaved to form toxic, mutagenic or carcinogenic intermediates (Fig. 7.5). Reduced glutathione (GSH) conjugation can also enhance toxicity or malignancy. Incoming chemicals, their metabolites, and their conjugated products can all be moved in or out of the cell by drug transporters. Hence, allelic mutants in any of these DME genes or DME receptor or drug transporter genes can play an important role in determining interindividual risk of environmental toxicity or cancer.

It therefore follows that exposure to environmental agents in a "high phase I–low phase II" metabolism individual might lead to more toxicity or cancer than that in a "low phase I–high phase II" individual (Fig. 7.6). An example of this concept has been demonstrated in epidemiologic studies in Japan, showing an increased risk of cigarette smoking-induced bronchogenic carcinoma associated with particular alleles of the *CYP1A1* and *GSTM1* genes (*see below*). DME receptors that up- and down-regulate the levels of the DME enzymes might also be responsible for contributing to this toxicity or cancer. The remainder of this Chapter is a series of brief summaries of some of the more extensively studied human polymorphisms. Lastly, drug transporters are likely to contribute to interindividual differences in toxicity in cancer; allelic variants in transporter genes have only begun to be studied.

7 Classification of Ecogenetic Differences

Various colleagues have differing opinions as to what might be included as an "ecogenetics difference," because some of these are commonly considered as "inborn errors of metabolism." Table 7.3 lists the classification we will use here, based on categories of less enzyme or defective protein, increased resistance (usually a receptor-mediated mechanism), altered response due to differences in enzyme induction, abnormal metal distribution, and "other" disorders of unknown etiology. The examples that are detailed below are selected from Table 7.3, and in the order in which they appear on this list. (For further discussion on many of these other ecogenetic differences, the reader is referred to Refs. 3, 4, 8, and 11–24).

Table 7.3. One Possible Classification of Human Ecogenetic Differences[a]

Less enzyme/defective protein
N-acetylation polymorphisms (*NAT2*, *NAT1*)
Increased susceptibility to chemical-induced hemolysis (G6PD deficiency) (*G6PD*)
a_1-Antitrypsin [protease inhibitor (*PI*)], defective alleles associated with increased toxicity by cigarette smoke
a_1-Antichymotrypsin (*AACT*), mutant alleles also associated with more toxicity by cigarette smoke?
Hereditary methemoglobinemias
P450 monooxygenase polymorphisms (oxidation deficiencies) debrisoquine (*CYP2D6*), phenytoin (*CYP2C9*, *CYP2C19*), nifedipine (*CYP3A4*), coumarin and nicotine (*CYP2A6*), acetaminophen (*CYP2E1*, *CYP1A2*)
Null mutants of glutathione transferase, m class (*GSTM1*), or q class (*GSTT1*)
Thiopurine methyltransferase (*TPMT*)
Paraoxonase deficiency, sarinase (*PON1*, *PON2*, *PON3*)
UDP glucuronosyltransferase (*UGT1A1*, *UGT2B7*)
NAD(P)H:quinone oxidoreductase (*NQO1*)
Epoxide hydrolase (*HYL1*)
Atypical alcohol dehydrogenase (*ADH*)
Atypical/lack of aldehyde dehydrogenase (*ALDH2*)
Increased resistance to chemicals
Inability to taste phenylthiourea
Coumarin resistance
Increased metabolism—atypical liver alcohol dehydrogenase (*ADH*)
Defective receptor—malignant hyperthermia / general anesthesia (Ca^{2+}-release channel ryanodine receptor) (*RYR1*, *MHS1*)
Defective drug transporters, *e.g. MDR1*, resistance to chemotherapeutic agents
Change in response due to enzyme induction
Porphyrias (esp. cutanea tarda)
Aryl hydrocarbon receptor (*AHR*) polymorphism (inducibility of *CYP1A1*,

CYP1A2) dioxin-caused chloracne, porphyria cutanea tarda, cancer, immunosuppression, (?) birth defects, (?) eye, (?) ovary

Abnormal metal distribution

Iron [hemochromatosis (*HFE*)], copper (Wilson's disease, Menkes's disease), (?) lead, (?) cadmium, (?) other metals

Disorders of unknown etiology (clinically observed to run in families)

Corticosteroid (eyedrops)-induced glaucoma

Halothane-induced hepatitis

Chloramphenicol-induced aplastic anemia

[a] From Nebert (Ref. 4a).

Note that the term *ecogenetic differences*, rather than *disorders*, is being used here. This is because a low enzymatic activity need not necessarily be associated with an adverse reaction or unwanted outcome. For example, an NAT2 slow acetylator who smokes cigarettes has an increased risk of urinary bladder cancer when working in the chemical dye industry, or increased risk of breast cancer, but has a reduced risk of colorectal cancer (4, 18).

7.1 N-Acetylation (NAT2) Polymorphism

Originally called the *isoniazid acetylation polymorphism*, this polymorphism was first identified in the late 1940s in tuberculosis patients treated with isoniazid. Individuals can be phenotyped as "slow" or "rapid" acetylators. Slow acetylators are homozygous for any one of dozens of slow acetylator (*r*) alleles, whereas rapid acetylators are either heterozygous or homozygous for the rapid (*R*) (wild-type) alleles. Therefore, the slow phenotype is inherited as an autosomal recessive trait. The frequency of the *r* alleles is about 0.72 in the United States, meaning that about one in every two individuals [according to the Hardy–Weinberg equation, *viz.*, $(p+q)^2 = p^2+2pq+q^2$, $q^2 = 0.72 \times 0.72 = 0.5184$, i.e., 52% of population] is homozygous for *r/r* and exhibits the slow acetylator phenotype. The frequency of the slow acetylator trait ranges worldwide (Table 7.4) from approximately 10% in Japanese populations to more than 90% in some Mediterranean peoples (24).

Table 7.4. Frequency of the Slow *N*-Acetylator *NAT2* Alleles (q) in Different Ethnic Populations[a]

Population	Number of Studies	Mean
Eskimo	4	0.23
South Pacific Islands	5	0.35
Korean/Chinese/Japanese	14	0.37
North and South American Indian	10	0.50
African (excluding Kung, 0.18)	19	0.71
Central and west Asian	22	0.74
European	50	0.75
Egyptian	2	0.96

[a] Data modified and condensed from Price-Evans 1992.

Two *N*-acetyltransferase functional genes (*NAT1*, *NAT2*) and one pseudogene (*NATP*) have been cloned and localized to the same region on human chromosome 8pter-q11. The rapid and slow acetylator phenotype was found to reflect principally the *NAT2* gene, encoding the NAT2 enzyme, which has a 10 times lower K_m (Michaelis constant) value for aromatic amines than does NAT1.

Three major slow acetylator alleles (two common in Caucasians, one common in Asians), each identifiable at a restriction endonuclease site, have independently been identified in several human populations (Fig. 7.7). The number of minor, rare *NAT2* alleles is now greater than 30 (25–27).

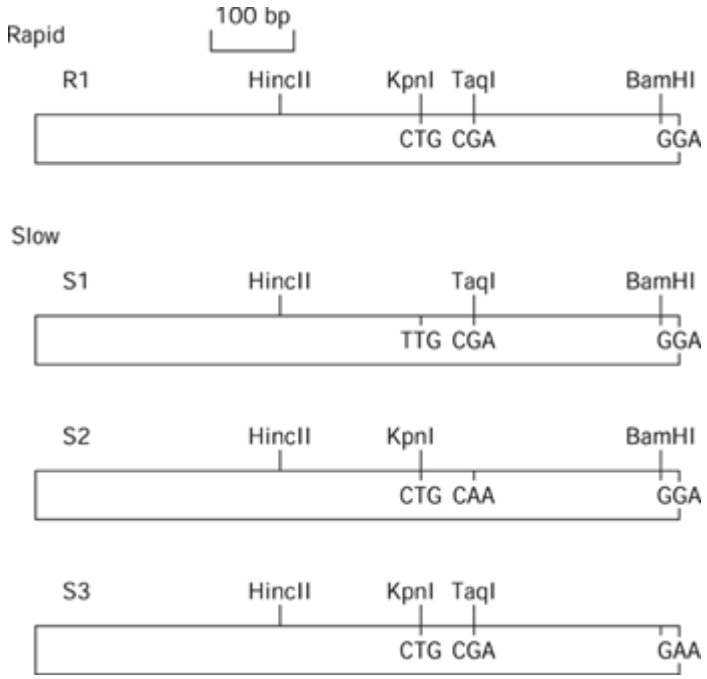

Figure 7.7. Diagram of the wild-type (R1, rapid) and three mutant (slow) alleles of the *NAT2* gene. The gene has only two exons, and these three variants can all be detected by changes in the patterns of restriction enzyme fragments: there is loss of a KpnI site in S1, loss of a Taq I site in S2, and loss of a Bam HI site in S3. The S1 and S2 alleles are the two most common among Caucasians, and the S3 allele is most common among Asians. There is now recommended nomenclature for all *NAT2* and *NAT1* alleles. Reproduced with permission from Nebert and Carvan 1997.

There are distinct associations between acetylation phenotypes and cancer or toxicity. For example, the slow acetylator phenotype shows a lower incidence of colorectal carcinoma but a higher incidence (odds ratio of 16.7) of bladder cancer (2). Both occupational exposure to arylamines and cigarette smoking are required, in conjunction with the slow acetylator phenotype, for development of bladder cancer, and no relationship was found between acetylator phenotype and smoking-related bladder cancer in the absence of exposure to arylamines. These findings have been independently confirmed by many laboratories. The slow acetylator phenotype has also been associated with enhanced plasma levels of drugs that are NAT2 substrates. Treatment of patients with certain drugs has resulted in the development of antinuclear antibodies and systemic lupus erythematosis at a much greater frequency among slow acetylators than among rapid acetylators (26).

7.2 Glucose-6-phosphate Dehydrogenase (G6PD)

G6PD is an enzyme in the hexose monophosphate shunt, one of the principal sources of NADPH generation in the normal red cell and many other tissues. Thiazolsulfone was the first arylamine sulfa drug shown to cause hemolytic anemia, and a bimodal distribution was seen in the treated population due to G6PD differences. The enzyme G6PD has perhaps more human variants than any other protein. Approximately 10% of the world population has one or another of the more than 350 different G6PD variants. Ethnic differences can be striking (e.g., >100-fold between Ashkenazic and Sephardic Jews). The *G6PD* gene has been cloned and is located on the X chromosome, which is consistent with the transmission of G6PD deficiency as an X-linked recessive trait; this means that a "carrier" mother and a healthy father will have children displaying one of four possibilities: a healthy female, a carrier female, a healthy male, and an afflicted male (16, 24).

Ecogenetics: The Study of Gene–Environment Interactions
Daniel W. Nebert, Amy L. Roe, Ph.D

8 Synergy between two Pharmacogenetic LOCI
A toxic response to an environmental agent can be greatly exaggerated by the combination of two ecogenetic differences in the same individual. For example, individuals with both the slow acetylator phenotype and G6PD deficiency can be affected quite dramatically by specific environmental agents (Table 7.5). Aniline-hemoglobin adducts among workers exposed to aniline were found to be ~50 times higher in G6PD-deficient slow acetylators than in G6PD-normal rapid acetylators. Thus, although individuals might be exposed to the same level of an environmental chemical or mixture—whether at a toxic waste site, in the form of a pesticide/herbicide, polluted urban air, or in the workplace—the risk of an adverse health effect may vary by two or more orders of magnitude, due to synergism caused by two or more ecogenetic differences. Furthermore, biomarker measurements—presumed to determine the amount of exposure in the workplace—may vary greatly because of underlying interindividual ecogenetic differences rather than actual occupational exposure. This point has very important implications to those who work in the biomonitoring field.

Table 7.5. Hemoglobin (Hgb) Adducts in Chemical Dye Workers Exposed to Aniline[a]

Acetylator Status		G6PD Deficiency		
Fast	**Slow**	**No**	**Yes**	**Aniline-Hgb Adducts**
+		+		2
+			+	30
	+	+		20
	+		+	100

Ecogenetics: The Study of Gene–Environment Interactions
Daniel W. Nebert, Amy L. Roe, Ph.D

9 Polymorphism and Other forms of Gene–Environment Adaptation
9.1 a_1-Antitrypsin Polymorphism (a_1-AT)
a_1-AT is a protease inhibitor (PI), the deficiency of which is associated with emphysema and liver disease. This secretory glycoprotein is formed primarily in liver cells for the purpose of inhibiting proteolytic enzymes produced by neutrophils; these enzymes include elastase, cathepsin G, and proteinase-3. a_1-AT deficiency is one of the most common lethal hereditary disorders in Caucasians of European descent. The disease is an autosomal recessive disorder characterized by reduced serum

a_1-AT levels. Serum a_1-AT concentrations of 20–53 mM are considered normal in humans (28). Individuals with serum levels of <20 mM are considered "deficient" in a_1-AT. Deficiencies in a_1-AT are caused by defects in the protease inhibitor (*PI*) gene, located at 14q31-31.2 (29). More than 70 different phenotypes for the *PI* gene (a_1-AT gene) have been identified as of this writing (30). The most common (wild-type) *M* in human populations represents at least six alleles, resulting in normal serum a_1-AT levels. a_1-AT deficiency is associated with the *Z* and *S* alleles. The prevalence in the Caucasian population of the *M/M*, *M/S*, and *M/Z* genotypes is 86, 9, and 3%, respectively (30). Individuals homozygous for the *Z* allele (i.e., *Z/Z*) display a severe deficiency in serum a_1-AT levels, and have a high risk for developing emphysema and liver disease, as well as an increased risk for chronic obstructive pulmonary disease (COPD) (28, 30). The *S/S* genotype occurs in ~ 0.1% of the Caucasian population. *S/Z* heterozygotes are also at risk for developing COPD, but only at mild risk for developing emphysema (28, 30, 31). A summary of the relative risk for emphysema based on serum a_1-AT levels and the risk of COPD as a function of phenotype is found in Table 7.6.

Table 7.6. Relative Risk for Emphysema Based on Seruma a_1-AT Levels and Risk of Chronic Obstructive Pulmonary Disease (COPD) as a Function of Phenotype[a]

Phenotype	Serum a_1-AT Levels (mM)	Emphysema Risk Compared to General Population	Risk of COPD Based on Phenotype
MM	20–53	No increase	None
MZ	12–35	No increase	None
SS	15–33	No increase	None
SZ	8–19	Mild increased risk	Yes
ZZ	2.5–7	High risk	Yes
Null–null[b]	0	High risk	*(?)

[a] Modified from Crystal (28). COPD data taken from Sandford et al. 30.
[b] Null–null individuals have not yet been studied for risk of COPD.

Several studies have examined the combined effects of deficient levels of a_1-AT and various environmental and occupational exposures. Environmental exposures—such as cigarette smoke, air pollution, and passive smoke—and occupational exposures to dust and fumes appear to predispose the a_1-AT-deficient individual to the development of respiratory diseases including COPD and emphysema (31–33).

9.2 a_1-Antichymotrypsin (AACT)

AACT is a plasma protease inhibitor, synthesized in the liver, belonging to the class of serine protease inhibitors. The normal AACT serum levels are about one-tenth that of a_1-AT (PI); the *AACT* and *PI* genes exhibit homology (34) and are located in the same region on chromosome 14 (35) within 220 kb of one another (36). The abnormal *AACT* allele is inherited as an autosomal dominant trait (37). When combined *PI-AACT* haplotypes were examined, there was no evidence of linkage disequilibrium between defective *PI* alleles and *AACT* alleles (38). Both proteins are major "acute phase" reactants; because their plasma concentrations are known to rise in response to trauma, surgery, and infection, it is reasonable to expect that individuals having a defective *AACT* gene will have more trouble with cigarette smoke–induced bronchitis and pulmonary fibrosis than will individuals having the wild-type *AACT* gene similar to what has been found with the *PI* gene.

9.3 P450 Monooxygenase Polymorphisms

Cytochromes P450 are phase I enzymes (Table 7.2) that metabolize virtually all drugs and other environmental chemicals—even certain heavy-metal ions. These enzymes carry out alkyl and aryl hydroxylations; *N*-, *O*- and *S*-dealkylations; *N*-, *O*-, and *S*-dehalogenations; and even reductions (39, 40). There appear to be 49 cytochrome P450 (CYP) genes in the human genome (41), and an increasing number of human allelic variants are described each month (4, 42).

9.4 The Debrisoquine Hydroxylase Polymorphism

Poor metabolizers (PMs) of the antihypertensive drug, debrisoquine, were found in the mid-1970s to represent 6–10% of Caucasian populations, as compared with extensive metabolizers (EMs) who handle the drug 10–200 times more efficiently. The human gene (*CYP2D6*, a cytochrome P450), along with related genes and pseudogenes in the same subfamily, have been localized to chromosome 22q13.1. As with almost every ecogenetic disorder, important ethnic differences in the incidence of phenotypes exist; for example, the PM phenotype is virtually absent in Chinese, Japanese, Laplanders, and Inuits (16, 26). The "debrisoquine panel" now encompasses more than 40 drugs and environmental chemicals, including antiarrhythmics, antihypertensives, b blockers, monoamine oxidase inhibitors, morphine derivatives, antipsychotics and tricyclic antidepressants, and nitrosamines found in tobacco smoke (2, 26). Whereas more than 60 alleles attributed to the PM phenotype have been identified (43), the most common are the *CYP2D6*3*, *CYP2D6*4*, and *CYP2D6*5* alleles, accounting for more than 70% of all null alleles in Caucasians. The *CYP2D6*5* allele (actual deletion of the entire *CYP2D6* gene) represents 19% of PM individuals. The latest nomenclature update of the human *CYP2D6* alleles can be found on the Web (42).

The EM phenotype has been associated with increased risk of liver, gastrointestinal and lung cancer. Innumerable epidemiological and ethnic studies linking the *CYP2D6* allelic differences with toxicity and cancer have been reported.

In addition to the defective (PM) *CYP2D6* alleles, there are duplicated or multiduplicated active *CYP2D6* genes, resulting in the ultra-rapid-metabolism (UM) phenotype (44). In the mid–late 1990s 29% of an Ethiopian population, and 21% of a Saudi Arabian population were identified as UM individuals (44, 45). The frequency of UM patients in black, Asian, and European populations is only 1–2% (45).

9.5 Alcohol-Inducible CYP2E1

CYP2E1 catalyzes the monooxygenation of dozens of drugs but is especially relevant to ecogenetics because it metabolically potentiates low molecular weight procarcinogens—such as vinyl chloride and vinyl bromide, dimethylnitrosamine and diethylnitrosamine, acrylonitrile, urethane, styrene, benzene, carbon tetrachloride, chloroform, and trichloroethylene—to reactive (toxic, mutagenic, carcinogenic) intermediates. Acetone is an endogenous substrate for CYP2E1. CYP2E1 metabolism is induced by alcohol, acetone, and fasting. Nine mutant *CYP2E1* alleles have been identified so far (4, 42), and *CYP2E1*2* has been demonstrated to exhibit lowered enzymatic activity due to an important amino acid change (46). The *CYP2E1*5A/*5B* alleles has been reported as a risk factor in nasopharyngeal cancer (see Ref. 47, and Refs. cited therein), although this polymorphism is located in the 5' flanking region and has yet to be proven that it is correlated with increases in transcription rate of the gene—leading to enhanced CYP2E1 metabolism. Further work on this allele is needed to corroborate whether *CYP2E1*5A/*5B* mRNA levels and enzymatic activity are indeed augmented. Studies looking at possible associations between *CYP2E1* variant alleles and environmental toxicity or cancer are predicted to explode within the next several years (at the time of writing). The same is true of all other P450 polymorphisms listed in Table 7.3.

9.6 CYP1A1 Gene Polymorphism

A restriction fragment length polymorphism (RFLP) affecting the size of Msp I fragments of the human *CYP1A1* gene on chromosome 15q22-ter was noted in 1987 (48). In Japan, this RFLP appears to be associated with a higher incidence of lung cancer, especially when combined with the *GSTM1* (glutathione transferase mu) null mutation (Table 7.7). From these studies, it seemed plausible that the human *CYP1A1* structural gene, or a region near this gene, might be correlated with the inducibility phenotype and with increased risk of lung cancer. Studies with *CYP1A1* in other ethnic groups do not, however, find any correlation with lung cancer; Norwegians, American

Caucasians and blacks, Finns, and eastern Mediterraneans lack the association between the Msp I RFLP, the I462V mutation, and/or lung cancer. Thus, it now appears that the Msp I RFLP might explain some of the genetically predisposed increased risk among Japanese high inducibility individuals for particular types of cigarette smoke–induced cancer, but it does not hold true for other ethnic groups (4, 11). The I462V amino acid change in the enzyme active site was reported to increase enzymatic activity; however, two studies have shown that cDNA-expressed CYP1A1 enzymatic activity *in vitro* is not different between the *CYP1A1*1* wild-type and *CYP1A1*2B/*2C* allelic products (4, 49, 50). It remains plausible that, in the Japanese population, the Msp I RFLP polymorphism is in linkage disequilibrium with another mutation that is important for CYP1A1 inducibility or another gene (*CYP1A2?*) involved in tumorigenesis, whereas—in non-Japanese populations—these mutations are not in linkage disequilibrium.

Table 7.7. Relative Risk Estimate of Lung Cancer Types in Japanese Patients Having the Combined Genotypes for CYP1A1 and GSTM1 Genes[a]

	Ile/Ile		Ile/Val		Val/Val	
CYP1A1:						
GSTM1:	+	–	+	–	+	–
Lung cancer	1.0	1.7	1.7	1.4	2.3	5.8
Kreyberg I	1.0	1.8	1.3	1.8	1.6	7.9
Squamous cell CA	1.0	2.3	1.2	1.5	2.0	9.1
Kreyberg II (adenocarcinoma)	1.0	1.6	2.2	1.0	3.1	3.5

[a] Modified and condensed from Hayashi et al. 1992.

9.7 CYP1A2 (Arylamine Hydroxylase)

CYP1A2 metabolizes aromatic amine procarcinogens, including tobacco smoke–specific nitrosamines, such as 4-(methylnitrosamino)-1-(3-pyridyl-1-butanone (NNK). Between 15- and ≥ 60-fold differences in human CYP1A2 mRNA levels, 1A2 protein levels, and CYP1A2 activities have been reported, suggesting that interindividual differences in CYP1A2 expression might play a role in toxicity and cancer (4, 11). Although expressed constitutively (and inducible by cigarette smoke) in liver, CYP1A2 has not been detected in human lung and has been found at very low levels in the gastrointestinal tract, brain, and endothelial cells of blood vessels. With the use of caffeine as a probe, a trimodal distribution of the enzymatic activity (consistent with high/high, high/low and low/low genotypes) has been detected in four separate populations (51, 52). The genetic basis of this polymorphism has been extensively searched for, but is not yet understood (4, 42).

Two *Cyp1a2(-/-)* knockout mouse lines—showing different phenotypes—have been developed (53, 54). These mouse lines will be helpful in elucidating the role of CYP1A2 in toxicity and cancer.

9.8 Thiopurine Methyltransferase (TPMT)

TPMT is an enzyme that can be regarded in a detoxification pathway for 6-mercaptopurine (Fig. 7.8), commonly used in chemotherapy for acute lymphocytic leukemia. The frequencies of the high/high, high/low, and low/low genotypes are 87, 13, and 0.3%, respectively, in the Caucasian population. This means that, when given the recommended dosage [from the *Physician's Desk Reference* (PDR)] of 6-mercaptopurine, one out of approximately 300 patients would die as the result of too much chemotherapeutic drug, 13% would have a high probability of being cured of their disease, and 87% patients would have relapses in their leukemia due to undertreatment (Fig. 7.8). Because this pharmacogenetic difference can lead to dire consequences, acute lymphocytic leukemia

patients are now routinely phenotyped for TPMT prior to the initiation of 6-mercaptopurine chemotherapy; high/high patients are then usually given a 4 times higher dose, and low/low patients are given a 10–15 times lower dose, leading to a much better cure rate and survival rate for childhood leukemia (21). At least eight PM allelic variants have been characterized for the *TPMT* gene (4).

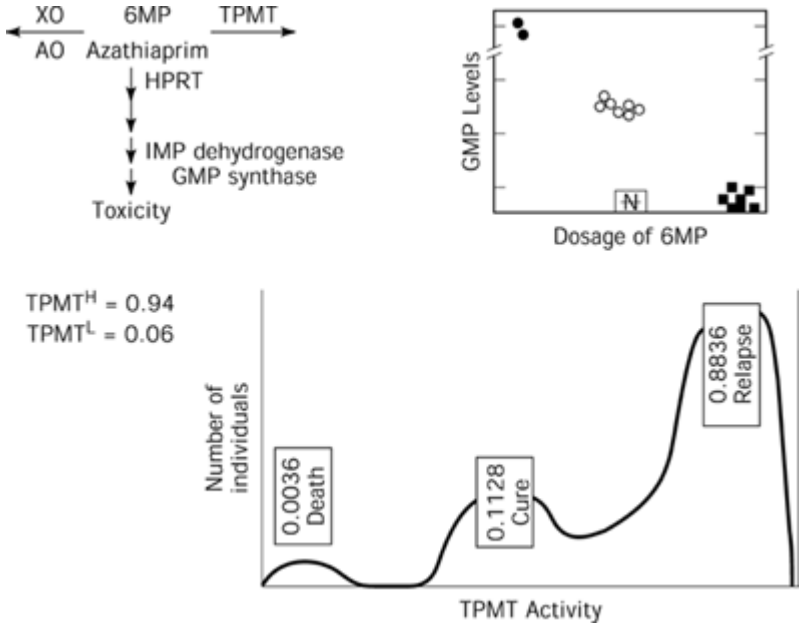

Figure 7.8. Diagram of 6-mercaptopurine (6MP) toxicity (which can occur in all cells but more so in rapidly growing malignant cells, due to disruption of purine biosynthesis), and the response of acute lymphocytic leukemia patients given the "recommended dose" of the chemotherapeutic agent. XO (xanthine oxidase), AO (adenine oxidase), and TPMT (thiopurine methyltransferase) are all enzymes that detoxify 6MP. Toxicity of 6MP occurs much more readily in individuals have the low activity allele, $TMPT^L$, than the high-activity allele, $TMPT^H$. About three in 1000 Caucasians are homozygous for the low/low genotype, and 87% are homozygous for the high/high genotype.

9.9 Paraoxonase Polymorphism

Paraoxon is the biologically active metabolite of parathion, an organophosphate insecticide. Interestingly, paraoxonases (PON1,2,3)—calcium-dependent A-esterases— are found in human plasma, and we have long believed that this enzyme must exist for some reason other than detoxifying organophosphates (which were first synthesized in the mid twentieth century). PON1 is now known to be an apoJ high density lipoprotein (HDL)-associated enzyme that hydrolyzes many toxic organophosphates, including sarin, and must play a role in cardiovascular homeostasis. The enzyme functions of PON2 and PON3 are not yet understood. The frequencies of the high/high, high/low, and low/low *PON1* genotypes are approximately 50, 40, and 10%, respectively, in Caucasians. Again, striking ethnic differences worldwide have been described (Fig. 7.9) (16). The *PON1*2* allele and *PON2*3* allele, both resulting in a low activity subunit of the enzyme represent mutations: R192Q, arginine changed to glutamic acid at position 192 (55), and C311S, cysteine changed to serine at position 311 (56). The organophosphates allegedly used as biological warfare, and pyridostigmine used as an antidote of anticholinesterase poisoning, have caused some to speculate that the "Gulf War syndrome," in which striking variations in illness occurred among some but not other soldiers in this 1991 war, might be explained at least in part by the paraoxonase polymorphism (57).

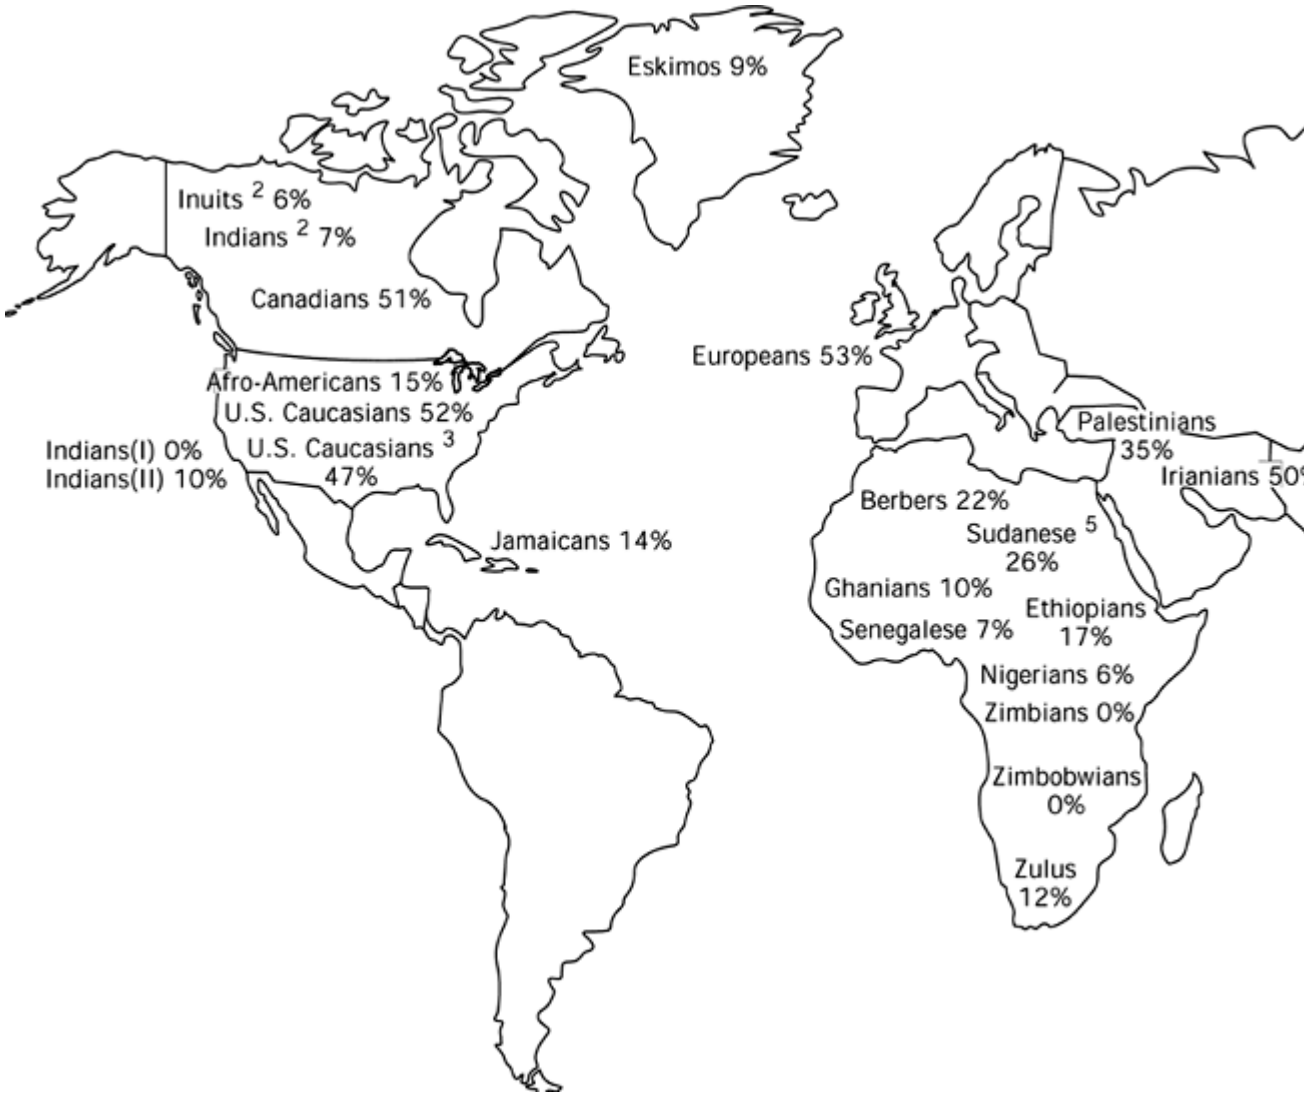

Figure 7.9. Genetic differences in paraoxonase. Reproduced with permission from Kalow and Bertilsson (16).

9.10 Aldehyde Dehydrogenase (ALDH2) Polymorphism

Out of the 17 human *ALDH* genes cloned and characterized by the late 1990s (58, 59), the mitochondrial *ALDH2* has the most clinical significance. When drinking alcohol, the enzyme alcohol dehydrogenase (ADH) converts ethanol to acetaldehyde, which is the toxic metabolite.

If the detoxification of acetaldehyde by ALDH2 is not rapid enough, alcohol intake tends to cause acetaldehyde buildup, facial flushing, rapid heart rate, and a drop in blood pressure (60). Interestingly, an inactive genetic variant of *ALDH2*—which represents a point mutation near the COOH terminus of the enzyme protein—occurs in some populations at a frequency as high as 50%, and there are very striking ethnic differences (Table 7.8. ALDH2 is a tetramer, and if the tetramer contains even one inactive subunit, the whole tetramer is enzymatically inactive. This means that ALDH2 deficiency is inherited as an autosomal dominant trait).

Table 7.8. Distribution of ALDH2 Isozyme Deficiency in Different Populations[a]

Population	Percent Deficient in ALDH2

Japanese	44
Central, East, and Southeast Asian	30–50
South American Indian	40–45[b]
North American Indian	2–5
European, Near-East, and African	0

[a] Data modified and condensed from Goedde and Agarwal 1986.
[b] Different mutation from that in Asians and North American Indians.

9.11 Phenylthiourea Taster/Nontaster Polymorphism

Proposed to be the first clinical example of an ecogenetics difference (3), the inability to taste phenylthiourea (PTU) was described as an autosomal recessive trait (24). In 1950 the frequency of "PTU nontasters" among American Indians and Africans was reported to be only 2 and 3%, respectively, compared with 30% PTU nontasters in the United States; hence, this was also the first appreciation of ethnic differences in response to an environmental agent. The mechanism for PTU nontaster is not yet known, but is presumed to be receptor-mediated.

9.12 Ryanodine Receptor/Ca^{2+} Release Channel (RYR1,2,3)

In response to particular inhalation anesthetics and muscle relaxants, the occasional patient will develop sustained muscle contraction and a fever of >44 °C, which can often be fatal; this was termed *malignant hyperthermia* (MH). The incidence of MH in humans is quite rare—1 : 12,000 to 1 : 40,000 (24). It was then realized that MH occurs in both humans and pigs and is caused by a mutant allele in the ryanodine receptor (*RYR1*) gene. The RYR is a calcium-release channel protein of high molecular weight (M_r = 565,000–590,000) (61). The *RYR1*2* allele (R614C), is the same amino acid variant in both humans and pigs Further studies have confounded the field, because three *RYR* genes have now been found: two loci on human chromosome 17q, and another on 19q. Moreover, another *RYR1* mutation (R2434H, inherited myopathy) has a possible association with central core disease.

9.13 The Ah Receptor (AHR) Polymorphism

The AHR polymorphism was originally identified from studies of inducible benzo[*a*]pyrene metabolism in mice. Aryl hydrocarbon hydroxylase (AHH; benzo[*a*]pyrene 3-hydroxylase; now named *cytochrome P450*, CYP1A1) was found to be highly inducible and controlled by a high affinity AHR in some inbred mouse strains, and a low affinity AHR in other strains. This difference was shown not to be due to changes in the *Cyp1a1* gene itself, but rather in the *Ahr* gene that encodes a receptor; the lack of inducibility is inherited as an autosomal recessive trait in genetic crosses between C57BL/6 and DBA/2 mice. There is convincing evidence, from inbred mouse studies, that allelic differences in the *Ahr* gene, which encodes the AHR, can result in striking differences in interindividual susceptibility to cancer, mutagenesis, birth defects, and cell-type-specific toxicity of the liver, eye, ovary, bone marrow, and immune system; some of the toxicity or cancer reported in mice have also been reported in clinical studies (62). Fig. 7.10 shows the enzyme reactions of CYP1A1 and CYP1A2; these two enzymes, encoded by the *CYP1A1* and *CYP1A2* genes, are regulated by the AHR in the mouse and human. There is a cascade of events by which environmental chemicals enter the cell, displace an (as yet unknown) endogenous ligand from the AHR, and lead to CYP1A1 and CYP1A2 induction (62–65) and chronic oxidative stress (66).

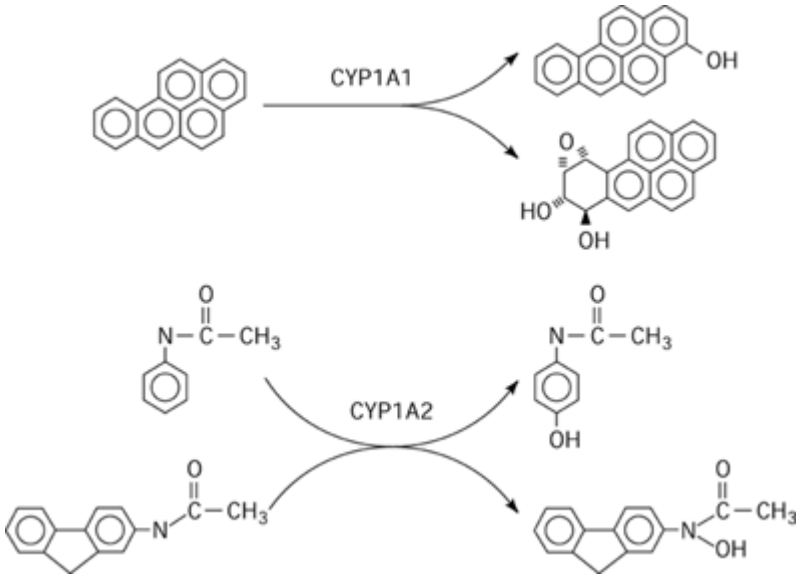

Figure 7.10. Enzymic reactions of CYP1A1 and CYP1A2. Polycyclic hydrocarbons, such as benzo [*a*]pyrene shown here, are substrates for CYP1A1; conversion of the 7,8-oxide to the *trans*-7,8-diol is carried out by epoxide hydrolase. Aryl amines, such as acetaminophen and 2-acetylaminofluorene shown here, are substrates for CYP1A2 (10).

Clinical correlations between genetic differences at the *AHR* locus and certain types of toxicity and forms of cancer have been suggested (4, 62, 67–70), but an experimental assessment of this hypothesis is, of course, hampered by the ethical difficulties of carrying out definitive experiments in humans. Heavy exposures of human populations to dioxin, halogenated hydrocarbons, or cigarette smoking have led to the manifestations of malignancies, birth defects, chloracne, mental problems, early onset of menopause, and immunosuppression—but no cause–effect relationship between the AHR phenotype and these types of toxicities or cancers has been rigorously demonstrated to date.

Using 20–40 cm^3 of blood from venipuncture, numerous laboratories have studied peripheral white cell cultures in the presence of mitogens and CYP1A1 inducers, in order to assess the human AHR phenotype and relationship to cancer (11). There is a continuous gradient from low to high inducibility phenotypes, with more than 12-fold differences between the lowest and highest inducibility phenotype (71). Studies from a number of independent laboratories have suggested that, among cigarette smokers, the highest inducibility (AHR^H) phenotype is at greater risk (estimates run between 3- and 20-fold) than the lowest inducibility (AHR^L) phenotype for bronchogenic carcinoma (Fig. 7.11), laryngeal carcinoma, and cancer of the oral cavity, but not cancer of the kidney, ureter or urinary bladder. These data are consistent with the fact that cells in contact with incoming cigarette smoke might be more prone to carcinogenesis than tissues distant to smoke inhalation. However, the mitogen-activated lymphocyte 3- or 4-day culture assay is not trivial to carry out, many laboratories have experienced difficulties in reproducibility of this assay, and numerous modifications of the assay were introduced in the 1980s and 1990s. Consequently, the reporting by several laboratories of an absence of association between the AHR^H phenotype and bronchogenic cancer (11) is likely to reflect technical difficulties in the white blood cell culture assay.

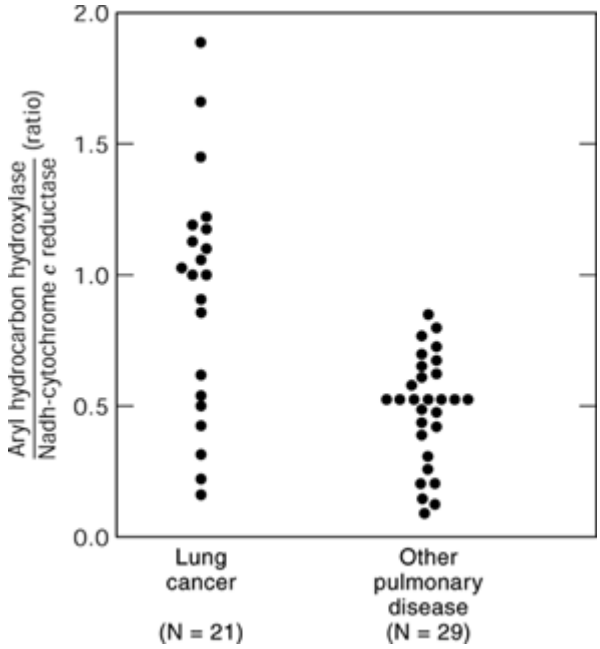

Figure 7.11. Ratio of CYP1A1 (aryl hydrocarbon hydroxylase) activity to microsomal reductase activity in 21 freshly diagnosed lung cancer patients and 29 (matched for age, sex, and cigarette smoking history) patients with other pulmonary disease. At least 12 of the lung cancer patients exhibit CYP1A1 inducibility that is significantly greater than that in any of the patients without cancer. The original study was reported by Kouri et al. (1982) [redrawn from Nebert and Gonzalez, (40), and permission of the copyright holder].

The fact that there are conflicting results from several laboratories underscores the importance of developing a reliable and simple noninvasive test, such as a DNA marker, for determining the AHR genotype in large populations. Such screening of human populations would resolve these conflicts in the literature.

The cDNAs for the C57BL/6 (*Ahr*^{b1} allele) and DBA/2 (*Ahr*^{d} allele) mouse have shown that there are five coding polymorphisms between the two alleles (72). Of these, the mouse A375V (and the corresponding human A381V) mutation appears to be one alteration that is critical for *in vitro* ligand affinity and possibly for CYP1A1 inducibility (11, 73–75).

The *Ahr(-/-)* knockout mouse line has been shown to exhibit impaired development of the liver and immune system, splenic atrophy, hyperkeratosis of the skin, and cataracts (76). This mouse line should be very helpful in delineating further the role of the AHR in toxicity and cancer.

10 Ethnic Differences and the “Edge Effect”
Hundreds of clinical trials have revealed not only that the rates of metabolism differ among individuals within the same ethnic group but also that the mean rates of drug metabolism differ significantly between ethnic groups. Fig. 7.12 is a representative example of such a study. In this report, the rate of codeine glucuronidation is shown to be slower in Chinese than in Caucasians.

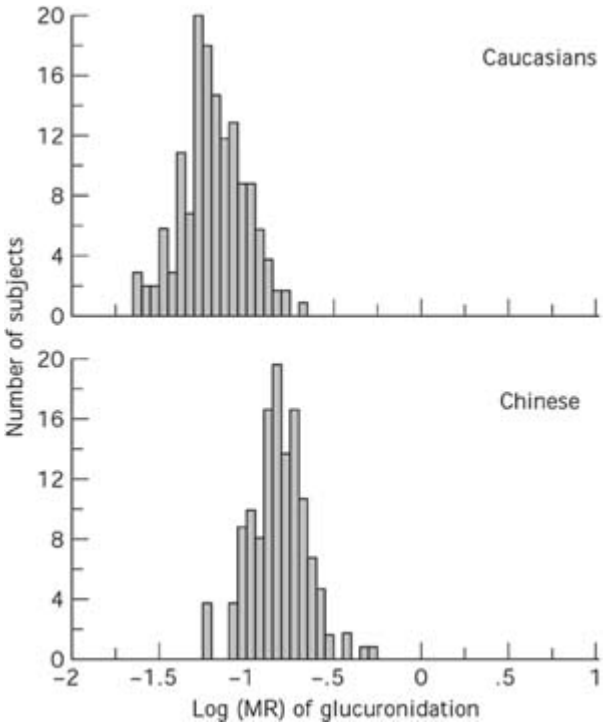

Figure 7.12. Frequency distributions of the $\log_{10}$ MR (metabolic ratio = parent drug divided by metabolite) of codeine glucuronidation. Total number of subjects, $N = 149$ and 133 for Caucasians and Chinese, respectively. Reprinted with permission from Yue et al. 1989 and permission from the copyright holder, Blackwell Scientific Publishers, Ltd., Oxford.

What significance can such ethnic differences have, for populations exposed to the same levels of hazardous waste, or for populations of workers exposed to the same concentrations of occupationally hazardous chemicals? Figure 7.13 illustrates the "edge effect," where the rate of metabolism (or clearance of a chemical) might be associated with a significant proportion of individuals at one end or the other on this graph. Clearly, if the same exposure of a chemical occurs in the workplace, and similar factories having workers of different ethnic groups are located in different parts of the United States or in different countries, the "percentage of workers exhibiting a toxic response" might differ quite dramatically.

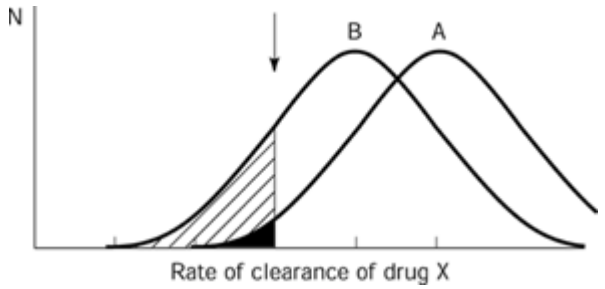

Figure 7.13. The "edge effect" of different averages from hypothetical curves A and B, representing normal frequency distributions for the elimination capacity of chemical X in two populations. The *abscissa* denotes the rate of chemical clearance, and the *ordinate* (N) indicates the number of individuals who show a particular rate of clearance. The *arrow* denotes the critical clearance rate below which the chemical causes toxicity. Curves A and B were drawn with identical standard deviations but their means are one standard deviation apart; i.e., the difference between the means is small compared with the range of variation within each population. In population studies, such small differences are often disregarded. The data imply that about 2% of population A (*solid*) and 16% of population B (*striped*) would suffer toxicity. Obviously, this eightfold difference between the two

ethnic populations would grow substantially if the *arrow* were shifted toward the left. Reprinted with permission from Kalow and Bertilsson (16), and permission of the copyright holder, Academic Press, Ltd., New York.

11 Why these Drug Metabolism Polymorphisms Exist

As mentioned earlier in this chapter, spontaneous mutation rates occur at frequencies between 1 in 10^6 and 1 in 10^8. Any allele that persists in a population at a frequency of <1 in 10^6 is thus regarded by geneticists as "having a reason for existing in that population, even though we might not yet understand the reason." Possible mechanisms for why a particular allelic variant might persist at high frequencies in a population include (*1*) balanced polymorphisms (in which presence of the mutant allele confers some advantage to the heterozygote), (*2*) genetic bottlenecks, and (*3*) founder effects (77). Many of the aforementioned polymorphisms exhibit striking ethnic differences in addition to interindividual differences among humans of the same ethnic group. From current epidemiological data for many of these genes discussed, it is not clear that the heterozygote offers any distinct clinical advantage over either homozygote. However, it is interesting to note that differences in the incidence of one phenotype between ethnic groups can be as large as 100-fold; for example, the incidence of G6PD deficiency is 0.4% versus 53% in Ashkenazic Jews and Sephardic Jews, respectively (24). One explanation for this degree of variability may relate to geographic differences in diet over thousands of years. Figure 7.14 illustrates the estimated rates of divergence for various ethnic groups over many thousands of years. From the periods of time since divergence of different ethnic groups (e.g., 10,000 years, 35,000 years), it is clear that this would be long enough for allelic variants to arise and persist in response to the selective pressures of a particular diet (e.g., tropical fruit versus goat milk and grains).

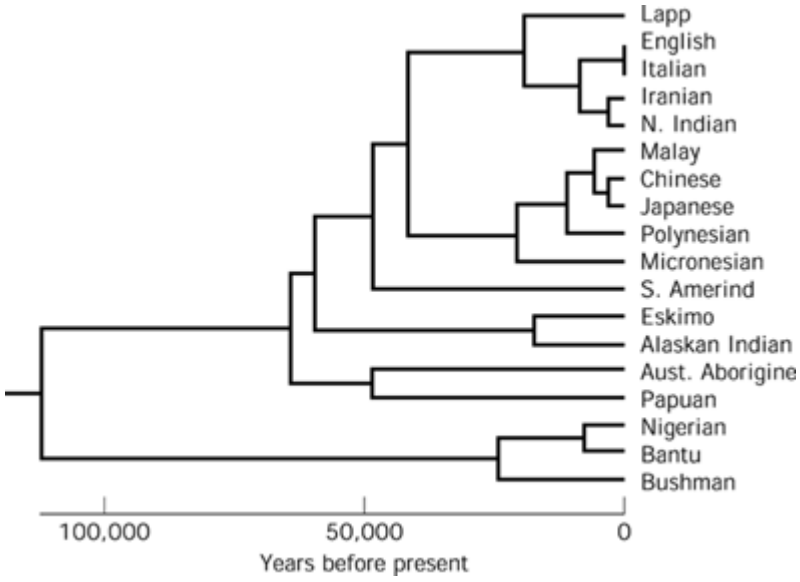

Figure 7.14. Genetic distance between various populations. Modified from Nei and Saitou 1986, and reproduced with permission from the authors and the copyright holder A. R. Liss, Inc.

Another explanation for ecogenetics variability might be the evolution of balanced polymorphisms. The classic example of a compensating, or "shared benefit," polymorphism (Table 7.9) is the sickle cell trait; whereas the homozygous carriers of this trait die (or fail to reproduce) because of severe anemia, the much larger number of heterozygotes resist malaria better than do wild-type homozygotes. It is becoming appreciated (78) that there are several classes of diseases in which the homozygote bears the risks while the heterozygote is believed to hold a distinct survival advantage: (*1*) resistance to bacterial and viral pathogens, (*2*) improved prenatal survival, and (*3*) improved postnatal survival in response to particular environmental stresses. These diseases are summarized in Table 7.9. Considering the ecogenetics polymorphisms described in this chapter, one might postulate that the homozygote bears the risks, whereas the heterozygote holds some distinct survival advantage (s). Considering the discussion at the beginning of this chapter—that DMEs are very old enzymes that are responsible for numerous critical life functions (9, 79)—it is reasonable to assume that at least some of the human DME allelic differences represent balanced polymorphisms that we presently cannot yet appreciate, such as improved rates of implantation, prenatal growth, postnatal development in response to dietary selective pressures, or resistance to bacterial or viral infections. As more DME genes are cloned and their functions uncovered, the reasons for the DME polymorphisms should become more apparent.

Table 7.9. Examples of a Balanced Polymorphism in Which the Heterozygote Appears to Have a "Shared Benefit" over Either Homozygote

Sickle cell anemia = resistance to malaria
G6PD deficiency = resistance to malaria
Congenital adrenal hyperplasia = protection against *Hemophilus influenzae B* infections
Tay–Sachs disease = resistance to tuberculosis
High pepsinogen I (gastric secretion) = resistance to tuberculosis
Idiopathic hemochromatosis = protection against iron loss (menses)
Non-insulin-dependent diabetes mellitus = protection against intermittent/limited food intake
Cystic fibrosis[a] = resistance to cholera toxin and/or bronchial asthma

[a] The cystic fibrosis transmembrane conductance regulator (CFTR) mutant allele might have arisen and been maintained in the population because the heterozygote might exhibit enhanced resistance to cholera and/or asthma, although a founder effect is also suspected of having played a role (discussed in Ref. 78).

DMEs, the DME receptors, and drug transporters have evolved over several hundreds of millions of years for critical life functions (e.g., cell division, sporulation, homeostasis, defense against infection, differentiation, apoptosis and neuroendocrine functions). In animals DMEs more recently expanded to include the role of detoxification of dietary products, evolving plant metabolites and, of course, drugs (8, 9, 79). There is a growing number of developmental disorders caused by "inborn errors of metabolism" that represent defects in a DME gene, which further underscores the fact that DMEs often modulate critical life processes. For example, congenital adrenal hyperplasia (CAH) is caused most commonly by defects in the *CYP21* gene but can also be caused, although rare, by mutations in the *CYP17*, *CYP11B1*, *CYP11B2*, and *CYP11A1* genes (80). Vitamin D–dependent rickets is an autosomal recessive trait caused by a defect in 25-hydroxy-D_3 1a-hydroxylase (*CYP27B1*), a kidney mitochondrial P450 (81). Mutations and deletions in the microsomal fatty aldehyde dehydrogenase (*FALDH*) gene were shown to be the cause of Sjögren–Larsson syndrome—characterized by mental retardation, spasticity, and ichthyosis—indicating the requirement of this enzyme for neurocutaneous homeostasis (82). Mutations in the *CYP1B1* gene are

responsible for primary congenital glaucoma (buphthalmos), implying that failure of the CYP1B1 enzyme to metabolize some endogenous substrate leads to this affliction (83). Progressive familial intrahepatic cholestasis (PFIC) is a heterogeneous group of autosomal recessive disorders leading to cirrhosis and liver failure before adulthood; mutations in the *MDR3* transporter gene are associated with PFIC (84).

12 Conclusions

Many studies have demonstrated the importance of phenotypic polymorphisms in DME genes and DME receptor and drug transporter genes as risk factors in the development of cancer, toxicity, and other diseases associated with chemical exposure. The genetic bases of many of these polymorphisms have been elucidated, and noninvasive genotyping methods that can be applied to large populations have been developed. The study of the relationship between genetic polymorphisms, cancer susceptibility, toxicity, and environmental exposure is a new, exciting and promising area of research. The identification of genetic factors—which, acting in conjunction with the amount of environmental exposure, might increase the interindividual risk of toxicity or cancer—will undoubtedly have important implications for the prevention, early diagnosis, and intervention of human disease.

Regulations and Guidelines In the Workplace

Eula Bingham, Ph.D., L. Faye Grimsley, MSPH, CIH

1.0 Introduction and History

Occupational diseases can be used as the first historical markers for concern about toxic substances in the workplace. The passage in 1798 of the Act for the Relief of Sick and Disabled Seamen established The Marine Hospital Service, which was later named the Public Health Service. This was the first real legislation that dealt with occupational disease. Most of the seamen who benefited in the early years probably had traumatic injuries or infectious diseases, but it is certain that some suffered from chronic exposures. In 1835, McCready described the role of trades, professions, and occupations in the development of disease and noted several toxic substances of importance (1), lead and dusts. In 1860, Freeman described problems with mercury among hatters. Actual legislation to regulate the workplace was slow to develop and was confined to conditions that affected children, for example, hours worked and ages when children could begin work (1a).

Research and technology provide the rationale and the methodologies used to develop legislation, regulations, and guidelines that reduced workplace hazards. However, the main factors bringing about the passage of laws and/or regulations are likely to be social. These have included catastrophes, such as mine explosions, asbestos disease, epidemics, and the Gauley bridge episode, political movements such as the environmental and civil rights movements, and organizations capable of pressing for legislation, such as labor organizations, community groups, and trade associations.

In the early part of this century, regulations and guidelines to control toxic substances in workplaces emerged out of social forces such as those introduced by labor unions and social reformers, one of whom was Alice Hamilton. She was instrumental in putting workplace health and safety on the agenda for U.S. federal activities during the early 1900s. Federal efforts were located in the Office of Industrial Hygiene and Sanitation of the U.S. Public Health Service.

States were at the forefront of early efforts on worker health. Anna Baetjer (1b) reported that a commission on Hygiene of Occupations and Railroads was established under the Health Department of Ohio in 1886. Early efforts to investigate and make recommendations to eliminate and/or prevent occupational disease were instigated by New York and Ohio in 1913, followed by Connecticut in 1928. In 1905, the Massachusetts Health Department had investigators of dangerous occupations. Later, this early program was placed in the Massachusetts Department of Labor (2).

It is of interest to note that the first academic programs to support these efforts were instituted before 1920. For example, C.E.A. Winslow gave a course in industrial hygiene in the Department of Biology and Public Health at MIT in 1905, followed by the University of Pennsylvania where there was a doctorate in public health in 1906 that emphasized industrial hygiene. In 1919, the University of Cincinnati established a one-year Certificate of Public Health in Industrial Hygiene (3).

An example of the roles various organizations had in the United States in establishing exposure levels can be found in the preamble to the benzene standard (4). A committee of the National Safety Council on Benzol chaired by C.E.A. Winslow reported that, even at 10 ppm or less, one in three workers were affected. The Committee notes the importance of substituting another solvent where possible (5). In the 1940s as a result of a death in the range of 40–80 ppm, Massachusetts lowered its permissible limit to 35 ppm. The American Conference of Governmental Industrial Hygienists (ACGIH) recommended a threshold limit value (TLV) of 100 in 1946, 50 in 1947, and 35 in 1948. In 1963, a TLV of 25 was recommended (6). Another private organization, the American National Standards Institute (ANSI), recommended a limit of 10 ppm. This value became the first PEL for benzene adopted in 1971 in the rulemaking 6(a).

In 1936, the Industrial Hygiene Committee of the State and Provincial Health Authorities of North America published a list of the duties and qualifications for physicians and engineers in industrial hygiene, that are similar to those recommended today. In addition to the professional requirements, this list included certain desirable personality characteristics: "*ability to establish contact with plant executives, foremen, and laborers; initiative; tact; good judgement, and address*" (1).

Among governmental bodies, the development of guidelines and regulations covering toxic substances was varied. Certain states developed both exposure limits and practices for reducing exposures, for example, New York, Massachusetts, and Pennsylvania, whereas others had few regulations. Most of these guidelines or regulations were in the Labor or Health Department codes. The U.S. Department of Labor first issued guidance for toxic substances encountered in the workplace through the Bureau of Labor Standards. In a review of the requirements that the state governments had for workplace safety and health, there is a compilation of the various provisions, responsible agencies, and selected subjects such as mines, workmen's compensation, reporting requirements, women and minors, and vocational rehabilitation. The sources used are provided. The requirements range greatly. Examples of several states are given in Table 8.1. It should be noted that even among the states that have one of the most extensive sets of requirements, Pennsylvania, a

comprehensive standard to protect coke oven workers did not result until after the federal Occupational Health and Safety Act was passed in 1970. One can speculate that the comprehensive nature of this federal standard as well as the federal inspection to enforce its provisions brought about safer working conditions (7).

Table 8.1. Selected Requirements in Three States Prior to OSHAct[a]

			Reporting of Occupational		Medical Surveillance		
State	**OEL[b]**	**Inspections**	**Injuries**	**Diseases**	**Lead**	**Solvents**	**Silica**
Texas	Limited	Yes	Yes	No	No	No	No
Pennsylvania	Limited	Yes	Yes	Yes	Yes	Yes	Yes
South Carolina	Limited	Yes	Yes	Yes	No	No	No

[a] From Ref. 7.
[b] OEL—Occupational Exposure Limits.

From these early beginnings, guidelines to prevent illness from toxic substances were developed as part of recommendations issued by various private organizations, the National Safety Council, and the American National Standards Institute (ANSI) in the 1920s and 1930s, and the ACGIH (TLV's) in 1941.

Other organizations provided guidelines for various toxic substances that would provide protection for workers. For example, the American Petroleum Institute published a series of pamphlets on toxic substances (8).

Among the governmental bodies in the United States, the development of guidelines and regulations for toxic substances evolved over the first half of the twentieth century by a fragmented process. Certain states developed both exposure limits and practices for reducing exposures. In the United States, two major sources of numerical limits for various chemical and physical agents were set by ANSI, which is made up of professionals mainly from industry, government, and sometimes academia. ACGIH membership consisted of professionals employed in government (federal, state, or local) and academia, but input was routinely sought from industry specialists.

The TLV Committee of the ACGIH, established in 1941, was composed of six nationally recognized industrial hygienists and toxicologists not associated with private industry. The first list comprising 144 substances with their Maximal Allowable Concentrations (MAC) was promulgated in 1946 as recommendations to industry. In 1943, the Division of Industrial Hygiene of the U.S. Public Health Service published a prior list of 45 substances. Before 1955, no formal documentation of these values was issued. The early documentation was for Committee use only as an aid in revising limits at some future time. Documentation published by the Committee appeared in 1962 and comprised 267 substances. A second revised edition appeared in 1966 and included almost 400 substances. Now, supplements appear annually as new substances are added or as revisions are made in the list (9).

The criteria and procedures of the ACGIH TLV Committee are governed by the following philosophy:

Threshold Limits for industrial settings are based on the premise that, although all chemical substances are toxic at some concentration experienced for a period of time, a concentration exists for all substances from which no injurious effect will result no matter how often the exposure is repeated (9).

However, the ACGIH recognizes this as a desirable goal but has adopted the following philosophy: Threshold Limit Values (TLVs) are airborne concentrations of substances to which it is believed that nearly all workers may be repeatedly exposed day after day without adverse health effects. Because of wide variation in individual susceptibility, a small percentage of workers may experience discomfort from some substances at concentrations at or below the threshold limit; a smaller percentage may be affected more seriously by aggravation of a preexisting condition or by development of an occupational illness. Individuals may also be hypersusceptible or otherwise unusually responsive to some industrial chemicals because of genetic factors, age, lifestyle, medication, or previous exposures. Such workers may not be adequately protected from adverse health effects from certain chemicals at concentrations at or below the threshold limits (10, 11).

TLVs were prepared only for the use of industrial hygienists, who could exercise their own judgment in applying these values. They were not to be used for legal purposes (1).

Several approaches for deriving occupational exposure limits (OELs) from animal data have been proposed and put into use during the past 40 years. Approximately 50% of the 1968 TLVs were derived from human data, and approximately 30% were derived from animal data. By 1992, almost 50% were derived primarily from animal data. Of those TLVs based on human data, most are derived from effects observed in workers who were exposed to the substance for many years. Consequently, most of the existing TLVs were based on the results of workplace monitoring, compiled with qualitative and quantitative observations of the human response (9). In recent times, TLVs for new chemicals have been based primarily on the results of animal studies, rather than human experience (12).

It is noteworthy that in 1968 only about 50% of the TLVs were intended primarily to prevent systemic toxic effects. Roughly 40% were based on irritation, and about 2% were intended to prevent cancer. By 1993, about 50% were meant to prevent systemic effects, 35% to prevent irritation, and 5% to prevent cancer (13).

TLVs are based on the best available information from industrial experience and human and animal experimental studies—when possible, from a combination of these sources (11, 14). The rationale for choosing limiting values differs from substance to substance. For example, protection against impairment of health may be a guiding factor for some, whereas reasonable freedom from irritation, narcosis, nuisance, or other forms of stress may be the basis for others. The age and completeness of the information available vary, consequently, the precision of each TLV is different. The most recent TLV and its documentation should always be consulted to evaluate the quality of the data upon which that value was set.

The issue of threshold effects is controversial, and scientists argue for and against threshold theories. Beginning in 1988, concerns were raised by numerous persons regarding the adequacy or health protectiveness of TLVs. The key question raised was, do the TLVs protect enough workers (15)?

Ziem and Castleman argued both that the scientific basis of the standards was inadequate and that they were formulated by hygienists who had vested interests in the industries being regulated (16).

A follow-up study by Roach and Rappaport (17) attempted to quantify the safety margin and

scientific validity of TLVs. They concluded that there were serious inconsistencies between the scientific data available and the interpretation given in the 1976 Documentation by the TLV Committee. They also noted that the TLVs were probably reflective of what the Committee perceived to be realistic and attainable at the time (17). This approach has been criticized, but it reflects the OSHAct where feasibility is critical criterion.

The TLV procedures and documentation continue to be debatable. It is clear that the process by which the TLVs and other OELs will be set will probably never be as it was between 1945 and 1990. It is likely that in the coming years, the rationale, as well as the degree or risk inherent in a TLV, will be more explicitly described in the documentation for each TLV. It is also certain that the definition of “virtually safe” or “insignificant risk” with respect to workplace exposure will change as the values of society change (18).

OELs have also been set by OSHA and NIOSH. Under the OSHAct, exposure limits are set via specific procedures. Criteria documents and literature reviews published by NIOSH serve as a basis for Recommended Exposure Limits (RELs). These RELs provide a scientific basis for OSHA to use in preparing a proposal (19), however, it should be noted that the constraints in the OSHAct require considering technical and economic feasibility, so that the permissible exposure limits (PELs) that OSHA sets are usually greater than the RELs that are based only on health considerations.

After a court decision that required OSHA to demonstrate the effect of a new standard, the number of adverse health effects reduced by lowering the PEL, OSHA has conducted quantitative risk assessments for the substance proposed for regulation showing the impact on illness, injury, or deaths at the old versus the proposed new PEL.

OSHA enforces approximately 400 PELs. These limits were adopted in 1970 under the Occupational Safety and Health Act and came from the 1968 list of the ACGIH TLVs and the standards of the American National Standards Institute (ANSI). An attempt was made in 1989 to adopt 428 chemicals from the 1989 TLV list as legally binding PELs, but legal challenges by various groups ultimately resulted in overturning these newly adopted values in 1992. The courts found that OSHA's approach was not consistent with the requirements set forth in Section 6(b) of the Act (20). The standards should be based on research, demonstrations, and experiments.

Regulations and Guidelines In the Workplace
Eula Bingham, Ph.D., L. Faye Grimsley, MSPH, CIH

2.0 Legislation, Standards and Guidelines in United States for Health and Safety in the Workplace
Standards, regulations, and guidelines are major tools for protecting workers and consumers from chemical and physical hazards in the workplace and the environment. In the United States as in other countries, there are specific procedures for developing standards, regulations, and guidelines for the workplace. In many countries, the governments pass the legal framework or laws that provide the basis for standards/regulations, guidelines, and exposure limits. The U.S. Congress passes laws that govern workplaces in the United States. To put those laws into effect, Congress authorizes certain governmental agencies such as the Department of Labor's Occupational Safety and Health Administration (OSHA) and Mine Safety and Health Administration (MSHA), the Environmental Protection Agency (EPA), and the Department of Transportation (DOT) to create and enforce rules.

Because laws often do not include all the details, regulations or standards are promulgated to describe specific rules for the legal requirements. Once the regulation is in effect, agencies then educate affected entities, such as employers and employees, as to how to comply. In some instances, guidelines are issued by governments and are not considered legally enforceable. Guidelines are sometimes developed by trade organizations to provide advice to members. The enforcement of the

legal requirements is usually delegated to a part of the agency separate from regulations or standards writing.

A process is followed to create regulations. First, an authorized agency such as OSHA decides that a regulation may be needed. The agency gathers information and provides an Advance Notice of Intended Rulemaking to the Federal Register. This notice provides an opportunity for interested persons to comment on the need for a standard. The need for new regulations may be based on new law, court order, public petition, or agency initiative. The proposal is published in the Federal Register, so that members of the public can consider it and send their comments to the agency. The agency receives all the comments, revises the regulation as appropriate, and issues a final rule. At each stage in the process, the Federal Register notices are available from the agency and are posted on the Internet. The specific processes to promulgate standards by OSHA are set out in section 6b and 3(8) of the OSHAct (4, 21).

The steps vary to some extent from those for regulations in that specific comment times are required as well as public hearings, if requested and a regulation follows. When a standard is completed, it is printed in the Federal Register as a final rule that includes the rationale, and the scientific and technical basis for the rule. The final rule without the supporting rationale is "codified" by being published in the Code of Federal Regulations (CFR). The CFR is the official record of all regulations created by the U.S. federal government. It is divided into 50 volumes, called titles, each of which focuses on a particular area. Almost all environmental and workplace regulations appear in Titles 40 and 29, respectively. The CFR is revised yearly, and one-fourth of the volumes is updated every three months.

The way research, technology, social and political movements interact determines the combination of laws, regulations, and guidelines that control toxic substances in the workplace. Standards are set as a measurable reference point consisting of specific guidelines by which the desired objective can be quantified and achieved (15). Regulations and guidelines for toxic substances in the workplace have been developed primarily to address injury and illness prevention, communicate hazards via training, and control hazards.

With passage of the Occupational Safety and Health Act in 1970 (OSHAct), workplace regulations and guidelines to control toxic substances were transformed and OSHA was established. Under the OSHAct, OSHA is authorized to issue and enforce regulations and standards that protect employees who work in businesses engaged in interstate commerce. Under Sections 6(a), 6(b) and 3(8) (4, 21), the process and criteria for promulgating standards for toxic substances in the workplace are provided. The federal or state governments (acting under special provisions provided in the OSHAct) can enforce final standards in the workplace. OSHA also has the authority to enforce an employer's obligation to protect employees from recognized hazards that are causing or likely to cause death or serious physical harm, even in the absence of a specific standard. This obligation is called the "general duty clause" (section 5(a) of the OSHAct), states:

"Each employer (1) shall furnish to each employee a place of employment which is free from recognized hazards that are causing or likely to cause death or serious physical harm to his employees; (2) shall comply with occupational safety and health standards promulgated under this Act" (21).

When the OSHAct was passed, it required the first standards to be national consensus standards or established federal standards as outlined in Section 6(a). Section 6(b) and 3(8) of the Act outline the criteria and guidelines for setting OSHA standards.

2.1 Types of Standards

Occupational health and safety standards have been set to cover four primary industry sectors that include General Industry which is found in 29 CFR 1910, Construction 29 CFR 1926, Maritime 29 CFR portions of 1915–1919, and Agriculture 29 CFR 1928. OSHA has three categories of standards

defined as follows:

(A) Standard means a standard which requires conditions, or the adoption or use of one or more practices, means, methods, operations, or processes, reasonably necessary or appropriate to provide a safe or healthful employment and places of employment; (B) National Consensus standard means any standard or modification thereof which (1) has been adopted and promulgated by a nationally recognized standards-producing organization under procedures whereby it can be determined by the Secretary of Labor or by the Assistant Secretary of Labor that persons interested and affected by the scope or provisions of the standard have reached substantial agreement on its adoption, (2) was formulated in a manner which afforded an opportunity for diverse views to be considered, and (3) has been designated as such a standard by the Secretary or the Assistant Secretary, after consultation with other appropriate Federal agencies; and (C) Established Federal Standard means any operative standard established by any agency of the United States and in effect on April 28, 1971, or contained in any act of Congress in force on the date of enactment of the Williams–Steiger Occupational Safety and Health Act (22).

In addition, a further breakdown of Consensus Standard was established to assist in implementing regulations, and they are defined as follows:

Specification standard is defined as a standard that sets detailed requirements for protecting employees from a workplace hazard. Vertical Standard is defined as an OSHA standard pertaining to a specific industry, such as construction or maritime trades. Performance Standard is defined as a standard that sets general requirements for protecting employees from a workplace hazard, allowing employers to choose their own means for complying with the regulation (23).

2.2 Other U.S. Agencies that Establish Workplace Regulation of Toxic Substances

Within the United States, some of the most common guidelines and regulations are established by the EPA and OSHA. The major U.S. federal agencies that have standards, regulations, or guidelines dealing with toxic substances are presented in Table 8.2. These laws regulate some aspect of toxic substances in the workplace. The OSHAct remains the most extensive piece of safety and health legislation in the United States and regulates conditions in six million private business establishments (23). However, other legislation and authorities have a major role in controlling chemical and physical exposures in the workplace.

Table 8.2. Federal Laws and Agencies Affecting Toxic Substance Control[a]

Statute	Year Enacted	Responsible Agency
Toxic Substance Control Act	1976	EPA
Clean Air Act	1970; amended 1977 & 1990	EPA
Federal Water Pollution Control Act (now Clean Water Act)	1972; amended 1977	EPA
Safe Drinking Water Act	1974; amended 1977	EPA
Federal Insecticide, Fungicide, and Rodenticide Act	1947; amended 1972, 1975, 1978	

Act of July 22, 1954 (codified as Section 346 (a) of the Food, Drug, and Cosmetic Act)	1954; amended 1972	EPA
Resource Conservation and Recovery Act	1976	EPA
Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA)	1980; amended as SARA 1986	EPA
Marine Protection Research and Sanctuaries Act	1972	EPA
Asbestos Hazard Emergency Response Act (AHERA)	1986	EPA
Food, Drug, and Cosmetic Act	1938; amended 1997	FDA
Food additives amendment	1958	FDA
Color additives amendment	1960	FDA
New drug amendments	1962	FDA
New animal drug amendments	1968	FDA
Medical device amendments	1976	FDA
Fair Packaging and Labeling Act	1976	FDA
Public Health Service Act	1944; amended 1997	FDA
Federal Meat Inspection Act	1967; amended 1997	USDA
Poultry Products Inspection Act	1957; amended 1997	USDA
Egg Products Inspection Act	1970	USDA
Poison Prevention Packaging Act	1970	CPSC
Lead Based Paint Poisoning Prevention Act	1973; amended 1976	CPSC, HHS, HUD
Hazardous Materials Transportation Act	1975; amended 1976	DOT—Materials Transportation Bureau
Federal Railroad Safety Act	1970	DOT—Federal Railroad Administration
Ports and Waterways Safety Act	1972	DOT and Coast Guard
Dangerous Cargo Act	1952	
Occupational Safety and Health Act	1970	OSHA, NIOSH
Federal Mine Safety and Health Act	1977	Labor (Mine Safety and Health Administration) and NIOSH

[a] CPSC = Consumer Products Safety Commission
DOT = Department of Transportation
EPA = Environmental Protection Agency
FDA = Food & Drug Administration
HHS = Health and Human Services
HUD = Housing & Urban Development
NIOSH = National Institute for Occupational Safety & Health

OSHA = Occupational Safety & Health Administration
USDA = United States Department of Agriculture
SARA = Superfund Amendments and Reauthorization Act

You will find some of the other legislation and regulatory agencies that have promulgated standards in the United States to address employee health and safety in Table 8.3. When the OSHAct was passed, the recognition of other agencies came in the form of a special provision in section 4(b) (1), which states "Nothing in this Act shall apply to working conditions of employees with respect to which other Federal agencies, and State agencies acting under section 274 of the Atomic Energy Act of 1954, as amended (42 U.S.C. 2021), exercise statutory authority to prescribe or enforce standards or regulations affecting occupational safety or health" (21).

Table 8.3. Regulations To Protect Workers from Toxic Agents in the U.S. Workplace[a]

Statute	Responsible Agency	Part/Section	Requirements[b]
Toxic Substance Control Act (TSCA)	EPA	TSCA Sections 8 (c, d, & e)	Premarketing testing and reporting of chemicals; and Reporting of substantial risks
Federal Insecticide, Fungicide, and Rodenticide Act	EPA	40 *CFR*, Part 170	Testing may deny registration, warnings, re-entry limits
Resource Conservation and Recovery Act	EPA	40 *CFR*, Part 263	Training
Asbestos Hazard Emergency Response Act (AHERA)	EPA	40 *CFR*, Part 763	Training
Hazardous Materials Transportation Act	DOT	49 *CFR*, Parts 171-180	Training and labeling
Occupational Safety and Health Act	OSHA	29 *CFR*, Part 1910 29 *CFR*, Part 1915 29 *CFR*, Part 1917 29 *CFR*, Part 1918 29 *CFR*, Part 1926	Promulgates health and safety regulations and enforces training requirements
Federal Mine Safety and Health Act	MSHA	30 *CFR* Parts 1-199	Promulgates health and safety regulations and enforces training requirements

[a] EPA = Environmental Protection Agency
DOT = Department of Transportation
OSHA = Occupational Safety & Health Administration
MSHA = Mine Safety and Health Administration
CFR = Code of Federal Regulations

[b] Refer to appropriate statutes and regulations for specific requirements.

2.2.1 Mine Safety and Health Administration (MSHA) Health and safety conditions in the mining industry are regulated by the Federal Mine Safety and Health Act of 1977 (MSHAct). This law, whose enactment was prompted by a number of mine disasters in the 1970s, amended the Federal Coal Mine Health and Safety Act of 1969 and repealed the Metal and Nonmetallic Mine Act of 1966, bringing many types of mines that previously had been covered by a variety of earlier laws under one system of regulation.

MSHA was created to set and enforce standards and established an independent Federal Mine Safety and Health Review Commission to hear challenges to MSHA citations. MSHA has jurisdiction over work activities in mines, and also over work activities on the roads leading to and from mines; on the roads belonging to the mine property; over the lands, structures, equipment, and property used in connection with mines; including milling operations; and over the work of preparing coal or other mined minerals, including custom coal preparation facilities. The MSHAct requires MSHA to inspect every underground mine at least four times a year and every surface mine at least twice per year.

The MSHAct procedures for setting standards are similar to those set by the OSHAct for OSHA. MSHA must publish a proposed standard in the Federal Register for comment and give interested parties the opportunity to request a hearing.

MSHA may issue emergency temporary standards when it determines that miners are “exposed to grave danger from exposure to substances or agents determined to be toxic or physically harmful, or to other hazards,” and that emergency action is needed to protect the miners. However, the agency must begin permanent rulemaking to address the hazard as soon as it publishes the emergency rule and must issue a permanent standard no more than nine months later. MSHA may modify the application of a permanent standard when petitioned to do so by a mine operator or a representative of the miners employed at the time, by a process that is similar to OSHA's process for variances from OSHA standards.

An interagency agreement signed between OSHA and MSHA on March 29, 1979, clarifies the jurisdictional authorities of the two agencies. As a general rule, the agreement specifies that MSHA will exercise its authority on mine sites and in milling operations. However, where the provisions of the mine act do not cover or otherwise do not apply to job-related hazards at these sites, or where MSHA has statutory jurisdiction but no MSHA standards exist that are applicable to particular working conditions, the OSHAct will apply.

OSHA may also exercise its authority over an employer who has control over working conditions at a mining or milling site, if that employer is neither a mine operator nor an independent contractor subject to the mine act, if application of the OSHAct to this type of employer would provide a more effective remedy than citing a mine operator or independent contractor that does not have direct control over those conditions (24).

MSHA has broad authority to develop, promulgate, and enforce mandatory health and safety standards to protect the health and safety of the nation's miners. MSHA's authority to regulate in the area of radiation is derived from its statutory mandate to protect and promote occupational safety and health in the mining and milling of minerals, including those that expose the miner to radioactivity. In addition, MSHA may exercise jurisdiction over any equipment used in mining that potentially exposes miners to radioactivity. MSHA had codified regulations dealing specifically with radiation in Title 30, subchapter N, Part 57, of the Code of Federal Regulations (24a).

The Powerplant and Industrial Fuel Use Act of 1978 substantiates MSHA's authority to protect

existing and future housing, property, persons, and public facilities located adjacent to or near active and abandoned coal, uranium, metal, and nonmetallic mines against mining hazards (24).

2.2.2 Department of Health and Human Services (HHS) Food and Drug Administration (FDA) Under the Radiation Control for Health and Safety Act of 1968, FDA is authorized to promulgate and enforce performance standards for controling radiative emissions by electronic products. FDA's regulations promulgating these standards are set forth in Title 21, Subchapter J, of the Code of Federal Regulations (24a). Although not specific for workers, provisions to protect consumers can also protect workers in some industries such as drug manufacturing and food production (24b).

National Institute for Occupational Safety and Health The National Institute for Occupational Safety and Health (NIOSH) has primary responsibility for certifying and approving respirators. After enactment of the OSHAct, NIOSH and the U.S. Bureau of Mines (USBM) promulgated 30 CFR, Part 11, which outlined the procedures for respirator approval. After reorganization of the USBM, function for respirator certification and approval were eventually transferred to the MSHA in 1977, and respirators were jointly approved by NIOSH and MSHA (25).

In 1995, a final rule (42 CFR part 84) was issued that addressed NIOSH and MSHA's certification requirements for respiratory protective devices. The provisions of this rule now give NIOSH exclusive authority for testing and certifying respirators. Certain mine emergency devices will continue to be jointly certified by NIOSH and MSHA (26).

2.2.3 Department of Transportation (DOT) The Federal Hazardous Materials Transportation Law (Federal Hazmat Law), formerly the Hazardous Materials Transportation Act, is the basic statute that regulates hazardous materials transportation in the United States. Under this law, DOT has broad authority to issue and enforce regulations for the safe transportation of hazardous materials, including radioactive materials, on the nation's highways. In addition, the Hazmat Law specifically directed DOT to issue regulations regarding the transportation of radioactive materials on passenger-carrying aircraft, railways, and waterways (27).

Pertinent regulations are codified in Title 49 of the Code of Federal Regulations. The Hazardous Materials Regulations (HMR; 49 CFR Parts 171–180) cover five areas and include hazardous materials definition/classification, hazard communication, packaging requirements, operational rules, and training. Those relating specifically to radioactive materials cover labeling, shipping, rail transportation, air transportation, carriage by vessel, and highway transportation (28).

2.2.4 Environmental Protection Agency (EPA) Several statutes administered by the EPA provide basic authorization for it to regulate worker health and safety directly, for example, the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA), which promulgates reentry limits for pesticide application in fields thus protecting farm workers. FIFRA also requires labeling and protections from low-level ionizing radiation. Other EPA statutes provide for indirect regulation that can impact worker health. The Clean Air Act regulates the emissions of pollutants, including radioactive materials, into the air. The Clean Water Act regulates the discharges of pollutants into waterways and sewage systems, including radioactive materials, except for those (source material, special material, and by-product material) regulated under the Atomic Energy Act. The Safe Drinking Water Act protects against contaminants, including radioactive materials, in public water systems, and underground injection which may contaminate public water systems. The Resource Conservation and Recovery Act (RCRA; Solid Waste Disposal Act, as amended) covers the disposal of hazardous wastes, and which requires worker training. The Toxic Substances Control Act (TSCA) regulates manufacturing, distribution, processing, use, and disposal of toxic substances, including radioactive materials, except for those regulated under the Atomic Energy Act, and the Marine Protection, Research, and Sanctuaries Act of 1972 regulates ocean dumping of all materials, including all radioactive materials. Several provisions of TSCA impact workers' health such as Section 8 c, d, and e. These sections require pre-market toxicity testing, reporting of chemicals, and reporting of

substantial risk.

In addition, under the Atomic Energy Act as amended by the Uranium Mill Tailings Radiation Control Act of 1978, EPA has authority to set standards for disposal of uranium mill tailings at active and inactive sites. Under Reorganization Plan No. 3 of 1970, EPA is further authorized to establish generally applicable environmental standards for protecting the general environment from radioactive material. These standards are promulgated by EPA but implemented by the Nuclear Regulatory Commission (NRC) and the Department of Energy (DOE). The standards are published in Title 40, Subchapter F, of the Code of Federal Regulations.

Also under Reorganization Plan No. 3, EPA is responsible for advising the President generally with respect to radiation matters that directly or indirectly affect health, including guidance for all Federal agencies in formulating radioactive standards and in establishing and executing cooperative programs with the states (29).

2.2.5 Nuclear Regulatory Commission (NRC) The NRC's authority to regulate radiative exposure, particularly in workers in DOE operations (under private corporations contracted to DOE), is derived principally from the regulatory authority of the Atomic Energy Commission (AEC). All licensing and related regulatory functions of the AEC were transferred to the NRC by the Energy Regulation Act of 1974, which created the NRC. Under this legislation, the NRC has broad authority to license and regulate the use and distribution of special nuclear material, source material, and by-product material and to establish minimum criteria for the issuance of licenses. In addition, the NRC has broad authority to regulate licenses. These authorities have been implemented by the NRC through regulations set forth in Title 10 of the Code of Federal Regulations, Parts 20, 30–35, 40, 50, 51, 70, and 71.

Title II of the Uranium Mill Tailings Radiation Control Act of 1978 extended NRC's licensing authority over by-product material to include uranium and thorium mill tailings. The act also subjects this class of by-product material to more extensive regulatory requirements than provided for other by-product material and authorizes the NRC to take appropriate measures to protect public health and safety and the environment from radiological hazards associated with such material.

In view of the overlap between the responsibilities of NRC and other agencies, NRC has entered into various Memoranda of Understanding with the DOT, the EPA, the Coast Guard, the Army Corps of Engineers, the Council on Environmental Quality, the Air Force, DOE, FDA, NOAA, and the FAA (30).

2.2.6 Coast Guard/Maritime Under U.S. maritime law, the U.S. Coast Guard (USCG) has authority over safety on tank and passenger vessels. Among Coast Guard standards pertaining to the safety of maritime employees are those regulating lifesaving equipment on tank vessels, fire-fighting equipment on tank vessels, lifesaving equipment on passenger vessels, and special construction arrangements and other provisions for carrying anhydrous ammonia, combustible liquids, and other dangerous cargoes in bulk (31).

In a memorandum of understanding (32), OSHA and the Coast Guard have agreed that OSHA retains its authority under the OSHAct to respond to complaints by seamen aboard Coast Guard-inspected vessels regarding alleged discrimination for safety-related activity. OSHA also has the authority to order vessel owners to post notices informing employees of their right to complain about working conditions to the Coast Guard, OSHA, or to the employer, and to be free from retaliatory discrimination.

The Outer Continental Shelf Lands Act gives the Coast Guard and the Department of the Interior's Minerals Management Services (MMS) the authority to set and enforce standards to regulate hazardous working conditions on the outer continental shelf.

Standards set by MMS pertain to safety in drilling operations by offshore rigs, well completion, and well workover; production safety systems; platforms and structures, including inspection and maintenance; and employee training (30).

The Coast Guard's regulations pertain to mobile offshore units—vessels engaged in drilling operations—rather than stationary rigs. They include rules for inspection and certification of vessels, including testing of firefighting equipment and lifeboats, design and equipment, including location of firefighting equipment and lifeboats, and operations, including practice drills and stowage of safety equipment.

There is also an agreement, Memorandum of Understanding (MOU), between OSHA and the Coast Guard regarding enforcement of standards covering working conditions for which the Coast Guard has no specific standards of its own. The Coast Guard notifies OSHA whenever a Coast Guard inspection finds apparent violations of OSHA rules and cooperates with any subsequent enforcement activity that OSHA undertakes.

Under the Federal Water Pollution Act, the Coast Guard has been delegated the authority to respond to discharges of oil into U.S. waters. Under the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA), the Coast Guard has been delegated the authority, as the designated On-Scene Coordinator, to respond to the release of hazardous substances into the environment within the U.S. coastal zone.

Coast Guard employees, other government employees, and contract personnel involved in oil spill response activities must comply with all applicable worker health and safety laws and regulations. The primary regulation is OSHA's hazardous waste operations and emergency response (29 CFR 1910.120). Other regulations may be applicable if employees are involved in cleanup operations at uncontrolled hazardous waste sites being cleaned up under government mandate and in certain hazardous waste treatment, storage, and disposal operations conducted under the Resource Conservation and Recovery Act of 1976 (RCRA). The regulations apply to both emergency response and post-emergency cleanup of hazardous substance spills. Most oils and oil spill responses are also covered in 49 CFR Part 172. The rules cover employee protection during initial site characterization and analysis, monitoring activities, materials handling activities, training, and emergency response (29, 31).

Regulations and Guidelines In the Workplace

3.0 Governmental Regulation of Toxic Chemicals in Workplaces
3.1 Rationale for Workplace Exposure Limits
Occupational health professionals are faced with the challenge of evaluating and controlling exposures to the thousands of chemicals used in the workplace. There are only a few hundred occupational exposure limits worldwide to provide guidance with regard to safe levels.

The rationale for setting occupational limits varies, depending upon the chemical and the country or specific organization that establishes the exposure limits. Some exposure limits are set to avoid nuisances such as odor, whereas another may be to prevent irritation or chronic diseases such as cancer. Overall, the goal of most occupational exposure limits is to protect workers during their entire working lifetime, which is approximately 40 years. Approximately 23 countries and organizations have established and published occupational exposure limits using various criteria (33). Some of the most common are presented in Table 8.4. In the United States, OSHA, ACGIH, NIOSH, and AIHA have set forth occupational exposure limits. The German Commission for the Investigation of Health Hazards of Chemical Compounds in the Work Area is responsible for

developing the Maximum Allowable Concentrations (MAKs).

Table 8.4. Selected Countries/Organizations That Have Occupational Exposure Limits[a]

Country	Enforcement (Monitored and Enforced)	Type of Standard Set[b]

USA-OSHA	Y	Y	Y	Y	Y

[a] Table 4 abridged from Ref. 31a.

[b] TWA = Time Weighted Averages
STEL = Short-term Exposure Limits
BEI = Biological Exposure Indices

Exposure limits for most workplace air contaminants are based on the premise that although all chemical substances are toxic at some concentration when experienced for a period of time, a concentration (e.g., dose) does exist for all substances at which no injurious effects should result, no matter how often the exposure is repeated (9, 11). Thinking differs throughout the world with regard to the amount of chemical exposure that constitutes a safe level. For example, one country might think that the optimal value and goal to be sought is zero concentration. Table 8.5 lists the numerical occupational exposure limits for many chemicals throughout the world. For this reason, the criteria and procedures for setting limits differ (9). Zero exposure is the goal that should be set forth, but it is not generally the reality in the workplace.

[e] Formulae: (10 mg/m^3) ÷ (% SiO_2 + 2)

Occupational exposure limits established both in the United States and elsewhere are derived from a variety of sources and based on different methodologies. The majority were developed from human experience and animal data. Because the process of carrying out the scientific work to obtain the necessary experimental, clinical, and epidemiological data is complex, only a few countries have been able to set validated exposure limits for any substantial number of industrial chemicals.

Some countries have also developed guidelines for biological monitoring in addition to exposure limits for inhalation of chemicals. According to the ACGIH, biological monitoring consists of assessing overall exposure to chemicals that are present in the workplace by measuring the appropriate determinants in biological specimens collected from the worker at the specified time. The ACGIH has developed Biological Exposure Indices (BEIs) as reference values intended as guidelines for evaluating potential health hazards. Other countries, including the United Kingdom and Germany, have also developed biological exposure limits (see Table 8.4).

Enforcement of occupational exposure limits varies greatly from country to country. Some countries use them as guidelines to assist in compliance with the law. Others believe that the occupational exposure limits have legal force and are enforced by regulatory agencies. In the United States, the OSHA permissible exposure limits are the most common airborne exposure limits enforced. Table 8.4 lists selected countries and their enforcement practices for their exposure limits. However, such limits set forth by the ACGIH and other organizations are also used as guidelines in the workplace, and some companies report that they abide by the lowest values.

3.2 Exposure Limit Definitions and Special Notations

Occupational exposure limits have been set for airborne contaminants by many countries and organizations. Some have also established exposure limits for biological and physical agents. Limits are established to protect against peak exposures and chemical exposures that may have long-term effects. The terminology for exposure limits can be confusing. Following, you will find some of the most common exposure limits and definitions.

TLVs are defined as guidelines by the ACGIH (34), which represent airborne concentrations of substances and representative conditions under which employees, generally, may be repeatedly exposed without suffering adverse health effects. Specifically, the ACGIH has three categories of

exposure limit values and the following definitions are based on information from the TLV booklet and are defined as follows: (1) Threshold Limit Value—Time-Weighted Average (TLV-TWA)—the time-weighted average concentration for a conventional 8-hour workday and a 40-hour workweek, to which it is believed that nearly all workers may be repeatedly exposed day after day without adverse effect; (2) Threshold Limit Value—Short-Term Exposure Limit (TLV-STEL)—is defined as a 15-minute TWA exposure which should not be exceeded at any time during the workday even if the 8-hour TWA is within the TLV-TWA. STELs were developed to set concentrations to which it is believed that workers can be exposed continuously for a short period of time without suffering from irritation, chronic or irreversible tissue damage, or narcosis of sufficient degree to increase the likelihood of accidental injury, to impair self-rescue, or materially reduced work efficiency, provided that the daily TLV-TWA is not exceeded; (3) Threshold Limit Value-Ceiling (TLV)—the concentration that should not be exceeded during any part of the working exposure.

Permissible exposure limits are established and published by OSHA and are legally enforceable. The PELs are TWA concentrations that must not be exceeded during an 8-hour workshift of a 40-hour workweek. These limits are deemed by the agency to be the highest level to which an employee may be exposed to a harmful substance or physical agent without harmful effects. The OSHA permissible exposure limits (PELs), are found in tables Z-1, Z-2, and Z-3 of the OSHA General Industry Air Contaminants Standard (29 CFR 1910.1000). OSHA has also set action levels for specific agents. The action level is defined as the concentration or level of an agent at which it is deemed that some specific action should be taken. Employers are required by OSHA to begin regular monitoring to measure ongoing exposure, and to use engineering controls and personal protective equipment if the action level is exceeded. Usually, in general practice the action level is set at one-half of the permissible exposure limit (10).

Recommended Exposure Limits (RELs) are set by the National Institute for Occupational Safety and Health (NIOSH) and are used as recommendations for criteria standards for specific substances identified by OSHA based only on projected health effects (feasibility is not a criterion). RELs are TWA concentrations for up to a 10-hour workday during a 40-hour workweek (19).

The German MAK value (“Maximale Arbeitsplatz-konzentration”, maximum workplace concentration) is defined as the maximum concentration of a chemical substance in the workplace air which should not have known adverse effects on the health of the workers nor cause unreasonable annoyance even when the person is repeatedly exposed during a 40-hour workweek (or 42-hour when averaged over four weeks in firms that have four work shifts). Usually, the MAK value is an average concentration obtained by integrating the concentrations determined during a period of up to one working day or shift. MAK values are established on the basis of the effects of chemical substances. When possible, practical aspects of the industrial process and the resulting exposure patterns are also taken into account; scientific criteria, for preventing adverse effects on health are decisive, not technical and economic feasibility (35). The values are estabished by the Deutsche Forschungsgemeinschaft (DFG), Federal Republic of Germany, Commission for the Investigation of Health Hazards of Chemical Compounds in the Work Area.

The MAK values were developed for healthy persons of working age. The unconditional adoption of MAK and BAT (Biological Tolerance value for the working Material) values as guidelines during pregnancy is not possible because observance of these values does not guarantee in every case that the unborn child is reliably protected from the prenatal toxicity of the substances. The expression “prenatal toxicity” is taken in its broadest sense by the Commission; it includes any effect of the substance that elicits an alteration from the physiological norm in the offspring or causes permanent morphological or functional damage. Many substances have not yet been investigated or have not been thoroughly evaluated for prenatal toxicity. It is usually not safe to justify or quantify a risk of prenatal toxicity in man on the basis of animal studies. In the individual case, risk to a human can exist, even if the result of animal tests are negative, if the dose is significantly lower than the threshold dose determined in animal experimentation.

The Commission is testing the substances in the lists of MAK and BAT values to determine whether a risk of prenatal toxicity can be excluded by observance of MAK values and BAT values, whether such a risk has been reliably proved or must be assumed as probable on the basis of the existing data.

Substances have been classified according to their prenatal toxicity and grouped in following categories:

Group A: A risk of damage to the embryo or fetus has been unequivocally demonstrated. Exposure of pregnant women can lead to damage to the developing organism even when the MAK and BAT values are observed.

Group B: Currently available information indicates that a risk of damage to the embryo or fetus must be considered probable. Damage to the developing organism cannot be excluded when pregnant women are exposed, even when MAK and BAT values are observed.

Group C: There is no reason to fear a risk of damage to the embryo or fetus when MAK and BAT values are observed.

Group D: Classification in one of the groups A–C is not yet possible because, although the data available may indicate a trend, they are not sufficient for final evaluation.

MAK values cannot be established for a number of carcinogenic and mutagenic substances for the following reasons: cancer and mutations become manifest only after years and decades and under certain circumstances in future generations. After extended periods of exposure to low doses of these substances, the effects are extensively accumulated; whether or to what extent repair occurs can not presently be stated. However, because certain carcinogens are unavoidable in industrial processes and to some extent also occur naturally and because exposure to these substances cannot be completely eliminated, quantitative guidelines for protective measures and their analytical surveillance are necessary to ensure protection at work. The German Commission has set up technical exposure limits (TRK) in special cases. TRK values are not MAK values and are not listed in Table 8.5 for carcinogens (35).

Skin Guidelines Some substances are designated with skin notations because absorption of substances through the skin can make a significant contribution to systemic exposure to the employee or can even be the main exposure route. The ACGIH, OSHA and the German Commission have developed criteria to address skin absorption. Substances that have a “Skin” notation refer to the potential significant contribution to the overall exposure by the cutaneous route, including mucous membranes and the eyes, either by contact with vapors or, of probable greater significance, by direct skin contact with the substance. Substances are designated with an “H” when systemic exposure may be increased by cutaneous absorption (6, 34, 35).

Mixtures Special attention should also be given to the application of the exposure limits in assessing the health hazards from exposure to mixtures of two or more substances. The ACGIH and OSHA have established guidelines for exposure values for mixtures. The guidelines state that when two or more hazardous substances which act upon the same organ system are present, their combined effect, rather than that of either individually, should be given primary consideration. In the absence of information to the contrary, the effects of the different hazards should be considered additive, that is, if the sum of the concentrations divided by the corresponding threshold value exceeds unity, then the threshold limit of the mixture should be considered exceeded. Exceptions to this guideline may be made when there is a good reason to believe that the main effects of the different harmful substances are not in fact additive but are independent, for example, when purely local effects on different organs of the body are produced by the various components of the mixture. In such cases, the threshold limit ordinarily is exceeded only when at least one member of the series of concentrations and exposure limits itself has a value that exceeds unity. For examples and more information, see the ACGIH TLV booklet or OSHA standard 29 CFR 1910.1000 (34, 36). In general, the MAK value is valid only for exposure to a single pure substance, and the German Commission has refrained from

calculating MAK values for mixtures (35).

Carcinogens Several organizations and agencies provide guidelines for defining and classifying chemical or physical agents as carcinogens. Three of the most well-known agencies that have developed procedures and protocols for testing and classifying agents for carcinogenic potential are the National Toxicology Program (NTP), the International Agency on Research for Carcinogenicity (IARC), and the U.S. EPA.

First, the listing of a substance in the Annual Report on Carcinogens is mandated by Public Law 95-622. The evaluation of substances listed in the Annual Report is performed by scientists from the National Toxicology Program (NTP) and other federal health research and regulatory agencies. The listing of a substance in the Annual Report is descriptive and qualitative in nature and represents an initial step in hazard identification, which is generally considered the first step in the analytical process known as risk assessment. It is necessary to conduct a risk assessment to estimate the potential of any substance to harm human health. Risk assessments are not conducted by the NTP for substances in the Annual Report.

For the purpose of the NTP Report, “known carcinogens” are defined as those substances for which there is sufficient evidence of carcinogenicity from studies in humans to indicate a causal relationship between the agent and human cancer. “Reasonably anticipated to be carcinogens” are those substances for which there is limited evidence of carcinogenicity in humans and/or sufficient evidence of carcinogenicity in experimental animals. Sufficient evidence in animals is demonstrated by positive carcinogenicity findings in multiple strains and species of animals, in multiple experiments, or to an unusual degree with regard to incidence, site, type of tumor, or age of onset. Only substances for which the evidence of carcinogenicity has been peer-reviewed are evaluated for possible inclusion in the Annual Reports (37).

In 1969, the International Agency for Research on Cancer (IARC) initiated a program to evaluate the carcinogenic risk of chemicals to humans and to produce monographs on individual chemicals. The monographs' program has since been expanded to include consideration of exposures to complex mixtures of chemicals and of exposures to other agents such as radiation and viruses.

The objective of the program is to prepare, with the help of international working groups of experts, and to publish in the form of monographs, critical reviews and evaluations of evidence on the carcinogenicity of a wide range of human exposures. The monographs represent the first step in carcinogenic risk assessment and may also state where additional research efforts are needed.

The monographs may assist national and international agencies in making risk assessments and in formulating decisions concerning any necessary preventive measures. The evaluations of IARC working groups are scientific, qualitative judgments about the evidence for or against carcinogenicity provided by the available data. These evaluations represent only one part of the body of information on which regulatory measures may be based. Other components of regulatory decisions may vary from one situation to another and from country to country, responding to different socioeconomic and national priorities. Therefore, no recommendation is given with regard to regulation or legislation, which is the responsibility of individual governments and/or other international organizations.

The overall evaluation of the carcinogenicity of substances has been categorized by the IARC. The agent, mixture, or exposure circumstance is described according to the wording of one of the following categories, and the designated group is given. The categorization of an agent, mixture, or exposure circumstances is a matter of scientific judgment, reflecting the strength of the evidence derived from studies in humans and in experimental animals and from other relevant data.

Group 1—The agent (mixture) is carcinogenic to humans. The exposure circumstance entails exposures that are carcinogenic to humans. This category is used when there is sufficient evidence

of carcinogenicity in humans.

Group 2A—The agent (mixture) is probably carcinogenic to humans. The exposure circumstance entails exposures that are probably carcinogenic to humans. This category is used when there is limited evidence of carcinogenicity in humans and sufficient evidence of carcinogenicity in experimental animals.

Group 2B—The agent (mixture) is possibly carcinogenic to humans. The exposure circumstance entails exposures that are possibly carcinogenic to humans. This category is used for agents, mixtures, and exposure circumstances for which there is limited evidence of carcinogenicity in humans and less than sufficient evidence of carcinogenicity in experimental animals.

Group 3—The agent (mixture or exposure circumstances) is not classifiable as to its carcinogenicity in humans. This category is used most commonly for agents, mixtures, and exposure circumstances for which the evidence of carcinogenicity is inadequate or limited in experimental animals.

Group 4—The agent (mixture) is probably not carcinogenic to humans. This category is used for agents or mixtures for which there is evidence that suggests lack of carcinogenicity in humans and in experimental animals (38).

The U.S. EPA has developed a similar system for stratifying evidence of human carcinogenicity. In the EPA system, chemicals are classified in one of five groups, based on the overall weight of the evidence for carcinogenicity. Group A comprises those chemicals for which there is "sufficient evidence from epidemiologic studies to suggest a causal association between exposure to the agents and cancer." Group B includes those compounds for which there is limited evidence of human carcinogenicity. As in the IARC scheme, this group is further divided into two subgroups, B1 and B, and the criteria for inclusion in B1 is limited evidence of carcinogenicity from epidemiological studies. B2 is for sufficient evidence in animals. The EPA system includes a group C, which comprises compounds that are designated as possible human carcinogens on the basis of a wide range of evidence, including limited long-term bioassays, short-term tests, and structure–activity relationships. Group D is for compounds that are not classifiable as human carcinogens, and Group E comprises compounds for which there is adequate epidemiological and experimental evidence that they are not human carcinogens. It is worth noting that EPA's classification of a chemical as a carcinogen often does not indicate whether the hazards exist for the inhalation or oral routes, even though EPA has acknowledged that cancer hazards may be route specific. The EPA Cancer Guidelines, unlike the OSHA Cancer Policy, discuss risk assessment methodology and suggest that as a special case of the multistage model, the linearized multistage model (LMS) is generally appropriate (39).

Regulations and Guidelines In the Workplace

Eula Bingham, Ph.D., L. Faye Grimsley, MSPH, CIH

4.0 Toxic Substance Exposure Prevention Guidelines

4.1 Communication of Chemical Hazards

The need for communicating health risks from chemical hazards in the workplace has resulted in a variety of classification schemes for toxicity data, so that organized interpretations of significance to humans can be made. These schemes typically exist as part of hazard communication, transportation, and labeling regulations, or as a part of various consensus standards, toxicity testing protocols, or independent publications (40). Unfortunately, the criteria used for hazard classification purposes are not always consistent (41–43). This can result in portraying a chemical differently by various classification schemes, thus leading to inconsistency and confusion, despite the fact that the same toxicity data have been used for classification. Examination of Material Safety Data Sheets (MSDSs) from two or more sources for the same chemical reveals such differences in interpretation. Efforts have been initiated to "harmonize" various classification schemes worldwide (44). However, a

disparity is likely to exist for some time to come. Consequently, the practicing occupational health professional needs to be aware of various health hazard classification systems to cope effectively with different regulations and the overall demands of hazard communication.

Many countries have requirements that address some aspect of chemical classification and labeling, but few have comprehensive systems. Different agencies have responsibility and authority for different parts of an overall system. Often there are different purposes or driving forces within different pieces of legislation and, although all have a general purpose of protecting people potentially exposed to the chemicals, the specific intents may vary. For example, the United States and Canada have workplace hazard identification systems that are based on the principle that workers have the “right to know” this information. Hence, they are driven by a necessity to communicate hazards to the ultimate users. In the European Community (EC), an added purpose is to facilitate trade within EC countries. Thus, there may be less emphasis on worker training. The degree of specificity also varies significantly among various schemes. The EC system is very specific and gives exact wording for label statements on particular categories of substances; however, the scope is narrower than comparable sysems in the United States and Canada where a performance-oriented, criteria-driven approach is used. This does not imply that one system is inherently better than another; rather the differences in the various schemes simply underscore how divergent results can occur (40).

4.1.1 OSHA Hazard Communication Standard The Occupational Safety and Health Administration (OSHA) recognizes that hazard evaluation is a process that relies heavily on the professional judgment of the evaluator, particularly in the area of chronic hazards. The performance orientation noted in the OSHA hazard identification standard of the hazard determination does not diminish the duty of the chemical manufacturer, importer, or employer to conduct a thorough evaluation to examine all relevant data and produce a scientifically defensible evaluation. Data used in making hazard determinations that meet the requirements of OSHA are human studies, animal studies, and other experimental data, for examples, mutagenesis.

OSHA's Hazard Communication Standard (29 CFR, 1910.1200) requires employers to inform workers of chemical hazards via MSDSs, container labeling, and training (45).

4.1.2 European Community's Classification of Dangerous Substances Within the European Community (EC), the objective of classifying chemical hazards is to identify the toxicological, physiochemical, and ecotoxicological properties of substances that may present a risk during normal handling and use. Individual chemicals and chemical mixtures are labeled in accord with identified hazard classes to warn and protect the user, the general public, and the environment. The EC label is intended to take into account all hazards in the form in which chemicals are placed on the market and not necessarily in any different form in which they may be used, that is, diluted. The most severe hazards are highlighted by specific symbols. Other hazards are specified in standard risk phrases and safety phrases that advise on handling precautions (46).

The data required for classification and labeling under EC provisions may be obtained from a variety of sources, for example, the results of previous tests, information required for the international transportation of chemical substances, information taken from reference publications in the scientific literature, or information derived from practical experience. EC rules do not require testing to classify chemical hazards. However, from a practical standpoint, testing is frequently conducted, especially for acute effects, by chemical suppliers to provide a rational basis for classifying and labeling.

4.1.3 Canada's Workplace Hazardous Materials Information System (WHMIS) The Workplace Hazardous Materials Information System (WHMIS) is the Canadian national system designed to ensure that all employers provide needed information and train employees properly in the handling of hazardous materials in the workplace. WHMIS is consensus legislation that represents input from government, industry, and labor. It is intended to ensure that the hazards of materials produced or

sold in, imported into, or used within Canadian workplaces are identified by suppliers and that standard classification criteria are used. Suppliers of chemical materials in Canada must convey hazard information in a specified manner by labeling on the containers of "controlled products" and by providing more detailed information in the form of material safety data sheets (MSDS). A controlled product for health purposes is defined for WHMIS under the Federal Hazardous Products Act as any material included in any of the classes outlined in the act (47). For health purposes, these classes include materials that cause immediate and serious toxic effects, materials that cause other toxic effects, biohazardous materials, and corrosive materials. Employers are responsible for evaluating all products produced in a workplace process using the hazard criteria identified in the Controlled Products Regulations.

Employers in Canada must ensure that supplier-provided containers of controlled products are labeled with WHMIS labels. As long as a controlled product remains in its supplier-provided container, the supplier label must remain attached to the container and be legible. For workplace processes, employers are required to furnish workplace warnings in the form of labels, tags, or appropriate markings. There is no specific format for workplace labeling; however, information on safe handling, hazard warnings, storage, and use of the controlled product must be provided. Reference must also be made to the availability of a Material Safety Data Sheet (48).

4.2 Worker Training Regarding Chemical and Physical Toxicity

Provisions are set forth in Section 21(c) of the OSHAct, for training and employee education. According to paragraph (c), "the Secretary, in consultation with the Secretary of Health and Human Services, shall (1) provide for the establishment and supervision of programs for the education and training of employers and employees in the recognition, avoidance, and prevention of unsafe or unhealthful working conditions in employments covered by this Act, and (2) consult with and advise employers and employees, and organizations representing employers and employees as to effective means of preventing occupational injuries and illnesses" (21).

Most regulations and standards set forth by OSHA and other agencies have training requirements. The training requirements vary for each standard but have been included in the regulation to increase an employee's awareness of health hazards in the workplace and to reduce injuries and illnesses. Employers are responsible for training employees about health hazards of biological, chemical, and physical agents.

Particularly, in the United States, the Federal Hazardous Materials Transportation Law requires the Department of Transportation (DOT) to regulate the training of all hazardous materials (hazmat) employees. The hazardous materials regulations (HMR) include training requirements in several sections of Title 49 Code of Federal Regulations (CFR) as follows: (a) General 173.1; (b) Specific 172.704; (c) Air 175.20; (d) Vessel 176.13; and (e) Highway 177.800, 177.816. Each employer that is covered by the regulation must train and test, certify and develop, and retain records of current training (inclusive of preceding three years) for each hazmat employee (during the period of employment and 90 days thereafter). The hazmat training must include general awareness/familiarization, function-specific, safety, and driver training for each hazmat employee who will operate a motor vehicle.

Initial training should be completed within 90 days of employment or change in job function. Recurrent training is required at least once every three years. The three-year period begins on the actual date of training. Relevant training received from a previous employer or source may be used to satisfy the requirements, provided that a current record of training is obtained from the previous employer or source.

Under the Superfund Amendments and Reauthorization Act of 1986 (SARA), OSHA and EPA are required to protect employees engaged in hazardous waste and emergency response operations. To enforce SARA, OSHA issued guidelines requiring employers to establish and implement site-specific plans for worker protection at hazardous waste sites and in emergency response operations, and to provide training, medical surveillance, protective equipment, and engineering controls for

hazards. SARA also requires OSHA to set limits for workers engaged in hazardous waste and emergency response operations and to set requirements for handling, transporting, labeling, and disposal of hazardous waste. To protect employees who do not fall within OSHA's jurisdication, EPA adopted OSHA's Hazardous Waste Operations and Emergency Response Standard (Hazwoper) (29 CFR 1910.120).

EPA is also responsible for administering specific guidelines for asbestos. The Asbestos Hazard Emergency Response Act of 1986 (AHERA), which requires school systems to inspect school buildings for asbestos hazards and to abate those hazards through removal, replacement, encapsulation, or other appropriate actions, addresses potential hazards to public and worker health resulting from such activities. The act requires contractors who perform such activities to be accredited through state governments.

The law requires EPA to develop model accreditation programs for the states. Under those accreditation plans, contractors are required to pass an examination that addresses such elements of asbestos safety and includes recognition of asbestos containing materials and knowledge of asbestos health hazards; assessing the risk of asbestos exposure, knowledge of respirators, appropriate work practices, and hazard-control measures; and knowledge of ways to prepare an area correctly for response action and of proper asbestos disposal.

EPA has jurisdiction over worker protection in the fields where pesticides and herbicides are used. Most of the regulations are in the category of training, labeling, and reentry times. OSHA regulations cover the manufacture of pesticides (29).

Regulations and Guidelines In the Workplace
Eula Bingham, Ph.D., L. Faye Grimsley, MSPH, CIH

5.0 Global Standards
A brief description of standards in several countries is provided here so that the reader can recognize the varied approaches to regulations for worker protection.
Australia
In Australia, occupational exposure standards for airborne contaminants in the workplace are set by the Australian National Occupational Health and Safety Commission (Commission). Section 38(1) of the National Occupational Health and Safety Commission Act of 1985 (Commonwealth Act) authorized the Commission to develop, facilitate, and implement a national occupational health and safety strategy. Within the Commission, the Expert Working Group (ESEWG) works under the Standards Development Standing Committee (SDSC) to recommend occupational exposure standards for individual chemical substances.

The first group of OELs established by the ESEWG in 1986 was adopted from the ACGIH TLVs. The Commission compared the ACGIH list with the lists of permissible exposure limits of other countries. When agreement was found among the lists, the Commission adopted the ACGIH value. If a discrepancy was found, the ESEWG reviewed the relevant information and selected the appropriate value.

Exposure standards set forth are meant to serve only as guides. They have no legal status unless they are adopted into Commonwealth, State, or Territory legislation (33).
Germany
The Commission for the Investigation of Health Hazards of Chemical Compounds in the Work Area (Commission), an organization within the German Research Institute (Institute), publishes MAK occupational exposure limits for air contaminants in the workplace. MAK values are adopted as regulatory guidelines by the German federal government under the Ordinance on Dangerous

Substances.

The Commission selects chemicals for establishing MAK values. In establishing these values, primarily the effects of the compounds are taken into consideration by utilizing toxicological and work practice information.

The Commission also establishes biological exposure limits. A Biological Tolerance Value for the Working Material (BAT) is defined as the maximum permissible quantity of a chemical compound or its metabolites in blood or urine.

Through the Ordinances on Dangerous Substances as technical guidelines, the German government imposes MAK values in the workplace. Employers are responsible for testing and ensuring that they comply with MAK values (35).

Japan

The Japan Association of Industrial Health (Association) issues permissible exposure limits as reference values for measuring exposure to chemical and physical hazards. The Association is a private, academic organization consisting of committees.

The procedures used to establish exposure limits in Japan were substantially influenced by the ACGIH, and a majority of the initial exposure limits was adopted from the ACGIH TLV list.

Because the organization that establishes the exposure limits is a private entity, they hold no legal means of enforcement and are issued as only reference values. They are meant to serve as guidelines to industry and government (33).

Ontario

The Joint Steering Committee on Hazardous Substances in the Workplace established the Occupational Exposure Limits Task Force to set up and review exposure limits for the workplace. Due to limited resources and time, the OELs were based on the review of five other countries: Germany, Sweden, the Netherlands, the United Kingdom, and Norway. The Task Force decided to adopt OELS that were lower than Ontario's as part of a proposed list of new OELs. After a public comment period, the Task Force makes a final decision on OEL values, and they are made available through publications.

Ontario's OELs are normally adopted by regulation and are thus compulsory. The province has teams of inspectors who routinely inspect establishments.

If violations are found by inspectors, the maximum penalty for corporations is $500,000 and $25,000 plus one year in prison for individuals (33).

Poland

In 1976, a list of “maximum permissible concentrations” (MACs) of more than 300 potentially injurious substances came into force under the administration of the Ministry of Labor, Wages, and Social Affairs. By 1982, a new system had been implemented for establishing OELs based on national legislation. A group of experts uses health-based criteria for recommending MACs to the Polish Permanent Commission on Hygienic Standards. After acceptance by the Commission, the MAC values are promulgated by the Minister of Labor, Wages, and Social Affairs as legally binding regulations (49).

United Kingdom

The Control of Substances Hazardous to Health Regulations (COSHH) of 1988 introduced legal procedures for controling exposures to hazardous substances in the workplace.

Occupational exposure limits are set by the Health and Safety Commission's (HSC) Advisory Committee on the Toxic Substances (ACTS) in conjunction with its Working Group on the Assessment of Toxic Chemicals (WATCH).

Before setting OELs, WATCH reviews relevant primary literature (published and unpublished),

assessment is performed by a scientific committee, and endorsement is conducted within a superior committee structure. All standard chemical databases are searched, and contacts are made with relevant industry sources to obtain any available toxicological, exposure, and occupational health data.

Occupational exposure limits and other relevant legislation are enforced actively by inspectors of the Health and Safety Executive under extensive powers provided by the Health and Safety at Work Act of 1974 (33).

Venezuela

Occupational exposure values are revised and updated by the Venezuelan Commission of Industrial Standards, a government-headed committee comparable to the American National Standards Institute (ANSI). The OELs, termed "Candidates Ambientales Maximas Permissibles (CAMPS), were originally based on the 1978 ACGIH TLV, and occasional substances were added. The standards that are related to health and safety are legally enforceable (49).

European Union

Many member states within the European Union (EU) have formulated their own occupational exposure limits. For example, in Germany MAK values have been established. The European Commission (Commission) was seeking to harmonize EU-wide OELs, and in 1990, decided to set up an informal group of scientists known as the Scientific Expert Group (SEG) to advise on setting occupational exposure limits. In 1995, the SEG became an official committee and was commissioned to set up a formal basis for the work on the scientific evaluation of risk at the workplace related to chemical substances.

Specifically, the committee was to give particular advice on setting OELs based on scientific data and where appropriate shall propose values such as eight-hour time weighted average (TWA), short-term/excursion limits (STEL), and biological limit values.

The scientific reliability of the SEG recommendations is the cornerstone for any of the Commission's legislative proposals to set limit values for chemicals. In 1994, the Commission approved a Guidance note (as an internal working document) on procedures to set limits, which sets out the arrangements for the scientific review and evaluation to establish OELs in the European Union. It includes the procedures to be followed and at what stage interested parties can make their contribution to this procedure.

The procedures entail a detailed evaluation of criteria documents from different sources, identification of critical health effects, development of a summary document describing the recommended OELs and their basis, and a description of the critical effects. Once the summary document is agreed upon by the Committee, the Commission makes it available for public review and comments for about six months. After this review, the SEG makes recommendations to the Commission, which then develops legal proposals for OELs. The Commission's proposal for a legislative text is submitted to the Advisory Committee for Safety, Hygiene, and Health Protection at Work (ACSHH) for comments and approval.

Although specific enforcement provisions in the area of occupational compliance do not exist at the EU level, member states have an obligation to satisfy both their own and EU requirements (50).

Nordic Countries

Scientific data in the literature are available internationally and have allowed smaller countries to use this information as the basis for developing occupational exposure limits (OELs). This initiated the development of the Nordic Expert Group (NEG). The task of the NEG was to develop scientifically based criteria documents for use as a common scientific basis of OELs by the regulatory authorities in the five Nordic countries: Denmark, Finland, Iceland, Norway, and Sweden. Joint international ventures are therefore advantageous to the involved parties because writing criteria documents is a time-consuming and costly process.

The criteria documents from the NEG lead to the definition of a critical effect and dose–

response/dose-effect relationship. The critical effect is the adverse effect that occurs at the lowest exposure. There is no discussion of safety factors, and a numerical OEL is not proposed. Since 1987, criteria documents are published yearly by the NEG concurrently in English (13, 15).

Of the Nordic Countries, according to the available literature, Norway and Sweden do not enforce their OELs but use them to guide entities on complying with law.

5.1 Uniform Approach for Setting Occupational Exposure Limits

According to Lundberg (51) each country should use a standardized approach when building the documents. A summary of the approach and characteristics follow: A standardized criteria document should reflect the up-to-date knowledge presented in the scientific literature. The literature used should preferably be peer-reviewed scientific papers, but at least be available publicly. The scientific committee should consist of independent scientists from academia and government. All relevant epidemiological and experimental studies should be thoroughly scrutinized by the scientific committee, especially "key studies" that present data on the critical effect. All observed effects should be described. Environmental and biological monitoring possibilities should be pointed out. Data permitting, the establishment of dose–response and dose–effect relationships should be stated. A no-observable-effect level (NOEL) or lowest observable effect level (LOEL) for each observed effect should be stated in the conclusion. If necessary, reasons should be given as to why a certain effect is the critical one. The toxicological significance of an effect is thereby considered.

Specifically, mutagenic, carcinogenic, and teratogenic properties should be pointed out, as well as allergic and immunologic effects. A reference list for all studies described should be given. If a document states that only relevant studies have been used, there is no need to give a list of references not used or explain why. However, it could be of interest to list those databases that have been used in the literature search.

There are only minor differences in the way OELs are set in various countries that develop them. Therefore, it should be relatively easy to agree upon the format of a standardized criteria document containing the key information. From this point, then, the decision as to the margin of safety that is incorporated in the limit would be a matter of national policy (51).

Toxic Chemical Information Sources
Barbara Cohrssen, MS, CIH

1 Introduction

Knowing where to go to get relevant up-to-date as well as state-of-the-art information about the health effects of a chemical is essential for effective protection of workers and the environment. The means to access information is changing every day and the amount of occupational health and safety information is expanding. Finding information to prepare a MSDS, to respond to an emergency, to meet legislative and regulatory requirements, to determine the cause of an illness, or to develop a health and safety program can be challenging, overwhelming, and time-consuming. Toxicological information and data are of interest to more than workers, toxicologists, industrial hygienists, lawyers, and regulators. The general public is increasingly interested in the health effects of industrial chemicals.

Depending upon who wants the information and why they want it affects the use it will have and the amount of detail required about the chemical. For some, knowing that the basic health effects are respiratory or skin irritation is enough. For others, knowing the mechanics of the way the chemical works in the body will be of interest and required. For still others, the information is needed for an emergency so that whatever information is obtained must be gained quickly.

The recency of the information may affect which information sources are used. Electronic data bases, which have become a fact of life and are probably now the first source of reference for most people looking for chemical information and toxicological data, may not be the best resource. Electronic data bases can include both CD-ROMs and on-line databases available either directly from the service provider such as DIALOG, MEDLINE, or CCOHS or via the Internet. The government sources of information are usually free; however, there are fees for many of the other services. Comprehensive information and data are necessary to develop regulations to protect people and the environment from the effects of exposure from a chemical; all of this information may not be available from an electronic source. But electronic data sources are the places to go to quickly to find current toxicological data. There are a number of different methods of finding electronic data sources, and they are discussed later in the chapter.

There are a number of different types of safety, health, and toxicological information sources. These include traditional paper sources such as books, journals, and periodicals which were the typical sources of information before about 1970. There are also gray data. Gray data can include private or government research reports that have not been published, company catalogs, and material safety data sheets (MSDSs). These information sources are called gray data because they are difficult to find and are not always readily available (1). Still other sources of health and safety data are laws, standards, and patents in print. A preamble to a Federal OSHA health standard provides historical epidemiological data about a chemical.

This chapter discusses basic mechanics of information searching, general or traditional places to go for information, and then specific resources. To provide a chapter with just specific sources in this age of greatly expanding possible resources would be both a waste of time and a disservice to readers.

Toxic Chemical Information Sources
Barbara Cohrssen, MS, CIH

2 Basics of Toxicological Literature Searching

In the old days of literature searching, people who wanted information would go to libraries and ask librarians for what they wanted. The librarian, familiar with the book and journal collection would direct the requester. Manual searches included looking in encyclopedias, going through card catalogs, and reviewing the abstracts provided by a number of different organizations. Now, however, information is available beyond the four walls of a building. In addition to the contents of a library, the library has access to the contents of other libraries, and in many instances the ability to access information on the World Wide Web, otherwise called the Web or the Internet. The Web makes available databases within the government, associations, academic libraries, and private industry. Many of them are free; some are not, and must be paid for either by an annual fee or on a per use basis. There are also CDs of databases containing toxicological information.

2.1 Search Strategy: Questions to Ask

What are some of the questions to ask before conducting a literature search or looking for information?

1. Why do I want the information, and what will I do with it?
2. How much information do I have already?
3. How soon do I need this information?
4. Do I need historical use information, toxicological data, or information about the chemical and physical properties?
5. Where is the best place to start?
6. What is the information that I need to conduct a literature search?

No matter where one starts, it may seem rudimentary, but knowing the correct spelling of the chemical and its correct chemical registry number are absolute essentials. If you have the wrong spelling or the wrong registry number, you would get information about the wrong chemical.

2.2 Information to Look for: Chemical Registry Numbers

There are several chemical registry numbers to use. The most commonly used registry number in the United States is one developed by the American Chemical Society (ACS). This registry contains over 19 million compounds. The ACS assigns a CAS number to a specific compound, regardless of the name or nomenclature system used. For all practical purposes, it is the social security number for a particular chemical.

Another registry number only for organic chemicals, was developed by Beilstein Institute, Frankfurt am Main, Germany. Beilstein currently maintains a computerized database of more than 7.5 million chemicals.

A third registry number was established by the National Institute for Occupational Safety and Health (NIOSH) in its Registry of Toxic Effects of Chemical Substances (RTECS). This registry number is a unique nine-position alphanumeric designation assigned to each prime chemical name.

Table 9.1 provides a summary of selected sources for obtaining chemical registry numbers and determining a chemical from only a chemical registry number or other limited information about a chemical.

Table 9.1. Selected Sources for Obtaining Chemical Registry Numbers and Other Identifying Information

Name of

Chemical Database	Source/Address	Information Available	Cost
American Chemical Society Chemical Registry	Internet or direct contact www.acs.org	CAS numbers for 19 million compounds.	ACS members: free nonmembers: fee/use
Beilstein CrossFire System	Internet: www.beilstein.com	Contains data on more than 7.5 million compounds dating back to 1648.	Fee
NIOSH RTECS	CCOHS: Internet or CD-ROM www.ccohs.ca	Profiles of more than 130,000 compounds	Fee for either format
	Chemfinder: Internet www.chemfinder.com	Limited information; links to other data; can access information with CAS Number	Free
NLM (SIS) ChemID*plus*	NLM Internet: igm.nlm.nih.gov/tehip(site currently unavailable)	Contains about 350,000 records, of biomedical and regulatory interest including drugs	Free
Acronym Database	Freie Universitat Berlin Institute of Chemistry Internet: www.chemie.de/tools	Will locate a chemical given only acronym; in English and German	Free
IUPAC Database of organic Chemicals	University of London, Queen Mary and Westfield College Internet: www.chem.qmw.ac.uk	Full text of IUPAC recommendations	Free
Pesticide Information Profiles	EXTOXNET Internet: ace.orst.edu/info/extonet	Specific information on pesticides	Free

2.3 How to Look for the Information: Using the Internet

Users can retrieve much information on their own. In 1995, Michael Blotzer published a user's guide to the Internet. This user's guide provides a road map for health and safety information, and it provides the reader with a means for understanding how to use the Internet (2). A number of journals and periodicals also publish lists of resources on the World Wide Web otherwise known as the Web (www). Journals such as *Chemical and Engineering News*, or *Science* provide new Web sites of interest to scientists; the periodical *Occupational Health and Safety* has a regular feature entitled "Computer Applications." Many professional organizations have Web sites at which there are safety links. These links can lead you to a number of other sources of information.

List Servers are subscriber-based computer-generated mailing lists designed so that subscribers of mutual interests can ask, discuss, or comment on topics of interest. There are several that have discussed topics as varying as flock worker's lung, the effects of isocyanate inhalation, and the odor threshholds of various chemicals. The reader is cautioned, however, that the List Servers in use now

may have changed, and there could certainly be additional ones. Examples of listservs pertinent to chemical information include

CHEMIND-L
CHEMINF-L

For information on signing up or joining a listserv, refer to *Internet User's Guide for Safety & Health Professionals* by Michael Blotzer (2).

2.4 Searching the Web

There are different ways to search the Web: search engines, directories, links, or knowing the Web address of the information desired. Search engines use software that crawls the Web and records the text on every page. When you make a query, the search engine goes into the depths of the page to find relevant keywords. Generally, the more times a keyword appears on a page, the higher it ranks on a list of results. Selected search engines include fast search (www.alltheweb.com), AltaVista (www.altavista.com), google (www.google.com), and Northern Light (www.northernlight.com). A directory is an organized selection of categories such as toxic, health, or chemistry. The content within those categories has been handpicked by humans. When you submit a query, it pulls up relevant sites from those in the library. Selected directory search sites include Yahoo (www.yahoo.com), Lycos (www.lycos.com), and Looksmart (www.looksmart.com). Links are provided by academic institutions, professional organizations, or governmental agencies to other locations on the Web where related and relevant information may be found.

However, it should be noted, that what is available when this chapter was written, may be only a small fraction of what is available when this book has been published. It is impossible to guess what will be on the Internet. Just use the premise that the information exists; the only question is where. With this in mind, how do you go about finding what you do not know may exist.

Toxic Chemical Information Sources
Barbara Cohrssen, MS, CIH

3 Sources of Toxic Chemical Information

3.1 United States Government Technical Information Centers and Sources

The U.S. government expends a large amount of its budget on research and development. Much of this research is in the field of chemical toxicology. A number of governmental agencies are involved in this research. These agencies include the Centers for Disease Control and Prevention (CDC), the Food and Drug Administration (FDA), the Environmental Protection Agency (EPA), the National Institutes of Health (NIH), and the Department of Defense (DOD), to name a few. The research efforts of these departments yield thousands of reports every year. In addition, the government reviews the medical, health, and safety literature and publishes information that is obtained from these reviews.

Information resources within the U.S. government are becoming more and more available and accessible via the Internet. Following are selected sources of government databases and toxic chemical information.

National Technical Information Service (NTIS) NTIS, a part of the U.S. Department of Commerce, located in Springfield, VA, is a central source for documents in a variety of formats (printed, electronic, audio, etc.) relating to government sponsored efforts in scientific, technical, and business fields. The NTIS collection contains nearly three million titles. The Internet location for NTIS is www.ntis.gov. From this location, one can search for products, find out about on-line subscriptions, learn about services of federal agencies, and order reports and subscriptions to databases or other

information available from the NTIS. Orders maybe placed by telephone, mail, fax, or E-mail.

Telephone Orders:

Sales Desk: 1-800-553-6847 or 703-605-6000
Subscriptions: 1-800-363-2068 or 703-605-6060
Mail Orders: NTIS, 5285 Port Royal Rd., Springfield, VA 22161
Fax Orders: 703-605-6900
E mail: www.ntis.gov

National Institute for Standards and Technology (NIST) Located in the U.S. Department of Commerce, NIST has several databases that can provide reliable physical properties and related data. Several of these databases are on-line. These include NIST Chemistry WebBook and Polycyclic Aromatic Hydrocarbon Structure Index. These databases may be accessed at webbook.nist.gov/chemistry. (site currently unavailable)

National Institutes of Health National Library of Medicine (NLM) The NLM, located on the campus of the National Institutes of Health in Bethesda, MD, is the world's largest medical library. The Library collects materials in all areas of biomedicine and health care, as well as works on biomedical aspects of technology, the humanities and the physical, life, and social sciences. The collection stands at 5.3 million items—books, journals, technical reports, manuscripts, microfilms, phonographs, and images. The Internet address for NLM is www.nlm.nih.gov. NLM is located at 8600 Rockville Pike, Bethesda, MD 20894. Phone: 888-346-3656.

Toxic Chemical Information Sources
Barbara Cohrssen, MS, CIH

4 Where are the Sources Found
The sources of information on toxic chemicals are found in libraries or electronically via computers. The computers may be located in academic institutions, governmental agencies, individual offices, or most anywhere.
4.1 Libraries
A number of library collections can be searched via the Internet. The premier library in the field of information on toxic chemicals is the National Library of Medicine. However, many universities, professional and labor organizations, and governmental agencies contain collections of printed materials that contain information on toxic chemicals. Telephone books, Internet Web sites, and local public libraries can provide the names of libraries that may have the information that you want. The easiest way to find a library is with your computer, if you can access the Internet and the Web.

The following libraries have their catalogs on the web:

- Norwegin Libraries which can be found at BIBSYS. BIBSYS is a shared library system of all Norwegian university libraries, the National Library, and a number of research libraries in Norway. This Web site provides a list of libraries in Norway. Internet address: www.bibsys.no.
- Online Computer Center (OCLC) is comprised of information from 17,000 libraries in the United States and 51 other countries and territories. The OCLC system helps libraries to locate, acquire, catalog, and lend library materials. Internet address: www.oclc.org.
- Library of Congress (Internet address: www.loc.gov) contains catalogs of all materials copyrighted in the United States. Catalogs of the Library may be searched at this Web site.

A number of college and university libraries have websites available for conducting literature searches. Their URL addresses are not being provided because their addresses are in continual flux. An *edu* at the end of a URL address signifies an academic institution.

Addresses on the Web at which information about libraries maybe obtained include

- Library Catalogs on the Web. Internet address: www.lights.com/webcats.

4.2 Electronic Sources

Many sources of information on toxic chemicals can be found on the Internet, the World Wide Web, or on CD-ROM. As they used to say about the Telephone Yellow Pages, "Let your fingers do the walking." Table 9.6 lists electronic databases related to occupational safety and health that are available either on floppy disk, CD-ROM, or on the Web. This database list was generated by the International Labour Organisation (ILO).

Use of Toxicological Data in Evaluating Chemical Safety
Gloria Rachamin, Ph.D.

1 Introduction

More than 70,000 chemicals are currently registered in the chemical substances inventory under the Toxic Substances Control Act (TSCA) in the United States (U.S.), and every year new chemicals are introduced to the market. Each chemical can produce toxic effects that may be reversible or irreversible. Exposure to chemicals in the workplace can result in a wide range of adverse health outcomes, for example pulmonary disease skin irritation and sensitization, neurotoxicity, lung and liver function impairment, cancer, and hereditary diseases.

Toxicological data provide the basis for evaluating the potential health risks of chemicals to humans. Information from human and animal studies is used to characterize the nature of the toxic effects of chemicals and to predict their risk to human health under given exposures. The ultimate goal of using data from such studies is to determine "safe" levels of human exposure to toxic substances. Because it is not possible to assure absolute safety to everyone for any chemical, "safe" does not imply risk-free but a level of risk that is acceptable in our society.

In practice, chemical safety is defined by setting numerical health-based exposure limits for chemicals, exposure levels below which the risk of adverse health outcome is acceptable. For more than 60 years, the American Conference of Governmental Industrial Hygienists (ACGIH) has developed "Threshold Limits Values" (TLVs) for airborne concentrations of substances that "represent conditions under which it is believed that nearly all workers may be repeatedly exposed day after day without adverse health effects," as well as "Biological Exposure Indices" (BEI) for chemicals and their metabolites in body fluids. Similarly, regulatory agencies in the United States (e.g., Occupational Safety and Health Administration/OSHA, Environmental Protection Agency/EPA, Food and Drug Administration/FDA) and other jurisdictions have set exposure standards or guidelines to protect the health of the working population and the general public from exposure to chemicals. These standards include "Permissible Exposure Limits" (PELs) and "Recommended Exposure Limits" (RELs) for chemicals in the workplace, "Acceptable Daily Intake" (ADI) levels of chemicals in food, and "Reference Inhalation Concentrations" (RfC) for ambient air contaminants.

The term risk, in this context, refers to the probability of an adverse health outcome resulting from chemical exposure. The risk of experiencing adverse outcomes varies from minimal to high depending on the inherent toxicity (hazard) of the chemical, the level of exposure, and the susceptibility of the individual. Because of wide interindividual variation in susceptibility to chemicals, the risk of an adverse outcome for an individual is generally different from that defined for a population. Risk estimates may be qualitative, quantitative, or semiquantitative, depending on the data and methods used to derive them.

Agreement on what constitutes an acceptable risk for human populations involves a value judgment and is often an object of intense controversy. As a result of the U.S. Supreme Court ruling on the proposed benzene standard in 1980, OSHA has been required to demonstrate that its proposed standards reduce significant risks to worker health. Significant was suggested to be an increase in lifetime risk of developing cancer greater than 1 in 1,000 (1). In contrast, most regulatory agencies whose mandate is to protect public health, (e.g., USEPA, FDA, Health Canada) consider an excess lifetime cancer risk of 1 in a million acceptable.

In addition to providing the basis for deriving numerical exposure limits, toxicological data are used to identify and classify chemicals based on their toxic effects. Toxicity classification systems have been developed in various jurisdictions, including the United States, Canada, and European Community, to communicate information on the nature of chemical hazards more simply to workers and other end users. It is important to note that toxicity classification systems are usually hazard-based and not risk-based; the substance is classified on the basis of its toxic effects observed in experimental studies rather than on the level of risk it may present to human health under given exposure conditions. Recently the Organization for Economic Cooperation and Development (OECD) endorsed globally harmonized classification criteria for acute toxicity and other toxic end points, including cancer and developmental toxicity (2).

During the past two decades, reliance on toxicological principles and experimental data has become an integral part of the process that regulatory agencies use to control human exposure to chemical hazards. The results of chemical risk assessment, along with socioeconomic, technical feasibility, statutory, and political factors, provide input to risk management decisions to regulate a substance and on exposure control options (3–5). Before regulating a chemical, it is necessary to determine the potential of a substance to cause harm to humans and that the exposure is likely to occur.

Within the U.S. regulatory framework, risk assessment is defined as the process of systematic scientific characterization of potential adverse health effects resulting from human exposure to hazardous agents (3, 4). It consists of four main steps: hazard identification, dose–response assessment, exposure assessment, and risk characterization. Exposure assessment characterizes actual exposure to a chemical in a specific population. The outputs from the dose–response assessment and the exposure assessment are used to characterize the risk of adverse health outcome for this population.

The qualitative and quantitative evaluation of toxicological data (hazard identification and dose–response assessment, respectively) to predict chemical health risks to exposed human populations and to derive exposure limits, using risk assessment methodologies, is traditionally referred to in toxicology as chemical hazard evaluation (6). This constitutes the process that is used to evaluate chemical safety. Note that the commonly used term “chemical safety evaluation” originated from drug safety evaluations. For drugs, a margin of safety is established by comparing the toxic dose to the effective therapeutic dose (7). For chemicals that have no beneficial effects, however, this ratio has no relevance. For nondrug chemicals, the term “margin of safety” has been adopted in risk assessment procedures to indicate the magnitude of the difference between an estimated dose to which a human population is exposed and the highest dose at which adverse effects are not observed in experimental studies.

To evaluate chemical hazard, data are required on all the toxic effects that a chemical can produce by acute or chronic exposure. The most direct evidence comes from well-conducted studies in humans under conditions that are identical to those of the exposed population. In most cases, however, human data are not available, and surrogate data from animal studies are extrapolated to humans by using different risk assessment methodologies. The validity of toxicological predictions obtained by extrapolating from experimental data depends on the quality of the data, the methods used, and the degree of uncertainty.

The purpose of this chapter is to provide an overview of the process of chemical safety evaluation in the context of the regulatory risk assessment paradigm from the perspective of occupational toxicology. As seen in Figure 10.1, toxicological data from studies of the chemical in humans and animals, including physicochemical, toxicokinetic, and mechanistic data, are used in this evaluation. First, the adverse effects are identified and categorized by toxic end point. Next, the dose–response relationship for each end point is characterized, and the overall evidence is evaluated to determine the hazard class of the substance. If the toxicological database for a chemical is adequate, potential health risks to humans are then estimated, and exposure limits are derived by using risk assessment methodologies. Depending on the dose–response relationship (threshold or nonthreshold) of the

adverse effect that is observed at the lowest dose (critical effect), three general risk assessment approaches can be applied: safety/uncertainty factor, low-dose extrapolation risk model, and a unified benchmark dose approach. Note that various risk assessment procedures have been developed over the years and continue to evolve as science advances. A new terminology has also emerged in large part from environmental risk assessment work that focuses on community exposures to chemicals.

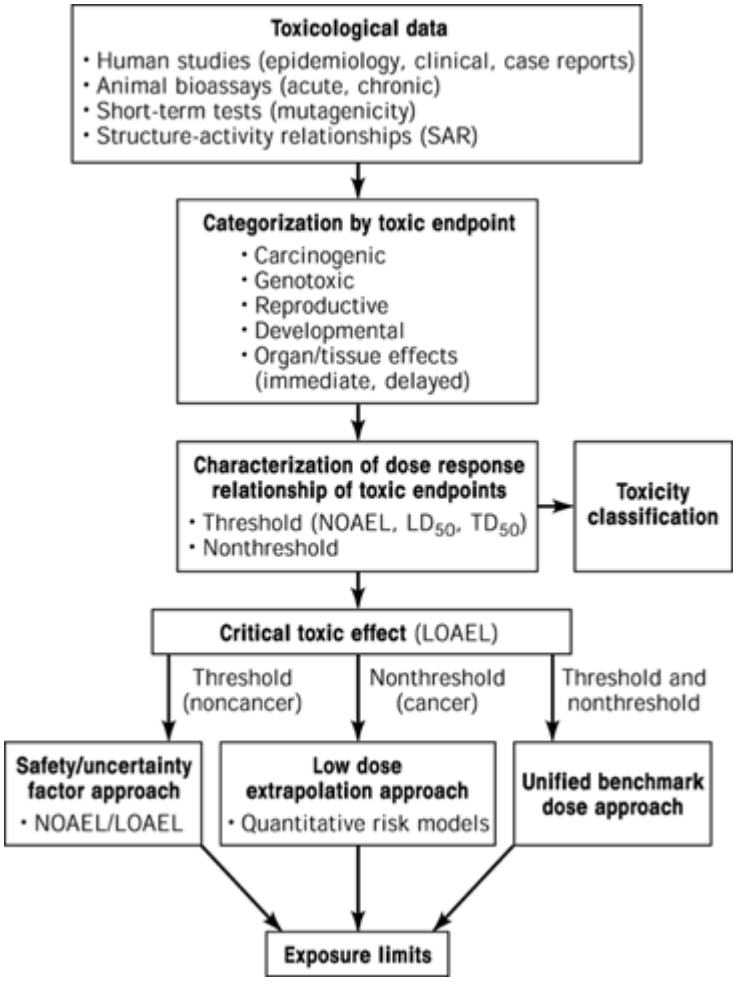

Figure 10.1. Chemical safety evaluation roadmap. This is a flowchart of the process of chemical safety evaluation indicating input and output data and the main steps (see Appendix 1 for definitions).

Toxicological principles are an integral part of chemical risk assessment, so basic toxicological concepts and references are included in Appendix 1. Key references on risk assessment that were used in preparing this chapter include government publications (3, 4, 8–18), books (19–23), reviews (6, 24–27), and other original papers cited in the text.

Use of Toxicological Data in Evaluating Chemical Safety
Gloria Rachamin, Ph.D.

2 Toxicological Data
A large volume of toxicological data is required to identify and characterize the nature of the toxic effects of chemicals and to predict their potential risk to humans under given exposure conditions.

To evaluate chemical safety, regulatory agencies use data from both human and animal toxicological studies. Such data can be obtained from various sources, including published literature, computerized databases, and submissions from chemical manufacturers.

Four main categories of toxicological data are used to evaluate chemical safety: human studies, whole body animal bioassays, short-term tests, and structure-activity relationship (SAR) data. Short-term tests and SAR data are used primarily to screen chemicals for mutagenicity or potential carcinogenicity and to support the interpretation of *in vivo* human and animal studies. Data from human studies are often scarce or inadequate, in practice, so whole body bioassays in animals provide the main source of toxicological information.

2.1 Human Studies

Studies of exposed humans provide the most direct evidence for predicting potential chemical hazard. The main source of human data available is from epidemiological studies, particularly in the working environment where exposures are relatively high. Data are available for some chemicals, from well-controlled clinical studies and also from case reports.

Analytical epidemiological studies, which include case-control and cohort studies, are most useful in identifying an association between human exposure and adverse health effects. Epidemiological studies under occupational settings attempt to determine whether an adverse health outcome is associated with a specific chemical exposure in the workplace. Benzene is an example of a substance that was first found to be carcinogenic in studies of workers, and only later was shown to cause cancer in animal studies (24, 28–30). The use of epidemiological studies, however, is generally limited due to several factors, including lack of adequate exposure data, confounding exposures, and a study population that is too small to detect a statistically significant effect (see section 3.1.1). In addition, from a public health perspective, positive findings in human studies are not desirable because the objective is to prevent disease before humans are harmed. Early detection of excessive exposure using biological markers in epidemiological studies is a valuable method for implementing interventions to prevent disease.

The advantage of clinical trials is that exposures can be controlled and quantified, and subjects can be selected to include susceptible individuals. Other than clinical trials for therapeutic agents, the use of this study design is limited because it is not ethical to expose humans to a potentially harmful agent. Only short-term reversible effects (e.g., irritation) of a chemical can be investigated in clinical trials but not the potential to cause chronic disease such as cancer.

Case reports of adverse effects in an individual are usually of limited value as evidence of causal association because they are not controlled studies and rely heavily on the recall of possible chemical exposure. Nevertheless, these observations should not be overlooked because the first suggestion that a number of substances cause disease such as cancer and peripheral neuropathy came from case that reports. Case reports can be used as indicators of the need to carry out controlled studies.

2.2 Whole Body Animal Bioassays

Studies of experimental animals provide the main source of data for assessing chemical safety. They provide information on the toxicity of a chemical under controlled experimental conditions (dose levels, effects measured, population size). Animal toxicity tests are particularly important because they provide an opportunity to identify toxic chemicals before people are actually exposed to them and, therefore, prevent potential adverse health effects.

In general, animal studies have a high predictive value for human health risks. Almost all known chemical carcinogens in humans cause cancer in some animal species. Further, it has been shown that exposure of animals to toxic agents in high doses is a valid method for discovering potential hazards to humans. Results can be extrapolated from high exposures in animal studies to lower exposures typically experienced by humans (see section 6.2).

To evaluate chemicals before humans are exposed, the U.S. TSCA requires the manufacturer of a new chemical to submit to the EPA any available toxicological data on the chemical before

manufacturing or distributing it. It has only limited authority, however, to order that toxicity tests be done. Similarly, premanufacturing or premarketing notification and submission of toxicological data on new chemicals is also required in other jurisdictions, including Canada and the European Community.

There are no set toxicity test protocols for every new chemical because the need is determined on the basis of the specific chemical, its intended use, and the toxic effects produced by structural analogues. A battery of screening tests is usually conducted first to determine whether further testing is required. Regulatory agencies (e.g., USFDA, USEPA) and other bodies such as the OECD have developed guidelines for toxicity tests. It is expected that toxicity tests to support the introduction of a new chemical to the market follow these guidelines. The guidelines are based on good laboratory practice (GLP) and provide direction on experimental design and methodology.

Numerous toxicity tests for evaluating chemical hazard have been developed and continue to evolve as scientific knowledge increases. It is generally recommended that bioassays be conducted in two mammalian species, one rodent and one nonrodent (usually dog or primate). The oral route of administration is used most often, but tests via inhalation and skin exposure are also performed when these are relevant. The following is a summary of the main types of bioassays that are used to identify toxic effects, target organs, and dose ranges of a chemical that causes adverse effects, emphasizing the principles and significance of each test (7, 31, 32).

2.2.1 Acute Toxicity The acute toxicity test is usually the first experiment performed with a new chemical. Different doses of the chemical are administered orally to groups of adult males and females of one or two species of rodents, most often the mouse and rat. If exposure via inhalation or skin absorption is expected, acute studies by inhalation and dermal exposure routes are also conducted. Most often the exposure duration in inhalation studies is 4 h. An acute dermal toxicity test is usually conducted in rabbits by applying the substance directly to the skin for 24 h. Mortality and other toxic end-point data are collected for up to 14 days after acute exposure.

The main objectives of this test are to obtain a quantitative estimate of the acute median lethal dose (LD_{50}, see Appendix 1) for comparing the potency with other substances, to identify target organs and clinical manifestations of acute toxicity, to determine whether an effect is reversible, and to provide guidance on the dose range for other studies. Acute toxicity tests, thus, identify highly toxic substances and their potential health hazards.

2.2.2 Skin and Eye Irritation/Corrosion The potential of a chemical to cause skin and eye irritation or corrosion is tested upon acute exposure, usually in rabbits. The agent is applied directly to the skin or the eye, and the degree of irritation from mild to corrosive is scored as specified in the test protocols. The Draize test (original or modified) is used to evaluate dermal irritation. The degree of skin irritation is scored for erythema, eschar, edema formation, and corrosive action.

2.2.3 Skin and Respiratory Sensitization Sensitization is a process mediated by the immune system whereby first exposure to a substance does not cause adverse reactions, but repeated exposure induces a significant immune response that may not be limited to the contact site. Many procedures have been developed to test the potential of a chemical to cause allergic sensitization to the skin or the respiratory tract upon repeated exposure. Skin sensitization is the most common form of sensitization in industrial settings, although respiratory sensitization also occurs often with some substances (e.g., toluene diisocyanate, trimellitic anhydride).

Sensitization tests are usually conducted in guinea pigs, a highly sensitive species. In general, a sensitization test protocol involves exposing the animals to multiple doses of the test substance during a period of two to four weeks. About two weeks after the last treatment, animals are challenged with a low dose of the test substance. Depending on the specific test, the animals are evaluated for an allergic response to the skin (e.g., erythema, or edema) or the respiratory tract (e.g.,

bronchoconstriction or asthma).

2.2.4 Subacute Studies These studies are conducted to obtain toxicity information after repeated exposure for one month or less and to establish doses for subchronic studies. Typically three or four doses are administered to the animals in their feed. Clinical chemistry and histopathology are performed 14 days after exposure.

2.2.5 Subchronic Studies Subchronic studies are conducted in two species by the oral route (or intended route of exposure) with at least three dose levels, most commonly for 90 days. The main goals of these studies are to establish a no-observed-adverse-affect level (NOAEL, see Appendix 1), and to further identify and characterize the specific toxic effects of a chemical on organs or tissues after repeated administration. The lowest observed adverse effect level (LOAEL, see Appendix 1) may also be obtained in these studies. The NOAEL and LOAEL depend on the doses and number of animals tested. These parameters are used to develop standards and have numerous regulatory implications. In addition to characterizing the dose–response relationship after repeated exposure, subchronic data provide information for appropriate doses in chronic studies.

2.2.6 Chronic/Carcinogenicity Studies Long-term or chronic exposure studies are conducted to assess cumulative toxicity or effects that require a long latency period. They are similar to subchronic studies, except that the duration of exposure is longer. Chronic studies are usually conducted in rodents for exposure durations of 6 months to lifetime (18–24 months for mice, 2–2.5 years for rats). Ideally, the design and conduct of chronic toxicity studies should allow the detection of general toxicity, including neurological, physiological, biochemical, and exposure-related morphological changes. The studies often include evaluation of carcinogenic effects following lifetime exposure, so that a separate carcinogenicity study is not required. Thus, animals are used as surrogates for humans to identify agents that pose potential risk for cancer induction in humans.

To detect a small but statistically significant increase in cancer incidence at the low doses that are usually encountered in human exposures, it is necessary to use a very large number of animals. Because this is impractical, a high dose is administered to the known most sensitive species to increase the probability of detecting a statistically significant increase in cancer incidence with a small number of animals (at least 50). This high dose, called the maximum tolerable dose (MTD), is usually estimated from subchronic studies. The U.S. National Toxicology Program (NTP) defines the MTD as the dose that suppresses body weight gain by no more than 10% in a 90-day subchronic study. Additionally, one or two lower doses and a control group are also tested.

2.2.7 Reproductive and Developmental Toxicity Studies Developmental toxicity is defined as the occurrence of an adverse health effect anytime during the life span that results from chemical exposure before conception (either parent), during prenatal development, or postnatally until puberty. Teratogenicity is the induction of birth defects by exposure during development between conception and birth. Reproductive toxicity is the occurrence of adverse effects on the male or female reproductive system resulting from chemical exposure.

Four types of tests, usually in rodents, are used to study potential effects on development and reproduction. General fertility and reproductive performance are tested by administering the chemical to male and female rats before mating and throughout gestation. Typical end points measured are the percentage of females that become pregnant, the number of stillborn and live offspring and the weight, growth, survival and general condition of offspring in the first three weeks of life. Teratogenic effects are tested by administering the chemical to pregnant females during organogenesis (day 6–15 of gestation in rats). The fetuses are removed by Cesarean section a day before the estimated time of delivery. The numbers of live, dead, and resorbed fetuses are recorded. Live fetuses are weighed, half of each litter is examined for skeletal abnormalities, and the other half for soft tissue anomalies.

Perinatal and postnatal toxicity are examined by administering the compounds to rats from the

fifteenth day of gestation throughout delivery and lactation. Birth weight, survival, and growth rate during the first three weeks of life are measured.

A multigenerational study is also often conducted to determine the effects of chemicals on the reproductive system. Male and females rats (F_0 generation) are exposed shortly after weaning throughout breeding, gestation, and lactation. The offspring (F_1 generation) are bred at about 140 days of age to produce the F_2 generation, and exposure is continued. Thus, both the F_1 and F_2 generations would have been exposed in utero and via lactation. F_1 and F_2 litters are examined as soon as possible after delivery, and indexes of fertility, gestation, viability, and lactation of F_0 and F_1 females are determined.

2.3 Short-Term Studies (Mutagenicity Tests)

Short-term tests have been used primarily to evaluate the potential mutagenicity of a chemical. A mutagenic chemical interacts with the genetic material in the nucleus of germ or somatic cells and produces changes that can be transmitted during cell division. Germ cell mutations damage the DNA in sperm or egg cells and can result in hereditary diseases or congenital abnormalities in offspring. Somatic cell mutations are implicated in the development of diseases such as cancer but are not heritable. The initiation of chemical carcinogenesis is thought to be via mutagenesis.

There are numerous short-term mutagenicity tests (33). The more commonly used tests include gene mutation assays in bacteria (*Salmonella*/mammalian microsome assay or Ames test), mammalian assays for chromosome damage *in vivo* (metaphase analyses or micronucleus assay in rodent bone marrow), and cytogenetic assays in cultured Chinese hamster or humans cells (chromosomal aberrations, micronuclei, aneuploidy). Of these tests, the Ames test (34) is the most widely used assay and allows evaluation of the mutagenicity of the chemical and its metabolites.

Screening for mutagens in short-term bacterial assays is a rapid and inexpensive method that is often used to predict potential carcinogenicity of chemicals in humans. Data indicate that the Ames mutagenicity test, combined with an evaluation of the chemical structure, allows identification of a large proportion of genotoxic (directly acting on the DNA) rodent carcinogens. Positive mutagenic response was also found with substances that are known human carcinogens. Although a similar relationship would be expected with germ cell mutagenicity, due to lack of data one can not evaluate the ability of the Ames test to predict mammalian germ cell mutagenicity.

2.4 Structure–Activity Relationships (SAR)

When the toxicity of a chemical is not known, toxicological data from another chemical with similar structure can be used to predict its potential to produce adverse health effects. It is assumed that a key molecular structure of the chemical termed “structural alert” is responsible for causing the toxic effect. This method has been used by regulatory agencies primarily to identify potential carcinogenic hazards. Examples of carcinogenic structural alerts include *n*-nitroso or aromatic amines, amino azo dye structures and phenanthrene nuclei. Eight of the first 14 occupational carcinogens regulated by OSHA belong to the aromatic amine class (25). The USEPA relies on SAR in the initial evaluation of premanufacturing submission of data for new chemicals. Computer-based SAR programs have been developed that are quite good in predicting the carcinogenicity of chemically related compounds. This method is applicable only when the toxicity of structural analogues has been studied.

Use of Toxicological Data in Evaluating Chemical Safety
Gloria Rachamin, Ph.D.

3 Adequacy of Toxicological Data

Several factors need to be considered in evaluating the adequacy of the toxicological database for a

chemical, including the quality of individual studies, the completeness of the database, the relevancy of studies to exposed populations, and the overall weight of evidence. Professional judgment must be exercised in evaluating the data. To bridge data gaps, default inferences are used by regulatory agencies based on science policy and the application of the precautionary principle.

3.1 Qualitative Evaluation of Toxicological Data

It is of utmost importance that chemical safety evaluation is based on data from well-conducted scientific studies. Criteria for assessing the quality of individual epidemiological and animal studies have been published to provide guidance (10, 16). These criteria address primarily the evaluation of factors related to the study design and methods used, including test subjects, controls, dose levels, exposure duration and frequency, measured end points, and statistical analysis. Some of the following specific issues need to be addressed in evaluating human and animal studies.

3.1.1 Human Studies There are three main areas of concern in assessing the quality of an epidemiological study. They relate primarily to the design and methodology used to measure exposure, measure health outcome, and to control confounding variables.

In most cases, direct measurements of exposure are not available or are inaccurate or unrepresentative. The accuracy and relevance of exposure measurements in epidemiological studies may also be questionable due their long-term nature. For example, exposure levels change over time with different industrial hygiene practices and as a result of individuals changing jobs.

Response data in epidemiological studies are usually reported as incidence, standardized mortality ratios, and relative risk ratios. It is important to carefully evaluate the study design, including selection of exposed and control groups, power to detect statistically significant association between exposure and effect, and the methods used to ascertain disease. For example, the causes of death in studies that report mortality data may be questionable because they are obtained from death certificates but are rarely confirmed by autopsy.

Epidemiological studies are designed to detect association between exposure and adverse health outcome. Various host risk factors, however, including preexisting health conditions or lifestyle habits such as smoking can influence the health index assessed. Often, an individual is also exposed to multiple chemicals that may not be identified or quantified. It is important to determine whether the study addresses and controls for risk factors and confounding exposures.

The following criteria have been developed to evaluate the causality of an association between adverse health outcome and chemical exposure in epidemiological studies (35):

1. Strength of association. This is usually expressed as a risk ratio of mortality or disease in an exposed population relative to an unexposed population. The higher the risk ratio, the more likely it is that the association is causal.
2. Consistency (reproducibility). Causal association is supported when positive results are found in several studies done independently by different investigators using different populations.
3. Specificity. Causality is more than likely if a particular exposure is associated with only one illness, for example, the relationship between vinyl chloride exposure and liver angiosarcoma.
4. Temporal relationship. Exposure should precede the development of the disease by a biologically relevant time period (i.e., latency).
5. Coherence of the evidence. An epidemiological inference of causality should not conflict with what is known about the history and biology of the disease.
6. Biological gradient. This requires demonstrating dose–response relationships between the exposure level and disease rate.
7. Biological plausibility. A causal association is strengthened when there are biological mechanisms that explain association between the substance and the disease.
8. Experimental verification. Removal of the substance should be followed by a decline in the

incidence of the disease.

3.1.2 Animal Studies The main issues to be considered in evaluating animal studies are the appropriateness of the test species as a model for humans, the study design, and its validity.

Several animal models for identifying carcinogens may not be appropriate because they have a high incidence of spontaneous tumors or the relevance to the tumor induced in humans may be questionable. Studies have shown that thyroid tumors mediated by hyperstimulation in rodents and renal tumors mediated by alpha2u-globulin induction in male rats do not predict human cancer due to species differences related to the mechanism of tumor production (25, 36). Acrylonitrile-induced carcinoma of the Zymbal gland (ear canal gland) has been reported in animals, but there is no counterpart organ in humans (20).

The study design should be consistent with good laboratory practice and include clear definition of all exposure elements, including dose, route, exposure schedule and duration, physicochemical properties of the substance, species, age, and gender. The study should include controls comparable to test animals in all respects except for the treatment variable. It should provide adequate data to establish a dose–response relationship, and a valid test must be performed that is relevant to humans. Studies should include appropriate statistical analysis, and conclusions should be justified by the data in the report and consistent with current scientific knowledge.

3.2 Completeness of Database

An ideal toxicological database should include all of the toxic effects that a chemical can produce by acute or chronic exposure via different routes of exposure and in several test species. It should also include data on the dose–response relationship for each adverse effect. Often, however, there is limited information on a chemical, and data gaps exist. It is important, therefore, to determine the magnitude of insufficiency of the database for a chemical because it will impact on whether risk assessment can be conducted and on the rating of uncertainties.

3.3 Selection of Principal and Supporting Studies

To predict human risks and set exposure limits, it is important to select studies that match the characteristics of the population for which the risk is characterized (e.g., workers). Variables to be matched include the identity and physicochemical properties of the substance (CAS Number, purity, dust, vapor, etc.), route of exposure, exposure level, dose rate, fraction of lifetime exposed, biokinetics, and mechanisms of toxicity (20).

Principal studies that contribute most significantly to the assessment of the potential toxicity of a chemical and to setting exposure limits need to be identified. Obviously, inhalation studies in humans are most relevant for deriving air standards for chemicals in the workplace. Supporting studies that provide information on the chemical with respect to the mechanisms of action, metabolism, and toxicokinetic data can also be used to refine the dosimetric adjustment.

3.4 Weight of Evidence

All available human and animal data should be considered to assess whether the weight of evidence supports a conclusion about potential adverse health outcomes in humans. This involves integrating evidence from all diverse data to evaluate the overall strength, consistency, and biological plausibility of the association between the chemical exposure and the adverse outcome (10).

Indicators of stronger association between exposure and adverse effect include low LD_{50}, low NOEL, high potency, evidence of a dose–response gradient, high incidence rate, large excess risk, and high level of statistical significance. High consistency is demonstrated if the association is found in various studies in several animal species, different routes of administration and dose regimens, and in epidemiological studies. The biological plausibility is further evaluated with respect to other scientific information that is related to causal mechanisms, including the gradient response observed, short-term *in vitro* studies and SAR data, toxicokinetics, mechanisms of toxicity, preclinical indicators of disease, and biological monitoring of exposure.

Use of Toxicological Data in Evaluating Chemical Safety
Gloria Rachamin, Ph.D.

4 Classification by Toxic Effect
An adverse effect, in the context of risk assessment, has been defined as any alteration in structure or function that is clearly deleterious to the living organisms or a degree of injury such that the body's normal compensatory and protective mechanisms are overwhelmed, resulting in irreversible or only partially reversible functional changes (10, 14).

Toxicological data are reviewed to identify the adverse effects that a chemical induces under given experimental exposure conditions. The acute lethality test is first evaluated to determine the median mortality dose (LD_{50}, see Appendix 1) for a chemical. The LD_{50} provides an index of potency relative to other chemicals but has limited value in assessing morbidity.

In evaluating chemical hazard, adverse health effects are usually grouped into five general categories based on toxic end points: carcinogenic, genotoxic, reproductive, developmental, and organ/tissue effects (e.g., irritation, sensitization, neurotoxic). The term “systemic toxicity” has been used in risk assessment in reference to all toxic effects other than cancer and gene mutations (13). In addition to general scientific principles, the following are special issues that need to be considered in evaluating these toxic end points (toxicity tests are described in section 2.2).
4.1 Carcinogenicity
A chemical carcinogen has been defined by the USEPA (8, 12, 16) as any substance capable of inducing neoplasia in humans or laboratory animals. The evidence for carcinogenicity is usually derived from long-term animal bioassays described in section 2.2.6.

4.1.1 Tumor Type In evaluating animal studies, the general practice by regulatory agencies is to assign almost the same weight to benign and malignant tumors, particularly if data suggest that benign tumors can progress to malignancy. The analyses of tumors are usually organ-specific or site-specific rather than for overall incidence of tumors. A statistically significant increase in the incidence of tumors in exposed animals compared to controls is considered indicative of carcinogenic potential.

4.1.2 Carcinogenicity Classification Classification of a chemical as an animal carcinogen is usually based on the weight of evidence from positive studies. The IARC's weight of evidence classification system (see Table 10.1) and other similar systems such as that of the EPA are used to classify carcinogens (37, 38). According to the EPA (8), a chemical is an animal carcinogen if it causes an increase in malignant or malignant and benign tumors in multiple species or strains or in multiple experiments, or even in a single experiment if the incidence is particularly high, the site or type of tumor is unusual, or the onset is at an early age. The EPA (16) has proposed changing the carcinogenic classification to a simpler descriptive weight of evidence system consisting of three categories: known/likely, cannot be determined and, not likely. The National Toxicology Program (NTP) criterion for classifying a chemical as a carcinogen is that it must be carcinogenic in at least one site in one sex of F344 rats or B6C31 mice.

Table 10.1. IARC Weight of Evidence Classification for Carcinogenicity[a]

Group 1	The agent is carcinogenic to humans
	— *sufficient* evidence of carcinogenicity in humans

Group 2A	The agent is probably carcinogenic to humans — *limited* evidence in humans and *sufficient* evidence in experimental animals — only *limited* evidence in humans or only *sufficient* evidence in experimental animals in the presence of other supporting data
Group 2B	The agent is possibly carcinogenic to humans — *limited* evidence in humans in the absence of *sufficient* evidence in experimental animals — *sufficient* evidence of carcinogenicity in experimental animals and *inadequate* evidence or no data in humans — *limited* evidence in experimental animals with other supporting data and inadequate or no data in humans
Group 3	The agent is not classifiable as to human carcinogenicity — category used for agents that do not fall into any other group
Group 4	The agent is probably not carcinogenic to humans — category for agents for which there is *evidence suggesting lack of carcinogenicity* in both humans and experimental animals — occasionally used for agents for which there is *inadequate* evidence or no data in humans and *evidence suggesting lack of carcinogenicity* in experimental animals which is "consistently and strongly supported by a broad range of other relevant data"

[a] Assembled by Calabrese and Kenyon (19) from IARC (37).

Overall, animal bioassays have high predictive value for human carcinogenicity. IARC considers chemicals that demonstrate sufficient evidence of carcinogenicity in animal experiments as potential human carcinogens. Almost all chemicals that IARC evaluated as carcinogenic in humans showed positive results in animal bioassays (39–42). Animal bioassays successfully predicted human carcinogenicity of many chemicals including 4-aminobiphenyl, diethylstilbestrol, mustard gas, aflatoxin, bis-chloro methyl ether, estrogens, vinyl chloride, 1,3-butadiene, dioxin, and formaldehyde (39, 43).

4.1.3 Test Dose Levels The use of high doses such as the maximum tolerated dose (see section 2.2.6) in bioassays is highly controversial. These doses are usually much greater than those experienced by humans, but some reported occupational exposures have been close to the doses of rodent carcinogens that are used experimentally (44).

The validity of the assumption of dose–response relationships with MTD has been questioned because it was suggested that overloading of metabolic and repair pathways may occur at higher doses and lead to overt toxicity, but this may not happen at low doses. Tissue damage from high doses can lead to regenerative cellular proliferation that may promote carcinogenesis. Although some studies reported cellular proliferation, a review of 52 long-term bioassays suggested that for most chemicals it is not the primary cause for carcinogenic response (43).

4.1.4 Carcinogenic Potency Gold et al. (45) recently published a supplement to the carcinogenic potency database (CPDB) that has been developed to provide a systematic and unifying analysis of the published results of chronic, long-term animal cancer tests on individual chemicals. According to this publication, the database includes the results of a total of 5620 experiments on 1327 chemicals

that have been reported in 1250 published papers and 414 National Cancer Institute/NTP Technical Reports. The TD_{50}, an index of potency, was estimated for each set of tumor incidence data reported and presented in a plot format. Gold et al. (45) further reported that 11 of the 25 chemicals that were tested in monkeys did not cause cancer (an additional three showed equivocal results), despite strong carcinogenic evidence in rodent or human studies. The authors suggested that this may be due to the fear that these studies lacked power to detect an effect. Among chemicals that were carcinogenic in both monkeys and rodents, potency values correlated highly between the two species.

4.1.5 Mechanisms of Carcinogenicity The dose—response relationship is one of the most contentious issues in evaluating animal carcinogens. Because animal bioassays are conducted at dose orders whose magnitude is greater than human exposure, mathematical models are used to extrapolate data from high doses in animals to low doses in humans to obtain a quantitative estimate of human risk (see section 6.2). Quantitative risk assessment of carcinogens has been widely used in the United States particularly for environmental carcinogens. The choice of a mathematical model depends on the mechanism of carcinogenesis of a chemical and on the science policy of selecting the more conservative model.

Chemicals can produce cancer via genotoxic (directly acting on DNA) or nongenotoxic (epigenetic) mechanisms (46). The current theory is that genotoxic carcinogenesis is a nonthreshold phenomenon that proceeds through initiation, promotion and progression. Initiation is an irreversible alteration of DNA caused by a chemical carcinogen. Promotion represents the process of replication of initiated cells that demonstrate a growth advantage over uninitiated cells. Progression is the irreversible change from benign lesion to malignancy. There is a general agreement that carcinogenesis is likely to be a nonthreshold phenomenon for classical carcinogens such as vinyl chloride and benzo(a) pyrene (24). The mechanisms of nongenotoxic carcinogenesis do not involve direct interaction with the DNA but as yet are poorly understood. There is debate over whether carcinogenesis is a threshold phenomenon for nongenotoxic carcinogens such as dioxin and trichloroethylene.

The decision whether to evaluate a chemical as a genotoxic or epigenetic carcinogen has a major impact on the derivation of exposure standards. For example, the estimated acceptable daily intake for dioxin in the United States is about 15 times lower than that in Canada. Because dioxin has been considered a genotoxic carcinogen in the United States but not in Canada, different risk assessment methods were applied that resulted in a large difference in the standards adopted by the two jurisdictions (24).

4.2 Genotoxicity (Mutagenicity)

Mutagenicity tests are used to predict carcinogenicity or to predict human germ cell mutagenicity. Data obtained are used to support findings in bioassays. The predictive value of short-term genotoxic tests depends on several factors, including the characteristics of the chemical, its mechanisms of action, and the sensitivity and specificity of the test used.

A mutagen can interact with the DNA to induce several alterations (33) including point mutations (changes in the base sequence of DNA), and structural or numerical chromosomal aberrations. Structural aberrations include deficiencies, duplications, inversions, and translocations. Numerical aberrations are gains (e.g., trisomy) or losses of whole chromosomes or sets of chromosomes (aneuploidy).

The development of batteries of short-term tests to predict which chemicals are carcinogens is an area of continuous research and debate. A comparison of results from four widely used mutagenicity tests with cancer bioassays of 73 chemicals in rodents showed a concordance of about 60% (47). An analysis of data for 301 chemicals tested for carcinogenesis in mice and rats showed that when the Ames test data was combined with “structural alerts” (see section 2.4), 93% of the structurally alerting chemicals that were carcinogenic in both these species were also mutagenic in the Ames test (33, 48–50). Positive mutagenic response was also reportedly associated with substances known as human carcinogens.

The IARC has recommended that short-term tests alone should not be used to determine whether an agent is carcinogenic nor to predict reliably the relative carcinogenic potencies of chemicals in animals. The IARC's (51) weight of evidence system for evaluating genetic activity of chemicals in short-term tests is based on four end points (DNA damage, mutation, chromosomal effects, and cell transformation) and the level of phylogenetic complexity of the test system ranging from prokaryotes to humans *in vivo* (see Table 10.2). According to the EPA's criteria for evaluating evidence for mutagenicity in germ cell DNA, a positive test in a well-characterized gene mutation assay in mammalian germ cells strongly suggests that the chemical would be mutagenic in human germ cells.

Table 10.2. IARC Scheme for Assessing Evidence of Genetic Activity in Short-Term Tests[ab]

Sufficient evidence	At least three positive entries, one of which must involve mammalian cells *in vitro* or *in vivo* and must include at least two of the three end points[b], DNA damage, mutation, and chromosomal effects
Limited evidence	At least two positive entries
Inadequate evidence	Only one positive entry or when too few data do not permit an evaluation of an absence of genetic activity or when there are unexplained, inconsistent findings in different test systems
No evidence	Applies when there are only negative entries; these must include entries for at least two end points and two levels of biological complexity, one of which must involve mammalian cells *in vitro* or *in vivo*

[a] *Source:* Assembled by Calabrese and Kenyon (19) from IARC (51).

[b] End points: *DNA damage* tests for covalent binding to DNA, induction of DNA breakage or repair, induction of prophage in bacteria, and differential survival of DNA repair-proficient/-deficient strains of bacteria.

Mutation tests for measuring heritable alterations in phenotype and/or genotype. These include tests for detecting the loss or alteration of a gene product and change of function through forward or reverse mutation, recombination, and gene conversion; they may involve the nuclear genome, the mitochondrial genome, and resident viral or plasmid genomes.

Chromosomal effects tests for detecting changes in chromosomal number (aneuploidy), structural chromosomal aberrations, sister-chromatid exchanges, micronuclei and dominant-lethal events. This classification does not imply that some chromosomal effects are not mutational events.

Cell transformation tests that monitor the production of preneoplastic or neoplastic cells in culture and are significant because they attempt to simulate essential steps in cellular carcinogenesis. These assays are not grouped with the end points listed before because the mechanisms by which chemicals induce cell transformation may not necessarily be the result of genetic change.

Data obtained from screening tests for mutagens are used for setting priorities for further testing of chemicals and provide input for making decisions on whether to develop a new chemical product or to regulate a substance. Many compounds have been evaluated for mutagenicity, and results have been compiled by various agencies, including a published list by IARC (51), the EPA's Gene-Tox database, and the U.S. Environmental Mutagen Information Center (EMIC, Tennessee).

4.3 Reproductive

Toxicity to the male reproductive system may be expressed as alterations to the male reproductive organs and/or related endocrine system. The manifestation of such toxicity may include changes in sexual behavior, fertility, pregnancy outcomes, or modifications in functions that depend on the integrity of the male reproductive system. Similarly, female reproductive toxicity includes, but is not

limited to, adverse effects on sexual behavior, onset of puberty, fertility, gestation, parturition, lactation, or premature reproductive senescence (17). (See also Chapter 3, "Reproductive Toxicology")

In evaluating chemicals for reproductive toxicity, it is important to distinguish between reproductive and developmental effects, particularly in multigenerational studies (see section 2.2.7). There is an overlap in the outcomes that are measured to evaluate reproductive and developmental toxicity, for example, the pregnancy outcome. An adverse pregnancy outcome in offspring of exposed males that are mated with unexposed females can be attributed to male reproductive toxicity. Similarly, such an outcome in the offspring of an exposed female, before gestation, that is mated with an unexposed male can be attributed to female reproductive toxicity. Difficulties arise in interpreting the results if males or females are exposed before conception and females are also exposed during pregnancy. Data from reproductive studies of different experimental designs can provide complementary information that can be integrated.

4.4 Developmental

The four general end points of developmental toxicity that are evaluated are death of the conceptus, structural abnormality, altered growth, and functional deficiency (11). Functional deficiency is not routinely evaluated for several reasons, including methodological difficulties and the time and cost involved.

Chemicals that cause adverse effects in developing offspring in animal studies are viewed as potential human toxins. Chemicals that cause adverse developmental effects at exposure levels that do not produce maternal toxicity present the greatest developmental hazard. The majority of chemicals that produce maternal toxicity in animal studies also cause adverse developmental outcomes (19). This complicates the interpretation of the observed adverse developmental effects in offspring because it is difficult to determine the influence of maternal toxicity on the adverse outcome. From a regulatory perspective, a developmental toxin is usually considered a substance that causes developmental toxicity in the absence of maternal toxicity or for which developmental effects are not specifically related to maternal toxicity.

4.5 Organ/Tissue Effects

This category includes all adverse effects that are not covered in the previous four categories. It encompasses all immediate and delayed systemic and local adverse effects that result from acute or chronic exposures and occur via threshold mechanisms. They represent a large proportion of chemically-induced adverse health outcomes that have been encountered in the workplace, including irritation, sensitization, neurotoxic effects, impaired pulmonary function, and liver or kidney pathology. Discussion of these effects is beyond the scope of this chapter.

Sensory irritation is unique because it is localized, rapid, noncumulative, and subjective. Occupational exposure limits have often been set on the basis of human data because it is difficult to determine irritation threshold from animal studies. An animal model in mice has been developed in which reduced respiratory rate provides an index of respiratory irritation.

Use of Toxicological Data in Evaluating Chemical Safety
Gloria Rachamin, Ph.D.

5 Characterization of Dose–Response Relationships

The quantitative relationships between dose and the incidence of adverse response (see Appendix 1) provide the basis for evaluating chemical hazard and the derivation of exposure limits. The approach used to assess the dose–response relationship depends on whether the chemical produces threshold or nonthreshold end points (19, 20).

5.1 Threshold and Nonthreshold Effects

A threshold dose–response relationship is used to evaluate chemicals that produce no adverse effects

below a certain dose. The underlying mechanism for a threshold is that multiple cells must be injured for an adverse effect to occur (52). A nonthreshold ("zero" threshold) dose–response relationship is used to evaluate chemicals that convey some risk of adverse response at any dose above zero. The mechanism of carcinogenesis is considered nonthreshold, whereby a genotoxic insult in a single cell is theoretically sufficient to produce a malignant tumor eventually.

Traditionally, the threshold dose–response relationship has been used for assessing noncancer end points and the nonthreshold approach for cancer end points. The use of a nonthreshold dose–response relationship to evaluate nongenotoxic carcinogens has been a subject of much debate because it has been suggested that these substances are likely to produce cancer via a threshold phenomenon (53). Both threshold and nonthreshold approaches have also been applied to evaluate reproductive and developmental toxins (54, 55).

5.2 Dose Scaling

To facilitate interspecies comparisons of the dose–response relationship for adverse effects, it is necessary to obtain an estimate of the human equivalent dose. The two methods that are most commonly used to convert animal dose or exposure to an equipotent dose for humans are based on body characteristics.

The first method calculates the equivalent human dose from an animal study by scaling (adjusting) the animal dose rate for animal body weight, often expressed as mg/kg body weight/day. Similarly, the second method is based on body surface area scaling by adjusting for differences in metabolic rate, using the factor of body weight to the power of 2/3 or 3/4. Body weight scaling, however, is simpler and has been used by the USEPA for risk assessment and derivation of numerical criteria.

Ideally, the concentration at the target site would provide the best dosimetry. A method has been developed to estimate target tissue exposure (concentration × time) using a physiologically based pharmacokinetic model that incorporates biological data and processes. Because input data on the biokinetics and mechanisms of toxicity are rarely available for animals or humans, it is difficult to verify the validity of using this model for dose scaling.

5.3 Critical Adverse Effect

The dose–response relationship is characterized for each of the adverse responses that a chemical produces by using data from the most relevant and scientifically sound studies. For threshold responses the NOAEL, TD_{50}, or LD_{50} are determined (see Appendix 1). Depending on the response that is modeled, each response to a chemical can have a different threshold. For nonthreshold end point, models for extrapolation from high doses to low doses below the observed range are applied (see section 6.2).

A chemical can produce various effects ranging from not toxic to very toxic or "frank effect level" (FEL) (25, 56). The critical adverse effect is defined as "the first adverse effect, or its known precursor that occurs as the dose rate increases" (14). Operationally, for threshold end points, the critical effect is the most conservative LOAEL. This end point is used to derive the exposure limit (see section 6).

Figure 10.2 shows a hypothetical example of a chemical that produces two adverse threshold effects at different dose ranges. Liver pathology occurs at higher doses than respiratory function impairment. In this case, respiratory impairment is considered the critical end point with a corresponding experimentally measured LOAEL. The highest dose level that does not produce a statistically or biologically significant impaired respiratory function is the NOAEL. The NOAEL or LOAEL can be used to derive the exposure limit (see section 6).

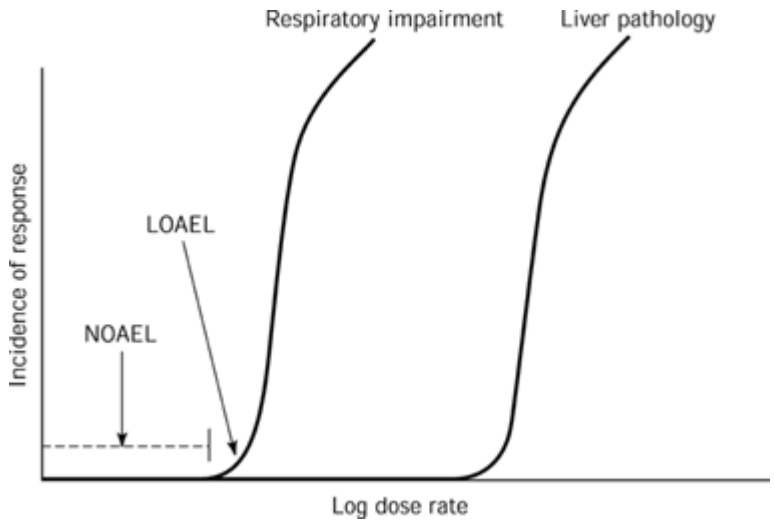

Figure 10.2. Hypothetical dose–response relationship curves for a chemical that produces two adverse threshold effects and illustrates the critical toxic effect, LOAEL, and NOAEL.

If a chemical produces both threshold and nonthreshold (cancer) adverse effects, exposure limits can be calculated on the basis of the threshold effect that is observed at the lowest dose and also on the nonthreshold end point (see section 6). For a nonthreshold effect, various curves of excess risk versus dose may be used to extrapolate downward from an experimental dose, depending on the quantitative risk model applied (see Fig. 10.3). Then the lowest concentration or the most conservative estimate for exposure limit is recommended.

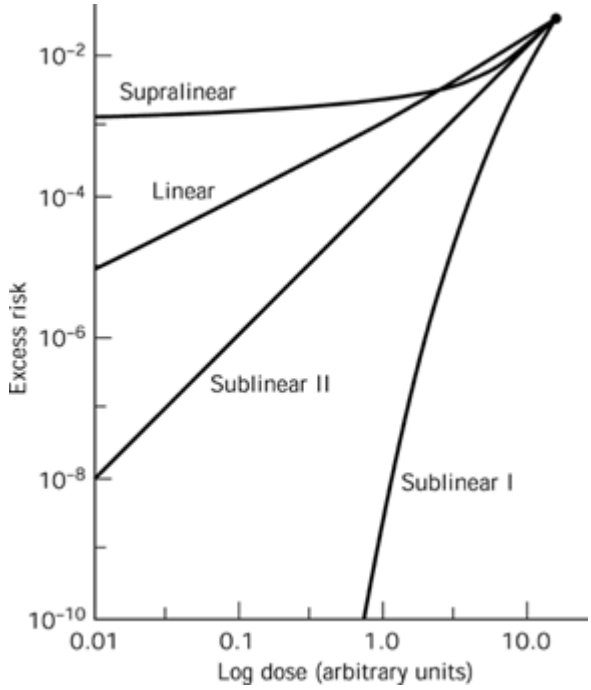

Figure 10.3. Alternative extrapolation models for the same experimental data set (from Ref. 3 with some modifications).

Use of Toxicological Data in Evaluating Chemical Safety
Gloria Rachamin, Ph.D.

6 Derivation of Exposure Limits
Traditionally, two different approaches have been used by regulatory agencies to derive exposure limits for substances that produce threshold and nonthreshold effects (19). The safety/uncertainty factor method has been used for threshold (noncancer) end points. For a cancer end point, the general approach has been to use a low-dose extrapolation risk model. Recently, a unified approach for threshold and nonthreshold effects has been proposed for deriving exposure limits by using the benchmark dose and uncertainty factors (57). The three approaches are described here.
6.1 The Safety/Uncertainty Factor Approach for Threshold Effects
The traditional safety/uncertainty factor approach of dividing the no-observed-adverse-effect level (NOAEL) of the critical effect by a safety factor has been widely used to derive "safe" exposure limits for chemicals that produce threshold effects (52). The ACGIH has used this approach for both threshold and nonthreshold effects in developing TLVs (58).

Historically, a safety factor of 100 has been applied to the NOAEL to account for all uncertainties, including interindividual and interspecies variation. Over the years, it became customary to divide this factor into two factors of 10 to account for interspecies and intraspecies variability, respectively (6).

Although the terms safety factor and uncertainty factor have the same meaning, the USEPA (13) recommended using the term uncertainty because "safety factor" may be inadvertently interpreted as absolute safety. It has further endorsed the use of uncertainty and modifying factors when deriving the oral reference (RfD) (13) and the reference inhalation concentration (RfC, USEPA 1994) for noncancer effects. The RfC (expressed in mg/m^3) is defined as "an estimate (with uncertainty spanning perhaps an order of magnitude) of a continuous exposure to the human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious effects during a lifetime" (14). The same general principles apply to the derivation of the inhalation reference concentration and the oral reference dose (13, 14), but the RfC methodology has been expanded to account for the dynamics of the respiratory system as the route of entry. In the RfC method, the NOAEL from animal studies is converted to a refined dosimetric adjustment referred to as human equivalent concentration (HEC). The dose is also defined as the agent mass deposited per unit tissue volume delivered to specific target sites in the respiratory tract or made available to uptake and metabolic processes for systemic distribution. This methodology further distinguishes between gases or particulates and the type of effect the substance exerts, pulmonary or extra pulmonary.

The RfC is derived from the NOAEL (or the LOAEL, if the NOAEL is not available) as follows (14):

$$\mathrm{RfC} = \mathrm{NOAEL}_{\mathrm{HEC}}/(\mathrm{UF} \times \mathrm{MF})$$

where

$\mathrm{NOAEL}_{\mathrm{HEC}}$ = NOAEL adjusted for dosimetric differences between animal species and humans, expressed as human equivalent concentration (HEC).
UF = uncertainty factors suited to the characteristics of the data:

- 10-fold to account for interindividual variation in susceptibility among thehuman population
- 10-fold for interspecies variation between animal and humans
- Five-fold or 10-fold for extrapolating from data in a subchronic study to chronic or from less

than a lifetime study to a lifetime study

- Five-fold or 10-fold for extrapolating downward from LOAEL to a NOAEL. These uncertainty factors are based on historical and experimental data and are independent multiplicative factors (59–63).

MF = modifying factor, that is, an additional uncertainty factor which is based on professional assessment of the adequacy of the entire database (e.g., relevancy to humans and mechanistic and toxicokinetic data), ranging in magnitude from 1 to 10.

The NOAEL approach has been criticized for several reasons, including (*1*) the NOAEL must be by definition a tested experimental dose, (*2*) experiments that test fewer animals would result in a higher NOAEL and thus a higher or less protective exposure limit, (*3*) the use of the NOAEL ignores the rest of the dose–response curve, and (*4*) the NOAEL approach does not identify actual responses at the NOAEL and, depending on the experimental design, will result in regulatory exposure limits being set at various levels of risk (15, 64, 65).

In view of these limitations, an alternative approach using the benchmark dose (BMD) has been proposed by Crump (64). In this method the dose–response is modeled and the lower confidence bound for a dose at a specified response level, usually 1–10%, is calculated. The BMD can be used as an alternative to NOAEL in calculating the oral reference dose or inhalation concentration:

$$\mathrm{Rfc} = \mathrm{BMD}/\mathrm{UF} \times \mathrm{MF}$$

The UF and MF are the same as those used for the NOAEL or LOAEL. This method has been adopted by the USEPA (15) for noncancer effects and has been applied to developmental end points (54, 66).

6.2 Risk-Model Approach for Nonthreshold Effects

For cancer end points, the general approach has been to use a mathematical model to estimate the excess risk for a given dose (e.g. lifetime exposure to 1 mg/m^3 of substance in air) or the dose for a given risk (e.g., one in a million). Different dose–response models can be proposed to extrapolate from high doses in animal bioassays to low doses that might be encountered by humans, that is, extrapolation beyond the region in the dose–response curve for which experimental data are available (3, 67). Depending on the model chosen, the level of risk can vary by orders of magnitude at the same exposure level (see Fig. 3).

The risk extrapolation models can be divided into two general categories, namely, mechanistic models and statistical (or probability distribution) models (25) as follows. The mechanistic models (e.g., one hit, multihit, multistage, linearized multistage) use a mathematical equation to describe dose–response relationships that are consistent with postulated mechanisms of response. The mechanistic models assume that a response in a subject (animal, human) results from a random occurrence of one or more biological events (stochastic events). The distribution models (e.g., Log-probit, Logit, Weibull), on the other hand, assume that each individual has a tolerance level to a chemical and that this response level is a variable that follows a specific probability distribution function. These responses can be modeled by using a cumulative dose–response function, as in the case of the normally distributed dose–response curve.

The linearized multistage model (LMS) is the model most commonly used by regulatory agencies in the United States (68). This model, consistent with proposed genotoxic carcinogenic mechanisms, assumes that a series of ordered stages is required for a cell to undergo initiation, transformation, and progression to form a tumor. The USEPA uses the upper 95% confidence limit of this model on the basis of biological plausibility and conservatism. It has been argued, however, that the use of the upper 95% confidence limit reduces the model to a worst-case scenario and does not take into account carcinogenic mechanisms (24).

Until recently, these models have been used to extrapolate from high to low doses without considering interspecies variation. This raised the question whether carcinogenic potencies derived from these models are relevant to humans. A comparison of potencies across species for known human carcinogens (e.g., aflatoxin, vinyl chloride) showed relative concordance, at least within one order of magnitude (24). The prudent public policy has been to assume a similar ranking across species for animal carcinogens, unless there is convincing evidence to assume otherwise.

The advancement of physiologically based toxicokinetic (PBTK) and biologically based dose–response (BBDR) modeling in recent years has improved the application of risk extrapolation models. The PBTK model is used to estimate the "effective target tissue dose," thereby, reducing uncertainties associated with extrapolation across species from high to low dose and across routes of administration (69). The use of PBTK models in risk assessments of methylene chloride and perchloroethylene reportedly reduced risk estimates relative to those obtained from linearized models (24, 69).

BBDR models are intended to make mechanistic risk assessment models reflect specific biological processes (70). This type of model was reportedly applied effectively to epidemiological data on retinoblastoma and to animal data on kidney and liver tumors in the acetylaminofluorene "megamouse" study and to bladder cancer in saccharin-exposed rats (25, 71, 72). The carcinogenic risk assessment guidelines proposed by the USEPA (16) indicate that the biologically based or case specific model is the preferred approach for evaluating dose–response relationship for carcinogens. In the absence of such data, the use of a linear or nonlinear approach is recommended, depending on the mode of action of the chemical.

A recent comparative evaluation of threshold and nonthreshold risk assessment methods for establishing safe occupational exposure limits for vinyl halides (vinyl chloride, vinyl bromide, and vinyl fluoride) was reported (73). Safe levels derived from nonthreshold methods ((LMS model and BMD with linear extrapolation) were two- to three-fold below 0.5–5 ppm, whereas those derived by using the threshold approach methods (LOEL/LOEL and BMD uncertainty factor approaches) fell within the 0.5–5 ppm range. Similar results were reported for vinyl bromide and vinyl fluoride. The authors concluded that these results undermine the USEPA default assumption of nonthreshold for vinyl halides and support the threshold methods because reducing occupational exposure to vinyl chloride to 0.5–5 ppm has, so far, successfully eliminated vinyl chloride liver angiosarcoma.

6.3 Unified Approach for Threshold and Nonthreshold Effects Using Benchmark Dose and Uncertainty Factors

Recently, Gaylor et al. (57) proposed adopting a unified approach for establishing human exposure guidelines for both cancer and noncancer end points. They suggest that a lower confidence limit on the estimated dose to produce an excess incidence of adverse outcome in 10% of the individuals in human studies or of the test subjects in animal studies be used as a benchmark dose. Then, uncertainty factors can be applied to this dose. For severe irreversible adverse health effects, they recommend a total default uncertainty factor for animal data of the order of 10,000 which is comparable to current environmental guidelines, and for reversible adverse effects, a smaller uncertainty factor of 1000, which is comparable to that often used for LOAEL. The use of the benchmark dose approach has been indicated for both genotoxic and nongenotoxic carcinogens in the USEPA (16) proposed guidelines for carcinogenic risk assessment.

6.4 Occupational Versus Environmental Exposure Limits

Due to differences in population characteristics, exposure characteristics, risk assessment methods used to derive exposure limits, and acceptable risk levels, ambient air exposure standards are usually significantly lower than occupational exposure limits for the same chemicals. Ambient air standards intend to protect all people, including high risk groups such as children and the elderly, from continuous exposure over their life time and also take into consideration exposure from other media (water, soil, food). In the case of occupational exposure standards, it is believed that workers constitute a subpopulation that is healthier than the general population, and exposure is assumed to occur during an 8-h workday and 40-h workweek over a working life span of 48 years.

Use of Toxicological Data in Evaluating Chemical Safety

7 Uncertainties in Chemical Safety Evaluation
In evaluating chemical hazards, it is most important that all sources of uncertainties are identified so that the limitations of the results are clearly understood. There are many sources of uncertainties, including extrapolation from high doses in animals to low doses in humans and across routes of administration, interspecies variability in biokinetics and mechanisms of toxicity, interindividual variation in biological response, poor specification of exposure conditions (concentration, duration, frequency and route of exposure, chemical identity), deficient control groups, and confounding factors in epidemiological studies. In some cases, an impact analysis of uncertainties can be conducted.

Use of Toxicological Data in Evaluating Chemical Safety

8 Global Harmonization of Hazard Classification System (GHS)
Hazard classification systems have been developed in various jurisdictions to provide information on the toxic effects of chemicals to protect human health. They are used for communicating information on chemical hazards to workers or other end users so that appropriate precautions can be taken for safe chemical use. Hazard classification systems are usually incorporated into sector-specific regulations for transport, consumer products, and occupational health. Due to differences in chemical use and exposure, hazard classification schemes vary between sectors and within sectors among countries.

Toxicity classification criteria for chemicals in the workplace are included in the OSHA Hazard Communication Standard (29 CFR 1910.1200) and the Canadian Workplace Hazardous Materials Information System (WHMIS) legislation (74). In general, chemicals are categorized by toxic end points (e.g., acute toxicity, cancer, irritation, sensitization etc.) based on evaluation of the toxicological evidence against set classification criteria. Untested product mixtures are classified by the toxic effects of the ingredients using cutoff concentrations. Toxicity classification systems are usually based on the inherent toxicity of the chemical (e.g., cancer induced in rodents via oral administration) rather than on the risks that a chemical poses to human health under given exposures.

The OECD Advisory Group on Harmonization of Hazard Classification and Labeling was established 1994 to develop proposals for a harmonized classification system for the hazards of chemicals to human health and the environment (2). Member countries in this initiative include the United States, Canada, and the European Community (EC). Recently, the OECD released a report endorsing harmonized hazard classification criteria for acute toxicity, skin irritation/corrosion, eye irritation/corrosion, respiratory or skin sensitization, mutations in germ cells, cancer, and reproductive toxicity. The acute toxicity criteria in several jurisdictions and those endorsed by the OECD are compared in Table 10.3 (74). The OECD harmonized hazard classification system may eventually be implemented globally.

Table 10.3. Comparison of Acute Oral, Dermal, and Inhalation Toxicity Criteria among U.S. OSHA, CANADIAN WHMIS, EC, AND OECD*[abcd]*

Category	Oral LD_{50} Rat (mg/kg)	Dermal LD_{50} Rat or Rabbit (mg/kg)	Inhalation LC_{50} Rat, 4-h Gas (ppm)	Inhalation LC_{50} Rat, 4-h Vapor (ppm)	Inhalation LC_{50} Rat, 4-h Dust/Mist/Fume (mg/L)
OSHA					
Highly toxic	≤ 50	≤ 200	≤ 200	≤ 200	≤ 2
Toxic	>50 ≤ 500	>200 ≤ 1000	>200 ≤ 2000	>200 ≤ 2000	>2 ≤ 20
WHMIS					
Very toxic	≤ 50	≤ 200	≤ 2500	≤ 1500	≤ 0.5
Toxic	>50 ≤ 500	>200 ≤ 1000	—	>1500 ≤ 2500	>0.5 ≤ 2.5
EC					
Very toxic	≤ 25	≤ 50			≤ 0.25
Toxic	>25 ≤ 200	>50 ≤ 400			>0.25 ≤ 1.0
Harmful	>200 ≤ 2000	>400 ≤ 2000			>1 ≤ 5
OECD					
Class 1	5	50	100	0.5 mg/L	0.05
Class 2	50	200	500	2.0 mg/L	0.5
Class 3	300	1000	2500	10 mg/L	1.0
Class 4	2000	2000	5000	20 mg/L	5.0
Class 5	5000				

[a] Material in this table was derived from OSHA Hazard Communication Standard (29 CFR 1910.1200), WHMIS Resource Manual (73), European Community Directive 67/548/EEC (Annex VI) and OECD (2).

[b] OSHA LC_{50} values are for 1-h continuous inhalation (all the other LC_{50} values are for 4-h).

[c] OECD criteria are upper limit cut-off values for each class.

[d] EC inhalation LC_{50} values for gas or vapor in mg/liter/4-h are ≤0.5 for very toxic, >0.5≤2 for toxic, and >2≤20 for harmful.

Appendix 1: Basic Toxicological Principles

The following is a summary of basic toxicological principles that are covered comprehensively in toxicology and pharmacology textbooks (7, 75).

Routes of Exposure and Fate in the Body

A chemical has to enter the body and reach sites of action ("receptors") at a concentration and for a length of time sufficient to produce toxic effects. Inhalation and absorption through the skin are the main routes of exposure to chemicals in the workplace. Accidental poisoning usually occurs by ingestion.

Metabolism is a term that refers to the total fate of a chemical in the body, including its absorption into systemic circulation, distribution to organs and tissues, biotransformation, and excretion. Absorption of a chemical into the blood and distribution in the body depend on the physicochemical characteristics of the substance. Depending on the specific chemical, biotransformation of the chemical usually occurs primarily in the liver and can result in chemical detoxification or activation to a toxic metabolite. Toxic chemicals and their metabolites are excreted via the kidneys or the lungs.

Toxicokinetics

Toxicokinetics quantitatively describes the rates of the various steps of chemical desposition in the body, absorption, distribution, and elimination by biotransformation and excretion. Mathematical models are used to describe the fate of chemical in the body and their validity is tested by comparing them with experimental observations. Variation in toxicokinetics among individuals and species plays an important role in differences in toxic effects.

Exposure Duration and Frequency

The terms acute, subacute, subchronic, and chronic refer to the duration of exposure to chemicals in animal studies via any route of exposure. Acute is defined as exposure to a chemical for less than 24 h. Repeated exposure for one month or less is subacute exposure, for one to three months is subchronic exposure, and for more than three months is chronic exposure. For many chemicals, the toxic effects that are produced following acute exposure are different from those produced by repeated exposure. To evaluate the toxic potential of a chemical, therefore, data from both acute and repeated exposure studies are required. In general, repeated exposure is a more common form of human exposure to chemicals and can result in delayed toxic effects.

The frequency of exposure is another important factor. Severe toxic effects that are produced by a single dose of a chemical may not occur if the total dose is divided and administered at several intervals. Depending on the elimination rate of the chemical from the body and the frequency of the dosing intervals, the chemical may or may not reach a toxic concentration. Even if the chemical does not accumulate, it still may be that some tissue damage occurs. The question is whether the interval between doses is sufficient to allow for complete repair. Chronic toxic effects, therefore, may be due to bioaccumulation of the chemical, to irreversible toxic effects, or to insufficient time for tissue recovery between dosing intervals.

Toxic Effects

Chemicals can produce a wide spectrum of undesirable effects ranging from deleterious (adverse, toxic) to slightly toxic. For many chemicals, toxic effects from acute exposure are different from those produced by chronic exposure. For example, acute exposure to benzene results in central nervous system depression, but chronic exposure can cause leukemia. Toxic effects may be reversible or irreversible and may occur immediately after exposure or after a long latency period as in the case of carcinogens. The effects may be local at the site of entry as seen with substances that are corrosive to the skin or irritating to the respiratory tract. Systemic effects require absorption and distribution of the chemical to a distant site where toxic effects occur. Usually, chemicals elicit their toxicity in specific sites or tissues called target organs.

Dose–Response Relationships (DRR)

The fundamental concept in toxicology is the dose–response relationship, which correlates the characteristics of exposure with the spectrum of effects. Although conceptually the same, in practice, there are two types of DRR:

1. “graded,” which describes the response of an individual to varying doses of a chemical, characterized by a dose–related increase in the severity of response; and
2. “quantal,” which characterizes the distribution of responses to different doses in a population by determining the dose required to produce a specific toxic effect (end point) in each individual; the presence or absence of a specific toxicity end point, such as death or a disease state, is called a quantal or all-or-none response.

The dose–response relationship assumes a causal association between the dose and response. The quantal dose–response–relationship is used extensively in toxicology, and the shape of the curve has

important implications in chemical risk assessment. It is customary to plot the response against the logarithm of the dose, and the resulting curve is typically S-shaped or sigmoidal (see Fig. 10.4a). Displaying the same data in a frequency histogram shows a normal frequency distribution bell-shaped curve (see Fig. 10.4b). The data can be further displayed in different ways for statistical analysis. Although typical, the dose–response relationship is not always normally distributed. Several concepts emerge from the classical dose–response curve of a normally distributed population (see figure 4) that are integral to evaluating chemical safety:

1. **The Median Toxic Dose (TD_{50}) and Lethal Dose (LD_{50})**

   The sigmoid curve has a relatively linear portion between 16 and 84% that represent the limits of one standard deviation of the mean. It is possible to statistically derive the single dose of a substance that would be expected to cause a toxic effect in 50% (or other percentage) of the subjects tested. If the response is mortality, then this dose is called the median lethal dose, or LD_{50} (LC_{50} is the median lethal concentration in inhalation studies). A relative toxicity index can be derived from the ratio of the TD_{50} of two different substances that produce an identical response or the ratio of the same chemical necessary to yield different toxic effects. The slopes of the curves, however, may differ.
2. **Threshold Dose, Lowest Observed Adverse Effect Level (LOAEL), and No Observed Adverse Effect Level (NOAEL)**

   A normally distributed sigmoid curve approaches 0% as the dose is decreased but theoretically never passes through 0%. The lowest dose of a chemical that evokes a quantal response is called the threshold dose, even if it cannot be measured experimentally. The identification of a threshold dose depends on the specific response measured, the sensitivity of the measurement, and the number of subjects. The LOAEL is the lowest experimentally measured dose that produces a toxic effect. The NOAEL is the experimentally measured dose that does not produce any adverse effect (Fig. 10.4a).

   The biological basis of thresholds for acute responses is well established and often is based on mechanistic information. The existence of a threshold for chronic responses is not as well defined, especially for carcinogens. Carcinogenic effects are often considered linear at low doses and do not exhibit a threshold. Thus, all doses are associated with a risk of cancer. Different methods of deriving “safe” exposure limits are applied to threshold effects and nonthreshold effects.
3. **Interindividual Biological Variation**

   It is evident from the normal frequency distribution curve (Figure 10.4b) that there are differences in susceptibility to chemicals among individuals in a population. Subjects who respond at the low end of the curve are hypersusceptible and those at the high dose end are resistant. It is important that individual differences and also species differences are considered when assessing chemical safety.

Silica and Silica Compounds
Richard Lemen, Ph.D., Eula Bingham, Ph.D.

1 Introduction

The uses of silica and the potential health hazards for workers or others exposed to dust particles date back thousands of years and are documented. Hippocrates and Pliny both mentioned silica's ability to cause disease and Pliny even described miners who used forms of respiratory protection (1). In 1556, Agricola described in *De Re Metallica*, women living in the Carpathian mountains who oftentimes would have as many as seven different husbands in their lifetimes because the men who worked in the local mines were dying of pulmonary disease at very young ages (2, 3). In his 1713 edition of *De Morbis Artificum*, Ramazzini discusses an observation by Diemerbroeck from Holland

who gives an extremely graphic description of the effects of exposure to silica on stonecutters (4). “Diemerbroeck gives an interesting account of several stonecutters who died of asthma; when he dissected their cadavers he found, he says, piles of sand in the lungs, so much of it that in cutting with his knife through the pulmonary vesicles he felt as though he were cutting a body of sand.”

The first study of silicosis, in the time of the industrial revolution, was that of Johnstone in 1796 who noted the high mortality of needlepointers at Redditch, England (5). Knight first wrote of silica-induced disease in Sheffield during the early 1800s and later Thackrah, acknowledging Knight's work, described the dangers of sandstone dust in mining compared to the harmlessness of limestone dust and noted that bricklayers and limestone workers were long-lived whereas the sandstone masons usually died at an early age (6). Flint knappers, the makers of flints for flintlock guns, had high rates of silica-induced disease. Studies of the English and French knappers found that more than 75% died of “phthisis” compared to less than 10% in the general rural populations (7). Phthisis is an obsolete term for tuberculosis of the lungs derived from Greek meaning “a wasting away” or “consumption” (8). South African women who used sandstone grindstones for maize and corn developed diseases similar to those developed by the makers of the grinding stones (9, 10). Silicosis comes from the Latin, *silex*, meaning flint and is defined as “a pathological condition of the lungs due to inhalation of particulate matter containing free or uncombined silica, silicon dioxide, ... ” (5). The term's first use is attributed to Visconte in 1870 (5). By 1918, English workers received compensation for disability as a result of silicosis (11). Silicosis is a pneumoconiosis, but the terms must not be used synonymously. Silicosis, of all the pneumoconioses, has probably claimed the largest number of victims, either alone or in combination with tuberculosis, a condition frequently associated with silicosis (5). Betts gave the first description of acute silicosis in the United States (12). In 1932, the American Public Health Association (APHA) developed the definition for the fibrotic lung disease silicosis as

A disease due to breathing air containing silica (SiO_2), characterized anatomically by generalized fibrotic changes and the development of miliary nodulations in both lungs, and clinically by shortness of breath, decreased chest expansion, lessened capacity for work, absence of fever, increased susceptibility to tuberculosis (some or all of which symptoms may be present) and by characteristic X-ray findings.” (13).

In 1917, Dr. Alice Hamilton described the life of stonecutters in the Barre, Vermont area of the United States. She quoted a stonecutter as saying “sure I know it will get me. It got my father, it's got my older brother, it's only a question of time when it will get me.” Dr. Hamilton went on to describe stonecutters as having a high standard of living and decidedly above average compared to manual workers in education and intelligence, but she described the site of the mill as “dreadful” and of men “ ... carving tombstones and, as they did it, preparing themselves for their own graves.” Dr. Hamilton was so incensed at the fate of these workers that she could not contain herself and implored, in a speech, to the Consumers' League in Baltimore “ ... begged my hearers never to fulfill their duty to their beloved dead by means of a granite tombstone” (14). Dr. Hamilton went on to describe the introduction of the air hammer to the granite mines of the Barre, Vermont area and how the ensuing dust had given the Barre stonecutters a death rate from tuberculosis of 60.6 per 1,000, whereas the rural Vermont death rate was only 1.5 per 1,000 (14). Later the United States Public Health Service studied these workers and issued a report giving preventive measures to combat silicotuberculosis and silicosis resulting from the inhalation of silica-containing dusts for Barre workers and also for other exposed workers (15).

Silica is a natural mineral composed of silicon dioxide, which occurs in either the crystalline or amorphous form. Silica makes up 21% of the earth's crust and is the most common of all chemical compounds (16). Pure silicon dioxide crystals are found naturally in three polymorphic forms:

quartz, the most common; tridymite; and cristobalite. Each of the three is important to human health and make up the crystalline form of silica (16, 17). Both tridymite and cristobalite appear more fibrogenic than quartz (18). Silicon dioxide is an acidic oxide, which is practically insoluble in water, but can be attacked by hydrogen fluoride (16). The amorphous form of silicon dioxide, also called vitreous silica, does not pose a significant threat to human health because it has not been associated with pneumoconiosis. In the few reports that have claimed an association between amorphous silica and disease, the truly amorphous nature of the material has been in doubt (19). Therefore, for the purposes of this discussion, the review and comments relate to quartz (the most common silicate), which is sometimes called free silica.

Human exposures to silica were encountered from the first time man dug into the ground because silica deposits are found in every land mass and stratum from every era and period of geological time (20, 21). The use of silica in the production of glass probably dates back thousands of years (22).

It is difficult to get accurate figures on the use and production of silica because it is such a universal material and has a multitude of uses including glassmaking, ceramic making, foundry castings, abrasives, sandblasting, hydraulic fracturing, production of silicon and ferrosilicon metals, silica gel desiccants, builders for detergents, filtering material, furnace linings and beds, and fine silica as fillers in paints, rubber, paper, plastics, asphalt, scouring powders, cements, etc. Large quartz crystals are used in jewelry and for electronic applications, this latter application resulted from discovery of the crystal's dielectric and piezoelectric properties in 1880 (17). More recently, quartz crystals are being used in fiber optics (23).

The uses of silica are quite varied and so is the production of silica. Processing operations depend upon the nature of the deposit as well as the desired end product and include crushing, secondary milling to refine particle size, and other methods to further refine the particles (22).

World production was estimated by Davis and Tepordei at 182 million tons in 1983, Asia was the largest producer, followed by Europe, South America, North America, and Africa. This production pattern has been relatively stable for the last 10–15 years (22). The largest deposits of quartz crystals are in Brazil; minor deposits are in the United States, Angola, India, and Madagascar, and the mining methods are still quite primitive, most are extracted by hand tools (21, 23, 24). Fine particles of silica flour are used industrially as abrasive cleaners and as inert fillers in toothpastes, scouring powders, metal polishes, paint, wood fillers and road-surfacing mixtures, and in some foundry processes (25).

When the pneumatic hammer drill was introduced in 1897, it produced so much dust that it was named a “widow-maker.” Sandblasting was introduced about 1904 and resulted in numerous cases of silicosis. In 1936, British sandblasters, many of whom had acute silicosis, were said to survive an average of ten years compared to 40 years for those with chronic silicosis (26). In 1929, Sutherland and Bryson (27) and Sutherland et al. (28) detected silicosis by X ray in 25% of sandstone workers and 53% of granite workers.

Case reports and surveys by the U.S. Bureau of Mines and the Public Health Service documented the occurrence of pulmonary disease in various worker groups exposed to silica. Public attention was galvanized by the Gauley Bridge (WV) outbreak of acute silicosis among tunnelers of nearby pure quartz. This incident provided an impetus for industrial health reform in the United States and led in 1937 to dust control standards and to the Walsh–Healy legislation (29). Silicosis rates among granite workers in Vermont decreased dramatically during subsequent decades. From that time to the present, standards have been under continued reevaluation, and decremental changes in permissible exposures to “free” silica dust have reduced but have not eliminated silicosis as a health hazard.

Silica and Silica Compounds

Richard Lemen, Ph.D., Eula Bingham, Ph.D.

1.0 Silicon Dioxide
Silicondioxide has three main forms: silica, crystalline quartz; silica, crystalline cristobalite silica, crystalline tridymite is a mixture.
1.0.1 CAS Number:
[*14808-60-7*] (crystalline quartz or a-quartz); [*14464-46-1*] (crystalline cristobalite or a-cristobalite); [*15468-32-3*] (crystalline tridymite)
1.0.2 Synonyms:
Chalcedony; chert; coesite; cristobalite; cryptocrystalline silica; flint; jasper; microcrystalline silica; novaculite; quartz; quartzite; sandstone; silica sand; stishovite; tridymite; tripoli
1.0.3 Trade Names:
BRGM; D & D; DQ12; Min-U-Sil; Sil-Co-Sil; Snowit
1.0.4 Molecular Weight:
60.085 except tridymite, which is a mixture.
1.0.5 Molecular Formula:
SiO_2
1.1 Chemical and Physical Properties
1.1.1 General (Table 11.1).

Silica and Silica Compounds
Richard Lemen, Ph.D., Eula Bingham, Ph.D.

2.0 Amorphous Silica
2.0.1 CAS Number:
[*7631-86-9*]
2.0.2 Synonyms:
Amorphous silica; colloidal silica; diatomaceous earth; diatomite; fumed silica; fused silica; kieselguhr; opal; precipitated silica; silica gel; silica glass; silica soot; vitreous silica
2.0.3 Trade Names:
Aerosil; Cab-O-Sil; Celite; Ludox; Silcron G-910
2.0.4 Molecular Weight:
60.1
2.0.5 Molecular Formula:
SiO_2
2.1 Chemical and Physical Properties
2.1.1 General
2.2 Production and Use
A number of silicate or aluminosilicate minerals are commercially important in their own right and/or as starting materials for manufacturing other compounds or materials. These minerals encompass a wide range of chemical compositions and display a variety of physical properties. Thus, for example, the materials discussed following range from minerals that occur naturally as loose fibrous networks, for example, erionite, to dense cohesive clays, for example, kaolin and attapulgite. Occupational health interest in these minerals stems from two concerns. First, they may be toxic in their own right. Second, some of them may occur naturally in association with other silicon-containing minerals that are toxic, such as crystalline silica or asbestos. For the second reason, many epidemiological studies of workers who are occupationally exposed to these minerals are difficult to interpret because observed health effects may be attributable to any or all of the components of the

mixed exposure. For example, the observation of increased incidences of malignant and nonmalignant respiratory diseases among workers exposed to talc may be attributable to asbestos in the talc or to talc itself.
2.4 Toxicity
Not all forms of silica are equally pathogenic. In general, the relatively insoluble forms of amorphous silica can be fibrogenic but are less so than pure crystalline samples. Both fused (amorphous) and unfused (crystalline) silica produced nodules in rabbits following intraperitoneal injection of 200 mg dust, but the nodules produced by crystalline quartz were larger at three months; this difference became more marked with time (122). In rabbits, inhalation of 40 mg/mL amorphous silica for up to 1100 days caused only diffuse tissue reaction (123). However, intratracheal injection of amorphous silica (particles, < 1 mm) produced lesions on the lymph nodes in rats six months after infection, which were described as identical to those produced by quartz dust (124). Similarly, typical silicotic lesions have been produced in rats by intraperitoneal injection of 50 mg amorphous silica (125). Following exposure of rats by intraperitoneal injection, intratracheal injection, or inhalation of a variety of silica preparations, it was reported that solutions of silicic acid and silica gels were nontoxic and nonfibrogenic, that colloidal amorphous silica was toxic but not fibrogenic, and that crystalline quartz produced a maximal fibrotic response (126). The effects of samples of silica that were either completely amorphous or had a low content of crystalline material have been examined in rats, guinea pigs, rabbits and monkeys by a number of authors (127–140).

Silica and Silica Compounds
Richard Lemen, Ph.D., Eula Bingham, Ph.D.

3.0 Erionite
3.0.1 CAS Number:
[*66733-21-9*]
3.1 Chemical and Physical Properties
3.1.1 General Prismatic crystals in radiating groups; finely fibrous or wool-like; erionite is not known in other than fibrous form (141).

Density: 2.02–2.08
Color: White

3.2 Production and Use
Erionite is a natural zeolite consisting of aluminosilicate tetrahedra in finely fibrous or wool-like form. The name derives from the Greek word for wool. When ground, erionite particles resemble amphibole asbestos fibers morphologically.

Worldwide production of natural zeolites increased dramatically in 1989 and was estimated at 250,000 tons (142), of which 12,000 tons was mined in the United States. Until 1990, erionite was mined at two locations in the United States, but these operations have been stopped. No known production of erionite takes place in the United States now.

Natural zeolites have a number of commercial uses based on their ability to adsorb molecules selectively from air or liquids. They are used in wastewater treatment, in odor control products, and in cat litter. Historically, erionite was used as a metal-impregnated catalyst in a hydrocarbon cracking process. Now, however, because of health concerns described following, there are no known commercial uses of erionite in the United States.
3.3 Exposure Assessment
3.4 Toxicity
Erionite is of particular occupational health interest because of experimental and epidemiological

evidence that it is similar to asbestos in inducing mesothelioma and, perhaps, lung cancer. Groups of 40 (20 per sex) Fischer 344 rats were exposed to either fibrous erionite, a synthetic nonfibrous zeolite that has the same composition as erionite, or crocidolite asbestos by inhalation for 7 h/day, 5 days/week for 1 year (143). Pleural mesotheliomas were found in 27 of 28 rats exposed to fibrous erionite that survived for at least 12 months. One pulmonary adenocarcinoma and one mesothelioma were observed in rats exposed to nonfibrous synthetic erionite and one pulmonary squamous-cell carcinoma was observed in the rats exposed to crocidolite asbestos. In other studies in which erionite was administered to rats and mice by intrapleural or intraperitoneal administration, high incidences of mesotheliomas were produced (144).

Pulmonary and pleural fibrosis have been observed in humans living in areas where there are natural deposits of fibrous erionite (144). High mortality due to malignant pleural mesothelioma was noted in three Turkish villages where the environment was naturally contaminated by erionite. Erionite had been used in construction. Descriptive studies conducted in these villages strongly suggest that the incidences of mesothelioma and nonmalignant radiographic changes in the lung and pleura among residents are correlated with exposure to erionite. The IARC working group concluded that there was sufficient animal and human evidence of the carcinogenicity of erionite (144).

Erionite is a striking illustration that the ability to cause mesothelioma and nonmalignant pulmonary and pleural fibrosis is not confined to minerals of the serpentine and amphibole groups, that is, asbestos. Clearly the physical form of the fibrous material is as important in determining its biological activity as its chemical and mineralogical characteristics.

Silica and Silica Compounds
Richard Lemen, Ph.D., Eula Bingham, Ph.D.

4.0 Wollastonite
4.0.1 CAS Number:
[*13983-17-0*]
4.0.2 Synonyms:
Aedelforsite; gillebächite; okenite; rivaite; schalstein; tabular spar; vilnite
4.0.3 Trade Names:
Cab-O-Lite; Casiflux; F1; FW50; FW200; FW325; NCI-C55470; Nyad; Nyad G; Nycor; Tremin; Vansil; Wollastokup
4.0.4 Molecular Weight:
NA
4.0.5 Molecular Formula:
$CaSiO_3$

4.1 Chemical and Physical Properties
4.1.1 General Crystals commonly tabular; usually massive, cleavable to fibrous; also granular and compact. Twinning on (100) common. Structure changes to monoclinic at 1150°C (1120°C, 145); this form is sometimes called para-wollastonite or wollastonite-2M (146, 147). A 10% water slurry has a naturally high pH (9.9) (145).

Hardness: 4.5–5 on Mohs' scale
Density: 2.87–3.09
Specific Gravity: 2.1
Water Solubility: < 0.1 g/100 mL at 21°C
Color: Brilliant white; may be greyish, pale green or brownish with impurities (21, 146)

4.2 Production and Use
Wollastonite is a natural calcium silicate that typically occurs in deposits with other silicate minerals. When crushed, it tends to cleave into particles that have length to diameter ratios of 7 or 8 to 1. Fibrous forms of wollastonite are not uncommon.

The largest commercially exploited natural deposits of wollastonite are in the United States and Finland. Significant commercial production began in the United States in about 1950. The United States is currently the largest producer. It is estimated that 83,000 tons was produced in the United States in 1983 (144). There has been a dramatic increase in use (> 10% per year) in recent years, and production was estimated at 180,000 tons in 1988 (148).

Wollastonite was first mined for the production of mineral wool. The most important use at present is in ceramics which accounts for more than half of the consumption. Ceramic materials may include up to 70% wollastonite. It is also used as an extender in paints and coatings and as a filler in plastics. Some of the recent increase in use is attributable to its increasing importance as a replacement for asbestos. It is combined with binders, fillers, and organic fibers to make heat containment panels, ceiling and floor tiles, brake linings, and high-temperature appliances.
4.4 Toxicity
Occupational exposures to wollastonite involve a significant exposure to fibers (67). Fiber concentrations ranging from 1 to 45 fibers/cm^3 have been measured in air at a Finnish quarrying operation and concentrations between 8 and 37 fibers/cm^3 were measured in the flotation and bagging plant. Fiber concentrations in the air in a mill in the United States ranged from 0.8 to 48 fibers/cm^3.

Very little relevant information is available about the potential health effects of wollastonite. Intrapleural administration of wollastonite to rats resulted in a significant increase in pleural sarcomas when the implanted material contained fibers > 4 mm long and < 0.5 mm in diameter (67). Mild changes characteristic of pneumoconiosis and pleural thickening have been seen in some workers exposed to wollastonite at facilities in Finland and the United States (144). In one small cohort mortality study of workers at a Finnish quarry, there was no indication of increased cancer mortality. In view of the increase in the use of wollastonite as an asbestos replacement, much more research is needed regarding its potential health effects.

Silica and Silica Compounds
Richard Lemen, Ph.D., Eula Bingham, Ph.D.

5.0 Attapulgite
5.0.1 CAS Number:
[*12174-11-7*]
5.0.2 Synonyms:
Palygorskite
5.0.3 Trade Names:
Attaclay; Attacote; Attagel; Attasorb; Diluex; Min-U-Gel FG; Permagel; Pharmasorb-colloidal; 2000/P-RVM; RVM-FG; X-250; Zeogel
5.0.4 Molecular Weight:
NA
5.0.5 Molecular Formula:
$(Mg, Al)_2 Si_4 O_{10} (OH) \cdot 4H_2O$
5.1 Chemical and Physical Properties
5.1.1 General The structure of attapulgite is similar to that of minerals of the amphibole group and differs only in minor respects from that of sepiolite. It occurs as elongated, lath-shaped crystals in

bundles that comprise thin sheets composed of minute interlaced fibers.

Hardness: Soft
Density: 2.2
Color: White, gray; translucent; dull

5.2 Production and Use
This material is closely related to sepiolite and is categorized as a hormitic clay. Attapulgite has a structure similar to minerals of the amphibole group. This structure results in long, thin crystals that are similar to chrysolite asbestos fibrils (144). Attapulgite occurs in large deposits in the southeastern United States. The term “fuller's earth” has been used to describe commercially mined absorbent clays in the United States, and most of this material is attapulgite.

Worldwide attapulgite production in 1983 was estimated at about 1.1 million tons, of which 84% came from the United States (144). The primary use of attapulgite is as an animal waste absorbent (cat litter). Other important uses of attapulgite in the United States are as a component of drilling muds, as oil and grease absorbents, and in fertilizer and pesticide formulations.
5.3 Exposure Assessment
5.3.3 Workplace Methods No ACGIH TLV standards or guidelines have been developed for attapulgite (149).
5.4 Toxicity
The results of long-term surveillance of workers at two sites in the United States where attapulgite was mined and milled indicated that there was an increased prevalence of pneumoconiosis and that the incidence increased with age and with duration of exposure (144). A decrease in pulmonary function was associated with total cumulative exposure to respiratory dust in the workers at one of these facilities.

The evidence relevant to the possible carcinogenic effects of attapulgite was reviewed by the IARC working group (144). Studies in which attapulgite was administered to rats by either intraperitoneal or intrapleural administration indicated that attapulgite containing significant number of fibers > 5 mm long produced mesotheliomas and sarcomas. A single epidemiological study of miners and millers exposed to high concentrations of attapulgite dust for long durations indicated that there was increased mortality from lung cancer, but no information on smoking behavior was determined. The working group concluded that there was limited evidence that attapulgite was carcinogenic in experimental animals but that the human evidence was inadequate to support a conclusion.
5.5 Standards, Regulations, or Guidelines of Exposure
No exposure standards or guidelines have been developed for attapulgite by OSHA, NIOSH, or ACGIH (150–152).

Silica and Silica Compounds
Richard Lemen, Ph.D., Eula Bingham, Ph.D.

6.0 Sepiolite
6.0.1 CAS Number:
[*18307-23-8*], [*15501-74-3*]
6.0.2 Synonyms:
Meerschaum
6.0.3 Trade Names:
NA
6.0.4 Molecular Weight:

NA
6.0.5 Molecular Formula:
$Mg_2Si_3O_8 \cdot 2H_2O$
6.1 Chemical and Physical Properties
6.1.1 General Sepiolite is similar to attapulgite but has an additional SiO_4 tetrahedron at regular intervals on the chain, so that the united cell is about 50% larger than that of attapulgite (21); usually clay-like, nodular and fibrous; also compact massive (meerschaum) or leathery (mountain skin) (153, 154).

Hardness: 2–2.5 on Mohs' scale

Density: ~2

Color: White with tints of grey-green or red; also light yellow

6.2 Production and Use
A particularly pure form of sepiolite mined in Europe and the Middle East is known as "meerschaum" and has been used historically for carving pipes and cigarette holders. Sepiolite production in 1983 was less than half of the estimated 1.1 million of attapulgite in the world. A primary use of sepiolite was as an animal waste absorbent (cat litter).
6.3 Exposure Assessment
6.3.1 Workplace Methods No ACGIH TLV standards have been developed for sepiolite (155).
6.4 Toxicity
Little information is available regarding the potential effects of sepiolite. A limited study of workers and residents in a village in Turkey who were exposed to sepiolite during mining and trimming indicated that exposed individuals did have clinical and radiological evidence of pulmonary fibrosis but no cases of mesothelioma or other pleural diseases were observed. The IARC working group concluded that the animal evidence was inadequate and that there was no human evidence available to evaluate the potential carcinogenicity of sepiolite (144).
6.5 Standards, Regulations, or Guidelines of Exposure
No exposure standards or guidelines have been developed for sepiolite by OSHA, NIOSH, or ACGIH (150–152).

Silica and Silica Compounds
Richard Lemen, Ph.D., Eula Bingham, Ph.D.

7.0 Kaolin
7.0.1 CAS Number:
[*1332-58-7*]
7.0.2 Synonyms:
Kaolinite; china clay; bolus alba; porcelain clay; aluminum silicate hydroxide; Kaopectate; aluminum silicate (hydrated); aluminum silicate dihydrate
7.1 Chemical and Physical Properties
Kaolin is a hydrous aluminosilicate mineral that is found in large natural deposits of kaolinite in Georgia, South Carolina, and Texas (156). A typical kaolin contains 38.5% by weight aluminum oxide, 45.5% silicon dioxide, 13.9% water, and 1.5% titanium dioxide, with small amounts of calcium, magnesium, and iron oxides. A single crystal consists of a layer of silicon dioxide that is covalently bonded to a layer of aluminum oxide. When the clay is processed by centrifugal classification, it can be separated into fractions consisting of stacks of the hexagonal plates (< 2 mm in diameter and particles greater than 2 mm in diameter consisting of stacks of the hexagonal plates). Kaolin, as mined, contains other minerals including quartz, muscovite, and altered feldspars (157). The purification process removes much of the crystalline silica, so that commercial products

typically contain less than 3% crystalline silica and the respirable dust contains less than 1%. On the other hand, if kaolin is calcined, some of it may be converted to cristobalite.

Color: white to yellowish or grayish powder (149)

7.2 Production and Use
Domestic production of kaolin was estimated at 8.6 million tons in 1988 (158). More than 80% was produced in Georgia. A major use of kaolin is as a filter and a pigment in the manufacture of coated paper. Kaolin is also used as an extender and pigment in paints, in ceramics, rubber, thermosetting resins, and adhesives.
7.3 Exposure Assessment
7.3.3 Workplace Methods The recommended methods for determining workplace exposures to kaolin are NIOSH Method #0500 for total dust and #0600 for respirable dust (31).
7.4 Toxicity
The health effects of exposure to kaolin dust by inhalation have not been adequately studied. Historically, reports of respiratory diseases among workers exposed to kaolin were attributed to possible contamination of the kaolin by crystalline silica. Before 1991, the ACGIH TLV for kaolin was that for a nuisance dust, namely, 10 mg/m^3 TWA. However, in 1991, ACGIH reviewed the available information and issued a notice of intended change (157). The ACGIH cited a number of case reports and epidemiological studies of workers who were exposed to kaolin during mining and processing in Georgia. For the most part, Georgia kaolinite contains little or no crystalline silica. In workers who were exposed to kaolin dust during the milling and bagging of kaolin, there was an increased prevalence of pneumoconiosis. The prevalence of pneumoconiosis was correlated with both the intensity and duration of exposure. Pneumoconiosis incidence was not increased in open pit miners, who were exposed to significantly lower dust concentrations than workers involved in milling, bagging, and loading. As with many epidemiological studies of the effects of respiratory particulate matter, quantitative data on past exposure for these workers were of poor quality, but exposure levels in the past were unquestionably very high.

There are no reports to suggest that workers exposed to kaolin free silica have a history of malignant respiratory diseases. The carcinogenic potential of kaolin has not been systematically studied in either experimental animals or exposed workers, however. Based on the available evidence that kaolin induces pneumoconiosis.
7.5 Standards, Regulations, or Guidelines
NIOSH has a recommended exposure limit of 10 mg/m^3 (total); 5 mg/m^3 (resp); OSHA has a standard of 15 mg/m^3 (total); 5 mg/m^3 (resp) (149). The ACGIH TLV standard is 2 mg/m^3 for matter containing no asbestos and <1% crystalline silica in the respirable fraction (157). It may be carcinogenic for humans but cannot be assessed conclusively because of lack of data. Pneumoconisis is the critical effect (155).

Silica and Silica Compounds
Richard Lemen, Ph.D., Eula Bingham, Ph.D.

8.0 Perlite
8.0.1 CAS Number:
[*130885-09-5*]
8.1 Chemical and Physical Properties
8.1.1 General Perlite is a natural glass formed by volcanic action. It is a sodium potassium aluminosilicate that has an amorphous structure. It possesses an unusual physical characteristic of expanding to about 20 times its original volume when heated to temperatures within the softening range, somewhere between 1400 and 2000°C. Expanded perlite is either a fluffy, highly porous

substance or a glassy-white particulate with low porosity, depending on how the material is heated. The bulk material has a density between 3 and 20 lb/ft^3.

8.1.2 Odor and Warning Properties The crystalline silica content of 16 samples of perlite ore collected from 19 deposits in 16 western states was quite low, < 2% in 15 and 3% in one sample (159). The crystalline silica content of typical expanded perlite ranged from 0 to 2% (160).
8.2 Production and Use
An estimated 517,000 tons of perlite was produced in the United States during 1988 (161). Most uses of perlite involve the expanded form. It is used in abrasives, acoustical plaster and tile, charcoal barbecue base, cleaner base, concrete aggregates, filter aids, fertilizer, metal foundries, insulation, and refractory products. It is used as a filler in numerous materials. Incorporation into construction materials accounts for about 70% of the domestic use of perlite.
8.3 Exposure Assessment
8.3.3 Workplace Methods The recommended methods for determining workplace exposures to perlite are NIOSH Method #0500 for total dust and #0600 for respirable dust (31).
8.4 Toxicity:
NA
8.5 Standards, Regulations, or Guidelines of Exposure
The NIOSH standard is 10 mg/m^3 for total dust and 5 mg/m^3 for respirable perlite. The OSHA standard is 15 mg/m^3 for total dust and 5 mg/m^3 for respirable perlite (149). The ACGIH TLV for perlite is 10 mg/m^3 for dust containing less than 1% crystalline silica and no asbestos (150).

Silica and Silica Compounds
Richard Lemen, Ph.D., Eula Bingham, Ph.D.

9.0 Pumice and Pumicite
9.0.1 CAS Number:
[*1332-09-8*]
9.1 Chemical and Physical Properties:
NA
9.2 Production and Use
Domestic production of pumice and pumicite was estimated at 400,000 tons in 1988 (162). About 70% of this came from mines in New Mexico and Idaho. Concrete admixtures and building blocks are the major uses for this material and account for 86% of the total production. A very finely groundform of pumice known as micronized pumice is used as an abrasive in toothpaste, polishes, and soaps. There is very little published information on potential occupational exposures to, and adverse health effects of, pumice.
9.5 Standards, Regulations, or Guidelines of Exposure
There are no hygienic standards or guidelines for controlling occupational exposure to these compounds. By default, pumice and pumicite containing no asbestos and less than 1% crystalline silica are considered inert or nuisance dusts for which the OSHA PEL is 15 mg/m^3 total dust or 5 mg/m^3 respirable dust TWA (151).

Silica and Silica Compounds
Richard Lemen, Ph.D., Eula Bingham, Ph.D.

10.0 Kyanite

10.0.1 CAS Number:
[*12183-80-1*]
10.1 Chemical and Physical Properties
10.1.1 General Kyanite, andalusite, and sillimanite are anhydrous aluminosilicate minerals that are closely related to several other aluminum silicate minerals such as topaz. Calcination of this mineral produces a refractory material that can be used to manufacture high-performance, high-alumina refractories (163).
10.2 Production and Use
It was estimated that in 1987, 90% of the kyanite produced in the United States was used in refractories, 55% of this for smelting and processing iron, 20% for smelting and processing nonferrous metals, and 15% for refractories in glassmaking and ceramics (163).
10.5 Standards, Regulations, or Guidelines of Exposure
As with pumice and pumicite, little is known about the occupational health and industrial hygiene aspects of this class of materials. There are no standards or guidelines for limiting occupational exposure to this material. By default, air concentrations are limited to those for inert or nuisance dusts according to OSHA policy (151).

Silica and Silica Compounds
Richard Lemen, Ph.D., Eula Bingham, Ph.D.

11.0 Mica
11.0.1 CAS Number:
[*12001-26-2*]
11.0.2 Synonyms:
Zimmwaldite, fluorophlogopite; margarite; silicates; soapstone, lipidolite; roscoelite
11.0.3 Trade Names:
Muscovite, Phlogopite; biotite
11.0.4 Molecular Weight:
Varies
11.1 Chemical and Physical Properties
11.1.1 General Nonflammable, nonfibrous, water insoluble

Color: Colorless, odorless flakes or sheets

11.2 Production and Use
Mica is a nonfibrous, natural silicate, found in plate form in nine different species. These materials are hydrous silicates, and the predominant minerals of commerce are muscovite, a hydrous aluminosilicate, and phlogophite, a magnesium silicate (164). Sheet forms of mica in the form of muscovite have historically been mined by hand from pegmatites. However, in the past decade, demand for sheet forms of mica have dropped dramatically as the electronics industry has switched to synthetic quartz to meet the traditional uses of this material. Most modern uses of mica involve ground material and almost all of this is derived as a by-product from mining lithium, feldspar, or kaolin. The state of North Carolina accounted for 75% of the domestic production of mica in 1988. The major uses of mica in 1988 were in wallboard joint cement, paint, rubber, and oil well drilling fluids. These uses totaled 95,000 tons (164).
11.5 Standards, Regulations or Guidelines of Exposure
The NIOSH recommended exposure limit is 3 mg/m^3, and OSHA's is 20 mppcf (149). ACGIH TLV has a TWA of 3 mg/m^3. This is the value for particulate matter containing no asbestos and < 1% crystalline silica. Pneumoconiosis is a critical effect (155).

Manufactured Products Containing Silicon

Silica and Silica Compounds
Richard Lemen, Ph.D., Eula Bingham, Ph.D.

12.0 Portland Cement
12.0.1 CAS Number:
[*65997-15-1*]
12.0.2 Synonyms:
Silicate, cement; cement, portland, chemicals: cement kiln dust; kiln precipitator catch; portland cement kiln dust: portland cement plant kiln dust; waste kiln dust; hydraulic cement; portland cement silicate
12.1 Chemical and Physical Properties
12.1.1 General Although it is not a natural silicate mineral, portland cement resembles this family of minerals in its physical and chemical characteristics. Portland cement is the most common form of cement used throughout the world and was named because of its resemblance to a well-known English building stone from the Isle of Portland. It is manufactured by blending lime, alumina, silica, and iron oxide as tetracalcium aluminoferrate (with the theoretical formula $4CaO \cdot Al_2O_3 \cdot Fe_2O_3$), tricalcium aluminate ($3CaO \cdot Al_2O_3$), tricalcium silicate ($3CaO \cdot SiO_2$), and dicalcium silicate ($2CaO \cdot SiO_2$). Small amounts of magnesia (MgO), Na, K, and S are also present. Sand is added to make concrete. Modern cement may be augmented with a variety of natural or synthetic additives to impart specific physical properties. Natural or synthetic fibers may be added to impart specific physical properties and to improve strength or thermal resistance. Polymeric materials such as epoxy resins may be added to impart strength, flexibility, improved curing properties, or moisture resistance.

Portland cement is produced by grinding and mixing the starting materials and calcining this mixture in rotary kilns at about 1400°C. The cooled clinker that is formed is ground and mixed with additives such as gypsum to form the final cement. The cement may then be mixed with sand or gravel to make concrete. The quartz content of cement is usually less than 1%.
12.2 Production and Use
Because most portland cement is used in the construction of buildings, consumption parallels building trends. The total consumption of cement in the United States in 1988 was 84 million tons (165). This was similar to the consumption in the previous two years and considerably higher than the approximately 65 million tons consumed in 1982, a recession year. Occupational exposure to portland cement occurs during its manufacture and use and is limited primarily to inhalation of, or dermal contact with, the dry material. The majority of the cement used in construction is mixed with sand and gravel and water at a central plant and trucked wet to the construction site. Thus there is little opportunity for exposure of workers at the site to cement dust. Nevertheless, many construction workers may be exposed to cement dust when small amounts are mixed on site or when cement or concrete materials are cut or ground.
12.3 Exposure Assessment
12.3.3 Workplace Method The recommended method for determining workplace exposures to Portland cement is NIOSH Method #0500 (31).

12.4 Toxicity
The potential adverse health effects of portland cement have not been extensively studied. The available evidence suggests that it has a low degree of toxic hazard. There does not appear to be any evidence that pneumoconiosis is associated with exposure to portland cement dust if that exposure is not accompanied by exposure to other fibrogenic dusts such as crystalline silica. Deposition of portland cement in the eye can result in alkali burns from calcium oxide (CaO) in the cement if the material is not washed out (166).
12.5 Standards, Regulations, or Guidelines of Exposure
The OSHA PEL TWA for exposure to portland cement dust is 10 mg/m^3 for total dust and 5 mg/m^3 for respirable dust (151). The NIOSH REL is the same (152). The ACGIH TLV TWA is 10 mg/m^3. This value is for particulate matter containing no asbestos and < 1% crystalline silica. It causes irritation and dermatitis (155).

Silica and Silica Compounds

13.0 Silicon Carbide
13.0.1 CAS Number:
[*409-21-2*]
13.0.2 Synonyms:
Carborundum; carbolon; silicon monocarbide; silicon carbide, 98.8%
13.0.3 Trade Name:
NA
13.0.4 Molecular Weight:
40.097
13.0.5 Molecular Formula:
SiC
13.1 Chemical and Physical Properties
In recent years, a crystalline form of silicon carbide, known as silicon carbide whiskers, has become an important industrial material. A silicon carbide whisker is a single crystal of silicon carbide that has a cylindrical shape, an aspect ratio of greater than 3, and a diameter of less than 5 mm (167).

Color: Yellow to green to bluish black iridescent crystals (149).

13.2 Production and Use
Silicon carbide, also known by the trade name Carborundum, has been manufactured and used as an abrasive material for more than a century. It combines desirable properties of hardness and thermal resistance. It is produced by heating high-grade silica sand with finely ground carbon at 2400°C in an electric furnace (178). In its powdered or granular form, it has been used as the abrasive material in “empty” paper and wheels. It is used as an abrasive in sandblasting and engraving. It has been incorporated into ceramics and glass and especially into refractory ceramic materials.

In silicon carbide, whiskers are used to impart strength and increased thermal resistance to structural materials that are used at high temperatures. Composite ceramics containing silicon carbide whiskers have been used in manufacturing sandblasting nozzles, rocket motor nozzles, heat shields for reentry vehicles, and parts for nuclear reactor fuel assemblies.
13.3 Exposure Assessment
13.3.3 Workplace Method The recommended method for determining workplace exposures to silicon carbide is NIOSH Method #0500 for total dust and Method #0600 for respirable dust (31).
13.4 Toxicity

13.4.1 Experimental Studies 13.4.1.1 Chronic and Subchronic Toxicity Silicon carbide whiskers accumulated in a dose-related manner in lung tissue during the exposure period and resulted in a significant increase in lung weight for the rats in the highest exposure group compared to controls. The whiskers were most concentrated at the bifurcations of the alveolar ducts and respiratory bronchioles. Most whiskers were either engulfed by alveolar macrophages or located intracellularly in the interstitial tissues. Whiskers also accumulated in the bronchial and mediastinal lymph nodes. Whiskers were present in the interstitial lung tissue and lymph nodes after the 26-week recovery period. Histopathologically, there was evidence of inflammation in both the alveoli and in the lymph nodes. Bronchiolar, alveolar, and pleural thickening, focal pleural fibrosis, and reactive lymphoid hyperplasia were observed in treated rats, and the incidence and severity were dose-related. At the end of the 26-week recovery period, inflammation and lymph node hyperplasia regressed but there was an increased incidence of alveolar and pleural thickening accompanied by a dose-related incidence of adenomatous hyperplasia of the lungs. Despite the relatively short exposure period in this study, the changes seen are consistent with early pulmonary responses to fibrogenic and carcinogenic mineral fibers, such as asbestos, and some of these changes were not reversible. Lapin et al. also noted that no "no-effect level" was demonstrated in their study and that lower exposure levels would need to be examined to detect such a level (167).

In vitro and *in vivo* studies of silicon carbide whiskers deposited on the ciliated epithelium of the respiratory system indicated that the whiskers were swept to the nonciliated regions by ciliary action (143). There they penetrated the epithelial layers and caused cell damage and death. The cytotoxicity observed was similar to that of asbestos. Intrapleural injections of 20 mg of silicon carbide whiskers once a month for three months caused a 47.7% incidence of pleural mesotheliomas in rats compared to a 34.1% incidence in rats treated with UICC chrysolite asbestos (168).

13.4.1.2 Epidemiology Studies Silicon carbide dust has been considered relatively inert when inhaled. However, in recent years, a number of publications have appeared, suggesting that inhalation of silicon carbide during its manufacture or use as an abrasive may result in pneumoconiosis, Individual cases were described in reports by Funahashi et al. (169), De Vuyst et al. (170), and Hayashi and Kajita (171). Peters et al. (172) found radiographic abnormalities and altered pulmonary function in 171 men employed in the manufacture of silicon carbide. Osterman et al. (173) and Gauthier et al. (174) studied workers from this same plant and also reported decrements in pulmonary function, increased respiratory symptoms, and radiographic changes related to the duration of exposure. Elding et al. (175), on the other hand, found no increases in total mortality, cancer mortality, or mortality from nonmalignant respiratory diseases among 521 men who manufactured abrasive materials using silicon carbide. Interpretation of the results from the studies by Peters et al. (172) and Osterman et al. (173) is complicated by the fact that workers involved in the manufacture of silicon carbide are also exposed to sulfur dioxide and polycyclic aromatic hydrocarbons. Furthermore, the particulate matter to which they were exposed contained small quantities of quartz and cristobalite (176). Durand et al. (177) examined chest radiographs of 200 workers at a Quebec silicon carbide manufacturing plant. Twenty-eight had abnormal radiographs providing clinical evidence of pneumoconiosis, half of which were typical of pure silicosis. Examination of these workers over a seven-year period indicated that the condition did not progress. These same authors examined the particulate materials to which these workers were exposed and conducted experiments in sheep designed to identify the agent that might cause the conditions that were seen (178). They discovered that the particulate matter in the air of the plant contained silicon carbide in both particulate and fibrous form. In the sheep model, silicon carbide particles were no more active than inert materials such as latex beads and graphite powder. The silicon carbide fibers, on the other hand, had fibrogenic activity comparable to that of crocidolite and chrysotile asbestos fibers. They concluded that workers in silicon carbide manufacturing plants may be exposed to silicon carbide fibers, which can contribute to the induction of interstitial lung disease.

13.5 Standards, Regulations, or Guidelines of Exposure

NIOSH has a standard of 10 mg/m^3 (total); 5 mg/m^3 (resp). OSHA has a standard of 15 mg/m^3 total (<1% silica) and 5 mg/m^3 (resp) (149). These standards and guidelines reflect the traditional view of

this material as relatively innocuous. Silicon carbide whiskers in particular and perhaps silicon carbide dust also may be more biologically active than is reflected by these numbers. Occupational exposure should be minimized while additional information is being developed. The ACGIH TLV has a TWA of 10 mg/m^3 which is the value for particulate matter containing no asbestos and <1% crystalline silica. There is concern that it is carcinogenic for humans, but not enough data exists for a definite determination. The critical effect is on the lungs (155).

14.0 Silicon Halides

	Silicon Tetrabromide	Silicon Tetrafluoride	Silicon Tetrachloride
14.0.1 CAS Number	[*7789-66-4*]	[*7783-61-1*]	[*10026-04-7*]
14.0.2 Synonyms	Silicon (IV) bromide; tetrabromo-silane	Silicon (IV) fluoride; tetrafluorosine	SIC-L (TM); silicon chloride; tetrachlorosilane; tetrachlorosilicon; silicon (IV) chloride
14.0.3 Trade Names	NA	NA	NA
14.0.4 Molecular Weight	347.40	104.080	169.90
14.0.5 Molecular Formula	$SiBr^4$	SiF^4	$SiCl^4$
14.1 Chemical and Physical Properties		Decomposes	
Color		Colorless gas	Colorless, mobile fuming liquid

14.1.1 General
Of the three silicon tetrahalides (also known as tetrahalosilanes), only two, the chloride and bromide, are of commercial significance, and silicon tetrachloride is of greatest importance. The tetrafluoride is a gas at room temperature whereas the tetrachloride and tetrabromide are fuming liquids. They are prepared by the direct halogenation of pure quartz or silicon carbide at elevated temperature and pressure.

The primary use of silicon tetrachloride is as the starting material for the manufacture of high-purity silicon, amorphous silica, and ethyl silicate. Silicon tetrafluoride is used as a starting material for fluorosilic acid (H_2SiF_6) for water fluoridation.

14.1.2 Odor and Warning Properties

Silicon tetrafluoride exhibits a very pungent odor. Silicon tetrachloride has a suffocating odor, is moisture sensitive.

14.4 Toxicity

Silicon tetrahalides are readily hydrolyzed to their corresponding hydrogen halides and silica upon contact with moisture. For this reason, all three silicon tetrahalides are highly toxic by either inhalation or ingestion and can cause severe irritation of the skin and mucous membranes. In this respect their occupational hazards are qualitatively similar to those associated with the hydrogen halides.

15.0 Silanes

	Silicon Tetrahydride	Trisilane	Trichlorosilane	Hexachloro-disilane
15.0.1 CAS Number	[*7803-62-5*]	[*7783-26-8*]	[*10025-78-2*]	[*13465-77-5*]
15.0.2 Synonyms	Silane; silicone anhydride; Si-H; monosilane; silicon hydride; silane, C. P. grade; Silicon Tetrahydride (silane)		Silicochloroform; trichloromonosilane	
15.0.3 Trade Names	NA	NA	NA	NA
15.0.4 Molecular Weight	32.118	92.321	135.45	268.89
15.0.5 Molecular Formula	SiH^4	Si^3H^8	$HSiCl^3$	Si^2Cl^6
15.1 Chemical and Physical Properties	Insoluble in H^2O		Decomposes	
Color			Colorless liquid	

15.1.1 General

Silicon forms a large homologous series of silicon hydride compounds analogous to the alkane series of hydrocarbons. The simplest member of this series is silicon tetrahydride, better known as silane. Subsequent members of the series are disilane (Si_2H_6), trisilane (Si_3H_8), and so on. As with the

hydrocarbons, individual hydrogen atoms may be replaced by certain functional groups such as halogens, aliphatic hydrocarbons, and hydroxyl groups to form parallel series of compounds.

The silicon–hydrogen bond in silanes is much weaker than the corresponding carbon–hydrogen bond in aliphatic hydrocarbons. Therefore, these compounds are much more reactive and undergo spontaneous oxidation in air. They also are readily hydrolyzed to silicic acid and silica in the presence of water. They decompose upon heating to liberate hydrogen and free silicon.

15.1.2 Odor and Warning Properties

Silicon tetrahydride is a highly toxic gas with a repulsive odor. It is spontaneously flammable in air. Trichlorosilane has an acrid odor, fumes in air and supports combustion. It is a lachrymator and is moisture sensitive. Octamethyl tetrasilane is moisture sensitive.

15.4 Toxicity

Because of their reactivity and specialized usage, there is relatively little opportunity for significant occupational exposure to the silanes and their derivatives. Perhaps the most extensively used compounds are trichlorosilane and hexachlorodisilane. These compounds decompose upon contact with moisture to form hydrogen chloride. The primary hazard associated with chlorosilanes is their extreme flammability. Silane ignites spontaneously in air and trichlorosilane has a flash point of 7 ° F. Apart from their flammability, these compounds have a relatively low order of acute toxicity relative to other volatile inorganic hydrides. The LC_{50} of trichlorosilane for rats is 1000 ppm and the oral LD_{50} is 1030 mg/kg. Silane is less toxic than trichlorosilane.

15.5 Standards, Regulations, or Guidelines of Exposure

The OSHA PEL for silane (silicon tetrahydride) is 5 ppm (7 mg/m^3), but was vacated (151). The NIOSH recommended exposure limit is also 5 ppm (149), and the ACGIH TLV si 5 ppm (7 mg/m^3) (151).

Asbestos

Charles H. Powell, ScD, CIH, Barbara Cohrssen, MS, CIH

1.0 Asbestos

Asbestos is a generic name given to six fibrous minerals that have been used in commercial products. The six types of asbestos are: chrysotile, the most widely used; crocidolite; amosite; anthophyllite asbestos; tremolite asbestos; and actinolite asbestos. The properties that make asbestos so versatile and cost-effective are high tensile strength, chemical and thermal stability, high flexibility, low electrical conductivity, and large surface area.

1.0.1 CAS Number

The CAS Numbers, mineral, and commercial names for the asbestos mineral group, and the chemical formulas are provided in Table 12.1.

Table 12.1. Asbestos Mineral Group

Mineral Name	Commercial Mineral Name for Asbestos	Mineral Group	CAS Number	Chemical Formula
Chrysotile	Chrysotile	Serpentine	[*12001-29-5*]	$Mg_3Si_2O_5(OH)_4$
Riebeckite	Crocidolite	Amphibole	[*12001-28-4*]	$Na_2(Fe^{2+},Mg)_3Fe^{3+}Si_8O_{22}(OH)_2$
Anthophyllite	Anthophyllite	Amphibole	[*17068-78-9*] or [*77536-78-*	$Mg_7Si_8O_{22}(OH)_2$

			9]	
Grunerite	Amosite	Amphibole	[*12172-73-5*]	$(Fe^{2+})_2(Fe^{2+},Mg)_5Si_8O_{22}(OH)_2$
Actinolite	Actinolite	Amphibole	[*13768-00-8*] or [*77536-67-5*]	$Ca_2Fe_5Si_8O_{22}(OH)_2$
Tremolite	Tremolite	Amphibole	[*14567-73-8*] or [*77536-68-6*]	$Ca_2Mg_5Si_8O_{22}(OH)_2$
Asbestos fiber	Asbestos		[*1332-21-4*]

Talc

Barbara Cohrssen, MS, CIH, Charles H. Powell, ScD, CIH

1.0 Talc

Talc is a natural mineral of the general chemical composition $Mg_3Si_4O_{10}(OH)_2$ (1). The composition varies widely from one geologic deposit to another and even within the same deposit. The main component, crystalline hydrated silicate of magnesium, is usually found as plates but rarely may also be found as fibers. In many talc deposits, other silicates such as the amphiboles, tremolite and anthophyllite, as well as serpentines, antigorite, lizardite, and even chrysotile, may be present. This chapter discusses only the health effects associated with talc that does not contain asbestiform fibers. However, a number of studies have been conducted to determine the health effects of talc in which the purity of the material was not known. The discussion of asbestos is covered in Chapter 12, Asbestos.

1.0.1 CAS Number:

[*14807-96-6*]

1.0.2 Synonyms:

Hydrous magnesium silicate; non abestiform talc; steatite talc

1.0.3 Trade Names for Talc

Synonyms for talc include the following: Agalite; Asbestine; B9 finntalc P40; B13; Beaver white 200; CP-10-40; CP 38-33; Crystalite; CR 6002; Desertalc 57; Emtal 500; Emtal 549; Emtal 596; Emtal 599; Fibrene C 400; French chalk; FW-XO; Hydrous magnesium silicate; HSDB 830; IT Extra; LMR 100; Microneeca K 1; Micro white 5000A; Microtalco IT extra; Mistron; MP 25-38; MP 40-27; MP 45-26; MST; MT 12-50; Mussolinite; nonfibrous talc; NCI CO6018; Nytal 200; Nytal 400; Pk-C; Pk-N; Polytal 4641; Polytal 4725; Potstone; Snowgoose; Soapstone; Steatite; Steawhite; Supreme; Supreme dense; Talcan PK-P; Talcron CP 44-31; Talcum (2).

Talc
Barbara Cohrssen, MS, CIH, Charles H. Powell, ScD, CIH

1.1 Chemical and Physical Properties
Talc has a hardness of 1 on the Mohs scale of hardness; a density of 2.58 to 2.83; is commonly composed of thin tabular crystals up to 1 cm wide and is usually massive, fine-grained, and compact. It is also found as foliated or fibrous masses or in globular stellate groups (3).

Talc is a natural single-phase mineral ideally composed of 31.88% magnesium oxide, 63.37% silicon dioxide and 4.75% water. Formation is said to have occurred by hydrothermal alteration of rocks rich in magnesium and iron and low grade thermal metamorphism of siliceous dolomites (4). It is an odorless, solid material that varies in color depending upon the minerals that are found with it. Talc may be pale green to dark green or greenish gray; brownish; translucent; white to grayish white; or pearly, greasy, or dull.

The term talc in the mineralogical connotation denotes a specific rock-forming mineral of the sheet silicate category. However, when talc is referenced in the industrial or commercial sense, it may represent a varied mixture of associated minerals that have physical properties similar to the mineral talc (5).

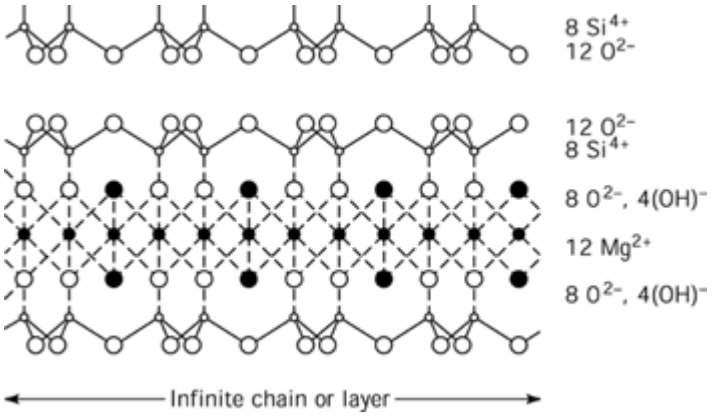

Figure 13.1. Molecular structure of pure talc mineral (1).

A number of minerals are commonly associated with talc deposits: calcite, dolomite, magnesite, tremolite, anthophyllite, antigorite, quartz, pyrophyllite, micas, and chlorites (5).

The most common type of talc is of ultramafic origin, formed by the alteration of serpentinite to talc-carbonate rock. It is common in Vermont, Quebec, and Finland. Talc of mafic origin, found in Virginia, North Carolina, and Georgia, is formed by hydration of mafic rock to serpentinite, followed by alteration of the serpentinite to talc-carbonate. It is usually contaminated with chlorite and silica. Talc of metasedimentary origin is formed by hydrothermal alteration of the dolomitic host rock by silica-containing fluid. This type of talc is commonly found in Montana and Australia. It is usually quite pure and quite white. The fourth type of talc is of metamorphic origin, where siliceous dolomite is first converted to tremolite or actinolite and then partially converted to talc. The New York and California deposits are of this type (1).

Talc
Barbara Cohrssen, MS, CIH, Charles H. Powell, ScD, CIH

1.2 Production and Use

Talc-containing rocks were first used in prehistoric times as utensils and ornaments. The term talc was first applied to this mineral in 869 AD. The abundance of talc, the ease with which it can be mined, and its properties have made it an important industrial mineral (6).

Talc is an extremely versatile mineral that has found a number of uses despite the relative impurity of most of the ores mined. Except for pure steatite grades, hand-picked, platy, cosmetic talcs and a few products from wet processing plants, industrial products are mixtures of many minerals. The principal uses are as an extender and filler pigment in the paint industry; for coating and filling paper; in ceramic products; and as a filler for plastics and roofing products. Miscellaneous uses of talc include binders and fillers in textiles; fillers in integral, foamed, latex rubber backings for carpets, rugs, and parquet hardwood floor panels; filler for upholstery fabric backing and draperies; lubricant in extreme temperature range greases; corrosion proofing composition; 10–15% in dry fire extinguishing powders; loading and bleaching materials such as cotton sacks, cordage, and rope string; cereal polishing; bleaching agents; food odor absorber; floor wax; water filtration; leather treatment; joint fillers and grouts; insecticides; shoe polishes; welding rod coatings; printing inks; encapsulant for acceleration testing artillery shells; coatings for iron ore pellets in direct reduction processes; source of magnesium in plant foods; pigment in white shoe polishes and white glove cleaners; dusting powder for salami; admixture for certain concretes; polishing medium for peanuts, gunpowder grains, and turned wooden articles; to prevent sticking of bottle, rubber and candy molds; and to impart a finish to wire nails and leather (7).

For example, much of the talc used by the ceramic industry is a mixture of platy talc and tremolite; most of the talc used by the rubber, plastic, and paper industry is at best about 90% talc and the balance is dolomite, calcite, serpentine, chlorite, actinolite, iron- and manganese-containing minerals, and carbonaceous material.

According to the U.S. Geological Survey, China was the largest producer in 1999 with 2.3 million metric tons, and the United States produced about 0.9 million metric tons. After these two countries, Finland, India, and Brazil are the next largest producers. In 1999, the total usage of talc totaled 796,000 metric tons. Consumption in decreasing order was in ceramics (31%), paper (21%), and paint (18%) (7a).

Talc
Barbara Cohrssen, MS, CIH, Charles H. Powell, ScD, CIH

1.3 Exposure Assessment

The NIOSH Method P&CAM #355 is recommended for determining workplace exposures to talc. This method involves drawing a known volume of air through a MCE filter. Then the sample is ashed and analyzed by X-ray diffraction (8). However, if the sample contains asbestos, several other methods are recommended. These include NIOSH Method 7400 that uses optical counting of asbestos fibers, NIOSH Method 7402 that uses transmission electron microscopy (TEM) for analysis of the sample, or NIOSH Method 9000 that uses X-ray diffraction for analysis. A method recommended for determining the presence of asbestos in talc is NIOSH Method 9002 that analyzes the sample by polarized light microscopy (PLM) (9).

1.4 Toxic Effects
1.4.1 Experimental Studies
Inhalation Studies

Inhalation studies have had technical problems due to the lack of methods to determine accurately the amount of talc inhaled by exposed animals.

1.4.1.1 Acute Toxicity Rats exposed to a "very dense" cloud of talc, whose particle size was less than 5 mm, for 3 hours per day up to 12 days may have died because of suffocation (10).

1.4.1.2 Chronic and Subchronic Toxicity None of a group of rats exposed to 30–383 mg/m^3 of "technical/pharmaceutical grade" talc for 6 hours per day, six days a week for up to nine months died as a specific consequence of exposure. However, they developed chronic inflammatory changes, including thickening of the pulmonary artery walls and eventually emphysema (11).

Hamsters exposed by inhalation to 8 mg/m^3 respirable "baby talc" for up to 150 minutes per day, five days a week for 300 days showed no negative effects (12, 13). According to a study conducted by Hildick Smith, hamsters exposed to respirable cosmetic grade talc dust showed no difference in incidence, nature, or pathological lesions from those observed in a group of untreated animals (14).

Heavy dosing of rats by inhalation of talc caused severe dyspnea. However, no histological change was observed within 20 days, and talc particles were trapped by alveolar macrophages (10).

Minimal fibrosis was observed in rats exposed by inhalation to 10.8 mg/m^3 of Italian talc (grade 00000, ready milled, mean particle size 25 mm) for three months; this did not change during the postexposure period. The rats exposed for one year had minimal to slight fibrosis, whose degree had increased to moderate within one year after exposure ceased (15).

However, Syrian golden hamsters exposed to 8 mg/m^3 of talc aerosols for up to 150 minutes per day, five days per week for 30 days showed no histopathological change in the lungs, heart, liver, renal tissues, stomach, or uterus (12, 13, 16).

The National Toxicology Program (NTP) (17) conducted a lifetime study of talc in rats. This study consisted of groups of 49 or 50 male and 50 female rats exposed to aerosols of 0, 6, or 18 mg/m^3 of talc until mortality in any exposure group reached 80%. This occurred at 113 weeks for males and 122 weeks for females. These exposures were based on 4-week inhalation studies of terminal lung talc burden in F344/M rats; concentrations greater than 18 mg/m^3 were expected to overwhelm lung clearance mechanisms and impair lung function. These exposure concentrations provided a dose equivalent of 0, 2.8, or 8.4 mg/kg per day for male rats and 0, 3.2, or 9.6 mg/kg per day for female rats. The survival of male and female rats exposed to talc was similar to that of the controls. Mean body weights of rats exposed to 18 mg/m^3 were slightly lower than those of controls after week 65. No clinical findings were attributed to talc exposure.

In another study, conducted by the NTP (17), groups of 22 male and 22 female rats were similarly exposed and examined for interim pathology or pulmonary function after 6, 11, 18, and 24 months and for lung biochemistry and cytology after 24 months. Absolute and relative lung weights of male rats exposed to 18 mg/m^3 were significantly greater than those of controls at the 6, 11, and 18 month interim evaluations and at the end of the lifetime study, whereas those of female rats exposed to 18 mg/m^3 were significantly greater at the 11, 18, and 24 month interim evaluations and at the end of the lifetime study. Lung talc burdens of male and female rats exposed to 6 mg/m^3 were similar and increased progressively from 6 to 24 months. Lung talc burdens of females exposed to 18 mg/m^3 also increased progressively from 6 to 24 months, whereas those of males exposed to 18 mg/m^3

remained about the same after 18 months. Lung burdens were generally proportional to exposure concentrations at each interim evaluation. It was also noted that a concentration-related impairment of respiratory function increased in severity with increasing exposure duration. The impairment was characterized by reductions in lung volume, lung compliance, gas exchange efficiency and nonuniform intrapulmonary gas distribution.

The NTP (17) also conducted a 2-year study of exposure to talc by mice. Groups of 47 to 49 male and 48 to 50 female mice were exposed to an aerosol containing 0, 6, or 18 mg/m^3 talc for up to 104 weeks. These exposures were selected based on 4-week inhalation studies of the terminal lung talc burden in B6C3F$_1$ mice; concentrations greater than 18 mg/m^3 were expected to overwhelm lung clearance mechanisms and impair lung function. These exposure concentrations provided a dose equivalent of 0, 2, or 6 mg/kg per day for male mice and 0, 1.3, or 3.9 mg/kg for female mice. Survival and final mean body weights of male and female mice exposed to talc were similar to those of the controls. There were no clinical findings attributed to talc exposure.

In a special study by the NTP, additional groups of 39 or 40 male and 39 or 40 female mice similarly exposed, were examined for interim pathology, lung biochemistry, and cytology after 6, 12, and 18 months of exposure. Lung talc burdens of mice exposed to 6 mg/m^3 were similar between males and females and increased progressively from 6 to 24 months, except for males at 18 months. The lung talc burdens of mice exposed to 18 mg/m^3 were also similar between the sexes at each interim evaluation. Although the talc burdens of males and females increased substantially from 6 to 24 months, the values at 12 and 18 months were similar. Generally, lung burdens of mice exposed to 18 mg/m^3 were disproportionately greater than those of mice exposed to 6 mg/m^3, suggesting that clearance of talc from the lung was impaired or impaired to a greater extent in mice exposed to 18 mg/m^3 than in mice exposed to 6 mg/m^3 (17). Oberdörster comments on the study that analysis of the particle accumulation kinetics in lungs of the rats shows that lung overload had been reached at both the 6 and 18 mg/m^3 concentrations, resulting in increased talc accumulation of high lung burdens (18).

In a previous study, a group of 24 male and 24 female Wistar-derived rats, six to eight weeks of age, was exposed by inhalation to a mean respirable dust concentration of 10.8 mg/m^3 Italian talc (grade 00000; ready milled; mean particle size 25 mm; containing 92% talc, 3% chlorite, 1% carbonate minerals, and 0.5 to 1% quartz) for 7.5 hours per day, five days a week for six or twelve months. Ten days after the end of each exposure period, six rats in each group were killed; another four rats were killed in each group one year later. Within 28 months of the start of the study, another 12 animals in each group had died. No lung tumors were observed in rats exposed to talc for six months, whereas one lung adenoma occurred among those exposed for 12 months. No lung tumors were found in 24 male or 24 female controls (15).

Three groups of 50 male and 50 female Syrian golden hamsters, four weeks old, were exposed to an aerosol of talc baby powder, prepared from Vermont talc by flotation, for 3, 30, or 150 minutes per day, five days a week for 30 days. The mean total aerosol concentration was 37.1 mg/m^3 with a mean respirable fraction of 9.8 mg/m^3. Two other groups of hamsters, seven weeks old, were exposed to a talc aerosol concentration of 27.4 mg/m^3 with a mean respirable fraction of 8.1 mg/m^3. Two control groups of 25 males and 25 females were sham exposed. No primary neoplasms were found in the respiratory system of any hamster. The incidence of alveolar cell hyperplasis was 25% in the groups exposed to aerosols for 30 or 150 minutes per day for 300 days compared with 10% in the control group (13, 14).

Guinea pigs exposed for eight weeks to continuously circulating talcum dust were sacrificed at intervals after dust exposure, and sections of the lungs were examined histologically. Chronic inflammatory changes were noted in one animal sacrificed immediately after four weeks of

exposure. There was no nodule formation and no increase in connective tissue, although masses of dust particles had accumulated in the lungs. In another animal exposed to talc for four weeks and not sacrificed for six months, fewer inflammatory changes were found, and there was much less dust present (19).

Pickrell et al. studied the lung deposition and effects of inhalation exposure in F344/Crl rats and $B6C3F_1$ mice. The rats were exposed to aerosols containing 2.3, 4.3, or 17 mg/m^3 talc for 6 hours a day, 5 days a week for 4 weeks. The mice were similarly exposed to 2.2, 5.7, or 20.4 mg/m^3 talc. The animals were killed 24 hours after the last exposure. Talc accumulated in the lungs in a dose-dependent manner. The average talc lung burdens in rats ranged from 0 to 0.72 mg per gram of lung tissue and in mice from 0 to 1.0 mg per gram. No exposure-related lung lesions were seen other than slight diffuse increases in the number of free macrophages containing talc particles within the alveolar spaces of rats and mice exposed to the highest doses (20).

Ingestion

Groups of 25 male and 25 female Wistar rats, ten weeks old, received about 50 mg/kg body weight per day of commercial talc (characteristics unspecified) in their diets for life (average survival 649 days). No significant difference in tumor incidence was found compared with controls (21).

A group of 16 male and 16 female Wistar-derived rats, 21–26 weeks of age, was exposed to 100 mg of Italian talc (grade 00000, ready milled; mean particle size 25 mm; containing 92% talc, 3% chlorite, 1% carbonate minerals, and 0.5 to 1% quartz) per day per rat in the diet for five months and then maintained on a basal diet for life (average survival 614 days). A control group of 16 rats was fed a basal diet. No difference in tumor incidence was found between the two groups (15).

Rats fed 100 mg of talc for 101 days showed no significant depression of mean life span (15).

Phillips et al. studied the effects of tritium-labeled talc fed to male albino Wistar rats, female LACA mice, female guinea pigs and intravaginally instilled in large white female rabbits. In rats, 75% of the single dose was excreted in feces in 24 hours; after 96 hours, 95.8% of the dose had been eliminated. Kidneys of rats that received multiple doses had less than 0.02% radioactivity. In the guinea pigs, nearly all of the radioactive dose was excreted in 96 hours, and less than 0.2% was in the urine. For the mice, all of the radioactivity was found in the GI tract and feces, and none in other tissues. In rabbits, after 72 hours, radioactivity was found only at the site of a single installation and at the site of administration (22).

Intravenous

Guinea pigs that received two or three 25-mg intravenous injections of talc in saline showed significant mortality (23). Guinea pigs that received single 200-mg intraperitoneal injections of one of several industrial grade talcs (up to 52% talc, up to 82% tremolite, and traces of quartz) developed nodules consisting of macrophages and giant cells after 10 days on the ventral parietal surface which became smaller after a 15-month period. Fibroblastic proliferation was pronounced in the early phases (24).

In contrast, there were no treatment-related deaths of rabbits injected daily for two weeks with 100 mg of talc in saline (25), of rabbits that received 50-mg injections of talc two times a week for ten weeks, or of rats that received injections of talc over a nine week period, total dose 100 mg. (26). In another study, rabbits were observed to have transient convulsions after cisternal injection of 1 mL of a 1:9 or 1:4 suspension of talc in saline (27).

Rats that received a single 50-mg/mL intratracheal injection of talc in water suffered a 79% mortality rate. Subsequently, it was found the rats could tolerate the dose if they were given two 25-mg/0.5 mL

injections at weekly intervals (28). Rats injected intratracheally with 25 mg tremolitic talc/mL of water had a 40% mortality rate. In another study of rats, granulomas at the injection site were common, and one small pulmonary adenoma was observed two years after the injection of 20 mg of Italian talc into the right pleural cavity, but no other relevant pathology was observed in the lungs (15). Albino rats that received an intraperitoneal injection of approximately 400 mg of talcum powder of the type used on surgical gloves exhibited typical granulomas and numerous foreign body giant cells when laparotomized six months later (29). No acute toxicity was observed after a single 10-mg injection into the bursa of rats (30). Three of 11 rats died within one day following injection of 1400 mg/kg body weight of talc into the lower pole of the spleen (31). Hamilton et al. studied the effects of talc on the ovaries of Sprague–Dawley rats. Animals were sacrificed at 1, 3, 6, 12, and 18 months. They concluded that changes in the ovarian surface may be related to the direct effects of talc or may be due to the buildup of high concentrations of steroid hormones in the distended bursa (30).

Two out of 14 chinchillas given five 40-mg intratracheal injections of talc in saline died (32). Chinchillas that received a single or several 40-mg intratracheal injections of "purified" talc in saline exhibited chronic pulmonary irritation, proliferative pneumonia, giant cell granulomas, and adjacent metaplasia of the alveolar epithelium. The hyperplastic cells subsequently transformed into cuboid cells that formed a continuous lining of the affected alveoli and finally acquired an adenomatous appearance (32).

Mice injected with 10 mg of talc (containing asbestos fibers) into the pleural cavity produced granulomas, some of which were firmly attached to the surface of the lungs or other chest contents and occasionally to the lung lobes (33). No acute toxicity was observed after a suprascapular subcutaneous 600-mg injection into mice (34).

1.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Seven different types of talc were administered *in vitro* to mouse peritoneal macrophages. All of the talcs caused cytoxcity as determined by the release of lactate dehydrogenase and beta-glucuronidase. All of the talcs were of high purity, except for one talc that contained high amounts of chlorite (35).

Mice that received a sterile subcutaneous injection of talc were studied by measuring the incorporation of radioactive leucine and glucosamine into liver and plasma proteins and the talc granuloma at various intervals between 2 and 528 hours after injection. Incorporation into plasma proteins indicated a biphasic response with a marked increased incorporation into the perchloric acid insoluble fraction at 21 hours, a return to normal values at 45 hours, and a similar marked increase into the perchloric acid soluble fraction at 45 hours with a gradual return toward normal values. The response was dependent upon the amount of talc injected (36).

Using radioactive tracer techniques in rats, mice, guinea pigs, and hamsters, no intestinal absorption or translocation of ingested talc to the liver and kidneys was detected (37).

In hamsters, the deposition, translocation, and clearance of talc was followed by giving them a single nose-only inhalation exposure to 40–75 mg/m^3 neutron-activated talc for 2 hours. High cosmetic talc was used, consisting of 95% platy talc. Alveolar deposition was approximately 6 to 8% of the inhaled amount. The biological half-life of talc deposited in the alveoli was 7 to 10 days, and the alveolar clearance was basically complete four months after exposure. No translocation of talc to liver, kidneys, ovaries, or other parts of the body was found (12, 38).

Rats that were exposed to aerosols of Italian talc retained 2.5, 4.7, and 12.2 mg per rat following exposures for 3, 6, and 12 months, respectively. These levels were roughly proportional to the cumulative exposures (15). In rats exposed for 2.3, 4.3, and 17 mg/m^3 of respirable talc for 6 hours per day, five days a week for 4 weeks, the amounts retained in the lung at the end of exposure were 77,187, and 806 micrograms talc per gram of lung (39).

In the NTP two-year study conducted of exposure of rats to talc which was discussed earlier, male rats exposed to 6 mg/m^3 talc had a significant increase in beta-glucuronidase and polymorphonuclear leukocytes after 24 months. Males exposed to 18 mg/m^3 had significant increases in beta-glucuronidase, lactate dehydrogenase, alkaline phosphatase, and total protein in bronchoalveolar lavage fluid. All exposed females had significantly increased alpha-glucuronidase, lactate dehydrogenase, alkaline phosphatase, total protein, and polymorphonuclear leukocytes; females exposed to 18 mg/m^3 also had significantly increased glutathione reductase. Viability and phagocytic activity of macrophages recovered from lavage fluid were not affected by talc exposure. The total lung collagen was significantly increased in rats at both exposure concentrations after 24 months whereas collagenous peptides in lavage fluid and the percentages of newly synthesized protein from females, but not males, were also significantly increased at the 6 or 18 mg/m^3 levels. In addition, lung proteinase activity, primarily cathepsin D-like activity, was significantly greater in exposed males and females. Rats exposed to talc also had significant increases in collagenous peptides and acid proteinase in lung homogenates.

In the NTP study conducted of exposure of mice to talc which was discussed above, increases in total protein, beta-glucuronidase, lactate dehydrogenase, glutathione reductase, total nucleated cells and polymorphonuclear leukocytes in bronchoalveolar lavage fluid were observed primarily in mice exposed to 18 mg/m^3, although some parameters were also increased in mice exposed to 6 mg/m^3. The amount of collagenous peptides in lavage fluid and total lung collagen were increased in male and female mice exposed to 18 mg/m^3. Acid proteinase activity, principally cathepsin D-like activity of lung homogenate supernatant fluid was also significantly increased in mice at the 18 mg/m^3 exposure.

Guinea pigs given a single 200-mg intraperitoneal injection of one of seven commercial talc samples were examined at intervals up to 15 months. Talc particles were found mainly on the ventral parietal surface of the peritoneum within macrophages and giant cells (24).

1.4.1.4 Reproductive and Developmental Talc produced nonspecific abnormalities in chicken eggs at an incidence similar to that induced by thalidomide and sulphadimethoxine (40).

No teratolological effects were observed in hamsters, rats, mice, or rabbits after oral administration of the following doses of talc: 1600 mg/kg body weight to rats on days 6–15 of gestation, 1600 mg/kg body weight to mice on days 6–15 of gestation, 1200 mg/kg body weight to hamsters on days 6–10 of gestation, and 900–mg/kg body weight to rabbits on days 6–18 of gestation (41).

Talc was not mutagenic to *Salmonella typhimurium* TA 1530, *his* G46, or *Saccharomyces cerevisiae* D3 *in vitro* or in host-mediated assays in mice given 30 to 5000 mg/kg body weight (42).

In human W138 cells treated with talc at 2 to 200 mg/mL, chromosomal aberrations were not induced nor were dominant lethal mutations induced in rats following oral administration of 30–5000 mg/kg body weight of talc (42).

Single 20-mg intraperitoneal injections of talc plus 2 mg of particulate prednisolone acetate in saline into mice induced significant numbers of multinucleated giant cells within 48 hours. Neither compound alone induced this response. The multinucleated cells arose by cell fusion, and the resultant polykarions exhibited severe chromosomal abnormalities. Prednisone in combination with talc also elicited the formation of multinucleated giant cells. Polykarions were not observed when talc was injected in combination with cortexone acetate, cortisone, or testosterone isobutyrate (43).

1.4.1.5 Carcinogenesis Hamsters given 10- or 25-mg intrapleural injections of tremolitic talc and maintained for 600 days were studied for tumorigenic effects. No tumors were seen in animals

treated with talc (44).

The NTP conducted a 2-year inhalation study with talc in rats and mice. In this study, male and female F344/N rats were exposed to aerosols of 0, 6, or 18 mg of nonfibrous talc/m^3, free of SiO_2 and asbestiform minerals, for 6 hours per day, 5 days per week for up to 113 weeks (males) and 122 weeks (females). Groups of $B6C3F_1$ mice were exposed similarly for up to 104 weeks. These exposures resulted in concentration-related chronic inflammation, cell proliferation, and fibrosis in the lungs of both male and female rats, and 13 out of 50 of the female rats of the high-exposure group developed lung tumors. The mice showed only limited chronic inflammation and no increased cell proliferative, fibrotic, or tumorigenic responses in their lungs (17).

A four-week talc inhalation study on rats was also conducted by the NTP. This study determined that exposure concentrations in excess of 18 mg/m^3 overwhelmed the lung clearance mechanisms and impaired the lung function of the animals (18).

1.4.2 Human Experience

Pathology

In persons exposed to talc by inhalation, gross examination of the lungs may reveal diffuse pleural thickening and fibrous adhesions of pleural surfaces. In some cases, localized pleural plaques, located on the costal parietal pleura and diaphragmatic surfaces may calcify. According to J.F. Gamble and M. Kleinfeld (7, 45), pulmonary parenchymal lesions may be classified in three general groups:

1. Diffuse interstitial fibrosis with collagen deposition in the alveolar walls and dust laden macrophages both in the alveolar septa and free in the alveolar spaces. Bronchi and bronchioles may be distended and distorted, and normal lung architecture may be obliterated with dilated spaces lined with cuboidal metaplastic cells replacing the alveoli.
2. Lesions of widespread, poorly defined nodules which consist of stellate collections of macrophages and fibroblasts. There may be some fine reticulin, but little collagen is found in these lesions.
3. Foreign body granulomata consisting of epitheloid cells and foreign body giant cells. Granulomata may be found in association with nodular fibrosis or isolated in the alveolar interstitium with normal thin alveolar septa intravening.

Health effects found in workers who have inhaled talc vary, depending upon the composition of the dust inhaled. A significant increase in mortality was found for nonmalignant respiratory disease, especially pneumoconiosis and obstructive lung disease. When silica is significant, the lesions resemble those in silicosis. When fibrous materials such as tremolite are present, diffuse interstitial fibrosis resembling that of asbestosis may be found.

1.4.2.3 Epidemiology Studies Merewether was one of the first to observe that rubber tire workers exposed to French chalk showed “diffuse interstitial fibrosis” by chest X-ray and nothing more than “peribronchial increase in the fibrous tissue” after 30 years. Exposure ranged from 10 to 32 years (7).

In 1949, Hogue and Mallett reported on 20 rubber workers exposed to talc for 10 to 36 years. Exposure concentrations averaged 20 mppcf for six tube machine operators, 15 mppcf for three tube bookers, 15 mppcf for 10 tube curemen, and 50 mppcf for a liner reroller. None of them had dyspnea, cough, shortness of breath, cyanosis, or clubbing of the fingers. Chest X-rays were all normal, and their vital capacity range was 71 to 122% with a median of 105% (46).

A number of studies looked at the health effects of mining and milling of talc on workers. The most significant exposures occurred in milling talc. Table 13.1 (47–78) summarizes a number of these

studies and includes several studies of rubber workers.

Table 13.1. Epidemiological Studies

Occupation	Focus of study	Length of exposure	Exposure concentration	No. of people	Findings	Date
Mining and milling			17 to 1,672 mppcf of Georgia talc	66	Of 33 patients exposed to high concentrations of dust, 22 had pneumoconiosis of varying severity. Persons with low exposures showed no signs of pneumoconiosis.	
Mining and milling	Lung fibrosis	15 to >30 years	Tremolitic talc; 6 to 5,000 mppcf in mines; 20 to 215 mppcf in milling	221	Fibrosis was found in 32 people. All of them had been exposed for at least 10 yrs. The highest incidence, 40.6 %, occurred with those who had been exposed 15 to 19 yrs. Of the eight workers who had worked >30 yrs, six had fibrosis.	194
Rubber worker	Fatal pneumoconiosis	37 years	Norwegian or Canadian varieties of talc	1	At autopsy, both lungs were found to be moderately pneumoconiotic.	
	Respiratory disorder	28 years		1	X-ray revealed two, dense, homogeneous, opaque masses with round irregular contours in the upper portion of the pulmonary field.	
Millers	Talc pneumonoconiosis			32	Talc plaques observed in all but one case. Six of 11 electrocardiographic configurations were abnormal. Four persons died who ranged in age from 48 to 84.	

Miners	Mortality studies	10 mo to 27 years	8	Causes of death: five died of cor pulmonale or TB; one of congestive cardiac failure; one of nephritis with cardiac complications; and one unknown.
Soapstone workers	Pneumoconiosis	16 to 60 mo.	8	Extent of disease varied with the time of exposure. Clinical signs included cough, mucopurulent sputum with talc bodies, dypsnea on exertion, and weakness.
Rubber workers	Talcosis	19 years average	12,000	During TB screening, 16 cases of symmetrical, modular foci of the lungs w/o swelling of the hilar glands, nine cases of definite talcosis (19 yrs exposure) and seven cases of slight talcosis (12 yrs exposure)were found.
Lead casters	Talc pneumoconiosis	15 to 39 years	7	One death from cor pulmonale and talc pneuomoconiosis after 15 yrs. exposure. Chest X-rays of all patients showed the presence of scattered opacities thoughout the lungs which coalesced to form larger masses with indefinite margins and uneven density.
Miners		>20 years	60	All had pneumoconisis; those with greater exposure had more severe disease.
Miners	Pneumoconiosis	>12 years	260	First radiographic

					signs of pneumoconiosis appeared in 89% after 12 yrs; after 22 yrs. it was 100%.	
Grinders	Pneumoconiosis	10 to 20 years		25	Incidence of pneumoconiosis was 52% after 10 to 20 yrs.	
Rubber workers	Pneumoconiosis	Unknown		72	Exhibited linear pneumoconiosis in 11% of workers.	
	Pneumoconiosis	24 years average		6	The most frequent pathological change was diffuse fibrosis containing macrophages with absorbed dust particles. Also found were diffuse or localized emphysema and granulomatous formation made up of focal areas of epitheliod and foreign body giant cells.	
Miners/millers	Pulmonary function	23 years average	Talc admixed with tremolite, anthopyllite, and free silica: >50 mppcf	20	Changes in pulmonary function indicate a restrictive or obstructive breathing disorder. No consistent correlation exists between degree of functional lung impairment and clinical symptoms or X-ray findings.	196
	Pulmonary function	>10 years	62.3 mppcf	43	Predominant symptoms were dyspnea, cough, basilar crepitations, and clubbing. Poor correlation between impairment and clinical and X-ray results.	
Electrical fitter	Pulmonary talcosis	15 years	Pharmacy talc	1	Thoracic radiography revealed large nodular trabecular	

					images with fairly abundant rounded spots in both lungs.
Miners or millers	Mortality	>15 years	Talc mixed with serpentine and tremolite	91	Nine lung carcinomas, one fibrosarcoma of the pleura, two stomach cancers, one case each of colon, rectal, and pancreatic cancer; 25 cardiac arrests and 28 deaths from pneumoconiosis.
Rubber workers	Talcosis	20 to 40 years		5	Granular pneumoconiosis resulting from long-term or intense exposures.
Milling		<5 to >25 years	> MAC for talc	50	Sixteen cases of talc pneumoconiosis diagnosed.
		16.2 years	Commercial talc with tremolite and anthophyllite	39	One worker showed a chest X-ray consistent with pneumoconiosis. Talc containing tremolite and anthophyllite may be less fibrogenic than chrysotile or amosite at the same exposure levels.
	Mortality	>15 years		260	The overall proportional mortality due to carcinoma of the lung and pleura was four times that of the general population. The carcinogenic effect was significant in workers exposed 15 to 24 yrs.
Rubber workers	Respiratory function			80	Workers exposed below 20 mppcf showed a greater prevalence of productive cough and positive criteria for COPD than control workers.

					Workers with < 10 yrs. exposure showed decreased FEV_1. TWA exposures below 25 mg/m^3 are recommended.	
Rubber workers	Stomach cancer			17,000	There was an association between exposure to talc materials and 100 cases of stomach cancer.	
Miners/millers	Morbidity study		NY State talc	121	With <15 yrs., increased prevalence of cough and dyspnea; with >15 yrs. increased prevalence of pleural calcification. Radiographic findings occur primarily after 15 yrs.	
Talc miners	Mortality patterns			1,260	Death was due primarily to pneumoconiosis and tuberculosis.	
Talc millers	Mortality patterns	22 years	11 mppcf	218	Radiographic evidence of pneumoconiosis after 22 years of exposure but little cancer.	
Mining/milling	Mortality/morbidity	13 years	N.Y. State talc	398	Significant increase in mortality due to bronchogenic cancer, nonmalignant respiratory disease, and respiratory tuberculosis. Four of 10 bronchogenic cancer deaths occurred in individuals with less than 1 yr. of exposure.	197
Grinding(milling)	Interstitial lung disease		U.S., Australian, and French talc	6	Large amounts of talc and talc bodies were found in the BAL fluid of all of	

					the workers 21 yrs. after last exposure. The authors suggest that examination of BAL fluid can provide information about talc exposure.
Mining	Morbidity/mortality (cancer)	> 1 year (1944–1972)	Talc with < 1% quartz	94	27 deaths, with 15 cases of cancer; cancers were of the stomach, prostate, and lung.
Milling	Morbidity/mortality (cancer)	> 2 years (1935–1972)	Talc with <1% quartz	295	90 deaths, with 31 cases of cancer; cancers of the bladder and kidney were elevated.
Mining	Bronchiolitis	> 15 years	Before 1976: 86 mg/m^3; after 1976: 3.5 mg/m^3. Smoked 21 cigarettes/day for 21 yrs.	1	Pulmonary function testing revealed a restrictive ventilatory defect and impaired diffusing capacity. Open lung biopsy revealed bronchiolitis.
Talc factory	Respiratory health		1.87 mg/m^3 to 15 mg/m^3	139	Increased exposure decreased FVC and FEV_1
Latex glove mfg.	Respiratory function		7.7 mg/m^3 total dust; 1.9 mg/m^3 resp. dust	17	FVC and FEV_1 were lower in latex workers than controls.

As can be noted from Table 13.1, a number of studies looked at the rate of cancer among talc workers. There have been several individual case reports of cancer, including a lung adenocarcinoma following talc pleurodesis (79) and a pleural mesothelioma following occupational exposure to talc (80–82).

Talc mining is attributed to causing four cases of mesothelioma reported to the tumor registry of the Cancer Control Bureau, New York Department of Health. These mines contain high levels of fibrous tremolite (83).

1.4.2.3.7 Other Health Effects In 1995, a workshop on consumer uses of talc was organized and held under the joint sponsorship of the U.S. Food and Drug Administration (FDA), the Cosmetic, Toiletries and Fragrances Association (CFTA), and the International Society of Regulatory Toxicology and Pharmacology (ISRTP). One of the issues discussed was the association of perineal talc exposure with ovarian cancer. The attendees agreed that, although some weak association between talc exposure and ovarian tumors has been reported, so far there was insufficient evidence for concern. Although it is theoretically possible that talc could reach the ovaries, the actual access to or the presence of talc in ovarian tissue has not yet been documented (84).

Standards, Regulations, or Guidelines of Exposure

A number of countries have standards, regulations, and guidelines for regulating exposure to talc in the workplace. The exposure limits vary depending upon whether the talc contains asbestos or silica or if it is total dust or respirable dust only. Total dust exposures for talc are 10 mg/m^3 in Switzerland and the United Kingdom, 5 mg/m^3 in Finland, 2.5 mg/m^3 in Australia, and 2 mg/m^3 in Belgium and Germany. Respirable dust exposures for talc are 2 mg/m^3 in Bulgaria, Columbia, Jordan, Korea, New Zealand, Singapore, and Vietnam; and 1 mg/m^3 in the United Kingdom (85).

In the United States, the OSHA PEL for talc not containing asbestos and containing less than 1% quartz is 20 mppcf. For talc containing no asbestos but 1% or more of quartz, the OSHA PEL is calculated from the formula for silica. For talc containing asbestos, the asbestos limit is used (86). The ACGIH has a TLV of 2 mg/m^3 for talc dust containing no asbestos and a TLV of 0.1 f/cc for talc containing asbestos (87).

Rock Wool and Refractory Ceramic Fibers
Carol Rice, Ph.D., CIH

1 Introduction

Man-made vitreous fibers (MMVF) is a generic descriptor for a group of fibrous materials made from melting inorganic substances such as sand, clay, glass, or slag. Synthetic vitreous fibers (SVF) or man-made synthetic vitreous fibers (MSVF) may also be used to describe these groups of materials. These terms have generally replaced earlier use of man-made mineral fibers (MMMF). MMVF are further classified by the raw material used in production; major categories include glass fibers (glass wool or continuous filament), mineral wool (rock or slag), and refractory ceramic fibers. The latter two types are covered in this chapter; glass fibers are described in Chapter. Within each category, a variety of commercial products have been produced and may be identified by manufacturer and product name and number. Each has a slightly different formulation and characteristics; therefore it is important where possible to identify the particular product number.

Dimension, durability, and dose delivered to the target organ are critical factors in the toxicity of MMVF. Fibers are generally distinguished from other particles by having a length to width ratio (aspect ratio) of at least 3:1. A maximum or minimum for one or more of the dimensions may also be specified. For example, a fiber meeting WHO (1) criterion has an aspect ratio of at least 3:1 and a diameter of 3 mm or less. MMVF counted in airborne exposure assessments in the United States are generally described as having an aspect ratio of at least 5:1, a diameter of 3 mm or less, and at least 5 mm long (2). Long fibers are thought to be more biologically active than shorter fibers (3).

MMVF are characterized by length (L) and diameter (D). The arithmetic mean or median of the observed distribution of lengths and diameters may be given as the count mean or median diameter (CMD) or length (CML). If the observed values are transformed by taking the natural logarithm of the measured parameters, the geometric mean (GM) of each dimension may be given with a geometric standard deviation (GSD). The size determinations may be made by either scanning (SEM) or transmission (TEM) electron microscopy. TEM has the lower limits of detection by which investigators can characterize fibers with diameters in the nanometer range. Dose by some routes of administration may be further described by the mass of material, for example, in implantation or single bolus injection studies. For inhalation studies, GM and GSD length and diameter are usually listed for the exposure aerosol, and often the number of fibers within specific size ranges are listed; for example, the number of WHO fibers or the number longer than 20 microns may be tabulated.

Following inhalation, fibers may be deposited on surfaces within the respiratory tract or exhaled. For the fibers that are deposited, the site of deposition (dose) depends upon the characteristics of the fiber and results from one of five mechanisms: impaction, interception, sedimentation, electrostatic precipitation, or diffusion. The majority of the deposition of MMVF is probably governed by the first three mechanisms. Impaction and interception occur when the fiber is removed from the airstream by physically contacting the surface of the airway or a bifurcation. Sedimentation occurs in the lower airways, where the velocity of the fiber becomes low enough for it to settle on the airway surface. Electrostatic precipitation results when the fiber carries a charge opposite to that of the airway surface; for mineral wool fibers, no reports have been found on surface charge measurements. Deposition due to diffusion requires that the air molecules collide with the fiber, resulting in movement toward the surface. This mechanism could contribute to deposition of very thin fibers, e.g., those with diameters substantially less than one-half micron, but few of them are expected in the work environment (4).

The clearance mechanism of the deposited fibers depends upon the characteristics of the fiber and the site of deposition. Fibers deposited in the tracheobronchial region are cleared with the mucous by the cilia and swallowed. This process is completed in a matter of days, during which little change in fiber dimensions would be anticipated. Fibers deposited lower in the respiratory tract are cleared more slowly. Here the fibers are cleared by translocation to another area of the lung or dissolve; translocation may be facilitated by partial dissolution of the fiber or breakage into particles of shorter length. When fibers recovered from the lung or other tissue are characterized by dimensions, comparison with the parent material provides information on deposition and distribution.

Solubility has been investigated as an indicator of durability. Guldberg et al. (5) noted that testing at pH 7.2 to 7.8 represents the neutral conditions of the lung; testing at an acidic pH of 4.5 to 5 represents the environment created by contact with the phagolysosomes. End points include 95% loss of leachable elements, 75% total mass loss, and mass lost in a specified number of days. Both pH values should be considered when evaluating biopersistence (6). The formulation of the test fluid for solubility studies also influences results (5, 7); however, for a given fluid, the rank order of dissolution rates is unchanged (5).

The interpretation of short-term bioassay results is still under study (8). Bernstein et al. (8a) suggested that the results of dissolution at neutral pH are correlated with *in vivo* biopersistence. Others report that the dissolution rates of MMVF that have high aluminum content are much greater in acidic environments (9). Evidence from animal studies shows that the macrophages may interact with long fibers and that multiple macrophages attach to a single fiber which can lead to dissolution (10–13).

Two reviews of animal studies should be consulted by the reader interested in contrasting the observations of effects among two or more MMVF (14, 15). The contribution of various types of studies to the overall assessment of the toxicity of MMVF was the focus of a 1994 workshop (16), and a 1995 review by De Vuyst et al. (17).

Rock Wool and Refractory Ceramic Fibers
Carol Rice, Ph.D., CIH

1.0 Mineral Wool
1.0.1 CAS Number:
none
1.0.2 Synonyms:
rock wool, slag wool

1.0.3 Trade Names
The major U.S. suppliers and product types include

American Rockwool, Inc.

- Rock/slag wool building insulation
- Rock/slag wool fire-accoustical thermal spray systems
- Rock/slag loose wool industrial and OEM fibers and insulation

Celotex Corporation

- Slag wool ceiling tile

Fibrex, Inc.

- Rock wool board, pipe and blanket insulation
- Slag blowing wool building insulation
- Rock wool roof insulation
- Rock wool marine insulation

Isolatek International

- Slag wool insulation (bulk)
- Slag wool fire protection (sprayed)
- Slag wool building insulation (sprayed)

MFS, Inc.

- Slag wool insulation (bulk)
- Slag wool fire protection (sprayed)
- Slag wool insulating cement (troweled, sprayed)

OCHT

- Rock wool pipe, board, and blanket insulation

Rock Wool Manufacturing Co.

- Slag wool building insulation
- Slag wool pipe and board insulation
- Slag wool commercial insulation

Roxul, Inc.

- Rock wool building insulation
- Rock wool pipe, board, and blanket insulation
- Rock wool roof insulation

Sloss Industries Corporation

- Slag wool insulation (bulk)
- Slag wool ceiling tile
- Slag blowing wool insulation

Thermafiber LLC

- Slag wool board and blanket insulation

Slag wool building insulation
Slag wool ceiling tile

USG Interiors, Inc.

Slag wool ceiling tile

Brand names are not given because a single supplier may have 200 products, each with a unique trade name.

Rock Wool and Refractory Ceramic Fibers
Carol Rice, Ph.D., CIH

2.0 Refractory Ceramic Fibers (RCF)
2.0.1 CAS Number:
[*142844-00-6*]
2.0.2 Synonyms:
NA
2.0.3 Trade Names
United States trade names:

Anchor Loc
Cerafiber
Cerawool
Cerafelt
Durablanket
Duraboard
Duraset
Fiberfrax
Kaowool
Kaoset
K-Lite
Pre Flex
Pre Mix
Pyro-blanket
Pyro-fold
Thermotect
Ultrafelt
Uni-Bloc
Z-Bloc

(Source: Refractory Ceramic Fiber Coalition, Washington, DC, 1999)
2.0.4 Molecular Weight
The molecular weight varies depending upon the raw materials used in the formulation.

Fiberglass
R. A. Lemen, Ph.D.

1.0 Fiberglass
1.0.1 CAS Number:
(none)
1.0.2 Synonyms:
Glass wool; Fiberglas®; Fiberglass insulation; boron silicate glass fibre; Saint Gobain; JM 100; JM 102; JM 104; JM 110; TEL
1.1 Chemical and Physical Properties
1.1.1 General Physical properties are listed in Table 15.1.

Table 15.1. Physical Properties of Fiberglass[a]

Glass Type	Form	Fiber Diameter Range (mm)	Specific Gravity (g/cm^3)	Refractive Index
I	Textiles	6–9.5	2.596	1.548
II	Mats	10–15	2.540	1.541
	Textiles	6–9.5		
III	Wood (coarse)	7.5–15	2.605	1.549
IV	Packs (coarse)	115–250	2.465	1.512
V	Wool, fine	0.75–5	2.568	1.537
	Ultrafine	0.25–0.75		
VI	Textile	6–9.5	4.3	—

[a] NIOSH (4) and taken from IARC (5).

Relative density of fiberglass is 2.5–2.6 (water = 1). It is not soluble in water. Components are listed below.

Continuous Glass Filament[a]		Glass Wool[ab] (Mohr and Rowe, Ref. 1)	% by Weight
Component	**% by Weight**		

SiO_2	52–56	63
CaO	16–25	7
Al_2O_3	12–16	(+Fe_2O_3)6
B_2O_3	8–13	6
MgO	0–6	3
Na_2O	0–3	14
K_2O	0–3	1
TiO_2	0–0.4	—
Fe_2O_3	0.05–0.4	—
F_2	—	0.7

[a] Ref. 2.
[b] Glass wool is an amorphous silicate manufactured from glass and may contain a binder and an oil for dust suppression (3).

1.1.2 Odor and Warning Properties Fiberglass can irritate the eyes, skin and the respiratory tract (3). It can also cause an itch called fiberglass itch (6).
1.2 Production and Use
Fiberglass is produced as a glass wool or glass filament by drawing, centrifuging, or blowing molten glass into fibers of certain predetermined widths and lengths or by continuously drawing or extruding glass filaments from molten glass (5).

Glass fiber production is in the 100s of million kg per year and continues to grow (5.
1.3 Exposure Assessment
1.3.1 Air: NA

1.3.2 Background Levels Fiber concentrations in the atmosphere have been generally low and range from undetectable to 0.00004 to 0.009 fiber/cm^3 (5).

1.3.3 Workplace Methods Fiberglass can be sampled by using a filter (0.45 to 1.2 mm cellulose ester membrane, 25-mm; conductive cowl on cassette) and measured by the light microscope, phase contrast technique. This allows a manual count of all fibers. If used for detecting one fiber type it will not be successful because other fibers with similar diameters and lengths will interfere. The working range is between 0.04 to 0.5 fibers/cc for a 1000-L air sample. The limit of detection depends on sample volume and the quantity of interfering dust, but in the absence of such interferences, the quantitative concentration goes down to <0.01 fiber/cc (7). NIOSH recommends alternate counting rules for non-asbestos fibers that include “B” rules given in NIOSH Method 7400. NIOSH further recommends the use of the 3 : 1 aspect ratio in counting fibers. Other methods are outlined by the IARC (5) and WHO (2). However, the phase contrast method described by NIOSH (7) is the most commonly used method and NIOSH recommends it be used in conjunction with the NIOSH electron microscopy method 7402. Optical and scanning electron microscopy are improving with time and can add to the level of quantification. Scanning electron microscopy is the method of choice for identifying fiber type and for accurate sizing. With a magnification of 5000×, it can detect fibers as small as about 0.5 mm in diameter.

1.3.4 Community Methods The same sampling methods apply to the community as for the workplace.

1.4 Toxic Effects
1.4.1 Experimental Studies 1.4.1.1 Acute Toxicity Inhalation can result in sore throats, hoarseness, coughs, and labored breathing. Skin contact can result in itching and redness; and eye contact can cause redness, pain, and itching (3).

1.4.1.2 Chronic and Subchronic Toxicity Studies of hamsters revealed hemorrhagic and edematous lungs after intratracheal instillation of 0.1 mm diameter fiber but not in animals given thicker fibers (median diameter, 2.3–4.1 mm). Gross et al. (1956) reported similar findings in rats. Other findings included pulmonary inflammation in rats, phagocytosis of short, thin fibers from the lungs by macrophages, as well as other cellular reactions to the fibers once in the lung (8–13). Other effects included filling of the alveoli of rats and hamsters with granular material that caused a condition of alveolar lipoproteinosis (14, 15). The asbestos fiber amosite did not cause alveolar lipoproteinosis.

Fibrosis tends to be related to the fiber length. Davis (16) found that finely ground material was much less effective in producing fibrosis than dusts containing long fibers.

1.4.1.3 Pharmacokinetics, Metabolism, and Mechansims [4]Deposition, retention, and clearance depend clearly on a large number of factors including, but not limited to, the fiber size (length and width); velocity; and aerodynamic properties. An excellent discussion of each these factors and others are found in IARC (5).

1.4.1.4 Reproductive and Developmental: NA

1.4.1.5 Carcinogenesis The IARC has concluded that there is sufficient evidence of the carcinogenicity of glass wool in experimental animals (5). The NTP has listed glass wool (respirable size), first in the Seventh, and now in the Eighth Report on Carcinogens as reasonably anticipated to be a human carcinogen (17, 18).

These conclusions are based on the findings of numerous animals studies supporting the carcinogenic potential of fiberglass. Excellent reviews of these studies can be found in IARC (5), WHO (2), and Infante et al. (19). Basically these reviews found that after intratracheal instillation, statistically significant incidences of lung tumors occurred in rats and that significantly increased incidences of thoracic tumors (lung tumors and sarcomas) and mesotheliomas were found in hamsters. The fiber diameters were generally less than 0.3 mm.

Intrapleural implanation and injection in rats caused incidences of pleural tumors (mesothelioma) which varied with fiber size, but not with physicochemical properties.

Injection of glass wool into the peritoneal cavity of rats caused mesotheliomas and sarcomas, and the incidence depended upon fiber size and dose. Leaching of fibers with hydrochloric acid in two of the studies reduced the number of tumors, whereas treatment of fibers with sodium hydroxide did not. One study of Fisher 344 rats inoculated intrapleurally with a single 20-mg dose of JM-100 fibrous glass (mean length 2.2 mm and width 0.15 mm; within respirable range) found that 3/25 developed mesothelioma, but because the authors observed such a spectrum of pleural mesothelial histopathological changes they concluded that there may be a gradual progression from mesothelial hyperplasia or dysplasia to mesothelioma (20).

Inhalation studies reviewed by both the IARC and NTP were insufficient to determine fiberglass carcinogenicity. However, as explained in the NTP report, those differences in particle deposition and retention in rodents are considerably different from those in humans and thus particles that may be important in inducing human disease may never reach the target tissues with sufficient quantities in rodents. Therefore, inhalation studies may well be less sensitive than tests by other routes. IARC indicates that it is often necessary to use other routes of administration when testing the carcinogenicity of mineral fibers (5).

Some inhalation studies have found that special application of 475 fiberglass can induce pulmonary fibrosis and pleural mesothelioma in hamsters as does amosite asbestos (21).

1.4.1.6 Genetic and Related Cellular Effects Studies Glass wool reportedly induced numerical and structural chromosomal alterations in mammalian cell *in vitro* and caused morphological transformation in rodent cells *in vitro*. The transformation depended on fiber diameter and length. Neither sister chromatid exchanges *in vitro* nor mutations in bacteria were induced by glass wool (5). It is reported that glass fiber-induced cell transformation could be the result of activating the H-ras, K-ras, c-myc, and c-fos proto-oncogenes and/or inactivating the p53 tumor suppressor gene as a result of gene amplification and/or point mutations, and that multiple mutations might be the result of genomic instability from chromosomal alterations induced by glass fibers (22).

1.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization

1.4.2 Human Experience 1.4.2.1 General Information Excellent summaries of human experience are found in IARC (5), WHO (2), and Infante et al. (19).

1.4.2.2 Clinical Cases 1.4.2.2.1 Acute Toxicity Inhalation can cause sore throats, hoarseness, coughs, and labored breathing (3). Skin contact can result in fiberglass itch and redness (3, 6) dermal effects reported have been as high as 61% in a worker population (23), but most other studies have reported lower incidences. Sometimes the irritant effects of dermal exposure can result in inducing eczematous reactions that mimic allergic responses, and allergic reactions to resins applied on the fibers can occur (24).

Irritation of the cornea was reported by Longley and Jones (25) after exposure to manmade mineral fibers (MMMF).

1.4.2.2.2 Chronic and Subchronic Toxicity There have been no consistent findings of pulmonary effects among workers exposed to fiberglass. However, some findings of pulmonary abnormalities have been reported. Radiological abnormalities have been reported among workers in the glass fiber manufacturing industry (26–28). Others who found radiological abnormalities have been unable to associate them clearly with exposure to fiberglass either because of a history of smoking or lack of correlation with duration or intensity of exposure (29–32).

1.4.2.3 Epidemiology 1.4.2.3.1 Acute Toxicity: NA

1.4.2.3.2 Chronic and Subchronic Toxicity: NA

1.4.2.3.3 Pharmacokinetics, Metabolism, and Mechanisms: NA

1.4.2.3.4 Reproductive and Developmental: NA

1.4.2.3.5 Carcinogenesis In 1988, the IARC concluded that there was inadequate evidence of the carcinogenicity of glass wool and glass filaments in humans, but that glass wool was possibly carcinogenic to humans, placing it in its Group 2B (5). Infante et al. (19) reviewed the studies evaluated by IARC and additional epidemiological studies (33–37) and concluded that when all studies were taken together, they were sufficient to conclude that respirable glass wool is carcinogenic and that when placed in combination with the experimental carcinogenic findings the data were sufficient to include fibrous glass in the category of a likely human carcinogen. These same data were reviewed by the NTP which concluded that glass wool (respirable size) is reasonably anticipated to be a human carcinogen (17). Chiazze et al. (38) reported a statistically significant lung cancer odds ratio of 23.4 (95% CI 32–172.9) in a case-control study among a group of fiberglass workers drawn from a historical cohort mortality study conducted on behalf of the Thermal Insulation Manufactures Association (TIMA). On further analysis, again using a case-control design,

it was reported that a history of cigarette smoking and not exposure to respirable glass was the most important variable for the increased lung cancer (39). New data continue to emerge evaluating fibrous glass and carcinogenicity. However, the evidence is still compelling enough given both the experimental data and the epidemiological data that neither IARC nor NTP have reversed their conclusions that glass wool can reasonably be anticipated to be a human carcinogen (17) or that glass wool is possibly carcinogenic to humans (5).

1.5 Standards, Regulations, or Guidelines of Exposure

OSHA regulates fibrous glass dust at a PEL of 15 mg/m^3 (total) and 5 mg/m^3 (respirable), and NIOSH recommends an REL of 3 fibers/cm^3 (fibers ~3.5 mm in diameter and ~10 mm in long) or 5 mg/m^3 (total dust) (40). The ACGIH recommends a TLV of 1 fiber/cc as a TWA (41).

Coal

Michael Attfield, Vincent Castranova, Eileen Kuempel, Gregory Wagner, MD

1.0 Coal

1.0.1 CAS Number:

NA

1.0.2 Synonyms:

Coal, anthracite, bituminous coal, lignite, brown coal.

1.0.3 Trade Names:

NA

1.0.4 Molecular Weight:

The molecular weight of coal *as mined* is indeterminate. Alkylated coal products have molecular weights from 500–2000 (low to high rank coal) (1).

1.1 Chemical and Physical Properties

1.1.1. General Coal is an organic, combustible, rock-like natural substance that occurs in various forms from hard and brittle anthracite to soft and friable lignite. Coal is sometimes classified into two types: hard coal and soft coal. These terms do not, however, have a standardized meaning. One definition calls anthracite hard coal and places all other coal types in the soft coal category. A more common convention is that of Speight (1), in which anthracite and bituminous coals are termed hard coal and lignite and brown coal are classified as soft coal. Research on the health effects of coal has been heavily concentrated on the more common anthracite and bituminous types. There, the results have shown more of a gradient in toxicological effect across coal types rather than any clear-cut divisions between types. Little research has been undertaken on lignite and other brown coals. This has prohibited drawing firm conclusions on its toxicity relative to its harder cousins. This lack of any obvious demarcation has led us to report on overall patterns of effect rather than to provide separate presentations by coal type. Where data are available, we draw attention to any findings especially

relevant to any particular coal type.

Coal varies considerably in composition and consists largely of carbon, hydrogen, and oxygen with smaller amounts of sulfur, nitrogen, trace elements, and metals. Coal originated from mostly organic material that was long ago buried by sediments. Heat and pressure converted the plant remains over geologic time to coal, the process thought to have led to peat, lignite, bituminous coal, and anthracite in turn. Coal, as extracted, contains many minerals in various proportions, including quartz, clays, carbonates, and sulfides. These minerals can be intrinsic to the coal, as in silica grains within the coal matrix, or may lie in pockets or layers. Although there are different methods for classifying coal—each developed for a specific geological or economic purpose—all tend to relate to the age of the coal. Older coals are purer, harder, more brittle, have less volatile matter, and have higher calorific value. They also contain higher amounts of fixed carbon. Fixed carbon is the basis of a commonly used classification index of coal—coal rank. High rank coals, such as anthracite, have the greatest amount of fixed carbon, whereas bituminous and subbituminous coals are defined as low rank. A rank-based system devised by the American Society for Testing and Materials (ASTM) divides coal into four main subtypes: anthracite, bituminous, subbituminous, and lignite (2). Each subtype is further divided, using fixed carbon, moist Btu, or other factors. For example, the main anthracite group is divided into meta-anthracite (98% or more fixed carbon), anthracite (92–98% fixed carbon), and semianthracite (80–92% fixed carbon). The lignite group is split into lignite and brown coal; the main distinction is whether the substance is consolidated (lignite) or not consolidated (brown coal).

Wood Dust

John Dement

1.0 Softwoods and Hardwoods

Wood dust is any particle arising from processing or handling wood (1). Woods are classified into two broad botanical classifications; hardwood is the common name given to the botanical classification *Angiosperms*, and softwood is the common name given to the botanical classification *Gymnosperms*. *Gymnosperms* have exposed seeds whereas angiosperms have encapsulated seeds. Although there are more than 12,000 species of trees recorded, most species are deciduous trees or hardwoods, and only about 800 species are coniferous trees or softwoods (2). Table 17.1 summarizes nomenclature for the more typical softwoods and hardwoods.

Table 17.1. Nomenclature of Some Softwoods and Hardwoods

Genus and Species	Common Name
Softwood	
Abies	Fir
Chamaecyparis	Cedar
Cupressus	Cypress
Larix	Larch
Picea	Spruce
Pinus	Pine
Pseudotsuga menziesii	Douglas fir
Sequoia sempervirens	Redwood
Thuja	Thuja, arborvitae
Tsuga	Hemlock
Hardwood	
Acer	Maple
Alnus	Alder
Betula	Birch
Carya	Hickory
Carpinus	Hornbeam, white beech
Castanea	Chestnut
Fagus	Beech

Fraxinus	Ash
Juglans	Walnut
Platanus	Sycamore
Populus	Aspen, poplar
Prunus	Cherry
Salix	Willow
Quercus	Oak
Tilia	Lime, basswood
Ulmus	Elm
Tropical Hardwood	
Agathis australis	Kauri pine
Chlorophora excelsa	Iroko
Dacrydium cupressinum	Rimu, red pine
Dalbergia	Palisander
Dalbergia nigra	Brazilian rosewood
Diospyros	Ebony
Khaya	African mahogany
Mansonia	Mansonia, bete
Ochroma	Balsa
Palaquium hexandrum	Nyatoh
Pericopsis elata	Afrormosia
Shorea	Meranti
Tectona grandis	Teak
Terminalia superva	Limba, afara
Triplochiton schleroxylon	Obeche

Wood Dust

Cotton and Other Textile Dusts
James A. Merchant, MD

1 Introduction

Byssinosis is a generic term applied to acute and chronic airway disease among those occupationally exposed to vegetable dust arising from the processing of cotton, flax, hemp, and possibly other textile fibers. Observations regarding respiratory disease attributable to these vegetable dusts date to the early eighteenth century (1).

Today the production of cotton products is commercially important to developed and developing countries alike. Processing of flax and hemp remains regionally important industries, which continue to provide traditional textile products. Thus several million workers are occupationally exposed to these vegetable dusts worldwide. In the United States more than 300,000 workers are directly

exposed to cotton dust, primarily in the textile industry, but also in cotton ginning, cotton warehousing and compressing, cotton classing offices, cottonseed oil and delinting mills, bedding and batting manufacturing, and utilization of waste cotton for a wide variety of products.

Two febrile syndromes characterized by fever, cough, and other constitutional symptoms including headache and malaise are also associated with byssinosis and textile manufacturing. These occur most frequently with exposure to low-grade, spotted cotton. Mattress-maker's fever and weaver's cough may be considered together because of their characteristically high attack rate and probable similar etiology. Mill fever, which is characterized by fever, malaise, myalgia, fatigue, and often cough, was a common complaint among workers first exposed to high levels of these vegetable dusts, with the prevailing cotton dust levels in the Western world it now rarely occurs. These febrile syndromes are similar to other febrile syndromes described among agricultural workers exposed to high levels of contaminated vegetable dusts. It is now also clear that symptoms typical of byssinosis are observed among others occupationally exposed to vegetable dusts. Many of those exposed are employed in agriculture, which typically involves daily exposure, rather than the cyclical workweek exposure of textile workers. It is also clear that exposure to organic dusts in textile and nontextile operations will often result in clinical asthma. This often results in self-selection or transfer of the affected worker out of dusty jobs or entirely out of the industry. There is also now evidence that exposure to textile dusts results in heightened airway reactivity and that atopy is a risk factor for the development of vegetable-dust-induced bronchoconstriction (2). These observations are likely to become more relevant with regulation of cotton dust to lower levels. This may allow toleration of lower exposure to cotton dust by many of those who were previously selected out of these industries because of asthma, thereby resulting in increased risk to the development of chronic airway disease.

1.1 Exposure Assessment

It is recommended that workplace exposures be determined using a vertical elutriator.

Cotton and Other Textile Dusts
James A. Merchant, MD

2 Epidemiology

The term *byssinosis* was first used by Proust in 1877 to describe respiratory disease among textile workers (3). It arises from the Latin *byssus*, which means fine and valuable textile fiber known to the ancients, usually referring to flax, but also cotton, silk, and other natural textile fibers. While Ramazzini was the first to describe asthma and chronic respiratory disease arising from the processing of textiles, there are abundant important historical descriptions of respiratory disease among textile workers, which were variously described as tracheal phthisis, spinner's phthisis, cotton pneumonia, stripper's asthma, or stripper's and grinder's asthma.

Mortality studies began with the collection of data on those exposed to cotton dust found in the Decennial Supplements to the Annual Report of the Registrar General of Births, Deaths, and Marriages in England and Wales between the years 1880 and 1932. Caminita et al. (4) reviewed these data and found a “marked excess” of deaths in higher age groups, particularly from bronchitis and pneumonia. Later reports emphasized that excess mortality from respiratory disease occurred chiefly among card room and blowing room operators, strippers, and grinders, rather than among other cotton workers. These observations were reconfirmed by Schilling and Goodman (5, 6), who showed that a substantial proportion of cardiovascular deaths should have been classified as respiratory deaths because cardiovascular disease was traditionally given priority in multiple certifications prior to 1939.

Barbero and Flores (7) studied 100 consecutive deaths among hemp workers and compared the results with 100 consecutive deaths among farm workers from the same region of Spain for the years 1938–1943. The mean age of death for hemp workers was 39.6 years; that for farm workers, 67.6

years. Cardiorespiratory disease was listed as the cause of death twice as often among hemp workers.

Contemporary studies of cotton textile workers' mortality have not revealed consistent excesses in overall mortality. Assessment of respiratory mortality has been difficult because of a lack of adequate work history data and lack of smoking histories. Enterline and Kendrick (8) studied 6281 white male cotton textile workers employed in Georgia mills. They found an overall mortality similar to that of asbestos building product and asbestos friction material workers but less than that of asbestos textile workers. There was no evidence of excess respiratory deaths among all cotton workers when cause-specific rates were compared to U.S. white male mortality rates. There was, however, an increase in cardiovascular and all causes of death with increasing duration of exposure. Of interest was a deficit in lung cancer deaths that led Enterline to suggest that there may be a cancer inhibitor, possibly endotoxin, in cotton dust (9). Recent studies of lung cancer in China have confirmed significantly less lung cancer among cotton textile workers after controlling for smoking (10). While methodologic factors were considered, these authors concluded that their findings are consistent with Enterline's hypothesis that some tumor-inhibiting factor(s) may be present in dusts from cotton and other vegetable fibers.

Daum investigated a South Carolina cohort exposed primarily to cotton processing and employed between 1943 and 1949 (11). In this small cohort, moderate increases in respiratory deaths were found among male carders with 10–20 years' exposure, and from respiratory and cardiovascular disease among female spinning room workers with greater than 20 years' exposure. A study of two North Carolina mills assessing exposure between 1936 and 1970 found no increase in respiratory mortality, but did report a trend towards increased respiratory mortality with increasing duration of exposure (12). Excesses in cardiovascular mortality were also observed and accounted for a high proportion of deaths. A proportionate mortality study of Rhode Island male textile workers who died during the period 1968–1978 reported a statistically significant increase in nonmalignant respiratory mortality that appeared to be consistent with cotton dust exposure (13). Prospective evaluation of mortality among Finnish women cotton workers hired between 1950 and 1971 found no excess in respiratory disease mortality but did report a fourfold excess in disability from respiratory disease (14). Mortality from cardiovascular diseases was lower than expected, and mortality from specific cancers did not differ from that expected. All these mortality studies suffer from the selection biases of the healthy worker effect, which becomes more pronounced with years of followup (12, 15). However, in a recent prospective mortality study of a cohort British textile workers, initially enrolled between 1968 and 1970, both the overall mortality and the respiratory disease mortality of the whole cohort were less than expected. However, there was an excess mortality from respiratory disease in those initially reporting byssinotic symptoms.

Early morbidity studies of cotton and flax workers found an unusually high prevalence of respiratory disease, particularly among those working in high dust exposure areas (16–18). In Great Britain, byssinosis was made a compensable disease in 1942 and, on the basis of the number of cases compensated, was thought to be a disappearing disease. Schilling and Goodman rediscovered byssinosis when they studied Lancashire mills to investigate an apparent increase in cardiovascular mortality (5, 6). In a series of studies extending over a 10-year period, Schilling contributed significantly to our understanding of the epidemiology of respiratory diseases among textile workers. He developed, and tested for reliability and validity, a series of questions that were added to the British Medical Research Council (BMRC) respiratory questionnaire, which provided the basis for his byssinosis grading scheme (19):

Grade O. No symptoms of chest tightness or breathlessness on Mondays

Grade 1/2. Occasional chest tightness on Mondays, or mild symptoms such as irritation (cough) of the respiratory tract on Mondays

Grade 1. Chest tightness and/or breathlessness on Mondays only

Grade 2. Chest tightness and/or breathlessness on Mondays and other workdays

Schilling's questionnaire and grading scheme has been the standard for worldwide epidemiologic studies of workers exposed to textile and other vegetable dusts. To validate the grading scheme, he demonstrated that cotton workers with increasing grades of byssinosis have corresponding increases in airway obstruction. Together with Roach, he was the first to quantify a strong linear dose–response relationship between total and respirable cotton dust and the prevalence of byssinosis, which largely explained differences in prevalence in various mill work areas (19). He was also the first to report that smoking was an important risk factor in determining byssinosis prevalence (5, 19).

Since Schilling's publications, similar findings have been reported among textile workers from many countries around the world. Recent studies confirm the presence of byssinosis, but especially nonspecific respiratory symptoms and associated lung function abnormalities among Chinese cotton textile workers (20, 21). While byssinosis is now much less prevalent, it is still found among Lancashire cotton textile workers (22) and flax workers in Normandy, France (23). In addition to those exposed in primary textile mill operations, the disease has been reported among cotton ginners (24, 25), cotton seed oil and delinting workers (24, 26), workers in waste cotton operations (27), those in garneting (bedding and batting operations) (28), and those processing soft hemp (29, 30) and flax (30–33). Byssinosis has not been typically found among those processing “hard” fibers of sisal or jute (34, 35). However, one study reported typical byssinosis among Tanzanian sisal workers with very high dust exposure (36). In addition, symptoms consistent with byssinosis have been reported among workers exposed to herbal tea processing and among workers engaged in swine confinement housing operations (37, 38).

Several investigations (25, 32, 39–42) have now confirmed, with remarkable uniformity, Schilling's early dose-response findings, despite differences in dose–measurement technique, study population composition, and source of raw product. More recent studies have demonstrated that reliance on total dust measurement may provide a misleading indication of risk, as much of the mass may be composed of cotton lint (43).

In the United States measurement of inhalable dust (<15 mm in aerodynamic diameter) has proven to be a reliable and valid dust measurement for assessment of vegetable dust dose–response (44). Most of these studies have concentrated on preparation and yarn-production workers, with little attention given to weavers and others exposed to cotton dust. One study examined both preparation and yarn processors, who were found to have similar dose–response relationships, and weavers, who were found to have a quantitatively different dose–response relationship (44) (see Fig. 18.1). Studies of changes in lung function over a Monday working shift have provided objective data on dose-related declines in FEV_1, which were consistent with the dose–response relationships based on byssinosis prevalence (44). Based on these data, a permissible exposure limit for exposure to raw cotton dust has been promulgated by the U.S. Department of Labor (OSHA): for preparation and yarn operations, a time-weighted concentration of 0.2 mg/m^3 of air, and for weavers, 0.75 mg/m^3 of air (45).

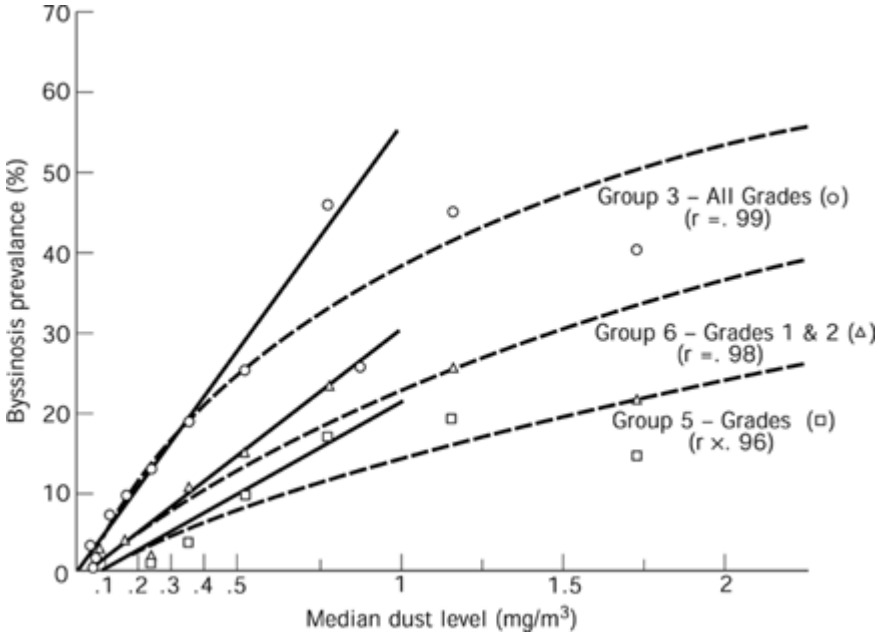

Figure 18.1. Byssinosis prevalence by grade and by median dust level among cotton preparation and yarn area workers: linear regressions and fitted probit dose–response curves.

Dose–response data are less available for cotton dust exposures outside the cotton textile industry, but there is evidence of a dose–response relationship for other cotton operations and for processing of flax and hemp (46, 47). Based on all available data, the World Health Organization has recommended exposure limits for several of these exposures (48).

Assessment of chronic cough and phlegm, as defined from the BMRC respiratory questionnaire (49), has been an integral part of most epidemiologic studies of cotton, hemp, and flax textile workers. While not a uniform observation, most surveys have reported increased rates of chronic cough and phlegm among those with heavy cotton dust exposure, especially among those with symptoms of byssinosis (50, 51). Similarly, indices of dyspnea, as assessed by the BMRC questionnaire, have been shown to be strongly associated with dustier exposures and have been found to be increased among those with more severe grades of byssinosis (29–31, 47). As with many other epidemiologic studies of respiratory disease, smoking has been found to be a powerful risk factor for chronic cough and phlegm and for measures of dyspnea (44, 52).

Two major effects of vegetable dust on lung function have been reported in epidemiologic studies. The first is a chronic effect characterized by airway obstruction and manifest by reductions in FEV_1, FVC, and FEV_1/FVC with increased dust concentration and duration of exposure. The second is an acute effect characterized by measures demonstrating bronchoconstriction over a working shift of exposure to cotton dust, especially after an absence from exposure for 2 or more days (Fig. 18.2) (41, 53). Spirometric evaluation, typically conducted prior to the Monday shift in Western countries, has confirmed Schilling's observation that those with symptoms of byssinosis, as a group, may be expected to have lower expiratory flow rates than comparable controls. Furthermore, those with chronic cough and phlegm, in addition to symptoms of chest tightness, have been found to have a further decrease in lung function (50–52, 54). In large cross-sectional studies, smoking has also been found to exert a significant additive decrease in preshift lung function (43, 44, 55). Recent studies by Schacter et al. suggest that smoking may be more related to abnormalities in maximum expiratory flows at 50% and 25%, whereas cotton dust appears to be either more important than or as important as the smoking effect on FVC and FEV_1 among cotton textile workers with long exposures (56).

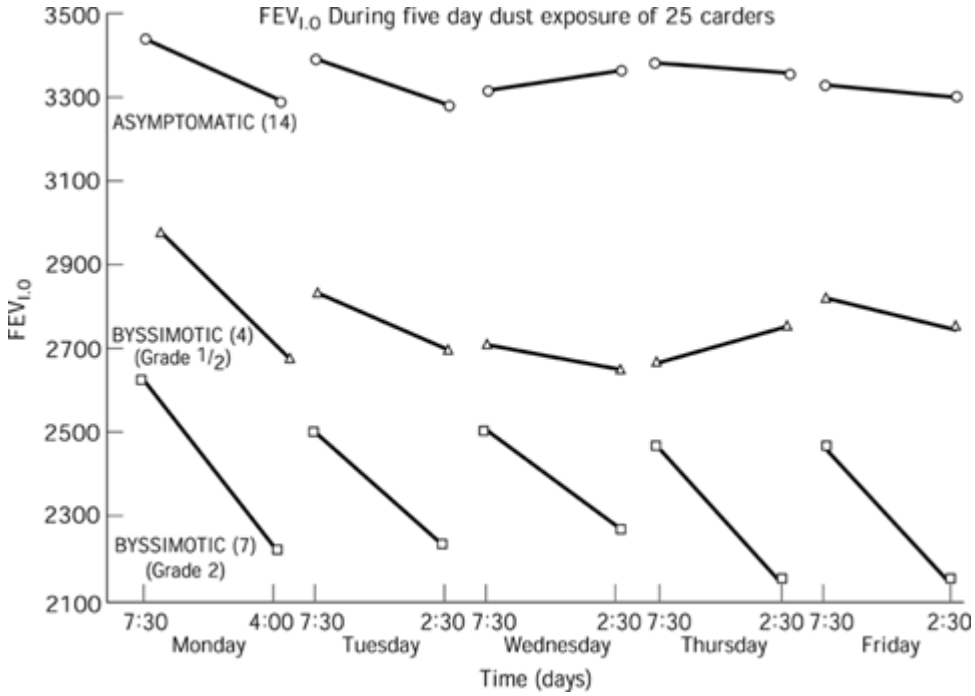

Figure 18.2. Pattern of response among 25 cardroom workers exposed to cotton dust.

McKerrow et al. (57) were the first to observe a reduction in expiratory flow rates over a work shift, a reduction that was most marked after an absence from exposure and especially among workers in areas with higher dust levels. From these observations they suggested that symptoms of Monday chest tightness and dyspnea might be explained by the reduction in expiratory flow rate. This hypothesis has been questioned, as many with symptoms of byssinosis do not exhibit work shift decrements and because the degree of reduction, although statistically significant in epidemiologic studies, is typically not considered clinically significant (decrement of 10% or more) (58).

It has been further observed that subjects with bronchitis and byssinosis tend to have greater cross-shift decrements in expiratory flow than those with byssinosis alone (50, 54). On the basis of the epidemiologic association between byssinosis grade and mean decrement in expiratory flow, Bouhuys et al. (59) proposed a functional grading scheme. Subsequent reports have shown that the relationship between a Monday decline in FEV_1 of 200 cm^3, as proposed by Bouhuys, is highly variable. An appreciable proportion of those without symptoms of byssinosis have a Monday decrement of greater than 200 cm^3 or 5%, whereas many with byssinosis symptoms do not show even a modest decline (50, 60). Nevertheless, because expiratory flow can be easily measured in untrained subjects and provides an objective indicator of biologic effect to vegetable dusts, spirometry before and following exposure has been widely used in epidemiologic studies. Those exposed to cotton, soft hemp, and flax dusts usually have greater decrements in expiratory flow than those exposed to similar dust levels from “hard fibers” (46, 47). Those exposed at higher dust levels have been found to show more marked decrements, and the dose–response relationship between respirable dust and decrement in flow rates approximates that for byssinosis symptoms (25, 28, 44).

In a series of experimental card room studies utilizing volunteer subjects exposed to a wide variety of cottons at different levels of dust exposure, Castellan et al. have demonstrated a stronger dose–response relationship between vertically elutriated endotoxin than vertically elutriated dust and have concluded that these observations strongly support the hypothesis that endotoxin plays a causative role in the acute pulmonary response to cotton dust (61, 62). As the volunteer subjects were not textile workers, these investigators were unable to assess the pattern of symptoms characteristic of byssinosis. Kennedy et al., in a dose–response study in Shanghai, reported a significant association with current endotoxin level and the prevalence of byssinosis and chronic bronchitis, but not with

dust alone (63). While smoking clearly affects baseline spirometric levels, there is conflicting evidence regarding the influence of smoking on acute changes in lung function (50, 53, 63). Cross-shift decline in FEV_1 remains a very useful epidemiologic tool, and despite its limitations in its application to individual workers, it has been incorporated as one feature of the medical surveillance examinations required by the U.S. Cotton Dust Standard (45).

Several studies have evaluated lung function prospectively (64–67). In each of these studies, conclusions were necessarily based upon survivor populations and include other selection biases, which usually tend to minimize occupational effects. Prospective assessments of decline in lung function have been carried out on workers exposed to high levels of cotton dust in Yugoslavia, India, and China, all of which demonstrated accelerated annual declines in FEV_1, which were associated with higher dust exposures that were several times higher than the U.S. Cotton Dust Standard (68–70). Berry et al. (65) reported roughly twice the annual decline in FEV_1 among cotton textile workers as among synthetic textile workers. The decline attributable to cotton dust was slightly greater, but similar in magnitude, to that attributable to smoking, and was somewhat greater among those working in dustier areas and among those exposed for shorter periods of time than longer periods. Merchant et al. (67), who studied a single cotton textile mill several times over a single year, found that those exposed to high levels of cotton dust (many of whom were new employees) had 10-month declines as high as 280 cm^3, and that smaller dose-related increased 10-month declines in FEV_1 occurred among workers in three other work areas with less dust exposure and longer tenure. A community study of active and retired older cotton textile workers found cotton textile workers to have a higher prevalence and attack rate of respiratory symptoms than controls, and that both men and women cotton textile workers had greater annual declines than did community controls. This study confirmed the cross-sectional assessment of this community and reported a significantly higher proportion of textile workers than nontextile worker controls to be severely impaired (55, 64).

In the first published prospective study of lung function among cotton textile workers exposed at or below the U.S. Cotton Dust Standard, Glindmeyer et al. (66) found no accelerated decline in FEV_1 among slashers and weavers exposed below the cotton dust standard and no accelerated decline among nonsmoking yarn-processing workers exposed at the cotton dust standard. However, smoking yarn-processing workers were found to have accelerated loss in annual FEV_1, even below the cotton dust standard of 0.2 mg/m^3; dose-related increases in decline in annual FEV_1 were observed among men and women smokers and nonsmokers, thereby unambiguously confirming the dose–response findings from the cross-sectional studies of byssinosis prevalence and cross-shift decline in FEV_1 on which the U.S. Cotton Dust Standard was based (40, 45). While these aggregate data support the hypothesis that those with increased acute responses are at increased risk for increased declines in lung function over time, as suggested by Bouhuys (30, 69), this question is not fully resolved.

Cotton and Other Textile Dusts

3 Clinical Evaluation
3.1 Signs and Symptoms
The hallmark of byssinosis is the characteristic symptom of chest tightness that typically occurs following a weekend away from exposure. Chest tightness is described by workers, often accompanied by placing a hand over their chest, as a heaviness on their chest, as chest congestion, as difficulty taking a deep breath, and sometimes as a bandlike feeling around their chest. The onset of chest tightness is variable in the British Home Office report (71), which described the symptoms in 100 card room workers: 93% described respiratory symptoms; of these 59% experienced their most

severe symptoms during the first half of the working shift, and 41% during the second half of the shift. In all workers symptoms were most severe on the first day of the working week. This time period is important as it distinguishes byssinosis from occupational asthma, which tends to increase in severity over the working week. Affected workers often compare the feeling of chest tightness to that of a chest cold. Frequently chest tightness is accompanied by a cough, which is more prominent on Monday. Indeed, a Monday cough may be the only symptom. A history of chronic productive cough is frequently obtained. Among older workers who have been exposed to cotton dust for many years, a history of exertional dyspnea is a common finding. Among those severely affected, chest tightness and dyspnea occur on all workdays, with relief coming only on weekends and holidays, if then.

All these symptoms become more severe if the period away from cotton dust exposure is prolonged; that is, the affected individual appears to lose exposure tolerance. Conversely, Monday symptoms do not occur if exposure occurs 7 days a week, as often occurs with cotton ginning. Symptoms are more severe and more frequent among smokers (42, 67). Occasionally, a worker with typical byssinosis will report that symptoms of Monday chest tightness disappeared when he or she stopped smoking without an apparent change in dust exposure (52).

There are no typical or characteristic signs found upon physical examination of workers with symptoms of byssinosis. While the symptomatic worker frequently exhibits a productive cough, on examination the chest is usually relatively quiet. Wheezing is not commonly found early in the course of the disease. Among those severely affected, all the physical findings of advanced chronic airflow limitation may be observed.

A number of nonspecific symptoms of occular and nasal irritation are often observed among those exposed to cotton dust, apart from byssinosis. Febrile syndromes that have been associated with cotton processing include mattress maker's fever and weaver's cough. These conditions occur among experienced workers and are characterized by a high attack rate, a clear-cut febrile episode, severe cough, and dyspnea. Most of these outbreaks have been attributed to mildewed yarn. These febrile syndromes are similar to those common among agricultural workers who are frequently exposed to high concentrations of moldy grain, hay, or silage (72–74). Because the clinical presentation is the same, and because the etiology of all these febrile syndromes is probably from microorganism toxins, the term organic dust toxic syndrome (ODTS) has recently been suggested in an attempt to codify this condition (75). It is likely that the febrile syndromes arising from high levels of cotton or grain dust are also attributable to endotoxins, which are now well-known constituents of these vegetable dusts.

Newly hired workers, and those who first go into dusty cotton-processing areas for a period of a few hours, may experience mill fever (76), which has also been called card room fever, dust chills, dust fever, cotton cold, cotton fever, weaver's fever, and, among flax workers, heckling fever (4). A similar syndrome has been described among those exposed to high concentrations of grain dust (75). Symptoms, which typically occur 8–12 h following heavy dust exposure, consist of chills, headache, thirst, malaise, sweating, nausea, which may be accompanied by vomiting, and a transient fever, followed by fatigue. Without further exposure, these symptoms subside spontaneously within a day or two, but the fatigue may continue for several days. With repeated exposure, such as that experienced by a newly hired textile worker, these symptoms may occur for several days until the worker is “seasoned” or develops a tolerance (77). This “seasoning” is well recognized by workers exposed to high dust concentrations.

Another common complaint of new workers or visitors to mills with high exposures to cotton dust is tobacco intolerance (52). Also a common finding among mill visitors who have a history of asthma, and who may not have had an asthma attack for years, is immediate onset of clinical asthma, which may be severe and often requires medical intervention (78). With the improved dust control achieved through implementation of the Cotton Dust Standard, mill fever and tobacco intolerance are now infrequent observations. However, it has been suggested that better dust control may allow many

more workers with airway hyperreactivity to remain in vegetable dust-processing operations and that these workers may constitute a high-risk group for future development of airway obstruction (79).

3.2 Lung Function

A series of studies of volunteer textile and nontextile workers in experimental card rooms have provided a good understanding of lung function abnormalities with cotton dust exposure (2, 41, 77, 80–82). These studies have documented a linear decline in expiratory flow over the period of exposure, which is most consistently and significantly discriminated by the FEV_1 (41). Measures of expiratory flow rates have been found to be more sensitive indicators, but increased variance in flow rate measurements decrease their discrimination. Closing capacity and total lung capacity have been found to increase and oxygen tension decrease, but not significantly, with exposure. Body plethysmography before and following exposure suggests that those who exhibit decreased expiratory flow with exposure have increased resistance primarily in peripheral airways, while increased resistance among those who do not have an expiratory flow response occurs primarily in central airways (77). Helium–oxygen spirometry in these subjects found significant decrements in specific airways conductance and found that smokers had greater spirometric responses than nonsmokers (82).

A temporal association between a peripheral leucocytosis and recruitment of leucocytes to the nasal mucosa and decline in FEV_1 has been noted with heavy dust exposure (41). Evaluation of a selected population of nonasthmatic volunteers demonstrated that atopy, defined as positive prick tests to at least two allergens, and cross-shift decline in FEV_1 were independent. However, those with atopy had significantly greater long-term declines in FEV_1, and the degree of atopy, as measured by the number of positive skin tests, was significantly associated with cotton-induced decrements in FEV_1 (2). It was suggested that this finding may reflect airways hyperresponsiveness described in nonasthmatic, atopic individuals. Studies by Boehlecke et al. (personal communication) now suggest that exposure to cotton dust heightens airways hyperreactivity, as has been previously reported with other organic dust exposures (83).

Only one detailed physiologic study has been done of an asthmatic with exposure to cotton dust (68). This followed an unexpected asthma attack triggered by cotton dust exposure in an investigator who had not had asthma since childhood. Highly significant declines in FEV_1 accompanied by marked declines in oxygen tension occurred within 15 min of exposure. Both FEV_1 and PaO_2 remained depressed following exposure and over 3 more days of cotton dust exposure. No significant change was noted in temperature, leukocyte, or eosinophil count. FEV_1 and PaO_2 returned to baseline level, without bronchodilation, after 3 days away from dust exposure.

Assessment of lung function in those with byssinosis and cotton textile workers with long-duration exposure has usually demonstrated a pattern of mild to moderate airways obstruction, but occasionally this may be severe (84, 85). A very significant proportion of older cotton textile workers (50% of men and 37% of women) have been found to have some lung function abnormality (85). One study of women with byssinosis assessed transfer capacity for carbon monoxide (TLCO) and found that smokers had significantly lower TLCO, despite shorter cotton dust exposure, while nonsmoking women had normal levels of TLCO. The authors concluded these results support the hypothesis that emphysema among cotton textile workers is probably due to concomitant cigarette smoking and is not itself a feature of byssinosis (86).

3.3 Treatment

Research on medical treatment for byssinosis has been confined to acute events. Clinical trials have relied almost exclusively on changes in flow rates among active workers as the indicators of effect. While propranolol has been shown to increase bronchoconstriction with hemp dust exposure, antihistamines and ascorbic acid have been found to protect against this effect (87, 88). Similarly, inhaled bronchodilators (87–89). Finally, preexposure treatment with cromolyn sodium tends to block bronchoconstriction (87–89). Inhaled beclomethasone also appears to reduce the flow-rate

response to cotton dust exposure (89). It must be emphasized that these beneficial physiologic effects occur without similar documentation in regard to symptoms. Thus, while the bronchoconstricting effect of these organic dusts, which is usually not severe, may be blocked or reversed, there is no evidence that use of these drugs will necessarily suppress byssinosis symptoms or retard the progression of cotton-dust-induced obstructive airway disease. Therefore, these drugs cannot be considered preventive measures. Management of severe cases of byssinosis does not differ from that for chronic bronchitis and emphysema.

3.4 Pathology

Schilling and Goodman reviewed pathologic observations on lungs of workers with long cotton dust exposure, as made by several early investigators, and concluded that the pulmonary pathology was that of chronic bronchitis and emphysema (6). In one report lungs were fixed in inflation from 10 autopsies of workers with over 20 years of cotton dust exposure. Nine of these cases were found to have chronic bronchitis and/or emphysema, which was more marked among those working in high dust exposure areas. These five and two others had evidence of right ventricular hypertrophy, and four of these cases were judged to have died of cor pulmonale. Gough and Woodcock described lungs of cotton textile workers with histories of byssinosis as having inflammation of the bronchi with squamous metaplasia and generalized emphysema, which was somewhat more prominent in proximity to dust deposits (6).

Three more recent studies of lung pathology in cotton textile workers have been reported (90–92). Edwards et al. (90) studied lungs from 43 patients who had long exposures to cotton dust and had been receiving industrial benefits for byssinosis. The lungs were distended with formalin at necropsy. Gross examination revealed 27 (63%) with no significant emphysema, 10 (23%) with varying degrees of centrilobular emphysema, and 6 (14%) with panacinar emphysema. Most cases showed heavy black dust pigmentation, often associated with centrilobular dilation of distal airspaces. There was, however, significantly more mucous gland hyperplasia and hypertrophy of smooth muscle in the upper and lower lobar bronchi and significantly less connective tissue and cartilage in cases than in controls. While the authors suggested that both smoking (17 cases) and air pollution from living in the Lancashire region could have contributed to these pathologic lesions, this study did not assess these possible risk factors.

Pratt and colleagues (92) studied lungs fixed in inflation from 44 textile workers and 521 nontextile workers. Their study had the advantage of using lungs properly prepared for evaluation of emphysema and knowledge of smoking status. It was limited, however, by lack of documentation of cotton dust exposure, the extent of that exposure, and the small numbers of nonsmoking textile workers (8 cases). Nevertheless, significantly more mucous gland hyperplasia and goblet cell metaplasia was found among textile workers. Centrilobular emphysema was slightly, but insignificantly, increased among textile workers. Moran (91), who conducted a study of cotton textile workers over an 18-year period, reported an odds ratio of 2.2 for emphysema among active and highly exposed cotton textile workers compared to a group of noncotton workers. The results of this study suggested that there may be a shift to an earlier age of onset of emphysema among certain exposed cotton textile workers, but details regarding specific cotton dust and smoking exposures were not available. Of relevance to the question of emphysema among cotton textile workers is a recent animal model of intratracheally instilled cotton dust endotoxin in hamsters, which revealed both functional and morphologic evidence of mild emphysematous lesions (63, 93).

In summary, the available pathologic data consistently find evidence of considerably more airway disease (both large and small airway lesions of chronic bronchitis), while the data regarding emphysema are incomplete. There appears to be historical evidence for the existence of emphysema and some recent clinical and animal morphologic evidence for an increase in emphysema among those with heavy cotton dust exposure. An autopsy study of a larger number of cotton textile workers with well-documented occupational and smoking histories is needed to resolve this issue.

3.5 Prevention

Given our current state of knowledge regarding the etiology of byssinosis and the lack of practical biological assays, risk assessment depends on measurement of dust concentrations, and prevention

depends largely on dust control in the workplace (94). Significant improvements in exhaust ventilation and in dust control technology and application have resulted in reduced risk in most areas of textile mills in the United States. A second control technology, which appears promising in experimental studies, is cotton washing (53). Although this preprocessing has been found to reduce symptoms and functional changes among experimentally exposed subjects (largely through removal of fine dust), it is not yet clear whether cotton washing will be technically feasible prior to spinning. It is recognized to be efficacious for certain cotton products (medicinal cotton and cotton batting) that do not require spinning and is so recognized by the U.S. Cotton Dust Standard (45).

While dust control is the foundation of a respiratory disease prevention program in the cotton-processing industries, medical surveillance and employee education also play important roles. Smoking, and the interaction between smoking and cotton dust exposure, are clearly important risk factors in byssinosis and chronic lung disease arising from cotton dust exposure. Therefore, it is essential that information regarding the adverse effects of smoking, and the combined effects of smoking and cotton dust exposure, be made available to workers through employee education and smoking cessation programs. Workers who continue to smoke should be placed in low dust exposure areas (44, 66). It is also essential to stress the use of appropriate work practices to reduce dust exposure. Periodic medical examinations designed to detect those acutely affected and those with chronic lung disease are important and can be effective (66). Through the use of a standard questionnaire, it is possible to ascertain a sound occupational and smoking history and to screen for byssinosis, bronchitis, dyspnea, and other common medical conditions. Simple, routine spirometry will identify many of those acutely affected and should detect all with significant impairment.

All these prevention provisions—allowable dust concentrations, work practices, and medical surveillance—are detailed in the Department of Labor Cotton Dust Standard promulgated in 1978 (45). With the 4-year grace period given to the industry to implement all provisions, this standard has now been in place for 10 years. Evaluation of the efficacy of the standard has been examined by Glindmeyer et al. (66), who found that the standard provided protection from progressive declines in lung function for all those working in slashing and weaving areas and for all yarn-processing workers, except for smokers, who still showed progressive losses in lung function below the 0.2 mg/m^3 standard. This finding, which is consistent with previous cross-sectional and prospective studies of smoking cotton textile workers, points up the importance of medical surveillance and appropriate placement of smoking textile workers, but raises the possibility that dust levels may need to be further controlled to protect this sector of the workforce.

Cotton and Other Textile Dusts
James A. Merchant, MD

4 Summary
Byssinosis is the term given to the acute and chronic respiratory disease arising from occupational exposure to textile vegetable dusts. It is characterized by chest tightness following an absence from regular exposure to dust. Symptoms of chest tightness have also been observed with a variety of other organic dusts, but this finding has not been referred to as byssinosis in nontextile processing settings. Also observed with exposure to textile vegetable dusts is an increased prevalence of nonspecific airway symptoms, modest cross-shift declines in spirometry, and progressive declines in lung function that may result in significant lung impairment among those with long exposure to these dusts. Linear dose–response relationships have been observed between byssinosis prevalence, cross-shift decline in FEV_1, and concentration of inhalable cotton dust. Similar findings for various dust fractions have been observed in other industries. These findings have led to regulation of cotton dust in the United States and in several other countries. While dust control is the hallmark of prevention of lung disease among textile workers, placement of smokers in low dust areas, periodic medical

surveillance, and appropriate work practices are essential components of an overall program to prevent lung disease among textile workers.

Bioaerosols and Disease
Donald E. Gardner, Ph.D.

1 Introduction
Airborne contaminants in the workplace can include chemical, physical, and biological agents. Although the primary focus of the industrial hygienist and toxicologist in the past has been on the health effects of chemical and physical contaminants, there is renewed interest in the science of "aerobiology"—the study of airborne particles of biological origin.

Millions of workers in hundreds of occupations are exposed to potential health hazards in their workplace because of substances they breathe in the air. Every year, an estimated 65,000 U.S. workers develop respiratory disease related to their jobs, and an estimated 25,000 persons die from occupational lung disease (1–3). Respiratory illness causes an estimated 657 million person-days of restricted activity and 324 million person-days of lost work (4). Occupational exposure to airborne particles (aerosols) is very common and may pose a potential hazard to human health because microbial cells are particulate matter, studies that deal with airborne microorganisms are concerned with aerosols. Many of the physical and chemical processes that describe aerosol behavior also apply to bioaerosols.

The term bioaerosol is used to describe a colloidal suspension of liquid droplets or solid particles in air, that contain or have attached to them one or more living or dead organisms, certain products of bacterial and fungal metabolism, or other biological material. Bioaerosols are ubiquitous indoors and outdoors and may contain cell fragments, dust mites, animal dander, skin scales, and a wide variety of microscopic organisms, including bacteria, viruses, fungi, algae, amoebae, and protozoa. Other nonliving biological substances (e.g., cotton dust, pollen, hemp, jute, sugarcane) also produce respiratory illness in workers. These are not considered in this chapter but have been reviewed elsewhere (5). This chapter focuses on those bioaerosols most likely to be related to the workplace, although nonoccupational sources can be prevalent. Bioaerosols such as house dust mites, animal dander, or cockroach products that are very important in inducing diseases like asthma may be referred to but are not discussed in detail because of their strong association with the home environment. Attention is given to infectious agents (and their products) because many working conditions are conducive to transmitting of such agents.

Although bioaerosols generally represent fewer hazards than those of a physical or chemical nature, there are certain occupations where the risk of such exposures may be more prevalent. Occupational settings of concern include agriculture, saw mills, textile manufacturing, meat and other food processing, biotechnology, research laboratories, waste disposal, construction, and health-care

institutions (6–8).

The extent of health problems caused by bioaerosols in the workplace is difficult to estimate partly because of the wide array of agents that evoke a variety of human responses. The workplace atmosphere may contain hundreds of different kinds of biological particles, both pathogens and nonpathogens, and today's technology cannot quantify all of them. The complexity is even greater because of the broad range of different types of industrial environments and because exposures are not often recognized until the workers experience illness. Understanding the cause and effect relationship associated with exposure to bioaerosols is a most difficult and vexing problem. Despite uncertainty about the magnitude of the health risk caused by exposure, the impact is appreciable and has been considered the largest single cause of morbidity (9, 10).

This chapter is intended primarily for those occupational health professionals who seek to understand the potential health risk of airborne biological agents in the workplace. It presents an overview of the basic concepts and methodologies useful in assessing the health effects of bioaerosols, including the (1) types and properties of bioaerosols; (2) sources of bioaerosols; (3) transmission, infections, and disease; (4) interaction with environmental and physiological factors; (5) health effects from the inhalation of bioaerosols; (6) sampling and identifying airborne microbial contaminates; (7) assessment of risk; and (8) control and prevention of airborne infectious disease.

Bioaerosols and Disease
Donald E. Gardner, Ph.D.

2 Types and Properties of Bioaerosols

Bioaerosols differ from other air pollutants because they have complex and varied organic structures and may be capable of reproducing, thereby causing infections. This section presents an overview of the different types and properties of agents associated with bioaerosols. For those who desire more details and further explanation, there are numerous excellent texts on microbiology, aerobiology, and the toxicology of airborne contaminants (11–14).

2.1 Bacteria

Bacteria are free-living, unicellular organisms that can self-perpetuate without the aid of a host cell. Their chemical composition is not greatly different from that of other living materials. They are composed of water, proteins, fats, carbohydrates, and various inorganic compounds such as sulfur, phosphorus, and salts. Nearly all bacteria are encased in porous but rigid cell walls that protect them from osmotic rupture and give different types of bacteria characteristic shapes. They occur in three general shapes: spherical (coccus), rod-shaped (bacillus), and spiral (spirochete, spirillum, and vibrio). They also differ in size. Cocci range from 0.15 to 2.0 mm in diameter. The smallest bacillus is about 0.5 mm long and 0.2 mm in diameter, and the largest pathogenic bacillus may approach 1 mm in diameter and 3 mm in length. The spirilla are usually 1 to 14 mm long. An important fact associated with bacterial cells is that the ratio of surface area to volume is extremely high. This high surface area provides a good opportunity for direct contact with the surface tissue of susceptible host cells. Typically pulmonary diseases resulting from bacterial infections include pneumonia, brucellosis, Legionnaires' disease, tuberculosis, meningitis, and anthrax.

A mucilaginous capsule surrounds many pathogenic bacteria. The presence of a capsule may increase the virulence of an organism by protecting it against certain host defenses. Most unencapsulated microorganisms are readily destroyed after being engulfed by local phagocytes. As an example, unencapsulated *Streptococcus pneumoniae* are generally considered avirulent, whereas encapsulated strains can produce pneumonia. Some airborne bacilli form resistant structures, known as spores. In a spore state, the organism has a relatively high degree of resistance to all sorts of injurious environmental influences such as high temperatures, germicidal chemicals, dryness, etc. When spores are brought under conditions favorable for growth, they germinate; the spore becomes

a vegetative form of the bacillus, which then multiplies and behaves in the usual manner.

2.2 Viruses

The large and heterogeneous group of microorganisms called viruses are alike in that they are all obligate intracellular parasites that live in cells of their selected hosts. Viruses, the smallest parasites (0.02 to 0.3 mm), are intracellular molecular particles, in some instances crystallizable. The virus particle consists of a central core of a nucleic acid for its reproduction. The nucleic acid core may be made up of either RNA (ribonucleic acid) or DNA (deoxyribonucleic acid), which represents the basic infectious material. When viruses invade a host cell, the genetic material takes over the host cell's own reproduction process and causes the cell to produce more viruses. Viruses cannot replicate themselves in the extracellular state and are highly specific in selecting cells that they will infect. Some viruses replicate within the cytoplasm of the host cells, and others replicate within the nucleus of the cell. Viruses can be released from the host cell when the cell ruptures, a process which is lethal to the host cell. Other viruses are released from the host cell gradually through a “budding-off” process. In this process, each newly formed virus particle released is surrounded by a host-derived membrane called an envelope. This process does not result in the death of the cell. The severity of the disease caused by viruses varies considerably in terms of their effect on susceptible individuals. Pulmonary diseases caused by viruses include influenza, the common cold, and bronchiolitis.

2.3 Fungi

Fungi are a diverse group of saprophytes that occur in many forms, inhabit air, soil, water, and vegetation, and also live on the bodies of humans and animals. It has been estimated that there are more than 50,000 species of fungi, but fortunately only about 50 are associated with human disease. Fungi are considered one of the most common forms of life on earth. They vary in shape and size from a single-celled microbe to giant multicellular mushrooms. Fungi reproduce by a variety of methods, including budding, fission, and spore formation. Pathogenic fungi generally produce no toxins. All fungi are heterotropic, requiring organic nutrients for existence, and most are obligate aerobes. Within the protoplasm of fungi are enzymes which, when diffused into the surrounding environment, change complex substances into simpler substances useful as nutrients for the cell. Human disease caused by fungi can vary from superficial infections of the skin to severe diseases that involve the respiratory system and other internal tissues and organs. The pulmonary diseases associated with fungal infection include asthma, aspergillosis, coccidioidomycosis, histoplasmosis, and various types of hypersensitivity pneumonitis. Fungi have a special tendency to cause infections in people with compromised immune systems. Fungal pneumonia may be dormant in the host respiratory system for months or years and cause disease only when the host's defenses are compromised.

Yeasts are filamentous, unicellular forms of fungi that are usually 3 to 5 mm in diameter. In view of the ubiquitous distribution of yeast in air, dust, and soil and also on surfaces of the body, it is not surprising that these forms have been associated with a variety of pathological processes. Morphologically they are oval or ellipsoidal and rarely form long filaments. Yeast cells are, on average, larger than bacteria and may have a volume thousands of time that of some bacteria. Yeast can be frequently found inhabiting the throats of healthy individuals. Many types of yeast infections are superficial, but serious systemic diseases may occur.

Molds are multicellular fungi found practically everywhere. The term mold is a general one which is used to describe the woolly, cobweb-like, cottony or powdery, black, green, yellowish, or white growths, seen on a variety of surfaces. Molds are very conspicuous in nature and are recognized by their filamentous and branching structures and macroscopic size. Molds have branching tubular structures that can be 2 to 10 mm in diameter and are associated with nutrition and reproduction. Molds produce enzymes that cause rapid fermentation, proteolysis, and other biochemical changes in a variety of substances. Some allergic diseases caused by the inhalation of molds include farmer's lung disease from the inhalation of moldy hay, bagassosis from dried stalks of sugarcane, grain fever from handling grain in all stages of production from harvest to storage, sequoiosis from moldy sawdust, and coffee worker's lung from coffee bean dust (5, 15).

2.4 Rickettsias

Rickettsias are closely related to viruses. They are smaller than bacteria, and their growth occurs

within the cytoplasm (e.g., typhus) or in the nucleus of the infected cell (e.g., Rocky Mountain spotted fever). These organisms have a diameter of about 0.3 mm and lengths seldom exceeding 2.0 mm. They are pleomorphic and may be found singly, in pairs, in chains, or in long filaments. No spores are produced. The normal natural reservoir and primary hosts of these organisms are a variety of infected insects (lice, fleas) or arachnids (ticks and mites). When these organism invade the human, they attack the reticuloendothelial system and colonize in the lining of the blood vessel walls. With such infection, there is hyperplasia of endothelial cells and a localized thrombus formation that leads to obstruction of blood flow and results in the escape of red blood cells into the surrounding tissue. The rickettsia that causes Q fever is resistant to drying and can survive in the dust for months until it becomes airborne and infects an individual.

2.5 Nonliving Contaminants of Biological Origin

The products of microbial metabolism are complex and numerous. Chemically, they can consist of a wide variety of proteins, lipoproteins, and mucopolysaccharides. The amounts of these materials produced are determined by the particular substrate available to the organism and the environmental conditions (i.e., temperature, humidity). Exotoxins are proteins produced within the cell and excreted into the surrounding environment and may be fatal in quantities of micrograms or less by causing diseases such as botulism, tetanus, gas gangrene, and food poisoning. Bacteria may also liberate endotoxins, which are lipolysarcharides intimately associated with the cell wall of certain gram-negative bacteria that can produce diseases such as typhoid fever, cholera, and brucellosis. They are not released until the cell disintegrates. Endotoxins are usually water soluble, relatively heat-stable but less potent than the exotoxins, and less specific in their action. Certain fungi may also produce toxins that may have health effects in sufficient doses. For example, the Aspergillus organism elaborates aflatoxins that can cause hepatic necrosis, liver cancer, and immunotoxic effects.

Microorganisms such as bacteria, actinomycetes, and fungi may also produce a variety of volatile organic compounds (VOCs) and semi-VOCs during metabolism. VOC metabolites such as higher alcohols, ketones, and organic acids are responsible for the odor often associated with the growth of these microbes.

Bioaerosols and Disease
Donald E. Gardner, Ph.D.

3 Sources of Bioaerosols

Microorganisms are the most versatile and most widely distributed kind of living thing and occur nearly everywhere in the environment. As such, they may be capable of replicating themselves or merely surviving in habitats that are extremely diverse. Any place that maintains viable microorganisms represents a reservoir from which they may be dispersed. Although certain organisms are known for their infectivity and are commonly referred to as pathogens, all organisms are potential pathogens under certain host conditions, especially in an immunocompromised individual.

The air does not constitute a normal bacterial habitat. Air is not a medium in which microorganisms can grow, rather it is a carrier of particulate matter, dust, and droplets that may be laden with microbes. The microbial flora of air are both transient and variable. Only those species resistant to desiccation and exposure to the conditions in the air can persist long in this medium.

The number and types of microbes that contaminate the air are determined by the source of contamination. The environment is laden with reservoirs of microorganisms that may become airborne when disturbed. Once airborne, success in reaching a susceptible host depends on the number of organisms present, the particle size, the force with which they are propelled into the environment, the resistance to drying, the temperature and humidity of the air, the presence of air currents, and the distance to the host. There are numerous processes and activities in industry that

may generate microbial aerosols. A few examples include facilities such as slaughter houses, textile mills, animal-waste rendering plants, hospitals, nursing homes, and various research and diagnostic laboratories. Biomedical researchers in hospitals, universities, and research institutions are at risk of infections with a wide variety of microorganisms. Workers may become infected because their occupation puts them in direct contact with animals, their secretions, and their by-products. Some of the animals used in research may harbor pathogens of human disease.

Although most of the microbial contaminants identified in the work environment are similar to those microbes found outdoors, the air within the workplace may actually become more heavily contaminated, even under normal working conditions, and may potentially place workers at greater risk (16). An enclosed work environment tends to confine aerosols under temperate conditions and may actually allow them to increase in numbers. Certain bacteria and fungi can flourish in improperly maintained air ducts, air conditioners, humidifiers, dehumidifiers, air-cleaning filters, carpets, and improperly ventilated places where moisture is likely to collect (17, 18). Fan coil units are potential sources of bioaerosols in health-care facilities and in certain offices. Ventilation systems can pick up contaminated air, distribute, and transport infectious microorganisms to other parts of the building and to susceptible individuals (19, 20). A good example is *Legionella pneumophila* which becomes airborne from contaminated cooling system water and is responsible for Legionnaires' disease (21, 22).

Bioaerosols are also produced as sprays in liquid droplets from nozzles in agricultural applications, spray from manufacturing processes, bursting bubbles from wastewater treatment plants, and spray drift from nuclear cooling towers or as dry particles from urban vehicular activity and rural agricultural practices.

Although progress in occupational health and safety has led to the disappearance of some occupational diseases, technological development has brought new challenges (15, 23, 24). New hazards could arise from the introduction of new products and technologies through biotechnology and genetic engineering. Genetic engineering technology can be used to alter the genetic material of living cells, allowing changes to be made to the inherited characteristics of plants, animals, and microorganisms. The methodology used ranges from traditional techniques such as natural mating methods for selective breeding to advanced recombinant DNA techniques where genetic material is altered and manipulated directly. The ability to produce organic materials with new characteristics offers many potentially useful products for the production of pharmaceutical products, food processing, agriculture advances (plant breeding and biological pesticides), mineral leaching and recovery, enhanced oil recovery, and pollution control. A major concern has been the fear of releasing such genetically engineered microbes into the environment. The metabolites produced by such organisms may be toxic and may even persist in the environment. For example, a potential concern regarding a microorganism being used to biodegrade toxic chemicals is the buildup of intermediary metabolites that could be more toxic, more mobile, or more resistant than the original chemicals. In addition, once such organisms are developed in the laboratory, it becomes necessary to test these organisms in the field. Such field testing can inevitably result in the use of large volumes of microorganism with possible decreased control of the exposure and a potentially increased health risk. This emerging threat results from microbes that develop new pathways, new proteins, and new strategies for survival. Microorganisms, even of different species, are known to exchange genetic material, including the gene for drug resistance.

Even in a outer space, numerous microorganisms have been identified in the spacecraft environment and may pose a potential health hazard for astronauts who work in space (25). The primary source of microorganisms in spacecraft habitats is the crew. The risk of infection among crew members has been well documented from previous missions, and the incidence of infections can be expected to increase as space missions lengthen (26). The potential health risk from airborne contaminants within the spacecraft is unique due to microgravity conditions, which affects the dispersion and transmission of airborne particles, including microorganisms. On earth, large droplets produced by coughs and sneezes settle to the floor quickly. For example, a spherical particle 100 mm in diameter

falls 3 m (the height of an average room) in 10 seconds, 40 mm particles take 1 minute, and 20-mm particles require 17 minutes to settle out. In the microgravity environment of space, atmospheric particles would possibly remain airborne indefinitely and continue to contaminate the breathing air regardless of their size (26, 27).

Microbial contaminants have been found in increasing levels in recent years because of the attempts to make buildings more airtight for energy conservation. This action reduces the rate of air exchange between outside (fresh air) and the inside environment. For example, older buildings may have air exchange rates that are 7–10 times greater than those in newer buildings. With this reduction, the levels of airborne particles, including microorganisms, can be higher than the concentration of these same materials outdoors. *Sick building syndrome* (SBS) is a term used to describe workers' discomfort and medical symptoms believed related to the accumulation of airborne contaminants indoors. Complaints include respiratory tract infections, irritation of the eyes, nose and throat, lethargy, and other flu-like symptoms (28). The range and severity of the symptoms vary greatly, depending on the sensitivity of the exposed individual. It has been proposed that the problems associated with SBS can be attributed to poorly designed and functioning ventilation systems, inadequate filtration, improper drain lines, and inadequate maintenance that result in subsequent increased levels of microbiological contamination and/or indoor pollution sources such as tobacco smoke and volatile organic compounds from building material and cleaning products (20, 29–32). The availability of moisture, increased CO_2, and the temperature have been factors that amplify microbial agents within this environment.

All forms of life harbor microorganisms in and on their bodies. Generally, the agents of infectious diseases are transmitted from one species to another or from one individual of a species to another member of the same species. Certain individuals may be carriers who harbor pathogenic agents in their bodies but show no signs of illness, that is, the carrier is infected but is asymptomatic. Human carriers play an important role in the spread of diphtheria, epidemic meningitis, hepatitis B, streptococcal infections, and pneumonia, and such individuals can be considered living reservoirs from which microbes can be dispersed. Consequently, many normal human activities generate airborne microbes during sneezing, coughing, talking, shedding of skin flakes, surgical and dental processes, and activities such as cleaning and sweeping (20, 27, 33). It has been estimated that a healthy individual maintains about 10^{12} bacteria on the skin, 10^{10} in the mouth, and 10^{14} in the alimentary canal (34). Microbes are being shed continuously from the skin. Humans shed about 10^{10} skin scales every 24 hours, including about 4.0×10^7 bacteria that are shed with these desquamated skin scales (17, 34, 35). Diseases spread from person to person by direct contact include tuberculosis, diphtheria, measles, pneumonia, scarlet fever, the common cold, smallpox, and epidemic meningitis.

Bioaerosols and Disease
Donald E. Gardner, Ph.D.

4 Transmission, Infection, and Disease
4.1 Transmission
Although bacteria exist in the air only as accidental contaminants, the air provides an effective means of disseminating the organisms. Once organisms are introduced into the air, they may be transported a few feet or many miles, some organisms die in a matter of seconds; others survive for an extended time. The ultimate fate of airborne microorganisms is governed by a complex set of circumstances. Their survival and hence their numbers is influenced by the environmental conditions of the air that transports them. Those that survive best have some resistance to heat, UV light, drying, and chemical agents. Some organisms can survive for months and attain survival as highly resistant spores. The simple presence of a microorganism in the air is insufficient evidence that it

will cause disease. The microorganisms must be transmitted to a host and have attributes that enable them to infect the susceptible host.

Transmission depends on the size of the particle, which may range from a single microorganism to large droplets containing agglomerations and/or rafts of microorganisms, often attached to various airborne particles. Liquid droplets may change in size due to evaporation (or condensation) and leave an aeroplanktonic residue of nonvolatile solute, particle matter, and/or viable or nonviable microorganisms.

The size of the bioaerosol is important for transmitting the organism and also is directly associated with the organism's ability to produce disease. Large particles (10 to 50 mm in aerodynamic diameter) are predominately deposited in the nasal passages. Particles less than 5 mm in diameter are considered respirable and are the most effective in establishing airborne infections. They can remain suspended in air for long periods and are most likely to be carried by air currents in a building's ventilation system. Particles <5 mm have a large deposition fraction in the alveoli, whereas particles between about 5 and 10 to 15 mm are predominately deposited in the tracheobroncheal region. Lung deposition can be influenced by the level of breathing and whether or not the breathing is through the mouth or nose.

4.2 Infection

It is important to understand the difference between infection and disease. Infection implies that a microbe has taken up residence in a host and may be capable of multiplying within the host—perhaps with no outward signs of disease. Thus, it is possible to be infected but not have the disease symptoms commonly associated with the agent, although disease may develop later.

At rest, the average adult breathes about 15 kg (10,000 to 20,000 liters) of air each day. When one compares this amount with the daily intake of food (1.5 kg) and water (2.0 kg), the potential exposure through inhalation becomes significant. During a lifetime, breathing brings approximately 300 million liters of air and airborne substances into contact with the respiratory surfaces (36). The lung also has nearly four times the total surface area (70 m^2) interfacing with the environment as the total combined surface area of the gastrointestinal tract and the skin. When comparing the potential exposure via inhalation to other routes of exposure, the seriousness and importance of bioaerosols becomes evident. This makes the respiratory tract the main portal of entry into the body and the lung the prime target organ for infection. In addition, the unique morphology of the conducting airways and the minute separation between the airspaces and the capillary circulatory system to the rest of the body highly suit the pulmonary milieu for microbial contamination.

The process of establishing an infection is complex and requires several steps. To initiate a respiratory infection, a sufficient number of organisms must escape from the existing reservoir, become airborne, enter the host's environment, be transmitted (directly or indirectly) to a susceptible host, and enter the host through the respiratory portal of entry. If there is a delay between these events, the organism must be able to survive in an unfavorable environment. Once the organisms have been deposited at a particular site in the host, the organism must enter into a relationship with the host (i.e., host–parasite relationship). After entry, the organisms must have been deposited on or be transported to a susceptible tissue particularly suitable for its multiplication and have the ability to remain viable and virulent during this process. The epithelial surfaces of the respiratory tract provide an appropriate medium for many microorganisms.

Elaborate defense mechanisms have evolved that enable the lung to protect itself from such microbial attacks (37–39). In spite of the vast exposure to many viable microorganisms, the normal respiratory system is efficient in clearing the lung of unwanted substances and in maintaining pulmonary health. Particles deposited in the tracheobronchial region may be transported out of the upper airways within a few hours by the mucociliary escalator system. The most effective defense of the alveolar region is provided by resident macrophages that can inactivate and kill microorganisms within a few hours of exposure. When normal pulmonary defenses are compromised by inhaled

substances, an individual's risk of disease can be significantly enhanced.

Once an organism has survived transport through the environment and has infected a susceptible host, several features of the bacteria are important in establishing disease. The term virulence is used as a quantitative expression of the disease-producing potential of a pathogenic organism. Measurement of the virulence of a microbe largely reflects the invasive properties of the organism. Certain organisms produce infections because they can invade tissue rapidly, spread throughout the body, and multiply extensively in susceptible tissue (40). A part of the invasiveness of microorganisms may also be attributed to certain surface components that protect the organism from normal host defenses, such as engulfment by phagocytic cells. Such surface substances may be polysaccharide capsules (e.g., pneumococci, *Klebsiella pneumoniae, Hemophilus influenza*), hyaluronic acid capsules, and surface "M" proteins (beta-hemolytic streptococci), or a surface polypeptide (anthrax bacillus). The pathogenicity of some organisms results from their ability to secrete complex toxins and extracelluar enzymes that aid in establishing infection and in spreading the organism through the tissue (41). Examples of factors and types of organisms that produce these factors include coagulase (staphlococci), hyaluronidase (staphlococcus, streptococcus, pneumococci), streptokinase or fibrinolysin (hemolytic streptococcus), hemolysins and leukocydins (streptococcus, staphlococcus), lecithinase, collagenase, exotoxins, endotoxins, and proteases (streptococcus).

Other factors that can influence exposure and the process of infection include specific occupational activities, as well as a various other factors related to age, drug use, alcohol consumption, smoking, hygienic habits, institutionalization (nurseries, day care, rest homes), and certain socioeconomic levels.

4.3 Disease

Once the host is infected, a number of factors influence the susceptibility of the host and the severity of the disease. The factors that function to prevent infection of a host can be divided into two categories: nonspecific and specific or acquired. Nonspecific or innate factors operate against a wide variety of organisms and include the body's natural physiological barriers at the portal of entry, inflammatory response, and phagocytic cells that engulf and destroy inhaled microbes. Certain specific defenses (immunological) are directed against specific organisms and are characterized by antigen-specific processes. An adverse change in the structure and functioning of these defense systems after exposure to a foreign substance is defined as an immunotoxic effect. Such immunotoxicity can be manifested in the host as an immunosupression, hypersensitivity, or an autoimmunite effect. Individuals particularly vulnerable to airborne infections are those whose normal pulmonary defenses are suppressed. Immunosuppression can be caused by inherited diseases, aging, alcoholism, HIV infections, radiation treatment, pregnancy, medication, and other concurrent infections (10, 42). Microbes that take advantage of a person's weakened state are called opportunistic organisms.

Individual susceptibility to airborne infections and the severity of the disease is also associated with the route of exposure (portal of entry), the duration of exposure, concomitant exposure to other pulmonary toxicants (tobacco smoke, air pollutants), age at the onset of infection, medication for treatment of other diseases, and nutritional status.

Race does not usually influence the infection process if exposure is equal, but the severity of the infection may vary, such as seen in Blacks with tuberculosis. However, there is overwhelming evidence that the conditions and the prevalence of health and disease may vary enormously among and within the regions of the world. The strikingly higher rates of mortality and morbidity in the less developed countries compared with the more highly developed countries are generally explained by a serious shortage of food, medical care, and extensive poverty due to socioeconomic conditions.

5 Contributing Environmental and Physiological Factors

In the natural environment, healthy individuals exist in equilibrium with a mass of potentially pathogenic microorganisms. The presence of microbes in humans and animals may be considered the normal state, and the process of disease is merely a disturbance of the equilibrium between the host, the parasite, and the environment. In addition to considering the virulence of the agent and the susceptibility of the host, attention must be given to a variety of environmental and physiological factors that might also influence the course of the disease. For this reason, a person exposed to a combination of stresses, such as those of a physical or chemical nature, may be more susceptible to certain biological agents and thus may be at a greater risk of contracting disease.

There is a need to learn more about the quantitative impact of a variety of physiological changes that may alter an individual's susceptibility to biological agents. The special conditions of the workplace may need to be taken into account in accurately assessing and characterizing the health risk associated with such exposures.

The nature, severity and likelihood of toxicity from bioaerosols are influenced by the total dose that ultimately reaches the sensitive target tissue. A number of generic factors significantly influence the dose of microbes reaching the lung. Ventilation is important because (1) the physics of airflow influences deposition and (2) the rate and depth of breathing influences the volume of air and hence the mass or number of infectious agents that enter the respiratory tract and the total surface area over which deposition will occur (43). An important element is the route of breathing (oral, nasal, or oronasal). This influences the efficiency of filtering inhaled materials in the nose and thus impacts the dose of infectious agents delivered to the respiratory system. Although most adults are nasal or oronasal breathers at rest, they often resort to oral breathing under certain work conditions or exercise that result in increased penetration of larger particles into the lung. Increased fatigue from a variety of stress factors (e.g., noise, vibration, temperature) may alter the homeostatic state of people and make them more susceptible to pulmonary disease.

A wide variety of gaseous and particulate airborne pollutants that may be present in the workplace can adversely affect the normal functioning of the host's defenses. Although the lung has an array of effective defense mechanisms available to kill, detoxify, and remove inhaled substances, numerous inhaled metals (e.g., Ni, Cd, Pb, V, and Mn), gaseous pollutants (e.g., NO_2, O_3, SO_2, phosgene, benzene, toluene, HCHO), particles (e.g., H_2 SO_4), and complex mixtures (e.g., auto exhaust, cigarette and wood smoke, and fly ash) can impair the functioning of these mechanisms which may significantly increase the susceptibility of the individual to infectious disease (37, 43–46). Infections have occurred in the workplace when uniquely sensitized workers were exposed to an airborne pathogen. Examples are *Acinetobacter pneumonia* in foundry workers and silicotuberculosis in workers with tuberculosis who are exposed to silica dust (47, 48).

Bioaerosols and Disease
Donald E. Gardner, Ph.D.

6 The Health Effects of Bioaerosols in the Workplace

Of the many diseases that have been associated with airborne contaminants in the workplace, the contribution of biological agents to total illness is presumed to be large. But to date, the attributable risk is not known with certainty. The frequency and severity of such diseases vary, depending on the particular work environment, types of organisms present, and the individual's susceptibility to the agent. Experimental and epidemiological studies have been used to evaluate the health effects of

bioaerosols. Respiratory infections, it has been estimated, cause 50–60% of all acquired illnesses (49). In the United States about two million people get pneumonia each year. It ranks sixth among all disease categories as a cause of death and is the most frequent lethal hospital-acquired infection (14). The economic impact from the standpoint of health-care cost and loss of productivity in the workplace is in the millions of dollars. A few examples of infectious diseases that are transmitted via inhalation are discussed later. This section addresses the potential for workplace exposure to biological agents, provides examples illustrating various mechanisms of action of different microbes, and identifies the great variety of illnesses that are associated with a broad range of diverse biological agents. Rather than attempt to list and discuss all organisms that might pose a threat within the workplace environment, this section uses a few examples to illustrate the principles involved in airborne infectious diseases. A broad base of understanding the basic concepts of the potential health risk of airborne microbes can aid in preventing and controlling such diseases. Excellent texts and handbooks on infectious diseases are readily available in most research and medical libraries for a more detailed discussion of specific types of organisms and the pathogenesis of their disease (4, 37, 50, 51).

6.1 Bacteria

6.1.1 Bacillus Anthracis As a disease of great antiquity, anthrax occupies an important place in the history of infectious diseases because it was the first human disease attributed to a specific pathogen (52). This organism is a large rod-shaped microbe that occurs frequently in chains. The bacterium can maintain itself in a spore state under severe adverse environmental conditions for many years. Anthrax is primarily a disease of farm animals (e.g., sheep, goats, cattle, and horses). The infected animal becomes a living reservoir from which the pathogens are dispersed. Human pulmonary anthrax, also called “woolsorter's disease” is rare but can be deadly. It is primarily an occupational disease among workers who come in contact with infected animals and/or their products (e.g., hides, hair, or meat) (53). It occurs occasionally in textile mills where imported animal products (goat, camel, sheep hair) are incorporated into fabrics. Such an occurrence can call for an immediate shutdown and disinfection of the entire plant, which is difficult and expensive. Pulmonary anthrax develops after aerosolized cells, usually spores, gain entry into the body through the respiratory system. The virulence of this organism results from the production of an exotoxin which allows this organism to spread rapidly through the circulation, and death can occur suddenly, usually as a result of cardiac failure (52, 54, 55).

Anthrax is a major military threat facing the armed forces and a biological agent that could be used in a terrorist attack. It has been estimated by the Department of Defense that more than ten countries may possess or are suspected of having anthrax as a biological warfare agent. The Department of Defense has plans to vaccinate more than 2.4 million military members against this organism by the year 2005.

6.1.2 Brucella The Brucella organisms are obligate parasites that can persist intracellularly in an infected host. Infected animals, typically cattle, swine, and goats are the reservoirs from which humans acquire brucellosis. In naturally acquired brucellosis, the organism usually enters the body through broken skin, the conjunctivae, or via the gastrointestinal tract. However, the organism may also enter the body via inhalation when contaminated dust becomes airborne. The symptoms are quite nonspecific, and the diagnosis may be overlooked unless a high degree of suspicion exist. Brucellosis has been associated with farm workers, packing house employees, livestock workers, and veterinarians and has been identified as one of the bacteria most infectious to laboratory personnel, probably by aerosols. In some developing countries, brucellosis is a reemerging communicable disease (56–58).

6.1.3 Klebsiella Pneumoniae This bacillus belongs to an enteric group of organisms whose natural habitat is the intestinal tract. The organism was initially described in 1882 by Friedländer who believed that it was the exclusive cause of pneumonia. These organisms are nonspore forming and are closely related to coliform bacilli. *Klebsiella pneumonia* can be found in the nose, mouth, and intestinal tract of healthy persons and is the etiologic agent responsible for about 5% of bacterial pneumonias. These pneumonias are usually very serious and are characterized by the production of

sputum and frequently the formation of lung abscesses which can be highly fatal. *Klebsiella* has a large mucoid capsule that surrounds the organism and is effective in protecting it against phagocytosis. It can be a secondary invader in the lungs of patients with bronchiectosis or chronic pulmonary diseases. Health-care workers are at risk of infection with these agents from daily exposure to patients who are admitted with this illness. It accounts for a significant proportion of pneumonias acquired in hospitals (59, 60).

6.1.4 Legionella Pneumophila The outbreak of this respiratory illness at the 1976 American Legion convention in Philadelphia focused attention on a common source of exposure to a bacterium later classified as *Legionella pneumophila*. Although morbidity rates are generally less than 5% for exposed individuals, the mortality rates may approach 10–15% (61). *Legionella* infections are not transmitted by respiratory droplets from one infected person to another but instead result from inhaling contaminated water droplets from sink outlets, shower sprays, humidifiers, water cooling towers, and air conditioners. Ingestion of contaminated water has not been implicated. The initial symptoms of the disease include malaise, headache, fever, chills, cough, and changes in mental status. At least 23 different species of Legionella have been implicated in human disease. This microorganism is very difficult to recover from air and usually detection depends on collecting and analyzing of water specimens (62–65).

6.1.5 Mycobacterium Tuberculosis Tuberculosis (TB) is caused by a rod-shaped bacterium and is a highly contagious disease easily passed from one person to another in the airborne droplets formed when a person with active tuberculosis sneezes or coughs. The causative agent (*Mycobacterium tuberculosis*) usually persists in the body long after the primary infection is over but can be reactivated, especially if immunosuppression occurs. Tuberculosis is a significant hazard to hospital personnel, medical students, and physicians who have two to three times the incidence of infection compared to nonmedical personnel. The AIDS epidemic has increased the likelihood that health-care workers will come in contact with active pulmonary tuberculosis because this organism is often one of the opportunistic infections seen in patients with AIDS. The TB incidence rate among people infected with HIV is nearly 500 times the rate for the general population. After a decline in rates of TB during the last several decades, the United States is experiencing a disturbing increase in such infections. The number of cases has gone from 22,200 in 1985 to more than 26,000 in 1991 or 10.4 per 100,000 population (7). Even more alarming is the rise of multidrug-resistant strains (14). Because of the importance of this highly communicable disease, a separate chapter (Chapter 21) has been dedicated to it (66–68).

6.1.6 Mycoplasma Pneumoniae These organisms are the smallest known free-living bacteria that, unlike most bacteria, do not possess cell walls. Mycoplasma are widespread in nature, commonly in pooled water and soils. This organism is associated with primary atypical pneumonia, an acute, febrile disease that usually begins in the upper respiratory tract and spreads to the lungs. The manifestations of the disease, including fever, cough, headache and malaise, can be fairly severe. Although the disease is transmitted by oral or nasal secretions, it is generally not considered very contagious. *Mycoplasma pneumoniae* can be recovered from sputum or pharyngeal swabbing. This disease typically occurs in young adults and children and also in institutions and among military personnel (69–71).

6.1.7 Neisseria Meningitis This organism causes meningococcus meningitis. Meningitis is a general term for inflammation of the meninges (membranes covering the brain and spinal cord). The cells may be either kidney-shaped or spherical, about 0.6 to 1.0 mm in diameter. They are nonmotile and nonspore forming. Early symptoms are excessive nasal secretions, sore throat, headache, fever, neck and back pain, and loss of mental alertness. Like most respiratory infections, the meningococcus organism is disseminated by direct contact through droplet infections from secretions of the nose, mouth, and throat. Some persons are temporary carriers, whereas others may discharge the organism continuously or sporadically. After being deposited in the nasopharynx, the organism directly invades the blood stream. This bacteremia is followed by the onset of acute purulent meningitis. The virulence of this organism is related, in part, to the antiphagocytic properties of its capsule. In

addition, these organisms produce an endotoxin that can cause extensive vascular damage. These organisms can withstand drying and other adverse physical conditions. Epidemics of meningoccus meningitis are prone to occur in military populations probably related to reduced overall resistance of the individual due to conditions of military life, fatigue, and exposure to inclement weather. It seems that with the relatively high carrier rate and the rather low rate of morbidity, there must be a high degree of normal resistance to this organism in the general population (72, 73).

6.1.8 Streptococcus Infections This organism is the commonest cause of community-acquired bacterial pneumonia and is also responsible for sore throats, bronchitis, meningitis, sinusitis, otitis, scarlet fever, rheumatic fever, and septicemia (55, 74). Streptococcal infection of the upper respiratory tract does not usually progress to involve the lungs. The various disease-causing strains of *Streptococcus* are grouped by their behavior, chemistry, and appearance. Group A streptococci are the most virulent species for humans. The ultimate source of these infections is usually a person who harbors these organisms. Such an individual may have a demonstrable or subclinical infection or may be a carrier. Nasal discharges of the organism are the most dangerous source of transmission of this disease. Although all streptococci are similar in cellular morphology, these organisms are extremely variable in pathogenicity. The high virulence of this organism is associated with its ability to produce several kinds of extracellular products, such as hemolysins, hyaluronidase, leukocidin, streptokinase, streptodornase, and erythrogenic toxins. Many of these products aid in spreading the organism within the host. The most virulent streptococci (beta-streptococci) produce hemolysins capable of destroying red blood cells. The less virulent organisms (alpha-streptococci) may also produce hemolysins but are characterized by their lack of complete lysis of the red blood cells. Of special concern is that a “new” form of highly virulent streptococcus has been identified (10, 75). The British tabloids have coined the term “flesh-eating bacteria” to describe this invasive, necrotizing infection. This new strain, like other streptococci, is transmitted by inhalation. However, the resulting infection is especially insidious. Its early symptoms are easily mistaken for signs of the flu. The infection is extremely difficult to treat even with massive doses of antibiotics, and there is no treatment for the deadly toxin produced which actually causes the pneumonia. Resistance against the streptococci is type-specific. Thus, a host who has recovered from infection by one Group A type is fully susceptible to infections by another type. Epidemics can occur in workplaces and institutions where large numbers of people are close together. Certain irritants (i.e., SO_2, NO_2, phosgene, and NH_3) in the workplace can increase the risk and incidence of this bacterial infection.

6.3 Fungi

A fungus infection is known as a mycosis. Environmental factors that can influence fungal growth in the workplace include outdoor air concentrations, type and rate of ventilation, and indoor moisture levels. Many of the diseases caused by these organisms occur in agricultural workers and workers exposed to contaminated air handling systems and open water spray chambers. The fungi that cause systemic mycoses are generally saprophytes in soil. Inhalation of these spores initiates the infection in humans. The spores germinate and develop vegetative organisms that initiate a localized infection. The earliest pulmonary infections are usually acute, consisting of self-limited pneumonitis that can be often overlooked or ascribed to a bacterial or viral disease. The infection subsequently begins to spread progressively to other tissues and often results in the development of granulomatous lesions that clinically resemble tuberculosis. Many fungi can spread by way of the bloodstream and can attack almost any tissue in the body. Because these organisms are not transmitted from human to human, they are not contagious. The organisms appear in infected tissue as small, oval cells (1–5 mm in diameter) frequently located within macrophages and/or reticuloendothelial cells. Miliary lesions appear throughout lung parenchyma, and the lymph nodes become enlarged. The disease may occur either in an acute or chronic state and may be localized or disseminated. Workers without adequate respiratory protection, who are exposed to atmospheres that have been contaminated with quantities of bird or bat droppings, are especially at risk of these types of respiratory diseases. The full range of health effects due to fungal exposure include allergic disease (e.g., allergic rhinitis, asthma, and hypersensitivity pneumonitis) and infectious diseases (e.g., histoplasmosis, blastomycosis, aspergillosis, coccidioidomycosis, and acute toxicosis). Fungi that cause these diseases are frequently opportunistic organisms that produce disease in compromised hosts, such as

those with reduced pulmonary defenses (e.g., from corticosteroids, X irradiation, medication), some concurrent disease, or a coexposure with some other air pollutants (76–79).

Of the more than 100,000 fungal species in our environment, only about 150 are pathogenic and of these only about 40 affect the lung. Of these, the two most pathogenic are *Histoplasma capsulatum* and *Coccidioides immitis*.

6.3.1 Histoplasma Capsulatum Histoplasmosis, sometimes called *Darling's disease*, is an infection resulting from inhalation of the fungus *Histoplasma capsulatum*. It was discovered in 1906 by Darling who observed it in sections of tissue taken from post-mortem cases. *H. capsulatum* is the most common endemic fungal disease in the United States, and it has been estimated that about 500,000 new cases of histoplasmosis occur each year (80). About 90–95% of these cases represent asymptomatic, self-limited pulmonary infections. The remaining 5–10% of patients may develop an acute pulmonary form, a disseminated form or a chronic pulmonary form of the disease (80).

Histoplasma capsulatum has been isolated from soil in more than 50 countries. In the United States, the most heavily endemic area includes Ohio, Kentucky, Indiana, Illinois, Tennessee, Arkansas, and Missouri. In these areas, up to 75% of the population has had primary pulmonary histoplasma infection before the age of 20, based on positive skin tests for the organism (80). Like other fungi that cause systemic mycoses, these organisms can be found as saprophytes in soil. Soil constitutes the reservoir from which infections with *H. Capsulatum* occur. These organisms are commonly found in areas heavily contaminated with the droppings of chickens and keratonaceous material, as well as in the soil beneath areas where pigeons, starlings, and other birds nest (80). Bats are implicated as carriers, and outbreaks of this disease have been traced to the inhalation of dust from bat guano found in caves. In these cases, the disease has been referred to as “cave fever” or “speleonosis.” Another source of soil contamination comes from decaying bodies of small rodents and excreta from a variety of wild and domesticated animals (81). Besides man, a variety of domesticated and wild animals are naturally infected (e.g., cats, fox, opossum; and dogs). Although chickens are heavily exposed, they do not develop the disease, nor do other birds, presumably because the fungus does not thrive at their high body temperature. No intermediate host has been identified, and the disease is not transmitted directly from one human to another or from an animal to a person.

Workers other than farmers who may be at risk include construction crews, operators of heavy equipment, such as bulldozers and graders, and maintenance workers. Any type of industrial activity that results in disturbing contaminated soil can disperse and scatter the infectious spores into the air, which then can be carried by prevailing winds to residents of adjacent areas who may also be at risk (81). Outbreaks of histoplasmosis have been associated with excavation of infected soil for construction of buildings and roads, working in soil fertilized by chicken manure, and breathing dust from silo towers or derelict houses where starlings have congregated or in caves inhabited by bats (82). Like all highly pathogenic fungi, these organisms are dimorphic, capable of changing their growth characteristic from a mycelial form normally found in nature and in laboratory culture, to a budding, oval, yeast-like structure found in infected tissue.

The pathogenesis of *H. capsulatum* has been clearly established. When soil or other contaminated matter is disturbed, aerosolized fungal spores called conidia are inhaled and they are transformed within the respiratory system, into yeast forms by the heat of the body. Most often, the infection remains localized within the lungs perhaps producing patchy areas of interstitial pneumonitis, but it is usually self-limiting (83). The host response to this infection varies with the dose of inoculum and the age and immunologic status of the host (84–86). In the lung, the spores are engulfed by macrophages and multiply intracellularly in the yeast phase with a generation time of about 4 h. The draining lymph nodes become quickly involved, and hematogenous spread of the organisms occurs. This fungemia is generally self-limited but results in seeding of reticuloenothelial organs throughout the body with this organism. Specific lymphocyte-mediated cellular immunity develops in 7–14 days that results in rapid limitation of the infection both in the lung and at distant sites with necrosis and

granuloma formation in involved areas. The lymphocytes of patients with healthy immune systems produce cytokines that activate macrophages and induce formation of granulomas. In a small number of individuals, an effective cell-mediated immune response may not develop, the infection becomes progressive and widely disseminated, and lesions occur in practically all tissues and organs. Ulcerating lesions may be found in the nose, tongue, and mouth. Fever, wasting, and enlargement of liver, spleen, and lymph nodes may occur, and the disease may closely simulate miliary tuberculosis. Histoplasmosis is also occasionally seen as a chronic pulmonary disease with cavitation that simulates chronic pulmonary tuberculosis.

Factors that may increase one's susceptibility to this infection include aggressive immunosuppressive therapy in organ transplant recipients and in AIDs patients and the presence of chronic debilitating diseases such as cancer, diabetes, Hodgkins disease, leukemia, and tuberculosis (83). Because this is an “opportunistic” organism, children and old and debilitated patients are also predisposed.

A provisional diagnosis of histoplasmosis is based upon clinical manifestations, serological tests, and a positive skin response to histoplasmin. The latter has virtually no value in those localities where the fungus is so prevalent that most persons have positive reactions to histoplasmin.

No treatment is needed for most patients with acute mild pneumonitis, but treatment is recommended for patients with severe, persistent, or progressive disease and for immunosuppressed patients. Amphotericin B remains the drug of choice (85).

6.3.2 Coccidioides Immitis This fungus causes the second most common endemic infection in the United States and is the cause of coccidioidomycosis (84). *Coccidioides immitis* was first observed in Argentina in 1892 when the causative agent was thought to be a protozoan but later was cultured and shown to be a fungus. This disease also goes by names of “valley fever,” “Joaquin fever,” or “desert rheumatism.” Approximately 100,000 cases occur annually in the United States and about 70 of these cases per year are fatal (84).

The fungus has a predilection for growth in desert soils and occurs endemically in the southwestern United States, especially in the San Joaquin Valley of California, and in areas around Tucson and Phoenix and western Texas, where the soil is arid and alkaline and the ambient temperature is usually higher than 26°C (84). In these areas, the majority of residents give evidence of past infection by a positive skin test. Both man and animals (e.g., wild rodents, dogs, and cattle) are infected by the inhalation of airborne spores contained in dust (82). The disease is not communicable, and there is no evidence that infected animals contribute directly to the spread of this disease.

In these endemic areas, the people who are particularly at risk include those individuals who work in agriculture and allied pursuits as well as oil field workers, highway maintenance and construction crews, operators of graders, bulldozers, and other heavy equipment, and occasionally train crews who pass through. Repair workers, mechanics, and those involved with handling the organism in a laboratory may also be exposed (81, 87). A high incidence has also been found in American Indian tribes who live in reservations in these dusty, desert areas (85).

Like other pathogenic fungi, *C. immitis* is dimorphic, that is, the infective stage within the tissue is morphologically different from that observed in nature and in culture. In body exudates and in histological sections, the organism appears as spherules or a mixture of spherules and hyphae (84, 88). The spherules are thick-walled structures as small as 5 mm in diameter but at maturity may be 20–60 mm. They are filled with hundreds of irregularly shaped endospores varying from 2 to 5 mm in diameter. These large spherules eventually rupture, and the endospores are released and develop into new spherules. In culture, growth is rapid, and fluffy white mycelia appear within about 5 days. A characteristic feature of the hyphae is the cast-shaped arthrospores, which alternate with smaller clear hyphal cells. When the hyphae fragment, they release huge numbers of arthrospores, which are easily airborne and highly infectious.

Coccidioides immitis can be both an acute, benign respiratory infection or a chronic disease, fatal if untreated. In about 60% of infected persons, the disease is not clinically apparent; infection is revealed only by the acquisition of delay-typed hypersensitivity (positive coccidioidin skin test reaction) in about three weeks. The rest of the individuals may develop a spectrum of symptoms ranging from a flu-like syndrome to frank pneumonia following an incubation period of 1–4 weeks. Symptoms include cough, fever, headache, chest pain, dyspnea, and malaise, often with pleurisy and skin eruptions. About 5% of infected persons ultimately develop chronic pulmonary cavitary disease resembling pulmonary TB. Dissemination occurs in less than 1% of the infected persons, producing infected granulomatous lesions that are indistinguishable from tuberculosis, unless spherules can be detected in numerous organs (84, 85). Death from disseminated coccidioidomycosis is usually attributed to meningitis (58%) or pulmonary disease.

Host factors associated with high risk of disseminated infection include race, sex, age, pregnancy, and immunosuppression. Dissemination occurs ten times more frequently in dark-skinned than light-skinned individuals. Men are 1.5 to 6 times more susceptible to disseminated infection than nonpregnant females. Pregnant females are more susceptible, especially during the second and third trimesters (84, 85). In endemic areas, this fungus is the third most frequent opportunistic infection of HIV-infected individuals. Many of these cases probably result from reactivation of latent infection rather than a recent primary infection.

Diagnosis is made by finding the fungi in the lesions. The organism can be found by direct microscopic examination of pus, sputum, gastric washings, spinal fluid, and biopsy specimens. The cocidioidin test, a test of skin sensitivity to an extract of the organism, is of value; however, cross reactions with other fungal infections such as histoplasmosis and blastomycosis may occur.

In endemic areas, infection can be diminished by dust control measures. Repeated spraying with oil has been used to reduce the incidence of *C. immitis* infections in very arid, dusty environments (81). No treatment is needed for most patients with acute pulmonary *Coccidioides immitis* but amphotericin B is the drug of choice for chronic or cavitary disease (85).

6.4 Viruses

Several hundred different viruses may infect humans. Examples of viruses found in indoors include rhinoviruses, influenza, parainfluenza, variola, adenoviruses, varicella zoster, paramyxoviruses, poliovirus, and cytomegalovirus (10, 23). The viruses that occur primarily in humans are transmitted chiefly by humans, mainly via the respiratory route. Diseases caused by viruses vary considerably in their effects on susceptible individuals, mild or moderate in some cases and extremely dangerous in others. Epidemics caused by viruses present formidable challenges to public health officials responsible for preventing and controlling the spread of such diseases. Infectious diseases caused by viruses are many and varied. This discussion focuses on viral infections such as influenza and the common cold that are associated with crowded working conditions.

6.4.1 Influenza Virus The 1918–1919 influenza pandemic is recognized as one of the most serious and devastating outbreaks of an infectious disease known. It was estimated that more than 20 million people died of this disease during that period (7, 78). Later, in the pandemics of 1957 and 1968, it was estimated that influenza killed 90,000 people in the United States alone and the direct cost of medical care exceeded $3.4 billion. Outbreaks have been associated with crowded working conditions and military posts. Influenza is an acute infection that enters the respiratory tract by direct contact with the mucus of an infected person. The virus can persist for hours in dry mucus. It is an RNA virus that possesses an unusual degree of genetic variability. As a result of this property, the virus frequently undergoes major antigenic shifts, and new variants emerge. Thus, individuals with immunity to prior strains have limited protection to the newly emerged strains. The infectious strain enters the body through the mouth and nose and replicates in the upper respiratory tract. Normally, the disease is self-limiting. However, serious effects may occur when the virus destroys the cells of the respiratory tract and secondary bacterial infection develops. The incubation period is short, only 1–2 days. The symptoms of infection include chill, fever, malaise, muscular aches, cough, and

general respiratory symptoms. Individuals with immunosuppression or chronic respiratory diseases have the greatest risk (89).

6.4.2 Common Cold The common cold is aptly named because it is one of the most common human maladies; it has been recognized since earliest recorded history. There are more than 200 agents that are etiologically responsible for clinical syndromes associated with pharyngitis or the common cold. These include certain bacteria and a wide host of viral agents, including respiratory syncytial virus, rhinovirus, adenovirus, influenza, parainfluenza virus, and certain echo- and coxsackieviruses. About 90% of colds stem from viral infections. Serological testing or viral isolation is necessary to establish the specific etiologic agent. Most colds develop in the nose and throat but then can spread to the trachea and larynx (laryngitis), the sinuses (sinusitis), or the lungs (bronchitis). Colds account for more time lost from work than any other cause. Although self-limiting, colds can lead to secondary infections. Health-care workers are at risk from these agents due to frequent exposure to infected individuals. Infection may be facilitated by excess fatigue, allergic nasopharyngeal disorders, or inhalation of certain noxious fumes in the workplace (90, 91).

6.5 Rickesttsial and Chlamydial Infections

Both chlamydia and rickesttsiae rely on host cells to compensate for their own metabolic deficiencies; thus they are obligate intracellular parasites. Although rickettsial infections in humans usually begin in the vascular system following the bite of an infected arthropod, an important rickettsial disease is acquired by inhaling contaminated dust particles, resulting in Q fever. Q fever is an acute febrile illness that affects veterinarians, farmers, dairy workers, and abattoir employees. Animals shed the organism (*Coxiella burnetii*) in their nasal and salivary secretions, and it can be inhaled by individuals who work in this environment. The organism remains viable in a dried state for long periods of time (92, 93).

Chlamydial infections are occupational diseases in the poultry industry. However, veterinarians, workers in pet bird industries, and bird owners may be infected. Psittacosis or ornithosis is the term used for human infections. At highest risk are workers engaged in plucking and eviscerating chickens and turkeys. Most infections are transmitted through inhalation. Because the symptoms resemble the “flu,” misdiagnoses are common (94).

6.6 Hypersensitivity Diseases

Microorganisms in the workplace may also affect the immune system. Allergic respiratory diseases may develop in response to inhaling aerosols of both viable and nonviable organisms and their antigens, as well as microbial products such as glucans, endotoxins, and mycotoxins. Fragments of microbial cells, including cell wall segments, flagella, genetic material, and by-products of metabolism that are transported as bioaerosols can cause health problems (95). Such allergic respiratory illnesses produce acute symptoms, including malaise, fever, chills, shortness of breath, and coughing. They can often be serious diseases possibly leading to permanent lung dysfunction. Individuals can become hypersensitive to the inhalation of thermophilic actinomycetes in heating, ventilating, and air conditioning systems (19, 96).

Potential allergens include dust mite wastes, mold spores, fungal hyphal fragments, and macromolecular organic dust deposited on floors and surfaces. Exposure to such allergens is an important cause of asthma and chronic allergic rhinitis in certain occupations. Worldwide, the incidence of asthma is increasing, and occupational asthma has become more prevalent. Various factors have been suggested to explain this increase, including increased exposure to allergens, possible adjuvant effects of environmental chemicals, and improved diagnoses. Occupational asthma, a common respiratory ailment, may be defined as a disease characterized by variable airflow limitations and/or hyperresponsiveness due to conditions in an occupational environment and not to certain stimuli outside the workplace. Symptoms include recurrent episodes of wheezing, breathlessness, chest tightness, and coughing. About 200 agents have been implicated in causing workplace asthma (97). Examples include baker's asthma in workers exposed to *Aspergillus and Alternaria*, workers exposed to mites found in grain dusts, handlers of animal, workers involved in the manufacture of detergents where certain proteolytic enzymes are added; and workers exposed to wood dusts, especially red cedar.

6.7 Diseases Related to Bacterial Toxins
Microorganisms that cause disease may produce certain toxins. Airborne endotoxins are ubiquitous in nature and may be distributed throughout the workplace. Given appropriate moisture content and temperature, organic substrates furnish the necessary nutrients to promote the growth and reproduction of a wide variety of microorganisms (gram-negative) capable of producing endotoxins. Adverse human reactions to these endotoxins have been associated with a number of occupational settings including agriculture (e.g., swine/poultry shelters, composting, rice hulling and silo unloading, animal feed), manufacturing (e.g., machining oils, bioengineering, and mattress making), and textile production (e.g., cotton spinning mills, flax and textile processing, cotton garnetting, and carpet weaving). Although most of the settings in which high aerosol levels of endotoxins may occur are occupational, bacterial endotoxins have also been implicated in nonoccupational exposures as well. Endotoxin exposure is a possible cause of humidifier fever and is related to SBS (20, 98–100). A very important type of reservoir for such organisms is recirculated water-based fluids that are found in many home and office humidifier systems and possibly in areas where humans live downwind from sewage outfalls, solid waste processing centers, or wastewater treatment plants (98, 99). Endotoxin inhalation may cause an acute illness with fever, sweating, muscle aches, and headaches; sometimes rhinitis, asthma, and breathlessness may occur. Symptoms usually start within hours after exposure and may resolve in a day; however, they can reappear again with repeated exposures.

Mycotoxins, such as aflatoxins, are products of fungal metabolism that can lead to respiratory distress and severe systemic toxicosis. Some mycotoxins may be immunosuppressive and increase the likelihood of opportunistic and secondary bacterial infections. Inhalation of such toxin-containing spores may lead to “pulmonary mycotoxicosis” due to the absorption of toxin through the mucous membranes of the respiratory tract (100).

Bioaerosols and Disease

7 Sampling and Identifying Airborne Microbial Contaminants
Before commencing extensive sampling for the presence of airborne microorganisms, medical evidence should suggest the occurrence of infectious or allergic disease among the workers that appears to be related to the workplace. Significant exposure to aerosolized infectious agents in the workplace can be suspected when there are (1) several important sources or reservoirs, (2) amplifiers or conditions favoring microbial survival, (3) highly susceptible individuals or known carriers, (4) complaints or epidemics of disease, and (5) a microbiological laboratory report of positive cultures. Of special concern are those environments with high occupant density possibly resulting in increased risk of the airborne transmission of infectious agents between individuals. An on-site inspection may aid in uncovering the potential source of biological contamination, which can be confirmed using standard microbiological techniques. The ventilating system should be examined for appropriate design, operation, and maintenance. Evidence of microbial growth in cooling coils and on wet surfaces can indicate a source of biological contamination and a possible microbial reservoir. In some cases, bioaerosol sampling may not be necessary if there is substantial evidence of visible microbial growth. With evidence of microbial growth on floors, walls, or ceilings, or in the ventilation systems, sampling for bioaerosols and appropriate remediation should be considered. Sampling for microorganisms should be undertaken, especially when medical evidence suggests the occurrence of disease. A careful on-site inspection can be of significant value in designing appropriate air sampling methods. Once the purpose or the goal of bioaerosol sampling is determined, appropriate sampling method(s) should be chosen. Sampling for bioaerosols in the workplace can provide useful information necessary to characterize the exposure conditions, determine whether the contamination represents a potential or real hazard, and establish the need for control measures.

Bioaerosol monitoring is a rapidly emerging area of industrial hygiene. Airborne sampling for bioaerosols is complex, expensive, and may include measuring bacteria, viruses, fungal spores, endotoxins, allergenic and toxic substances of plant and animal origin, and protein aerosols (3). The airborne concentration may be expressed in different ways, depending on the type of particle. Bacteria and fungal spores, for example, may be expressed in terms of the number of bacteria entities of a given type per unit volume of air (i.e., number per m^3 of air). On the other hand, viable particles may be expressed in terms of their ability to reproduce—that is, the number of "colony-forming units" per unit of volume of air (i.e., cfu per m^3 of air). For endotoxin and allergenic materials, it is appropriate to express concentration in terms of the mass of the active component per unit volume of air (i.e., mg per m^3 of air) Such diversity presents many difficulties in sampling and measurement methodology for exposure assessment.

Although there are no standard methods for sampling and analysis of microbiological agents in air, the same principles that apply to measuring and collecting any particulate aerosol also govern air sampling for microorganisms (101). The sampling methods most commonly used to collect airborne microbes are described in detail elsewhere (101–103). Methods commonly used include glass impingers, cascade impactors, sedimentation, and real-time samplers. A recent comprehensive review compares the various experimental, theoretical, and physical characteristics of the commonly used bioaerosol samplers (104).

The selection of the sampling methods and subsequent laboratory analyses are determined by the medium to be sampled (air, water, surface) and the type of agent to be detected (6). Samplers used to isolate viable microbes in the air must be capable of collecting the aerosol with high efficiency, must minimize injury to the organism during the collection process, and must maintain the culturability of the collected microorganisms. In monitoring viable microorganisms, only culturable microorganisms are enumerated and identified, thus possibly leading to an underestimation of bioaerosol concentrations.

Aeroallergens (pollen and fungi) may be sampled without culturing the microorganisms. This can be done using passive aerobiological monitors that rely on gravity collection on an appropriate medium or on some collection surface. Then the collected microorganisms can be enumerated and identified using microscopy, classical microbiology, molecular biology, or immunochemical techniques. With this method, large particles are collected more effectively than small particles. These passive monitors can be used either as area or personal monitors, but they provide only semiquantitative information because only particles of certain dimensions will settle onto the surface in a given time and there is no way of knowing the volume of air that is being sampled.

In sampling culturable bacteria and fungi, the bioaerosol is generally collected by impaction onto the surface of a solid medium (agar), filtration through a membrane filter, or impingement into an isotonic liquid medium. Such an air sampler consists of a pump that draws a known quantity of air over or through a collection surface that contains appropriate growth or collection medium for the organism suspected of being present.

After impaction onto a medium surface and incubation, the organisms may be transferred onto selective or differential media and incubated at different temperatures for identification and enumeration of the microbes (105). When using collection fluids, the sample can be placed directly on agar or serially diluted and plated, or the entire volume of fluid can be filtered through a membrane filter. The membrane filter is then placed on an appropriate growth medium. Microbes may be identified by using microscopy, classical microbiology, or molecular biology techniques such as restriction fragment length polymorphic (RFLP) analysis. Classical microbiology techniques include observation of growth characteristics, cellular or spore morphology, simple and differential staining, and biochemical, physiological, and nutritional tests for bacteria. DNA analytical techniques which may be applied to both nonviable and viable microorganisms include polymerase

chain reaction and enzyme-linked immunosorbent assay. Such methods may be used to identify specific microorganisms and to locate areas of contamination. Concentrations of endotoxin determined by using the *Limulus* amebocyte lysate assay method have been correlated with patient symptoms in some studies (105).

Bioaerosols and Disease

8 Assessment of Risk
Remarkable changes have occurred in the way human health and environmental risks have been assessed and regulated during the past few decades. The passage of many federal, state, and local governmental regulations and statutes enacted to protect the health of workers and general public from occupational and environmental exposure and consumer products have provided a major stimulus to develop a formalized approach for assessing human health risk from exposure to radiation, physical and chemical agents, and other conditions that may pose human health or environmental hazards. The National Academy of Science/National Research Council has provided a structured approach to the risk assessment process that has become increasingly accepted (106). This method has been widely used by several governmental agencies, including the U.S. EPA, for assessing the risk of cancer and other health effects that result from exposure to chemical agents. Much has been written about the risk assessment process as it relates to chemical exposure (107–112). Such quantitative risk assessment has been widely used for (1) assessing human effects from exposure to chemicals, (2) developing regulatory standards, and (3) conducting risk/benefit analysis used to inform major policy decisions. A complete risk assessment approach that emerged in the 1980s involved four interrelated components but conceptually distinct steps: (1) hazard identification (the potential of the source for releasing a risk agent); (2) exposure characterization (the intensity, frequency, and duration of exposure and the nature of the population that might be exposed); (3) exposure–response characterization (the relationship between exposure and the resulting health consequences); and (4) risk characterization (the combined influence of these three factors on risk will provide estimates of the magnitudes of possible adverse health effects, including a characterization of the probabilities, uncertainties, and degree of confidence associated with these estimates).

With increase awareness of the potential for disease from exposure to microorganisms in our working and living environment, there has been an interest in developing similar risk assessment models to evaluate the likelihood of adverse human health effects from exposure to infectious microorganisms. Currently, the process being used to assess risk from exposure to pathogens uses the conceptual framework developed to assess risks of chemical exposures.

However, there are several reasons that these methods presently being used for chemicals may not be appropriate for assessing the risk of exposure to microorganisms. Issues that must be considered that are unique to assessing risks of the infectious disease process include an assessment of pathogen/host interaction, consideration of secondary spread, the possibility of short- and long-term protective immunity, and an assessment of those conditions that might allow the microorganism to propagate.

The development of a pathogenic risk assessment process is complex and may consist of several interrelated components but conceptually distinct steps (113).
8.1 Phase One
The initial phase is a systematic planning step that identifies the goals, breadth, and focus of the risk assessment. A critical component of this problem formulation phase is to determine the purpose of the risk assessment and to identify those specific questions that the assessment analysis is to answer. A risk assessment may be initiated for a number of reasons. For example, if it is known that microorganisms are present in air, food, or water without a recognized outbreak of the disease, it

may be desirable to assess the potential for human risk of exposure to the organism. Conversely, a risk assessment may be initiated as the consequence of an infectious outbreak but where the specific pathogen or the vehicle of infection (medium of concern) is unknown. Such analysis can be useful in determining critical points for control, such as reducing airborne contamination, activating specific water treatment processes, or initiating certain food handling activities.

8.2 Phase Two

The second phase consists of a number of technical evaluations of the existing database to gain a better understanding of the potential for exposure and consequential health effects. In characterizing the exposure, one attempts to determine the properties of the organism that are expected to influence its ability to be transmitted to the host, to infect, and to cause disease. The properties of the pathogen to be considered include virulence, host specificity, ability to survive in the environment, portal of entry, and mode of transmission. Characterization of the expected occurrence, distribution, and physical state of the microorganism can aid in determining the expected concentration of the organism in the environment and the sources of the microbes. Data gathered from this phase should provide useful information about relevant factors pertaining to the occurrence and distribution of the organism.

Included in this second phase is an exposure analysis step that characterizes the source and temporal nature of human exposure. This includes identifying and elucidating the vehicle of transmission, such as air, drinking water, food, as well as the size and demographics of the potentially exposed population. Such exposure analysis may aid in identifying whether a single airborne exposure to a certain organism with high transmission potential may have substantially different consequences than multiple exposures to pathogens with low transmission and virulence potential. The route of exposure and the transmission potential can in turn be influenced by the behavioral characteristics of the individuals exposed.

From this evaluation, an exposure profile can be developed to provide a qualitative and/or quantitative description of the magnitude, frequency, and patterns of exposure focused on those scenarios developed during the problem formulation phase. The exposure profile draws heavily on information obtained from the characterization and occurrence of the pathogen and the exposure analysis phase. The exposure profile should include an assessment of the various assumptions, modifying factors, and uncertainties that are included in the analysis, providing insight into the strengths and weaknesses of the assessment process.

The final task in this second phase is to characterize the human effects from exposure to the microorganisms. To meet these needs, one collects data necessary to adequately characterize the host. Host characterization involves evaluating the nature and characteristics of the population that might be exposed and the susceptibility to a particular pathogen. High-risk groups may develop severe symptomatic illness, whereas low-risk groups may develop asymptomatic infections or mild illnesses. Many other factors can influence susceptibility and severity, but not all are important for all microorganisms. The outcome of host characterization is the identification of factors that influence susceptibility and severity and the identification of susceptible subpopulations.

In the analysis of the health effects from exposure to the microorganism, the clinical illnesses need to be characterized. This should include characterizing the whole spectrum of clinical manifestations, including symptomatic and asymptomatic infections, duration of clinical illnesses, mortality, and sequelae. In most cases, the assessment of health effects usually relies on epidemiological and clinical information, but animal studies can provide useful information.

Dose–response analysis can be valuable in evaluating the relationship between dose, infectivity, and the manifestation of clinical illness. This relationship is complex, and in many cases a complete understanding of this relationship may not be possible. Often only crude indirect measures for dose–response assessment can be made because an actual dose of the microorganism is not available. When this phase is successfully completed, it provides valuable insight into the host–pathogen profile that provides qualitative and/or quantitative descriptions of the nature of the illness a

quantitative dose–response analysis for the scenarios developed during problem formulation, and serves as input for risk characterization.

8.3 Phase Three

The final step of the pathogenic risk assessment is the risk characterization phase. This consists of combining information from the other phases and provides estimates of the magnitude of the adverse health effect. This includes an estimated number of people who experienced health impacts of various severaties over time, a measurement that indicates the nature and magnitude of adverse consequences to the exposure, and the likelihood that adverse human health effects will occur. The degree of confidence in these risk estimates should be expressed in the risk description and should include consideration of the sufficiency, defensibility, quality, and uncertainties of the database and the evidence of causality.

The use of such risk assessment models can aid significantly in integrating our existing knowledge, identifying data gaps, and improving our planning and designing of future research to fill those gaps. Although the current methodology used in risk assessment has significant limitations and shortcomings, it still provides a useful short-term approach for addressing health, safety, and environmental risks and for providing a logical and effective means for analyzing and evaluating limited information to understand specific risk. In developing risk assessment processes for infectious diseases, the emphasis should be on the dynamic and iterative nature of the risk assessment process in providing individuals with a variety of options for planning and conducting risk analysis under a variety of diverse conditions often found in occupational environments (113).

Bioaerosols and Disease

9 Control and Prevention of Airborne Infectious Disease

The fundamental aim of occupational hygiene is to protect the health of individuals by preventing or reducing risk from exposure to chemical, biological, or physical agents in the workplace. In controlling and preventing infectious diseases, the ultimate aim must be to quickly identify the causative agent and to establish reliable approaches for prevention and control. A well-designed, well-implemented surveillance program can detect unusual clusters of disease, document an outbreak, estimate the magnitude of the problem, and identify factors responsible for its emergence. Although specific guidelines for each industry are obviously beyond the scope of this chapter, there are certain practices that can significantly reduce the incidence of illness (114). Employing the control and prevention measures listed here will aid in (1) eliminating the reservoir of the microorganism, (2) interrupting the transmission of the infection, and/or (3) providing increased resistance of the individuals to the microorganism.

- Personal hygiene will lessen the spread of disease.
- The elimination and control of the source of the hazard is preferable to relying on personal protection, but in some work environments, the use of personal protective equipment, (e.g., clothing, gloves, face mask, and respirators) may be necessary for an acceptable level of protection.
- Cleanliness in the workplace, conforming to appropriate standards (e.g., refuse removal, hosing down abattoirs, disinfection of surfaces and articles in day-care centers and medical practices) is always indicated.
- Proper disposal of wastes, especially those suspected of microbial contamination, and proper cleaning of contaminated articles is critical.
- Special attention should be paid to the design and construction of buildings to avoid bioaerosol contamination. For example, the structure should consist of nondeteriorating material, so as not to offer a substrate for microbial growth. Control of moisture (i.e., maintaining relative humidity at

levels less than 70%) is an important factor in minimizing fungal growth. Proper maintenance, repair, and cleaning of air handling equipment (HVAC) is a cost-effective means of controlling contamination. Removal of pollutants from air can be accomplished by increasing effective ventilation and by air cleaning.

- Special care is necessary in the case of immunocompromised and particularly sensitive or susceptible employees.
- Prevention can occur through immunization or allergic desensitization. In certain professions where there is a high risk of exposure (e.g., veterinarians, researchers, animal handlers, and medical care personnel), immunization can be provided to maintain a high level of protection.
- Education and training helps workers to recognize conditions (e.g., sources, reservoirs) that contribute to bioaerosols. Individuals can use such information to reduce their exposure and to remove themselves from contaminated areas.

Bloodborne Pathogens In the Workplace
Debra L. Hunt, Jerry J. Tulis, MD

1 Human Immunodeficiency Virus 1

On June 5, 1981, the CDC reported several cases of *Pneumocystis carinii* pneumonia in young male homosexuals (7). Several weeks later, Kaposi[apos]s sarcoma was reported in 26 male homosexuals, some of whom also were diagnosed with *P. carinii* pneumonia (8). These reports represented the first recognized cases of what is now defined as acquired immunodeficiency syndrome (AIDS). Seventeen years later, in June 1998, over 657,077 AIDS cases had been reported to the CDC among persons of all ages in the United States (9, 10), with an estimated 50 million infected throughout the world.

Within 3 years of the recognized syndrome, the virus causing AIDS was isolated and found to be a new human retrovirus (11–13). Retroviruses had been studied primarily in animal diseases and were

found to be a cause of a human disease in 1980 by Poiesz et al. (14). Although the virus was originally called *human T-cell lymphotropic retrovirus III* (HTLV-III) by Gallo, and lymphadenopathy-associated virus (LAV) by Montagnier, the virus has subsequently been termed *human immunodeficiency virus 1* (HIV-1) by committee (15).

1.1 Biological Characteristics

Certain biological characteristics of HIV-1 are important to the epidemiological and clinical aspects of the virus, and contribute to the risk involved with viral transmission. These include (16):

1. HIV-1 belongs to a group of RNA viruses known as *human retroviruses* named for the novel reverse transcriptase (RT) enzyme. The RT enzyme allows a DNA chain to be copied from the viral RNA. The double-stranded DNA material from the viral template is then incorporated into the host cell genome. This step is important epidemiologically, because the retroviruses are able to exist in a latent period for years to decades before disease develops. More specifically, HIV-1 belongs to the lentivirus group (*lenti-* = "slow"). It is estimated that the average incubation period between HIV-1 infection and the development of the disease, AIDS, for both homosexual men and adults with transfusion-associated HIV infection via transfusion is 8 years (17), and may be extended with treatment with antivirals or protease inhibitors.
2. The reverse transcriptase enzyme is a natural target for antiviral agents. For example, azidothymidine (AZT) inhibits HIV-1 replication by blocking reverse transcriptase activity. Such agents can block further transmission of HIV to other cells, but cannot eliminate the HIV provirus from reservoirs in cellular DNA.
3. Since reverse transcriptase activity is specific for replication of retroviruses, its detection provides an excellent indicator of retroviral activity in laboratory tests.
4. The polymerase enzyme of HIV that is involved in transcription is error-prone, contributing to the antigenic hypervariability on the viral envelope. This complicates the development of a universal vaccine and perhaps influences the virulence of the different strains of virus.
5. Surrounding the RNA viral core and viral enzymes, the lipoprotein envelope contains several important glycoproteins that help bind the virus to host cell receptors and are the focus of several vaccine studies. Evidence of antibodies to glycoproteins GP120, GP160, and GP41 is essential to laboratory testing for infection with HIV-1 (18).
6. Retroviruses, like other enveloped viruses, are rapidly destroyed by common laboratory disinfectants and detergents (19).
7. The HIV-1 viruses replicate intracellularly in the host. The major target cells are those that possess the CD4 protein receptor, primarily the T4 lymphocytes. The T4 cell is lysed or severely limited in function by viral replication, leading to eventual depletion of immunological capabilities. The monocyte–macrophage cell, another target cell for HIV-1, harbors the virus, but is more resistant to the cytopathic effects. The monocyte–macrophage cell serves as a reservoir for the latent viral state, a "Trojan horse" that transports the virus throughout the body, protecting it from host defenses. Evidence also indicates that the Langerhans cells of the skin may also harbor the virus (20).
8. The HIV-1 virus is found in body fluids as cell-associated as well as cell-free. The numbers of virally infected cells and infectious viruses in plasma vary with the stage of HIV-1 infection. For example, HIV p24 antigen, a marker of HIV-1 replication, has been demonstrated during the acute stage of HIV infection, and at the late stages of infection when CD4 lymphocytes decrease in number (21). Also, increased HIV-1 plasma titers are associated with the later stages of the disease (22). This higher "dose" of virus may be an important determinant of an increased risk of viral transmission.
9. The HIV-1 virus has been cultured from blood (12), semen (23), vaginal and cervical secretions (24, 25), saliva (26), breast milk (27), tears (28), urine (29), cerebrospinal fluid (30), alveolar fluid (31), and amniotic fluid (32); however, human transmission of the virus has occurred only via blood, bloody body fluids, semen, vaginal and cervical secretions, breast milk, or concentrated viral material. Proteins found in urine, tears, saliva, and mother[apos]s milk neutralize HIV and may explain why HIV is not transmitted via these fluids (33).

1.2 Inactivation Studies

Retroviruses are classified by Klein and Deforest (19) as protein and lipid viruses and, as such, are susceptible to many common disinfectants found in the laboratory. Since 1984, several studies have evaluated the inactivation of HIV-1 by a variety of physical and chemical means. The methods of testing for viability of HIV-1 after exposure to disinfectants or physical methods include the determination of reverse transcriptase activity and the ability of the treated virus to infect T-cell lines in tissue culture. The tissue culture assay appears to be more sensitive for small amounts of virus than the RT assay (34). It is yet unknown if the tissue culture assay is able to measure the critical human infectious dose. Therefore, the observed log reductions in virus titer and extrapolated decay rates using high concentrations of virus allow for inferences about effectiveness of the disinfectant or method of inactivation.

1.2.1 Environmental Stability Under experimental laboratory conditions and grown in high concentrations of 7–10 logs tissue culture infectious dose ($TCID_{50}$), HIV-1 demonstrates stability at room temperature in both dry and liquid forms. One $TCID_{50}$ is the amount of virus required to infect half of the cells in tissue culture. In aqueous suspensions of tissue culture fluid, the virus has remained viable after 1–2 weeks (34). Several authors have demonstrated the recovery of viable HIV-1 after 3–7 days in the dried state as a viral film on glass or a petri dish (34–36). Resnick et al. (34) and Prince et al. (36) calculated the amount of time required to reduce viral infectivity by 1 log or 90% (the D_{10} value) in a dried state at room temperature to be 8–9 h. It follows that a blood spill containing 1–3 logs of virus per milliliter (22) in a clinical or laboratory setting could potentially contain viable HIV-1 for over a day if allowed to dry. Prompt cleaning with appropriate disinfectants should be initiated to remedy this situation.

1.2.2 Heat Inactivation Although the HIV-1 appears stable at room temperature, it is very heat-labile. McDougal et al. (37) found that the virus follows first-order kinetics, and calculated the D_{10} values for a series of temperatures (see Table 20.1) (37–39). The study found little difference in the thermal decay rate when the virus was suspended in culture medium, serum, or liquid factor VIII, but found that the virus in the lyophilized state was somewhat resistant to heat.

Table 20.1. Environmental Survival of HIV-1

Condition	Temperature	Parameters	D_{10}[a]	Comments	Ref.
Heat	60°C	2 min	ND	Virus in factor VIII preparations	37
	60°C	2 h	ND	Lyophilized virus	37
	56°C	10 min	ND	—	38
	56°C	20 min	ND	50% serum	39
	56°C	10 min	2 min	—	37
	56°C	5 h	20 min	50% plasma	34
	50°C	—	24 min	—	37
	45°C	—	3.3 h	—	37
	37°C	—	4.8 days	—	37
	37°C	11 days	ND	50% plasma	34
	37°C	6 days	ND	Dried virus	36
Aqueous	RT[b]	15 days	—	—	34

solution	RT	>7 days	—	—	35
Dried virus	RT	>3 days	9 h	50% plasma	34
	RT	>7 days	—	In petri dish	35
	RT	>7 days	8 h	5% serum on glass	36

[a] D_{10} = amount of time required to reduce viral infectivity by 1 log or 90%.

[b] RT = room temperature (20–27°C).

Martin, as well as other authors (38, 39), reported inactivation of HIV-1 suspensions at 56°C within 10–20 min (D_{10} value = 2 min). Resnick et al. (34), however, found that heating at 56°C for 5 h was necessary, calculating a D_{10} value of 20 min. The reason for discrepancies in these studies is undetermined.

A 1988 survey of laboratories evaluating HIV-1 tests for CDC (40) reported that 3.9% of the laboratories heat-inactivated serum specimens at 56°C as a safety measure before testing. However, the heating process can cause false-positive results for enzyme immuno assay (EIA) and Western Blot tests (41, 42), changes in laboratory enzyme levels, and turbidity problems with plasma (43). The CDC recommended that heat inactivation of serum does not preclude the use of standard precautions and should *not* be used as a routine means of protection of laboratory workers (40).

The heating process has better applicability in the preparation of safe therapeutic blood products. Piszkiewicz (44) found that pasteurization of antithrombin III concentrate at 60°C for 7 min reduced HIV-1 to below detectable levels. Others have found alternative methods of inactivation of blood products, including exposure to tri- (*n*-butyl) phosphate and sodium cholate for 20 min at room temperature (45). A promising method that destroys HIV-1 but does not effect changes in hematological parameters is the "photodynamic method," a hematoporphyrin photosensitizer (46).

1.3 Epidemiology

Since the recognition and reporting of AIDS in 1981, more than 650,000 persons with AIDS have been reported to public health departments in the United States (9). In the United States, AIDS was the leading cause of death among those aged 25–44 years in 1993 (47), but dropped to the fifth leading cause in 1997 (48). Worldwide, at the end of 1997, approximately 30.6 million people were living with HIV infection, 20.8 million of them in sub-Saharan Africa (49).

Epidemiological information gathered since the early 1980s indicate that the modes of transmission of HIV-1 have remained the same. HIV-1 is transmitted through sexual contact, percutaneous or mucous membrane exposure to blood, birth, or breastfeeding from an infected mother, or transfusion of HIV-contaminated blood. However, trends of HIV infection for certain populations reflect the evolution of the epidemic. For example, in the United States, AIDS cases attributed to homosexual or bisexual behavior decreased from 65% of cases in 1984 to 48% in 1998. Heterosexual contact cases increased from 1.2% in 1984 to 10% in 1998 (50, 51).

The findings demonstrate a disproportionate increase in U.S. women and racial[sol]ethnic minorities. Women accounted for only 7% of AIDS cases in 1984 (50), 10% in 1987 (52), and increased to 16% in 1998 (51). The overall rate of AIDS per 100,000 population in 1998 was 34; however, the rate for African-Americans was 125 (51). Dr. Helene Gayle (53) noted that African-Americans make up 13% of the U.S. population, but accounted for 48% of all AIDS cases in 1998, and that higher annual infection rates are seen with young homosexual men, intravenous drug users, women, and minorities.

The annual incidence of AIDS cases associated with blood transfusions and therapeutics for hemophilia stabilized with about five cases per year after the serological screening of blood donations and heat-treatment of clotting factors was initiated in 1985. Currently (at the time of writing), it is estimated that the risk of any unit of blood being contaminated with HIV after the

screening process is 1:200,000–1:2,000,000 (54). The American Red Cross began testing donated blood units via nucleic acid testing (NAT) in June 1999 for early detection of viruses, such as HIV and hepatitis C virus (HCV) (55). Because NAT detects viral DNA or RNA, rather than the donor [apos]s antibodies, it can detect HIV virus within 6–10 days after exposures and HCV within about 41 days after exposure. This reduces the risk of transmission of undetected HIV or HCV via blood transfusions.

In 1998, 8% of all AIDS cases were assigned to a "no identified risk" (NIR) category, representing a large caseload of those recently diagnosed (51). For many of these cases, follow-up investigation is incomplete or the patient has died before an investigation could be performed. Historically, on investigation, 83% of the NIRs are classified into an identified risk category.

Bloodborne Pathogens In the Workplace
Debra L. Hunt, Jerry J. Tulis, MD

2 Occupational HIV-1 Transmission
2.1 AIDS in Healthcare Workers
National surveillance data about AIDS in healthcare workers demonstrate that there is no high risk for working in the healthcare or laboratory setting. As of 1998, approximately 20,769 (5.1%) of reported AIDS cases whose work history was known had related a history of working in a healthcare or laboratory setting since 1978 (4). This percentage is comparable to the proportion of the U.S. population working in the healthcare area (56). The occupations of those healthcare workers with AIDS are as follows: 22% nurses, 21% health aides, 13% technicians, 8% physicians, 5% therapists, 2% dental workers, and 2% paramedics (4). Overall, 75% of the cases of AIDS in healthcare workers have died.
2.2 Prevalence Studies
More indirect evidence that the risk of transmission of HIV-1 in the healthcare setting is small is found in HIV prevalence studies conducted on cohorts of healthcare workers around the country, many of whom work in areas of high community seroprevalence. These studies have examined 7595 U.S. and European healthcare workers with reported HIV exposures and found nine seropositives (0.12%) in workers with no identified community risk (57–69). The prevalence of infection in healthcare workers does not appear to be any higher than that of the comparable population at large.

The lack of association of HIV transmission in the healthcare setting has also been demonstrated in a recent serosurvey of hospital-based surgeons in 21 hospitals in moderate to high AIDS incidence areas across the United States conducted by the CDC Serosurvey Study Group (70). This study also found a low prevalence of 0.14% (one seropositive in 740 surgeons with no community risk identified). This same finding is demonstrated in prevalence studies from Kinshasa, Zaire (71, 72), where community prevalence of HIV is high (6–8%), infection control practices are limited, and needles and syringes are usually washed by hand, sterilized, then reused. No higher rates of seropositivity were found in the hospital staff, nor were there any significant differences among the medical, administrative, and manual workers (6.5, 6.4, and 6%, respectively). These findings reaffirm the apparent low risk for occupational transmission of HIV.
2.3 Documented Case Studies
Occupational HIV infection following a specific exposure is the best indicator of the mode of HIV transmission in the healthcare setting. Although the risk of occupational HIV transmission appears to be low, case reports of healthcare workers infected with the virus through occupational exposure have been reported. Between 1981 and 1998, 54 healthcare workers in the United States have been documented as having seroconverted to HIV following occupational exposures. Twenty-five have developed AIDS. Individuals who seroconverted include 22 nurses, 19 laboratory workers (16 of whom were clinical laboratory workers), 6 physicians, 2 surgical technicians, 1 dialysis technician, 1 respiratory therapist, 1 health aide, 1 embalmer[sol]morgue technician, and 1 housekeeper[sol]

maintenance worker (4). The modes of transmission in these cases appear to be: 46 percutaneous (puncture[sol]cut injury) exposures, 5 mucocutaneous (mucous membrane and[sol]or skin) exposures to blood, 2 had both percutaneous and mucocutaneous exposure, and 1 unknown. Forty-nine exposures were to HIV-infected blood, 3 to concentrated virus in a laboratory, 1 to visibly bloody fluid, and 1 to an unspecified fluid.

Additionally, 133 other cases of HIV infection or AIDS have been reported among healthcare workers who were found to have no other social risk factors for HIV infection, but who experienced nondocumented occupational exposures to blood, body fluids, or laboratory levels of HIV. These include 33 nurses, 18 clinical laboratory workers, 17 physicians, 15 health aides, 12 paramedics, 10 housekeepers[sol]maintenance workers, 9 technicians, 7 dental workers, 3 dialysis technicians, 2 surgical technicians, 2 embalmers[sol]morgue technicians, 2 respiratory therapists, and 2 others (9).

Worldwide, including the United States, 94 documented and 170 possible occupational HIV infections have occurred among healthcare workers as of September 1997 (73). The United States accounted for 62.9% and Europe for 28.4% of documented and possible cases. Of the European countries, France had the highest number with 14.3% of cases. According to case descriptions, the majority of documented infections occurred among nurses or clinical laboratory workers (70.2%) after contact with infected blood (89.4%) from patients with AIDS (76.5%) by percutaneous exposure (88.3%) during a procedure involving placement of a device in an artery or vein (68%).

Bloodborne Pathogens In the Workplace

3 Occupational Risk Assessment
Prevalence and epidemiological studies indicate that occupational HIV infection seldom occurs. Documented HIV seroconversion due to exposures demonstrate that an occupational risk of HIV transmission exists. Factors that may contribute to the magnitude of that risk include the type and extent of injury, the body fluid involved, the "dose" of inoculum, environmental factors, and recipient susceptibility. The interactions and additive effect of these factors on the individual laboratory worker are complex and unknown. However, some data are available that can help further define risks associated with several procedures or circumstances. The type, extent, and frequency of occupational HIV-1 exposure are summarized in Table 20.2.

Table 20.2. Summary of Published Prospective Studies of the Risk for Occupational HIV-1 Transmission in the Clinical Setting

Exposure Type	*N* Studies[a]	*N* Exposures	*N* Infected	Infection Rate (%)
Percutaneous	23	6202	20	0.32
Mucous membrane	13	1364	1	0.07
Cutaneous	1	5568	0	0
Routine patient care activities (no exposures)	3	929	0	0

[a] Refer to text for references (N = number of).

3.1 Route and Extent of Exposure
3.1.1 Parenteral Of the 54 occupationally acquired HIV infections reported, 46 (85%) have been

associated with parenteral exposure (needlesticks, cut with contaminated objects, or nonintact skin exposure to blood) (4). In 1995, a case control study described risk factors associated with occupational HIV infection after percutaneous exposures in cases reported from national surveillance systems in the United States, France, Italy, and the United Kingdom (74). The findings indicate an increased risk for occupational infections following a percutaneous exposure if it involved a larger quantity of blood, such as a device visibly contaminated with the patient's blood, or a procedure that involved a large-gauge, hollow-bore needle, particularly if used for vascular access. Other factors associated with increased risk include a source patient in the terminal stage of illness and lack of zidovudine prophylaxis of the healthcare worker (discussed in more detail later).

The best direct measure of risk of HIV transmission from a single exposure is accomplished through prospective cohort studies that document an HIV exposure event with follow-up serological monitoring of the exposed healthcare worker. In 23 prospective studies that have reported 6202 percutaneous exposures in healthcare workers, 20 instances of seroconversion have been documented, for an overall risk of transmission per percutaneous injury from an HIV-infected patient of 0.32% (66, 75–88). The risk of 0.3% is the average of all the types of percutaneous exposures to blood from patients in various stages of HIV infection. Certain factors, discussed below, contribute to a subset of exposures for which the risk is higher than 0.3%.

There have been two cases of HIV transmission from bites reported (89, 90). Both indicated that blood was involved. In one case (90), the biter died of AIDS 13 days after the bite.

3.1.2 Mucous Membrane Four mucous membrane exposures resulting in HIV infection have been reported in healthcare workers (91, 92, 92a), although in both instances, nonintact skin contact with blood could not be ruled out as a route of exposure. One of them was a laboratory worker whose face was splattered with blood when a vacutainer top flew off the tube while she collected blood from a patient. She also reported having acne (91).

Thirteen prospective studies have included mucous membrane exposures in their risk evaluations and have reported only one seroconversion from 1364 exposures (66, 75–77, 79–82, 84–87). Therefore, the risk of transmission of HIV via mucous membrane is extremely low (0.07%), much lower than that of a percutaneous injury: <0.3% per exposure.

3.1.3 Cutaneous The identification of the Langerhans' cell in the subepithelial tissue as a target cell for the HIV (20) has caused concern among some healthcare workers that cutaneous exposure to HIV may result in transmission of the virus via these cells into the body (93). Infection of the Langerhan's cells is usually a consequence of septic HIV infection (20). Enormous protection against all pathogens is provided by intact skin; however, penetration of the skin into the subepithelial tissues and subsequent inoculation of the Langerhan's cells might occur during a needlestick or cut injury, or other breaks in the skin (94).

One reported case of HIV transmission via skin contact has been reported in a mother caring for her HIV-infected child (95). Although no specific cuts, punctures, or splashes were noted, the mother reported that she used no barrier precautions such as gloves or gowns, and did not always wash her hands after caring for her child. She frequently handled blood and bloody body fluids. It is likely that tiny cuts on the skin may have actually been the route of transmission of the virus.

A report of a laboratory worker infected with a laboratory strain of HIV (60) considered the source of that exposure to be “contact of the individual's gloved hand with H9/HTLV-III$_B$ culture supernatant with inapparent and undetected exposure to skin.” The subject worked with concentrated HIV and reported wearing gowns and gloves routinely. The subject admitted episodes when pinholes or tears in gloves required that they be changed. The subject also related accounts of leakage of virus-positive culture fluid from equipment, and the subsequent decontamination efforts with a hand brush. The subject also recalled an episode of nonspecific dermatitis on the arm that was always

covered by a gown.

A subgroup of 98 other laboratory workers who also worked with concentrated HIV were seronegative. An incidence rate of 0.48 per 100 person-years of exposure has been calculated for prolonged laboratory exposure to *concentrated* virus, approximately the same magnitude of risk of infection as healthcare workers who experience a needlestick HIV exposure (60). Over a 45-year career, this rate would lead to a risk of 195 infections per 1000 exposed workers in research and production facilities.

Three prospective studies have reviewed the risk of HIV transmission as a result of routine patient care activities without a known percutaneous or mucous membrane exposure (66, 81, 96). None of the 929 healthcare workers studied has been infected. Henderson et al. (77) summarized a 6-year, ongoing study of the risk of HIV transmission to healthcare workers sustaining a variety of occupational exposures, including cutaneous exposure. Responding to a questionnaire, 149 National Institute of Health workers reported 5568 cutaneous exposures to blood or other body fluids from HIV-infected patients or their specimens and more than 10,000 cutaneous exposures to blood from all patients. No seroconversion occurred from these exposures despite the high frequency of occurrence, confirming the lack of evidence of any measureable risk of transmission of HIV by cutaneous exposure in a clinical setting.

3.1.4 Other Routes of Exposure There have been no documented cases of HIV transmission through the respiratory, ingestion, or vector route of exposure. Some have questioned the possibility of respiratory transmission of HIV (97), specifically with the research laboratory-acquired infection with no documented percutaneous exposure (60). It is well known that common laboratory procedures using blenders and centrifuges have been evaluated and shown to produce infectious aerosols. Prior to the CDC and NIH recommendations for biological containment in laboratories, agents such as rabies (98), which are not transmitted by aerosols in the community or clinical setting, were documented to cause infection under laboratory conditions when *concentrated* agents were aerosolized by blending or purification procedures. The reported laboratory worker infected with the laboratory strain of HIV may have been exposed to aerosols released during reported rotor-seal failures involving the continuous-flow zonal centrifuge.

However, an expert safety review team convened by the Director of NIH addressed this issue and agreed that the potential for direct contact transmission was much greater than for aerosol transmission (100). Procedures that generated aerosols were carried out in biological safety cabinets. They cite other instances involving overt aerosol exposure in laboratory and production facilities involving concentrated HIV that have not resulted in seroconversions in exposed workers (100). Nevertheless, the occurrence of infection through an unknown exposure emphasizes the need for laboratory workers, particularly in research or production facilities, to strictly adhere to published safety guidelines.

The potential for respiratory transmission of HIV in individuals performing aerosol-producing procedures in a clinical setting (e.g., surgery, dentistry) has also been raised (93, 97). No epidemiological information supports this theory. In fact, several studies have shown a low prevalence of HIV infection in dentists who are routinely exposed to aerosolized body fluids (64, 65, 68, 101, 102). Likewise, surgeons are not overrepresented in the reported AIDS cases compared with other healthcare workers (4).

Johnson and Robinson (97) demonstrated that HIV can remain viable in cool vapors and aerosols generated by common surgical power instruments, but not in the heated vapors produced from electrocautery. In a companion study, Heinsohn et al. (103) demonstrated that aerosols of nanometer and micrometer sizes are produced by the instruments. Questions remain as to whether any respirable-size particles generated contain viable HIV and if there exists an infectious dose required for aerosol transmission of HIV.

3.2 Other Factors

3.2.1 Viral Concentration The transmission of HIV and subsequent infection may also depend on the "dose" of the virus present at time of exposure. The dose is determined by the size of the inoculum or the concentration of virus in the inoculum. The dose of HIV required to infect humans is unknown. Fultz et al. (104) studied the infection of chimpanzees with HIV-1 and found that those receiving >1 $TCID_{50}$ by intravenous injection were persistently infected for up to 18 months. Chimpanzees inoculated with low doses (0.1 $TCID_{50}$) did not become infected, suggesting that immune systems can contain small inocula of virus.

A large inoculum of HIV-infected blood such as a unit of transfused blood carries a higher likelihood of virus transmission. Donegan et al. (105) examined recipients of infected blood units with no other risk factors for HIV infection and found 89.5% were seropositive. Ho et al. (22) estimates that 250 mL of HIV-contaminated blood contains 10^4–10^6 $TCID_{50}$ of HIV. In contrast, a much lower risk is associated with occupational exposures (0.3%) in which the amount of blood involved is unknown, but calculated by Ho to contain 0.06–7 $TCID_{50}$ of HIV.

A risk factor for occupational HIV infection identified by a CDC case control study (74) was injury with a large-gauge, hollow-bore needle, which may be directly associated with the amount of blood exposure. This is consistent with laboratory studies that have indicated that less blood is transferred by suture needles (solid bore) than by phlebotomy needles (hollow-bore) of similar diameter (106, 107).

The concentration of virus in blood or body fluid is dependent on the stage of the patient's illness and the antiviral treatment of the patient (21, 22). In the CDC case control study of occupationally acquired HIV infections transmitted by percutaneous injury, a factor associated with increased risk of infection was exposure to a source patient in the terminal stage of illness (74), and may have a direct association with the amount or dose of virus present at the time of exposure. Saag et al. (21) evaluated the plasma viremia levels in patients infected with HIV and found that (*1*) none of the asymptomatic adults, (*2*) 12% of adults with AIDS-related complex, and (*3*) 93% of AIDS patients had cell-free infectious virus in their plasma. Titers of the virus ranged from 10 to 10^8 TCID/mL of plasma, with a mean of $10^{2.8}$ TCID/mL in patients with AIDS. Patients with acute HIV infection had viral titers of 10–10^3 TCID/mL.

Saag et al. (21) also found that therapy with zidovudine (AZT) led to a significant decline in titer. Ho et al. (22) found a 25-fold lower titer mean in AIDS patients treated with AZT versus untreated AIDS patients. Reverse transcriptase inhibitors, such as AZT, and protease inhibitors protect uninfected cells from becoming infected and, therefore, reduce the viral burden in patients' blood (108).

Research or production laboratory workers, by the nature of the work performed, are placed at greater risk because of the high viral concentrations in culture (>10^8 TCID/mL). Published recommended barrier protection and precautions developed by NIH and CDC reduce worker exposure to high risk operations (6, 109, 110).

3.2.2 Specimen Age The length of time the blood has been removed from the source prior to exposure may also influence the number of infectious viruses present in the inoculum. Although most occupational infections have occurrred after exposure to "fresh" blood, HIV has demonstrated stability in the environment in both liquid and dry states (34), and may survive for hours to days at room temperature.

3.2.3 Other Other factors contributing to the overall risk of HIV transmission may include the virulence of the viral strain (111), post exposure first aid or prophylactic practices, or inflammation around the exposure site (numbers of CD4[plus] cells available) (77). Other healthcare-worker-

related factors contributing to risk are skin integrity and immunological status (66). Pinto et al. (112) demonstrated that parenteral exposure to HIV can induce cell-mediated immune response in the absence of seroconversion. It is possible that this immune response is protective against a low HIV infection, and may contribute to the low infectivity rates of healthcare workers.

Bloodborne Pathogens In the Workplace

4 Hepatitis Viruses
At the time of writing, at least six viruses are known to cause hepatitis: hepatitis A, B, C, D, E, and G. Epidemiologically, the viruses can be divided into two groups according to mode of transmission. The hepatitis A and E viruses are transmitted primarily by the fecal–oral route. The hepatitis B, C, D, and G viruses are transmitted by direct contact with blood or body fluids. Hepatitis B and C viruses are frequently responsible for occupational infections.
4.1 Hepatitis B Virus (HBV)
Hepatitis B virus is transmitted parenterally, sexually, and perinatally, and is the major cause, worldwide, of acute and chronic hepatitis, cirrhosis, and hepatocellular carcinoma. High risk groups in industrialized countries include intravenous drug users, homosexual men, and those with multiple sexual partners (113). Others at substantial risk of infection include hemodialysis patients, institutionalized patients, and healthcare workers with occupational exposure to blood (114).

Healthcare personnel have been known to be at greater risk for HBV infection than the general population (115, 116). The incidence of clinical cases of hepatitis B in healthcare workers before the availability of the hepatitis B vaccine (*i.e.*, before 1982) was reported to be between 50 and 120 per 100,000 (117, 118), much higher than that of the general population of <10 cases per 100,000 (114). Level of risk was related to several factors, including the frequency of exposure to blood, body fluids, or blood-contaminated sharps; the duration of employment in a high risk occupation where blood exposure was common; and the underlying prevalence of HBV infection in the patient population. High prevalence of infection was found in occupations associated with the emergency department, laboratory, blood bank, intravenous team, and the surgical house officers (119).

Since 1982, changes in infection control practices, including the recommendation in 1987 of "universal precautions" (6), and the availability of the hepatitis B vaccine to at-risk workers have undoubtedly been responsible for the decline in the numbers of occupational hepatitis B infections (120). The proportion of reported hepatitis B cases associated with healthcare workers has declined from 4% in 1982 to 1% in 1988. The annual number of new HBV infections in healthcare workers has steadily declined from 12,000 in 1985 to 1000 in 1994 (121). Several reports from university hospitals confirm the decline after initiation of the hepatitis B immunization programs. Lanphear et al. (122) reported a decline in clinical hepatitis B in healthcare workers from 82 cases per 100,000 in 1980–1984 to no cases between 1985 and 1989. At Duke University, the number of cases of clinical hepatitis B in hospital employees has declined from 2 cases per 1000 in 1979 to none since 1992, with a vaccine acceptance rate of 90% (122a).
4.2 Hepatitis C Virus (HCV)
Choo et al. (123) discovered the hepatitis C virus (HCV) genome in 1989 and developed a serological test for the agent. Since then, HCV has been found to be the primary agent of parenterally transmitted non-A, non-B (NANB) hepatitis and a major cause of acute and chronic hepatitis throughout the world (124). High rates of HCV infection occur in intravenous (iv) drug users, where it has been estimated that two-thirds of addicts are anti-HCV seropositive within 2 years of regular use of IV drugs, increasing to close to 100% seropositivity after 8 years (125). Other groups at high or moderate risk include patients with repeated direct exposures to blood such as hemodialysis patients (126) and hemophiliacs (127). Lower rates are found in those with inapparent parenteral or mucosal exposures such as sexual contacts of infected persons (128) or transmissions

from mother to infant (129). Blood transfusions have transmitted the virus. Before testing of the virus was available in 1989, the risk of HCV infection per unit was 0.45%; after antibody testing became available, 0.06% (130).

Although HCV transmission occurs in the healthcare setting, the seroprevalence rate in workers is only slightly higher than the corresponding general population. In general, most studies document an HCV seroprevalence of between 1 and 2.8% for healthcare workers compared with the rate of 0.3–1.5% in blood donors (the community rate) (131).

Prospective studies that record seroconversions after documented percutaneous exposures indicate the risk of HCV infection after a single injury to a healthcare worker can range from 0.75% (132) to 10% when PCR methodologies are used to determine HCV-RNA (133). The wide range of risk reflects the differences in study design, diagnostic tests used, number of cases followed, source patient status, and community prevalence. In general, after pooling data from 9 published prospective studies, a risk of 2.5% after a percutaneous injury is a reasonably accurate estimate (132).

Bloodborne Pathogens In the Workplace
Debra L. Hunt, Jerry J. Tulis, MD

5 Relative Risks for Occupational Infection
The anxiety surrounding HIV in the laboratory setting has been partially due to the historical problem of occupational hepatitis B infection and its designation as a model for transmission of a bloodborne pathogen. In the early 1980s, the CDC estimated that 12,000 healthcare workers became occupationally infected with hepatitis B each year, resulting in over 250 deaths (134). In contrast, the total number of occupationally acquired HIV infections in 17 years is estimated to be 187 (54 documented, 133 possible), an average of approximately 10 per year.

The risk of hepatitis B infection following a single parenteral exposure to hepatitis B surface antigen–positive blood (6–30%) (135) is much higher than the risk of HIV infection from a similar exposure to HIV–infected blood (0.3%). The risk of hepatitis C infection from a single percutaneous exposure to antihepatitis C–positive blood is approximately 2.5% (131). The differences in transmission rates correlate directly with average titers of the viruses found in infected sources. Viral titers of hepatitis B during the acute stage of disease can reach 10^2–10^8 viral particles per milliliter of blood (136, 137), hepatitis C titers generally reach 10–10^6 viral particles per milliliter (137), and HIV titers average around 10–10^3 viral particles per milliliter (22).

Although hepatitis B transmission rates are higher than other bloodborne pathogens in the occupational setting, it is generally a self-limiting disease in the general population (only 5% develop chronicity) and is entirely preventable with vaccination for workers at risk. The chronic nature of hepatitis C and HIV infection increases the reservoir of infected sources in the population and the potential for exposures.

Bloodborne Pathogens In the Workplace
Debra L. Hunt, Jerry J. Tulis, MD

6 Other Bloodborne Pathogens
6.1 Retroviruses

Since 1980, five types of human retroviruses have been isolated: HTLV-I, HTLV-II, HIV-1 (formerly HTLV-III), HIV-2 (formerly HTLV-IV), and HTLV-V. On the basis of morphological features and molecular hybridization studies, HTLV-I, II, and V are classified as oncornaviruses and are associated primarily with malignancies such as leukemia and lymphoma. HIV-1 and HIV-2 have likewise been classified together as lentiviruses (16) and cause cell lysis and death.

6.1.1 Human T-Lymphotropic Virus Types I and II (HTLV-I, HTLV-II) The HTLV-I and -II viruses are classified as oncornaviruses and are associated with malignancies such as leukemia and lymphoma. The HTLV-I was the first human retrovirus to be isolated (14), and is a cause of adult T-cell leukemia–lymphoma, and tropical spastic paraparesis (138). The seroprevalence of the virus is 1.4 per 10,000 in screened blood donations in the United States (139). HTLV-I is transmitted as other bloodborne pathogens, namely, sexual contact, perinatally, and through contaminated blood. One occupational transmission has been reported in a healthcare worker from Japan who was caring for a patient with adult T-cell leukemia–lymphoma (140).

In 1982, a related virus, HTLV-II, was isolated from a patient with a T-cell variant of hairy cell leukemia (141). The epidemiology of HTLV-II is not as well defined as HTLV-I because of the lack of a specific screening test. However, when specific DNA amplification tests were performed in one study, a risk factor of IV drug use was associated with HTLV-II seropositivity (142).

6.1.2 Human Immunodeficiency Virus, Type 2 (HIV-2) In 1986, a second human retrovirus capable of causing AIDS was isolated from patients of western African origin (143). Originally named human T-lymphotropic virus type IV (HTLV-IV) and later renamed HIV-2, the virus is endemic to western Africa, where it is the dominant HIV. Because of the high incidence of HIV-2 in this region, but low rate of AIDS, there is speculation that the ability of this virus to cause disease is less efficient than HIV-1 (144).

In June 1992, the U.S. Food and Drug Administration recommended screening all blood and blood products with the combined HIV-1/HIV-2 enzyme immunoassay (145). Only a few cases of HIV-2 have been detected among the blood donations in U.S. blood centers, and most of them have been from donors with western African association (146).

HIV-2 seems to be transmitted in the same way as HIV-1. As of 1988, no occupational infections have been documented, although there is documentation of parenteral transmission through IV drugs and blood transfusions (147).

6.1.3 Human T-Lymphotropic Virus, Type V (HTLV-V) The HTLV-V is the designation given to an apparently new retrovirus isolated from a cluster of patients in southern Italy with a clinical syndrome resembling mycosis fungoides. This virus is significantly cross-reactive with and genetically related to HTLV-I (16). As with HIV-2 and HTLV-II, there is a lack of epidemiological data regarding HTLV-V.

6.2 Other Pathogens

Concern over laboratory-acquired infections has focused on HIV and the hepatitis viruses. Several other infectious agents may not be included under the category of classic “bloodborne pathogens,” but may warrant mention because of the potential for occupational transmission because: (*1*) the agents may be found in high titers during the septic phases of their disease processes, (*2*) rates of community infections may be increasing and thus provide a larger reservoir for exposure, or (*3*) occupational infections may not be recognized or diagnosed because of the unusual route of exposure.

No published information is available regarding the risk of occupational transmission of any of these agents; however, documented cases of occupational parenteral transmission or transmission through blood transfusions has been recorded in the literature.

Many of the agents are rarely found in the United States and may not pose a significant risk at this

time. For example, Chagas disease is endemic in Latin America where blood transfusions frequently transmit the trypanosomes. However, Kerndt et al. (148) discovered a 2.4% seropositivity rate in Los Angeles after testing over 1000 blood donations.

Treponema pallidum, the causative agent of *syphilis*, is found in highest numbers during the secondary, hematogenous stage, but is also found intermittently in blood if syphilis is left untreated. During 1990, the rate for primary and secondary syphilis in the United States (20.3 per 100,000) was the highest since the 1940s (149). Outbreaks have been linked epidemiologically to increased crack-cocaine use and HIV infection. The increasing numbers of patients with syphilis and HIV increases the possibilities for occupational exposures and infection. Nosocomial transmission of syphilis has occurred by needlesticks, blood transfusions, and tattooing (150, 151).

Few agents have been implicated in documented occupational infections with clinical exposures, but the amount of infectious agents present during septic phases of infection indicate the real potential for percutaneous transmission. For example, *Babesia microti* is present in 30–85% of peripheral red blood cells during the parasitemia stage of infection (152), and has been transmitted through blood transfusions (153, 154). In acute *Brucella melitensis* infections, 70–90% of blood cultures will grow the organism (155, 156). Human parvovirus B19 can demonstrate a high viral titer (10^{10} virions/mL) during a brief viremic stage (157), and has been transmitted through blood transfusions. In fact, Barbara and Contreras (157) estimated that up to 90% of recipients of factor VIII are likely to be seropositive for parvovirus B19, the causative agent of erythema infectiosum, also known as "fifth disease."

Amplification of some bloodborne agents in the laboratory environment has resulted in laboratory-acquired infections due to contact with higher doses of agent than is found in clinical situations. Examples include Arboviruses (158) or *Leptospira sp.* (151). In many of the reported laboratory-acquired cases, no specific incident for exposure could be recalled. Rather, the worker simply "worked with the agent" (151, 158), implying either aerosolization of high titers of organisms or inadvertant inoculation of mucous membranes or nonintact skin by contaminated hands. Most of the agents caused an occupational infection prior to the publication of the standard laboratory containment guidelines (159) designed to protect laboratory workers from aerosols, splashes, and other hazardous exposures.

Bloodborne Pathogens In the Workplace
Debra L. Hunt, Jerry J. Tulis, MD

7 Strategies for Infection Prevention
Within one year of the first recognized cases of the newly defined disease, AIDS, the CDC issued guidelines (160) for clinical and laboratory staff regarding appropriate precautions for handling specimens collected from AIDS patients. Later, the CDC reemphasized precautions that had been recommended previously for handling specimens from patients known to be infected with hepatitis B, specifically, minimizing the risk for transmission by the percutaneous, mucous membrane, and cutaneous routes of infection. After anecdotal laboratory-associated infections with HIV reports of the CDC issued its first agent summary statement for work with HTLV-III/LAV in 1986 (100). The statement included a summary of laboratory-associated infections with HTLV-III (HIV), the hazards that might be encountered in the laboratory, and advice on the safety precautions that should be taken by laboratories. Biosafety level 2 precautions were recommended for work with clinical specimens, body fluids, or tissues from humans or laboratory animals *known or suspected to contain* HTLV-III/LAV (HIV). Biosafety level 3 additional practices and containment equipment were recommended for activities involved with culturing research laboratory-scale amounts of the virus. A biosafety level 3 facility and biosafety level 3 practices and procedures were recommended for all

work involving industrial-scale, large-volume concentrations of the virus (see Table 20.3).

Table 20.3. CDC/NIH Recommended Precautions for Laboratory Work with HIV-1[a]

Facility	Practices and Procedures	Activities Involving
BL2	BL2	Clinical specimens
		Body fluids
		Human/animal tissues infected with HIV
BL3	BL3	Growing HIV at research lab scale
		Growing HIV-producing cell lines
		Working with concentrated HIV preparations
		Droplet/aerosol production

[a] Refer to text for references (BL = biosafety level).

Reports issued by CDC (91) in May 1987 documented that laboratory workers and other clinical staff were occupationally infected with HIV via nonintact skin and mucous membrane exposures. Because the HIV serostatus of the patient sources were unknown at the time of exposure and the exposures were nonparenteral, the CDC issued the "universal blood and body fluid precautions" recommendations in August 1987 (6). The major premise involved the *careful* handling of all blood and body fluids as if *all* were contaminated with HIV, HBV, or other bloodborne pathogens. This "universal precautions" concept formed the basis for all subsequent recommendations from CDC (109, 134) and other professional organizations such as the National Committee for Clinical Laboratory Standards (NCCLS) (161).

The counterpart of universal precautions in a laboratory situation involves the *consistent* use of biosafety level 2 facilities and practices as outlined in the CDC/NIH manual, *Biosafety in Microbiological and Biomedical Laboratories* (110). The biosafety level 2 precautions are most appropriate for clinical settings or when exposure to human blood, primary human tissue, or cell cultures is anticipated. Standard microbiological practices form the basis for biosafety level 2 with additional protection available from personal protective equipment (PPE) and biological safety cabinets (BSCs) when appropriate.

In 1988, two reports of research laboratory workers with documented occupational HIV infection prompted an investigation by an expert team to review possible sources of exposure and any need to revise current practices to reduce hazards in the research laboratory (99). Subsequently, an agent summary update was issued and included in the 1988 edition of *Biosafety in Microbiological and Biomedical Laboratories* (162). The expert team did not advise alteration of the CDC/NIH biosafety recommendations for laboratories, but stressed the need for reinforcement of safety practices through proficiency and administrative discipline.

In addition to the advisory nature of the CDC/NIH guidelines, the federal Occupational Safety and Health Administration (OSHA) issued a final standard to regulate occupational exposure to bloodborne pathogens (163). The standard builds on the implementation of "Universal Precautions" specifying the need for control methods, training, compliance, and recordkeeping.

OSHA also recognized that employees in HIV/HBV research laboratories and production facilities may be placed at a higher risk of infection following an exposure because of the concentrated

preparations of viruses. Requirements for practices and special procedures, facility design, and additional training for these workplace situations are included in the OSHA standard and are consistent with the CDC/NIH laboratory biosafety guidelines for biosafety levels 2 and 3.

7.1 Specific Precautions

OSHA has issued the bloodborne pathogen standard as a "performance" standard. In other words, the employer has a mandate to develop an exposure control plan to provide a safe work environment, but is allowed some flexibility in order to accomplish this goal. OSHA embraces the basic philosophy of the CDC "universal precautions," and marries it with combinations of engineering controls, work practices, and personal protective equipment in order to accomplish the intent of the standard.

Recognizing the risks inherent in needlestick and sharps exposures, OSHA recently (at time of writing) introduced the Healthcare Worker Needlestick Injury Prevention Act of 1999 (164). The bill would amend the federal Bloodborne Pathogens Standard to require that employers utilize needleless systems and devices with engineered sharps protections to prevent occupational exposure to bloodborne pathogens. It also enhances needlestick reporting requirements and establishes a national clearinghouse to collect data on safety devices. Four states have already adopted revised bloodborne pathogens regulations requiring the use of safety devices as of August 1999: California, Maryland, Texas, and Tennessee.

Exposure control plans for laboratories must adhere to the rules of the OSHA standard, but can also benefit from safety recommendations from other professional organizations such as CDC, NIH, or NCCLS (National Commitee for Clinical Laboratory Standards). Specific rules and recommendations that might augment a laboratory safety plan are worth noting.

7.1.1 Sharps Precautions Since injuries from contaminated sharps represent the highest risk for HIV transmission, clinical and research laboratory safety plans should restrict the use of needles and other sharp instruments in the laboratory for use only when there is no alternative, such as performing phlebotomy. For laboratory procedures, other means should be considered to achieve the job, such as the use of blunt cannulas or small-bore tubing. If needles must be used, investigate the use of "self-sheathing" needles or "needleless" systems that have recently been designed to prevent needlesticks.

Used needles should never be bent, broken, recapped, removed from disposable syringes, or otherwise manipulated by hand before disposal; rather, they should be carefully placed in conveniently located puncture-resistant containers (110). Removal of needles from nondisposable vacutainer sleeves or syringes should be accomplished with a mechanical device such as forceps or hemostats, or by using notched slots designed into needleboxes for safe removal of the needle. The OSHA standard allows a "one-handed" recapping technique only if there is no alternative feasible. All disposable sharps encountered in the laboratory, including pipettes, microtome blades, micropipette tips, capillary tubes, and slides, should also be carefully placed in conveniently located puncture-resistant containers for disposal. Nondisposable sharps should be placed in a hard-walled container for transport to a processing area.

Plasticware should be substituted for glassware whenever possible. Broken glassware should never be handled directly by hand, but must be removed by mechanical means such as a brush and dustpan, tongs, or forceps. Cotton swabs can be used to retrieve small slivers of glass.

7.1.2 Engineering Controls Recognizing that human behavior is inherently less reliable than mechanical controls, OSHA advocates the use of available technology and devices to isolate or remove hazards from the worker. The use of "self-sheathing" needles is an example of an engineering control to help isolate the worker from the hazard of needlestick exposure.

Another engineering control in the laboratory is the use of a properly maintained biological safety cabinet (BSC) to enclose work with a high potential for creating aerosols or droplets, namely, blending, sonication, necropsy of infected animals, intranasal inoculation of animals, or opening lyophilized vials under pressure. *All* work with infectious material in an HIV research laboratory

should be performed in a BSC or other physical containment device. For example, high energy activities such as centrifugation that are performed outside a BSC should be designed for aerosol containment. Sealed safety cups or rotors should be used for centrifugation, and changed out in a BSC. Before centrifugation, tubes should be examined for cracks, and any glass fragments in the centrifuge cups should be carefully removed with forceps or hemostats. Microwell plate lids can be sealed with tape or replaced with adhesive-backed Mylar film prior to centrifugation.

Plastic shielding can be used to reduce the exposure to splatter or droplets from fluorescent activated cell sorters or other automated laboratory equipment that might generate droplets of infectious material. Likewise, the plexiglass radiation shield used in reverse transcriptase assays offers protection from splatter. However, if used in a BSC, the sloped top may divert airflow in the cabinet, and must be removed to provide optimal protection by the BSC.

High speed blenders and grinders are available that contain aerosols of infectious material, and need to be opened in a BSC after processing. Enclosed electrical incinerators are preferable to open Bunsen burner flames for decontaminating bacteriological loops to prevent splatter, and may be used within or outside a BSC.

7.1.3 Work Practice Controls The manner in which a task is performed can minimize the likelihood of exposures in the laboratory. For example, careful disposal of used needles without recapping or otherwise manipulating by hand can reduce the likelihood of needlesticks.

Standard microbiological practices have been recommended by CDC and NIH guidelines for all laboratory containment levels (110). Most of the practices are designed to prevent indirect transmission of infectious material from environmental surfaces to the hands, and from hands to the mouth or mucous membranes. Such practices include prohibition of mouth pipetting, eating, drinking, smoking, applying cosmetics, or handling contact lenses in the laboratory, and attention to environmental decontamination.

One of the best work practices for any laboratory setting is that of frequent and adequate handwashing when hands are visibly contaminated, after completion of work, before leaving the lab, after removing gloves, and before eating, drinking, smoking, or changing contact lenses. Any standard handwashing product is adequate, but products should be avoided that disrupt skin integrity. When knee- or foot-pedal-controlled faucets are not available, faucets should be turned off by using paper towels used to dry hands to prevent recontamination of hands. Proper attention to handwashing will prevent inadvertant transfer of infectious material from hands to mucous membranes.

In clinical settings, skin lesions may be covered by occlusive dressings and, if lesions are on the hands, gloves worn over the dressings to prevent contamination of nonintact skin. However, workers with skin lesions or dermatitis on hands or wrists should not perform procedures with concentrated HIV material even if wearing gloves. Other work practices can reduce the amount of splatter from laboratory procedures. Covering pressurized vials with plastic-backed or alcohol-soaked gauze when removing needles or when removing tops of pressurized vacutainer tubes will minimize the exposure to splatter. To prevent popping stoppers on evacuated tubes or vials, blood should never be forced into the tube by exerting pressure on the syringe plunger; rather, tubes and vials should be filled by internal vacuum only. Extreme caution should be used when handling pressurized systems such as continous-flow centrifuges, apheresis, or dialysis equipment. Use of imperviously backed absorbent material (“lab diapers”) can reduce the amount of splatter on laboratory work surfaces when liquids accidentally leak or fall during lab procedures and can aid in laboratory cleanup. Remember to keep the air-intake and exhaust grilles in BSCs clear of any surface covers or equipment.

Safe transport of specimens or infectious material within the laboratory or to other areas can minimize the potential for accidental spills or injuries. Specimens should be contained in a closed, leakproof primary container, and placed in a secondary container (*i.e.*, a plastic bag) to contain leaks during transport. OSHA regulations do not mandate labeling or color-coding specimens if the

specimens are handled only within the facility, a policy implementing "universal precautions" is in effect, and the containers are recognizable as human specimens. Bulk samples may be safely transported in a rack within a sealable plastic container such as a modified "tackle box." The box may need to be labeled with a biohazard symbol or color-coded if the contents are not clearly visible as specimens. Luer caps should be used to transport syringes (needles removed with forceps or hemostats and properly disposed) or needles carefully recapped using a one-handed technique. Capillary tubes should be transported in a solid-walled secondary container such as a screw-top test tube. Transport of cultures or hemocytometers from the BSC within the laboratory may be facilitated by placing them on a tray to limit the number of trips and opportunities for spillage.

Designation of "clean" versus "dirty" areas of the laboratory or within BSCs can help to prevent inadvertent contamination. Work should be planned to move from clean areas to dirty areas. Routine cleaning of work surfaces must be done after procedures are completed and at the end of each workshift, with additional decontamination as needed for spills. Routine cleaning can be accomplished using a variety of disinfectants, including iodophors registered as hard-surface disinfectants, phenolics, and 70% ethanol [with consideration given to the need for longer contact time when decontaminating dried viral cultures (165)]. Diluted bleach has been most widely used for routine disinfection [10% bleach (0.5% sodium hypochlorite) for porous surfaces and 1% bleach (0.05% sodium hypochlorite) for cleaned, hard, and smooth surfaces]. Aldehydes are not recommended for surfaces because of their potential toxicity.

Prompt decontamination is important following spills of infectious materials, since HIV is able to survive for several hours in the environment (see Table 20.1). Appropriate spill cleanup in a clinical setting should involve the following steps:

1. Absorb the spill with towels or "lab diapers" to remove the extraneous organic material.
2. Clean with soap and water.
3. Decontaminate with an appropriate disinfectant [CDC recommends an EPA-registered "hospital disinfectant" that is also "tuberculocidal" or, a 1–10% bleach solution is sufficient (6)].

Large spills of cultured or concentrated agents may be safely handled with an extra step:

1. Flood the spill with an appropriate disinfectant *or* absorb the spill with granular material impregnated with disinfectant.
2. Carefully soak up the liquid material with absorbent material (paper towels), or scrape up the granular absorbent material and dispose of according to the waste-disposal policy.
3. Clean the area with soap and water.
4. Decontaminate with fresh disinfectant.

Laboratory equipment (analyzers, centrifuges, pipettors) should be checked routinely for contamination and appropriately decontaminated. Any equipment sent for repair must also be decontaminated before leaving the laboratory, or labeled as to the biohazard involved.

Because the intent of the OSHA Bloodborne Pathogen Standard is worker protection, the rules for appropriate waste disposal emphasize adequate packaging. Sharps disposal containers must be puncture- and leakproof as well as easily accessible. Other "infectious" or "medical" waste must be placed in leakproof containers or bags that are color-coded red or orange, or labeled with the word "biohazard" or the universal biohazard symbol. All disposal containers should be replaced before they are full.

Blood or body fluids may be disposed of by carefully pouring down the sanitary sewer if local health codes permit, but not poured into a sink where handwashing is performed. Liquid and solid culture materials, however, *must* be decontaminated before disposal, most commonly by steam sterilization

(autoclaving). Tissues, body parts, and infected animal carcasses are generally incinerated. *All* laboratory waste from HIV research-scale laboratories or production facilities and animal rooms must be decontaminated before disposal (biosafety level 3 practices). Additional "medical" or "infectious" waste definitions and requirements may exist locally and must be consulted for proper disposal policies.

7.1.4 Personal Protective Equipment (PPE) Another strategy to minimize worker exposure to infectious material is the use of PPEs that are appropriate for the laboratory procedure and the type and extent of exposure anticipated. Examples include a variety of gloves, gowns, aprons, and face, shoe, and head protection. Personal protective equipment may be used in combination with engineering controls and/or work practices for maximum worker protection.

Gloves are required by OSHA when hand contact with blood, other potentially infectious materials, mucous membranes, or nonintact skin is reasonably anticipated. The federal regulations also require gloves when handling or touching contaminated items or surfaces, and for performing vascular access procedures. Gloves are appropriate in the laboratory when handling clinical specimens, infected animals, or soiled equipment, when performing all laboratory procedures in research laboratories, cleaning spills, and handling waste.

For routine procedures, vinyl or latex gloves are effective when appropriately used for prevention of skin exposure to infectious materials. Gloves are not intended to prevent puncture wounds from needles or sharps. However, evidence of a "wiping" function exists that may reduce the amount of blood or infectious material exposure from the outside of the needle as it penetrates a glove or combination of gloves. Johnson et al. (166) found that two or three layers of latex gloves appeared to reduce the frequency of HIV-1 transfer by surgical needles to cell cultures. They also found that Kevlar gloves (untreated), Kevlar gloves (treated with the virucidal compound, nonoxynol-9), and nonoxynol-9-treated cotton gloves used as intermediate layers between two layers of latex gloves significantly reduced the amount of HIV-1 transfer when compared with a single latex glove barrier. Gerberding et al. (167) reported that when surgeons wear double gloves, the rate of puncture of the inner glove is 3 times less than the rate of puncture of a single glove.

Other gloves are available that provide puncture "resistance" such as stainless-steel mesh (chain mail) gloves to protect against injury from large sharp edges such as knife blades. Nitrile gloves (synthetic rubber) have some degree of puncture resistance that may eliminate problems with rings or fingernails, yet retain the necessary dexterity required for performing laboratory procedures. A thin leather glove has been developed that can be worn under latex gloves for an an additional barrier against needlesticks or animal bites. Even heavyweight utility gloves (dishwashing gloves) provide extra protection and should be worn when the procedure permits, such as cleaning contaminated equipment or spills.

Undetected physical holes and leaks require that gloves be frequently inspected and changed. The U.S. Food and Drug Administration (FDA) has issued acceptable quality limits (AQLs) for defects at 2.5% defective for surgeons' gloves and 4.0% for latex exam gloves (168), although the AQL varies widely among manufacturers. The reported percentage defective due to holes for nonsterile latex gloves ranges from 0 to 32%; for nonsterile vinyl gloves, from 0 to 42% (161). Clearly, for high risk situations such as gross contamination of gloves with blood, bloody body fluid, or high concentrations of HIV-1, the use of double gloves will lower the risk of hand contamination from seepage through undetected glove defects. Although they are more puncture-resistant, nitrile gloves are designed to tear apart when any pressure is applied to a hole in the glove, so that any violation of the glove will be detected.

Gloves must never be washed or disinfected for reuse. Detergents may cause enhanced penetration of liquids through undetected holes causing a "wicking" effect (134, 161). Disinfectants, such as 70% ethanol, can also enhance the penetration of the glove barrier and facilitate deterioration (161, 169).

Gloves must be changed when visibly contaminated, torn, or defective, or when tasks are completed. Since hands may be inadvertently contaminated from laboratory surfaces, gloves should be removed before handling telephones, doorknobs, or “clean” equipment. Alternatively, “dirty” equipment may be designated and marked to be handled only with gloved hands. Laboratory workers should practice the aseptic technique for glove removal, specifically, the contaminated side remains on the inside as gloves are removed to protect the worker from skin contamination. Hands should always be washed after glove removal.

When soiling of clothing is anticipated, laboratory coats, gowns, or aprons are recommended. However, when a potential for splashing or spraying exists, solid-front, fluid-resistant gowns are appropriate. If the anticipated exposure involves soaking, solid-front fluidproof gowns are required, as well as hoods/caps, facial protection, and shoe covers. Biosafety level 3 practices advise a solid-front or wraparound, long-sleeved gown or coveralls for adequate protection in research laboratories or production facilities.

Gowns with tightly fitting wrists or elasticized sleeves should be worn for work in BSCs. Alternatively, water-resistant “gauntlets” that provide a barrier between the glove and the laboratory coat are available to reduce skin exposure of the wrist and arm.

Laboratory coats or gowns should not be worn outside the laboratory. In HIV-1 research laboratories or production facilities, the gowns or other protective clothing must be decontaminated before laundering or disposal (BSL-3 practices).

When splashing of blood or infectious material into the mucous membranes of the face is anticipated, a mask and goggles or faceshield must be used. Most laboratory procedures involving this degree of exposure should be conducted within containment equipment such as a BSC. Face protection might be needed for activities conducted outside a BSC, such as performing an arterial puncture, removing cryogenic samples from liquid nitrogen, or in some animal care areas. Masks and eye goggles or faceshields also serve a passive function as a means of preventing accidental contact of contaminated gloved hands with the eyes, nose, and mouth during the course of work activities.

Whatever the PPE needs of any particular laboratory, OSHA requires that the employer provide an adequate supply of PPEs in the appropriate sizes. Hypoallergenic gloves must be available for employees who develop allergies to glove material or the powder inside gloves. Any defective PPE must be replaced, and reusable protective clothing must be laundered and maintained by the institution. Finally, all laboratory workers must be instructed in the proper use of PPEs and their location.

7.2 Employee Training and Monitoring

One of the most important components of an exposure control plan for the laboratory is a formal training program. “On-the-job training” is not acceptable as adequate safety training in the laboratory. The recommendations from CDC (109) and NCCLS (161) that emphasize education of laboratory workers have been incorporated into the OSHA bloodborne pathogen standard (163).

Interactive training sessions must be conducted on initial hire and with annual updates by a person knowledgeable about the standard. Employees must be educated regarding their risks and the institution's plan to control these risks.

Recognizing the increased risk of working with concentrated viral preparations, OSHA requires that employees in HIV research laboratories and production facilities receive *additional* initial training. Employees in these situations must demonstrate proficiency in standard microbiological practices as well as practices and techniques specific to the facility *prior* to work with HIV. This might include prior experience in handling human pathogens or tissue cultures, or participation in a training program with a progression of work activities to develop proficiency before pathogens are handled.

Employers must ensure compliance with the OSHA standard. The CDC (109) and NCCLS (161) recommend that workplace practices be monitored at regular intervals by a biosafety expert. The NCCLS suggests that audits be conducted that evaluate the existence and effectiveness of training programs and the job descriptions of the safety trainers. The audit should also examine the adequacy of the laboratory facilities and equipment, the standard operating practices, and the written safety protocols. Corrective measures should be implemented if needed. If breaches in protocol are detected, employees should be reeducated and, if necessary, disciplinary action taken.

8 Postexposure Management
The implementation of a bloodborne pathogen exposure control program that includes Universal Precautions and the recommendations from CDC and NIH may reduce the incidence of occupational exposure to HIV and other bloodborne pathogens; however, use of prevention strategies will not entirely eliminate the risk of accidental exposures and subsequent occupational infection. OSHA estimates that full compliance with the bloodborne pathogen standard would reduce the risk of mucous membrane and skin exposure by 90%, and the risk of parenteral exposure by 50% (170). Therefore, a postexposure evaluation program is a necessary and mandated component of a workplace safety program.

Work settings in which workers handle blood, other potentially infectious materials, or concentrated HIV viral material must adhere to the OSHA postexposure protocol that requires confidential medical evaluation, follow-up, and documentation of an exposure incident. OSHA defines an "exposure incident" as a "specific eye, mouth, other mucous membrane, non-intact skin, or parenteral contact with blood or other potentially infectious materials that results from the performance of an employee's duties" (163). The bloodborne pathogen standard requires follow-up according to the U.S. Public Health Service recommendations, specifically, CDC guidelines.

The postexposure management of hepatitis B exposures has been well defined on the basis of the vaccination status of the exposed employees (4, 171). The management of such exposures involves serological testing of the vaccinated employee for a protective antibody level against HBV. If antibody levels are negative or not detectable, a booster dose of HBV vaccine is given. For nonvaccinated employees, the HBV vaccine is offered in combination with hepatitis B immune globulin (HBIG).

HCV postexposure management has been defined (172) and involves serological testing of the employee at intervals up to 6 months postexposure for antibody to HCV as well as liver enzyme testing. The CDC does not recommend immune globulin for such exposures.

Analysis of data in the CDC case control study of occupationally acquired HIV infection suggested that use of AZT postexposure might be protective for healthcare workers (74). The risk for HIV infection in this study was reduced approximately 79% in workers who were given AZT prophylactically following exposure. Because of these results, the CDC recommended the use of antiviral agents for postexposure treatment after high risk exposure to HIV-infected patients (9). These guidelines outline a number of considerations in determining whether a healthcare worker should receive postexposure prophylaxis and in the choosing the type of prophylaxis regimen.

Tuberculosis and Other Mycobacteria
Donald E. Gardner, Ph.D., Fellow ATS

1 Introduction

The genus *Mycobacterium* is one of the most widely distributed bacteria genera in nature and includes those organisms that cause two of the world's most prevalent infectious diseases in humans, *M. tuberculosis*, the agent of tuberculosis and *M. leprae*, the agent of leprosy. A large number of other species in this genera are widespread and occur as contaminants in soil, water, or organic debris. These organisms may be ingested or inhaled in dust particles and produce syndromes that are indistinguishable from classic tuberculosis. The term tuberculosis (TB) is commonly applied to all cases of mycobacterial infections except leprosy. Many of these infections are now being recognized more frequently in immunosuppressed patients who have organ transplants, individuals being treated for leukemia or cancer, and patients suffering from AIDS. In most cases of TB in humans, the lungs are the major organ affected but other tissues and organs such as bone, skin, and the digestive tract may also be infected. Although this chapter focuses primarily on tuberculosis, a discussion of a few of these other opportunistic organisms in this genus that are associated with human disease are also discussed.

The bibliography provided will guide the readers to works which they can consult for more detailed information about these organisms. These references contain discussions on taxonomy, growth requirements, as well as the morphological characteristics, physiology, pathogenicity, and the metabolic activity of these organisms (1–6).

Tuberculosis and Other Mycobacteria
Donald E. Gardner, Ph.D., Fellow ATS

2 Historic Perspective

Throughout the ages, tuberculosis has been a scourge of humankind. Human fossils excavated from Neolithic burial grounds dating about 6,000 years ago show evidence of TB of the spine (7). Robert Koch is credited with discovering the tuberculosis bacillus in 1882 and reporting that it was the causative agent of TB in both humans and cattle. Tuberculosis gets its name from the small nodules (tubercles) commonly found in infected individuals; however, throughout history it has been known

by many other names, including scrofula, phthisis, and consumption.

The Industrial Revolution created ideal conditions for the spread of this organism. Malnutrition, overcrowding, poorly ventilated factories and homes, unsanitary conditions, poverty, and certain occupational settings provided the means for this organism to spread. Tuberculosis was the leading cause of death from infectious disease in the United States and Western Europe until the first decade of this century, and it remained the second leading cause of death (the first was malaria) from that time until the advent of antimicrobial drugs in the 1950s, when infection rates began to decline steadily (8). This trend was reversed between 1985 and 1992 when the frequency of TB started to increase at an alarming rate. At that time, many hospitals lacked the appropriate ventilation systems, ultraviolet lights, isolation areas, and clinical expertise needed to treat active tuberculosis and to prevent this organism from spreading.

Among persons infected with the tubercle bacillus, as detected by a positive tuberculin test (see later), only a small proportion develop overt disease. Thus humans seem to have a considerable natural resistance to TB. It is important to understand the difference between infection and disease (this series, Chapter 19). Infection implies that a microbe has taken up residence in a host and may be capable of multiplying within the host—perhaps with no outward signs of disease. Thus, it is possible to be infected but not have the disease symptoms commonly associated with the agent, although disease may develop at a later time. This is often the situation with exposure to the TB organism. The transition from infection to mild or severe disease depends strongly on various factors besides the presence of the bacilli.

Even with this natural resistance to TB, today worldwide, this organism kills more people than any other infectious disease and infects more than 1 billion people; of these, an estimated 20 million actually develop the disease. Each year, the number of new infections continues to increase. For example, in 1990, the number of new TB infections was 7.5 million with 2.5 million deaths, and by 1995 new infections increased to 8.9 million and the death rate had increased to 3 million. By the year 2000, 10.2 million new cases are expected with 3.5 million deaths. (9–12).

In the United States, about 30,000 active cases are reported yearly, but the number of Americans infected could be as high as 15 million. From 1985 to 1991, the estimated number of new cases increased nearly 20%. Tuberculosis is even more threatening elsewhere in the world. During this same period, TB increased 30% in Europe, and it rose nearly 300% in parts of Africa (12).

TB is reemerging for a number of reasons. First, the prevalence of drug-resistant strains has risen dramatically. Initially, only about 1–2% of the strains of *M. tuberculosis* had significant drug resistance (8, 13). In the 1960s and 1970s, the number of new resistant strains increased by about 3–5% in the United States. Today, about 33% of the tuberculosis strains isolated are resistant to at least one drug, and about 19% are resistant to two or more antimicrobial agents (13). This makes the disease more lethal and treatment longer and more difficult. When multiresistant TB strains are identified, the case fatality rates may exceed 80% in certain compromised individuals.

Secondly, a weakening of the host's immune system through inherited diseases, aging, immunosuppressive medications, and human immunodeficiency virus (HIV) infections has resulted in a massive increase in the incidence of tuberculosis in individuals who might have otherwise been able to defend themselves against this illness. The HIV epidemic is perhaps the most significant factor responsible for this dramatic upsurge in tuberculosis. TB is often the first sign that a person harbors HIV (14). The TB incidence rate among people infected with HIV is nearly 500 times the rate for the general population. An alarming aspect of these coepidemics is that the impaired defenses caused by HIV infection facilitate the transmission of drug-resistant strains of tuberculosis (8, 13, 15). In the United States, 50% of the autopsied AIDS patients have mycobacterial infections (8, 13).

Another reason for this increase is attributed to inadequate health care provided for the poor,

homeless, and drug addicts. Many of these people have little access to health care, some refuse care when it is offered, and many quit treatment before the disease could be arrested. The latter event facilitates drug-resistant strains. Some of the most recalcitrant dropouts are individuals who are drug-addicted, alcoholic, or mentally ill. Many have no permanent homes and cannot be traced by public health officials. A final reason that more cases are appearing today is the increase in number of elderly people in our society. TB is common among the elderly. Of the total cases reported in the United States in 1995, about 25% involved individuals over 65. It is possible that many of them could have been infected years previously, when TB was more common, but their disease broke out only as a consequence of the immunosuppression associated with natural aging. In addition, these individuals often spend later life in health-care facilities where people are more likely to be in close contact with other elderly individuals, thus increasing the risk of contracting the disease. For example, nursing home residents are 10 times more likely to contract TB than the general population.

Tuberculosis and Other Mycobacteria

3 The Organisms
Human TB is caused by *Mycobacterium tuberculosis* var. hominis. The genus *Mycobacterium* is the only genus in the family *Mycobacteriaceae* and is represented by various pathogenic species, which characteristically produce chronic granulomatous lesions. Although the genus *Mycobacterium* includes other obligate parasites, saprophytes, and opportunistic pathogens that live freely in soil and water, the major ecological niche for *M. tuberculosis* is the tissue of humans and other warm-blooded animals. The following section contains a description of some of the important species of *Mycobacterium*. The reader can consult various text and review articles for additional information about these organisms (5, 16–20).

These bacilli are straight or slightly curved, rod-shaped organisms. They vary from about 0.2–0.6 mm wide, and from 1–10 mm long, occasionally occurring as filaments but rarely branching. On the surface of a liquid media, their growth appears mold-like. The name “myco” suggests fungus-like and was derived because they occasionally exhibit filamentous or mycelium-like growth. These organisms are aerobic, nonmotile, and nonspore forming. Although mycobacteria have previously been described as unencapsulated organisms, recent electron microscopic data have provided evidence that pathogenic *Mycobacterium* has a capsule that aids in protecting the cells from the activities of the host's alveolar macrophages (21). These bacilli are very resistant to drying, thus increasing their ability to remain viable during prolonged stays outside the body. This resistance to drying is due to the large amounts of complex long-chain lipids (C_{78}–C_{90}) in their cell walls (40% of total cell dry weight). This high lipid content is also responsible for the fact that mycobacterial cells are difficult to stain by conventional methods, and once stained, they resist decolorization by either 95% ethanol or 3% hydrochloric acid. All mycobacteria have this characteristic and are often referred to as “acid-fast.” Acid fastness is the most important characteristic of a mycobacterium because it can be used to differentiate these types of bacteria from other organisms. *Mycobacterium* species are euphemistically also referred to as “red snappers” because they appear red when stained and appear to break sharply when they reproduce. Another important component of the cell wall of these organisms is trehalose dimycolate, an indicator of the virulence of the organism. When this is present, the virulent strains tend to grow in a characteristic “serpentine” cord-like pattern in an artificial medium, where avirulent strains do not (22).

Because the great majority of *Mycobacterium* can be cultured on artificial media, these organisms are not considered obligate parasites. The major exception is *M. leprae* which has not been cultured on artificial media but grows only in certain animal or tissue cultures of macrophages. Growth rates

for these organisms in culture range from slow to very slow. The transport of nutrients into the cell through the lipid layer in the cell wall is very slow, which is a factor in the slow growth rate of these organisms. It sometimes takes weeks for a visible colony to form. Waxes that make up the cell wall of these organisms also play a major role in their pathogencity and aids them in resisting digestion by phagocytes. In fact, this organism can actually multiply inside phagocytes.

Except for *M. leprae*, the *Mycobacterium* are classified into two broad categories—typical (e.g., *M. tuberculosis*, *M. bovis*, and *M. africanum*) and atypical which includes virually all the other species. All of these various members of *Mycobacterium* are closely related on the basis of DNA homology (23). The different organisms can be separated and identified by their growth rate, pigmentation in the light or dark, catalase and niacin production, nitrate and tellurite reduction, and Tween 80 hydrolysis. They have also been called MOTT (Mycobacteria other than tuberculosis). These atypical mycobacteria cause diseases that mimic TB and are clinically, roentgenographically, and pathologically identical to the disease produced by *M. tuberculosis*, except for one major difference. These infections are usually not communicable. In most cases, the causative agent can be differentiated from tuberculosis only by culturing the organism (24).

Mycobacterium africanum causes TB in tropical Africa; *M. bovis* causes TB in cattle, and it is highly virulent in humans and other primates, certain carnivores (e.g., dogs, cats, and swine), parrots, and some birds of prey. The organism is a bit shorter and plumper than *M. tuberculosis*, but the difference is slight. The disease produced in humans is virtually indistinguishable from that caused by *M. tuberculosis* var. hominis and is treated similarly (25). However, there are some differences between these two organisms. For example, *M. bovis* is highly pathogenic in rabbits, whereas *M. tuberculosis* is much less so. In culture, *M. bovis* tends to grow more slowly and cannot tolerate as high a concentration of glycerol. Serological tests and skin tests, however, cannot be used to differentiate between the two organisms.

Drinking unpasteurized milk and other dairy products from tuberculous cows has been responsible for much human TB. The ingested organisms presumably penetrate the mucosa of the oropharynx and intestines and give rise to early lesions in the cervical or mesenteric lymph nodes. Subsequent dissemination from these sites infects principally bones and joints. Such infection of vertebrae was largely responsible for the hunchbacks in previous generations. When inhaled (e.g., dairy farmers), the organism can also cause human pulmonary tuberculosis. TB due to *M. bovis* has now become very rare in many countries as a result of widespread pasteurization of milk and the elimination of tuberculosis in cattle.

In poultry and swine *M. avium* is an important cause of disease and can also infect humans. It was first recognized in the 1800s as the causative agent of a disease in chickens, but was not recognized as a cause of human disease until 1943. These organisms, which are collectively known as *M. avian* complex (MAC) are ubiquitous in nature and have been isolated from water, soil, plants, house dust, and a myriad of other environmental sources. These organisms usually have low pathogenicity and frequently colonize in individuals without causing disease. Human cases of MAC infection, unrelated to AIDS, occur more frequently in farming populations than in urban patients. The risk of contracting *M. avium* disease is very high among HIV + individuals. Lung infections caused by MAC most often occur in individuals (primarily men) who are smokers, whose lungs have been damaged by an old tuberculosis infection, bronchitis, or emphysema, or who have AIDS (14). There seems to be a clear difference in the disease pattern for the different types of mycobacterial infection in AIDS patients. Exposure to the usual human strain of TB seems to be related to an early onset of the disease in HIV + individuals, whereas the *M. avium* strain emerges only in the later stages of the disease (26). There has been speculation that there are different levels of immunity against the two organisms (i.e., an immunocompetent host, in general, can better control the growth of *M. avium* than *M. tuberculosis*) (25).

Some mycobacteria grow in swimming pools and even in aquariums. Aquarium workers and fishermen are at risk of being exposed to *M. marianum*, an organism that is associated with fish

(swimmer's granuloma). The site of this infection is primarily soft tissue, usually of the extremity.

Leprosy (Hansen's disease) is a chronic infectious disease caused by *M. leprae*, which has a unique tropism for two tissues—peripheral nerves and skin. The World Health Organization estimates that the global prevalence of leprosy is 10–12 million and the majority of cases occur in Asia and Africa. *M. leprae* is virtually indistinguishable in morphology and staining properties from *M. tuberculosis* and has many clinical features in common with TB. Because *M. leprae* has never been cultured successfully *in vitro*, it appears to be an obligate intracellular pathogen that requires the environment of the host macrophage for survival and propagation. This bacillus resists intracellular degradation by macrophages, perhaps by escaping from the phagosome into the cytoplasm, where it can accumulate to high levels (10^{10} bacilli/g of tissue) in lepromatous leprosy.

In voles, guinea pigs, rabbits, and calves, *M. microti* are associated with TB lesions. Other species such as *muris* and *piscium* are tubercle bacilli that cause a similar type of disease, but the primary hosts are fish, frogs, and turtles. *Mycobacterium cheloni* is frequently found in the soil and water, and in 1980 a microbiologist recognized this bacillus as a cause of lung disease, wound infections, and skin abscesses in humans (4, 22). In 1991, *M. haemophilum* surfaced as a pathogen when cases occurred in immunocompromised individuals in New York hospitals (4, 22).

4 Sources
In the United States, humans are the most common reservoir and source of human TB. Individuals with active pulmonary TB are potential sources of danger to all those with whom they come in contact. Numerous studies of TB epidemics in closed populations (e.g., on naval vessels, in nursing homes) have documented the highly contagious nature of this organism. Because the infection is acquired by inhalation in most cases, it is natural that the lung should be the most common target organ for the disease. (Chapter 19, this volume). These organisms are spread by droplet aerosols released when a person with active TB coughs, sneezes, talks, or even sings. An individual with a moderately advanced case of TB may expel from 2–4 billion bacteria in a single 24-h period. The small droplets (1–10 mm) may stay afloat in room air for several hours, increasing the risk of infection (27). Because of the high lipid content of their cell walls, mycobacteria can retain their pathogenic properties in dried sputum for months or even years. When inhaled, these organisms can reach the smallest terminal airway passages without being trapped and removed by the host's upper airway clearance mechanisms (Chapter 19, this volume). Prime settings for transmitting this disease are hospitals and other health-care facilities that place health-care workers in close proximity to patients with this disease. The recent outbreaks of multidrug-resistant organisms have refocused attention on the detection, transmission, and prevention of TB in these health-care settings. Airborne transmission of these organisms is a major concern in other institutions such as jails, homeless shelters, AIDS hospices, and drug treatment facilities.

Fomites do not play a major role as a source of these organisms. However, within a clinical laboratory environment or autopsy rooms, workers may come into contact with them.

A clinical difference between *M. tuberculosis* and the nontuberculosis (atypical) mycobacteria is the lack of transmission of the latter from patient to patient (24). Rather, these organisms exist saprophytically in the soil or water or in association with some infected-animal reservoir. In developing countries, where bovine TB has not been eliminated, cattle are the reservoirs for the bovine strains, and transmission to humans commonly occurs by ingestion of unpasteurized milk or dairy products. Sometimes these organisms may be transported through the air to infect farmers and

animal handlers.

Individuals who work with marine life or in an aquatic environment may be exposed to *M. marianum* infections. Those at risk include fishermen, marine biologists, pet store employees, and zoo personnel. The organism gains entry into the host through breaks in the skin or through bites by marine organisms, and *M. marianum* may cause nonhealing skin ulcers, arthritis, lymphadenitis, or tenosynovitis.

With *M. leprae*, the primary source of infection is the infected individual, and the route of transmission is through the air. A patient with untreated leprosy may discharge up to 8×10^8 bacilli in a single nose blow. Leprosy may also be transmitted via penetrating wounds and insect bites. However, shedding from the nose is more important in the transmission of this disease, than shedding from skin lesions (28). Even with this high number of organisms released into the air, leprosy is not very contagious and human-to-human transmissions usually requires prolonged contact. Natural infections that can be transmitted to humans have also been documented in certain animals such as monkeys and armadillos.

5 Health Issues
TB is a particularly good illustration of an infectious disease process that involves an ecological lifelong balance between a host and a microbe. TB in humans is predominately an airborne infection of the lungs that is almost always initiated by inhalation. Once the organisms have been inhaled and deposited in the lung, these organisms can be found in the lung's phagocytic cells (alveolar macrophages) that tend to protect them from antibodies and other host immune defenses. Individual susceptibility to TB and the severity of the disease are based on the virulence of the organism, the duration of exposure, concomitant exposure to other toxicants, medication for treatment of other diseases, and the nutritional status of the host. Once the organism has survived the transport through the environment and has infected a susceptible host, the TB infectious process can be divided into two stages that are commonly referred to as primary and secondary infections. During the primary phase, after an incubation period of 4–8 weeks, the infected individual is usually asymptomatic but may produce nonspecific symptoms such as fatigue, weakness, anorexia, and low-grade fever. However, in most cases the host may not even be aware that such a pathogen has invaded the body. Initially, the infecting organisms do not elicit a marked inflammatory reaction because they do not immediately produce any toxins or tissue-destructive enzymes. In most healthy people, the primary infection often subsides spontaneously as a result of the activities of the immune system, especially if the infecting dose is low. Even so, a scar remains on the lungs as evidence of a previous infection. At this stage, approximately 5–10% of the individuals infected with this organism show symptoms and develop active TB within the first year; the remaining infected individuals continue to be at risk with a latent infection. Initially, the macrophages that have become laden with numerous intracellular bacilli may be unable to destroy the invading cells. However, after a few weeks a cell-mediated immunity develops. Sensitized lymphocytes attract and activate these macrophages, which greatly enhances the phagocyte's bactericidal capability. As the initial lesion heals, tiny granulomas or tubercles are formed that can harbor the bacilli indefinitely. In the majority of cases, the infection is arrested, and the bacilli remain in a dormant state walled up in these primary lesions (tubercles).

The pathogenesis of this infection cannot be separated from the host's immune response. During the infectious stage, much of the tissue damage is caused by the host's own immune response, rather than by bacterial toxins. Activated macrophages may release various enzymes and cytokines that may ultimately cause damaging inflammation at the site of the infection. TB is a good example of

such a host-mediated pathogenesis where the tissue damage is actually caused by toxic factors released from the lymphocytes and macrophages that infiltrate the site of the infection. Often the host response is so intense that the tissue is substantially destroyed, allowing the invading bacteria to proliferate further (6). In most of these infections, the host's cell-mediated immunity generally continues to control the infection. However, within the “healed” lesions, there may still be viable organisms that remain dormant for years, even decades, without producing any further symptoms of the disease.

Most individuals recover from primary TB, but in a small percentage of cases, the primary infection may progress, and further lung destruction can occur. In general, about 10% of the people with latent infections develop active TB sometime in their lives. The risk of reactivating a primary infection is greatest during the first two years after the initial infection. An individual with HIV has a 10–15% risk per year of progression of the infection. This reactivation of the disease is referred to as secondary TB. During this reactivation process, symptoms may include a cough that produces mucopurulent sputum, occasional hemoptysis, and chest pain. During reactivation, the individual pulmonary lesions may merge and enlarge; the resulting necrotic tissue (interior of the tubercle) will become cheese-like (caseous). If the body's defenses arrest the disease at this time, this caseous lesion slowly heals, undergoes fibrosis, or becomes calcified with cavities containing the living bacilli. These cavities show up on X-rays and are referred to as Ghon complexes. Later, this lesion may become more liquid, a process called liquefaction, and will commence to discharge the isolated viable organisms. Within these liquidified cavities, the bacilli can replicate to very high numbers (as many as 10^9 bacilli in a single lesion). At this stage, the organisms are highly infective and can be expected to serve as a source for the continual spread of the disease.

The organism can exist in these lesions for long periods or can disseminate to almost any organ of the body, including the central nervous system, the genital tract, bone, kidney, or lymph nodes. When the organisms spread to other parts of the body, this condition is known as miliary tuberculosis. The name is derived from the numerous millet seed-like tubercles formed in the infected target tissue. The tubercle bacilli can spread to other organs in three ways: (1) the organism may continue to gradually destroy the infected tissue at the primary site of infection and then proceed to invade other tissues from this initial site; (2) the organism can spread from the initial site of infection along the lymphatic vessels to the lymph nodes that drain the infected area; or (3) the tuberculous lesion may perforate the walls of a blood vessel, releasing millions of bacilli into the blood stream.

Pulmonary disease due to *M. avian* complex (MAC) typically occurs in white males, 45–65 years old with some preexisting lung disease such as chronic bronchitis, emphysema, a previous TB lesions, bronchiectasis, or pneumoconiosis. Patients with AIDS may have either a focal or disseminated MAC infection. MAC is commonly isolated from sputum or stool cultures from patients with HIV infection. It is thought that MAC is acquired and colonizes in either the gastrointestinal or respiratory tract before dissemination in HIV-infected patients. MAC infectious may also involve the peripheral lymph nodes. Bacteremia occurs in almost all such patients, and the organism can be found in the circulating monocytes (29).

Leprosy is a chronic granulomatous disease. The principal manifestations of the disease includes anesthetic skin lesions and peripheral neuropathy with peripheral nerve thickening. The medical complications of leprosy arise from nerve damage, immune reactions, and infiltration of the organisms to other sites (28).

6 Who is at Risk?

A number of factors increases the risk of infection and can substantially increase the likelihood of reactivation. These include certain diseases such as diabetes mellitus, Hodgkin's disease, silicosis, AIDS, chronic renal failure, and other conditions, such as body weight 10% below the ideal, children under 5 years old, and treatment with corticosteroids or other immunosuppressive drugs.

Cases of TB are not evenly distributed throughout all segments of the U.S. population. Certain ethnic subpopulations have a higher risk of TB, either because they have a higher likelihood of exposure and infection or because they are more likely to progress to an active disease state (19). For example, African-Americans, Eskimos, Native Americans, Asians, and Hispanics account for about two-thirds of the new cases. This organism affects twice as many men as women and is four times more likely to infect non-Whites as Whites. The literature also indicates that certain other individuals may have a greater risk of developing TB, including those in correctional institutions, alcoholics, intravenous drug users, the homeless, and the elderly.

At particular high risk are those whose immune systems are suppressed, such as cancer patients receiving chemotherapy, organ transplant recipients, and individuals with AIDS. Generally at risk are people living in crowded, poorly ventilated, and unsanitary conditions. The risk of infection with TB is proportional to the duration of exposure to an infected individual and the concentration of the airborne infectious droplets. Individuals infected with tuberculosis have a 100-fold greater risk of developing active TB if they are also HIV+. *Mycobacterium* infections that occur in HIV infected people may represent either a reactivation of a latent infection or a new infection. Progression from tuberculous infection to clinical disease occurs in only about 5% of non-HIV infected individuals, but this increases to about 30% in HIV infected persons. Today, a major risk factor is the increasing incidence of the disease and also the increased prevalence of cases that display multiple drug resistance. Such cases are difficult to treat and further the possibilities for widespread transmission of the disease. Delays in diagnosing and treating TB contribute to increased morbidity and mortality and the nosocomial spread of TB.

Transmission of this disease in the workplace is not well understood, and a cause–effect analysis is often not possible. The infectious dose required to cause an infection may be influenced significantly by environmental contaminants in the workplace. At high risk are individuals with certain occupations where the atmosphere may be contaminated with substances that may adversely effect the functioning of the host's normal defense mechanisms. This includes occupational environments encountered by miners, tunnel diggers, quarry workers, steel and iron foundries workers, ceramic workers, stone cutters, workers manufacturing abrasive soaps, glassmakers, and those involved in sandblasting operations. For example, the association between silicosis (silicotuberculosis) and pulmonary tuberculosis is well-accepted. Silicosis, one of the oldest known occupational lung diseases, develops in people who inhale silica dust for many years. People with silicosis are three times more likely to develop TB than people without silicosis. Mycobacterial infection must always be suspected when a silicotic patient experiences worsening respiratory symptoms and chest radiographs. In some incidences, (foundry workers) an increased incidence of pulmonary tuberculosis may occur, even in individuals who did not show radiographic evidence of silicosis but had been employed in the industry for more than 25 years.

Tuberculosis remains a significant hazard to hospital personnel despite the widespread use of certain screening tests for the early identification of cases and knowledge of the way the disease is spread. Medical students and physicians have two to three times the prevalence of infection with tuberculosis as nonmedical, age-matched controls (16). The AIDS epidemic has increased the likelihood that health-care workers will come in contact with an individual with active pulmonary tuberculosis. This is often unrecognized by medical personnel at the time of admission, when transmission is most likely to occur.

Direct contact with infectious material is possible at all stages in a diagnostic laboratory, and these infectious organisms are known to be transmitted during autopsies (30, 31). Certain medical

procedures routinely performed on patients may carry additional risk of TB transmission due to the generation of large amounts of infectious respiratory droplets. Procedures needed for sputum induction, such as aerosolized pentamidine treatment that induces coughing in the patients, bronchoscopy, and endotracheal intubation and suctioning, should be carried out in well-ventilated, negative-pressures rooms, and health-care workers should wear particulate respirators while in these areas.

The fetus may also be at risk of acquiring TB from its mother before or during birth by breathing or swallowing infected amniotic fluid.

6.1 Sampling Analysis and Detection

A key to the diagnosis of TB is a high index of suspicion of the disease and the prompt use of appropriate sampling and diagnostic procedures for identifying the causative agent. Sampling, isolation, staining procedures, cultural media, and procedures for identifying the *Mycobacterium* (e.g., growth characteristics, biochemical tests) have been outlined and recently reviewed (2, 3). The initial step in laboratory diagnosis is a microscopic examination of smears taken from collected sputum or other specimens. Although different types of specimens may be submitted for mycobacterial examination, the vast majority submitted will be specimens from the respiratory tract. They may include sputum (both expectorated and induced), bronchoalveolar lavage fluid, or bronchial washings from patients unable to produce sputum. Other samples commonly tested include blood, urine, and gastric aspirates. Blood and stool specimens may be submitted from patients with AIDS. Miliary TB usually requires transbronchial liver or marrow biopsy samples for diagnosis. Samples should be stained for the acid-fast bacilli. However, a positive confirmation of TB requires isolating the suspected organism in culture, which may take from 3–6 weeks.

Because the bacteria grow more rapidly in broth culture, many clinical laboratories grow the specimens in a medium containing radiolabeled palmitic acid as a substrate; the release of CO_2 indicates the presence of mycobacteria. However, this procedure may still take from 7–14 days. Although many different media are available for culturing the organism, the most commonly used medium in the United States is Middlebrook–Cohn 7H11. This has the advantage of transparency, and permits earlier recognition of the colonies. But it has the disadvantage of requiring 5% CO_2 in the incubator. The availability of biphasic isolation media, the refinement of high-performance liquid chromatography for identifying mycobacteria, the widespread use of nonisotopic probes for culture identification, and the application of nucleic acid amplification techniques for direct detection of *M. tuberculosis* in clinical specimens are important new developments in sampling and detecting these organisms. In addition, progress in understanding the molecular genetics of drug resistance in mycobacteria has been substantial, and sensitive growth indicator systems for more rapid susceptibility testing are being developed (3).

6.2 Prevention and Treatment

Growing support for the germ theory of disease in the late 1800s and the early 1900s led to a dramatic reduction in the frequency of infectious disease epidemics. It was reasoned that if microorganisms cause disease, then it is possible to control disease by controlling the microorganism. Today it is generally agreed that there is little possibility of stopping the transmission of TB. Thus it seems clear that the complete eradication of TB is not immediately possible. Therefore, controlling the transmission of these organisms is essential.

The occupational risk of TB continues to be a subject of considerable debate in the United States (32). The Occupational Safety and Health Administration (OSHA) has issued an enforcement policy dealing with occupational exposure to TB (33). This OSHA document specifies administrative actions, engineering controls, and personal protective equipment for workers in health-care facilities, correctional institutes, homeless shelters, long-term health-care centers, and drug treatment facilities. Early identification of potentially infected patients and worker training are aspects that are emphasized (31, 32).

Although the Centers for Disease Control and Prevention (CDC) officially have no regulatory

responsibilities, they have provided guidelines and recommendations for health-care workers to prevent and control nosocomial infectious. These guidelines include providing consultation on methods for disease diagnosis, antimicrobial susceptibility testing, defining risk factors for transmission, conducting surveillance of health-care workers, exposure incidence, and the development of strategies for prophylaxis (19, 33, 34). Institutional outbreaks of TB have been associated with the failure to isolate infectious patients, delays in initiating therapy, inadequate treatment, and placing of TB patients in rooms with ventilation that directs contaminated airflow into other rooms or hallways.

The most effective intervention to halt the transmission of TB is early identification of infectious cases and antituberculosis therapy. Three hierarchical elements compose the core of these recommendations (34). The first recommendation is isolation of potentially infectious cases. Early detection of TB is difficult because the disease has a slow chronic course and individuals may be infective for months before seeking treatment. The undiagnosed case of TB has long been considered the greatest potential disseminator of disease. Placing patients into respiratory isolation has been effective in reducing the rate of employee infections. Respiratory isolation of patients in appropriate ventilated rooms is necessary for inpatient facilities. Patients should be instructed to cover their mouths and noses when coughing or sneezing, which will reduce respiratory droplet generation.

The second recommendation is the use of appropriate environmental controls. The three types commonly used are discussed here; they include the use of (1) appropriate ventilation, especially in isolation rooms; (2) high-efficiency filtration; and (3) germicidal irradiation.

Droplet nuclei generated by coughing of an individual with pulmonary TB may remain suspended in room air for long periods of time. The concentration of droplets may be reduced or eliminated by appropriate ventilation. Air contaminants can be removed from the room by either direct exhaust to the outside or by recirculating the air through the general ventilation system. Care must be taken when the air is recirculated into other rooms; otherwise additional individuals may be exposed to the organism. Vents that exhaust to the outside should be located away from intake vents and pedestrian traffic. Currently, ventilation rates of six air exchanges or greater per hour are recommended in TB isolation rooms in existing facilities and ≥than 12 air changes per hour are recommended in new or renovated facilities. Isolation rooms need to be maintained under negative air pressure, which requires that the rate of air exhaust exceed the rate of air intake.

The use of high-efficiency particle air filters (HEPA) in ventilation systems can be effective in removing particles ≥0.3 mm in diameter with 99.7% efficiency. The use of HEPA filtration may be useful in the recirculation of air in waiting rooms or emergency rooms where an increased risk of TB exists.

Ultraviolet (UV) germicidal irradiation is an effective means of air disinfection for droplet infections such as TB. UV lamps have been recommended as a supplement to a well-designed ventilation system in high-risk settings. Such lamps are usually installed on ceilings; however, adequate air mixing within the room is important to ensure its effectiveness. They may also be installed in ventilation ducts.

The third recommendation is the use of personal respiratory protective equipment. Standard surgical masks do not provide adequate protection against infectious droplet nuclei produced by persons with pulmonary TB. However, the use of protective devices, such as high efficiency particulate respirators that filter particles ≥1 mm in size with ≥95% efficiency, has been recommended for individuals, who working in rooms in which patients with known or suspected TB are isolated, during cough-inducing procedures, and in other settings where the risk for TB exposure is greatest (34). There is much controversy surrounding the recommendations for the use of mask and respirators. It has been argued that a safer working environment awaits new means of diagnosis, not a better respirator.

In 1986, the EPA published guidelines for infectious waste management. The Agency suggested that

all generators of such infectious waste develop proper management for its disposal. Most states have developed specific regulations for handling infectious waste, but these vary considerably in scope and complexity (35). In general, these guidelines direct each institute to have a written plan for properly managing infectious waste, including properly training all personnel who are involved in generating, collecting, transporting, and/or storing infectious waste.

A good discussion of prophylactics and treatment methods available can be found in Merck (24). In the nineteenth century, some of the treatments for the disease included drinking elephant's blood, spending time by the sea, or touching the hand of a reigning monarch. During the late 1880s, the medical community came to believe that fresh air and relaxation were beneficial. Consequently, the use of sanitariums, where patients were assured of clean fresh air, rest, and care, became the preferred treatment. In 1944, with the discovery of the drug streptomycin by Dr. Selman Waksman, the medical community began to actually control the disease.

Because the risk of *M. tuberculosis* carriers developing an active disease depends on the individual's standard of living, working environment, and general health, individuals who have TB must take special care not to spread the disease. Sputum should be safely disposed of. In the future, the ability of infected individuals to survive such an infection will depend on the availability of adequate medical care and whether drug research can outpace the evolution of new drug-resistant strains of this bacillus. The risk of infections can be reduced by improving social conditions, such as overcrowding, education of the public in the mode of spread, and appropriate methods for control.

Presently a combination of antibiotics is used to treat TB. The most common combination is isoniazid, rifampin, and pyrazinamide. If drug resistance occurs, these medications can be supplemented with other antimycobacterial agents (e.g., ethanbutol and streptomycin) (3, 15, 36, 37). For individuals with strains that are sensitive to the usual antituberculosis drugs, correct treatment yields an excellent prognosis. However, in people with strains that resist two or more of the major drugs, the death rate may approach 80%. Prolonged treatment is necessary because the bacillus grows slowly, and these antibiotics are effective only against growing cells.

Diagnostic tests include chest X rays, tuberculin skin tests, sputum smears, and cultures to identify the organism. Chest X rays may show nodules, patchy infiltrates, cavity formation, scar tissue, and calcium deposits. However, it may not be possible to distinguish active from inactive TB. As stated earlier, the diagnosis of TB disease requires isolating the organism from sputum or other suspected materials.

TB is easy to detect by a skin test with tuberculin, which is a purified protein derivative (PPD) of the tubercle bacilli. Infected persons develop a cellular immune reaction against *M. tuberculosis*, demonstrated by a positive tuberculin skin test within 2 to 8 weeks after the initial exposure. Conversion of the tuberculin skin test from negative to positive reveals only whether a person has had previous exposure to the organism, either from immunization or from coming in contact with the TB organism. It has been estimated that 5% of the U.S. population is tuberculin positive; however, the rate varies considerably according to age, ethnic group, and location. Hospital personnel should be skin tested for tuberculosis when they are first employed and after known exposures. In some cases, skin testing should be repeated annually. For health-care workers who “convert,” their skin test should be evaluated by physical examination and a chest X ray to rule out the possibility of a progressive primary infection. If active pulmonary infection is identified, combination therapy with isoniazid and other antituberculous drugs can be effective in controlling active infection and decreasing the likelihood of additional respiratory transmission. Smoking must be stopped and nutrition improved.

A second method of prevention is to initiate a vaccination program to protect uninfected populations. The vaccine available is called BCG (bacillus of Calmette and Guerin). Worldwide, the BCG vaccine is one of the most common vaccines used today (3). It is a live strain of the tuberculin bacilli which has been rendered avirulent. It has been recommended that all individuals at high risk,

including health personnel, be vaccinated.

Elimination of bovine tuberculosis among cattle can be accomplished by identifying the animals at risk by routine tuberculin testing. The proper pasteurization of milk and milk products can be effective in preventing the spread of this disease to humans.

Controlling dust and other airborne contaminants is essential in industrial plants and mines. When such airborne substances cannot be controlled, such as in the sandblasting industry, workers should wear hoods or masks that filter out the particles.

Petroleum, Coal Tar, and Related Products
Richard W. Niemeier, Ph.D.

Introduction
In 1619, Dudley discovered that when certain (bituminous) coals wre heated in the absence of oxygen, referred to as “charking,” “coak” was produced, which could be substituted for wood charcoal. By 1800, commercial products included coke-oven gases (“illuminating gas”), a low-boiling distillate known as coal naphthas (light oil of tar, also known as light liquid naphtha or benzine), and a “buttery-solid” condensation product containing carbon, “naphthaline,” paranaphthaline or anthracene, paraffin, chrysene, pyrene, phenanthrene, fluorene, and biphenyl, called coal tar. Further fractional distillation of coal tar yields coal tar creosote “oil” (containing phenols, cresols, and xylenols, in contrast to pharmaceutical creosote, which contains guiacol, cresol, phenol, and xylenol from beechwood tar), coal tar pitch, and naphthalene (1). Because coal tar, coal tar pitch, and coal tar pitch volatiles (CTPV) may occur together, they are combined in this review.

The chemical composition of coal tar, coal tar pitch, and related materials is complex and variable. The estimated number of compounds present in these complex mixtures is in the thousands. Because of variation in source materials and manufacturing processes, including different temperatures and times of carbonization, no two coal tars or pitches are chemically identical, and their toxicity may differ with their origin (2). In general, however, approximately 80% of the total carbon present in coal tars exists in aromatic form (3).

Benzo[a]pyrene (B[a]P) is probably the most potent, widespread occupational carcinogen in coal tar, coal tar pitch and its volatiles, coke oven emissions, and creosote, all of which have corresponding work exposure standards (4); however, there is no occupational workplace standard for B(a)P. It may account for more than 75% of the carcinogenic activity of coal tar pitch fume condensate (5). Individuals who work in tarring facilities, roofing operations, power plants, and asphalt and coke manufacturing facilities may be exposed to benzo[a]pyrene and related PAHs. These mixtures may differ qualitatively and quantitatively.

Coal tar is completely or nearly completely soluble in benzene and nitrobenzene and it is partially soluble in acetone, carbon disulfide, chloroform, diethyl ether, ethanol, methanol, petroleum ether, hexane, and sodium hydroxide solution, and slightly soluble in water. It has a characteristic naphthalene-like odor. Coal tar is heavier than water and on ignition it burns with a reddish, luminous, and very sooty flame. Coal tar fumes are highly flammable and are easily ignited by heat, sparks, or flames. Vapors are heavier than air. They may travel to a source of ignition and flash back and may form explosive mixtures with air. Vapors will spread along ground and collect in low or confined areas (sewers, basements, tanks). Vapor explosion is a potential hazard indoors, outdoors, or in sewers. Some may polymerize explosively when heated or involved in a fire. Runoff to a sewer may create a fire or explosion hazard. Containers may explode when heated. Coal tar may be transported hot (3).

The greatest complexity occurs when toxicity is based on the effects of a class of compounds or of a material of a certain physical description. Some polynuclear aromatic hydrocarbons (PNA) and polycyclic aromatic hydrocarbons (PAHs) are carcinogens of varying potency, and they usually exist in mixtures with other PNAs/PAHs and with compounds (activators, promoters, inhibitors) that modify their activity. Analysis of each individual compound is very difficult and when done does not yield a clear answer. Given the complexity of the mixture of biologically active agents and their interactions, a calculated equivalent dose would have little accuracy. In these instances, it is common to measure some quantity related to the active agents and to base the occupational exposure limit on that index. An occupational exposure limit for PNAs has been based on the total weight of benzene- or hexane-soluble airborne material (6). This limit may be appropriate for coal tar pitch volatiles for which it was developed, but it may not work for other PNA/PAH containing materials. Crude oil, asphalt fumes, and cracked petroleum stocks may contain PNA/PAH. The coal dust particles mixed in with coal tar pitch volatiles are not soluble in benzene, but almost all of the petroleum-derived

materials admixed with PNAs/PAHs are soluble in benzene. For example, a heavy aromatic naphtha may or may not contain PNAs/PAHs depending on the manufacturing process but is completely soluble in benzene. Thus a measurement of the benzene-soluble fraction of a heavy aromatic naphtha aerosol will reveal nothing about the PNA/PAH content. Alternate indices include the single carcinogen B(a)P, the sum of a subset of six carcinogenic PNAs (benz[a]anthracene, benzo[b] fluoranthene, benzo[j]fluoranthene, benzo[k]fluoranthen, benzo[a]pyrene, and benzo[e]pyrene) or 14 or more individual PNAs (7, 8). The NIOSH Manual of Analytical Methods (6) contains numerous methods for coal tar pitch volatiles (#5042), coal tar naphtha (#1550), benzene, cresols, PNAs, and PAHs (6).

Some of the highest measured levels of coal tar pitch volatiles (CTPV) have occurred in the aluminum reduction industry, especially in the Soderberg process potrooms where concentrations as high as 63 mg/m^3 have been reported (9). That same review mentioned that the highest level reported in a roofing operation using coal tar pitch was 2.38 mg/m^3. The NIOSH (10) review of coke oven plant workers exposed to CTPV stated that one category of worker, the lidman, had the highest exposure, a range up to 18 mg/m^3, and an average exposure of 3.2 mg/m^3. The NIOSH Immediately Dangerous to Life and Health (IDLH) value has been revised for CTPV from 700 mg/m^3 to 80 mg/m^3 based on toxicity data in animals (11–14).

The problem of differentiating the several classes of compounds in a mixed atmosphere such as coal tar pitch volatiles adds complexity to sampling method selection, and it is sometimes necessary to make, and clearly state alongside the results, certain simplifying assumptions. It is commonly assumed when measuring the more toxic soluble form of an element, that the "safe" assumption may be made that all the element present was soluble (8).

In a study of bioremediation effectiveness, the ability of indigenous soil microorganisms to remove these contaminants from aqueous solutions was determined by GC analysis of organic extracts of biotreated groundwater. Changes in potential environmental and human health hazards associated with the biodegradation of this material were determined at intervals by "Microtox" assays and fish toxicity and teratogenicity tests. After 14 days of incubation at 30°C, indigenous microorganisms effectively removed 100, 99, 94, 88, and 87% of measured phenolic and lower molecular weight polycyclic aromatic hydrocarbons and S-heterocyclic, N-heterocyclic, and O-heterocyclic constituents of creosote, respectively. However, only 53% of the higher molecular weight polycyclic aromatic hydrocarbons were degraded. Despite the removal of a majority of the organic contaminants through biotreatment, only a slight decrease in the toxicity and teratogenicity, of biotreated goundwater was observed (3).

Table 22.1. Typical Fractions from Continuous Tar Distillation[a]

Fraction number	Synonyms	Boiling Range (°C)	% Crude Tar (by Weight)
1	Crude benzene, Light oil	106–107	2.4
2	Naphtha, Carbolic oil, Phenolic oil	167–194	3.1
3	Heavy naphtha, Carbolic oil, Naphthalene oil	203–240	9.3
4	Naphthalene oil	215–254	3.5
5	Wash oil, Benzene absorbing oil, Light creosote	238–291	10.2
6	Creosote	271–362	11.5

7	Heavy creosote, Heavy oil	285–395	12.1
Residue	Medium-soft pitch	—	40.5
Liquor and losses	—	—	7.4

Table 22.2. Occupations with Potential Exposure to Coal Tar Products[a]

Artificial stone makers	Impregnated felt makers
Asbestos goods workers	Insecticide-bomb makers
Asphalt workers	Insulation-board makers
Battery box makers	Insulators
Battery workers, dry	Lens grinders
Boatbuilders	Linemen
Brickmasons	Miners
Brick pressers	Painters
Brickyard workers	Paper conduit makers
Briquette makers	Pavers
Brushmakers	Pipeline workers
Cable makers	Pipe pressers
Carpenters	Pitch workers
Coal tar still cleaners	Railroad track workers
Coal tar workers	Riveters
Coke-oven workers	Road workers
Corkstone makers	Roofers
Creosoters	Roofing-paper workers
Diesel engine engineers	Ropemakers
Electric equipment makers	Rubber workers
Electricians	Shingle makers
Electrode makers	Shipyard workers
Electrometallurgic workers	Soapmakers
Farmers	Smokeless fuel makers
Fishermen	Stokers
Flue cleaners	Tar paintmakers
Fuel pitch workers	Tile pressers
Furnace men	Waterproof-concrete workers
Gashouse workers	Waterproofers
Glassblowers	Wood preservers

Table 22.3. Types of Industrial Processes Using Coal Tar Products[a]

Type of Coal Tar Product	Industry	Industrial Process	Products
COAL TAR PITCH	Aluminum	Aluminum production	Aerospace equipment parts
			Siding, windows, doors
			Packaging
			Foil, wires, cans
			Hardware
	Steel	Electric steel	Automobiles
			Appliances
			Hardware
			Furniture
		Oxygen furnace steel	Construction material
			Transportation
	Foundry	Large casting production	Machine tools for consumer products
	Carbon-graphite	Carbon and graphite products	Batteries for portable equipment
			Pencils
			Streetlighting arcs
			Movie projector arcs
			Clay targets
	Electrical	Electrical conduit production	Motors and parts for household appliances, TV sets, pumps, power tools, construction
CREOSOTE	Construction	Treatment of construction and marine pilings	Construction of buildings, factories, pipelines, roads, etc.
		Tar-based pipeline coatings	
		Tar road, roofing, and waterproofing material	
Railway	Treatment of railway ties	Rails, roadways	
Utility	Treatment of utility poles	Poles for power and telephone utilities

Table 22.4. Petroleum Distillates and Their Uses[a]

Fraction	Carbon Atoms	Boiling Range (°C)	Class of Compounds	Synonyms[b]	Use
Crude oil	C_1–>C_{50}	<0–>1000	More than 300 organic substances, some heavy metals	Earth oil, petroleum	Petrochemicals and petroleum distillates
Natural gas	C_1–C_2	–164 to –88	Methane (83–99%), ethane (1–13%), propane (0.1–3%), and butane (0.4–1%)		Fuel, chemical
Liquefied gas	C_3–C_4	–44.4 to +1.0	Propane and butane with mercaptans added for odorant warning properties	Bottled gas, LPG (liquefied petroleum gas)	Fuel gas, stock for petrochemicals
Petroleum ether	C_5–C_6	30–60	Paraffins (pentanes, hexanes, isohexanes); principally 80% *n*-pentane and 20% isohexane	Petroleum benzine, ligroine, Skellysolve	Dry cleaning, thinner, solvents
Naphthas	C_5–C_{11}	95–160	55.4% paraffins, 30.3% mono- and 2.4% dicycloparaffins, 0.1% benzene, 11.7% alkylbenzenes, 0.1% indans and tetralins.	VM&P naphtha, varnish makers and painters naphtha, light naphtha, dry-cleaner naphtha, and spotting napththa	Cleaning fluids, solvents, thinner, polish, refining stock
	C_7–C_{12}	150–204	Paraffins, naphthenes, aromatics	High flash naphtha	
	C_5–C_{12}	185–207	60.8% paraffins, 24.5% mono- and 11.2% dicycloparaffins, 0.07% benzene, 3% alkylbenzene, 0.3% indans and tetralins	140° flash naphtha, aliphatic solvent naphtha	

	C_8–C_{13}	93–315	Paraffins, alkylbenzenes	Aromatic petroleum naphtha, Coal tar naphtha	
				High aromatic naphtha, high	
	C_8–C_{13}	184–206	Paraffins, mono-, di- and tricyclic naphthenes, alkylbenzenes, naphthalenes, and olefins	Aromatic solvent	
Rubber solvent	C_5–C_7	45–125	41.4% paraffins, 53.6% monocycloparaffins, 0.1% olefins, 1.5% benzene, 3.4% alkylbenzenes	—	Rubber solvent
Gasoline	C_4–C_{12}	32–210	Isoparaffins, olefins- and aromatics	Petrol, benzin, petroleum spirits, motor or aviation gasoline	Aviation fuel automobile fuel, thinner
Mineral spirits	C_6	150–200	80–86% paraffins, 1% olefins, 13–19% aromatics and naphthenes	White spirits, petroleum spirits, refined petroleum solvent	Solvent, degreasing, dry cleaning
Stoddard solvent	C_7–C_{12}	160–210	47.7% paraffins, 26% mono- and 11.6% dicycloparaffins, 0.1% benzene, 14.1% alkylbenzenes, 0.5% indans and tetralins	White spirits	Solvent
Kerosene	C_5–C_{16}	175–325	Alkylbenzenes, 25% normal paraffins, 11% branched paraffins, 30% mono- and 12% dicycloparaffins, 1% tricycloparaffins,	Gas turbine fuel, jet fuels (JP1–6)	Jet and turbofuel

			16% mononuclear aromatics, and 5% dinuclear aromatics		
			Aliphatic, olefins, mono- and dicycloparaffins, alkylbenzenes	Tractor fuel, coal oil, stove oil	
Diesel fuel	C_5–C_{16}	177–400			Fuels, solvent, lighter fluid
Deodorized kerosene	C_6–C_{14}	209–274	55% paraffins, 41% naphthenes, 4% aromatics		Solvent
Fuel oil	C_9–C_{16}	184–334		Gas oil, heating oil, furnace oil	Fuel
Lubricating oil	C_7–C_{20}	204–400		Oil, white oil, mineral oil	Lubricating oils and greases, laxative, ointment
		260–370	Predominantly paraffinic, but may contains some naphthenic and alkyl aromatic hydrocarbons	Mineral seal oil	
	C_{17}–higher	366–588		Grease, petroleum jelly, petrolatum	
Paraffin wax	C_{20}–higher	204–400	*n*-Alkanes with varying proportions of iso- and cycloalkanes	Paraffin, waxes, petroleum waxes	Sealant, polish, food component, sealing wax
Asphalt	C_{20}–higher	400–higher		Road oil, tar, bitumen, bottoms	Sealant, construction

Petroleum, Coal Tar, and Related Products
Richard W. Niemeier, Ph.D.

Petroleum Distillates

Petroleum distillates is a very complex topic which has been described by many authors (21, 110–112, 134). Much variation is found in the literature in describing the various fractions tested and/or described, and these descriptions have been made by classes of usage (i.e., diesel oil, jet fuel, thinners), distillation fraction cuts usually classified by boiling ranges, refining categories, such as hydrotreated, catalytic cracking, or clay treated, or viscosity ranges in the case of refined oils. For example, NIOSH (110) considered only the refined petroleum solvents that have a total aromatic content of less than 20%. Other hydrocarbon solvents such as thinners, whose total aromatic content may exceed 20%, were not discussed in this document. In another criteria document, NIOSH (143) described only alkanes. Tomes (15), HSDB (3), REPROTOX (19), TERIS (87), and the Canadian Domestic Substances List (144) list petroleum distillates by distillation treatment and refining categories. Many synonyms have been listed for each component. However, there may be overlap in names from one CAS Number to another. This is especially evident for the naphthas and fuel oils. In RTECS (18), data from both refining categories and primary chemical names, including the Chemical Abstracts Number (CAS) and other related information such as commercial uses (145, 146) can be found. This review will not attempt to weave all of these categories into one unified presentation but will convey what is available in the literature.

Table 22.6 illustrates the complexity of products that are available through distillation, cracking, and secondary refining proceses (134) leading only to the high boiling petroleum products.

Table 22.6. High Boiling Petroleum Products

- **Products of distillation and cracking processes**
  - Light and uncracked distillates
    - *Heavy aromatic naphthas*
    - *Spraying oils*
    - *Diesel fuels*

Cutting oils (metalworking fluids)	[*64771-79-5*]		0.4 mg/m^3 (thoracic particulate mass) ≅0.5 mg/m^3 (total particulate mass)		
Petrolatum	[8009-03-8; 8020-83-5]	None	None		
Residual oils	see text	None	None		
Asphalt	[*8052-42-4*]	None	1 mg/m^3 total particulates and 0.3 mg/m^3 benzene solubles	None	None

[a] Occupational exposure limits, sampling, and analytical methods were based on the CAS Number because of discrepancies and confusion in using synonyms.

Lubricating Stock Distillates

Petroleum, Coal Tar, and Related Products
Richard W. Niemeier, Ph.D.

Other Descriptions of Distillate Fractions

Table 22.10 lists characteristics of higher molecular weight petroleum distillate products processed by various methods. Some toxicity information is provided where available. It is assumed that many of these fractions would be similar to other higher viscosity cuts. Severe solvent or hydrogen treatment has been found to remove many impurities found to be more carcinogenic in the less refined fractions.

Table 22.10. Fractionation of Various High Molecular Weight Petroleum Distillates[a]

Petroleum Fraction	CAS Number	Carbon Content	Boiling range °C (°F)	Viscosity	Method of Production	Principal Components
Catalytic, reformer fractionator residue, low-boiling	[*68477-31-6*]		<288° C (550° F)		Distillation of catalytic reformer fractionator residue	Complex combination of hydrocarbons
Clay-treated heavy naphthenic	[*64742-44-5*]	C_{20}–C_{50}	NA	>100 SUS at 100°F	Treatment with natural or modified clay through contact or percolation to remove the trace amounts of polar compounds and	Complex combination of hydrocarbons containing few normal paraffins

					impurities	
Clay-treated light naphthenic	[*64742-45-6*]	C_{15}–C_{30}	NA	<100 SUS at 100°F	Same as for clay-treated heavy naphthenic	Complex combination of hydrocarbons containing few normal parafins
Clay-treated heavy paraffinic	[*64742-36-5*]				Same as for clay-treated heavy naphthenic	Lower content of aromatic compounds.
Hydrodesulfurized middle	[*64742-80-9*]	C_{11}–C_{25}	205 to 400°C (401 to 752°F)		H_2 to convert organic S to H_2S for removal	
Hydrotreated heavy naphthenic	[*64742-52-5*]	C_{20}–C_{50}	NA	>100 SUS at 100°F	H_2 in presence of catalyst	Few normal paraffins
Hydrotreated heavy paraffinic	[*64742-54-7*]	C_{20}–C_{50}	NA	>100 SUS at 100°F	H_2 in presence ofcatalyst	Large portion of saturatedhydrocarbons
Hydrotreated light	[*64742-47-8*]	C_9–C_{16}	150 to 290°C (302 to 554°F)		H_2 in presence of catalyst	
Hydrotreated light naphthenic	[*64742-53-6*]					
Hydrotreated light paraffinic	[*64742-55-8*]	C_{15}–C_{30}	NA	<100 SUS at 100°F	H_2 in presence of catalyst	Large portion of saturated hydrocarbons
Hydrotreated middle	[*64742-46-7*]	C_{11}–C_{25}	205–400°C (401–752°F)		H_2 in presence of catalyst	
Hydrotreated (mild) heavy naphthenic	[*64742-52-5*]	C_{20}–C_{50}	NA	>100 SUS at 100°F	H_2 in presence of catalyst	Contains relatively few normal paraffins
Hydrotreated (severe) heavy naphthenic	[*64742-52-5*]				H_2 in presence of catalyst	
Light catalytic cracked	[*64741-59-9*]	C_9–C_{25}	150–400°C (302–752°F)		Catalytic cracking	Large portion of bicyclic aromatic hydrocarbons

[a] Adapted fom TOMES (15) and Canadian Environmental Protection Act (144).

33.0 Petroleum Distillates, Catalytic, Reformer Fractionator Residue, Low-Boiling

33.0.1 CAS Number: See Table 22.10.

33.0.2 Synonyms: Petroleum distillates; distillates, petroleum; catalytic reformed naphtha; catalytic reformer fractionator residue, low-boiling; low-boiling catalytic reformer fractionator residue; naphtha, catalytic reformed; reformate

33.1 General

Commonly used as pesticide diluents. In subchronic inhalation studies with petroleum distillates in the form of full-range catalytically reformed naphtha (reformate), rats were exposed to the partially vaporized material at concentrations up to 8050 mg/m^3 for 13 weeks. The highest exposure group had reduced body weights and liver and kidney weights (284).

Chronic exposure to some low-boiling petroleum fractions has been associated with permanent central and/or peripheral nerve damage. No studies were found on the possible genetic or carcinogenic activity of these petroleum distillate fractions in humans or experimental animals. Petroleum distillates in the form of full-range catalytically reformed naphtha (reformate) were not teratogenic or fetotoxic in rats exposed at airborne levels up to 7,800 mg/m^3 of vapors on days 6 through 19 of gestation (284).

34.0 Petroleum Distillates, Clay-treated Heavy Naphthenic

RTECS (18) reported equivocal tumorigenic effects on the skin of mice of 410 gm/kg/78 weeks or 406 gm/kg/22 weeks at the site of application.

35.0 Petroleum Distillates, Clay-Treated Light Naphthenic

RTECS (18) reported that this material is an equivocal tumorigenic agent in mice at 577 gm/kg/78 week, and tumors were found at the site of application.

36.0 Petroleum Distillates, Heavy Paraffinic, Clay-Treated

This product may be a mild skin and eye irritant. Inhalation of large amounts of vapor may produce symptoms of CNS depression, including nausea, headache, weakness, dizziness, loss of coordination, and coma. It is unlikely that high enough concentrations of the vapors would be present to cause death unless bulk quantities of this product are handled under conditions of poor ventilation.

36.4 Toxic Effects

Repeated skin contact with this product may produce dermatitis or oil acne. Inhalation of large amounts of the mist may result in accumulations of mineral oil in the lungs, accompanied by pulmonary fibrosis. It is possible that this product may contain substances which have caused cancer in laboratory animals. It may be noted that used lubricating oils tend to contain higher amounts of cancer-causing substances than new oils. Mineral oils that have high levels of aromatic compounds have been linked with scrotal and lung cancer in humans. Newer mineral oils generally do not contain high levels of these aromatic compounds.

37.0 Petroleum Distillates, Hydrodesulfurized Middle

No information was available on the toxicity of this fraction.

38.0 Petroleum Distillates, Hydrotreated Heavy Naphthenic

No information was available on the toxicity of this fraction.

39.0 Petroleum Distillates, Hydrotreated Heavy Paraffinic

RTECS reported (18) an oral LD_{50} in rat of >15 gm/kg and a dermal LD_{50} in rabbit of >5 gm/kg. This product, listed by EPA, is used frequently as a spray oil in pesticide preparations (146).

40.0 Petroleum Distillates, Hydrotreated Light

No information was available on the toxicity of this fraction.

41.0 Petroleum Distillates, Hydrotreated Light Naphthenic

No information was available on the toxicity of this fraction. This product, listed by EPA, is used frequently as a spray oil in pesticide preparations (146).

42.0 Petroleum Distillates, Hydrotreated Light Paraffinic

No information was available on the toxicity of this fraction.

43.0 Petroleum Distillates, Hydrotreated Middle

No information was available on the toxicity of this fraction.

44.0 Petroleum Distillates, Hydrotreated (Mild) Heavy Naphthenic

44.0.1 CAS Number: See Table 22.10

44.0.2 Synonyms: Distillates (petroleum), hydrotreated (mild) heavy naphthenic; hydrotreated (mild) heavy naphthenic distillate; hydrotreated (mild) heavy naphthenic distillates (petroleum); petroleum distillates, hydrotreated (mild) heavy naphthenic
44.4 Toxic Effects
RTECS (18) listed a rat LD_{50} by the oral route at >15 gm/kg, and dermal application in rabbits resulted in a LD_{50} >5 gm/kg. Skin irritation in rabbits was severe at 500 mg. An IARC review of animal data led to the conclusion that there was sufficient evidence for carcinogenicity (Group I). RTECS listed a mouse skin-painting study with an dose intermittent of 398 gm/kg/22 weeks which resulted in classifying it as an equivocal tumorigenic agent by RTECS criteria, and skin and appendage tumors were at the site of application. Another study cited by RTECS in a mouse skin-painting study with an dose intermittent of 402 gm/kg/78 weeks led to the conclusion that it is an equivocal tumorigenic agent by RTECS criteria, and skin and appendage tumors were at the site of application. An additional mouse skin-painting study was cited where the intermittent dose was 480 gm/kg/80 weeks, the results were considered neoplastic by RTECS criteria, and skin and appendage tumors were at the site of application.
45.0 Petroleum Distillates, Hydrotreated (Severe) Heavy Naphthenic
45.0.1 CAS Number: See Table 22.10

45.0.2 Synonyms: Distillates (petroleum), hydrotreated (severe) heavy naphthenic; hydrotreated (severe) heavy naphthenic distillate; hydrotreated (severe) heavy naphthenic distillates (petroleum); petroleum distillates, hydrotreated (severe) heavy naphthenic
45.4 Toxic Effects
RTECS (18) listed a rat LD_{50} by the oral route at >15 gm/kg, and dermal application in rabbits resulted in a LD_{50} >5 gm/kg. IARC determined that the evidence in animal studies was inadequate (Group 3).
46.0 Petroleum Distillates, Light Catalytic Cracked (Light Catalytic Cycle Oil)
RTECS (18) listed an inhalation LC_{50} in the rat at 3400 mg/m^3/4h and an oral LD_{50} in the rat as 3200 mg/kg.

Ionizing Radiation
Roy E. Albert, MD

1 Introduction

Ionizing radiation is undoubtedly one of the most intensely studied of all toxic agents. The impetus for understanding its manifold effects came from its extensive use since the beginning of the century in medical diagnosis and in treating cancer. With the development of atomic energy during World War II, the field expanded dramatically. Atomic energy became one of the country's largest industries. The potential health hazards from occupational and environmental sources of radiation became an important area for research; it spawned a new field in the post-World War II era of measurement and control called health physics.

Under the Atomic Energy Commission (AEC), a great national laboratory complex was established for research on weapons and power production and for biomedical and physics research. Long-term biomedical research was also initiated at large university-based facilities and by the support of individual grants. The development and sale of radioisotopes and radiation measuring instruments was subsidized by the AEC to the great benefit of biomedical research in general. Radiation biology has its own society, (the Radiation Research Society), and its own journal, the *Journal of Radiation Research*. In recent years, radiation has become an integral tool for understanding cellular function at the molecular level, for example, the tumor suppressor gene, p53. However, the level of biomedical research on radiation is much lower in the last few decades than earlier.

This chapter gives the toxicologist the basic features of radiation biology. Because of the scope of the field, only the essential concepts are presented. The reader is referred to textbooks (1–6) and other publications cited for more details.

Ionizing Radiation
Roy E. Albert, MD

2 Physical Considerations
There are two forms of ionizing radiation: high energy electromagnetic waves and subatomic particles. Their common property is the ability to eject electrons from molecules, a phenomenon called ionization. At levels of lesser energy deposition, they are also capable of raising electrons to higher energy levels which are called excitation. Both ionization and excitation can lead to chemical change. Thermal effects are of no consequence in the biological effects of ionizing radiation. A whole body exposure of 2000 rads enough to kill everyone twice, would raise the body temperature by only 0.01°C.

The energy of ionizing radiation is expressed in electron volts. The energy range of ionizing radiation is large, from a few electron volts to billions of electron volts. Most commonly encountered is the kilovolt (keV) and megavolt (MeV) domain. The average energy that causes ionization in tissue is about 75 eV.
2.1 Electromagnetic Radiation
Electromagnetic radiation is propagated in packets called photons. The energy of photons is a function of the wave frequency. These frequencies range through many decades. Electromagnetic radiation, in order of increasing frequency and energy, includes radio waves, infrared radiation, visible radiation, ultraviolet radiation and ionizing radiation. Among the nonionizing radiation, ultraviolet light can cause excitation but not ionization, and infrared radiation causes heating.

There are two kinds of electromagnetic ionizing radiation (photons): gamma rays and X rays. They have identical properties but different sources. X rays are generated by machines that accelerate a beam of electrons so that it impacts a metallic target releasing X rays whose energy depends on the speed (energy) of the impacting electrons. This is the bremsstrahlung (braking radiation). Gamma rays are emitted by disintegrating atomic nuclei of radioactive isotopes. The energies of the gamma radiations released by the disintegration process are unique to each radioactive isotope.

There are three modes of interaction of electromagnetic radiation with matter: pair production, compton scattering, and the photoelectric effect.

2.1.1 Pair Production Pair production occurs when a photon whose energy is in excess of 1.02 MeV, passes near an atomic nucleus and is transformed into an electron and a positron. The probability of pair production increases rapidly above the threshold of 1.02 MeV and is a function of the square of the atomic number of the irradiated material. When the positron loses energy to about 1.022 MeV by interactions with the absorbing medium, it undergoes an “annihilation” reaction when it contacts an electron. This results in the release of two photons in opposite directions each with an energy of 511 keV. Pair production is not important in tissue-equivalent materials at photon energies less than 10 MeV.

2.1.2 Compton Scattering Compton scattering is the dominant form of interaction in tissue-equivalent materials at photon energies in the MeV range, such as the gamma radiation from radioactive cobalt-60. The process involves loosely bound electrons. With Compton scattering, the incident photon causes the ejection of an electron and the emission of a photon whose energy is lower than the incident photon. The amount of energy lost by incident photons covers a broad range from virtually zero to 80%. The scattered electrons form a continuous spectrum of energies with a maximum somewhat below the energy of the incident photon and with a peak at both high and low energies. The process is independent of atomic number and is important in the energy range of 100 keV to 10 MeV.

2.1.3 The Photoelectric Effect The photoelectric effect predominates over Compton scattering in the kilovolt energy range used in diagnostic X ray. The photoelectric effect involves only bound electrons in the K, L, and M shells of the atoms in the absorbing material. This is in contrast with Compton scattering that involves loosely bound electrons. The incident photon gives all of its energy to the electron. Some energy is required to overcome the binding energy of the electron; the rest is given to the electron in the form of kinetic energy. When the orbital electron is ejected from the atom, it is replaced by an electron from an outer shell. The difference in the binding energies of the two shells is released as a fluorescent X ray with the characteristic energy of the electron shell. For example, a device for measuring the amount of lead paint in walls is based on the photoelectric effect; it works by shining a source of gamma radiation from cadmium-108 on the wall and measuring the intensity of one of the fluorescent X rays characteristic of lead (7). The intensity is a function of the amount of lead in the paint.

Both Compton scattering and the photoelectric effect occur in the kilovolt range X rays used for diagnostic purposes; the former is dominant at the higher energy range, and the latter at the lower energies. The photoelectric effect is strongly dependent on the atomic number (Z) of the absorber, namely Z^3; hence, diagnostic X rays display bone shadows because of the higher Z of bone compared to soft tissues. Energies in the MeV range are desirable for radiation therapy because Compton scattering predominates, and there is an advantage of having equal absorption by bone and soft tissue.

The radiobiological effects of absorption by the Compton and photoelectric processes are similar because they both result in converting the energy of the photons to electrons. However, the energy of fluorescent photons is small, in the range of 500 eV, and has little biological effect.

In fact, the final common pathway for biological effects for both particulate and electromagnetic radiation, that is, all forms of radiation, is the production of electrons.

2.2 Particulate Radiations

There are two types of particulate radiation: those that are charged and eject electrons by collision and those that are uncharged and interact with matter to form charged particles. The important particulate forms of ionizing radiation that are charged include alpha rays (helium nuclei), protons (hydrogen nuclei), and beta rays (electrons). Neutrons are uncharged atomic nuclear particles that eject protons by collision with hydrogen nuclei.

Alpha and beta particles can be released by the decay of radioisotopes. Neutrons are produced mainly by nuclear fission in reactors or nuclear weapons. Charged particles such as electrons and protons, as well as heavier ones such as carbon, neon, and argon, can be produced in accelerators.

There are two important mechanisms for energy loss by electrons. The first is by scattering. This involves ionization and excitation. The second, bremsstrahlung, involves passage of the electron near an atomic nucleus. Electrostatic forces around the nucleus bend the path of the electron; the consequent acceleration causes the release of a photon. Bremsstrahlung has a broad continuous spectrum of energies characterized by its peak energy; for example, a 250-keV X ray machine produces X rays that range continuously in energy from a few hundred electron volts to a peak of 250 keV.

Electrons undergo multiple collisions in an absorbing material, and each electron has a zigzag track. Secondary electrons that are released by the collision of a primary electron are called delta rays; each has its own zigzag track. The penetration of electrons, for example, into the skin from an isotopic source applied to the surface of the skin, resembles the diffusion of a gas. The dose varies with depth. There is an initial increase due to the buildup of scattered electrons and then a monotonic decrease with increasing depth in skin down to the maximum range.

In the zigzag paths of electrons, short branching tracks are called “spurs”; these contain an average

of three ion pairs. In the case of gamma or X rays, 95% of the energy is deposited in spurs. Larger and more densely ionizing tracks are called “blobs,” and when they overlap the DNA molecule, they produce sites of multiple damage.

With all particulate radiations, the energy transferred is proportional to its charge, the Z of the absorber, and inversely proportional to the square of its velocity. Hence, the rate of energy transfer from particulate radiations per unit path length rises toward the end of its track when the kinetic energy approaches zero. This terminal rise in energy deposition, the Bragg peak, is most important with heavy charged particles whose tracks are straight. It is the basis for selective irradiation of deep tissues within the body, such as the pituitary gland, by highly energetic accelerator-produced particles.

Neutrons are generated over a very wide range of energies, depending on their source. They do not interact electrically with matter but are scattered or absorbed. The modes of interaction are complex and energy dependent. For example, one important mode of interaction is elastic scattering. This is particularly important with hydrogenous material. Both the neutron and the hydrogen nucleus recoil. The recoiling hydrogen nucleus, which is a proton, causes ionization over a distance of microns and the recoiled neutron, now at lower energy, undergoes further collisions. This is the reason that hydrogenous material such as paraffin can be used as a neutron shield.

Another important neutron reaction is absorption by an atomic nucleus, in which the nucleus with its added neutron becomes unstable and undergoes radioactive decay and releases ionizing radiation. Neutron bombardment in a nuclear reactor is one method of producing radioisotopes commercially. The formation of radioactive isotopes in a neutron-irradiated body can also be used to estimate the neutron dose from radiation accidents.

The penetration into tissue of charged particles such as alpha, beta, and protons is very limited. Heavily charged particles produce densely ionizing tracks of short length because their energy deposition per unit path length is so high. Alpha particles deposit energy in short tracks whose length depends on the energy but commonly is on the order of 35 to 50 microns long and a few microns wide. Alpha particles and protons are blocked by tissue-equivalent material no thicker than a sheet of paper. Electrons penetrate one or two centimeters depending on their energy. Electromagnetic radiation and neutrons easily pass through the entire human body because they deposit energy in a widely scattered fashion.

The energy deposition per unit path length, called “linear energy transfer” (LET), has significant consequences with respect to biological effects. There is great inhomogeneity in the dose distribution of high-LET radiation at the microscopic level: many cells receive no radiation at all, and others receive very high doses. A cell can be killed by a single alpha track that traverses its nucleus in sharp contrast with the more diffuse radiation patterns from the low-LET electrons and gamma or X rays.

Densely ionized tracks produced by alpha and protons are qualitatively different from X or gamma rays because the damage, although focal, is so intense that it is difficult for the cells to accomplish repair. The temperature within alpha tracks is several million degrees.

2.3 Dose

Because all forms of ionizing radiation have the final common pathway of ionization and excitation caused by electrons, the important determinant of the way they produce biological damage is the pattern and energy of electron release. Radiation dosimetry can be exceedingly complicated (8). The concept of dose is energy deposition per unit mass of the absorber. The pattern of energy deposition depends on (1) the type of radiation, particulate or electromagnetic; (2) the energy of the radiation; and (3) the geometrical characteristics of the applied radiation. The whole human body can be exposed more or less uniformly throughout all of its tissues by exposure to a broad beam, high-energy external source of gamma or X rays. By contrast, an equal dose can be delivered to the surface epithelium of the tip of one finger by an external isotopic source of alpha radiation. The biological consequences in this example are very different. Hence, the biological effects depend on

both the magnitude and location of the dose.

The basic unit of absorbed dose is the rad, which is 100 ergs per gram. This assumes that one gram units of tissue have a uniform deposition of energy. Since 1977, with the introduction of the SI system (Systeme Internationale), the gray (Gy) has been introduced to supplant the rad as the unit of dose. One gray equals 100 rads. Thus a bridge between the rad and the gray that is commonly used by those who think in terms of rads is one centiGray (cGy) which equals one rad.

Because the biological effects of the various kinds of radiation can be different at equal average tissue doses due to the differences in the microscopic pattern of energy distribution, it has been useful to introduce a weighting factor that makes doses from different types of radiation equivalent in terms of biological effect. Multiplying the dose in rads or grays by a weighting factor yields a dose in terms of rem (roentgen equivalent man) or the sievert. One sievert equals 100 rem just as one gray equals 100 rads. The weighting factor for a specific type of radiation is its relative biological effectiveness (RBE) in relation to a reference type of radiation, namely 250 keV X rays. RBE is commonly used in radiobiological research. In radiation protection, the weighting factor is called a quality factor. As a matter of practicality the RBE is constrained to a specific biological effect, but the quality factor applies to a given type of radiation without reference to a specific biological effect.

2.4 Radionuclides

In its gross structure, the atomic nucleus consists of protons and neutrons (4). The number of protons determines the atomic number (Z) which is the net positive charge of the atom. The negative orbital electrons balance the positive charge. The number of neutrons contributes to the atomic mass number (A). Each element has a unique value of Z. Each nuclide of an element has specific value of Z and A, and is designated by its name and A, for example, Chromium-51. If a nuclide is unstable, it is called a radionuclide. Isotopes of a given element can have different values of A due to different numbers of neutrons. The terms radioactive isotopes and radionuclides are used synonymously.

Unstable nuclides undergo nuclear rearrangements called radioactive decay because they result in the emission of radiation and transmutation to a different element. Generally, the greater the ratio of neutrons to protons, the more unstable; nuclides of A>200 are all radioactive. Ultimately, radioactive decay reduces the ratio of neutrons to protons, but in chain decay there may be a temporary increase in the ratio due to electron emission.

Alpha decay involves the emission of helium nuclei, each consisting of two protons and two neutrons. This reduces Z by 2 and A by 4. Beta decay is equivalent to converting a neutron to a proton, and it results in an increase in Z. The resulting nuclide may be stable or in a excited state which is relieved by the emission of a gamma ray. The energy of alpha radiation emitted by a given radionuclide is constant; usually, the shorter the half-life, the more energetic. However, beta rays are not monoenergetic but exhibit a spectrum of energies which is characteristic of the radionuclide.

More unusual forms of decay involve (1) positron emission (positive electrons) which is the equivalent of converting a proton to a neutron, (2) electron capture with the apparent engulfment of a K orbital electron by the nucleus to convert a proton to a neutron and with the emission of a K electron X ray, (3) Auger electron emission which is the equivalent of electron capture where the fluorescent X ray itself is captured by an orbital electron which is then ejected from the M shell of the decayed atom. Both electron capture and Auger emission reduce the value of Z by one.

Radionuclides undergo decay by a number of alternative pathways so that mixed forms of decay are frequent. The relative frequency and energies of gamma radiation constitute a signature that can be used to identify radionuclides by gamma spectroscopy.

Radionuclides have the property of decaying on a probabilistic basis. Each radioactive atom has a 50% chance of decaying in a fixed period of time, called a “half-life.” In each successive half-life, the number of undecayed radioactive atoms is reduced by a factor of 2. Half-lives range from fractions of a second to billions of years. Most of the stable lead in the world came from the decay of

the uranium and thorium series. The parent isotopes, uranium-238 and thorium-232, have half-lives in the billions of years (9).

Radioactive decay series involve two or more sequential decays before a stable isotope is reached. Starting with a pure sample of the parent isotope, the buildup and decay of the successive daughter isotopes can have complex patterns that are a function of their respective half-lives. These patterns are readily calculable by using partial differential (Bateman) equations. When a decay series reaches equilibrium, the decay rate (e.g., disintegrations/second) is equal for each member of the series; the number of radioactive atoms of each member is proportional to its half-life. The mean life of an isotope is 1.44 times its half-life. The mean life is useful for calculating the total number of atoms of an isotope at time zero; the number of atoms of an isotope is the disintegration rate (disintegrations/minute) multiplied by the mean life (in minutes).

The dose rate from radionuclides deposited in the body decreases as the radioactive atoms decay and because the radionuclide is excreted. If the excretion is exponential, there is an "effective half-life" of the radionuclide in the body which is the product of the radiological and biological half-lives divided by their sum. For example, if the radiological and biological half-lives are each 2 hours, the effective half-life in hours $2 \times 2/2 + 2 = 1$.

The original metric for radioactive decay rate was the curie (Ci) which is the number of disintegrations per second in a gram of radium-226. One Ci = 3.7×10^{10} d/s. One mCi = 3.7×10^{7} d/s. One mCi = 3.7×10^{4} d/s or 2.2×10^{6} dpm. A more recent unit for radioactivity is the becquerel (Bq) which is 1 disintegration per second.

Isotopes of a given element differ chemically only in atomic mass which affects the diffusion rate. The fissionable isotope, uranium-235, was isolated from its parent uranium-238 by gaseous diffusion despite the small mass differential; this was the essential step in the development of atomic energy. Biologically, the mass differences are significant only with the lightest elements. Significant diffusion differences exist between stable hydrogen and heavy hydrogen (deuterium) and tritium (hydrogen-3). Otherwise the behavior of radionuclides is essentially identical to the normal stable isotopes found in living organisms. This is the reason that they can be used as biological tracers.

2.5 Measurement of Radiation

Many commercial instruments are used for measuring ionizing radiation, but the basic principles behind their operation are relatively few. Ionization devices depend on the ionization of air or other gases by radiation. One of the oldest instruments is the gold leaf electroscope, in which a strip of gold foil is hung over an insulated arm, forming two adjacent but connected leaves. The application of an electrostatic charge to the foil causes the leaves to fly apart where they remain until ionization of the air discharges them and causes them to fall toward each other. The extent to which they do so in a given time is a measure of the radiation dose. The loss of a static charge is the basis for the commonly used pocket dosimeters. Ionization chambers measure current flow from ionized gas in a voltage field applied to parallel conducting plates. A cascade of ions in a high-voltage field between a cylinder wall and a central electrode is the basis for the Geiger counter which records individual ionization as clicks or as current flow. Depending on the thickness of the walls of an ionization chamber, they can be adapted to measuring gamma rays, beta rays of different energies, or alpha particles.

Photographic film responds to ionizing radiation much as it does to visible light. A piece of uranium ore unwittingly placed on a wrapped sheet of unexposed film led to the discovery of radioactive isotopes by Becquerel. Film packs are commonly used as personal dosimeters.

Single crystals of sodium or cesium iodide are commonly used scintillation detectors. When struck by penetrating radiation, they emit a flash of light whose intensity is proportional to the energy of the radiation. Photomultiplier tube(s) placed against the scintillation detectors convert the flash of light into an electrical impulse whose size is proportional to the intensity of the flash. Scintillation

detectors count both the number and energy of the detected radiation, providing an energy spectrum that can be useful in identifying the radiation source, generally of gamma-emitting isotopes. These devices are used extensively for imaging in nuclear medicine by using multiple, small, columnated scintillation detectors for gamma radiation and for coincidence counting of positrons that annihilate to form 0.511 MeV gamma rays that are released back-to-back, 180° apart.

Liquid scintillation counters are widely used to measure radionuclides whose radiations are too weak to penetrate the light seal around solid scintillation detectors. The radiation-emitting samples are suspended or dissolved in the fluorescent liquid. As with solid detectors, the intensity of the light signal can be used to count isotopes with different energies, such as tritium-3 and carbon-14, simultaneously.

Thermoluminescent detectors, such as lithium fluoride pellets, store radiation energy during exposure; heating releases the stored energy in the form of light. The intensity of the light is a function of the amount of absorbed energy. Because of their small size, thermoluminescent dosimeters can be very useful in determining the dose distribution in tissue-equivalent phantoms that simulate the radiation of body parts.

Ionizing Radiation
Roy E. Albert, MD

3 Radiation Damage at the Molecular Level
The biological effects of radiation result principally from damage to DNA. Other molecules in the cell are also damaged but they are either present in large numbers or can easily be replaced. DNA may be damaged directly by deposition of ionizing energy within the molecule itself or indirectly by the diffusion of radiation-induced free radical ionization products of water into the DNA molecule.
3.1 Radiation Chemistry
The radiative chemistry of water is extremely complicated (10). However, the most important sequence of reactions between water and radiation is the production of an ionized (charged) water radical, H_2O^+, which reacts with a normal water molecule to yield a free OH^* (hydroxyl) radical. The hydroxyl radical accounts for most of the indirect radiative damage and has a lifetime of only about 10^{-5} seconds. Its short lifetime limits the diffusion distance to a cylinder of about twice the diameter of the DNA molecule. Hence, free water radicals have to be produced in the immediate vicinity of DNA molecules to do damage. About two-thirds of the radiation damage is indirect, caused by water radicals.

Molecular radiation damage can be reversed by several mechanisms. Recombination of radicals and ions can occur before they diffuse apart, within the first 10^{-11} seconds. This is the coming together of the ion and radical pairs to produce the original molecule. A molecule such as DNA can be restituted by reaction of the free radical on DNA with a sulfhydryl molecule, yielding a sulfide radical and normal DNA.

$$\mathrm{DNA^* + RSH \rightarrow DNA + RS^*}$$

The free radical on DNA is thereby transferred to the sulfhydryl moiety restoring the DNA to a normal state. Enzymatic repair, as discussed later, can also reconstitute DNA to its normal state.

The OH^* radical can react by extraction of hydrogen atoms as in

$$\mathrm{R - H + OH^* \rightarrow R^* + H_2O}$$

The OH^* radical can undergo addition reactions as in

$$R - C = C - R + OH^* \rightarrow RCHOH - C^* - R$$

with the formation of a carbonium ion.

Oxygen can play an important role in the fixation of radiation damage as in

$$R^* + O_2 \rightarrow RO_2^*$$

This peroxidation radical is relatively stable and, more importantly, prevents chemical restitution. The presence of oxygen has a dramatic effect in increasing the biological damage from ionizing radiation, as discussed later.

3.2 DNA Damage

Radiation of DNA can damage purine and pyrimidine bases, as well as the sugar backbone (11). The most important mode of radiative damage is to the sugar backbone and results in either single- or double-strand breaks. The single-strand breaks are repaired rapidly within a period of minutes and so efficiently that the DNA is restored to normal with a high degree of freedom from errors in the sequence of base pairs. Single-strand breaks undergo excision repair in which the gap is trimmed back and then reconstituted by polymerase enzymes using the intact strand as a template. Damaged bases per se are removed by glycoylase enzymes, and then the strand is reconstructed by an excision repair process.

Double-strand breaks are much more serious because rejoining the broken ends can result in abnormalities of chromosomal structure. Double-strand breaks can be formed when two single-strand breaks occur simultaneously from an ionization track or if the two single-strand breaks are formed sequentially within ten bases of each other in a period less than that required for repair. Double-strand breaks take hours to be rejoined. With low-LET radiation, single-strand breaks occur about one hundred times more frequently than double-strand breaks. Double-strand breaks are much more common with high-LET radiation.

The principal form of nonlethal genetic damage caused by radiation is the loss (deletion) of chromosomal segments. Less important is single base pair damage that results in point mutations, that is, altered base sequences.

One double-strand break on an unreplicated chromosome results in a broken arm that can rejoin (with some loss of DNA) or remain fragmented either in the form of a rod or, when the ends fuse, as a ring (12). Both the damaged chromosome and the fragment can replicate to form two short-arm chromosomes and acentric fragments. The acentric fragments remain in the parent cell, and the short-armed chromosome segregates into the parent and daughter cells. Two double-strand breaks on one arm of a prereplicated chromosome can lead to the displacement and loss of the segment between the breaks and also results in a short-armed chromosome and a fragment. Acentric fragments, those that have no centromeres, can become encapsulated in a membrane. Such structures are called microsomes and are useful quantitative markers for the action of genotoxic agents, including chemicals and radiation. The microsomes eventually disappear.

When multiple double-strand breaks occur on different chromosomes in close proximity, rejoining can lead to a wide variety of chromosomal abnormalities. Lethal abnormalities include dicentric and ring lesions. Abnormalities that are not necessarily lethal include deletions and translocations.

A double-strand break on each arm of two nearby unreplicated chromosomes can result in a translocation in which the chromosomal fragments switch places. Alternatively, the amputated arm of each unreplicated chromosome can anneal to form a single chromosome with two centromeres. The dicentric chromosome can replicate and become observable in metaphase preparations during

mitosis.

If cells are irradiated after the chromosomes have replicated (during the G2 period) but before being separated during mitosis, a lethal lesion can be formed that is called an anaphase bridge. This is caused by a simultaneous break in the arms of the paired (replicated) chromosomes and subsequent annealing of the stumps. The parent and daughter cells cannot separate during anaphase because of the chromosomal bridge, and they die.

These chromosomal abnormalities are important because they are a mechanism of cell killing and genotoxicity. They can be quantitated in metaphase spreads giving informative dose–response relationships. The shape of the dose–response curve for dicentrics and rings is linear-quadratic. At low doses, the curve is linear because some of the two double-strand breaks are produced simultaneously by a single ionization track. The quadratic higher dose portion of the curve is due to production of each of the two double-strand breaks by separate ionization tracks. Here the probability that two chromosomes are hit by separate tracks within a short time in about the same location is a function of the square of the dose. These relationships make it possible to reconstruct the radiation dose received by an individual by quantitating chromosomal abnormalities in circulating lymphocytes; some lymphocytes have a long residence time in the blood and can be stimulated to undergo cell replication.

Ionizing Radiation
Roy E. Albert, MD

4 Radiation Effects at the Cellular Level
Cell death is reproductive in nature. This means that cells die when they try to divide. This phenomenon was shown in the classic studies of Spear with X irradiation of fibroblast cultures (13). The number of mitotic cells falls promptly after radiation. The magnitude and duration of the decrease in mitosis increases with dose. The presence of necrotic cells first makes its appearance at about the time when there is recovery from mitotic depression. It follows that the first appearance of radiation damage is a function of the proliferative rate of tissues. For example, white blood cells have a rapid turnover of precursors in the bone marrow and a short life in the peripheral circulation. There is a prompt decrease in white blood cell counts shortly after radiation in contrast to red blood cells whose precursors have a slower reproductive rate in the marrow, and the red cells have a relatively long life in circulation.
4.1 Cell Survival Curves
A great deal of quantitative information about reproductive cell killing, cellular repair, and dose–response relationships has been obtained by using the colony formation method developed by Puck (14). This approach involves dispersing cultured cells into single-cell suspensions. Aliquots are loaded into petrie dishes where they settle and attach. The petrie dishes may have a “feeder” layer of lethally irradiated cells that cannot multiply but are metabolically active and facilitate the growth of the single-cell aliquots. After attaching, the reproductively competent cells grow to form colonies several millimeters in diameter in a few weeks. Irradiation of the petrie dishes at the single-cell stage reduces the number of reproductively viable cells monotonically with increasing dose. Colony counts at two weeks give the fraction of cells, corrected for the plating efficiency of controls, that are rendered sterile. Those cells that are “reproductively dead” actually survive and multiply a few times but cannot form colonies. A plot of the log of the fraction of the plated cells, normalized to unity on the basis of the plating efficiency of the controls plotted against the dose on an arithmetic scale, gives a survival curve. The survival curve for high-LET radiation is exponential, a straight line on a semilog plot. The slope is a function of the sensitivity of the types of cells that are exposed to a given type of radiation. The slope is expressed as the D_0 dose, a reduction of survival to 37% which is equivalent to an average of one “hit” per cell. Typical D_0 values are on the order of 1–2 Gy.

The survival curves for low-LET radiation have a flat shoulder in the low-dose region, where relatively little cell killing occurs (15). At higher doses, the curves tend to become exponential, a straight line on a semilog plot. The shoulder reflects repair of the radiative damage. This can be shown by irradiating cells twice with an increasing amount of time between the two exposures. With increasing intervals and replating the cells soon after the second exposure, the shoulder reappears, growing from a small size to the magnitude encountered with single radiative exposures. The repair is complete in a few hours and likely represents the repair of single-strand breaks. After sufficient time for repair, the surviving cells behave as if they had not been previously irradiated. They show the same shoulder and the same survival slope as cells that are irradiated for the first time. This kind of radiative damage, called "sublethal" refers to damage that will be repaired unless additional radiation is administered before the repair period is over. The lack of a shoulder with high-LET radiation indicates that there is no repair, and the interval between split radiative exposures has no effect on the kinetics of survival. There is another kind of damage that is called "potentially lethal." It is a form of damage that is inevitably lethal unless circumstances interfere with the progress of the cell cycle, as with confluent growth in tissue culture where cell-to-cell contact inhibits proliferation. Under these circumstances, the irradiated cells have a chance to recover somewhat from the potentially lethal damage, probably by repairing double-strand breaks. The repair of potentially lethal damage is considerably slower that of sublethal damage.

Back-extrapolation (from high dose to low dose) of the exponential slope to a survival of unity gives a quasi-threshold measure of the width of the shoulder. This varies according to cell type by a factor of 2–3. Some survival curves with a "true" exponential high-dose region can be construed to reflect a multihit process; back-extrapolation of the linear slope to zero dose gives an intercept that can be interpreted as a "hit" number, the number of hits required to render the cell reproductively sterile. The magnitude of the hit number is also an indication of the size of the shoulder.

Some survival curves show a gradually increasing slope without a convincing linear exponential portion. These curves are better interpreted as linear-quadratic in nature. There is a low-dose linear portion and a quadratic portion in the higher dose range.

The equation for the linear quadratic dose response, where R is reproductive cell death, D is dose, and A and B are constants, is

$$R = AD + BD^2$$

This is the same equation used to describe the dose response for the induction of chromosomal damage discussed earlier, and the same interpretation holds that the cell killing has a single-hit component and a two-hit component.

The linear and quadratic components of the cell killing are equal when the dose D is equal to the ratio of the constants A and B:

$$AD = BD^2$$

or

$$D = A/B$$

There is compelling evidence that cell death is a function of chromosomal damage, for example, in terms of a linear relationship between the number of chromosomal aberations (dicentrics and rings) per cell and the log of the cell survival. Other evidence includes cell lethality by tritiated thymidine which is incorporated in DNA and which irradiates only DNA, the increased sensitivity to cell killing by halogenated pyrimidines that are incorporated into DNA, etc.

Tissues of a given type tend to show a relatively narrow range of sensitivities. However, tumors that arise in a given tissue tend to show a broader range of radiosensitivities, some higher and others lower than normal but with considerable overlap. This is an impediment to effective radiative treatment.

The kinetics of cell killing with the Puck technique have proved to be comparable to the kinetics observed *in vivo*. Estimates of cell survival in cancer radiotherapy have some utility. Because single-cell preparations from freshly excised tissue do not do well in the Puck technique, surrogates based on cell numbers in agar suspensions and total DNA content of tumors have been used as measures of reproductive survival.

Radiotherapy involves repeated exposures at intervals that allow for repair in normal tissues. Survival curves for repeated irradiation are exponential without a shoulder because the cell killing from each radiative fraction combines with subsequent fractions multiplicatively. For example, four successive fractions, each reducing survival by a factor of 0.6 will combine to reduce survival to $0.6 \times 0.6 \times 0.6 \times 0.6 = 0.13$. This type of multiplicative interaction yields an exponential survival curve.

Survival curves provide the basis for useful radiotherapeutic calculations. For example with a tumor of 10^9 cells, a 90% chance of cure would involve reducing the population by a factor of 10^{-10}. This target would be achieved with an estimated dose of 69 Gy. This estimate is based on a survival curve without a shoulder, a D_0 of 3 Gy and daily dose fractions of 2 Gy. A tenfold reduction in survival would be equal to $2.3 \times D_0$. Therefore a dose required to reduce survival by ten orders of magnitude (D_{10}) would be $D_{10} = 2.3 \times 3 = 6.9$ Gy $\times$ 10 = 69 Gy.

4.2 Modifiers of Radiation Damage

Survival curves provide a useful means of quantifying the effects of modifiers of radiation damage. For example, the oxygen effect increases the slope of the survival curve by a factor of about 2–4 from the hypoxic to the aerated state (16). The character of the survival curve stays the same, but the effect of oxygen is to decrease the dose by a constant factor for the same level of effect. This applies to both the high-dose quadratic and the low-dose linear portion of the survival curve, although the factor, called the “oxygen enhancement ratio” (OER), is 3.5 for the former and 2.5 for the latter. By contrast, the (OER) is smaller for the higher LET radiations. For example, for alpha radiation, it is 1.0 (no effect), and the OER is 1.6 for 15 MeV neutrons.

Equal total doses given at low dose rates for low-LET radiation have a smaller effect than higher dose rates because the lower dose rates permit repair. This is not true for high-LET radiation. However, if the dose protraction becomes large, the mitotic cycle has an effect because different parts of the mitotic cycle have different radiosensitivities.

The mitotic cycle has a quiescent phase, called G1, which, depending on the proliferative rate, can last for a matter of hours to weeks. Then cells given appropriate stimulation enter the phase of DNA replication, called the S period, which lasts on the order of ten hours. A short period, called G2, follows that lasts a few hours, in which the chromosomes condense. Finally the mitotic phase, called M, takes place which also lasts a few hours; here, the chromosomes line up at an equatorial plate and are pulled by spindle fibers to opposite sides of the cell which then divides in the middle to form two cells. Then the divided cells are either in the G1 phase, and the cycle repeats itself, or are in a G_0 phase which is out of the cell cycle.

The influence of the cell cycle on radiation sensitivity can be easily studied in tissue culture because cells in mitosis round up and are easily detached from the surface of the culture dish by gently agitating the medium. Then the harvest of synchronized mitotic cells can be studied by the Puck technique of colony formation after radiation. The pattern varies with cell type, but the constant feature is that the sensitivity is highest in the G2 and M phases and lowest at the end of the S period.

In some cell types sensitivity is increased at the begining of the G1 period as well (17).

Radiative sensitivity, according to cell cycle, plays a role in the effects of dose rate on cell survival. The effect of dose rate on cell survival is complicated but predictable on the basis of what is known about the dynamics of DNA repair and the effects of the cell cycle on radiative sensitivity. When low-LET radiation is given in a short period at relatively high dose rates, the typical survival curve is obtained with its shoulder and high-dose exponential fall-off. As the dose rate is decreased, the first effect is an increase in the size of the shoulder and a more shallow exponential drop, that is, the D_0 increases. This is due to the fact that DNA repair proceeds during the radiative exposure and nullifies some of its damaging effects. At this level of dose rate, cells are substantially arrested at the junction between G1 and S and between S and G2. The rate of mitosis is much depressed. The reason for the arrest at these checkpoints is the action of the p53 gene. DNA damage activates the p53 gene which then expresses more of its protein. The p53 protein interacts with proteins of related genes to activate the checkpoints that arrest the flow of cells through the mitotic cycle. The effect of this arrest is to give more time for DNA repair, which, if inadequate, triggers cell death by apoptosis.

With a further lowering of dose rate, the checkpoint block is only partial, and cells move through the cycle into G2 and M, where they are more radiation sensitive. This reverses the trend toward shallower survival curves, and the slope of the survival curve increases toward those of the higher dose rates. As the dose rate further decreases, the flow of cells into mitoses is further increased toward normal, and cell proliferation counterbalances the losses due to reproductive death. This further decreases the slope of the survival curve, and it may be flat or have a positive slope indicating that the number of cells increases during radiation.

5 Cell Survival in Tissues
A number of assays have been developed to determine the survival of clonogenic cells in tissues. These cells include the skin, the villi of the small intestine, the testes, the tubules of the kidney, and cells of the bone marrow and thyroid. The skin assay depends on the formation of regenerating nodules on the skin surface arising from cells that have migrated upward from the underlying hair follicles that have survived the radiative exposure (18). The intestine assay examines the proportion of the villi that are regenerating after irradiation (19). The bone marrow assay looks at colony formation in the spleen after irradiated cells have been injected into the bloodstream and have been deposited there (20). The testes assay determines the proportion of tubules that contain spermatogenic epithelium (21). These assays are done with graded doses of single, multiple, or split exposures. The results of these studies resemble those with cell cultures in terms of a wide range of widths of the shoulders and fairly uniform high-dose slopes.

Assays have been done on functional end points in contrast to cell survival. Typical of such studies are the effects of X rays on skin reactions in the mouse (erythema, desquamation, and ulceration) with single and fractionated exposures. It is evident that fractionation permits a great deal of radiative repair in the skin. As shown later, this holds true for skin carcinogenesis as well.

6 Radiation Sensitivity According to Cell Type

As early as 1906, Bergonie and Tribondeau (22) noted that different kinds of mammalian tissues have very different radiation sensitivities. The most sensitive were those that have a high mitotic rate, undergo many cell divisions, and are primitive in character, that is, are undifferentiated.

Rubin and Casarett's categorization of types of cells according to decreasing levels of radiosensitivity is still used (23). Category I includes the most radiosensitive: these are cells like the basal cells of the epidermis that undergo regular cell division and show no differentiation between divisions. Category II cells are like myelocytes in the bone marrow that also divide regularly but do undergo some differentiation between divisions. Category III cells are relatively resistant like the hepatocytes in the liver that normally divide very infrequently but can be triggered into rapid mitosis. In the case of the liver, this occurs with toxic liver damage or partial hepatectomy. Category IV has the most resistant cells, including muscle cells and the neurons of the central nervous system. These cells are highly differentiated, and it is questionable that they divide at all once the organism reaches maturity.

Cell death is reproductive in nature. It follows that the first appearance of radiation damage is a function of the proliferative rate of tissues. For example, white blood cells have a rapid turnover of precursors in the bone marrow and a short life in the peripheral circulation. There is a prompt decrease in white blood cell count shortly after radiation, in contrast to red blood cells whose precursors have a slower reproductive rate in the marrow, and the red cells have a relatively long life in the circulation (24).

7 Chemicals that Modulate Radiation Effects

Some chemicals increase and others decrease radiation effects. One class of chemicals that increases radiosensitivity is the halogenated pyrimidines, including 5-bromodeoxyuridine (BUdR) and 5-iododeoxyuridine (IUdR) (25). The halogen is recognized as a methyl group, and these chemicals are treated metabolically as if they were thymidine and are incorporated into DNA. The DNA bonds are weaker with the halogen moieties, and radiation-induced strand breakage occurs more readily. The degree of incorporation is a function of the rate of cell proliferation. Therapeutic effectiveness for cancer depends on the relative rates of turnover of cancer cells compared to normal surrounding tissues. In cultured cells, the dose required to reduce survival to a given level of reproductive death is about one-half in halogenated pyrimidine treated cells compared to untreated cells. The use of these agents has received some clinical attention.

There are chemicals that increase the radiation sensitivity of hypoxic cells but not those that are well oxygenated (26). Their potential use in cancer radiotherapy depends on the presence of hypoxic cells in tumors because such cells are relatively radioresistant. These chemicals belong to the class of nitroimidazoles such as etanidazole. They mimic the action of oxygen and fix radiative damage by preventing chemical restitution of the damaged molecules. They have an enhancement ratio of about 2. Their use is limited by neurotoxicity. They also sensitize cells to cancer chemotherapeutic drugs, particularly alkylating agents.

Chemicals that decrease radiation effects are called radioprotectors. The sulfhydryl compounds are an important class of radioprotectors, including the natural amino acid cysteine and its metabolite cysteamine (27). The factor for dose reduction (the ratio of doses for equal effect) is about 2 for these compounds. They work by scavenging free radicals and promote chemical repair by restitution. Because of the short life of free radicals, the radio protector must be present at the time of irradiation. Their behavior with respect to LET is analogous to the oxygen effect, strong for the low-

LET radiations and minimal for the high-LET radiations. Like the oxygen effect, the maximum dose reduction factor would be 3. The nausea and vomiting produced by cysteine and cysteamine are reduced by covering the SH moiety with a phosphate. Such a compound is activated intracellularly by metabolic removal of the phosphate. The best of the synthetic compounds is WR2721 which is S-(2-(3-amino propylamino)) ethylphosphothioic acid (28). Its effectiveness depends on penetration of cells. Its failure to protect the central nervous system is due to the blood–brain barrier. Radioprotective agents do not have important uses. For practical reasons they are of no help in radiation accidents, where the administration is necessarily delayed. Their use for anticipated exposure is limited by hypotensive toxicity. Use in cancer radiotherapy is problematic because benefit requires protection of normal tissues but not the tumor which cannot be readily determined except after the fact.

Ionizing Radiation

8 Let and RBE
As indicated earlier, gamma and X rays are sparsely ionizing; there is substantial separation of the ionization in tissue. Particulate radiation such as alphas, protons, and neutrons are densely ionizing because they produce dense columns of ionization (29). LET refers to the energy deposition per micron of path length. Typical values are 0.3 keV/mm for 1 MeV gamma rays, 2 keV/mm for 250 keV X rays and 100–2,000 keV/mm for heavy charged particles. The relative biological effect (RBE) is the ratio of doses for equal biological effect for a given type of radiation relative to the benchmark radiation of 250 keg X rays. RBE increases with LET to a peak of 100 keV/mm and decreases at higher LETs (30). The reason for this pattern is that at 100 keg/mm the average separation between ionizations is about 2 nm which is similar to the diameter of the DNA helix, thus maximizing the efficiency of a double-strand break. LETs less than 100 keg are more likely to produce single-strand breaks that are more readily repaired than double-strand breaks. LETs higher than 100 keg represent overkill for double-strand breaks and are less efficient and more wasteful of radiation dose.

The RBE for high-LET radiation compared to low-LET radiation increases at lower doses because of the shoulder in the dose–response curve for low-LET radiation, whereas the high-LET radiation is linear. Hence, RBEs are not dose invariant. RBEs differ according to tissue type and tend to be higher where DNA repair is rapid for sublethal damage so that the shoulder on the dose–response curve is broad. The oxygen enhancement ratio (OER) is about 3 for low-LET radiation. It decreases when the LET reaches 30 keV/mm and reaches unity at 160 keV/mm (31).

9 Whole Body Radiation Syndrome
The duration of survival and the nature of the effects of brief whole body exposure to penetrating ionizing radiation is related to dose. Most of our information on the whole body radiation syndrome in humans has been the result of accidental nuclear criticality incidents and the study of atom bomb survivors (32).

At the highest doses in the domain of ten thousand rads (100 gray), the reaction is immediate. One example is that of an individual who worked in a uranium-235 recovery plant. Uranium 235 is the fissionable isotope of the uranium-238 decay chain. Late Friday afternoon, he inadvertently poured a

container held under his left arm, filled with a solution of ^{235}U-enriched uranium, into a barrel already containing a similar solution. He apparently lost track of how much fissionable material the barrel contained. The amount he added exceeded criticality. There was a blue flash as the liquid exploded, and he was drenched with the radioactive fluid. He immediately became disoriented. His coworkers did a partial decontamination. He was taken by ambulance to a series of hospitals which refused admission. An admitting hospital was finally located, and he was installed in an evacuated emergency ward, placed on a rubber sheet and further decontaminated by sponging with wet towels. During the night, his blood pressure dropped sufficiently to warrant continuous intravenous vasopressor medication. The next morning, his left arm and the left side of his face abruptly became severely edematous. In spite of the vasopressor medication, he went into irreversible shock and died that afternoon about 22 hours after exposure. This pattern is known as the central nervous system/cardiovascular syndrome. The disabling effect of high doses of radiation on the function of the nervous system was the basis for considering the wartime use of atomic weapons to disable pilots.

The gastrointestinal syndrome predominates at doses of about 1000 rads (10 gray). It is expressed as a cholera-like syndrome that results from denuding the lining of the small intestine. Nausea and vomiting are immediate and intense. Diarrhea begins in a day or two. If not treated, the outcome is fatal in about 9 days. The reason for the GI syndrome is the radiosensitivity of the stem cells of the crypts of the intestinal villi. These villi are numerous finger-like projections of the intestinal mucosa that enormously increase the absorptive capacity of the small intestine. As the stem cells reproduce, the daughter cells move up the villi, undergo differentiation, and eventually slough off the tips of the villi. The proliferating stem cells at the base of the villi are more radiosensitive than the postmitotic cells on the villi. The effect of the radiation is to cut off the supply of new cells on the villi. After a number of days, the surface of the intestine is denuded. Transmucosal water transport is deranged, and fluids pour into the lumen of the intestine causing diarrhea which can be bloody. Supportive therapy with fluid replacement and antibiotics to restrain bacterial growth in the gut can be helpful but the damage at doses of 1000 rads or greater is too severe to permit survival. Death can supervene before the lethal consequences of hemopoietic damage take effect.

The radiation dose required to kill half the population of humans (LD_{50}) is about 400 rads if no medical treatment is used. With treatment by antibiotics and the use of sterilized environments, the LD_{50} is about 800 rads. The cause of death is the hemopoietic syndrome or bone marrow death.

The mechanism is similar to the GI syndrome. The stem cells in the bone marrow are more radiosensitive than their differentiated offspring, and they stop replicating. There is a drop in the concentration of circulating blood cells which is a function of the life spans of the various types of blood cells. The drop in red blood cells is slow because of the 120-day life span of mature erythrocytes. Adult lymphocytes are unusual in being directly destroyed by radiation, and their disappearance from the blood is precipitous. Leukocytes and platelets fall in a matter of 2–3 weeks. When the concentration of leukocytes and platelets falls to critical levels, the irradiated individual develops infection particularly in the mouth and oropharynx and bleeding of the skin (petechia) and from the kidney into the urine. Transfusion of bone marrow cells has been used to treat the hemopoietic syndrome by replacing stem cells of the marrow. There is a relatively narrow window for success. Doses at or greater than 1000 rads are lethal because of the GI syndrome, and doses up to double the LD_{50}, 800 rads, are recoverable with medical treatment. So the dose range where bone marrow transfusion is life-saving is between 800–1000 rads. The dosimetry of radiative accidents is generally uncertain, so the need for bone marrow transfusion is mostly with high-dose radiotherapy of disseminated cancer such as leukemia. The required bone marrow dose is on the order of 2×10^9 cells.

Ancillary damage with the whole body radiation syndrome on the order of the LD_{50} is hair loss because of the relatively high sensitivity of cells in hair follicles. This sensitivity was the basis for

the Adamson–Keinbock method of depilation of the scalp by X radiation for treating scalp ringworm (*Tinea capitis*). Previous to this, the hair was pulled out manually to decontaminate the scalp of the fungus. Hair grew back in a few months.

Ionizing Radiation
Roy E. Albert, MD

10 Heritable Effects
As indicated earlier, ionizing radiation can produce genetic damage by chromosomal breakage or single base pair changes (point mutations). Classic studies by Muller in the 1920s on *Drosophila* demonstrated the linearity of the dose–response for mutations (33). There was no effect of dose rate or fractionation. Effects on the male gametes depend on the stage of sperm development, and mature sperm (spermatogonia) are the least sensitive, and dividing meiotic cells are eight times more sensitive. Oocytes are relatively insensitive. Concern about the applicability of these data to humans led to massive studies of millions of mice by the Russells at Oak Ridge (34). Using a number of specific traits such as various hair colors, they confirmed the linearity of the dose–response but found that, unlike *Drosophila*, there is a pronounced dose–rate effect that amounts to a reduction factor of 3 in dose for a given level of mutagenic effect.

The female is so much less sensitive than the male that for practical purposes almost the entire burden of radiation-induced mutations falls on the male. It was found that a delay of a few months in conception after radiation in the mouse markedly reduced the number of mutations. Humans are advised to delay conception for 6 months after heavy radiation. This reduction is presumed to be due to a repair mechanism.

Based on the mouse data, the estimated doubling dose in humans, the dose required to double the background incidence of mutations, is about 100 rads (1 gray) (35). Using a variety of indicators, the doubling dose in A-bomb survivors was in the same domain, about 156 rads although the data were not statistically significant (36). The ICRP uses an estimate of 0.6×10^{-4} per rem for radiation-induced hereditary disorders in a working population. The effect of radiation on the induction of congenital malformations is far more important than on heritable effects.

Ionizing Radiation
Roy E. Albert, MD

11 In Utero Effects
Radiation damage at the preimplantation stage leads to fetal death. In the period of organogenesis, radiation causes structural malformations. In the stage after organogenesis, called the period of fetal development, radiation causes growth retardation manifested by low birth weight which may or may not be reversible during childhood. The stages of preimplantation, organogenesis, and the fetal period corresponds to 0–9 days, 10 days to 6 weeks, and 6 weeks to term, respectively, in humans. All in utero effects are due to cell killing, abnormal differentiation, and impairment of cell migration in the brain (37).

Irradiation during organogenesis in mice results in major malformations such as anencephaly, evisceration, and spinal bifida, as well as minor terata such as extra ribs. Humans are apparently not as susceptible as mice to the induction of malformations although some have been reported anecdotally from clinical experience. In the study of Japanese survivors of the A-bomb, growth

retardation, microcephaly, and mental retardation have been encountered (38). The occurrence of mental retardation peaked at 8–15 weeks (fetal age) of irradiation. There was a fairly linear dose–response relationship that reached 60% at doses in the range of 135 rads (39). Before and after this period of fetal development, radiation produced little mental retardation. Radiation before 8 weeks can lead to microcephaly without mental retardation. The dose response for mental retardation suggests a threshold at 25 rem.

Minimal doses with effects on the embryo and fetus include oocyte death in primates (LD_{50} = 5 rads), CNS damage in mice at 10 rads, brain damage in rats at 6 rads, small head circumference in humans at 6 rads (38).

The NCRP recommends that the maximum permissible dose during the entire gestation period in women should not exceed 0.5 rem and the monthly exposure should not exceed 0.05 rem (40). The data on mental retardation suggest that a reduction in IQ would be undetectable at 10 rads. Exposure of the conceptus/fetus during the period 10 days to 26 weeks, which is the period of sensitivity to malformations, reduction in head circumference, and mental retardation, to radiation above 10 rads should raise concern about the advisability of therapeutic abortion.

Ionizing Radiation
Roy E. Albert, MD

12 Carcinogenesis
Radiation is probably the most thoroughly studied of all known carcinogens in both animals and humans. The impetus for this effort stemmed from the frequent appearance of cancer in X ray pioneers at the beginning of this century, soon followed by the demonstration that radiation can induce cancer in animals. These findings made it clear that radiation is dangerous and that there is a need to protect the large numbers of individuals involved in the extensive use of radiation in medicine and in the atomic energy industry that was developed during and after World War II.

Some generalizations can be made about radiation in relation to other carcinogens. Radiation can induce cancer in virtually every organ of mammalian species but not necessarily in the same species. It can induce cancer de novo in tissues that do not normally develop cancer, and can accelerate the spontaneous occurrence of cancer. The kinds of cancers that are induced by radiation do not differ from those that occur spontaneously or are induced by other carcinogens. This makes it difficult to detect small carcinogenic effects of radiation. Radiation behaves like other carcinogens. Higher doses elicit tumors faster than low doses. As with other carcinogens, there is a substantial delay from the onset of exposure to the induction of cancer by radiation. As with other carcinogens and with spontaneous cancer, the latency is a function of the life span of the species in which cancer is induced; the shorter the life span, the shorter the latency. Latency in humans is a matter of years and can range from a few years up to about 40 years, depending on the target organ and the level of exposure. For example, leukemia induction in Japanese atom bomb survivors began to appear in a few years, whereas excesses of solid tumors in this group did not begin to appear until several decades after exposure. Most cancers take on the order of 15 years to develop after the onset of exposure. Most cancers induced by radiation or chemicals, once started, continue to appear unabated over the lifetime. Leukemia induction by radiation is an exception because it peaked at 5 years. Among chemical carcinogens, bis-chloromethyl ether was also unusual in having a wave of tumor induction in humans. The cause of either the continuous or limited response pattern is not known.

All of the types of radiation can produce cancer if they penetrate to the target cells of the target organ. Generally, high-LET radiations have a linear dose–response pattern, whereas low-LET radiations generally have a linear quadratic shape. This makes the RBE of high-LET radiation

greater in the low-dose range. Radiation can induce cancer by external exposure or internal exposure from implanted isotopic sources or from inhaled or ingested radioactive isotopes.

The mechanism of action of radiation is similar to that of chemical carcinogens in their ability to damage DNA with the activation of oncogenes or the deactivation of tumor suppressor genes. The former involves a “single hit” process. Activation of an oncogene on one allele is tumorigenically sufficient. By contrast, it is necessary to deactivate both alleles of tumor suppressor genes to induce cancer most effectively.

Radiation interacts with other environmental carcinogens. For example the interaction between irradiation of the lung by radon and cigarette smoking is multiplicative and therefore far larger than the effects of either agent separately.

The induction of cancer by radiation is similar to other biological effects in terms of the importance of repair processes. Generally, there is a comparable reduction in the effectiveness of cell killing and tumorigenesis by low-LET radiation with split-dose or low-dose rate exposures. No such effects occur with high-LET radiation. There are exceptions to this generalization such as the more efficient induction of lymphoma by split X ray doses in mice (41) and increased cell killing and tumorigenesis with neutron radiation.

Radiation is unusual among carcinogens in that a single dose can induce cancer, whereas with chemical carcinogens, repeated doses are required to induce tumors. Tissue damage is a common accompaniment to the induction of malignancy.

Although these generalizations are valid, they do not give the flavor of the complexity of tumor induction in individual tissues, different species, and by different kinds of radiation. We illustrate the point by considering skin cancer induced by radiation in the rat, compared with the mouse and humans.

12.1 Skin Tumorigenesis

With single beta-ray exposures of the back of the rat, radiation induces a wide variety of tumor types, most of which resemble the differentiation patterns of various parts of the hair follicle: the sebaceous glands, the external sheath, the hair germ, and the squamous keratinization pattern (squamous carcinomas) of the upper part of the hair follicle or the surface epidermis (42). There are also tumors whose cells are undifferentiated that arise from the hair follicles and from the surface epithelium. All of these tumor types are seen in humans, but with radiation of the scalp most of the tumors are of the basal cell variety; squamous carcinomas arise from irradiation of relatively nonhaired parts like the hands. Squamous tumors are the only type induced in the mouse skin with radiation (43). Skin tumors in the mouse therefore have a more limited range of differentiation than in either the rat or human.

The dose–response pattern in the rat does not fit any simple formulation, linear quadratic or dose square. The dose–response has a sigmoid shape with a sharp peak and a rapid fall with further increases in dose. The fall is associated loss of viable skin due to increasingly severe and extensive ulceration with progressively narrower scars. The tumor types also change with increasing dose. Hair follicle tumors are not formed in the ulcerating dose range, only squamous carcinomas. The growth rate of the tumors increases with dose even among the squamous carcinomas. In the high-dose range, the rats generally carry one or two large squamous carcinomas on their backs. In the lowest tumorigenic dose range, all of the tumors are sebaceous cysts that look like clusters of mature sebaceous glands. The clumps of overreplicated sebaceous glands are nodular. These quasi-tumors give way at higher doses to the less differentiated hair follicle and squamous tumors. Hence, this rat skin model is not consistent with the stochastic concept of carcinogenesis, namely, that malignancy is independent of dose, that is, only the incidence is a function of dose. Similarly, in the harderian gland tumor model, the lesions are more benign at low dosage, although of the same histological type (44). The relationship of dose to malignancy is insufficiently studied in the field of both radiation and chemical carcinogenesis. Its importance relates to the cancer risks of low levels of

exposure to carcinogens.

The hair follicle tumors in the rat can be seen histologically to arise from atrophic hair follicles at a ratio of about one tumor per 2000 atrophic follicles. The follicles are completely eliminated at higher doses where the tumor type is limited to squamous lesions. This suggests that the differentiation pattern of tumors reflects that of the surviving cells. The shapes of the dose–response for tumors and hair follicle damage are very similar. The both have the typical sigmoid shape of toxic responses.

The mouse is different from the rat. With increasing dose, the hair follicles survive intact up to the point where they are obliterated completely. There is no intermediate form of partially killed (atrophic) follicles. This is apparently the reason that the mouse does not develop hair follicle tumors. The tumor induction in the mouse appears at dose levels that eliminate hair follicles.

Chemical carcinogens show a different response pattern in the rat, as illustrated by a study with the polycyclic aromatic carcinogen, anthramine. No hair follicle killing was observed, but there was a profuse yield of hair follicle tumors and squamous tumors. Thus, the association of hair follicle atrophy would seem to rest on the similarity of the dose response for cell killing and malignant cell transformation, not the role of tissue damage in the cause or enhancement (promotion) of tumor induction (R.E. Albert, personal communication).

The skin is markedly sensitive to the depth of penetration of radiation (45). This was first noted with proton irradiation of rat skin where doses up to 10,000 rads to the skin surface produced no tumors. The penetration of the proton radiation was only about 200 microns. Subsequent studies showed that with electron radiation, tumor formation increased for equal surface doses when the penetration of the radiation was increased by increasing the energy of the electrons. Subsequent studies showed that the effects of penetration depth could be reconciled by relating the tumor responses to the dose at a depth of 330 microns in the skin. This is the location of the hair follicle bulge region that contains the stem cells for the hair follicles. Thus, the tumor response is related only to the dose to the stem cells. This finding has subsequently been confirmed by studies of chemical carcinogenesis. It is now commonly assumed that the target cells for tumor induction in every tissue are its stem cells.

Split doses with low-LET radiation showed dramatic reductions in tumor formation indicating the importance of repair processes. Increasing the intervals between the two doses from 1 to 24 hours demonstrated that the repair has a half-life of about 2 hours (46). This is consistent with the time required to repair double-strand breaks in DNA, suggesting that the dominant process in skin tumorigenesis is chromosomal damage. Skin exposed to high-LET radiation such as accelerator-produced argon nuclei showed no repair with split doses. Apparently, the amount of damage to DNA by high-LET radiation is too great to repair.

The characteristics of tumors are so closely linked with those of the parent tissues that cancer is frequently considered a collection of individual diseases that have some features in common. Although this is an exaggerated idea, it conveys the point that extrapolation of carcinogen-induced responses of one tissue to another should be done with circumspection.

12.2 Epidemiological Studies

Many epidemiological studies have been done to characterize the nature and magnitude of the carcinogenic effects of radiation in humans (47). These populations include Japanese atom bomb survivors and patients treated by X radiation for ankylosing spondylitis, acute mastitis of the breast, tinea capitis infection, and thymic enlargement in infants. Follow-up studies have been done on children whose mothers were given X-ray pelvimetry when they were in utero, as well as women who had repeated fluoroscopic examinations for tuberculosis in relation to their breast cancer experience. Studies have been done on uranium miners and miners of other ores that are contaminated with uranium to determine the effect of radon exposure on lung cancer induction. Women who were occupationally exposed to radium were studied for bone cancer, and a number of studies have been done on radiation workers in the atomic energy industry to determine their cancer experience at low levels of exposure.

Only a relatively few studies characterize dose–response relationships in radiation-induced cancer in humans. The rest are useful for giving estimates of risk at one specific dose level.

Two approaches have been used to characterize cancer incidence or death rates in epidemiological studies. One method is to subtract background cancer from the observed response and to regard the excess as the radiation effect. This is known as the "absolute risk" model. The underlying idea is that the radiation effect is independent of whatever it is that causes background cancer. The alternative method is the "relative risk" model which regards radiation as interacting with whatever it is that causes background cancer. This approach is similar to the doubling dose concept mentioned above in the context of the mutagenic response to radiation. Experience with a wide variety of radiation cancer responses tends to support the use of the relative risk model, although not exclusively.

The kinds of tumor studies that provide dose–response relationships include leukemia, breast cancer, lung cancer from radon and bone cancer from radium.

Leukemia induction has been studied mainly in two populations: atomic bomb survivors in Japan and patients with ankylosing spondylitis, a form of rheumatoid arthritis of the spine, which is treated with X radiation. A wave pattern of leukemia was found in both studies. Leukemia in the Japanese peaked at 10 years after exposure and declined thereafter without returning to normal. The same was true for the spondylitics, except that leukemia began earlier at about 2 years postexposure. Japanese up to 20 years of age at the time of irradiation showed an earlier peak than those over 20 years of age at irradiation with a more rapid decline, so that the overall risk was about the same. The dose–response in the Japanese for leukemia is consistent with a linear nonthreshold pattern with the lowest dose at 40 rem and a peak induction at 300–400 rem. Above this dose range, the incidence declines with increasing dose presumably due to the killing of potentially leukemogenic cells. The relative excess risk was 4.2–5.2. No excess cases of chronic lymphocytic leukemia were observed. The effect was limited mainly to acute and chronic myelogenous leukemia. The leukemia risks in the spondylitics were considerably lower than in the Japanese presumably due to the partial bone marrow exposure, because the radiation was centered over the spine, the radiation was more protracted, and the population was older.

The effect of radiation in inducing breast cancer in women has been studied in Japanese atom bomb survivors, tuberculosis cases that were repeatedly fluoroscoped, and cases of X-irradiated postpartum mastitis. These studies have all shown low-dose linearity of cancer induction. There was no effect of fractionation on the cancer response. The cancer risk was highest in women who were less than 20 at the time of radiation; those over 40 showed no increase in the incidence of cancer. The latency of breast cancer was about 10 years with a peak incidence at 15–20 years after exposure and a peak in mortality about 5 years later. There was no effect of dose on latency. Whether this was due to the relatively short period of exposure is not clear. Short periods of exposure in animals do not show much of a dose effect on latency, compared to chronic lifetime exposure.

Lung cancer has been studied mainly in Japanese atom bomb survivors and uranium miners, as well as in ankylosing spondylitics. There are dose–response data only for the uranium and other underground miners exposed to radon. Here again the dose–response is consistent with a linear nonthreshold character (48).

It is apparent that most of the data on dose–response relationships is linear, suggesting that there is no level of exposure that does not have an associated cancer risk. However, in all of these cases the lowest doses are substantial, for example, 40 rem in the Japanese leukemia data. Hence for radiation protection purposes, it is assumed that the radiative dose response is linear nonthreshold.

A considerable body of information has been accumulated on cancer risks in the absence of dose–response data. There is considerable variation in the radiosensitivity among the various organs, on the order of a factor of 7 at the extremes (47).

Ionizing Radiation

13 Cataracts of the Optic Lens
One of the important nonstochastic late effects of ionizing radiation is damage to the lens of the eye (49). The lens is an onion-structured epithelial tissue located inside a fibrous capsule that is situated immediately behind the pupil. The epithelial cells constitute the outer anterior layer. They divide near the equator of the lens. The replicated cells are displaced inward where they flatten and become transparent fibers. There is no mechanism for removing damaged cells. When the proliferating cells are damaged by radiation, they migrate as opaque granules to the posterior surface of the lens. If the amount of damage is mild as with scattered radiation to the eyeball from tinea capitis radiation, where the dose was about 50 rads, the only observed effect was scattered posterior granules. These had no effect on eyesight. Furthermore, the damage was not progressive (50, 51).

The threshold for sight-impairing cataracts is on the order of 250 rads. Doses of this magnitude and greater produce more extensive opacities on the posterior face of the lens which can become progressive to the point of obscuring eyesight.

The experience with radiation-induced cataracts has been largely with the untoward effects of radiation therapy. Workers around accelerators in the early days were particularly at risk for cataracts because of the high RBE of neutrons (52). The dose response in mice for neutron radiation is linear, unlike that from low-LET radiation. The RBE at high doses is on the order of 10. At low doses, the RBE is in the range of 50.

In humans, the time for developing cataracts depends on the dose and can range from months to decades. The latency is on the order of 8 years for doses between 250 and 650 rads. The reason for the long delay and the progressive nature of some cataracts is not clear. Presumably, it has to do with the delays associated with reproductive cell death, where consecutive normal cell replications can occur before cell death supervenes; the slowly accumulating cellular debris is undoubtedly a factor.
13.1 Other Late Nonstochastic Tissue Effects
Late irreversible and progressive damage to tissues results from clonal depletion of tissue cells with particular reference to blood vessels (53). This process leads to fibrosis and circulatory insufficiency. Depletion of cells can occur in terms of functional subunits, such as, kidney nephrons. Damage to the vasculature can occur at the level of both the larger vessels and the microcirculation. An example of the former is the case of accidental radiation of the lower extremities from cyclotron-produced X rays. This resulted in progressive sclerosis of the major arteries in the lower extremities requiring amputation about 6 months after exposure.

Other examples of late damage include fibrosis and stenosis of the esophagus, fibrous atrophy of the stomach and intestinal mucosa, atrophy of the epidermis of the skin and permanent loss of hair follicles, fibrosis of the lung, and necrosis of the brain. Fractionation and dose protraction generally reduce the effectiveness of low-LET radiation in inducting late tissue damage.

Ionizing Radiation

14 Health Effects of Radionuclides
The health significance of radionuclides lies in their ability to enter the body where their biological

behavior is determined by their chemical properties and their radioactive properties allow them to irradiate tissues in which they localize. Thus alpha- and low energy beta-emitting isotopes, which are essentially innocuous outside the body, can produce radiation damage when taken into the body. The two principle routes of exposure to nuclides are inhalation and ingestion. If the inhaled particles are soluble, they are absorbed promptly from the lung and distributed in the body according to their chemical properties. If insoluble, the particles deposited on the bronchial mucosa are swept out of the lung by ciliary action and swallowed. The particles that are deposited in the air spaces of the lung (alveoli) can remain there for long periods of time if they are sufficiently insoluble, such as thorium dioxide which has a half-life of years. Such particles can be slowly relocated to the pulmonary lymph nodes. Particles that are ingested or swallowed after inhalation can be absorbed from the gut and distributed in the body. Some chemicals such as the actinides, thorium and plutonium, are not absorbed regardless of their solubility.

Of the hundreds of radionuclides only relatively few constitute a source of health concern.

14.1 Nuclear Fission Products

The enormous number of nuclear fragments resulting from the fission of nuclear materials in bombs and fuels in nuclear reactors constitutes a potentially dangerous radioactive source of external and internal exposure. Large-scale release of fission products such as happened at Chernobyl (54) can make large geographic areas uninhabitable for years and is one of the deadliest consequences of nuclear war or reactor accidents. The decay of fission isotopes follows a log-log pattern with a rapid initial disappearance of short-lived isotopes and slower disappearance of the residual long-lived isotopes. Yet the quantities of isotopes are so large in nuclear fuels that liquid storage in tanks requires refrigeration to prevent their boiling and exploding. The core of the earth is molten because of heat from the decay of uranium and thorium. Fallout from atomic weapons testing in this country resulted in the dissemination of two important isotopic health hazards: iodine-131 and strontium-90; these are cancer hazards for the thyroid gland and bone, respectively.

14.2 Radium-226

Radium-226 is one of the elements in the decay chain of the naturally occurring uranium-238 decay chain. Radium-226 has a half-life of 1600 years and decays to the gas Radon-222, and then to a series of bismuth, polonium, and lead isotopes to stable lead (55). Young women painted aircraft instrument dials with luminous paint that contained mainly radium-226 mixed with a phosphor so that the dials would glow in the dark. To paint thin lines, the women tipped the brushes with their tongues and thereby ingested substantial amounts of radium (55).

Metabolically, radium behaves like calcium, and the major site of deposition was in the calcified parts of the bone. Radiation, primarily from the alpha rays, heavily damaged the bone and caused cancer in skeletal and nasal sinuses of the most heavily exposed individuals. Follow-up studies were done on many of the women involving evaluation of the skeletal burdens by measuring radon in exhaled air and direct measurement of the skeletel radium-226 in whole body counters. These coumters are steel chambers on the order of 6 inches thick that reduced the ambient background to very low levels and permit measuring the gamma rays from radium-226 with large sodium iodide scintillation detectors. By following the urinary excretion of radium and successive whole body counts, the effective disappearance of radium from the body was determined to be a log-log function, and back-extrapolation gave the initial body burdens.

The exposure standard for radium-226 was set at 0.1 mCi because no evidence of bone cancer was seen at this level of exposure. The dose–response curve for bone cancer looks like a threshold response (56). When it became evident that strontium-90 from atomic weapons tests was widely disseminated in the environment and from there into milk via grazing cattle, great efforts were made to formulate standards of exposure in relation to radium-226. This was done by comparing skeletal cancer induction by radium-226 with strontium-90 in dogs. It was felt that the dosimetry of these bone-seeking isotopes was too complex to rely on comparisons of the isotopes in terms of absorbed dose. The distribution of the radionuclides was spotty in the bone and partially buried in the calcium matrix, and there was uncertainty about which cells were the targets for cancer induction. Hence the comparison was based on skeletal burdens in relation to tumor induction.

Another isotope of radium, radium-224 (thorium X), a 3.6-day half-life, alpha emitter has been used to treat children with tuberculosis and ankylosing spondylitis. Bone tumors (osteosarcomas) were induced with appearance times of 3–22 years after the initial injection (57).

14.3 Plutonium-239 and Plutonium-238

Plutonium-239 and Plutonium-238 are alpha-emitting man-made elements (48). Plutonium-239 has a half-life of 24,400 years and is the principle fissionable material in atomic weapons. Plutonium 238 has a half-life of 86 years, is intensely radioactive, and is used mainly as a heat source to power thermoelectric devices such as cardiac pacemakers and batteries for use in space vehicles.

Plutonium localizes principally in the liver and skeleton. Like other actinides (thorium), plutonium is taken up on the trabecular and periosteal bone surfaces not in the calcium matrix like radium and strontium. In the bone, plutonium is in relatively close proximity to cancer-inducing target cells and is a formidable bone carcinogen. Both the GI tract and the skin are impermeable even to the soluble forms of plutonium, except for penetrating wounds of the skin, and the main route of exposure is by inhalation. The residence time of insoluble forms of plutonium in the lung is a matter of years, a half-life of 1500 days. With high levels of exposure in dogs, there is induction of pneumonitis, followed by pulmonary fibrosis and lung cancer. With inhalation exposure to soluble plutonium, there is rapid redistribution to the liver and skeleton and induction of cancer in both organs. Although five thousand to ten thousand people have been exposed to plutonium in the atomic energy industry, the levels have not been sufficient to cause perceptible injury to date.

14.4 Iodine-131

Iodine-131 is a beta-gamma emitting fission-product isotope with a half-life of 8 days that attracted a great deal of attention because of its wide dissemination via milk from atomic weapons testing (58). Even with atmospheric tests of atomic weapons as far away as the USSR, iodine-131 was easily measured in the thyroid glands of children living on the east coast of the United States. Like strontium-90, iodine-131 posed a cancer threat to children.

Iodine is a component of the thyroid hormone and is concentrated in the thyroid. Thyroid uptake of radioiodine, as measured by external gamma-ray counting, is used as a diagnostic test of thyroid function. Its localization in the thyroid gland is also the basis for treating hyperthyroidism by destroying thyroid tissue to reduce the production of thyroid hormone. Thyroid tumors can be induced by ionizing radiation, especially in children. This was shown in children whose thyroid glands were exposed in association with irradiation of the thymus gland as infants (59). External exposures of the thyroid gland at doses as low as 5–10 rads in children who were treated by X radiation for ringworm of the scalp showed in the induction of thyroid adenomas and carcinomas (60). However, equivalent average doses of radiation from iodine-131 have not produced tumors of the thyroid gland. This apparent discrepancy may be due to inaccurate dosimetry because some of the beta radiation is lost to the gland when deposited in its outer portions, and much of the radioiodine is in the inert colloid storage areas in the gland where some of the radiation is absorbed. However, there is no question that radioactive iodine can produce cancer of the thyroid gland as evidenced by the study of populations exposed to radioactive fallout in the Marshall Islands and in the USSR from the Chernobyl release.

14.5 Radon-222

Radon-222 and its decay products are the most important radiation hazard to the lungs (61). It was the cause of a mysterious illness known since the Middle Ages as “mountain sickness” among miners in the central European silver mines of Jochimsthal and Schneeberg. The disease was identified as lung cancer only in the 1920s. Since then lung cancer has occurred among domestic uranium miners, Chinese tin miners, and other types of miners of different countries where significant amounts of radon occur.

Radon-222 has a half life of 3.82 days and is the immediate gaseous decay product of radium-226. In turn, it decays through eight daughters of bismuth, polonium, and lead to reach the stable isotope, lead-206. The series has an effective half-life of about 30 minutes down to the sixth daughter, Lead-210, which has a half-life of 22 years and effectively stops radiation in the lung. The series is a

composite of alpha and beta emitters but the alpha radiation accounts for most of the dose. Radon itself, distributes throughout the body and localizes in fat; its dose in the lung is unimportant compared to the radiation dose to the mucosa of the lung from the daughters. Radon decay products are solids and when formed in the air, attach to a considerable extent to smaller airborne particles. The deposition pattern in the lung follows that of the particles to which the daughters are attached except for those that are unattached ions. The ions have a high velocity in air and plate out in the upper part of the respiratory tract, whereas those that are attached to small particles tend to deposit deeper in the lung in the lower part of the tracheobronchial tree and in the alveoli.

Once deposited on the bronchial mucosa, the radon daughters are entrained in the mucus layer that coats the mucosa which is propelled by the beating of the mucosal cilia toward the top of the trachea from whence they are swallowed. The daughters are presumably mixed in with the mucus as it is being transported. The alpha particles are the most important component of the radiation, but their penetration is limited to about 70 microns which barely reaches the basal cells of the mucosa; these cells seem to be the target cells for cancer induction, but this is not known for sure. Inhalation of the analog of radon-222 daughters, namely, the gamma-emitting daughters of thoron-220 which have an effective half-life of 10 hours, did not show any clearance from the lung at all (62). It was not possible with the scintillation counting equipment available at the time to determine whether there was any redistribution in the bronchial tree. It is evident that the dosimetry of radon daughters is complex and uncertain.

Of environmental importance is the fact that some homes are situated on radium-rich soils which emit substantial amounts of radon gas into the homes. Using a linear dose–response model based on the radon cancer data in mines and extrapolating the risk to homes, it can be estimated that at the average indoor radon levels of about 15 Bq/m^3 (0.1–0.2 WLM), about 5–10% of the total lung cancer incidence can be attributed to radon. In homes on radium-rich soils, where the radon concentration can be 20 times higher, close to 50% of the total lung cancer incidence can be attributed to radon (63). The presumed factor of the greater susceptibility of children to the carcinogenic effects of radiation lends concern to these estimates. However, the dosimetry of radon in mines is crude, and there is evidence for a strong interaction with cigarette smoking in the miners which is applicable to children only in terms of passive exposure to cigarette smoke in the households of smokers.

Ionizing Radiation
Roy E. Albert, MD

15 Background Radiation
Background radiation occurs from sources external to and within the body. External sources include cosmic radiation and gamma radiation from uranium and thorium decay chains in soil, rocks, and building material. Radiation from within the body arises from naturally occurring radionuclides, mainly potassium-40. Naturally occurring radioactive isotopes that originate outside the body and enter the body include the gas, radon, and its decay products that arise from radium-226 deposits in soil that are inhaled and carbon-14 which is produced by the interaction of cosmic radiation in the atmosphere. Another source of background radiation stems from the diagnostic and therapeutic uses of radiation.

The effective dose from background sources is the dose in rads (or grays) multiplied by the radiative weighting factor, which is 20 for alpha particles emitted by radon daughters and multiplied by the tissue weighting factor which is 0.12 for the lungs. The annual effective dose to the U.S. population is about 646 millirems of which more than half comes from radon (55%); a total of 82% comes from natural sources: cosmic (8%), terrestrial (8%), and internal (11%). Man-made sources (18%) include

medical X rays (11%), nuclear medicine (4%), and consumer products (3%). Less than 1% comes from other sources, including occupational exposure (0.3%) (64).

The intensity of cosmic radiation is a function of altitude. Radiation in Denver is about twice that of regions at sea level. There are regions of high radiative background on the Colorado Plateau because of the high content of uranium and thorium in the soil and rocks. A number of places around the world have high backgrounds for similar reasons. For example, in Kerala, India, the background is triple that in the United States at 1.3 rem/year. There has been a lack of perceptible increases in cancer or severe heritable defects in such areas, lending credence to the position that restricting excess radiation exposures to levels that are double the background level will ensure that no "detectable" harm will be suffered.

Ionizing Radiation
Roy E. Albert, MD

16 Radiation Protection
Historically, occupational standards were developed separately for radon-222, radium-226, and for whole body exposure.
16.1.1 Radon-222
Setting a standard for radon-222 to prevent lung cancer is complicated by the fact that radon-222 rarely exists in equilibrium with its daughters. The difficulty was circumvented by using, as a unit of radon activity, the *Working Level (WL)*, defined as any combination of radon daughters in one liter of air that releases 1.3×10^5 MeV of alpha energy. This is equivalent to 100 pCi per liter of radon-222 in equilibrium with its daughters. A pCi is 10^{-12} Ci. A Ci is 3.7×10^{10} disintegrations per second (d/s). Therefore 100 pCi is 3.7 d/s for each of the isotopes in the decay chain. Most of the dose to the tracheobronchial mucosa comes from the alpha-emitting isotopes, polonium-218 (Ra A) and polonium-214 (Ra C'). When the disintegration rate equivalent to one WL continues for a working month, which is 170 hours, the cumulative exposure is called a Working Level Month (WLM). So far as the tracheobronchial mucosa is concerned, a WLM is a total dose from about 1.5×10^7 disintegrations of Ra A and Ra C'. This number of disintegrations can occur during any period of time, for example, a year. The dose to the bronchial epithelium is 0.2 mrem/year per pCi/L using a radiation weighting factor of 20. The occupational standard for radon-222 is 4 WLM per year. This is equivalent to a bronchial dose of 80 rem/year (65).

Radon in homes in the United States averages from 0.5–1.6 pCi/L and 2.7 pCi/L in Scandinavia. The U.S.EPA has set an "action level at 4 pCi/L suggesting that remedial action should be taken at levels higher than this. This affects 1 in 12 homes in the United States, a total of about 6 million. The action levels in Europe are 2 to 5 times higher. The EPA action level of 4 pCi/L is 100 times lower than the occupational standard. This action level translates into an effective dose of 0.8 rem/year and a cancer risk of 4×10^{-4}/year. Despite the complexity and uncertainty of the lung dosimetry, these crude dose estimates for the occupational standard are far higher than those permitted for external exposure. The bronchial dose associated with the EPA action level for background radon exposure is far higher than the background exposure from other sources.
16.1.2 Radium-226
A standard for radium-226 was based on studies of radium dial workers. The standard is a maximum body burden of 0.1 mCi. This value was picked because at that body burden, no cases of bone cancer were observed. Subsequently, the standards for other bone-seeking isotopes were derived mainly from dog studies that compared the potency of radium-226 with strontium-90 and plutonium-239. The dosimetry of radioisotopes in bone is so complex that the standards were based on skeletal burdens rather than on dose estimates.
16.1.3 External Radiation Standards

External radiation standards were originally focused on preventing acute responses, first skin erythema in the 1920s. Later, with higher energy X-ray machines, the concern shifted to deeper tissues, particularly the bone marrow, as manifested by depressed white blood counts. Subsequently there was a shift to preventing more sensitive responses, namely, cancer and mutations. Today, standards are based largely on preventing cancer. All of these changes were accompanied by progressively lower standards.

As indicated earlier, the absorbed dose is absorbed energy per gram of tissue (100 ergs/gram). The absorbed dose is expressed in rads or Grays (Gy = 100 rads). The radiation weighting factor (Wr) is based on the RBE combined with judgment factors about the relative effectiveness of different kinds of radiation at low doses. The radiation weighting factor converts the absorbed dose to equivalent dose measured in rems or sieverts (Sv = 100 rems). The radiation weighting factor for gamma rays and electrons = 1; protons = 5; alpha particles, fission fragments and heavy nuclei = 20; neutrons = 5–20, depending on energy (66).

The concept of effective dose is used for stochastic effects (cancer and hereditary effects) with uniform whole-body radiation. It is a measure of the total harm that can be ascribed to the sum of the deleterious effects on individual organs. Therefore, effective dose is the sum of the equivalent dose multiplied by the tissue weighting factor (W_T) for each organ. $W_T = 0.20$ for the gonads; 0.12, for the colon, lung and stomach; 0.05 for the bladder, breast, liver, esophagus, and thyroid; 0.01 for the skin and bone surfaces; and 0.05 for the remainder (66).

The concepts of committed equivalent dose and committed effective dose are applied to internally deposited radionuclides where the total dose is obtained by integrating over a period of 50 years.

The concept of collective equivalent dose and collective effective dose is used to express the radiative dose to an exposed population. It is the average individual dose multiplied by the number of people exposed. When combined with the cancer risk per unit dose, for example, the collective dose gives the number of people who will get cancer. The collective equivalent dose is expressed in person-rads or person-Gy and the collective effective dose is expressed as person-rem or person-sievert.

The basic NCRP occupational whole body radiation standard is 1 rem/year (0.01 Sv/year). Occupational radiation exposure is not permitted under the age of 18, except for training purposes when the limit is that for the general population described later. The maximum occupational exposure in any one year, as an effective dose, is 5 rem (0.05 Sv). Extra exposure is allowed for limited areas of the skin (50 rem/year) and 15 rem/year for the lens of the eye. Emergency occupational limits up to 50 rem/year are allowed but with subsequent restrictions on exposure. Occupational exposure of the fetus after pregnancy is declared should be no more than 50 millirem/month (0.0005 Sv/month).

The limit for general population exposure is 0.1 rem/year (0.001 Sv) or 0.5 rem/year if such exposure is very infrequent. Individuals under the age of 18, if in occupational training, are allowed the general population exposure limit.

A uniform whole-body exposure to a population is estimated to produce a total detriment of 5.6×10^{-4}/rem. This is made up of the sum of 4×10^{-4}/rem for fatal cancer and equal contributions from nonfatal cancer and hereditary effects of 0.8×10^{-4}/rem each. The comparable figures for the general population are somewhat higher because of the higher sensitivity of the young, namely, 7.3×10^{-4}/rem, which is made up of 5×10^{-4}/rem for fatal cancer, 1×10^{-4}/rem for nonfatal cancer, and 1.3×10^{-4}/rem for hereditary effects (66).

A negligible individual dose is one millirem (0.01 mSv). This is the dose below which further

expenditure to improve radiative protection are unwarranted. It carries a risk of between 10^{-6} and 10^{-7} of carcinogenesis or heritable effects.

For occupational radionuclide exposures, the Annual Limit On Intake (ALI) (67) is the maximum intake in a year whose committed equivalent dose would not exceed the occupational limit.

All of the radiative standards are coupled with the ALARA principle: as low as reasonably achievable, given economic and social factors. This makes the standards upper limits of exposure. The concept is that all exposure is potentially harmful. No unnecessary exposure should be allowed. Facilities should be designed to keep exposure to a minimum and not as much as the standard. No exposure should be permitted unless risks, benefits, and alternatives are considered.

Metallocenes

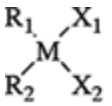
Gary P. Bond, Ph.D., DABT

1 Introduction to Metallocenes

Metallocenes are organometallic complexes with a central metal atom attached to aromatic ligands. Group II iron, which has a 2+ valence, was in one of the earliest metallocenes, but group IV metals such as titanium are currently more common. For group IV metallocenes, halides (e.g., chlorine), pseudohalides (e.g., carboxylates), or other similar molecules can also be attached to the metal. There is some debate among metallocene scientists whether one or two aromatic ligands are required for the complex to be a metallocene, but it is currently generally accepted that two aromatic ligands attached to the metal are a basic definitional criterion for metallocenes (1).

Metallocenes have been used as chemical intermediates, antiknock additives to gasoline, lubricants, and for other uses, but the main current application is as catalysts in the plastics industry. Metallocenes are also currently being actively investigated as a cancer treatment agent. Catalysts, substances that initiate or speed up desirable chemical reactions, have made possible the development of several modern plastic polymers. Metallocene catalysts are improved over the initial plastics polymerization catalysts of the 1950s of Karl Ziegler and Giulio Natta (Ziegler–Natta catalysts), which catalyzed polymerization of ethylene and propylene into polyethylene and polypropylene. Metallocenes provide better control of polymerization, making it possible to create plastics with physical properties designed for particular uses. For example, precise control over polymer growth allows making plastics that are durable for gearwheels or can withstand high temperatures for piping. The billions of pounds of plastics produced and sold every year can be light, waterproof, resistant to corrosion, and used in such items as water pipes, trash bags, hair combs, fibers for clothing and road construction, and packaging for food and medicines, just to name a few uses.

Metallocene catalysts, first synthesized in 1953 by John Birmingham, contain a metal. Unlike the Ziegler–Natta catalysts, metallocenes contain just a single atom of metal. The basic metallocene structure is



$R_{1,2}$ = cyclic group (e.g., cyclopentadiene, indene, fluorine, other)
M = metal (e.g., Ti, Vd, Hf, Mo, Zr, other)
$X_{1,2}$ = halide, carboxylate, NCS, N_3, other

The metal is frequently titanium or zirconium but can be hafnium, tin, germanium, or another group IV metal. Group II metals, chromium, cobalt, and iron, can also be the metal in the metallocene. Group IV metals are linked to two rings of carbon atoms (e.g., cyclopentadienyl or a wide variety and complexity of other cyclic molecules), which can be linked to one or more other groups. These other groups are often other carbon atoms with attached hydrogens (2). The other carbon-based groups attached to the cyclic molecules can also vary in complexity from methyl groups to longer chain carbon groups, some with unsaturated double bonds. For a more complete and thorough description of the chemistry of the metallocene catalysts refer to such technical references as the Kirk–Othmer Encyclopedia of Chemical Technology (3). Because of the widespread production of plastics via metallocene catalysts, metallocenes have become worthy of consideration for potential effects on the worker and the workplace. The antitumor effects of metallocenes underscore the importance of this consideration for protecting workers from workplace chemicals that interact with nuclear material and the cellular duplication process. Two important examples of metallocene catalysts discussed in this chapter are ferrocene and titanocene. Ferrocene, an atypical group II metallocene that has iron (Fe) as the central metal with two cyclopentadiene cyclic groups has no halide groups and is considered first because it was one of the early metallocenes. Ferrocene is the first metallocene to have the “sandwich” structure created by two cyclopentadiene rings attached to the metal. Titanocene, with group IV titanium as the metal, has two cyclopentadiene rings and two chlorine molecules attached to the metal. Little toxicological data are available at present for most metallocenes and limits the number of metallocenes covered in this chapter. If metallocenes are developed into anticancer agents for humans, the amount of available toxicological data will certainly increase. The initial chemical listed, dicyclopentadiene, although not a metallocene, is presented as a baseline for its health effects, and the intention is to compare it to dicyclopentadiene iron and the other metallocenes presented.

Metallocenes
Gary P. Bond, Ph.D., DABT

2 Metallocenes as Cytostatic Anticancer Drugs
Numerous studies have compared the cancer potency and toxicity of several metallocenes (4–14). The anticancer potential of metallocenes has been investigated in cell culture and in intact animals. Metallocene dichlorides were the first organometallic complexes that exhibited both antitumor and antiviral activities. Although early studies considered that they act similarly to the cell cycle arresting agent cisplatinum, later studies suggested that the metallocene dihalides have additional cytostatic mechanisms. Metallocene dihalides form DNA adducts, and they also disrupt DNA, RNA, and protein synthesis. Because of these additional cytostatic effects on cancerous cells at doses that are relatively nontoxic and clearly less toxic than cisplatinum, metallocene dihalides are being considered for development as human cancer treatment drugs for such human cancers as ovarian cancer.

Different structural variants of metallocene dihalides have been tested. *In vitro* testing of group IV metals showed that vanadium is ~ 10- to 100-fold more potent than titanium and molybdenum which were ~ 10- to 100-fold more potent than zirconium and hafnium. Similar potency relationships were observed *in vivo*. Titanium-based metallocene exhibits increased potency compared to the vanadium metallocene.

Metallocenes
Gary P. Bond, Ph.D., DABT

1.0 Dicyclopentadiene
1.0.1 CAS Number: [*77-73-6*]

1.0.2 Synonyms: 1,3-Cyclopentadiene dimer; 3A,4,7A-tetrahydro-4,7-methanoindene; biscyclopentadiene

1.0.3 Trade Names: NA

1.0.4 Molecular Weight: 132.22

1.0.5 Molecular Formula: $C_{10}H_{12}$

1.0.6 Molecular Structure:

1.1 Chemical and Physical Properties (15, 16)
1.1.1 General Dicyclopentadiene is a colorless crystalline solid.

Boiling point	172°C
Melting point	33.6°C
Solubility (at 20° C)	insoluble in water; soluble in 95% ethanol, carbon tetrachloride, acetic acid, and petroleum ether
Flash point	32°C (90°F)
Stability	stable
Density	0.93 g/mL at 35°C
Specific gravity	0.979 at 20/20°C
Vapor pressure	10 mm Hg at 47.6°C
Vapor density	4.55 g/mL
Viscosity	0.736 centipoise at 21°C
	Octanol/water partition coefficient log K_{ow} = 2.89 (estimated)

1.1.2 Odor and Warning Properties Dicyclopentadiene has a disagreeable, camphor-like odor that is not distinguishable from the odor of other hydrocarbons with closely related structures, such as terpenes. Human sensory response studies indicate that dicyclopentadiene can be detected in the range of 0.003–0.2 ppm but does not become noticeably irritating below 10 ppm. It must be inhibited and maintained under an inert atmosphere to prevent polymerization.
1.2 Production and Use
Dicyclopentadiene is produced by recovery from hydrocarbon streams from high temperature cracked petroleum fractions. It is also a by-product of the coke oven industry. Cyclopentadiene polymerizes to dicyclopentadiene on standing. It is used as a chemical intermediate for insecticides, certain (e.g., EPDM) elastomers, metallocenes, paints and varnishes, and flame retardants for plastics (15, 16).
1.3 Exposure Assessment
1.3.1 Air Although no air-specific method of exposure assessment was reported, analysis of products

and residues of dicyclopentadiene can be done by gas–liquid chromatography with a flame ionization detector (16).

1.3.2 Background Levels Dicyclopentadiene has been reported in effluent samples as a result of pesticide production.

1.3.3 Workplace Methods None reported.

1.3.4 Community Methods None reported.

1.3.5 Biomonitoring/Biomarkers None reported.
1.4 Toxic Effects
1.4.1 Experimental Studies 1.4.1.1 Acute Toxicity (15–18) Dicyclopentadiene causes mild to severe eye, skin, and respiratory tract irritation, and severe response of the eyes and skin result from 24-hour exposure. The acute toxicity varies with the route of exposure. The LD_{50}/LC_{50} in mice has been reported as 200 mg/kg (i.p.), 190 mg/kg (oral), and 145 ppm/4 hours (inhalation). The LD_{50} and LC_{50} in rats has been reported as 200 mg/kg (i.p.), 353 mg/kg (oral), and 500 ppm/4 hours (inhalation). The LD_{50} and LC_{50} in rabbits have been reported as 5080 mg/kg (dermal) and 771 ppm/4 hours (inhalation). The inhalation LC_{50} in guinea pigs is 770 ppm/4 hours and the oral LD_{50} in cattle is 1200 mg/kg. Pathological findings following acute lethal exposures were typical for large doses of irritant hydrocarbons, namely, general congestion, hyperemia, and focal hemorrhage in affected organ tissues such as the lung, kidney, and bladder.

1.4.1.2 Chronic and Subchronic Toxicity Rats were exposed to dicyclopentadiene by inhalation for 7 hours per day, 5 days per week for 10 days at levels of 72, 146, and 332 ppm (17, 18). Death, observed only in the highest dose group, included all six males and females by day 4 of dosing and was characterized by convulsions, hemorrhage in the lungs, blood in the intestines, and blood in the thymus (females only). In similarly exposed mice at 47, 72, and 146 ppm, all mice exhibited convulsive deaths on the first day of exposure. Death at 72 ppm occurred in five of six mice of each sex during the 10 days of exposure and was not associated with the convulsions or gross lesions observed in rats. No deaths occurred at 47 ppm and no other effects of treatment were observed. Male beagles (1 per group) were also exposed similarly to levels of 20, 40, and 72 ppm. Signs of toxicity included inactivity at 72 ppm, diarrhea and excessive salivation on day 2 with hind quarter spasticity on day 9 at 47 ppm, and diarrhea at 20 ppm. No treatment-related gross lesions were reported.

Groups of 12 male and female rats were exposed to dicyclopentadiene by inhalation at levels of 19.7, 35.2, and 73.8 ppm, 7 hours per day, 5 days per week for 89 days (17, 18). Some convulsions were observed only in the highest dose group. Mean body weight gains were significantly reduced for the highest dose group through only the first four days of exposure. Organ weights exhibited no clear treatment-related effects. Kidney effects, which included tubular degeneration, were observed in males and females of the two high-dose groups, and males exhibited increased frequency and severity. Three dogs per group of male beagles were exposed using the same dosing schedule of 8.9, 23.5, and 32.4 ppm. Clinical chemistry was the only biological parameter affected by treatment with dicyclopentadiene, and this occurred only at the highest dose. The microscopic pathology of 28 organs and electrocardiograms were normal.

The results of other chronic and subchronic toxicity tests were reported in the literature but could not be confirmed by obtaining the original literature. Refer to various databases in Ref. 16 for additional information.

1.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms (16) In general, although some dicyclopentadiene can be exhaled unchanged, most of that absorbed is hydroxylated in the liver,

undergoes glucuronide conjugation, and is excreted in the urine. When dicyclopentadiene was given by mouth to lactating cows, only trace amounts were secreted in the milk, and the majority was contained in the urine and feces.

1.4.1.4 Reproductive and Developmental (19) The National Toxicology Program (NTP) reported the completion of teratology studies in rats and rabbits at doses of 50, 200, 300, 400, and 500 mg/kg. Dicyclopentadiene was administered by oral gavage. The results of these studies were not available.

1.4.1.5 Carcinogenesis None reported.

1.4.1.6 Genetic and Related Cellular Effects Studies The NTP (19) and the EPA GENETOX (16, 20) programs reported that dicyclopentadiene was negative in the *Salmonella typhimurium* histidine reversion assay.

1.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization None reported.

1.4.2 Human Experience Human sensory responses to dicyclopentadiene were studied in three human volunteers (18). The odor threshold was reported as low as 0.003 ppm. In two of the subjects exposed to 1 and 5.5 ppm for 30 minutes, one subject experienced mild eye and throat irritation after 7 minutes at 1 ppm, and the other subject reported olfactory fatigue after 24 minutes. Eye irritation was reported after 10 minutes, but no olfactory fatigue was reported by either test subject at 5.5 ppm. The researcher interpreted these results to indicate that dicyclopentadiene does not lose its warning properties under conditions of longer exposures. During the conduct of these studies, which also included animal studies as reported in section 1.4, workers accidentally exposed to dicyclopentadiene reported headaches during only the first 2 months of the 5-month study period. No other information was found regarding human effects of exposure to dicyclopentadiene (17, 18).
1.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV for dicyclopentadiene is 5 ppm as an 8-hour TWA. The NIOSH REL is 5 ppm as a 10-hour TWA. The OSHA PEL is 5 ppm as an 8-hour TWA. The ACGIH TLV has been adopted and/or is the same value as standards in numerous other countries such as those in Europe, Australia, Colombia, Jordan, Korea, and New Zealand (15–17).
1.6 Studies on Environmental Impact
None reported.

Metallocenes
Gary P. Bond, Ph.D., DABT

2.0 Ferrocene
2.0.1 CAS Number: [*102-54-5*]

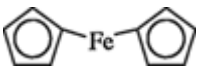
2.0.2 Synonyms: dicyclopentadienyl iron; biscyclopentadienyliron; iron bis (cyclopentadiene)

2.0.3 Trade Names: Catane, Ferrosten

2.0.4 Molecular Weight: 186.05

2.0.5 Molecular Formula: $(C_5H_5)_2Fe$

2.0.6 Molecular Structure:



2.1 Chemical and Physical Properties

2.1.1 General Ferrocene is an orange crystalline solid (16).

Boiling point	249°C
Melting point	173–174°C
Solubility	19 g/100 g benzene, 10 g/100 g catalytically cracked gasoline, 6 g/100 g jet fuel (JP-4), 5 g/100 g diesel fuel, insoluble in water, slightly soluble in petroleum ether
Flash point	unknown
Stability	stable
Sublimes	>100°C
Specific gravity	unknown
Vapor pressure	0.03 mm Hg at 40°C
Iron content	29.4–30.6%

2.1.2 Odor and Warning Properties Ferrocene has a camphor-like odor and reacts violently with ammonium perchlorate. It is classified as a flammable solid.

2.2 Production and Use

Ferrocene is produced from the reaction of cyclopentadiene with reduced iron in the presence of metal oxides. It is used as a catalyst for vulcanization acceleration and polymerization, as a chemical intermediate for polymeric compounds such as high temperature polymers, as an antiknock additive for gasoline, as a coating for missiles and satellites, and as a high-temperature lubricant (16).

2.3 Exposure Assessment

2.3.1 Air NIOSH Methods 173 (21) and 351 (20, p. v7 351-1) are available air sampling methods for iron, and the analytical laboratory methods use atomic absorption and atomic emission spectroscopy, respectively (16).

2.3.2 Background Levels None reported.

2.3.3 Workplace Methods See 2.3.1.

2.3.4 Community Methods See 2.3.1.

2.3.5 Biomonitoring/Biomarkers No information is available for ferrocene.

The use of biomonitoring/biomarkers for iron should be considered in instances of suspected ferrocene overexposure. Refer to the section on iron in this publication.

2.4 Toxic Effects

The toxicological properties of ferrocene have not been extensively investigated. Toxic effects have usually been associated with the iron in the ferrocene, but some data indicate that cyclopentadienyl may be a causative agent in liver cirrhosis (see 2.4.1.2).

2.4.1 Experimental Studies 2.4.1.1 Acute Toxicity Ferrocene may cause eye, skin, and respiratory tract irritation. The LD_{50} in mice has been reported as 335 mg/kg (i.p.), 178 mg/kg (i.v.), 600 mg/kg (oral), and 832 mg/kg (oral). In the rat, the LD_{50} is 500 mg/kg (i.p.) and 1320 mg/kg (oral) (16, 22).

2.4.1.2 Chronic and Subchronic Toxicity Male and female rats and mice were exposed to vapors of

ferrocene for 6 hours/day for 2 weeks at target concentration levels of 2.5, 5, 10, 20, and 40 mg/m^3 (actual levels of 2.33, 5.29, 9.89, 20.02, and 36.47 mg/m^3) (23). No mortality, clinical signs of toxicity, or gross histological effects were observed. Decreased body weight gains in treated versus control animals were observed for the male rats and mice exposed to 40 mg/m^3 ferrocene and the female mice exposed to 10, 20, and 40 mg/m^3. Relative liver weights decreased in male rats (40 mg/m^3). Dose-related decreases were observed in relative liver and spleen weights (male and female mice) and relative spleen weights (female mice). The thymus weights were increased in a dose-related manner in male mice. Nasal turbinates, lungs, liver, and spleen were observed microscopically. The only effect observed was inflammation of the nasal turbinates in both species with a dose-dependent severity. Observed toxic effects from ferrocene inhalation were attributed to iron.

Male and female dogs received ferrocene in gelatin capsules at doses of 30, 100, and 300 mg/kg/day for 6 months and at 1000 mg/kg for 3 months (24). No deaths or urinalysis differences, except for an amber color of urine, were associated with ferrocene exposure. A dose-related accumulation of iron with hemosiderosis was observed (liver, spleen, bone marrow, adrenals, lungs, gastrointestinal tract, lymph nodes, testes). Blood effects (decreased hemoglobin, packed cell volume, and erythrocyte count) occurred within 4 weeks at 300 mg/kg. Liver cirrhosis, considered to be related to the cyclopentadiene, was observed in the 300- and 1000-mg/kg group. Dose-related testicular hypoplasia was observed. Treatment of other dogs with ferrous sulfate determined that only liver cirrhosis was specifically ferrocene-related because the other effects were related to iron overload. No other effects were observed during 12–26 months after treatment ended.

Male and female rats and mice were exposed to vapors of ferrocene for 6 hours/day, 5 days/week for 13 weeks at target concentration levels of 3, 10, and 30 mg/m^3 (actual levels of 3.06, 10.06, and 29.89 mg/m^3) (25). No mortality, clinical signs of toxicity, or gross histological effects were observed. Decreased body weight gains versus control animals were observed in the male rats at 3 and 30 mg/m^3 of ferrocene and in female mice at 3 and 10 mg/m^3. Increases in the lung burden of iron were dose- and time-related. Decreased thymus and testes weights in male rats and liver weights in female rats (3 and 30 mg/m^3) and decreased liver (all doses), heart, and spleen (30 mg/m^3) in female mice were observed. Increased relative liver weights (30 mg/m^3 male rats, 10- and 30-mg/m^3 female rats, and 30-mg/m^3 male mice) and kidney weights (30-mg/m^3 male rats) were observed. Decreased relative liver weights were observed in female mice (3 mg/m^3). No ferrocene-related changes were observed in respiratory function, lung biochemistry, bronchoalveolar lavage cytology, total lung collagen, clinical chemistry, and hematology. Exposure-related histopathological lesions, primarily iron accumulation, were observed in the nose, larynx, trachea, lung, and liver of both species and in the kidneys of mice. Nasal lesions were dose-related in severity and included necrotizing inflammation, metaplasia, and regeneration. Observed toxic effects from ferrocene inhalation were attributed to iron ions released from the ferrocene.

2.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms The metabolism of ferrocene was studied in rats following a 17-minute inhalation exposure (26). Ferrocene deposition was significant in the nasopharynx and lungs. The half-life for clearance of radiolabeled iron was 200 days for the bronchopulmonary region and 70 days for the nasopharyngeal region. Within 24 hours after exposure, 75% of the radiolabeled hydrogen was cleared from the respiratory tract. For the retained radiolabeled iron, 90% was in the bronchopulmonary and nasopharyngeal regions of the lungs, 10% was in the liver, and 1% was in the spleen.

2.4.1.4 Reproductive and Developmental Dose-related testicular hypoplasia was observed in dogs that received ferrocene in gelatin capsules at doses of 30, 100, and 300 mg/kg/day for 6 months and at 1000 mg/kg for 3 months (24). Treatment of other dogs with ferrous sulfate determined that this effect was related to iron overload because administered ferrous sulfate caused similar effects.

2.4.1.5 Carcinogenesis Ferrocene was administered by intramuscular injection at a dose of 5175 mg/kg/2 years. By the criterion established by the Registry of Toxic Effects of Chemical Substances (RTECS), ferrocene was an equivocal tumorigenic agent and tumors were most evident at the site of multiple injections (16, 27).

2.4.1.6 Genetic and Related Cellular Effects Studies Ferrocene was tested for the potential to cause genetic mutations by point and frameshift mutations in bacteria (*Salmonella typhimurium*), by sister chromatid exchange in Chinese hamster ovary cells, and by heritable effects (sex chromosome loss/nondysjunction and heritable translocation test) in *Drosophila melanogaster* (28–30). Results indicate that ferrocene is not mutagenic.

2.4.2 Human Experience None reported.
2.5 Standards, Regulations, or Guidelines of Exposure (16)
The ACGIH TLV for ferrocene is 10 mg/m^3 as an 8-hour TWA. The NIOSH REL is 10 mg/m^3 as a 10-hour TWA for total dust and 5 mg/m^3 for the respirable fraction. The OSHA PEL is 15 mg/m^3 as an 8-hour TWA for total dust and 5 mg/m^3 for the respirable fraction. The ACGIH TLV has been adopted and/or is the same value as standards in numerous other countries. The U.S. EPA, Canada, and Mexico have drinking water standards for iron of 0.3 mg/L.
2.6 Studies on Environmental Impact
None reported.

Metallocenes
Gary P. Bond, Ph.D., DABT

3.0 Titanocene Dichloride
3.0.1 CAS Number: [*1271-19-8*]

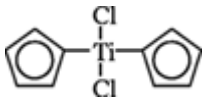
3.0.2 Synonyms: dicyclopentadiene titanium; dichlorotitanocene; bis (cyclopentadienyl) titanium dichloride

3.0.3 Trade Names: NA

3.0.4 Molecular Weight: 248.99

3.0.5 Molecular Formula: $(C_5H_5)_2TiCl_2$

3.0.6 Molecular Structure:



3.1 Chemical and Physical Properties (16)
3.1.1 General Titanocene dichloride is a reddish-orange crystalline solid.

Melting point	289°C
Solubility	moderately soluble in toluene, chloroform, alcohol, and other hydroxylic solvents; sparingly soluble in water, petroleum ether, benzene, ether, carbon disulfide, and carbon tetrachloride
Stability	stable (tetravalent titanium compounds are the most stable of the variable

	valence compounds of titanium)
Density/specific gravity	1.6

3.1.2 Odor and Warning Properties (16) Titanocene dichloride is irritating to the skin and mucous membranes.

3.2 Production and Use

Titanocene dichloride is produced by the reaction of titanium tetrachloride with cyclopentadienyl sodium. It is used as a research chemical, as a catalyst in Ziegler–Natta polymerization reactions, and as an implant material in orthopedics, oral surgery, and neurosurgery. Titanocene dichloride is being investigated as a chemotherapeutic agent (16).

3.3 Exposure Assessment

3.3.1 Air Atmospheric concentrations of titanium have been reported at an average urban concentration of 0.04 mg/m^3 with a maximum concentration of 1.10 mg/m^3 (16, 31).

3.3.1 Background Levels Titanium, an apparently nonessential metal for humans or animals, has been detected in North American rivers at levels of 2–107 mg/L with mean concentrations in U.S. drinking water of 2.1 mg/L. Titanium has been detected in food and seafood (levels unreported) (31).

3.3.2 Workplace Methods NIOSH Methods 7300 (32), 600 (33), and 500 (34) are available air sampling methods for titanium, and the analytical laboratory methods use atomic emission spectroscopy, gravimetric (respirable dust fraction), and gravimetric (airborne particulate matter) procedures, respectively (16).

3.3.3 Community Methods NIOSH method 3111 is available for determining titanium in water and wastewater by using direct aspiration atomic absorption spectrometry (35).

3.3.4 Biomonitoring/Biomarkers (16) 3.3.4.1 Blood None reported.

3.3.5.2 Urine NIOSH method 8310 is available for detecting titanium in urine by using atomic emission spectroscopy (36).

3.3.5.3 Other The estimated body burden of titanium is ~15 mg, most of which is in the lungs as a result of inhalation exposure (31).

3.4 Toxic Effects (16)

The toxicological properties of titanium dichloride have not been extensively investigated. Toxic effects have usually been associated with the titanium.

3.4.1 Experimental Studies 3.4.1.1 Acute Toxicity Titanocene dichloride may cause skin and mucous membrane irritation. The LD_{50} in mice has been reported as 60 mg/kg (i.p.), and 180 mg/kg (i.v.). In the rat, the LD_{50} is 25 mg/kg (i.p.) (16, 22).

3.4.1.2 Chronic and Subchronic Toxicity In studies conducted as part of the National Toxicology Program (NTP), titanocene dichloride was administered by gavage in corn oil to male and female rats for 14 days, 13 weeks, or 2 years (37).

In the 14-day study, titanocene dichloride was administered at doses of 0, 65, 125, 250, 500, or 1,000 mg/kg (37). All high-dose rats and four of the five males and two of the five female rats given 500 mg/kg died during the studies. A dose-related decrease in body weight gain was seen in rats at all but the 65-mg/kg dose. Treatment-related lesions included hepatocellular necrosis, tubule necrosis in the kidney, erosions and ulcers of the glandular stomach, and hyperplasia of the

forestomach epithelium.

In the 13-week study, titanocene dichloride was administered at doses of 0, 8, 16, 31, 62, or 125 mg/kg (37). One female rat in the highest dose group died due to the titanocene dichloride during the fourth week of the studies. Body weight gain was reduced compared to controls in rats given 62 or 125 mg/kg. Histopathological lesions related to treatment with titanocene dichloride were observed in the stomachs of high-dose males and all groups of females. Hyperplasia and metaplasia of the glandular stomach and hyperplasia and hyperkeratosis of the forestomach were observed.

In the 2-year study, titanocene dichloride was administered at doses of 0, 25, and 50 mg/kg (37). These doses were selected based on the stomach and body weight effects observed in the 3-week study. The principal toxic effects of administering titanocene dichloride for 2 years occurred in the stomach. Lesions observed at 15 months were similar to, but less severe than, those observed at 2 years. The lesions included focal erosions of the glandular mucosa, inflammatory responses, hyperplastic and metaplastic responses, and fibrotic changes. Effects were observed in both groups administered titanocene dichloride, but not in control animals. Macrophages with blue-gray pigment accumulated in many organs of dosed rats including the gastrointestinal tract, liver, lung, and lymph nodes. The pigment was believed to contain titanium. Inflammation of the nasal mucosa and lung was also attributed to administration of titanocene dichloride, resulting from reflux and/or regurgitation and aspiration of gavage solution due to the severe stomach lesions.

3.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms 3.4.1.3.1 Absorption Titanium compounds are generally considered to be poorly absorbed upon ingestion and inhalation (38). However, detectable amounts of titanium can be found in the blood, brain, and parenchymatous organs of individuals in the general population; the highest concentrations are found in the hilar lymph nodes and the lung. Titanium is excreted with urine (16).

3.4.1.3.2 Distribution The subcellular distribution of titanium in the liver of mice was determined at 24 and 48 hours after administering titanocene dichloride (39). At 24 hours, titanium was accumulated mainly in the cytoplasm of endothelial and Kupffer cells lining the hepatic sinusoids. Titanium was also detected in the nucleoli and the euchromatin of liver cells. It was packaged as granules together with phosphorus and oxygen. At 48 hours, titanium was still present in cytoplasmic inclusions within endothelial and Kupffer cells, but there were only a few deposits in hepatocytic nucleoli. Titanium was found in hepatocyte cytoplasm, incorporated into cytoplasmic inclusion bodies which were considered most likely to be lysosomes. Location of these inclusions near bile canaliculi with occasional extrusion of the content into the lumen of bile capillaries suggests biliary elimination of titanium.

Titanium concentrations were not elevated in mouse embryos after injection (i.p.) of pregnant mice on day 10, 12, or 14 of gestation compared to untreated controls (40). On day 16 of gestation, after the period of organogenesis, small amounts of titanium were detectable in the fetal compartment in excess of that of controls. These results are consistent with the result of a teratology study in which there was an absence of histological lesions in developing embryonal organs and a lack of multiple teratogenic effects in newborns after application of therapeutic doses of titanocene dichloride to pregnant mice during embryonal organogenesis (see section 3.4.1.4). The teratogenic effect is considered to result from indirect effects on the maternal animal such as altered hormonal status (40–42).

3.4.1.3.3 Excretion (16) Titanium is excreted with urine, and gastrointestinal excretion via the bile is possible (38, 39).

3.4.1.4 Reproductive and Developmental The teratogenic and embryotoxic effects of titanocene dichloride were investigated after intraperitoneal injections of single therapeutic doses of titanocene dichloride (30 or 60 mg/kg) to pregnant mice on days 8, 10, 12, 14, or 16 of gestation (43). The

fetuses were removed on day 18 by caesarean section and examined for external, internal, and skeletal malformations, as well as for toxic effects of treatment. Cleft palate was observed in numerous fetuses (10% of the fetuses at 30 mg/kg; 40–50% of the fetuses at 60 mg/kg) after titanocene dichloride administration on days 10 and 12. Skeletal malformations were observed in some fetuses. No other malformations were observed. Toxic effects of treatment included a decreased number of live fetuses per litter, dose-dependent reduction of mean fetal body weight, and delayed skeletal ossification. The lack of a broad range of effects observed with other cytostatic chemicals was consistent with effects on maternal hormonal status, namely, increased cortisol release (42).

3.4.1.5 Carcinogenesis Based on the results of 2-year gavage studies, the National Toxicology Program determined that there was equivocal evidence of carcinogenic activity of titanocene dichloride in male and female rats based on a marginal increase in the incidence of forestomach squamous cell effects. Refer to study results in section 3.4.1.2 for more details (37).

3.4.1.6 Genetic and Related Cellular Effects Studies (16) Titanocene dichloride was evaluated for mutagenic potential as part of the EPA GENETOX and National Toxicology Programs. Positive and negative mutagenic effects were observed, consistent with the equivocal carcinogenic data and characterization by the National Toxicology Program. The results were as follows:

positive in *Salmonella typhimurium* strain TA100 in the absence of exogenous metabolic activation/S9 microsomal enzymes and negative in TA100 with S9 (44);

negative in all other *Salmonella typhimurium* strains with or without S9 (44);

inconclusive in bacteria *Escherichia coli* polA point mutation assay without S9 microsomal enzymes (45);

negative in yeast *Saccharomyces cerevisiae* host-mediated assay (45);

positive and dose-responsive in mouse cell transformation (45);

negative for sister chromatid exchanges or chromosomal aberrations in Chinese hamster ovary cells, with or without S9 (45);

positive in unscheduled DNA synthesis assay using human fibroblasts (*in vitro*) (45);

positive in SHE-clonal assay and in the transformation of rat embryo cells (45);

positive in neoplastic transformation of a cloned mouse cell line, hamster embryo cells, and virally-infected rat embryo cells (20);

3.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization None reported.

3.4.2 Human Experience The spermicidal activity of several metallocene complexes on human sperm was investigated (46). Of the metallocene complexes investigated, neither titanocene dichloride nor any other metallocenes except vanadium-based metallocenes caused immobilization of sperm.

3.5 Standards, Regulations, or Guidelines of Exposure
None reported.

3.6 Studies on Environmental Impact
None reported.

Metallocenes
Gary P. Bond, Ph.D., DABT

4.0 Vanadocene Dichloride
4.0.1 CAS Number: [*12083-48-6*]

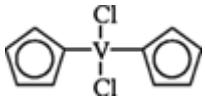
4.0.2 Synonyms: cyclopentadienylvanadiumdichloride, bis; bis (cyclopentadienyl) vanadium dichloride

4.0.3 Trade Names: NA

4.0.4 Molecular Weight: 252.04

4.0.5 Molecular Formula: $(C_5H_5)_2VCl_2$

4.0.6 Molecular Structure:



4.1 Chemical and Physical Properties
4.1.1 General Vanadocene dichloride is a pale green crystalline solid (15, 16).

Boiling point	not available
Melting point	>250°C
Solubility (at 20°C)	10–50 mg/mL in DMSO; <1 mg/mL in 95% ethanol; <1 mg/mL in acetone; soluble in chloroform, ether, benzene, and many organic solvents; insoluble in petroleum ether; slightly soluble in carbon disulfide and carbon tetrachloride
Flash point	not available
Stability	sensitive to air and moisture
Specific gravity	1.60
Density	1.60 g/mL
Vapor pressure	not available

4.1.2 Odor and Warning Properties None reported.
4.2 Production and Use
Vanadocene dichloride is used like other metallocenes as a catalyst, ultraviolet absorber, reducing agent, free radical scavenger, antiknock agent in gasoline, and as a developmental anticancer drug (15).
4.3 Exposure Assessment
None reported.
4.4 Toxic Effects (15, 16)
Little toxicity information was found. The only toxicity reported is in reference to vanadium compounds, which act chiefly as irritants to the conjunctivae of the eye and the mucous membranes of the respiratory tract. The oral LD_{50} in rats was reported at 87 mg/kg. Vanadocene dichloride was tested using the Ames bacterial mutagenicity assay, but the results of the assay were not available by press time.

4.4.1 Experimental Studies Very little data was reported other than those listed in the section on metallocenes as cytostatic anticancer drugs.

4.4.2 Human Experience The spermicidal activity of several metallocene complexes on human

sperm was investigated (46). Of the metallocene complexes investigated, only vanadium-based metallocenes caused immobilization of sperm.
4.5 Standards, Regulations, or Guidelines of Exposure
None reported.
4.6 Studies on Environmental Impact
None reported.

Metallocenes
Gary P. Bond, Ph.D., DABT

5.0 Cobaltocene
5.0.1 CAS Number: [*1277-43-6*]

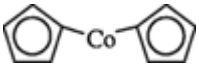
5.0.2 Synonyms: bis (cyclopentadienyl) cobalt

5.0.3 Trade Names: NA

5.0.4 Molecular Weight: 189.13

5.0.5 Molecular Formula: $(C_5H_5)_2Co$

5.0.6 Molecular Structure:



5.1 Chemical and Physical Properties
5.1.1 General Cobaltocene is a black-purple crystalline solid (15, 16).

Boiling point	not available
Melting point	173–174°C
Solubility (at 20°C)	5–10 mg/mL in DMSO; <1 mg/mL in water; <1 mg/mL in 95% ethanol; 50–100 mg/mL in acetone; soluble in other hydrocarbons
Flash point	not available
Stability	sensitive to air and moisture
Specific gravity	not available
Density	not available
Vapor pressure	not available

5.1.2 Odor and Warning Properties None reported.
5.2 Production and Use
Cobaltocene is used to catalyze the synthesis of pyridines from alkynes and nitriles, as a polymerization inhibitor of olefins up to 200°C in Diels–Alder reactions, and as a paint drier and oxygen stripping agent (15).
5.3 Exposure Assessment
None reported.
5.4 Toxic Effects
Little toxicity information was found. The intraperitoneal LD_{50} is 55 mg/kg and 80 mg/kg in the rat

and mouse, respectively. Intramuscular doses of 200 mg/kg intermittently for 60 weeks caused tumors at the dose site. Cobaltocene was classified as an equivocal tumorigenic agent. It was tested using the Ames bacterial mutagenicity assay, but the results of the assay were not available by press time (15, 16).

5.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV and NIOSH REL for cobalt is 0.02 mg/m^3 as an 8-hour TWA. The ACGIH lists an A3 designation for cobalt because it is considered an animal carcinogen. The NIOSH IDLH is 200 mg/m^3. The relevance of the cobalt standard to cobaltocene itself has not been determined (15, 16).

5.6 Studies on Environmental Impact

None reported.

1 Importance of Considering Neurotoxicity

1.1 Neurotoxic Episodes

Neurotoxicity is important to consider as a component of occupational and environmental safety and health programs. The failure to do so has contributed to a number of tragic cases in which workers, consumers of manufactured products, and people exposed in the environment were irreparably harmed by exposure to industrial compounds that proved toxic to the nervous system (1–3). The National Institute for Occupational Safety and Health (NIOSH) has listed neurotoxic disorders as one of the ten leading occupational problems in the United States (4, 5). Many of the most severe environmental, industrial, and commercial human health disasters attributable to chemical exposure have involved neurotoxic effects (6). In Detroit, Michigan, in 1934, for example, an automotive redesign required grinding large amounts of excess lead solder from each car. Inhalation of the

resulting lead dust produced between 2,700 and 4,000 cases of lead poisoning whose symptoms ranged from mild gastrointestinal upset to severe neurological deficits, including peripheral neuropathy and encephalopathy. As many as 12 people may have died. In another case that occurred during the Prohibition Era, a single batch of the popular ethanol-based elixir "Ginger Jake" was adulterated with tri-*o*-cresylphosphate (TOCP). This batch was then distributed throughout the southeastern and midwestern United States. As many as 50,000 people suffered peripheral neuropathy caused by degeneration of the large, long axons in the peripheral nerves of the legs and spinal cord (7). In a food contamination episode, 459 people were killed and more than 6,500 became ill in Iraq from methylmercury which was applied as a fungicide to seed grain intended for planting, but which was instead ground into flour and cooked into bread (8, 9). Methylmercury was also the cause of environmental poisonings in Minamata Bay, Japan, in which industrial effluent discharged into the Bay bioconcentrated in the food chain and eventually led to exposure of thousands of inhabitants who consumed seafood from the bay (10, 11). The effects on Minamata children exposed in utero were particularly severe. Since that time methlymercury poisoning has been referred to as "Minamata disease."

Fortunately, catastrophic disasters are relatively rare occurrences that typically involve exposures to high concentrations of neurotoxic compounds. A more common concern in occupational and environmental settings is exposure to lower levels of potentially neurotoxic compounds, for long periods of time. It is important to consider neurotoxicity in long-term, low-level exposure situations. Many occupational and environmental exposure standards have been established on the basis of effects on the nervous system. There is also concern that subtle neurotoxic damage might not be evident at the time of exposure due to the plasticity and functional reserve capacity of the nervous system but may become manifest later (12–14). Damage inflicted long ago may become evident as individuals age or undergo other stresses. Alternatively, low-level exposure to neurotoxic compounds may cause a progressive accumulation of damage that becomes apparent only over an extended period of time. The possibility that there could be a latent period between exposure to neurotoxic compounds and the time at which functional impairments become evident should be considered.

Neurotoxicology and Behavior
William K. Boyes, Ph.D.

2 General Description of the Nervous System
The nervous system is diverse and complex. It contains many different types of cells, each expresses unique proteins that can act as selective targets for neurotoxic compounds. The cells of the nervous system operate using many different neurotransmitter substances and second messenger systems and interact in complex networks that perform many vital functions. A simplified view of the role of the nervous system is that it receives information through the sensory systems, processes and integrates that information in the central nervous system, and then takes actions through the motor systems. The nervous system also is responsible for regulating many vital life functions through the autonomic nervous system and helps control the neuroendocrine and neuroimmune systems as well. More extensive information on the structure and function of the nervous system can be found in a number of excellent sources such as Kandel et al. (35).
2.1 Structure of the Nervous System
2.1.1 Regions of the Nervous System The nervous system as a whole consists of the central nervous system (CNS) and the peripheral nervous system (PNS). The CNS includes the brain and spinal cord, and the PNS includes the sensory and motor nerves that innervate the many peripheral organs and tissues of the body. Peripheral nerves enter and leave the CNS through the cranial nerves, connecting directly to the brain, and spinal nerves that enter the spinal cord through the dorsal spinal roots (sensory nerves) or leave the spinal cord through the ventral spinal roots (motor nerves). The spinal cord is divided into four sections including the cervical, nearest the head; the thoracic, in the upper

trunk; the lumber, in the lower trunk; and the sacral at the base of the spine. The brain includes the hindbrain that contains the brainstem (the pons and medulla) and the cerebellum, the midbrain, and the forebrain, including the diencephalon (the hypothalamus and thalamus), the cerebral hemispheres and other underlying structures, including the basal ganglia, the hippocampus, and the amygdaloid nucleus. The central nervous system is covered by meninges, a set of three protective membranes called the dura, the arachnoid, and the pia. The CNS is also protected by the blood–brain barrier, which limits diffusion of large and polar compounds from the blood into the CNS.

2.1.2 Cellular Components of the Nervous System The nervous system contains two distinct classes of cells, the nerve cells (or neurons) and the glial cells (or glia). Nerve cells are the primary information-processing cells of the nervous system. The more numerous glial cells serve a variety of roles, including physical structure and support, electrical insulation, metabolic and nutritive activity, maintenance of the extracellular ionic balance, forming part of the blood–brain barrier, and responding to injury.

2.1.2.1 Neurons Neurons come in many different shapes and sizes, but there are general characteristics that are representative for most of them. The cell body contains a nucleus and extranuclear organelles. Two types of structures extend from the cell body: dendrites and the axon. Neurons may have between one and many dendrites, which are typically long, multibranched structures. The dendrites contact other neurons to receive and integrate incoming neural signals. The other structure coming from the cell body is a single axon, which may branch many times, and transmits neural activity from the neuron to other cells. The axon of some neurons is covered intermittently by a myelin sheath, formed by specialized glial cells, that serves to increase the velocity of nerve impulse transmission. The region where one nerve cell transmits information to another is called the synapse. In the CNS, a single cell may have thousands of synaptic contacts with other neurons.

2.1.2.2 Glia There are several different types of glial cells that play complex roles in the normal structure and function of the nervous system and in the response to injury. The major types of glia in the CNS are astrocytes, oligodendrocytes, and microglia.

Astrocytes Astrocytes were named for their “starlike” appearance resulting from the abundance of processes extending from the cell body. Astrocytes are often located between neurons and blood vessels. The foot processes of astrocytes surround the capillaries and play a role in forming the blood–brain barrier. The fibrous type of astrocyte is abundant in the gray matter of the central nervous system and undergoes hypertrophy in response to neural injury.

Oligodendrocytes Oligodendrocytes are the type of glial cell that forms the myelin sheath for axons in the CNS. A different type of cell named the Schwann cell produces myelin in the PNS. One oligodendrocyte may form a myelin sheath around the axons of several different neurons. The myelin sheath is a multilayered spiral wrapping around the axon that is composed of lipid-rich material. This covering electrically insulates portions of the axon and increases the velocity of nerve conduction. The high lipid content of the brain provided by myelin is a reason that lipophilic compounds often show preferential distribution to brain tissues.

Microglia Microglia are the type of glial cells that function as macrophages in the central nervous system. The microglia respond to CNS injury by enlarging, becoming more prolific, and then by phagocytic ingestion of cellular debris. Normally, the CNS is considered “immune privileged,” meaning that the normal blood-borne immunological cells usually do not enter the CNS in response to damage or infection. The presence of immunological cells within the CNS indicates a breakdown of the normal barriers.

2.1.3 Blood–Brain Barrier The concept of a diffusional barrier between the blood and the brain developed from observations that vascular injection of dyes stain many tissues of the body, yet do not stain brain tissues. The so-called blood–brain barrier is a misnomer, however, because it is not an

absolute, but rather a selective or semipermeable diffusion barrier between the blood and the brain. The capillary endothelial cells in the brain are joined by tight junctions and lack the fenestrations and intracellular clefts found in other organs that allow relatively free exchange between the blood and the tissues. In addition, the capillaries of the brain are entirely surrounded by foot processes of astrocytic glial cells. This capillary structure limits diffusion of large and polar molecules from the blood into the brain tissue. The dyes used in the early studies of the blood–brain barrier were largely bound to proteins that could not penetrate into the brain. Smaller lipophylic dyes, however, do cross from the blood into the brain, demonstrating that the blood–brain barrier is relatively permeable to these types of compounds. The physiological role of the blood–brain barrier is the protection of the extracellular concentrations of ions, glucose, and protein, as well as the pH and osmolarity of the brain. All of these factors are critical to neuronal function. Selective uptake mechanisms in the brain capillaries are responsible for transporting specific nutrients such as particular ions, amino acids, and glucose. As a result of the blood–brain barrier, many potentially toxic compounds are effectively excluded from the brain. Compounds that have ready access to the brain include lipophilic compounds that move readily across lipid bilayers of epithelial and astrocytic cell membranes and may concentrate in brain tissues. In addition to passive diffusion, many compounds are actively transported into the brain, including compounds that resemble necessary nutrients, and are transported into the brain by the nutrient uptake pathways.

There are regions of the brain that do not have a blood–brain barrier. These include the circumventricular organs, the olfactory bulbs, and the optic nerve near the lamina cirbrosa. The circumventricular organs are regions of the brain that contain chemoreceptors that monitor blood constituents or that monitor and produce hormones. Access to plasma filtrates is necessary for the function of these areas. A list of the circumventricular organs includes the area postrema, median eminence, neurohypophysis, subcommissural organ, and choroid plexus. Areas of the brain not protected by a blood–brain barrier may be at risk of neurotoxicity from compounds that are excluded from the other areas of the brain. Further information about the role of the blood–brain barrier in neurotoxicity can be found in Jacobs (36).

2.2 Function of the Nervous System

Information is processed within neurons electrically and transmitted between neurons both electrically (gap junctions) and chemically. This combination of electrical and chemical signaling forms the basis of neuronal activity. Many neurotoxic compounds alter neuronal function by disrupting these processes.

2.2.1 Electrical Properties of Excitable Nerve Cells

Electrical informational processing by nerve cells begins with an ionic charge differential between the intracellular and extracellular sides of the cell membrane. The interior of nerve cells is usually about 60–70 mV more negative than the outside, a difference called the resting membrane potential. The resting membrane potential results from an uneven distribution of Na^+, K^+, and Cl^- ions and negatively charged organic acids and proteins. The cell membrane separates high extracellular Na^+ and intracellular K^+ concentrations. Negatively charged chloride ions in most cells align with a higher concentration outside the cell than inside so that a balance between the forces is created by the charge and ionic concentration differentials. The ionic concentration gradients are maintained through an energy-dependent process. The Na^+–K^+ pump, also known as Na^+–K^+ ATPase, transports Na^+ ions out of the cell and K^+ ions into the cell against electrical and chemical concentration gradients through an energy-dependent process. Intracellular concentrations of Ca^{2+} are typically low, allowing this ion to serve as an intracellular second messenger substance, and also protecting against toxicity associated with high intracellular Ca^{2+}.

In the area of the dendrites and axon cell body, synaptic input leads to transient depolarizing or hyperpolarizing changes in the resting membrane potential. Synaptic input may excite the cell by opening Na^+ channels, causing the membrane to become permeable to Na^+ ions. Na^+ ions then enter the cell through the opened channels along charge and concentration gradients, resulting in

depolarization of the transmembrane potential. Other synaptic contacts are linked to chloride channels. Opening of chloride channels allows Cl^- ions to flow into the cell and make the inside of the membrane more negative than the normal resting membrane potential, or "hyperpolarized". Hyperpolarization counteracts depolarizing currents and makes the cell less likely to fire. Chloride ion-based hyperpolarizing currents are called inhibitory currents. These excitatory and inhibitory currents spread in a graded fashion along the cell membrane. At any one time, the cell body trans-membrane potential reflects an integrated sum of the activity of the many incoming synaptic contacts acting upon that cell.

The region of the neuronal cell body that contacts the axon is called the axon hillock. In this region, the graded potentials of the dendrites and cell body can be transformed into an all-or-none signal called the action potential. When the transmembrane potential reaches a criterion depolarization voltage, the voltage-sensitive ion channels in the region of the axon hillock open. Opening of voltage-sensitive Na^+ channels leads to an inward flow of depolarization current carried by positively charged Na^+ ions. Shortly afterward, voltage-sensitive K^+ channels open, and Na^+ channels begin to close. Because the membrane is now permeable to K^+ and the transmembrane potential is depolarized, K^+ ions move out of the cell and create repolarizing potassium current. This rapid wave of depolarization–repolarization is called the axon potential. Unlike the graded potentials of the dendrites and cell body, the action potential occurs in an all-or-none fashion and is transmitted down the entirety of the axon.

In nonmyelinated axons, the wave of reciprocal sodium and potassium currents that constitute the action potential spreads continuously down the length of the axon. The speed with which action potentials spread, termed the "nerve conduction velocity," is relatively slow in nonmyelinated axons. In contrast, the transmembrane ion currents in myelinated axons occur only at exposed portions of the axon located between the insulated axon segments that are called the nodes of Ranvier. By restricting the current flow to the nodes of Ranvier, the wave of depolarization need not occur along the entire axon but leapfrogs rapidly from one node to the next down the length of the fiber. The nerve conduction velocity in a typical nonmyelinated axon might be a few meters per second, whereas myelinated axons can transmit nerve impulses as rapidly as 50–70 m/sec. Exposure to compounds that damage myelin, such as triethyltin or lead, reduces nerve conduction velocity (37). Electrical resistance to transmembrane currents, which is lower in larger diameter fibers, also influences nerve conduction velocity. Larger diameter axons have faster nerve conduction velocities. Myelinated axons tend to be larger in diameter than nonmyelinated axons, further adding to their advantageous conduction velocity.

2.2.2 Chemical Neurotransmission Across the Synapse When an impulse traveling down an axon reaches the region of the nerve terminal, the electrical signal of the action potential becomes converted to a chemical message for transmission across the synapse. The presynaptic region of the nerve terminal contains voltage-sensitive calcium channels that open when the action potential depolarization enters the terminal region of the nerve. Ca^{2+} ions enter the cell according to their charge and concentration gradients. The resulting rise in intracellular Ca^{2+} concentration causes small vesicles that contain neurotransmitter molecules to fuse with the presynaptic cell membrane and release the neurotransmitter substance into the synaptic cleft. Neurotransmitter molecules contact receptor proteins on the cell membrane of the postsynaptic cell. Contact of the neurotransmitter substance with the postsynaptic receptor can lead to several different events, depending upon the type of receptor involved. Postsynaptic events can involve neurotransmitter receptors linked to ion channels that can then lead to either excitatory or inhibitory postsynaptic currents as described earlier. Alternatively, postsynaptic receptors can be linked to intracellular second messenger systems that drive many different types of responses or alter the sensitivity of the cell to further stimulation.

After the neurotransmitter substance acts on the postsynaptic receptors, it is normally removed from

the synapse rapidly, which preserves the discrete nature of neural signaling. Removal of the neurotransmitter may involve passive diffusion, active reuptake into the presynaptic nerve terminal, or enzymatic degradation. The latter is particularly important for the neurotransmitter acetylcholine, which is broken down into acetate and choline by the enzyme acetylcholinesterase. Inhibition of acetylcholinesterase is the primary target of organophosphate and carbamate insecticides and several chemical weapon nerve agents such as sarin. Compounds that inhibit acetylcholinesterase cause a buildup of still active molecules of acetylcholine in the synapse, leading to repeated and prolonged stimulation of the postsynaptic cell. Acetylcholine is a neurotransmitter in the central and peripheral nervous systems, notably at neuromuscular junctions and postganglionic neurons of the autonomic nervous system. Acute overexposure to acetylcholinesterase inhibitors leads to a variety of signs and symptoms characteristic of cholinergic overexcitation, including salivation, lacrimation, urination, and defecation (the "SLUD" syndrome). In addition, cholinergic overstimulation produces pupil constriction (miosis), muscle fasciculations and tremor, headache, blurred vision, and mental confusion. Exposure to high doses can lead to respiratory paralysis and death.

In addition to acetylcholine, many substances have been identified as neurotransmitters. This list of known or suspected neurotransmitters continues to grow with new neurobiological research. A partial listing of some of the major established neurotransmitters includes acetylcholine; the catecholamines epinepherine, norepinephrine and dopamine; serotonin; the excitatory amino acids glutamate and aspartate; the inhibitory neurotransmitters gamma-aminobutyric acid (GABA) and glycine; the family of endogeneous opioids; and a variety of peptides such as substance P. Each neurotransmitter may act on several different types of receptors. The application of molecular biological techniques to identify new neurotransmitter receptor molecules has recently led to a rapid expansion of the number and types of receptors known.

Many neurotoxic and neuroactive compounds act at voltage-sensitive and ligand-gated ion channels (38–42). Among the compounds active at Na^+ channels are tetrodotoxin from Japanese puffer fish, a variety of toxins from different species of scorpions and dinoflagellates, and pyrethroid and DDT insecticides. The pyrethroids prolong the duration of the opened state of the Na^+ channel and cause spontaneous depolarization of the resting membrane potential and repetitive action potentials to a single stimulus input (42). Type II pyrethroids keep the channel open longer than Type I pyrethroids, which may account for the differences in toxicity. Compounds that block K^+ channels include tetraethylammonium and 4-aminopyridine. Compounds active at Ca^{2+} channels include a number of divalent metallic cations such as Pb^{2+} (43), Hg^{2+} (44), and Cd^{2+} (45). In addition to elemental mercury, methylmercury also blocks Ca^{2+} channels (46, 47). Many compounds interfere with intracellular second messenger systems or intracellular calcium signaling such as Pb (48, 49), and polychlorinated biphenyls (PCBs) (50).

2.2.3 Energy Metabolism in the Nervous System The brain demands a high flow rate of metabolic energy. The brain accounts for a large proportion of the cardiac output and consumes a large amount of oxygen. Unlike other organs, the brain consumes almost all of its energy in the form of glucose used through oxidative metabolism. The more active neurons become, the more active the metabolic machinery must become in response. This high metabolic demand makes the central nervous system particularly vulnerable to interruption of the supply of blood and oxygen and to compounds that interfere with glucose metabolism or which otherwise impair oxidative respiration, such as carbon monoxide. Exposure to carbon monoxide or to other hypoxic gases causes a series of symptomatic and behavioral changes that progress with increasing dose. Feelings of headache and nausea are commonly reported during CO exposure, but systematic investigations of behavioral deficits during low level exposure have produced inconsistent results (51). Of course, exposure to high concentrations is lethal.

2.2.4 Axonal Transport The axonal processes of neurons range in length from relatively short, as in CNS interneurons, to very long for sensory and motor cells. The latter reach from the spinal cord out

to the end processes in the periphery. At the extreme are sensory neurons that innervate the toes, have cell bodies in the dorsal root ganglion at the spinal cord, and send an ascending process to the brain stem at the top of the spinal cord before synapsing. These single cells can be more than five feet long. Much of the material necessary for maintaining the structure and function of the axon and terminal regions is synthesized in the cell body and transported along the length of the axon. This axonal transport process is vulnerable to disruption by certain types of compounds, especially in the largest and longest axons. Disruption of axonal transport leads to degeneration of the axonal segment distal to the blockage site.

2.3 Response to Injury

The neurons of the central nervous system are derived from neuroblastoma cells during development. These cells divide, migrate to their positions in the mature brain, differentiate into mature cell types, and establish functional synaptic contacts as a part of normal developmental processes. Once the maturation process is completed, however, neurons in the CNS lose the ability to replace themselves. When neurons die in the CNS of mature mammals, they are not replaced. In recent years there have been interesting reports that, in some cases, neurons in the CNS can regenerate. However, in mammalian species, the vast majority of the evidence is that mature CNS neurons are not replaced. Lost neurons are lost forever.

A permanent loss of neurons does not necessarily mean that the functions performed by that neural tissue are also lost forever. The remaining neural tissue retains a great deal of plasticity. Even in the mature brain, synaptic contacts are continuously being modified through changes in structure and functional plasticity. Patients who suffer from brain injury often experience gradual recovery as remaining areas of the brain subsume lost functions. The recovery may not restore function to its original state, however, because the loss of the brain tissue can diminish the overall functional capacity of the brain. Reduced overall functional capacity may lower the ability to deal with future challenging or stressful situations and impair recovery from further injury. Conceptually, a loss of reserve capacity could also cause the functional deficits from normal aging to appear earlier (14).

Axons that are sufficiently damaged degenerate. Severing an axon from the cell body interrupts the flow of essential materials and nutrients from the cell body down the axon. The segment of the axon distal to the cut degenerates gradually over a period of weeks to months in a characteristic sequence of changes referred to as Wallerian degeneration. Cells that have synaptic contact with damaged neurons may be affected. Trophic factors associated with synaptic function are required to maintain viable contacts. When one neuron degenerates, the loss of trophic factors can cause a range of transsynaptic changes in the contacted neurons ranging from mild to so severe as to cause degeneration in the contacted neuron.

Damaged dendrites and axons can regenerate, although repair is often incomplete. This repair process is linked to the functional plasticity of the nervous system and the ability of neuronal processes to change in a use-dependent fashion. Central nervous system axons, however, typically fail to regenerate more than short processes. These abbreviated fibers do not establish restored functional connections. Improving the ability of severed nerve fibers in the CNS and PNS to regenerate and form functional contacts with lost targets is an active area of neuroscience research, particularly with regard to spinal cord injuries. At the present time, however, the ability to recover from neurotoxic or other injuries to neurons and their processes in the CNS must be considered limited at best.

The capacity for repair of nerve fiber injury and recovery of function in the PNS is better than in the CNS. If the original pathway of the nerve fiber, the nerve sheath, is intact after the injury, it is likely that the fibers can regenerate and form functional contacts again. A study of acrylamide intoxication in baboons demonstrated the gradual decline of electrophysiological function in peripheral sensory and motor nerves during the course of chronic treatment and when treatment ceased, a gradual return to normal approximately two years later (52). If the pathway is blocked or disrupted, however, then it is likely that regeneration will not be successful. In the peripheral nervous system, additional branches from remaining healthy nerves might replace lost fibers. In the case of motor neurons, this

can result in more muscle fibers being innervated by a single motor neuron. Electrophysiological studies that stimulate an individual motor nerve fiber elicit a larger muscle response than normal due to the higher number of motor units innervated. In the case of sensory neurons, such as those innervating the skin, the process is similar. If surviving neighbor neurons innervate a region of previous denervation, then the ability to discriminate between stimulation of the skin in different locations is reduced in proportion to the increased size of the receptive field surface innervated by the individual surviving neurons.

2.3.1 Glial Response Injury to the central nervous system induced by physical trauma, hypoxia, or neurotoxicant exposure elicits a stereotypical response pattern. The glial fibrillary astrocytes play a prominent role in this response. Following injury, the astrocytes surrounding the damaged region hypertrophy, support the physical structure of the remaining brain tissue, and clean up the damage. Microglial cells then invade the area and digest and remove cellular debris, as would macrophages elsewhere in the body. An astrocytic glial scar remains in the site of a lesion.

The hypertrophy of astrocytes in response to injury is associated with an increased amount of glial proteins. A protein expressed only in fibrillary astrocytes, glial fibrillary acidic protein (GFAP), has become useful as a general marker for neurotoxicant-induced injury to the CNS (53–55). This glial marker is useful in part because of the uniform nature of the astrocytic response to neural injury. Given the diverse nature of neural tissue, it is difficult to predict what neurochemical or neuroanatomical measures are sufficient to ensure that an experimental toxicity study does not miss subtle nervous system damage. An assay of GFAP utilizes the brain's own injury response system to signal neural damage and therefore can detect many types of damage.

Neurotoxicology and Behavior

3 Neurotoxic Outcomes
3.1 Pathological Changes
Spencer and Schaumburg classified different types of neurotoxic damage, depending upon the region of the nervous system and cell types involved (56). Neurotoxic substances may damage neuronal cell bodies and produce a neuronopathy, they may damage the axon and produce an axonopathy, or they may damage the myelin and produce a myelinopathy. In addition, the damage may occur in the central and/or peripheral nervous system. Chang reviewed neurotoxicological aspects of neuropathology (57).

3.1.1 Neuronopathy Pathological changes in neurons can be observed as a response either to injury to the axonal processes or to the cell body (19, 56, 57). Damage to the axon can produce a reaction in the neuronal cell body called central chromatolysis. This reaction is observed microscopically as a slight distending of the cell body and dissolution of the Nissel substance (the neuronal version of rough endoplasmic reticulum) beginning around the nucleus and extending over time to involve the entire cell. Central chromatolysis has been observed in neurons of the dorsal root ganglion after methylmercury poisoning and in neurons of the brain stem after alkyl lead poisoning. Neurons may survive axonal injuries and sprout new processes.

A somewhat different reaction to injury is called peripheral chromatolysis. In this case, there is a slight reduction in neuronal size and depletion of the Nissel substance in the peripheral portions of the cytoplasm. The reaction is observed in motor neurons of the spinal cord anterior horn after degeneration or atrophy of muscles.

Atrophy and degeneration of neurons are irreversible injuries. Neurons in the process of degeneration often shrink in size and become hyperchromatic. Acute intoxication may initially

produce neuronal or axonal swelling and vacuolation, which eventually is followed by atrophy and degeneration. In some cases, an accumulation of neurofibrils is observed in the cytoplasm of neurons. This is called neurofibrillary degeneration and is commonly seen in Alzheimer's patients. A similar fibrillary condition, but not identical, has been observed in animals intoxicated with aluminum. Neuronal death (necrosis) is observed as a densely stained cell body and condensed nuclear chromatin called pyknosis.

3.1.2 Axonopathy Neurotoxic substances may cause damage to nerve axons. Axonopathies are classified by the site of damage: close to the cell body, a proximal axonopathy, or far from the cell body, a distal axonopathy. Axonopathies are typically characterized by a tangled accumulation of neurofilaments inside the axon, which blocks axonal transport and causes transported materials to accumulate. The axonal segment around the tangle swells as a result of the accumulated material. Giant axonal swellings are a hallmark of axonopathy. In some cases, the swellings resolve if treatment with the neurotoxic compound is terminated, but in other cases the portion of the axon distal to the swellings degenerates in a Wallerian fashion. Depending on the dose level and dose rate, experimental exposure to b,b'-iminodipropionitrile (IDPN) can produce proximal giant axonal swellings, whereas exposure to acrylamide, *n*-hexane, or carbon disulfide can produce distal axonal swellings (58). Primary axonal degeneration can lead to secondary degeneration of the myelin that once surrounded the now missing axons..

4 Classes of Neurotoxic Compounds
Detailed information about the neurotoxic effects of specific chemical compounds is provided elsewhere in this series of volumes. Therefore, only a brief overview of the major classes of neurotoxic chemicals is provided here. The major classes of environmental and occupational neurotoxicants are metals, insecticides, and organic solvents. There are also many other compounds that produce neurotoxic effects but do not fall within these three categories.
4.1 Metals
Numerous metallic compounds have proven neurotoxic in humans or in experimental animals. The form of the metal compound, whether it is elemental, an inorganic salt, or contained within an organic compound, can strongly influence neurotoxicity. In general, organometallic compounds are more neurotoxic than the inorganic forms due to the greater penetration of these compounds into the brain. In addition, the route of exposure and age of the subject are critical determinants of toxicity. Inhalation exposure to mercury vapor is much more dangerous than oral exposure, for example. Developing organisms are often more sensitive to metals than adults. There is very little information regarding the sensitivity of the aged to metal toxicity, but many now suspect that the aged may be more at risk than young adults. The neurotoxicities of lead, mercury, and manganese compounds are well established in working populations. In addition, a variety of other metals produce neurotoxic effects.

4.1.1 Lead The neurotoxicity of lead has been known since ancient times. Today, lead is arguably the most widely recognized environmental pollutant. Much has been written about lead toxicity, and the interested reader can find many thorough reviews (161, 162). Lead is toxic acutely and chronically to adults and children. In the United States, regulatory actions have made a large impact in reducing sources of exposure to lead from occupational, environmental, and food and water sources. The range of toxic signs and symptoms is a function of the dose.

In worksite situations, exposure to lead has been one of the most extensively studied compounds. Anger summarized the data from 33 studies conducted in 9 or 10 countries involving a total of 3271 exposed workers and 2309 referents (6). Consistent deficits were observed across these studies in the

performance of tests designed to assess several aspects of cognitive function, including intelligence, memory, vigilance, acquisition, coding, spatial relationships, distractibility, and vocabulary. In addition, these studies consistently reported deficits in motor coordination and response speed and changes in affect. These consistent findings across a large number of studies clearly indicate the potential of occupational exposure to lead to produce adverse neurological consequences.

Currently, a major concern for lead neurotoxicity is for the cognitive function of children exposed to what was once considered an acceptable level of lead. The work of Needleman and colleagues was instrumental in demonstrating an association between the body burden of lead, measured as elevated blood and/or dentine lead levels, and deficits in performing a variety of cognitive tasks (154). A number of ongoing prospective studies around the world have confirmed and advanced the relationship between developmental lead exposure and impaired cognitive function (163, 164). Animal models of cognitive function confirm the deleterious actions of lead exposure (162, 165, 166). Recently, neurophysiological measures have shown that lead-treated animals show deficits in long-term potentiation, which is thought to reflect the cellular processes involved in learning and memory (167–169). Less appreciated are the other effects of lead on the nervous system, including toxicity to vision (170–176); and perhaps, somatosensory systems (126). The mechanisms of action through which lead produces its neurotoxic effects remain unknown despite numerous hypotheses (48, 161). Hopefully, the continued development of conceptual models and mechanistic research will lead to an eventual understanding of this most infamous of neurotoxicants.

4.1.2 Mercury Mercury in many forms can produce neurotoxic effects by inhalation of mercury vapor, ingestion of inorganic mercury salts, or by exposure to organomercurial compounds (155). Methylmercury is the most notorious of the organic forms of mercury because of its role in poisoning hundreds of individuals in Minamata Bay, Japan, (10, 11) and thousands in Iraq (8). Methylmercury is produced from industrial sources and through methylation of inorganic mercury by microbes in soils and sediments. Methylmercury is lipophilic and bioaccumulates in environmental food chains. Fish and marine mammals may have enriched methylmercury concentrations in their tissues.

Exposure to inorganic forms of mercury in the workplace has been the focus of numerous studies of neurobehavioral function. Anger (6) reviewed data from 18 studies conducted in eight or nine countries involving a total of 1002 exposed workers and 831 referents. Consistent deficits in exposed workers were observed in tests designed to assess intelligence, memory, and coding ability. In addition, exposed workers consistently performed poorly on tasks of motor coordination, response speed, and steadiness. Exposed workers also consistently showed changes in responding to personality tests. These data demonstrate that neurological function should be a concern in industrial hygiene programs for workers potentially exposed to inorganic mercury.

As with lead, exposure of children to low levels of methylmercury is currently a primary health concern. Two ongoing longitudinal studies are investigating populations that rely heavily on ocean-caught fish for their diets. One is a study of the neurobehavioral development of children who reside in the Seychelle Islands, where methylmercury-contaminated fish represent a substantial portion of the diet. No deleterious relationship between the concentration of methylmercury in hair samples and neurological development has been observed in this population (177, 178). In contrast, a study of residents of the Faroe Islands, where marine mammals contaminated with methylmercury are consumed, has observed significant deficits in the performance of cognitive tasks as a function of hair methylmercury concentration (179). Several factors might account for these apparently discrepant results, including different levels of mercury exposure, coexposure to other contaminants such as PCBs in the Faroe Islands, the older age of the children evaluated in the Faroe Islands, and more sensitive neurobehavioral evaluative procedures used in the Faroe Islands.

4.1.3 Manganese Manganese (Mn), a transitional metal and essential trace nutrient, can become neurotoxic under certain exposure conditions. The range of toxicological outcomes following exposure to Mn varies as a function of dose. Low levels of exposure cause subtle subclinical changes

in the performance of motor tasks and nonspecific subjective complaints such as fatigue, poor memory and insomnia. Workers occupationally exposed to low dose levels of Mn have changes in mood and deficits in performing cognitive and motor tasks (180–186). Continued or higher levels of exposure lead to an intermediate phase of toxicity, including psychomotor excitement, dysphoria, and abnormalities of gait and posture. This is followed by the late stage development of severe, debilitating, extrapyramidal deficits. Humans who have advanced Mn intoxication display prominent signs of basal ganglia dysfunction including bradykinesia, rigidity, fatigue, masked face, intention tremor, and disturbances of gait and balance (187, 188). The clinical, neurochemical, and pathological manifestations of Mn poisoning resemble those of Parkinson's disease but are distinct in the more global distribution of changes throughout the basal ganglia, more inclusive neurochemical changes, the spectrum of clinical manifestations, and the response to pharmacological therapy (188, 189). The motor disturbances in advanced Mn intoxication are linked to identifiable lesions in nuclei of the extrapyramidal motor system, including the globus pallidus, caudate, and the substantia nigra. The nigrostriatal pathway, which degenerates in Parkinson's disease, is evidently spared in manganese poisoning.

4.2 Solvents

Organic solvents are widely used in many industrial and commercial operations. Many solvents are highly volatile, creating an opportunity for substantial inhalation exposure. Because of their high lipid solubility, organic solvents gain ready access to neural tissues in the central and peripheral nervous system. Exposure to organic solvents can produce a variety of acute and chronic effects on the nervous system. This combination of factors makes potential neurotoxic effects a concern for workers and others exposed to organic solvents. Many different chemicals are used as organic solvents. The neurological effects of acute exposure are similar for many organic solvents, making it tempting to consider the toxic effects of these chemicals as a class. Arlien-Søborg (190) has extensively reviewed solvent neurotoxicity. Toluene, xylene, styrene, *n*-hexane, methyl *n*-butyl ketone, methyl ethyl ketone, 2,5-hexanedione, methylene chloride, methyl chloride, trichloroethylene, 1,1,1-trichloroethane, white spirits and solvent mixtures are covered in this work. Workers are often exposed to a combination of different organic solvents used either individually or as chemical mixtures. This factor can make it difficult or impossible to attribute any toxic effects observed to a particular chemical compound, and consequently the outcomes in several occupational exposure studies have been attributed to mixed solvent exposure. In some cases coexposure to multiple solvents may show greater than additive toxic effects (191).

Each organic solvent has a different chemical structure, forms a different set of metabolites and, therefore, can produce unique toxic effects (192). Despite this fact, this chapter will consider the neurotoxicity of organic solvents grouped under general categories of neurotoxic effects, rather chemical by chemical, because chemical specific information is presented elsewhere in these volumes. Four general categories of neurotoxic effects of exposure to organic solvents are of concern. These include the effects sedative/narcotic like effects of acute exposure, central/peripheral polyneuropathy produced by exposure to some organic solvents, ototoxicity that has been observed primarily in laboratory animals to date, and chronic solvent-induced dementia and toxic encephalopathy, the most controversial of the neurotoxic effects of organic solvents. The issues of ototoxicity and peripheral neuropathy produced by organic solvents were discussed previously. Therefore, this section focuses on the neurotoxic effects of acute and chronic exposure to organic solvents.

4.2.1 Neurotoxic Effects of Acute Exposure to Organic Solvents Acute exposure to many volatile organic compounds produces effects on the nervous system that resemble those of other CNS depressants, such as ethanol, barbiturates, or benzodiazapines (75, 128, 193, 194). Indeed, some commonly used industrial solvents, such as trichloroethylene, were used historically as medical anesthetics. Initial exposure produces a mild excitation or giddiness, similar to imbibing a moderate amount of an alcoholic beverage. Animal studies may show an initial increase in behavioral activity (128, 194) or an excitatory change in electrophysiological recordings (195). Continued exposure or higher concentrations produce CNS depression and deficits in cognitive function, sensory perception, and motor performance. Studies of laboratory animals or exposed human subjects show

changes in electrophysiological recordings from the brain and impaired performance of behavioral tasks (192, 196–204). Humans in such a state are prone to make errors in judgment, to have poor motor coordination, and slowed reactions. Operation of motor vehicles, industrial machinery, or other heavy equipment while exposed to organic solvent vapors can be acutely hazardous, just as is driving a car while under the influence of alcohol. Coexposure to alcohol or CNS depressant drugs and organic solvent vapors further increases the danger. The occupational exposure limits for many organic compounds have been established specifically to avoid the narcotic effects of exposure.

Many experimental laboratory studies have been published in which human volunteers were acutely exposed to organic solvents and a variety of neurobehavioral procedures were administered. Dick has extensively compiled this literature in a review article (205). Because of safety and ethical concerns, experimental studies of exposed human subjects are limited to dose levels low enough to ensure that no irreversible effects are produced. Typically, human subject protection committees will not approve deliberate exposure concentrations above the occupational exposure limits. Consequently, most of the procedures in these studies have reported negative results. However, a number of these studies have reported that solvent exposure was associated with changes in task performance. Many studies reported effects of solvents on symptom and sensory irritation questionnaires, tests of attention and vigilance, short-term memory (digit-span) tests, simple and choice reaction time, manual dexterity and motor speed, EEG and visual evoked potentials, postural sway, and various measures of visual perception (205).

The acute effects of exposure to many organic solvents have a rapid onset and rapid reversal. After inhalation, organic solvents readily cross the alveolar membranes and enter the blood where they are carried largely in the membranes and lipophilic regions of proteins in blood cells. These compounds travel from the lungs directly to the brain where favorable blood–brain partition coefficients encourage movement into brain tissues. The blood–brain barrier does not effectively restrict movement of these compounds into the brain. Once in the brain, the mechanism of action of these compounds to produce narcosis or other functional changes is not known. One hypothesis is that these compounds partially dissolve neuronal cell membranes, increasing their fluidity (206, 207). Another view is that organic solvents are attracted to the lipophilic regions of cell membrane proteins, where they alter protein function (208–211). Which proteins are critical is in question. Changes in receptors for the dopamine (190), GABA (194) and excitatory amino acid (212) neurotransmitter systems have been proposed. Following cessation of exposure, the acute neurological effects of most organic solvents rapidly dissipate as the compound is quickly eliminated. This can present a problem for the experimental study of acute solvent if the subjects must be tested after removal from the exposure chambers. The interpretation of such studies should consider that the tissue concentrations of the compound and the associated behavioral changes rapidly diminish after termination of exposure.

In expressing occupational exposure limits as a time-weighted average (TWA), it is assumed that the average amount of exposure over a workday is the critical determinant in producing an adverse outcome. Short-term excursions above the TWA may produce acute symptoms even though the average daily exposure is well within the TWA. It is important to adhere to short-term excursion limits (STELs) for volatile organic solvents because of the rapid onset of symptoms. In assessing the risk of short-term exposures, it is important to consider the relationship between exposure concentration (C) and duration (t) in producing adverse outcomes (213). If extrapolation is based on a classical linear form of Haber's Rule (i.e., $C \times t = k$, where k represents a constant toxic effect) to predict the effects of short duration exposures, it is not sufficiently protective (214, 215). A better option may be to determine the tissue concentrations of the compound associated with a toxic effect (216) and then use a physiologically based pharmacokinetic model to calculate the various exposure conditions that can achieve that critical tissue concentration (217).

4.2.2 Solvent-Induced Toxic Encephalopathy The possibility that chronic occupational exposure to organic solvents could lead to cognitive and neurological deficits was one of the most controversial issues in neurotoxicology. Concern first grew from a number of studies conducted in Scandanavian

countries (reviewed in Refs. 190, 218–220). Because many of the original cases described involved painters, the condition became known as "*painter's syndrome*," or alternatively, as solvent induced "*psycho-organic syndrome*." The later label emphasized the psychological deficits and the belief that there was organic damage to the brain as a result of solvent exposure. The cognitive deficits included global impairment of intellect, changes in personality, and loss of memory. These studies were disputed for a number of reasons; a principal reason was inadequate matching of exposed and control populations, particularly with regard to preexposure intelligence (221). The ability to use postexposure outcome measures to match groups for preexposure levels of intelligence remains controversial (222, 223). Recently, however, a growing set of studies demonstrate associations between chronic solvent exposure and neurological deficits (66, 224–229). The expression of chronic solvent neurotoxicity progresses with continued exposure from mild symptoms to severe debilitating dementia. The stages of the disorder have been categorized according to various schemes (218, 230). Milder stages feature complaints of fatigability, memory impairment, and difficulty concentrating. Intermediate phases involve sustained changes in personality and mood, emotional liability, and difficulty with impulse control and mood. As the condition progresses, there are objectively demonstrable cognitive impairments and neurological signs. The final stage of dementia features global deterioration of intellect and memory, hard neurological signs, and positive neuroradiological findings. Upon cessation of exposure, the effects of chronic solvent exposure are thought to remain stable and not degenerate further over time (231).

Worksite neurobehavioral studies of solvent exposed workers have observed a number of consistent types of deficits. For workers exposed to carbon disulfide, deficits have been reported in three or more independent studies on tests of intelligence, memory, vigilance, coding, spatial relations, motor coordination, response speed, and personality (6). For exposure to styrene, consistent deficits have been observed in tests of memory, motor coordination, and response speed (6). Consistent deficits have been reported in three or more independent studies of workers exposed to mixed solvents in tests of intelligence, memory, vigilance, acquisition, coding, concept shifting, spatial relations, categorization, motor coordination, response speed, color vision, and personality (6).

Workers with a diagnosis of solvent-induced encephalopathy after occupational exposure to solvents show ventricular and cortical atrophy by CT and MRI imaging (232). MRI was a more sensitive measure and showed changes in workers normal by CT. A case-control study of 23,000 residents in Seattle, Washington, found that a work history of potential exposure to organic solvents increased the risk of subsequent diagnosis with Alzheimer's disease (233). The risk was particularly strong for males for whom working jobs with potential solvent exposure increased the risk of being diagnosed with Alzheimer's disease sixfold over controls.

Although now there is considerable evidence that chronic exposure to solvents can lead to a degenerative neurological state, uncertainties remain as to the dose–response relationships. In most of the occupational studies to date, an objective and thorough characterization of exposure levels and exposure history is lacking. Are the effects due to current lower level exposures, or can they be attributed to past exposures when the levels were often higher? Also, the role of repeated exposure to spikes that may go well above the TWA exposure limits is unknown. One handicap in addressing these questions is the lack of good animal models that show persistent cognitive deficits following chronic solvent exposures. Answers to these questions must await further research.

4.3 Pesticides

By design, pesticides are toxic to living organisms. Ideally, they are preferentially toxic to the target pest organisms and less toxic to nontarget organisms, including humans, wildlife, and beneficial plants and insects. Many insecticides have been developed specifically for their toxicity to the nervous system. For the most part, these insecticides act on the neural tissues of humans in the same manner as they do on the target insect species. The extent to which humans are less sensitive to these agents than insects is typically due to metabolic factors. The mammalian toxicity of insecticides varies widely across agents and classes of compounds. Some compounds such as parathion or aldicarb are highly toxic, whereas others such as malathion and carbaryl have relatively low mammalian toxicity. Because insecticides typically have a known mechanism of toxicity, it is

tempting to focus toxicity studies on the known mechanisms of action. However, it is also important to consider alternative mechanisms of action and toxicity mediated through other potential actions of the compounds. The major classes of insecticides that are designed to be neurotoxic include organophosphorus, carbamate, pyrethroid, and organochlorine compounds. This section considers the mammalian neurotoxicity of organophosphorus insecticides because of the widespread use of these compounds and recent concern for their safety.

4.3.1 Organophosphorus Compounds Organophosphorus compounds are the most widely used class of pesticides. Approximately 50 compounds are currently registered for use in the United States, and more than one hundred are used worldwide. More than 50,000 organophosphorus compounds have been synthesized and screened for pesticidal activity (234). A metabolite of chloropyrifos, the most widely used organophosphorus compound, was detected in the urine of 82% of a sample of 1000 adults living in the United States (235). Exposure to organophosphorus compounds can be particularly hazardous if not used according to approved applications. For example, recently several hundred homes in the southern and midwestern United States were illegally sprayed with methyl parathion, a practice potentially lethal to residents, especially children, and had to be decontaminated at an estimated cost of over $50 million (236). A number of extensive review articles cover the toxicity of organophosphorus insecticides (234, 237–242).

Some organophosphorus compounds are active as the parent compound. Others must be metabolically activated in the liver to an oxon derivative to become active. Organophosphorus compounds produce acute toxicity through inhibition of acetylcholinesterase, the enzyme that inactivates the neurotransmitter acetylcholine in synapses and neuromuscular junctions. A discussion of the actions of acetylcholine and the consequences of acetylcholinesterase inhibition was presented earlier. The enzyme acetylcholinesterase is found in the central and peripheral nervous systems and in red blood cells. Butyrylcholinesterase, also known as nonspecific cholinesterase, pseudocholinesterase, or simply as cholinesterase is another enzyme that hydrolyzes acetylcholine and is inhibited by organophosphorus compounds and many other acetylcholinesterase inhibitors. Butyrylcholinesterase is found in myelin in the nervous system, liver, and plasma. The physiological roles of acetylcholinesterase in blood and butyrylcholinesterase in plasma are not known, but the inhibition of these enzymes is widely used as an indicator of exposure to organophosphorus compounds.

4.3.1.1 Acute toxicity Symptoms of acute overexposure to organophosphorus compounds are attributable to acetylcholinesterase inhibition and the consequent overstimulation of neurons, muscles, and glands postsynaptic to cholinergic synapses. Acute symptoms include abdominal pain, nausea, vomiting, diarrhea, dizziness, blurred vision, constriction of the pupils (miosis), increased salivation, lacrimation, and sweating. High doses lead to severe poisoning marked by dilated or nonreactive pupils, muscle twitching, pulmonary edema, tachycardia, convulsions, coma, respiratory paralysis, and death. Timely antidotal treatment, including atropine, that blocks cholinergic muscarinic receptors, and oxime compounds such as 2-PAM, that promote regeneration of active acetylcholinesterase molecules, is effective in mitigating the effects of acute organophosphate poisoning. Although the actions of organophosphorus compounds as cholinesterase inhibitors are well known, recent evidence shows that these compounds also have direct actions at cholinergic muscarinic receptors (243, 244) and, perhaps secondarily, on intracellular second messenger systems (245). Recovery of normal acetylcholinesterase activity follows the time course of new enzyme synthesis. Exposure to organophosphorus compounds also induces a down-regulation of muscarinic cholinergic receptors, that, it is thought, mediates tolerance to repeated dosing (246). Recovery of behavioral and motor functions from acute exposure can precede the return of normal levels of acetylcholinesterase and of cholinergic muscarinic receptors (247, 248).

4.3.1.2 Chronic Toxicity A number of studies have demonstrated that individuals who survive acute poisoning from organophosphorus compounds may have long-term deficits in memory, attention, mood, and changes in EEG and peripheral nerve function (249–252). Three or more worksite behavioral studies have found deficits in tests of intelligence and memory in organophoshate

exposed workers (6). Animal studies have shown persistent changes in the second messenger systems of the brain (253) and retina (254) after a single dose of an organophosphorus compound. Until recently, there was no evidence that workers exposed to organophosphorus compounds, but who were never acutely poisoned, suffered any long-term consequences (255, 256). A series of recent reports from the study of sheep dippers in Great Britain, however, show deficits in performing cognitive tests, including tests of attention and information processing speed, and peripheral nerve function, including two-point sensory discriminations, among organophosphorus workers who have not experienced acute poisoning (257–259).

4.3.1.3 Organophosphorus-Induced Delayed Neurotoxicity Exposure to some, but not all, organophosphorus compounds causes axonal degeneration in the spinal cord and peripheral nerves. This syndrome became widely recognized first during the American Prohibition Era in which the organophosphorus compound, tri-*o*-cresyl phosphate (TOCP; now called tri-*o*-tolyl phosphate) adulterated the popular drink, Jamaican ginger extract. The syndrome has since become known as organophosphorus pesticide-induced delayed neurotoxicity (OPIDN), even though many of the compounds that produce the syndrome (such as TOCP) are not actually used as pesticides. After a single or repeated dose of an active organophosphate, axons of the spinal cord and peripheral nerves degenerate in a distal, dying-back style that is distinct from that of acrylamide and the hexacarbons (260). Symptoms appear after a delay period of approximately 6–14 days. Affected individuals show weakness and sensory loss in the distal portions of the feet and legs, ataxia, and with continued dosing, progressive debilitation that can spread to the upper limbs and autonomic nervous system in severe cases. Young animals are more resistant to OPIDN than mature ages. Rats do not develop clinical signs of OPIDN such as ataxia, despite the presence of neuropathology similar to other sensitive species (261). Hens, in contrast, are quite sensitive to OPIDN and have become a standard species for screening compounds for this potential problem. The production of OPIDN does not involve inhibition of acetylcholinesterase. Johnson devised a test of enzymatic activity that does correlate well with a compound's potency to produce OPIDN, that is referred to now as neurotoxic esterase or alternatively, as neuropathy target enzyme (NTE) (262). Compounds that inhibit NTE activity by 50–70% or more are considered potential axonal pathogens. Organophosphorus pesticide products registered in the United States undergo a gait test in hens and testing for NTE inhibition to detect and eliminate compounds with this potential. More information on OPIDN can be found in review articles by Abou-Donia (234, 263), Lotti (264), and Richardson (265).

4.3.1.4 Issues Arising Recently there has been increased public concern about the susceptibility of children to exposure to organophosphorus compounds and other pesticides (266). This concern led to passage of the Food Quality Protection Act that contains provisions for assessing the safety of pesticide residues in foods. Among the novel provisions of the act are that pesticide safety evaluations should consider specifically the susceptibility of young individuals and also that cumulative and aggregate exposures to pesticides should be considered. Among adults, there is evidence that genetic differences in the enzyme human serum paraoxonase (PON1) can markedly influence susceptibility to organophosphorus agents (267). Another public concern is for the possibility for ocular toxicity resulting from exposure to organophosphorus compounds (268–270). Combining these two different concerns, recent evidence suggests that developmental exposure to organophosphates might interfere with the visual control processes necessary for proper ocular development (271). Future research on organophosphorus compounds will feature factors that influence individual susceptibility differences, understanding compound exposures, nontraditional toxicity targets such as the eye, and other, perhaps noncholinergically mediated, effects.

5 Preventing Neurotoxicity

The prevention of neurotoxic disorders should be a primary goal of occupational and environmental health programs. The National Research Council (2) outlined several facets of a program to better prevent future neurological disorders from exposure to toxic chemicals. A simplified distillation of this program might include more extensive efforts at the following:

1. screening of new and existing chemicals for potential neurotoxicity, so that neurotoxic hazards can be identified and avoided;
2. surveillance of exposures in occupational and environmental settings;
3. monitoring the neurological health of those potentially exposed, and
4. training medical and occupational health professionals to better recognized and understand neurotoxic conditions.

Silver and Gold
Daland R. Juberg, Ph.D., F. Terry Hearne, MS

1.0 Silver
1.0.1 CAS Number: [*7440-22-4*]

1.0.2 Synonyms: argentum; collargol; C.I. 77820

1.0.3 Trade Names: NA

1.0.4 Moleculer Weight: 117.86

1.1.1 General Silver, an element of the II(B) Group, is in the second transition series of the periodic table. It is a white, lustrous, relatively soft and very malleable metal. Silver has high thermal and electrical conductivity and resists oxidation in air that is devoid of hydrogen sulfide. Silver is insoluble in water although it can exist in an aqueous environment in three cationic forms, Ag(I), Ag (II), and Ag(III), in addition to its metallic state (Ag0) (1). Most silver compounds are made from silver nitrate, which is prepared from silver metal. Although the chemical and physical properties of various silver compounds and salts may be quite variable depending on the nature of the base, some common properties of metallic silver are listed in Table 26.1.

Table 26.1. Selected Silver Compounds and Physical/Chemical Properties (REF)

Compound	Molecular Formula	CAS Number	Molecular Weight	Aqueous Solubility (g/L H_2O at 25°C)	ACGHIH TLV-TWAand MSHA Standard-air
Silver	Ag	[*7440-22-4*]	107.87	Virtually insoluble	
Silver chloride	AgCl	[*7783-90-6*]	143.32	1.9×10^{-3}	
Silver nitrate	$AgNO_3$	[*7761-88-8*]	169.87	2.2×10^{2}[a]	
Silver oxide	Ag_2O	[*20667-12-3*]	231.74	2.2×10^{-2}[b]	
Silver sulfide	Ag_2S	[*21548-73-2*]	247.74	1.4×10^{-4}	
Silver bromide	AgBr	[*7785-23-1*]	187.8	Slightly soluble	
Silver sulfadiazine	$C_{10}H_9AgN_4O_2S$	[22199-08-02]	357.1	Insoluble in H_2O and acid	0.01 mg (Ag)/m^3

4-Amino-N-(2-pyrimidinyl)benzenesulfonamide silver salt,
benzenesulfonamide, 4-amino-N-2-pyrimidinyl-, monosiliver(1+) salt,
Dermazine,
Flamazine,

Geben, Silvadene, silver sulfadiazine, silver sulphadiazone, sulfadiazone silver, sulfadiazine silver salt				
Silver acetate	$C_2H_3AgO_2$	[*563-63-3*]	166.9	Insoluble in H_2O and acid
Silver iodide	AgI	[*7783-96-2*]	234.8	Insoluble in H_2O and acid
Silver trifluoroacetate	$C_2AgF_3O_2$	[*2966-50-9*]	220.9	Insoluble in H_2O and acid
Silver fluoride	AgF	[*7775-41-9*]	126.9	Insoluble in H_2O and acid
Silver lactate	$C_3H_5AgO_3$	[*128-00-7*]	196.9	Slightly soluble in H_2O
Sodium aurothiomalate		[*12244-57-4*]		

[a] Value is per 100 g H_2O.

[b] Measured at 20°C.

Silver and Gold
Daland R. Juberg, Ph.D., F. Terry Hearne, MS

2.0 Gold
2.0.1 CAS Number: [*7440-57-5*]

2.0.2 Synonyms: Burnish gold, colloidal gold, gold powder, gold-197, gold flake

2.0.3 Trade Names: NA

2.0.4 Molecular Weight: 197
2.1 Chemical and Physical Properties
2.1.1 General Gold is a dense, yet malleable, lustrous, yellow metal widely found in nature as elemental gold or in combination with sulfides in igneous rocks and ores. Gold is very stable and nonreactive and does not burn or oxidize in air. Other than in its atomic state, the metal does not react with oxygen, sulfur, or selenium at any temperature. Gold does react with various oxidizing agents at ambient temperatures provided a good ligand is present to lower the redox potential below that of water. Therefore, gold is not attacked by most acids under ordinary conditions and is stable in

basic media. Gold does, however, dissolve readily in 3:1 hydrochloric–nitric acid to form $HAuCl_4$ [*16903-35-8*], and in alkaline cyanide solutions in the presence of air or hydrogen peroxide to form $AuCN_2$, and these chemical reactions are important to the extraction and refining of the metal. Gold reacts with halogens, particularly in the presence of moisture, and at low (≤200°C) temperatures, chlorine is adsorbed on the gold surface to form surface chlorides. Its melting and boiling points are 1064 and 2807°C, respectively. Information about common gold compounds is presented in Table 26.6.

Table 26.6. Selected Gold Compounds and Physical/Chemical Properties (REF)

Compound	Molecular Formula	CAS Number	Molecular Weight	Aqueous (H_2O) Solubility (g/L) at 25°C
Gold	Au	[*7440-57-5*]	196.97	Virtually insoluble
Gold chloride	AuCl	[*10294-29-8*]	232.42	Soluble in HCl, HBr, KCN
Gold potassium chloride	$KAuCl_4·2H_2O$	[*13682-61-6*]	414.16	618
Sodium aurothiomalate	$C_4H_6O_4S·Au·2Na$	[*42722-04-3*]	393.05	Very soluble
Aurothioglucose	$C_6H_{11}AuO_5S$	[*12192-57-3*]	392.08	Very soluble
Gold (I) sodium thiosulfate 2-water	$AuNa_3(S_2O_3)_2·2H_2O$		526.24	500
Gold trichloride	$AuCl_3$	[*13453-07-1*]	303.33	680
Gold potassium cyanide		[*554-07-4*]		
Gold (I) potassium cyanide	C_2AuKN_2	[*13967-50-5*]	288.09

Magnesium, Calcium, Strontium, Barium, and Radium
Mary Beth Genter, Ph.D., DABT

1.0 Magnesium
1.0.1 CAS Number:
[*7439-95-4*]
1.0.2 Synonyms:
Magnesium turnings, metal turnings
1.0.3 Trade Names:
NA
1.0.4 Molecular Weight:
24.31
1.0.5 Molecular Formula:
Mg
1.1 Chemical and Physical Properties
1.1.1 General Magnesium is one of the most common elements found in the earth's crust (2.1% by weight). There are three naturally occurring isotopes of magnesium: ^{24}Mg (78.7%), ^{25}Mg (10.13%), and ^{26}Mg (11.17%). Magnesium metal is not found as such naturally; rather, it occurs in mineral or salt form, such as magnesite, carnallite, dolomite [$CaMg(CO_3)_2$], epsomite, and many other minerals. Over 50 magnesium salts are known. Magnesium is one of the alkaline-earth elements; as such, it is insoluble but reactive in water, liberating hydrogen gas, and extremely flammable. Magnesium burns with a brilliant white flame. Melting point: 650°C; boiling point: 1107°C; flash point: 500°C; specific gravity: 1.74; vapor density: 0.84.

1.1.2 Odor and Warning Properties None attributable to magnesium, but the associated anions may be responsible for an odor characteristic of the various magnesium salts.
1.2 Production and Use
Magnesium is found in seawater and plant and animal tissues. Chlorophylls *a* and *b* are magnesium chelates of porphyrin (2, 3). Magnesium metal may be prepared industrially by reduction of MgO-containing materials (4). Magnesium is used as a constituent of light alloys, in the manufacture of precision instruments, as a deoxidizing and desulfurizing agent in metallurgy, in the production of flashbulbs and flares, for Grignard reagents, and in semiconductor research (4). Magnesium is an essential element in the diet [recommended daily allowance (RDA) is 4.5 mg/kg] and is a cofactor in over 300 enzymatic reactions (5). Magnesium is essential in the synthesis of ATP and other enzymes involved in muscle contractility and neuronal transmission. Several magnesium salts, most commonly the citrate, are used as cathartics. Magnesium nitrate is used in the production of pyrotechnics. Magnesium sulfate [*7487-88-9*] is used as an anticonvulsant in preeclampsia or eclampsia (5). Magnesium oxide and the trisilicate are used as antacids (4).
1.3 Exposure Assessment
1.3.1 Air Air samples for magnesium analysis should be collected on 0.8 mm mixed cellulose ester filters. Analysis is by inductively coupled argon plasma atomic absorption spectroscopy (6).

1.3.2 Background Levels: NA

1.3.3 Workplace Methods: NA

1.3.4 Community Methods: NA

1.3.5 Biomonitoring/Biomarkers 1.3.5.1 Blood The reference value for magnesium in blood is 1.5–2.8 mg/dL (or 1.2–2.3 meq/L) (5). Intracellular magnesium concentrations are much higher than serum magnesium concentrations, so serum measurements may not be meaningful. Ion-specific electrodes have become available for determining ionized magnesium in plasma (3). Magnesium oxide can be measured in whole blood (6). Magnesium can also be measured in blood and plasma via neutron activation analysis (7).

1.3.5.2 Urine: NA
1.4 Toxic effects
1.4.1 Experimental Studies 1.4.1.1 Acute Toxicity Magnesium chloride was administered intravenously to ICR mice, and an LD_{50} value of 14.4 mg/kg was determined (8).

1.4.1.2 Chronic and Subchronic Toxicity: NA

1.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Magnesium can interact with and block calcium channels (9). Parenterally administered magnesium decreases acetylchloline in motor nerve terminals and acts on myocardium by slowing rate of S-A node impulse formation and prolonging conduction time (5).

1.4.1.3.1 Absorption Magnesium absorption following oral ingestion is reported to range from 40 to 60%, with a lower percentage of absorption at higher daily intakes. The transport of magnesium into or out of cells appears to require a carrier-mediated transport system, and a Mg^{2+}/H^{+} exchanger has only recently been described in *Arabidopsis thaliana* (3, 10). Magnesium decreases the absorption of fluoride (11), and excess calcium may partially inhibit the absorption of magnesium.

1.4.1.3.2 Distribution In the plasma, magnesium is about 65% in the ionic form, with the remainder bound to plasma proteins. Of the approximately 20 g body burden of magnesium, most is stored primarily in bone and muscle following absorption (12).

1.4.1.3.3 Excretion The kidney is the primary organ involved in magnesium homeostasis, with filtration–reabsorption, but not tubular secretion, occurring. Approximately 12 mg of magnesium is excreted in the urine per day. Magnesium excretion can also occur via the sweat and breast milk. Hypermagnesiumemia has been reported in individuals with renal impairment. Severe toxicity has been reported in individuals with renal impairment who were administered magnesium-containing laxatives or antacids; cardiac and neurological symptoms can occur if serum levels reach approximately 4.8–8.4 mg/dL (3, 12, 13). Unabsorbed magnesium is excreted in the feces.

1.4.1.4 Reproductive and Developmental No teratogenicity studies were found for magnesium salts. However, magnesium deficiency (0.2 mg Mg/100 g diet during days 6–12 of gestation) has been associated with defects in rat fetuses (14). These defects occurred in 14% of the viable fetuses and reportedly included skeletal malformations, cleft lip, hydrocephalus, and heart, lung, and urogenital anomalies. A significant number of fetal resorptions was also noted. Gunther et al. (14) similarly reported a high rate of resorption in rats subjected to gestational magnesium deficiency. No significant increase in congenital defects was seen in surviving pups.

1.4.1.5 Carcinogenesis MgO is regarded as an “experimental tumorigen” (15), although the only reference in the literature that could be found relating to the carcinogenicity of MgO was an

instillation study, in which MgO dust instilled intratracheally for 30 weeks resulted in induction of histiocytic lymphomas in hamsters (16). It was also demonstrated that MgO enhanced the tumorigenesis of benzo[*a*]pyrene and was an effective carrier agent for the experimental induction of respiratory tract tumors (17).

1.4.2 Human Experience 1.4.2.1 General Information Magnesium is an essential element for human survival. The recommended intakes are 30–75 mg/day for infants; 80–130 mg/day for children; 240 mg/day (age 9–13 years), increasing with age to 420 mg/day for males >70 years of age; 240 mg/day (age 9–13 years), increasing to 320 mg/day for females >70 years of age. Normally, serum contains 2–5 mg/dL of magnesium; the total body burden is estimated at 20 g. Recommended daily allowances for pregnancy range from 360 to 400 mg/day, and 320 to 360 mg/day during lactation (3). Hypocalcemia is a prominent manifestation of magnesium deficiency in humans (3). Early clinical signs of hypermagnesiumemia include hypotension, hyporeflexia, and decreased respiration (18). Magnesium deficiency has been associated with neuromuscular irritability, pathological calcification, and damage to the heart and kidneys (19). Toxicological concerns arise from exposure to magnesium oxide [*1309-48-4*] (particulates and fumes), and, to a lesser extent, magnesite [*546-93-0*] ($MgCO_3$).

1.4.2.2 Clinical Cases 1.4.2.2.1 Acute Toxicity Large pharmacological doses of magnesium can have serious adverse effects, including metabolic alkalosis, diarrhea, dehydration, and cardiac arrest. In a number of cases, renal impairment contributed to magnesium toxicity (3). Inhalation of MgO fumes produced a febrile reaction and leukocytosis, analogous to metal fume fever induced by ZnO (12). Dermal contact with magnesium compounds, or embedded magnesium particles, can induce "chemical gas gangrene," which is slow to heal (15).

1.4.2.2.2 Chronic and Subchronic Toxicity: NA

1.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanism Oral doses of some magnesium salts, namely, the sulfate and citrate, are poorly absorbed; osmotic withdrawl of water from the gut wall causes their purgative effects.

1.4.2.2.4 Reproductive and Developmental No increase in birth defects was noted in the offspring of 141 women treated with magnesium sulfate (including six treated during the first 4 months) during pregnancy (20). Twenty-seven hypertensive women were treated with magnesium hydroxide during the third trimester of pregnancy; no effect was noted on the newborns, except a slight increase in body weight in the children born to the treated mothers vs. controls (21). Cord serum levels of magnesium were reported to be 70–100% of the maternal levels after maternal therapy. In such cases, neurological depression may occur in the neonate, characterized by respiratory depression, muscle weakness, and decreased reflexes (22). No decrease in Apgar scores was noted in infants of females treated for pregnancy-induced hypertension, although the magnesium levels in the infants reflected hypermagnesiumemia (23). Prolonged magnesium treatment during pregnancy may be associated with maternal and fetal hypocalcemia and adverse effects on fetal bone mineralization (22).

1.4.2.2.5 Carcinogenesis: NA

1.4.2.2.6 Genetic and Related Cellular Effects: NA

1.4.2.2.7 Other: Neurological, Pulmonary, Skin Sensitization, etc.: NA

1.4.2.3 Epidemiology Studies When ingested as a naturally occurring food source, magnesium has not been demonstrated to have adverse effects.

1.4.2.3.1 Acute Toxicity The initial sign of excessive oral magnesium intake from nonfood sources is

diarrhea; in fact, various magnesium salts are used pharmacologically for their cathartic effects.

1.4.2.3.2 Chronic and Subchronic Toxicity: NA

1.4.2.3.3 Pharmacokinetics, Metabolism, and Mechanism: NA

1.4.2.3.4 Reproductive and Developmental: NA

1.4.2.3.5 Carcinogenesis: NA

1.4.2.3.6 Genetic and Related Cellular Effects: NA

1.4.2.3.7 Other: Neurological, Pulmonary, Skin Sensitization, etc Habitual low magnesium intake or prolonged hypomagnesiumemia is associated with alterations of vascular and cardiac function, as well as with cardiovascular disease. Magnesium supplementation after a heart attack reduces the incidence of therapy-requiring arrhythmias, and individuals exposed to drinking water with high concentrations of magnesium reportedly have a reduced incidence of hypertension (3, 18). A study involving 2316 patients with acute myocardial infarction showed a 24% reduction in 28-day mortality when intravenous magnesium was used either before or at the time of thrombolytic administration (24). A subsequent study in which magnesium was administered over a different time course did not confirm these observations, so further evaluation of this issue has been undertaken (25). Magnesium supplementation may also be beneficial in the treatment of burns and migraine headaches (26, 27).
1.5 Standards, Regulation, or Guidelines of Exposure
No drinking-water standards have been established for magnesium or magnesium salts. The threshhold limit value (TLV) for magnesium oxide [*1309-48-4*] fume is 10 mg/m^3. The OSHA time-weighted-average permissible exposure limit (TWA PEL) is also 10 mg/m^3 (total particulates) and 5 mg/m^3 (respirable particles). Magnesite [*546-93-0*] ($MgCO_3$) is considered by both OSHA and ACGIH to be a dust that does not produce significant organic disease or toxic effect when exposures are kept under reasonable control. The ACGIH TLV TWA is 10 mg/m^3, measured as total particulate, and the OSHA TWA PEL is 15 mg/m^3 as total particulate, and 5 mg/m^3 for respirable fraction.

2.0.5 Molecular Formula:
Ca
2.1 Chemical and Physical Properties
2.1.1 General Melting point: 845°C, boiling point: 1484°C, specific gravity: 1.54; vapor density: 1.4. Calcium is a silvery-white alkaline-earth metal that is seldom found as the free metal in nature. It is

an essential component of leaves, bones, teeth, and shells. It is a hard, silvery-white metal that forms a white coating of nitride in air. Calcium is found as limestone, gypsum, and fluorite, and makes up >3% of the earth's surface (fifth most abundant element). Calcium imparts a red color to flames. Calcium occurs naturally as six isotopes: ^{40}Ca (97%), ^{44}Ca (2.06%), ^{42}Ca (0.64%), ^{48}Ca (0.18%), ^{43}Ca (0.145%), and ^{46}Ca (0.003%).

2.1.2 Odor and Warning Properties No odor or warning properties are attributable to calcium itself, although calcium salts may have an odor characteristic of the associated anions.

2.2 Production and Use

The principal commercial source of calcium is limestone. Calcium metal can also be produced by electrolysis of calcium chloride. Seawater contains approximately 400 g of calcium per ton. Calcium is an essential element, required for normal physiological function of all cells. It is also a cofactor required for the function of multiple metabolic enzymes, and is required for neurotransmitter release. Calcium is used in metallurgy as a deoxidizer for copper, beryllium, and steel and to harden lead for bearings. Calcium is alloyed with cerium to make flints for cigarette and gas lighters. Calcium is used in the manufacture of electronic vacuum tubes as a “getter” to fix residual gases as oxides, nitrides, and hydrides of calcium. Calcium gluconate is used as a treatment for acute hypotension, and many calcium salts are used in the treatment of hypocalcemia. Calcium carbide is used in the production of acetylene (4). Calcium cyanamide is used medically for its Antabuse–like effect. Many calcium compounds are used as food additives for a variety of functions including calcium acetate as a texturizer and stabilizer, calcium bromate as a flour treatment, calcium carbonate as a nutritional supplement, and calcium chloride as a humectant (28). Calcium EDTA is used in the treatment of lead poisoning, as it has been shown to be effective in removing lead from soft tissues (29).

2.3 Exposure Assessment

2.3.1 Air Calcium compounds can be measured (as Ca^{2+}) using ICP-AES (NIOSH method 7300) or atomic absorption (NIOSH method 7020) (6).

2.3.2 Background Levels: NA

2.3.3 Workplace Methods: NA

2.3.4 Community Methods: NA

2.3.5 Biomonitoring/Biomarkers 2.3.5.1 Blood Measurement of serum calcium is a routine part of various clinical blood profiles. Reference values for serum calcium concentrations: up to 1 month of age: 7.0–11.5 mg/dL; 1 month of age to 1 year: 8.6–11.2 mg/dL; up to 30 years of age: 8.2–10.2 mg/dL, with a continuing slight decrease with advancing age (5). Calcium can also reportedly be measured in blood and plasma via neutron activation analysis (7).

2.3.5.2 Urine: NA

2.4 Toxic Effects

2.4.1 Experimental Studies 2.4.1.1 Acute Toxicity Calcium chloride was administered intravenously to ICR mice, and an LD_{50} value of 42.4 mg/kg was derived from these studies (8). Severe mucous membrane irritation can result from ingestion of plant tissues containing calcium oxalate crystals (*e.g., Philodendron, Diffenbachia*), and calcium oxalate is the causative agent of the renal toxicity associated with ethylene glycol poisoning.

2.4.1.2 Chronic and Subchronic Toxicity: NA

2.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms In general, toxicological effects of concern related to calcium are associated with sustained increases in intracellular calcium. Although this situation can have a therapeutic benefit in certain instances, such as the increase in intracellular calcium caused secondarily to inhibition of Na^+, K^+-ATPase by such compounds as digitalis—thus causing enhanced contractility and excitability of cardiac muscle (30), sustained increases in

intracellular calcium are rarely beneficial. The intracellular concentration of cytosolic free Ca^{2+} is approximately 100 nM (31). The 10,000-fold gradient between extracellular and intracellular calcium is maintained by the impermeability of the plasma membrane to calcium and by calcium pumps that either move calcium up the concentration gradient across the plasma membrane, or sequester excess intracellular calcium in the endoplasmic reticulum or mitochondria. Because mitochondria have a low affinity transporter, they are active in calcium sequestration only when concentrations rise into the micromolar concentration range.

Sustained increases in intracellular free calcium can occur via a number of mechanisms (Table 28.1) (32, 33) and can cause cell damage in at least three ways. First, increased sequestration of calcium in mitochondria is associated with decreased ATP synthesis, with depletion of cellular energy reserves. This can potentiate a destructive cycle, as the extrusion of calcium from cells is ATP-dependent. A second means by which increased intracellular calcium can have toxic effects is via its effect on cellular cytoskeletal proteins. Increased intracellular calcium causes diassociation of actin filaments from a-actinin and fodrin; these two proteins promote anchoring of actin filaments to the plasma membrane. Without this anchoring, membrane blebbing occurs, which predisposes the membrane to rupturing (30). A third mechanism by which increased intracellular calcium can exert a toxic effect is via activation of hydrolytic enzymes that degrade protein, phospholipids, and nucleic acids. Neutral calcium-activated neutral proteases, or calpains, target integral membrane proteins and can proteolytically activate protein kinase C. Activation of phospholipases by calcium ions causes membrane degeneration directly and by the generation of detergents. Chromatin fragmentation occurs with the activation of Ca^{2+}-Mg^{2+}-dependent endonucleases. In addition, elevated intracellular Ca^{2+} can lock topoisomerase II in a form that cleaves—but does not ligate—DNA, contributing to chromatin fragmentation (30).

Table 28.1. Mechanisms and Agents Associated with Sustained Elevated Intracellular Ca^{2+}[a]

Mechanism	Agent(s)
Increased influx of Ca^{2+} into cytoplasm via	
Glutamate receptor agonists	"Excitotoxins": glutamate, domoate
Vanilloid receptor agonists	Capsaicin, resiniferatoxin
Voltage-gated Ca^{2+} channels	Maitotoxin
Newly formed membrane pores	Amphotericin B, ionomycin, A23187
Disruption of cell membranes	Detergents, hydrolytic enzymes, lipid peroxidants, cytoskeletal toxins
Release from mitochondria	Alloxan, ninhydrin
Release from sarcoplasmic reticulum	Ryanodine, also mutation in ryanodine receptor
Inhibition of Ca^{2+} export from the cytoplasm	
Inhibition of Ca^{2+}, Mg^{2+}-ATPase	DDT, cyclodiene insecticides, pyrethroid insecticides
Blockage of voltage-gated Ca^{2+} channels	Nickel, manganese, lanthanum
Inhibition of Ca^{2+}-activated K^{+} channels	Barium, apamin (bee venom), dendrotoxin

Impairment of mitochondrial ATP synthesis	
Inhibition of hydrogen delivery to the electron-transport chain	Fluoroacetate, dichlorovinylcysteine
Inhibition of electron transport	Rotenone, MPP^+, dinitroaniline, cyanide, formate
Inhibition of oxygen delivery to the electron-transport chain	CNS depressants, carbon monoxide
Inhibition of ADP phosphorylation	DDT, *N*-ethylmaleimide, dinitrophenol
Hydrolysis of $NAD(P)^+$ in mitochondria	Alloxan, *t*-butyl hydroperoxide, menadione

[a] Adapted from Refs. 9, 30, 32, 33 and 33a.

2.4.1.3.1 Absorption Calcium is absorbed from the gastrointestinal (GI) tract as a two-step process. Absorption occurs rapidly from the gut lumen into mucosal cells, and is then extruded into the interstitial fluid, with the first step faster than the second. 1,25-Dihydroxyvitamin D ($1,25(OH)_2D$, the active form of vitamin D) is required for both steps in calcium transport. Fractional calcium absorption varies inversely with dietary calcium intake. With a prolonged decrease in calcium intake, serum parathyroid hormone and $1,25(OH)_2D$ concentrations increase and the fraction of ingested calcium which is absorbed increases (3).

2.4.1.3.2 Distribution Calcium in the bloodstream is predominantly associated with albumin (33b).

2.4.1.3.3 Excretion Unabsorbed calcium is excreted in the feces. Renal calcium excretion is a function of the filtered load and the efficiency of reabsorption; the latter of these is regulated by parathyroid hormone. A high sodium diet increases the renal excretion of calcium, as both compete for reabsorption at the same sites in the renal tubules. The absorption of calcium from foods can be decreased by the presence of oxalic acid (found in spinach, sweet potatoes, rhubarb, and beans) or phytic acid (found in unleavened bread, nuts, grains, and soy isolates) (3).

2.4.1.4 Reproductive and Developmental Shackelford et al. (34) fed rats up to 1.25% dietary calcium carbonate for 6 weeks prior to mating and during gestation and found no adverse effects.

2.4.1.5 Carcinogenesis No studies on the carcinogenicity of elemental calcium were noted. The carcinogenicity of calcium chromate is attributed solely to intracellular soluble chromium (1).

2.4.1.6 Genetic and Related Cellular Effects Under normal physiological conditions, intracellular calcium concentrations are maintained approximately 10,000-fold lower than extracellular levels. Calcium cyanamide was weakly positive and inconclusive in the *Salmonella* assay, and it was negative in the mouse lymphoma assay, *Drosophila* tests, and cytogenetic tests for chromosomal aberrations and sister-chromatid exchanges (35).

2.4.2 Human Experience 2.4.2.1 General information Calcium accounts for 1–2% of adult human body weight, and the greatest proportion is found in bone and teeth. Adequate calcium ingestion is critical for proper bone and tooth development, as well as for the proper function of nerves, muscles, and other tissues. Adequate calcium ingestion is also felt to be critical in preventing osteoporosis. Recommended daily allowances (RDAs) range from 210 to 270 mg/day for infants, 500 to 800 mg/day for children, 1250 mg/day for males and females up to age 18, and 700 mg/day for

adults (3). Toxicological concern is associated with exposure to such calcium salts as calcium silicate [*1344-95-2*], calcium oxide [*1305-78-8*] (lime), calcium hydroxide [*1305-62-0*], and calcium cyanamide [*156-62-7*].

2.4.2.2 Clinical Cases 2.4.2.2.1 Acute Toxicity Calcium oxide (also known as unslaked lime) is a component of Portland cement and many commercial wall plasters. On contact with water, calcium hydroxide and heat are liberated. When calcium oxide comes into contact with the eye, both the heat and the tendency for the formation of clumps can result in ocular damage (36).

2.4.2.2.2 Chronic and Subchronic Toxicity The available data on the adverse effects of excessive calcium intake in humans primarily concerns calcium intake from nutritional supplements. The three most significant biological effects of excessive calcium intake are kidney stone formation (nephrolithiasis), the syndrome of hypercalcemia and renal insufficiency with and without alkalosis, and the interaction of calcium with the absorption of other minerals.

It is clear that other minerals, such as magnesium, are also important in kidney stone formation, but there is a clear association between high calcium intake and kidney stone formation. Hypercalcemia and renal insufficiency, also known as the *milk–alkali syndrome* (MAS), was recognized in the context of a formerly popular treatment of peptic ulcers by administering large amounts of milk and absorbable antacids. MAS was associated with progressive renal failure, which in turn led to the deposition of calcium in soft tissues, particularly the kidney. Calcium can clearly decrease the absorption of iron, although clinically, human data do not show an association between iron deficiency and high calcium intake (3).

2.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms: NA

2.4.2.2.4 Reproductive and Developmental Supplemental doses of calcium salts taken during pregnancy are regarded as unlikely to pose a teratogenic risk (37). Heinonen et al. (20) reported the results of a survey of 1007 women who took calcium compounds during the first trimester of pregnancy. In this study, 10 central nervous system (CNS) defects were observed (no specific deformity was described), and 4.7 were expected; this is likely to be a sporadic observation, as the standardized relative risk with 95% confidence interval ranged from 1.02 to 3.87. A congenital condition known as *infantile hypercalcemia* has been associated with supravalvular aortic stenosis, failure to thrive, mental retardation, and areas of dense calcification in the skull, vertebrae, and long bones. This rare condition appears to develop in children taking normal vitamin doses and whose mothers took a normal vitamin supplement during pregnancy (38).

2.4.2.2.5 Carcinogenesis Although calcium chromate is reportedly carcinogenic, the carcinogenicity is solely attributable to intracellular soluble chromium, not the calcium cation (1). The carcinogenicity of calcium cyanamide has not been evaluated.

2.4.2.3 Epidemiology Studies 2.4.2.3.1 Acute Toxicity: NA

2.4.2.3.2 Chronic and Subchronic Toxicity: NA

2.4.2.3.3 Pharmacokinetics, Metabolism and Mechanisms: NA

2.4.2.3.4 Reproductive and Developmental: NA

2.4.2.3.5 Carcinogenesis: NA

2.4.2.3.6 Genetic and Related Cellular Effects Studies Malignant hyperthermia susceptibility (MHS) is an autosomal dominant disorder of skeletal muscle and a major cause of death due to anesthesias. Malignant hyperthermia arises from stimulus-elicited release of Ca^{2+} from the sarcoplasmic

reticulum. Many individuals diagnosed with MHS have one of several known mutations in the Ca^{2+} release channel, known as the *ryanodine receptor* (39, 40). Intravenous administration of dantrolene blocks release of Ca^{2+} from the sarcoplasmic reticulum, decreasing heat production and acidosis, which characterize this condition (41).

2.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH has a TLV TWA of 0.5 mg/m^3 for calcium cyanamide. OSHA similarly has an 8-h TWA PEL of 0.5 mg/m^3 for calcium cyanamide. The ACGIH TLV TWA and the OSHA PEL for calcium hydroxide are 5 mg/m^3. Calcium silicate and calcium carbonate, regulated as nuisance dusts, have 8-h TWAs of 10 mg/m^3, and the OSHA standards are 15 mg/m^3 for the 8-h TWA, and 5 mg/m^3 limit as the respirable fraction. The TLV TWA and OSHA PEL for calcium hydroxide are both set at 5 mg/m^3. The TLV TWA and OSHA PEL for calcium oxide are 2 and 5 mg/m^3, respectively. No drinking-water standards have been established for calcium or calcium salts.

Magnesium, Calcium, Strontium, Barium, and Radium

3.0 Strontium

3.0.1 CAS Number:

[*7440-24-6*]

3.0.2 Synonyms:

NA

3.0.3 Trade Names:

NA

3.0.4 Molecular Weight:

87.62

3.0.5 Molecular Formula:

Sr

3.1 Chemical and Physical Properties

3.1.1 General Strontium is a silvery-white alkaline-earth metal that rapidly assumes an oxide film and yellow color on exposure to air. Strontium salts impart a brilliant red color to a flame. The finely divided metal ignites spontaneously in air; therefore, the metal should be stored under oxygen-free liquid. Naturally occurring isotopes include ^{88}Sr (82.56%), ^{86}Sr (9.86%), ^{87}Sr (7.02), and ^{84}Sr (0.56%) (4). In addition, at least 11 strontium isotopes are produced by fission; of these, the ^{89}Sr and ^{90}Sr isotopes are considered to be environmentally significant. ^{89}Sr emits b particles with an average energy of 583 keV (1.46 MeV maximum) and has a half-life of 50.5 days. ^{90}Sr is a long-range b-emitter (mean energy 195.8 keV; maximum 540 keV) with a half-life of 28 years (42). At least 20 strontium salts are known.

3.1.2 Odor and Warning Properties No odor or warning properties are attributable to strontium itself, although Sr salts may have an odor characteristic of the associated anions.

3.2 Production and Use

Strontium is found in small quantities associated with barium and calcium minerals. Strontium has been used in the past in the production of radioluminescent paints for use particularly on watch dials. Strontium bromide is used as a sedative; the chlorate, chloride, nitrate, and sulfate salts are used in the production of pyrotechnics. $^{89}SrCl_2$ [*14158-27-1*] (Metastron) is used therapeutically for relief of bone pain in patients with skeletal metastases (5).

3.3 Exposure Assessment

3.3.1 Air: NA

3.3.2 Background Levels Strontium is widely found, generally in association with calcium. Seawater contains 10 ppm. Celestite ($SrSO_4$) and strontianite ($SrCO_3$) are strontium-containing minerals (43). The concentration of strontium in drinking water from nine communities in Ohio and Wisconsin ranged from 0.02 to 33.9 mg/mL (44). ^{90}Sr was detected at significantly higher concentrations in soil than in food crops grown at the Los Alamos National Laboratory, New Mexico (45).

3.3.3 Workplace Methods: NA

3.3.4 Community Methods: NA

3.3.5 Biomonitoring/Biomarkers A unique body counting system (SICH-9.1) has been described for determining body burdens of ^{90}Sr via bremsstrahlung (46).

3.3.5.1 Blood A method for determination of strontium in human blood samples by ICP–AES has been described (47). Strontium can also reportedly be measured in blood and plasma via neutron activation analysis (7).

3.3.5.2 Urine A three-column system composed of a chelating concentrator column, a cation-exchange column, and an ion–exchange separator column has successfully been used to determine ^{90}Sr in water and urine samples (48).

3.3.5.3 Other Because strontium readily substitutes for calcium in many biological reactions, the content of strontium in milk is of particular interest. Several methods for determination of ^{90}Sr in milk have been described (48, 49).
3.4 Toxic Effects
3.4.1 Experimental Studies 3.4.1.1 Acute Toxicity In general, stable (nonradioactive) strontium salts are of little toxicological concern, particularly on oral ingestion, because of their limited absorption from the GI tract. Strontium chloride was administered intravenously to ICR mice, and an LD_{50} value of 147.6 mg/kg was derived (8).

3.4.1.2 Chronic and Subchronic Toxicity: NA

3.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms 3.4.1.3.1 Absorption Strontium is highly associated with calcium throughout the food chain. However, in humans, absorption of calcium is preferred to strontium, and calcium is used preferentially over strontium in bone and milk production. The Sr:Ca ratio in bone is relatively constant for members of a species, regardless of age. Gastrointestinal absorption of strontium was reported to be approximately 20–30%. Combined nasal and gastrointestinal absorption of soluble ^{85}Sr was about 85%, with >50% directly absorbed from the nasal cavity (50).

3.4.1.3.2 Distribution Strontium is either deposited in bone or distributes into an exchangeable pool composed of plasma, cellular fluids, soft tissues, and bone surfaces. Orally administred $Sr(NO_3)_2$ accumulated in rat skeletons proportional to the administered dose, averaging 2.7% (1). $^{90}SrCl_2$ administered via inhalation (aerosol) was rapidly translocated from the lung to the skeleton, behaving similarly to intravenously administered soluble Sr on reaching the bloodstream (51). Following intravenous administration of $^{89}SrCl_2$ at two different doses (0.74 kBq/g body weight or 74 kBq/g), approximately 1.30 and 1.50%, respectively, of the administered dose was retained in the femurs 7 days after administration (52). Skeletal Sr can be mobilized during late pregnancy and lactation, migrating to the fetal skeleton and to the infant via breast milk (53). An active transplacental transfer of strontium has been demonstrated, with discrimination between strontium and calcium early in pregnancy and equal transplacental transport of the two ions later in pregnancy (54).

3.4.1.3.3 Excretion Excretion of unabsorbed Sr is predominantly via the feces, with smaller amounts in urine and sweat (1).

3.4.1.4 Reproductive and Developmental In a multigenerational miniature swine study, dams were fed ^{90}Sr at various levels, and then the offspring were exposed via lactation and feed. It was observed that levels of ^{90}Sr high enough to affect fetal or neonatal mortality would not permit the survival of the dam through gestation (51). Injection of pregnant mice with ^{90}Sr was associated with a decrease in the number of fetal oocytes (20 mCi on gestational day 11 or 16) and skeletal malformations (5–10 mCi) (14).

3.4.1.5 Carcinogenesis The carcinogenicity of stable (nonradioactive) strontium chromate was attributed solely to intracellular soluble chromium (1). ^{90}Sr has been examined in long-term studies in four species, involving beagles, mice, monkeys, and pigs. A summary of the findings of these studies can be found in Ref. 51. Following intravenous injection of ^{90}Sr at doses ranging from 0.027 to 362×10^4 Bq/kg, the most prominent ^{90}Sr-induced endpoint was bone sarcoma. Neoplasms involving the soft tissues near bone in the oronasopharynx and paranasal sinuses and bone marrow dysplasia were also significantly elevated over controls. Feeding studies in beagles extending from the *in utero* period to age 540 days resulted in the development of the same array of tumors, and, in addition, myeloproliferative disorders. Inhalation exposure to $^{90}SrCl_2$ was associated with multiple carcinogenic and non-neoplastic lesions in dogs, with an excess of bone tumors reported as the major finding. Interestingly, inhalation exposure of dogs to insoluble forms of ^{90}Sr was associated with lung tumors, but not bone tumors (51). In an additional study in which beagle dogs were injected with low levels of ^{90}Sr (21.1 kBq/kg, or 5 times the maximum permissible (retained) body burden), ^{90}Sr was not associated with a decrease in survival time (55). It has been estimated that ^{90}Sr is approximately two orders of magnitude less toxic than radium (56). Two monkey studies were also summarized by the Council on Radiation Protection and Measurements (51). One of these studies involved administration of single intravenous injections of ^{90}Sr (0.10–6.21 MBq) to rhesus monkeys. These monkeys had no symptoms or disease attributable to ^{90}Sr 20 years after exposure. In another study, administration of 1.85 or 3.7 MBq of ^{90}Sr as a single oral dose resulted in bone sarcomas (51).

3.4.1.6 Genetic and Related Cellular Effects Studies Oral administration of strontium chloride to mice resulted in dose-dependent chromosomal aberrations in bone marrow metaphase preparations (57). An increased mutation frequency was noted in the bone marrow, but not liver or spleen, in the lacZ transgenic mouse (Muta mouse) following intravenous administration of 74 MBq/kg of ^{89}Sr (58).

3.4.2 Human Experience 3.4.2.1 General Information In general, the nonradioactive salts of strontium are of little toxicological concern, particularly on oral administration, because of the low GI bioavailability of the strontium ion. However, strontium is highly dangerous in its radioactive forms. On absorption, strontium concentrates primarily in bones.

3.4.2.2 Clinical Cases 3.4.2.2.1 Acute Toxicity In patients administered $^{89}SrCl_2$ for relief of bone pain associated with metastatic bone cancer, the major side effects noted are bone marrow supression and thrombocytopenia (5).

3.4.2.2.2 Chronic and Subchronic Toxicity: NA

3.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms: NA

3.4.2.2.4 Reproductive and Developmental Leikin and Paloucek (5) list $^{89}SrCl_2$ as a pregnancy risk factor D, meaning that there is positive evidence of fetal risk, but the benefits from use in pregnant women may be acceptable despite the risk. There are equivocal data, summarized in Shepard (14), regarding the relationship between fetal ^{90}Sr body burden and incidence of birth defects in humans.

3.4.2.3 Epidemiology Studies 3.4.2.3.1 Acute Toxicity: NA

3.4.2.3.2 Chronic and Subchronic Toxicity: NA

3.4.2.3.3 Pharmacokinetics, Metabolism and Mechanisms: NA

3.4.2.3.4 Reproductive and Developmental: NA

3.4.2.3.5 Carcinogenesis The U.S. EPA has categorized stable strontium as a cancer group D, which indicates that there is inadequate or no human or animal evidence of carcinogenicity (59). Strontium chromate is a suspected human carcinogen, an effect attributable to the chromate component.
3.5 Standards, Regulations, or Guidelines of Exposure
Strontium is listed by the U.S. EPA as a candidate for establishment of a maximum contaminant level, but none presently exists. The reference dose (RfD) for strontium has been estimated at 0.6 mg/kg per day; this corresponds to a daily level of exposure that is likely to be without appreciable risk of deleterious effects over a lifetime. The TLV TWA for strontium chromate is 0.0005 mg/m^3 as chromate, because strontium chromate is regarded as a class A2, or suspected human, carcinogen.

Magnesium, Calcium, Strontium, Barium, and Radium
Mary Beth Genter, Ph.D., DABT

4.0 Barium
4.0.1 CAS Number:
[*7440-39-3*]
4.0.2 Synonyms:
NA
4.0.3 Trade Names:
UN 1399, UN 1400, UN 1854
4.0.4 Molecular Weight:
137.33
4.0.5 Molecular Formula:
Ba
4.1 Chemical and Physical Properties
4.1.1 General Melting point: 725°C; boiling point: 1640°C; specific gravity: 3.51 at 20°C. Barium exists as multiple isotopes: 138 (71.66%); 137 (11.32%); 136 (7.81%); 135 (6.59%); 134 (2.42%); 132 (0.097%); 130 (0.101%) (4). Barium participates in chemical reactions typical of alkaline-earth metals, that is, it reacts violently with acids, water, and carbon tetrachloride. Pure barium metal exists as yellowish-white, slightly lustrous lumps that are somewhat malleable and very easily oxidized (must be kept under petroleum or other oxygen-free liquid to exclude air). Typical of other alkaline-earth metals, barium decomposes in water, evolving hydrogen gas. There are approximately 40 different barium salts. Of these barium salts, approximately half are freely soluble in water, whereas others are practically insoluble (notably barium sulfate and carbonate). Solutions of soluble barium salts give a white precipitate with sulfuric acid or soluble sulfates, and they color nonluminous flame green. Water or acid soluble barium salts should be regarded as poisonous.

4.1.2 Odor and Warning Properties Most barium salts are odorless or have an odor and characteristic of the associated anion.

4.2 Production and Use

Barium carbonate occurs in nature as the mineral witherite; barium sulfate occurs in nature as the mineral barite; also as barytes, heavy spar. Barium is used as a carrier for radium. Alloys of barium with Al or Mg are used as getters in electronic tubes. Barium carbonate is used as rodenticide (4, 60) and in paints, enamels, and marble substitutes (4). Barium sulfate (multiple trade names, including Bakontal, Esophotrast, Micropaque, Raybar) is used as an X-ray-contrast material (4) and as a weighting substance for golf balls (61). Barium nitrate is used in the manufacture of pyrotechnics and green signal lights. Barium sulfide is used as a depilatory and in luminous paints.

4.3 Exposure Assessment

4.3.1 Air Barium can be released into the air during mining and in various industrial processes.

4.3.2 Background Levels Barium's abundance in earth's crust is approximately 0.05%. The background concentration of Ba in groundwater is approximately 0.1 mg/L, although significant regional excursions from this value have been documented (62). Seawater reportedly contains approximately 13 mg/L (5). Various measurements have revealed soil concentrations to range from 15 to 3000 ppm, and the average atmospheric concentration in North America is reported to be 0.12 mg/m^3 (5). Brazil nuts are exceptionally high in barium, with a concentration of 3000–4000 ppm (5). Depending on the geographic site, daily barium intake is estimated to be 300–1700 mg/person (63, 64).

4.3.3 Workplace Methods Barium-containing fluxes used in welding can result in significant airborne barium fumes and elevated urinary barium concentrations in exposed workers (65).

4.3.4 Community Methods In addition to workplace exposures, consumer products can be a source of barium exposure. For example, about half of a sample of crayons was demonstrated to contain barium capable of migrating, thus representing a potential source of exposure for children (66). It has also been predicted that some lipsticks can represent a significant source of barium exposure (64).

4.3.5 Biomonitoring/Biomarkers No biomarkers of exposure to barium have been recognized, although methods to measure barium in various physical media have been described (67).

4.3.5.1 Blood Inductively coupled plasma–atomic absorption spectrometry (ICP-AES) has been used for measurement of barium compounds (as Ba) in biological materials, including blood. The detetion limit for Ba in blood by this method is reported to be 0.6 mg/L of blood (68). Neutron activation analysis has also been used for determining levels of Ba in human blood, with detection limits of 7 mg Ba/L of red blood cells and 66 mg Ba/L of plasma (7).

4.3.5.2 Urine Barium concentrations in urine of workers exposed to barium welding fumes reportedly increased, but the method used was not described (65). Subsequently, methods for detecting barium in urine have been published (6, 68, 69). The detection limit for Ba in urine measured by ICP-AES is reported to be 0.26 mg/L of urine (68). A proposed reference value for Ba in urine for biological monitoring purposes is <15 mg/g creatinine (70).

4.3.5.3 Other In the workplace soluble barium compounds can be monitored in air by flame atomic absorption. Samples can be collected on 0.8-mm cellulose ester membranes at a flow rate of 1 to 4 L/min (6).

4.4 Toxic Effects

4.4.1 Experimental Studies 4.4.1.1 Acute Toxicity LD_{50} values were derived following intravenous administration of soluble barium salts in two strains of mice: Swiss Webster and ICR. The Swiss Webster mice were the more sensitive strain, with LD_{50} values of 8.1, 8.5, and 11.3 mg/kg for barium chloride, nitrate, and acetate, respectively. The corresponding values for the ICR mice were 19.2, 20.1, and 23.3 mg/kg for barium chloride, nitrate, and acetate, respectively (8). In rats, the oral

LD_{50} of barium zirconate was reported to be >1.98 g/kg and the inhalation LD_{50} of barium zirconate was calculated to be 0.42 g/kg (71). A soluble form of barium, barium chloride, was considerably more acutely toxic in rats, with the LD_{50} calculated to be 220 mg/kg (as Ba) in weanling rats, and 132 mg/kg (as Ba) for adult rats (72). Elevated blood pressure, bronchoconstriction, ECG abnormalities, and myocardial hyperexcitability were demonstrated in guinea pigs administered barium-containing fume extract. These effects could be modified by nifedipine and propranolol (73). Similarly, intravenous administration of barium chloride to rabbits resulted in severe ventricular dysrhythmias, which were relieved by treatment with doxepin or verapamil (74).

4.4.1.2 Chronic and Subchronic Toxicity Barite dust inhaled by guinea pigs was reportedly associated with nodular pulmonary granulation, characteristic of human baritosis (1). A more recent study revealed no pulmonary granulomas following inhalation exposure to barium zirconate, although thickening of alveolar walls, as well as the medial layer of arteriole walls, was noted, with the general picture of a chronic interstitial pneumonitis (71).

The results of at least three subchronic barium chloride drinking-water studies have been published. In the first of these, groups of young adult Charles River rats of both sexes were exposed at concentrations of barium chloride of ≤250 mg/L (ppm) for 4, 8, or 13 weeks. No significant toxic effects were noted. A tissue distribution study revealed that barium concentration in several tissues increased with dose, but not duration of exposure, and that the highest concentrations were found in bone (72). A subsequent subchronic study in which Fischer 344/N rats and B6C3F1 mice were administered barium chloride in the drinking water at levels up to 4000 ppm revealed renal toxicity as the major toxicological finding (75). Barium-treated male and female rats exhibited higher serum phosphorous than did controls, but other electrolytes and hematological values were within normal ranges. In both species, the animals in the 4000-ppm treatment group exhibited alterations in motor activity, grip strength, and thermal sensitivity. Central nervous system effects were also reported after subchronic–chronic subcutaneous injection of barium chloride (43).

A third barium chloride drinking water study was designed to evaluate the potential *in vivo* cardiovascular effects of long–term barium exposure. Long–term administration of barium chloride (100 ppm) resulted in hypertension, hypersensitivity to barbiturate anesthesia, disturbances in myocardial energy metabolism, and depressed cardiac excitability, preferentially in the arterioventricular nodal region of the heart (76).

4.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms The barium ion is a chemical antagonist to potassium, and it appears that symptoms of barium poisoning are attributable to Ba^{2+}-induced hypokalemia (77). a-Adrenergic responsiveness was found to be enhanced in barium-treated Purkinje fibers (78). Barium mimics calcium in its effects, but their kinetics in subcellular stores may be different (79). Barium also inhibits Ca^{2+}-activated K^{+} channels, which prolongs excitation and can cause potentially lethal neuroexcitatory and spasmogenic effects (30).

4.4.1.3.1 Absorption Barium, in food sources, is absorbed from the GI tract into the bloodstream at approximately 6% of the administered dose (5). Approximately 75% of inhaled barium is absorbed (5). In beagle dogs, respiratory tract absorption of inhaled particles (1.2–2.1 mm median aerodynamic diameter) contributed significantly to the absorption of $BaCl_2$. Approximately 75% of the body burden was absorbed into the circulatory system within hours of inhalation exposure; 55% was attributed to absorption deposited in the pulmonary regions of the lung and 2% to GI absorption (50).

4.4.1.3.2 Distribution Studies in rats showed that barium is cleared from the serum by deposition in bone and teeth (5, 80). Barium is also deposited in muscles, and is stored in lung, with little retention in liver, kidneys, spleen, brain, heart, or hair (81).

4.4.1.3.3 Excretion A study of the metabolism of ^{140}Ba in rats showed the urinary and fecal excretions to be 7 and 20%, respectively (1). The half life in the human body is estimated to be 3.6 days (5).

4.4.1.4 Reproductive and Developmental A subchronic study in which Fischer 344/N rats and B6C3F1 mice were administered barium chloride in the drinking water at levels of ≤4000 ppm revealed no anatomical effects in either species, but the offspring of the high dose rats exhibited a marginal reduction in pup weight. No effects were seen on reproductive indices (75). An earlier study in which $BaCl_2$ (20 mg) was injected into chick yolk sacs revealed curled toes in 50% of the surviving chicks (Ridgeway and Karnofsky, cited in Ref. 14).

4.4.1.5 Carcinogenesis A National Toxicology Program (NTP) 2-year study with male and female rats and mice, in which barium chloride hydrate was administered in drinking water, reported no evidence of carcinogenicity in either species (82). Bronchogenic carcinomas reportedly developed in rats injected intratracheally with $[^{35}S]BaSO_4$ (80).

4.4.1.6 Genetic and Related Cellular Effects Studies Barium nitrate was not positive in the Ames assay (*S. typhimurium* strains TA1535, TA1537, TA1538, TA97a, TA98, TA100, TA102c) with or without metabolic activation, with plate incorporation assay and preincubation assay methods. It was also negative in the mitotic crossing-over test, in the mitotic genic conversion test, and in the retromutation test in *Saccharomyces cerevisiae* D7 strain with or without metabolic activation (83). Genotoxicity studies with barium chloride hydrate were positive in the mouse lymphoma assay but negative in *Salmonella* assays and assays for increased frequencies of chromosomal aberrations and sister–chromatid exchanges in cultured Chinese hamster ovary cells (82).

4.4.2 Human Experience 4.4.2.1 General Information: NA

4.4.2.2 Clinical Cases Epidemic poisonings from soluble barium salts are rare. The most common poisoning occurs after ingestion of barium carbonate, which is used as a rodenticide (60). Onset of symptoms occurs within minutes to hours of ingestion and includes perioral paresthesias, vomiting, and severe diarrhea. Hypertension and cardiac dysrhythmias may follow. Profound hypokalemia and weakness progressing to flaccid paralysis are additional characteristics of barium poisoning. In one instance, a family was poisoned following accidental ingestion of barium carbonate, and one of these individuals also developed respiratory failure and rhabdomyolysis (60).

Following intentional ingestion of approximately 13 g of $BaCl_2$, a patient was hospitalized with intractable diarrhea, abdominal pain, weakness, and hiccups (84). The patient developed paralysis and profound hypokalemia, despite aggressive potassium replacement therapy. The patient also developed renal failure, possibly because he was administered intravenous magnesium sulfate. Oral magnesium sulfate is the treatment of choice to precipitate insoluble barium sulfate, thus preventing systemic absorption of barium; intravenous administration may have contributed to this patient's renal failure as a result of precipitation of barium sulfate in the bloodstream and/or kidneys (84).

4.4.2.2.1 Acute Toxicity The lethal dose of barium by ingestion is reported to be between 1 and 15 g (85), or 56 mCi/kg (5). The initial symptoms of toxicity are irritation of the gastrointestinal tract with nausea, vomiting, and diarrhea. Premature ventricular contraction and systemic hypertension often follow. The poisoned victim may progress to hiccups, convulsions, and flaccid paralysis. The paralysis often progresses centrally, and death occurs as a result of respiratory or cardiac arrest (84). Barium hydroxide and barium oxide are strongly alkaline in solution, causing severe burns of the eye and irritation of the skin (61).

4.4.2.2.2 Chronic and Subchronic Toxicity A benign pneumoconiosis, baritosis, was first described in humans in the 1930s (1). The condition occurs in individuals exposed to finely-ground $BaSO_4$ as

well as barite miners (1, 86). Because of the high radiopacity of barium, the chest radiologic picture shows discrete, dense images; however, no symptoms, abnormal physical signs, interference with lung function, or increased susceptibility to thoracic disease is believed to occur. The radiographic abnormalities disappear slowly with cessation of exposure (86). Bronchial irritation has been associated with $BaCO_3$, and BaO dust is considered a potential agent for dermal and nasal irritation (1).

4.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms The toxicity of barium is related to its direct stimulation of smooth, striated, and cardiac muscles and to severe depression of serum potassium levels. The reduced serum potassium levels are the result of increased intracellular potassium, rather than increased urinary excretion.

4.4.2.2.4 Reproductive and Developmental: NA

4.4.2.2.5 Carcinogenesis: NA

4.4.2.2.6 Genetic and Related Cellular Effects Studies: NA

4.4.2.2.7 Other: Neurological, Pulmonary, Skin Sensitization, etc There is some debate as to the appropriateness of the use of insoluble $BaSO_4$ as a contrast material in patients with obstructive bowel disease. The controversy centers on the fact that, whereas $BaSO_4$ is an excellent contrast material, it causes serious peritonitis when in contact with the peritoneal cavity; such contact could potentially occur if the patient requires surgery or if there is a rupture of the bowel (87).

4.4.2.3 Epidemiology Studies 4.4.2.3.1 Acute Toxicity: NA

4.4.2.3.2 Chronic and Subchronic Toxicity There are a number of epidemiological studies which together are inconclusive concerning the health impacts of barium in drinking water. An epidemiological study released in 1979 (88) associated an elevated risk of cardiovascular mortality with barium concentrations in drinking water > 1 ppm. The area in question was a region of northern Illinois where the barium concentration in drinking water was in the range of 7–10 ppm. However, another study in the same area did not reveal an associated elevation in blood pressure in individuals consuming high barium drinking water (62). A systematic follow-up study to these reports was conducted in eleven healthy men who were monitored for cardiovascular risk factors following 4 weeks of drinking water with 0 ppm of barium, followed by 4 weeks of drinking water with 5 ppm of barium, followed by 4 weeks of drinking water with 10 ppm of barium. Diet and water volume consumption were strictly monitored. It was determined that there were no changes in blood pressure, plasma cholesterol, lipoprotein, or apolipoprotein levels, serum potassium or glucose levels, or urine catecholamine levels. There were no arrhythmias related to barium exposure. Therefore, it was concluded that barium exposure at 5 or 10 ppm in the drinking water did not appear to affect any of the known modifiable cardiovascular risk factors (89).

4.5 Standards, Regulation, or Guidelines of Exposure

The U.S. Environmental Protection Agency (U.S. EPA) has established a maximum contaminant level (MCL) of 2 ppm of barium in the drinking water. The MCL represents the maximum level of a contaminant in water that is delivered to any user of a public water-supply system. U.S. EPA also requires that discharges or environmental spills of 10 lb or more of barium cyanide be reported. The Occupational Safety and Health Administration (OSHA), the National Institute for Occupational Safety and Health (NIOSH), and the American Conference of Governmental Hygienists (ACGIH) have set occupational exposure limits of 0.5 mg/m^3 (threshold limit value [TLV]) for an 8-h workday, 40 h/week for soluble barium compounds. The OSHA limit for barium sulfate dust in air is 10 mg/m^3 (total particulate; 5 mg/m^3 for respirable particles). NIOSH currently recommends that a level of 50 mg/m^3 be considered immediately dangerous to life and health. Australia and the United Kingdom have established exposure values of 0.5 mg/m^3 as Ba. Germany has additional exposure

values for the inhalable fraction of the aerosol: TWA short-term, 0.5 mg/m^3 1 mg/m^3; 30 min, 4 times per shift.

Magnesium, Calcium, Strontium, Barium, and Radium
Mary Beth Genter, Ph.D., DABT

5.0 Radium
5.0.1 CAS Number:
[*7440-14-4*]
5.0.2 Synonyms:
^{228}Ra (mesothorium); ^{223}Ra (actinium X); ^{224}Ra (thorium X)
5.0.3 Trade Names:
NA
5.0.4 Molecular Weight:
226.03
5.0.5 Molecular Formula:
Ra
5.1 Chemical and Physical Properties
5.1.1 General Pure metallic radium is brilliant white when freshly prepared, but blackens on exposure to air, likely because of formation of the nitride. Radium and its salts exhibit luminescence; like other alkaline-earth metals, radium decomposes on exposure to water and is more volatile than barium. Radium imparts a carmine red color to a flame. There are four naturally occurring isotopes of radium: ^{226}Ra, ^{228}Ra, ^{223}Ra, and ^{224}Ra. All isotopes of radium are radioactive, emitting a, b, and g rays. ^{226}Ra (half-life 1600 years) emits a radiation with an energy of 4.87 MeV. The endpoint of ^{226}Ra radioactive decay, emitting radioactive radon gas (^{222}Rn), is the formation of lead. ^{224}Ra has a much shorter half-life (3.62 days) and also decays via a particles (5.8 MeV). ^{222}Ra has a half-life of 11.4 days and similarly emits an a particle in its decay (5.98 MeV), whereas ^{228}Ra (half-life 5.7 years) decays by release of a b particle. Radium is over a million times more radioactive than the same mass of uranium (90). Melting point: 700°C, boiling point: 1737°C, *d*: 5.5.
5.2 Production and Use
Radium is extremely scarce but may be found in uranium ores such as pitchblende at approximately 1 g/ton. The commonly occurring salts are the chloride, bromide, carbonate, and sulfate. Radium may be made on a very small scale by the electrolysis of molten radium chloride (90). Radium was discovered in the early twentieth century, and found medicinal uses and, because of its luminescence, use in the painting of watch and clock dials, as well as military instruments. Radium therapy (^{226,228}Ra) was accepted by the American Medical Association (AMA) for treatment of rheumatism and as a general tonic, as well as for the treatment of mental disorders. ^{224}Ra was used in Europe for over 40 years in the treatment of tuberculosis and ankylosing spondylitis. The isotopes ^{223}Ra, ^{224}Ra, ^{226}Ra, and ^{228}Ra have all been used as radiation sources for treating neoplasms in humans (5).
5.3 Exposure Assessment
5.3.1 Air The combustion of coal is probably the most important mechanism of release of radium into the atmosphere. The mean concentration of ^{226}Ra in coal is on the order of 1 pCi/g. Radium combustion products may condense onto coal fly ash. The concentration of ^{226}Ra in fly ash ranges from 1 to 10 pCi/g; the ^{228}Ra content has been reported to vary from 1.8 to 3 pCi/g (91). It has been estimated that 2.2 Ci of total radium is released in this manner annually in the United States. Global release of ^{226}Ra is estimated at 150 Ci per year. ^{226}Ra concentrations in glacial ice samples have increased 100 fold since the 1920s, likely as a result of the increased combustion of fossil fuels (92).

5.3.2 Background Levels The concentration of radium in surface water is generally quite low. Shallow wells reportedly have lower ^{226}Ra concentrations than do deeper wells, and the total content in municipal water supplies is generally lower than that in untreated well water. A summary of several sampling studies reveals that ^{226}Ra generally occurs at concentrations ranging from 0.1 to 0.5 pCi/L in surface water, and the mean concentration in drinking water is 0.91 pCi/L. ^{228}Ra activity in several midwestern states in the United States ranged from 0.3 to 32 pCi/L, with typical concentrations < 1 pCi/L. The main source of radium contamination in water is believed to be from uranium mine tailings. Radium in water exists as the divalent cation and can interact significantly with sediments and dissolved solids in water.

The mean concentration of ^{226}Ra in soil in 33 states was 1.1 pCi/g, similar to levels reported for various types of rocks (91). Analysis of garden plots in Port Hope, Ontario, Canada revealed radium-contaminated plots with up to 830 pCi/g soil, compared to 1.2–2.6 pCi/g in plots uncontaminated by adjacent uranium mines (93). It has been estimated that the mean concentration of radium in the diet is approximately 0.73 pCi/kg of food (94).

5.3.3 Workplace Methods: NA

5.3.4 Community Methods: NA

5.3.5 Biomonitoring/Biomarkers Exposure to radium can be determined by the use of a whole body counter to measure the g radiation emitted by radium (95, 96).

5.3.5.1 Blood Radium can be measured in urine, feces, and other biological media by use of g-ray spectroscopy (91).

5.3.5.2 Urine Radium can be measured in urine, feces, and other biological media by use of g-ray spectroscopy (91).

5.3.5.3 Other The body burden of radium can be established by quantitation of radon in exhaled breath (94).

5.4 Toxic Effects

5.4.1 Experimental Studies 5.4.1.1 Acute Toxicity: NA

5.4.1.2 Chronic and Subchronic Toxicity For a variety of reasons, rodent studies examining the effects of a-particle emitters have been difficult to extrapolate to humans. Therefore, because of its long lifespan and the similarity of its biological properties to those of humans with regard to target organs, the beagle dog has been used as the model for study by several groups. Studies in beagle dogs indicate that a particles emitted by ^{226}Ra are bone-seeking and associated with bone tumors, whether administered as a single or repeated doses (97). Primary bone tumors (n = 155) were reported in 131 of 246 beagles injected with ^{226}Ra (5 primary bone sarcomas in 4 of 158 unexposed controls). The predominance of these (94%) were osteosarcomas (98). Mice injected with ^{224}Ra (69–550 Bq/g body weight) developed myeloid leukemia and osteosarcoma, with a dose–response correlation observed for both tumor types (99). In terms of extrapolating to human carcinogenic response to radium, these studies were interesting because a number of the mice in this study developed leukemia in the absence of osteosarcoma, and historically leukemia has not been a cancer linked to radium exposure (97, 100, 101). C57Bl/Do (black and albino) mice receiving approximately 10 mCi/kg of ^{226}Ra similarly developed bone sarcomas (102). In a beagle dog study designed to evaluate the appropriateness of permissible body burdens for humans, ^{228}Ra, administered at 16.6 times the human maximum permissible body burden (MPB), caused a shortened lifespan, whereas ^{226}Ra at 10 times the MPB was associated with neither a significant number of excess bone tumors or shortened lifespan (55).

5.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms 5.4.1.3.1 Absorption In rats, oral administration results in 1–7% retention 400–500 days after administration; in contrast, 77% retention was observed 140–300 days after intradermal administration (91). In a study in which human volunteers ingested small amounts of ^{224}Ra, 20% of the ingested dose reached the bloodstream (95). Following oral administration of radium, 80% appeared in the feces 10 days following expousre, with 20% retained and distributed systemically. The fecal:urine excretion ratio was also high (30:1) following IV administration (91). Accidental human inhalation exposure was associated with sequestration of radium in the bones, suggesting absorption from the lung and distribution via the bloodstream (91).

5.4.1.3.2 Distribution Following ingestion, radium is similar to calcium in its metabolism and is incorporated on bone surfaces into the mineralized portion of bone. The long half-life of ^{226}Ra allows for distribution throughout the mineral skeleton over life.

5.4.1.3.3 Excretion The loss of radium from the body by excretion was determined to follow a relatively simple power function: $R = 0.54t^{-0.52}$, where R = total body retention and t = time in days (103). As more data became available, it became apparent that the Norris equation is relatively accurate except at very long times after exposure e.g., (106). In practical terms, one year after exposure, approximately 2% of a dose of radium is retained in the body, but after 30 years, 0.5% still remains (104).

5.4.1.4 Reproductive and Developmental An old study (14) revealed that intravenous or subcutaneous administration of 5 mCi of radium to rats late in pregnancy caused fetal death associated with hemorrhage in the head and dorsal areas.

5.4.1.5 Carcinogenesis Although the National Toxicology Program has not classified radium with regard to its carcinogenicity, multiple laboratory studies document the ability of radium isotopes to cause cancer in animals.

5.4.2 Human Experience 5.4.2.1 General Information The maximum permissible (retained) body burden for bone of ^{226}Ra for humans has been tentatively set at 1 mCi (3.7 kBq) for a 70-kg man, or 0.529 kBq/kg (55). This body burden is expected to be without radiation-induced injury.

5.4.2.2 Clinical Cases 5.4.2.2.1 Acute toxicity: NA

5.4.2.2.2 Chronic and Subchronic Toxicity Two types of cancer—sarcomas of the bone and carcinomas of the paranasal sinuses and mastoid air cells (called “head cancers”)—have been shown to be associated with radium exposure (105, 106). It is significant to note that, although all isotopes of radium are bone-seeking, and despite laboratory animal studies in which rodents exposed to radium developed both leukemia and bone sarcomas, human leukemia is not recognized as a long-term sequela of radium exposure. Raabe et al. (107) modeled bone sarcoma risk in the human, dog, and mouse and determined that there is a threshold dose and dose rate, representing a dose low enough so that bone cancer will not appear within a human lifespan; this dose is 0.04 Gy/day, or a total dose of 0.8 Gy to the skeleton. A population of 900 German patients, both juveniles and adults, who had been treated with ^{224}Ra had 54 patients who developed bone sarcomas. The average skeletal dose in this population was 4.2 Gy. In a second cohort followed by Wick et al. (91), two ankylosing spondylitis patients (mean skeletal dose = 0.65 Gy) have developed osteogenic sarcoma, with no cases in the control group.

5.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms The a-particles emitted by radium, once deposited on bone surfaces, can penetrate approximately 70 mm. The long half-life of ^{226}Ra allows distribution throughout the mineral skeleton over a lifetime. The target cells for osteogenic sarcoma reside in marrow on endosteal surfaces approximately 10 mm from the bone surface (104). With its

shorter half-life, ^{224}Ra delivers its a dose while the radium is still on bone surfaces (104).

5.4.2.2.4 Reproductive and Developmental Although many of the humans occupationally exposed to radium were women, there is little published about reproductive or developmental consequences of radium exposure. It has been reported that the adult heights of humans injected as children with ^{224}Ra for treatment of tuberculosis were markedly lower than the heights of nontreated persons (91).

5.4.2.2.5 Carcinogenesis The U.S. EPA has classified radium as a class A carcinogen, meaning that there are sufficient data to support a link between exposure to radium and the development of human cancer. The a-particle radiation associated with radium is recognized as the causative agent for sarcomas of the bone and carcinomas of the paranasal sinuses in humans (106). A study attempting to ascertain the dose–incidence relationship for induction of these tumors examined 1474 women employed in the U.S. radium dial painting industry before 1930. This population exhibited 61 known cases of bone sarcoma and 21 cases of carcinoma of the paranasal sinuses or the mastoid air cells (106). Of these individuals, the radium body burden was known for 759, among whom there were 38 cases of bone sarcoma and 17 head carcinomas.

5.4.2.2.6 Genetic and Related Cellular Effects Studies In an analysis of a number of human proto-oncogenes in persons with internal systemic exposure to radium, alterations in the c-*mos* proto-oncogene were found in many, but not all, tissues from 6 of 7 subjects (105). The changes were EcoRI restriction fragment length alterations, and these were noted in normal (*i.e.*, neoplasm-free) tissues from these individuals.

5.4.2.2.7 Other: Neurological, Pulmonary, Skin Sensitization, etc Leikin and Paloucek (5) report that adverse reactions associated with the use of radium in the treatment of neoplasms include leukopenia, cirrhosis, and cataracts.

5.4.2.3 Epidemiology Studies 5.4.2.3.1 Acute Toxicity: NA

5.4.2.3.2 Chronic and Subchronic Toxicity Evans (95) summarized quantitative studies of more than 450 humans who carried skeletal deposits of ^{226}Ra and ^{228}Ra for up to 50 years. For residual skeletal burdens >0.5 mCi, the occurrence of osteoporosis, dense-bone necrosis, trabecular coarsening, and spontaneous bone fractures increased with increasing skeletal burden.

5.4.2.3.3 Pharmacokinetics, metabolism, and mechanisms: NA

5.4.2.3.4 Reproductive and Developmental: NA

5.4.2.3.5 Carcinogenesis Evans (95) summarized >450 cases of humans with skeletal burdens of ^{226}Ra and/or ^{228}Ra. For residual skeletal burdens ranging from 0.5 to 60 mCi of ^{226}Ra, the fractional incidence of osteogenic sarcoma and carcinoma of the paranasal sinuses or mastoids was about 40% and appeared to be independent of residual body burden. However, in individuals with tumors, the latency period was determined to be related to the residual body burden. It has been noted that breast cancer, liver cancer, and chronic myeloid leukemia have also been associated with radium exposure (5).

5.5 Standards, Regulation, or Guidelines of Exposure

No oral reference dose or inhalation reference concentration for radium has been established. The USEPA has established a maximum contaminant level of 5 pCi/L for combined ^{226}Ra and ^{228}Ra in drinking water and has classified radium as a class A carcinogen; this represents an agent for which sufficient evidence exists to support a causal relationship between exposure and cancer.

Zinc and Cadmium

Marek Jakubowski, Ph.D.

1 Zinc and Zinc Compounds
1.0 Zinc
1.0.1 CAS Number: [*7440-66-6*]

1.0.2 Synonyms: Zinc dust, zinc powder

1.0.3 Trade Names: Asarcor; L15; Blue Powder; CI 77945; CI pigment Metal 6; Emanay Zinc Dust; Granular Zinc; JASAD; Merrilite; PASCO (97).

1.0.4 Molecular Weight: 97.45

1.0.5 Molecular Formula: Zn
1.1 Chemical and Physical Properties
1.1.1 General Zinc is a relatively soft, bluish-white shiny metal. It exhibits a strong tendency to react with both the inorganic compounds (*e.g.*, oxides, sulfates, and phosphates) and the organic ones. The physical and chemical properties of zinc are displayed in Table 29.1.

Table 29.1. Physical and Chemical Properties of Zinc and Zinc Compounds

Compound	CAS #	Molecular Formula	MW	Boiling Point (°C)	Melting Point (°C)	Specific Gravity	Solubility in Water (at 68°F)	Refractive Index (20°C)	
Zinc	[*7440-66-6*]	Zn	65.38	908	419.5	7.14 at 25°C	Insoluble	—	1 I 4
Zinc oxide	[*1314-13-2*]	ZnO	81.38	No data	100 (decomp.)	5.607 at 20°C	0.0016 g/L at 29°C	—	
Zinc chloride	[*7646-85-7*]	$ZnCl_2$	136.29	732	290	2.907 at 25°C	4320 g/L at 25°C	—	
Zinc sulfate	[*7733-02-0*]	$ZnSO_4$	161.44	No data	600 (decomp.)	3.54 at 25°C	1667 g/L at 25°C	—	
Zinc acetate	[*557-34-6*]	$Zn(C_2H_3O_2)_2$	183.47	—	200 (decomp.)	1.84	300 g/L at 20°C	—	
Zinc stearate	[*557-05-1*]	$Zn(C_{18}H_{35}O_2)_2$	632.23	—	130	—	Insoluble	—	
Zinc ammonium sulfate	[*7783-24-6*]	$(NH_4)_2SO_4$ ċ$ZnSO_4$ċ$6H_2O$	401.66	—	Decomp.	1.931	70 g/L at 0°C	1.489, 1.493, 1.495	

Zinc and Cadmium
Marek Jakubowski, Ph.D.

2 Cadmium and Cadmium compounds
1.0 Cadmium
1.0.1 CAS Number: [*7440-43-9*]

1.0.2 Synonyms: Cadmium dust fume, cadmium powder, colloidal cadmium

1.0.3 Trade Names: NA

1.0.4 Molecular Weight: 112.40

1.0.5 Molecular Formula: Cd
1.1 Chemical and Physical Properties
1.1.1 General Cadmium (oxidation state 2, density 8.6, melting point 320.9°C, boiling point 765°C), is a silver-white metal that belongs to the group IIb in the periodic table. Its natural isotopes are 106 (1.22%), 108 (0.88%), 110 (12.37%), 111 (12.75%), 112 (24.07%), 113 (12.26%), 112 (24.07%), 1139 (12.26%), 114 (28.86%), and 116 (7.59%). Cadmium is insoluble in water and soluble in acids. It has a relatively high vapor pressure. In ambient air cadmium vapor is oxidized rapidly to produce cadmium oxide. In the presence of reactive gases or vapors, such as carbon dioxide, water vapor, sulfur dioxide, sulfur trioxide, or hydrogen chloride, cadmium vapor reacts to produce, respectively, cadmium carbonate, hydroxide, sulfite, sulfate, or chloride. These compounds may be formed in stacks and emitted to the environment. The physical and chemical properties of major cadmium salts are summarized in Table 29.4.

Table 29.4. Physical and Chemical Properties of Cadmium and Cadmium Compounds

Compound	CAS #	Molecular Formula	MW	Boiling Point (°C)	Melting Point (°C)	Specific Gravity	Solubility in Water (at 68°F)	Refractive Index (20°C)	Vapor Pressure (mm Hg)
Cadmium	[*7440-43-9*]	Cd	112.41	765	320.9	8.642	Insoluble	—	1 at 394°C
Cadmium chloride	[*10108-64-2*]	$CdCl_2$	183.32	960	568	4.047 at 25°C	1400 g/L at 20°C	—	10 at 656°C

Mercury
Ernest Foulkes, Ph.D.

Introduction

Mercury is a heavy metal widely distributed in nature, both as the metallic element (Hg^0) and as inorganic or organic compounds of its oxidation products, the mercurous (Hg^+) and mercuric (Hg^{2+}) ions. These mercury species are readily interchangeable in the environment and in the body, and evidence suggests that their toxicity in many cases reflects the actions of the mercuric ions formed by oxidation of mercury or by breakage of the mercury–carbon bond. To that extent, different toxicities of individual compounds can largely be attributed to differences in their toxicokinetic properties such as rates of absorption, distribution, degradation, or oxidation to Hg^{2+}, and finally excretion. Monosubstituted organic compounds of mercuric mercury may also react directly with biological molecules before degradation to Hg^{2+}.

Although all biological tissues contain traces of mercury, no essential biological function has been identified for the metal. To the contrary, because the end product of the metabolism of mercury and mercurials is usually the mercuric ion, which has high affinity for proteins and other biological molecules, many of the organic and inorganic compounds of the metal strongly inhibit biological reactions in very low concentrations. The high chemical reactivity of Hg^{2+} also helps explain the relatively nonspecific nature of mercury toxicity in the target organs. For instance, mercuric mercury accumulates primarily in the kidney, but in that organ it inhibits a large number of different enzymatic and other functions.

Natural sources of mercury include primarily deposits of the metal itself or of insoluble mercuric sulfide (HgS, cinnabar). Most of the world's production of mercury comes from mines in Algeria, China, Spain, and Kyrgyzstan. The background concentration of mercury in the environment reflects outgassing from the earth's crust and the result of volcanic activity. Large amounts of mercury are also contributed to the environment by human activities. The use of Hg by humans has been traced back thousands of years, and the high morbidity observed in mercury miners was well recognized in Roman days. Among major anthropogenic contributions to mercury pollution are the combustion of fossil fuels, the application of inorganic fertilizers and sewage sludge to agricultural lands, the amalgam process of extraction and purification of noble metals, losses incurred during the extensive use of mercury and its compounds in industry, and leaks from waste disposal. Natural and anthropogenic releases of mercury into the atmosphere in the 1980s were roughly equivalent and reached values of more than 6000 tons per year (quoted in Ref. 1).

Human exposure to mercury and mercurials also was, and in part still is, associated with their direct application for cosmetic and therapeutic purposes. Even in the twentieth century, such uses have included topical treatment with mercury-containing skin whiteners, antiseptics, and infants' teething powder. Organic mercurials have also been prescribed routinely as diuretics for treating salt and water retention. These human applications have mostly been abandoned, but the presence of the element in dental amalgams remains a significant and continuing source of human exposure.

The interchangeability of various mercury species in the environment and in the body and the overlap between the toxic effects of individual mercurials and between the biomarkers available for monitoring exposure to these mercurials make it impractical to consider the different mercurials under entirely separate headings. This chapter, therefore, discusses the occupational toxicology of mercury and selected mercury compounds under three main overlapping headings: A. Elemental Mercury, B. Inorganic Mercury Compounds (primarily the chloride salts of mercuric and mercurous mercury, although other inorganic mercury salts are also cited), and C. Organic Mercury Compounds (mostly methylmercuric chloride and phenylmercuric acetate). A very extensive literature has accumulated on all of these topics. However, no attempt will be made here to provide an exhaustive survey; a detailed listing, for instance, of all occupational uses and reported health effects of each chemical species of mercury in every animal species tested and in humans, under all exposure conditions would have to cover thousands of references and is hardly necessary to emphasize the major problems potentially associated with human occupational and general exposure to mercury and its compounds. Additional details on mercury and mercurials may be obtained from a number of informative recent publications, including the EPA document on mercury (2), a toxicological profile placed into the Federal Register by the Agency for Toxic Substances and Disease Registry (ATSDR) (3), the NIOSH Manual of Analytical Methods (4), and the authoritative review of Clarkson (5). The volume edited by Chang on the *Toxicology of Heavy Metals* (6) provides an extensive discussion of the toxic properties of mercury. Environmental health criteria for inorganic mercury were discussed by WHO (7). An earlier volume on the history of mercury contains much fascinating information on this important element (8).

Mercury
Ernest Foulkes, Ph.D.

A. Elemental Mercury
Although elemental mercury is readily oxidized to mercuric ions, the industrial applications and the toxicity of the two mercury species differ greatly. This is related to their physicochemical properties and their different distributions in the body. It is therefore appropriate to discuss the two species under separate headings.
1.0 Mercury
1.0.1 CAS Number: [*7439-97-6*]

1.0.2 Synonym: Quicksilver

1.0.3 Trade Names: NA

1.0.4 Molecular Weight: 200.61

1.0.5 Molecular Formula: Hg^0
1.1 Chemical and Physical Properties
1.1.1 General Metallic mercury at room temperature is a silvery and volatile heavy liquid (specific gravity 13.546) with a vapor pressure of 0.0012 mmHg at 20°C. The metal is slowly oxidized to mercuric oxide (HgO) near its boiling point (356.9°C) in the presence of oxygen. This reaction is reversed at higher temperatures. Similarly, the element may be reversibly oxidized to mercuric mercury in the environment and in the body. The metal reacts with halogens and sulfur and dissolves in nitric acid or concentrated sulfuric acid; it is little affected by hydrochloric acid (1). Mercury vapor is very slightly soluble in water (56 mg/L at 25°C).

Among physical and chemical properties which make the metal important for many technical

purposes are (1) the high vapor pressure of Hg^0, which permits purification of the metal by distillation. Vaporization also provides a convenient tool for spectroscopic analysis of mercury (see section 1.3). The volatility of mercury makes inhalation exposure an important potential risk. (2) The high surface tension of Hg^0 reduces wetting of glass and other surfaces. This property, together with its uniform thermal expansion, makes the metal ideal for use in thermometry. (3) The high electrical conductance of Hg^0 is important in thermostats, electrical switches, electrodes, etc. (4) The high specific gravity of Hg^0 is important in manometers, barometers, and other control devices. (5) Hg^0 forms amalgams with gold and other metals that are used extensively in extracting and purifying of noble metals and in dental fillings.

1.1.2 Odor and Warning Properties The metal is odorless, but its presence can readily be detected by UV spectroscopy or cold-vapor atomic fluorescence measurements, as proposed by the EPA (9). These techniques have also proven useful for analyzing biological and other samples for trace amounts of inorganic mercury compounds following their reduction to the element by reagents such as stannous chloride (see section 2.1.2). Listing of other techniques for estimating total mercury content may be found in Ref. 1.

1.2 Production and Use

Mercury is mined primarily in underground mines as the metal or as the red sulfide cinnabar (HgS). Like HgO, the sulfide decomposes at higher temperatures. Heating of the ore and condensation of the mercury vapor constitute a convenient procedure for reducing, extracting, and purifying mercury from its ore. Total world production fell from 8698 metric tons in 1975 to 1760 in 1994, reflecting in part increasingly prohibitive environmental, health, and safety regulations. In the United States, mercury is produced primarily from secondary sources; this involves recycling a variety of industrial waste products. Total consumption of the element in the United States in 1995 amounted to 463 metric tons (3). More than 150,000 workers are believed to have been potentially exposed to mercury and its compounds in the United States in 1990 (10); the majority of these exposures involved mercury vapor.

Some of the many uses of the metal have been described in section 1.1.1. Others include, for instance, mercury vapor lamps, and as a heavy liquid in fluid bearings and clutches. A major application is as a cathode in chloralkali plants that produce NaOH and chlorine by electrolyzing NaCl. The significance of the exposure from this process can be illustrated by the work of Langworth et al. (11) who found fourfold increases in blood Hg levels and 13-fold increases in normalized urinary levels in workers engaged in this process. The toxicity of mercury and the cost of its safe disposal have led to the search for alternative, Hg-free processes. Thus, total U.S. consumption of mercury fell from 1503 tons in 1988 to 621 in 1992. By way of illustration, about 50% of chloralkali plants used Hg-free processes in 1994 (2). Although as much as 16% of mercury consumed by industry has been recovered and recycled (3), the remaining major portion represents a very significant addition to the environment.

1.3 Exposure Assessment
