B. Alkyl and Aryl Phosphines

4.1 Chemical and Physical Properties
4.1.1 General

4.1.2 Odor and Warning Properties
4.2 Production and Use
Tributylphosphine is used as a gasoline additive.
4.4 Toxic Effects
4.4.1 Experimental Studies 4.4.1.1 Acute Toxicity The overall toxicity is expected to be relatively high (58); however, a moderate degree of toxic effects for triphenylphosphine and low toxicity for triisooctylphosphine has been demonstrated (6). This is also confirmed by an oral LD_{50} of 4.29 mL/kg (14). Conversely, according to Carpenter et al. (14), an inhalation exposure of rats to saturated vapor required 8 h for lethal effects. A dermal LD_{50} in the rabbit was greater than 5 mL/kg. Triisooctylphosphine appears to be less toxic by the oral route at 21.4 mL/kg, but is more readily absorbed through the skin, showing an LD_{50} of 3.97 mL/kg (7). It is also more of an irritant to the skin, but less so to the eye (7).

Esters of Carbonic and Orthocarbonic Acid, Organic Phosphorous, Monocarboxylic Halogenated Acids, Haloalcohols, and Organic Silicon
Michael S. Bisesi, Ph.D., CIH

C. Phosphinates
Alkyl aryl phosphinic acid esters bear the chemical structure $R_2P(O)OR'$. A paucity of toxicological data were found. Some data are summarized in Table 81.5 for the following phosphinates: octylphosphinic acid *O*-butyl ester, $C_8H_{17}PH(O)OC_4H_9$, phenylphosphinic acid *O*-ethylester, $C_6H_5PH(O)OC_2H_5$, allylphenylphosphinic acid *O*-butyl ester, $(CH_2{:}CHCH_2)(C_6H_5)P(OH)OC_4H_9$, and butylphenylphosphinic acid *O*-allyl ester, $(C_4H_9)(C_6H_5)P(O)OCH_2CH{:}CH_2$.

Esters of Carbonic and Orthocarbonic Acid, Organic Phosphorous, Monocarboxylic Halogenated Acids, Haloalcohols, and Organic Silicon
Michael S. Bisesi, Ph.D., CIH

D. Phosphonates
Phosphonates are esters of phosphoric acid of the type $RP(O)(OR')_2$, whereby R and R' can constitute alkyl, aryl, cyclic, or heterocyclic groups. They are less acidic and hydrolyze with less ease than the corresponding phosphates (51). The phosphonates often occur as mixed products, unless they are prepared through their ester anhydrides (51). Some derivatives, especially the halogenated types, are used as pesticides.

Various aliphatic, aromatic, and substituted phosphonates appear to be moderately to highly toxic. The toxicity appears to be lowest for the alkyl derivatives, but rises with increasing aromatization and even further with halogen or nitro group substitution. Diisopropyl fluorophosphonate, $FP(O)[OCH(CH_3)_2]_2$, is neurotoxic against the housefly (59).

51). Such esters in the presence of allyl halides tend to convert easily from the trivalent to the pentavalent form, the thermodynamically more stable phosphonates.

The biologic properties of the organic phosphites resemble closely those of the phosphonates, possibly owing to their chemical similarity or transformation possibilities. Most animal experiments have been carried out with rats or rabbits, which are not particularly sensitive to neurotoxic stimuli. Thus no definite toxicologic conclusions can be drawn from these experiments. The differential irritancy characteristics may be due to the hydrolyzability of the individual esters.
5.1 Chemical and Physical Properties
5.1.1 General Organic phosphites are esters of phosphorous acid and alkyl or aryl alcohols, of the type $(RO)_3P$. Chemically, they can undergo transesterification with alcohols (51). The biologic properties of the organic phosphites resemble closely those of the phosphonates, possibly owing to their chemical similarity or transformation possibilities.
5.3 Exposure Assessment
5.3.3 Workplace Methods: NA
5.4 Toxic Effects
5.4.1 Experimental Studies 5.4.1.1 Acute Toxicity The oral acute toxicity of trimethyl phosphite was found to be comparatively low and the material was not appreciably absorbed through the rabbit skin (23); however, it caused moderately severe irritation lasting several days. Introduction into the rabbit eye caused severe irritation and edema that persisted for several days. In vapor inhalation experiments, rats survived a 6 h exposure to saturated air. However, the material produced considerable discomfort, restlessness, and severe irritation of the eyes and respiratory tract (23).

According to Deichmann and Gerarde (23), the dermal LD_{50} of tridecyl phosphite in the rat is greater than 10 mL/kg. This indicates that the material is not absorbed through the skin, but still may cause irritation. It may also indicate that it has similar physical properties to those of tri(2-ethylhexyl) phosphite.

Triphenyl phosphite appears to be more toxic than the aliphatic derivatives. In addition, its neurotoxic properties, first described by Smith et al. (26), it was used for a convulsive model in experimental epilepsy (60). In addition, the authors studied the phosphite blood distribution and the motor cortex, diencephalon, and brain activity with radioactive triphenyl phosphite (60).

Aird et al. (60) using 0.3 mL/kg ^{32}P-labeled triphenyl phosphite intraperitoneally in the cat, observed considerable hydrolysis of the phosphite and only a very small quantity of original material in the central nervous system. The authors concluded that even this small quantity could have degenerative effects (60). The cresyl derivatives, similar to the phenyl, are charactersitically more toxic than the aliphatic equivalents. Nonetheless, triphenyl phosphite causes a delayed neuropathy with related ataxia and degeneration of the spinal cord in animals (61). The chemical inhibits neurotoxic esterase activity, but the structurally related compounds triphenyl phosphate, triphenyl phosphine, and trimethyl phosphite did not at the experimental doses (61). Animal studies have demonstrated that triphenyl phosphite causes potent neurotoxic effects due to cellular and axonal degeneration in the spinal cord, medulla, cerebellum, thalmus, and cerebral cortex (62).

Mixed alkyl–aryl phosphites tend to have lower toxicities than the aryl phosphites, as might be predicted. An oral LD_{50} in the rat for 2-ethylhexyl octylphenyl phosphite was7–10 g/kg (23), and an oral LD_{50} in the mouse for diphenylnonyl phosphite was 0.1 g/kg (27).

Chlorination of alkyl phosphites increases the toxicity, as demonstrated with bis(2-chloroethyl) phosphite with an intraperitoneal LD_{50} in the mouse of 250 mg/kg (17).

5.5 Standards, Regulations, or Guidelines of Exposure
Both the ACGIH TLV and the NIOSH REL for trimethyl phosphite is 2 ppm.

Esters of Carbonic and Orthocarbonic Acid, Organic Phosphorous, Monocarboxylic Halogenated Acids, Haloalcohols, and Organic Silicon
Michael S. Bisesi, Ph.D., CIH

F. Alkyl Phosphates
Organic phosphates constitute a highly hazardous class of compounds. The materials most extensively investigated concern the organophosphate insecticides that are discussed in a separate chapter. The summary here is limited to the alkyl, aryl, and their lower-molecular-weight derivatives. The phosphates are chemically the most stable, and thus the most persistent phosphorus esters in biologic systems.
6.1 Chemical and Physical Properties
6.1.1 General

6.1.2 Odor and Warning Properties
6.2 Production and Use
The aryl phosphates are used widely in industry as plasticizers, as motor lubricants and gasoline additives (63), and as part of fire-resistant hydraulic fluid (63). Certain types of organic phosphates have found application as military defense agents (64). For the treatment of aryl phosphates poisoning, see Mieth and Beier (65). Zech et al. (64) reported that the oximes, which had raised great hopes in the field of medicine, however, do not always act as antidotes, but as synergists in certain cases. Trimethyl phosphate is used as an ethylating agent and as raw material to prepare insecticides, such as tetraethyl pyrophosphate (23). Triethyl phosphate is used as a plasticizer for cellulose esters, lacquers, plastics, especially vinyl resins, and as an antifoaming agent. The di(2-ethylhexyl) phosphate has wide industrial use.
6.3 Exposure Assessment
6.3.3 Workplace Methods NIOSH Method 5034 is recommended for determining workplace exposures to tributyl phosphate (3a).
6.4 Toxic Effects
6.4.1 Experimental Studies Male rats fed 0.5% of trimethyl phosphate, triethyl phosphate, tri-*n*-butyl phosphate, trioctyl phosphate, or tricresyl phosphate for 9 wk exhibited decreased body weight relative to controls (66). To date, it has been the only alkyl phosphate with documented flaccid paralytic effects (28). Orally, it is in the toxicity range of the phenyl phosphates. According to Jones and Jackson (67), trimethyl phosphate is not a teratogen. However, subtoxic oral or parenteral administration caused mutagenic effects in mice (68). Incubation experiments of TMP and DNA solutions have shown decreased sedimentation coefficients of the biopolymers. This is presumably the result of DNA alkylation, followed by depurination and scission of the phosphodiester's backbone. Gas chromatographic analysis yielded a compound, 7-methyldeoxyguanosine.

6.4.1.1 Acute Toxicity Toxicological data in Table 81.5 show a somewhat higher degree of toxicity. Fassett and Roudabush conducted a subacute study by injecting rats intraperitoneally with 400 mg/kg TEP five times a wk for 4–6 wk (69). The animals still gained weight, and no side effects were noted. Experimental work with triethyl phosphate has so far failed to show neurotoxic effects. This is partially confirmed by the *in vitro* studies with the neurotoxin antidote pyridine-2-aldoxime methylchloride (PAM), whereby TEP was not hyrolyzed *in vitro* (70).

The acute oral toxicity of tributyl phosphate is relatively low, although it is a weak inhibitor in rats and *in vitro* human red blood cells (25). It also is a CNS stimulant. Affected rats show muscle twitching, general weakness, dyspnea, coma, and pulmonary edema. No latent paralysis has been observed. The material is a respiratory, eye, and primary skin irritant, and may be dermally absorbed (30, 55). Intraperitoneally, the dose with the lowest effect in the mouse was 63 mg/kg (30). The same toxicological properties are expected to hold for triisobutyl phosphate. Male rats exposed to the compound exhibited decreased body weight, alteration of brain cholinesterase, and increased blood coagulation rates (71).

An oral LD_{50} in the rat has been recorded as 4940 mg/kg (7), a dermal LD_{50} in the rabbit as 1250 mg/kg (7), and a lowest-effect level intraperitoneally in the mouse of 63 mg/kg (17).
6.5 Standards, Regulations, or Guidelines of Exposure
The ACGIH TLV for tributyl phosphate is 0.2 ppm.

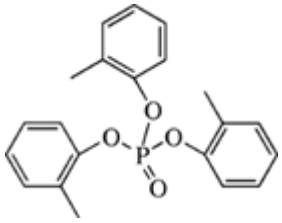
7.0.6b Molecular Structure:



7.1 Chemical and Physical Properties
7.1.1 General Triphenyl phosphate (TPP) is crystalline solid with a faint, aromatic odor.

Tri-*ortho*-cresyl phosphate (TOCP) is a liquid, also available as triaryl phosphate oil containing a mixture of the three isomers, the *ortho*, *meta*, and *para* forms. However, whenever possible, the portion of the *ortho* isomer is reduced or eliminated because of its paralytic properties.

7.1.2 Odor and Warning Properties
7.2 Production and Use
Triphenyl phosphate serves as a noncombustible substitute for camphor in celluloid, as a fire retardant in acetylcellulose, nitrocellulose, and airplane glue, as a plasticizer for lacquers and varnishes, and to impregnate roofing paper.

The tri-*o*-, *m*-, or *p*-cresyl phosphates, also named *o*-, *m*-, or *p*-tritolyl phosphates, phosphoric acid tri-2-, 3-, or 4-tolyl or methylphenyl phosphate esters, are widely used industrial additives. Tri-*o*-cresyl phosphate is used widely as a gasoline additive, plasticizer, fire retardant, solvent, extreme pressure additive, and as a lead scavenger in gasoline.
7.3 Exposure Assessment
7.3.3 Workplace Methods Table 81.1 describes the method recommended for determining workplace exposures to TPP and TOCP.
7.4 Toxic Effects
7.4.1 Experimental Studies 7.4.1.1 Acute Toxicity The basic animal experiments were carried out by Smith et al. (72) in 1930, who observed low acute toxicity in the commonly used laboratory species, and no effects in rats and mice when administered 1/10 to 1/20 of the oral LD_{50} for 3 mo. It caused generalized delayed illness and paralysis in cats and primates. The observed demyelination of the spinal cord resembled that obtained with tri-*o*-cresyl phosphate (72). Neuromuscular signs were observed above 0.2 g/kg in the cat. *In vitro* studies showed a 50 mg/kg no-effect level on whole blood cholinesterase, but a 20% decrease at the 100 mg/kg level (32). The material is poorly absorbed through the intact skin (23) and had no irritant effects in the rat skin (33). Dermal sensitization has been reported (73).

The compound studied most extensively has been tri-*o*-cresyl phosphate, since it has proved to be the causative agent in most epidemics. Some experiments by Hine et al. (58), using White Leghorn cockerels as test animals, were carried out in order to test the neurotoxic properties of a series of substituted aromatic phosphorus and related compounds for anticholinesterase activity. The authors demonstrated that in the fowl, only the *o*-tolyl phosphate produced paralytic properties either as a tri-*ortho* derivative or mono- and disubstituted compounds mixed with phenyl or *p*-tolyl phosphates. The *o*-tolyl and other substituted aryl and arylalkyl phosphates caused cholinesterase inhibition *in vivo* but not *in vitro* (58).

Of the aryl phosphates, only the tri-*o*-cresyl, the mono- and di-*o*-cresyl, and di- or monophenyl derivatives cause paralysis in the cockerel, and also have anticholinesterase activity. The fact that a series of aryl phosphates possess only anticholinesterase activity indicates that these pathological signs are due to different, nonrelated mechanisms (58). TOCP was also found to inhibit true erythrocyte cholinesterase in rats (77). This has been studied by Bleiberg and Johnson (78), who confirmed that TOCP, when administered orally, was toxic to mice and chickens and produced cholinesterase inhibition in red blood cells of the dog and the chicken. TOCP is a low dermal irritant and has been documented as the causative agent in a dermatitis case (73). *In vitro* studies with whole blood, using about 10 mg/kg TTP, depressed the acetyl cholinesterase level approximately 30% (32). Mechanistically, it appears that TOCP causes biochemical changes in the sciatic nerve of hens, marked by evidence of phosphorylation of proteins (79, 80).

Pathological effects observed in the human have been reproduced in various experimental animals, such as the cat, chicken, rabbit, dog, primate, and calf. The rat, the mouse, and the guinea pig are more resistant. Smith et al. (46, 81) report some minor fatty changes in animal liver and some degenerative deviations in the kidney. Barnes and Denz (82) studied the histopathology of the nervous fibers produced by TOCP and other phosphates. They determined that the demyelination did not appear to be directly related to anticholinesterase activity. Rayner et al. (83) have noted hyporeflexia in some workers chronically exposed to more complex organophosphate insecticides.

The chicken appears somewhat more resistant to tri-*o*-cresyl phosphate (26). The *o*-cresyl phosphate reduces the cholinesterase activity of whole blood in mice, accompanied by symptoms of tremor and diarrhea, resembling other cholinesterase inhibitory agents in the rat. A study revealed that tributyl, tributoxyethyl, and dibutylphenyl phosphate inhibited brain neurotoxic esterase activity as high as 70% (84). Rats were exposed to a fire-resistant hydraulic fluid containing dibutyl phenyl phosphate and tributyl phosphate at airborne levels ranging from 5 to 300 mg/m^3 6 h/d, 5 d/wk for 6–13 wk (85). The data revealed observations of a reddish nasal discharge and simultaneous oral salivation, and, at high exposures reduced body weights, increased liver weights, decreased number of erythrocytes, decreased hemoglobin levels, and decreased hematocrit values (85).

Injection into the yolk sac of fertile eggs prior to incubation has shown TOCP to cause reductions in survival rates with 100% deaths at 0.02 mL of undiluted material. At a concentration of 0.01 mL, 40% of the chicks hatched, but showed growth retardation and developed paralysis in 2–6 wk after hatching (86). The typical paralysis in the majority of the chicks is associated with demyelination in the spinal cord, cerebellum, and peripheral nerves (81), as observed in humans. Investigators of another study involving hens exposed to oral doses of solutions containing triphenyl phosphate, tricresyl phosphate, or butylated triphenyl phosphate additives in synthetic polyol-based lubricating oils concluded that there was low neurotoxicity and hazard under realistic conditions of exposure (87). A study by Barrett et al. in 1994 showed decreased acetylcholine esterase activity in red blood cells and plasma and decreased neurotoxic esterase activity in leukocytes due to single oral exposures of swine tri-*o*-cresyl phosphate (88).

An *in vitro* study involving use of immunocompetent cells (peritoneal cells and splenocytes) isolated from mice and subsequently exposed to triphenyl phosphate and triphenylphosphine oxide (TPPO) revealed signs of altered immune functions (89). Another study conducted *in vivo* and involving rats exposed to oral doses of TPP indicated no significant immunotoxicity (90). Another study showed that TOCP caused inhibition of several cytoplasmic enzymes (proteases) that are important in processes of intracellular protein turnover, processing hormonal peptides, and processing immune system antigenic proteins (91). Accordingly, the investigators suggest that the data may represent a previosuly unrecognized toxicity hazard.

7.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Some studies have shown that TOCP is readily absorbed, transported by the vascular and central nervous system, and distributed into the

brain, cord, and cerebellar tissue within 24 h of oral administration (58). Of 17 compounds tested, tri-*o*-cresyl phosphate is one of the most active inducers of drug-metabolizing enzymes. The compounds had in common low systemic toxicity, but high lipid solubility (92). Cohen and Murphy have shown that TOCP is capable of potentiating malathion activity (93). A study published by Wu and Leng (94) using white Leghorn hens suggested that TOCP causes phosphorylation of brain membrane proteins leading to organophosphate-induced delayed neuropathy, but treatment with the drug Verapamil, a calcium channel blocker, eliminated enhancement and caused some inhibition of the adverse effects. Saligenin cyclic *o*-tolyl phosphate (SCOTP) is thought to be an active metabolite of TOCP and is more neurotoxic (95). Hodge and Sterner demonstrated with radioactive materials that TOCP was absorbed through the intact human palm and the abdominal skin of the dog (35). About 0.10% of the quantities administered were excreted in the urine within a few hours. Experimentally, a dermal LD_{50} of 2.8 cm^2/kg was determined for the mouse, 1/5 to 1/25 as toxic for the cat, dog, or rabbit (35). Paralysis of hind legs, however, was observed in mice (35). It also was reported that TOCP was found in the blood of the dog at 8 mg/100 cm^3 within 24 h of application and was found distributed throughout the visceral organs, muscle, brain, and bone in the dog (35).

7.4.1.4 Reproductive and Developmental TOCP is toxic to the male reproductive system due to damage caused to the testes (96). Rats exposed to 135 d of oral doses of TCP and butylated triphenyl phosphate (BTP)-based hydraulic fluids were studied to evaluate reproductive toxicity (97). The results showed decreased fertility and number of litters born for BTP-exposed groups and decreased fertility and litter sizes in TCP-exposed groups. Rat studies also have shown that both BTP and TCP appear to be associated with endocrine toxicity (98). A study involving rats fed a diet containing various levels of triphenyl phosphate for a period from 4 wk postweaning for 91 d, through mating and gestation, indicated that there was no significant impact to the mothers or their offspring (99).

7.4.1.5 Carcinogenesis TOCP was shown in a study by Mentzshel et al. (100) to be associated with detection of DNA adducts in tissues harvested from rats treated with the chemical. The authors concluded that a metabolite formed from biotransformation of TOCP may be associated with initiation of carcinogenesis.

7.4.2 Human Experience 7.4.2.1 General Information Of the three isomers, the toxicities and neurotoxic character increase *para* < *meta* < *ortho* (54). The lethal oral dose for adults is 1–10 g for the *ortho* isomer; *meta* and *para* isomers are practically nontoxic and do not cause demyelination (27). Most human intoxications have involved accidental ingestion of adulterated alcoholic beverages, cooking oils (48, 50), or, as an unusual case, industrial inhalation of heated vapors (76).

Reviews of human incidents have been presented by Hunter et al. (76), Susser and Stein (50), Smith et al. (72), and Smith and Lillie (81). The minimum paralytic dose in humans is unknown, but from studies by Smith et al. (26, 72), it can be estimated as about 10–30 mg/kg of tri-*o*-cresyl phosphate for an adult. The clinical picture after ingestion has been similar in all reported cases. Immediately post ingestion usually no symptoms occur or occasionally there may be gastrointestinal disturbances lasting from a few hours to 2 d; sharp cramplike pains may occur in the calves with some numbness in the hands and feet. A few hours later weakness in legs and feet may progress to bilateral foot drop, but the cramping pain may disappear. Within another few days, weakness of fingers and wrists may develop, but not extending above elbows and thighs. There is a dispute over the extent of sensory loss; however, it is agreed that it may run parallel to the extent of dysfunction of the motor system. In mild cases, sensory changes regress rapidly (50). The progress of affected cases varies considerably, but in general, the muscular weakness may increase over a period of several weeks or even months, and then become more or less stationary. The extent to which the paralysis may be permanent depends mainly on the quantities involved, intake rates, and cumulative effects. Fatalities are quite rare and occur mainly in response to the ingestion of very large phosphate quantities in a short time.

Due to the lack of human autopsy material of the rarely fatal cases, little is known of the progressive

microbiological changes. The pathology described by Smith and Lillie (81) in six human cases was characterized by some involvement of the anterior horn cells, fatty degeneration of the white substance of the cord, tigrolysis of nerve cells, displacement of the nucleus to the periphery, and particularly demyelination with marked fragmentation and fatty degeneration of the myelin sheath. Exposure of personnel for various time periods to TCP, a preparation that contains several aryl derivatives, including tri-*o*-cresyl phosphate, handled as a component of hydraulic oil on an aircraft carrier, showed no physiological effects. Exposed and control personnel were checked intensively for neurological signs, hematologic effects, and blood cholinesterase levels (74).

7.4.2.2 Clinical Studies Tabershaw and Kleinfeld (101) have described a monitoring study of a chemical TOCP manufacturing plant. Results revealed TOCP air concentrations ranging from 0.27 to 3.40 mg/m^3, depending on the type of operation. The effect on the worker population (101) indicated some plasmic cholinesterase depression. However, no evidence of neuromuscular difficulties attributable to the industrial exposure was found.Tabershaw et al. (102) have described a triphenyl and tricresyl phosphate manufacturing plant with air concentration measurements ranging from 0.27 to 3.4 mg/m^3. The authors found no correlation between results from cholinesterase determinations and minor gastrointestinal or neuromuscular symptoms and the degree and duration of exposure (102). Occupational exposures have occurred on various occasions. Sutton et al. (32) have published a study covering the chemical, toxicological, and industrial aspects of triphenyl phosphate exposure. Fourteen employees were exposed to triphenyl phosphate vapor, mist, or dust over a period of 8–10 yr. The particle sizes of the dusts measured < 1 mm in diameter for 90%, and the average air concentration was determined as 3.5 mg/m^3 with occasional excursions to 40 mg/m^3. Results showed no signs of illnesses, but a slight statistically significant reduction in red blood cell cholinesterase activity. The human data were confirmed by Smith et al. (46, 81).

A similar report of men handling lubricating oils containing some cresyl phosphates on an aircraft carrier showed no signs of illnesses or chemical changes (74). One report by Hunter et al. (76) describes three cases of polyneuritis from the manufacture of various aryl phosphates, with the suspicion that exposure to TOCP was the causative factor. One case of permanent paralysis in a worker has been reported by Bidstrup and Bonnell (103). He had been engaged in the manufacturing of *m*- and *p*-tricresyl phosphate isomers, where the final product contained only 1% of the *ortho* form (TOCP), but 6–10% appeared during the processing. Large quantities of TPP inhibit human cholinesterase *in vitro* and *in vivo*; however, it is not considered a potent anticholinesterase agent. No adverse clinical effects were found in men exposed to TPP vapor mist and dust for 10 yr at a concentration of 3.5 mg/m^3 (23). Another study reported polyneuropathy in a mechanic exposed to hydraulic fluids containing isopropylated tricresyl phosphate (ITP) (104). The investigators concluded that this observation and results from a related cross-sectional study of eight other exposed men and eight controls suggest a possible relationship between heavy exposure to ITP and polyneuropathy. A report indicated a case of allergic contact dermatitis associated with exposure to TPP that was contained in plastic eyeglass frames (105). In relation to the observed dermatitis associated with wearing the plastic eyeglass frames, the investigators reported positive dermal patch test results for TPP and tri-*m*-cresyl phosphate, but not for tri-*p*-cresyl phosphate.

Triaryl or tricresyl phosphate (TCP) is a mixture of various aryl phosphates, including tri-*o*-cresyl phosphate. One study indicated that personnel exhibited no toxicological effects when exposed for various durations to TCP, a preparation handled as a component of hydraulic oil on an aircraft carrier and that contained several aryl derivatives including (74). Exposed and control personnel were checked intensively for neurological signs, hematologic effects, and blood cholinesterase levels (74). An epidemiological study in Italy of workers handling rubber-base materials and cements containing triaryl phosphate revealed 47 cases of motor polyneuritis (75). However, in addition, the workers had also handled a variety of other neurotoxic chemicals when previously employed in the shoe, tire, rubber, or adhesive tape industry.

7.4.2.3 Epidemiology Studies An epidemiological study in Italy of workers handling rubber-base

materials and cements revealed 47 cases of motor polyneuritis (75). One of the causative agents was suspected to be triaryl phosphate (75). However, in addition, the workers had also handled a variety of other neurotoxic chemicals when previously employed in the shoe, tire, rubber, or adhesive tape industry.

7.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV, NIOSH REL and OSHA PEL for triphenyl phosphate are all 3 mg/m^3.

The ACGIH TLV, NIOSH REL and OSHA PEL for triorthocresyl phosphate are all 0.1 mg/m^3 for tri-*o*-ethylphosphate.

Esters of Carbonic and Orthocarbonic Acid, Organic Phosphorous, Monocarboxylic Halogenated Acids, Haloalcohols, and Organic Silicon
Michael S. Bisesi, Ph.D., CIH

I. Halogenated Phosphate Esters

In contrast to the previously discussed phosphate esters, the chlorinated derivatives possess anesthetic-like and muscle-relaxant properties, even at relatively high doses, without pathological side effects.

8.0 Trichloroethyl Phosphate

8.0.2 Synonyms: Trichloroethyl phosphate, also known as trichloroethyl phosphate (TCEP; trichloroethyl phosphoric acid mono ester; Triclofos), $P(O)(OH)_2(OCH_2CCl_3)$ and tris(b-chloroethyl) phosphate, (tri(2-chloroethyl) phosphoric acid ethyl ester; TRCP), $P(O)(OCH_2CH_2Cl)_3$

8.4 Toxic Effects

Triclofos is a sedative or hypnotic. Tri-2-chloroethyl phosphate produces prolonged epileptiform convulsions in the rat intraperitoneally at levels of 0.28 g/kg (38). At higher doses, convulsions occur, but only weak cholinesterase inhibition (6). The material does not appear to be absorbed through the skin, nor is it a dermal irritant. A subacute study comparing triethyl phosphate and trichloroethyl phosphate by Fassett and Roudabush (69) showed a definite hemorrhagic tendency by the trichloroethyl phosphate. A variety of chlorovinyl phosphates are available, which serve as pesticides and insecticides. For example, an acute human poisoning by 2-chloro-1-(2,4-dichlorophenyl) vinyl diethyl phosphate, chlorfenvinphos, has been reported. The clinical picture was dominated by the nicotinic, mascarinic, and central nervous syndromes with severe respiratory difficulties, accompanied by acidosis and by initial hyperglycemia, which converted into hypoglycemia (106). Siggins et al. have tested a series of 2-chloroethanol esters of a-keto acids and similarly found some to possess hypoglycemic properties (107).

A. Overview

The halogenated acid esters are discussed in the order of prevalence of the halogen, that is, the chlorine, the fluorine, bromine, and iodine derivatives. The esters are listed with increasing molecular weight or complexity. Halogenation of hydrocarbons increases their toxicity considerably. The halogen formates are highly irritating and are used as lacrimators. The halogenated acetates serve chiefly as intermediates in various organic syntheses. They are generally colorless liquids with relatively high densities, soluble in water, and more stable toward hydrolysis than the chloroformates, although ethyl iodoacetate may release iodine on extensive heating. Physiologically, the halogenated acetates behave similarly, such as producing pulmonary edema. Especially, their lacrimatory and irritant properties can be classified in the order of potency I > Br > Cl > F. According to Dixon (108), the lacrimatory mechanism may involve specific reactions of the halogen with certain enzyme-sulfhydryl groups. The ester groups appear to enhance this activity. The reaction appears to occur rapidly, is reversible at low and irreversible at very high concentrations in some tissues (109, 110). Some physical and chemical properties and characteristics are listed in Table 81.7 and toxicological information in Tables 81.8, 81.9, 81.10 (111–117) (118, 119).

Michael S. Bisesi, Ph.D., CIH

A. Overview

The alkyl silicon esters can be classified into several categories, namely, the silanes, which are alkyl-substituted silicon tetrahydrides (R_4S) and the next more highly oxygenated derivatives only, silanols (R_3SiOR' $R_2Si(OR')_3$). Some silanols can be polymerized to form silicones of the type $[R_xSiO_{(4-x/2)}]_n$. The most highly oxygenated compound is silicic acid and its esters, the silicates, which are chemically $Si(OR)_4$.

Some of these compounds are important industrial raw materials used to produce a variety of widely used end products, such as the silicones that serve as lubricating fluids, oil baths, resins, and plastic copolymers. The toxicological effects vary from inert to caustic, depending on the oxidation potential and the molecular size. Some chemical and physical properties and characteristics are listed in Table 81.11 and toxicological information in Table 81.12 (127–130).

Table 81.11. Chemical and Physical Properties of Representative Esters of Organi

Esters of Carbonic and Orthocarbonic Acid, Organic Phosphorous, Monocarboxylic Halogenated Acids, Haloalcohols, and Organic Silicon
Michael S. Bisesi, Ph.D., CIH

B. Silanes

For comparative purposes, some physical properties and range-finding toxicological data are presented in Tables 81.11 and 81.12. Toxicological data show high oral and intraperitoneal toxicities for the methyl and ethyl chlorosilanes. Tetrachlorosilane, $SiCl_4$, an irritant gas, has been used as a warfare agent and to prepare smoke screens (128). The chlorinated derivatives appear to be most toxic of this series, as shown with tri(2-chloroethoxy)silane, $HSI(OCH_2CH_2Cl)_3$.

Esters of Carbonic and Orthocarbonic Acid, Organic Phosphorous, Monocarboxylic Halogenated Acids, Haloalcohols, and Organic Silicon
Michael S. Bisesi, Ph.D., CIH

C. Silanol Esters

The silanol esters are commonly called silanes, but should more correctly be called silanates. They represent the basic raw materials for the commercial production of silicones. Range-finding toxicological data are shown in Table 81.12. Trimethylethoxysilane (ethoxytrimethylsilane), $(CH_3)_3SiOC_2H_5$, is a liquid at ambient temperatures. Intraperitoneal injections of 1000 mg/kg tetramethoxysilane (TMOS), tetraethoxysilane (TEOS), tetrapropoxysilane (TPOS), and tetrabutoxysilane (TBOS) caused renal toxicologic effects in mice. TMOS and TEOS caused acute tubular necrosis; TEOS, TPOS, and TBOS caused elevated creatinine and blood urea nitrogen; and TMOS exposed mice died exhibiting cytolysis suggestive of spleen damage (131). Mice exposed via inhalation to 100 ppm TEOS 6 h/d, 5 d/wk, for 2–4 wk developed tubulo-interstitial nephritis (132). The mice exposed to 50 ppm TEOS for the same period did not develop nephritis; however, histopathological changes developed in their nasal mucosa. Dimethyldiethoxysilane (diethoxydimethylsilane), $(CH_3)_2Si(OC_2H_5)_2$, is a liquid at ambient temperatures. A mixture of dimethyldiethoxysilane and glycerol has successfully been applied in the rabbit as a model for the

prevention of arterial wall and metabolic disorders (133). Amyltriethoxysilane (amyltriethoxysilanate), $C_5H_{11}Si(OC_2H_5)_3$, is of relatively low toxicity.The vinyl triethoxy derivative appears in the same toxicity range.

D. Silicates
16.0a Methyl Silicate
16.0.1a CAS Number: [*681-84-5*]

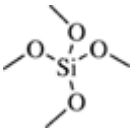
16.0.2a Synonyms: Tetramethyl orthosilicate, silicic acid tetramethyl ester; methyl orthosilicate, Tetramethoxysilane, tetramethyl silicate, and TMOS

16.0.3a Trade Names: Dynasil M

16.0.4a Molecular Weight: 155.22

16.0.5a Molecular Formula: $C_4H_{12}O_4Si$

16.0.6a Molecular Structure:



16.0b Ethyl Silicate
16.0.1b CAS Number: [*78-10-4*]

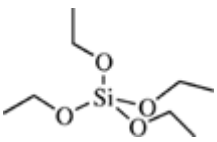
16.0.2b Synonyms: Silicic acid tetraethyl ester

16.0.3b Trade Names: NA

16.0.4b Molecular Weight: 208.30

16.0.5b Molecular Formula: $C_8H_{20}O_4Si$

16.0.6b Molecular Structure:



16.3 Exposure Assessment
16.3.3 Workplace Methods NIOSH Method S264 is recommended for determining workplace exposures to ethyl silicate.

Alkyl silicates, tetraalkyloxysilanes, are organic derivatives of hydrocarbons esterified with silicic acid of the type $Si(OR)_4$. The methyl and ethyl silicates have industrial uses in protective coatings and as preservatives or waterproofing agents for stone and concrete. Range-finding toxicological data are shown in Table 81.12.

Methyl silicate (tetramethyl orthosilicate; silicic acid tetramethyl ester), $Si(OCH_3)_4$, is a liquid under ambient conditions. Methyl silicate has been used in the ceramic industry for closing pores, including those in concrete and cement, for coating metal surfaces and as a bonding agent in paints and lacquers. It is of moderate toxicity, and under certain humid conditions effects progressive necrosis of the cornea.

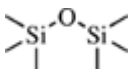
Ethyl silicate (silicic acid tetraethyl ester), $Si(OC_2H_5)_2$, is a high-boiling liquid. Ethyl silicate is used as a preservative for stone, brick, concrete, and plaster. It is used in water, weather- and acid-proofing processes, heat- and chemical-resistant paints, and protective coatings. Orally, the ethyl silicate is moderately toxic, but may be narcotic in high concentrations. Injected into the skin of the rabbit, it produced transient erythema, edema, and slight necrosis at the injection site (128). In the rabbit eye, it produced transient irritation (128). Inhalation of 400 ppm by rats for 7 h/d for 30 d caused mortalities and lung, liver, and kidney pathological effects. Under similar conditions, 88 ppm caused no effects. Inhalation exposure of the guinea pig to ethyl silicate revealed that humid air was related to more severe effects than dry air (130).
6.5 Standards, Regulations, or Guidelines of Exposure
Both the ACGIH TLV and the NIOSH REL are 1 ppm for methyl silicate. The ACGIH TLV and the NIOSH REL for ethyl silicate is 10 ppm while the OSHA PEL is 100 ppm for ethyl silicate.

Esters of Carbonic and Orthocarbonic Acid, Organic Phosphorous, Monocarboxylic Halogenated Acids, Haloalcohols, and Organic Silicon
Michael S. Bisesi, Ph.D., CIH

E. Silicones (Siloxanes)
17.0a Hexamethyl Disiloxane (HMS)
17.0.1a CAS Number: [*107-46-0*]

17.0.5a Molecular Formula: $C_6H_{18}OSi_2$

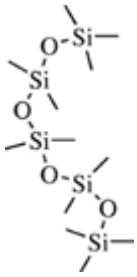
17.0.6a Molecular Structure:



17.0b Dodecamethylpentasiloxane
17.0.1b CAS Number: [*141-63-9*]

17.0.5b Molecular Formula: $C_{12}H_{36}O_4Si_5$

17.0.6b Molecular Structure:



The silicones, organopolysiloxanes, may be divided into the commercial materials, the fluids, and the resins, structurally $R_2[R_2SiO_{n-1}]_n$ for the linear compounds. The final products are water repellent, insoluble in most solvents, and resistant toward oxidation and chemical attack (128). Silicones are used medically and for cosmetic prosthetic devices.

In chronic feeding experiments, rats on HMS showed widespread systemic irritation. Rabbits injected intradermally with HMS showed irritation with edema and necrosis at the injection site (128). Siloxanes injected into the rabbit eye resulted in transient irritation with complete clearing after 48 h (128). When inhaled at 4400 ppm for 19–26 d, HMS caused slight depression in the rat and the guinea pig, with a very slight increase in rat liver and kidney weights (128).

Silicone resins had no influence on health when fed for 94 d to rats, and did not result in irritation to the rabbit skin or eye or when injected into rats intraperitoneally (128). It has been postulated and reported in the literature, however, that implanted silicone prostheses may cause granulomas, lymphadenopathy, cancer, and various autoimmune diseases in humans (134–136). Other reports indicate, however, that a definite correlation has not yet been confirmed by scientific data (137, 138).

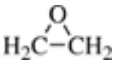
Epoxy Compounds—Olefin Oxides, Aliphatic Glycidyl Ethers and Aromatic Monoglycidyl Ethers

John M. Waechter, Jr., Ph.D., DABT, Lynn H. Pottenger, Ph.D., Gauke E. Veenstra, Ph.D.

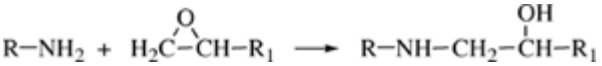
Introduction

An epoxy compound is defined as any compound containing one or more oxirane rings. An oxirane ring (epoxide) consists of an oxygen atom linked to two adjacent (vicinal) carbon atoms as follows for the example compound, ethylene oxide:



The term alpha-epoxide is sometimes used for this structure to distinguish it from rings containing more carbon atoms. The alpha does not indicate where in a carbon chain the oxirane ring occurs.

The oxirane ring is highly strained and is thus the most reactive ring of the oxacyclic carbon compounds. The strain is sufficient to force the four carbon atoms nearest the oxygen atom in 1,2-epoxycyclohexane into a common plane, whereas in cyclohexane the carbon atoms are in a zigzag arrangement or boat structure (1). As a result of this strain, epoxy compounds are attacked by almost all nucleophilic substances to open the ring and form addition compounds. For example,



Among agents reacting with epoxy compounds are halogen acids, thiosulfate, carboxylic acids, hydrogen cyanide, water, amines, aldehydes, and alcohols.

A major portion of this chapter presents information on the two olefin oxides, ethylene oxide and propylene oxide, which are produced in high volume and are largely used as intermediates in the production of the glycol ethers. In addition, these compounds are used in the production of several other important products (e.g., polyethylene glycols, ethanolamines, and hydroxypropylcellulose) and have minor uses as fumigants for furs and spices and as medical sterilants. The other olefin oxides discussed are used as chemical intermediates (e.g., vinylcyclohexene mono- and dioxide), as gasoline additives, acid scavengers, and stabilizing agents in chlorinated solvents (butylene oxide) or in limited quantities as reactive diluents for epoxy resins. The discussion of the toxicology of certain olefinic oxides may be pertinent to their respective olefin precursors. However, it must be pointed out that the olefinic precursors of these different oxides demonstrate widely varying degrees of toxicity in mammalian models, mostly attributable to pharmacokinetic/metabolism differences in metabolic conversion of olefins to their respective oxide metabolites. For example, chronic bioassay results range from repeated negatives (ethylene, propylene) to clear positives (butadiene). A major use of the glycidyl ethers discussed in this chapter are as reactive diluents in epoxy resin mixtures. However, some of these materials are also used as intermediates in chemical synthesis as well as in other industrial applications.

The concept that epoxides, through their binding to nucleophilic biopolymers such as DNA, RNA, and protein, can produce toxic effects is well established. However, the magnitude and nature of physiological disruption depend on the reactivity of the particular epoxide (2–4), its molecular weight, and its solubility (5), all of which may control its access to critical molecular targets. In addition, the number of epoxide groups present, the dose and dose rate, the route of administration, and the affinity for the enzymes that can detoxify or activate the compound may affect the degree and nature of the physiologic response. A key enzyme for epoxide detoxification is microsomal epoxide hydrolase (EH), which is widely distributed throughout the body, but it is organ, species, and even strain variant (6). It should be noted that mouse tissues have a much lower level of EH activity than human tissue; in fact, at least two strains of mice, C57BL/6N and DBA/2N, have no EH activity in their skins (7). Hence, the relevance of risk assessment based on the toxicity findings from studies of epoxides in mice is moot. Epoxy compounds may also be metabolized by the cytoplasmic enzyme glutathione-*S*-transferase (GST), which conjugates epoxides with its co-substrate, glutathione (GSH), leading to formation of 2-alkylmercapturic acids. This enzyme, because it is in the aqueous phase, may play a minor role in the detoxification of larger more lipophilic epoxides but is active against low-molecular-weight epoxides (8, 9). GST also exhibits organ, species, and strain differences in expression and activity as well as genetic polymorphisms.

Acute toxic effects most commonly observed in animals have been dermatitis (either primary irritation or secondary to induction of sensitization), eye irritation, pulmonary irritation, and gastric irritation, which are found in these tissues after direct contact with the epoxy compound. Skin irritation is usually manifested by more or less sharply localized lesions that develop rapidly on contact, more frequently on the arms and hands. Signs and symptoms usually include redness, swelling, and intense itching. In severe cases, secondary infections may occur. Workers show marked differences in sensitivity.

Most of the glycidyl ethers in this chapter have shown evidence of delayed contact skin sensitization, in either animals or humans. The animal and human data available on skin sensitization of epoxy compounds do not assist in determining the structural requirements necessary to produce sensitization, but do provide some practical guidance for industrial hygiene purposes. Specifically, of the alkyl glycidyl ethers, only the C8–C10 alkyl glycidyl ether appears to be a human sensitizer. Despite equivocal results in tests for delayed contact sensitization in guinea pigs, *n*-butyl glycidyl ether and cresyl glycidyl ether do produce dermal sensitization in some humans. Skin sensitization reactions can be elicited from much less agent than is required for an irritative response. Because this condition is difficult to treat, sensitized individuals may require transfer to other working areas.

Animals exposed to vapors of gaseous or volatile epoxy compounds, primarily ethylene oxide and propylene oxide, have shown pulmonary irritation. Sequelae of this effect may include pulmonary edema, cardiovascular collapse, and pneumonia. However, this route of exposure is unlikely for some of the other epoxy compounds owing to their lower volatility.

For those epoxy compounds for which repeat exposures have been conducted, respiratory epithelium or nasal mucosa (when inhalation was the route of exposure) and stomach (when given by gavage) appear to be the major target organs. In some cases liver and kidney have been target organs. These effects on the liver and kidney have been relatively nonspecific or adaptive, as indicated by an increased organ weight without accompanying histopathology. Exceptions include ethylene oxide, which caused renal tubular degeneration and necrosis in mice; vinylcyclohexene dioxide, which produced kidney tubule cell necrosis; *n*-butyl glycidyl ether, which produced liver necrosis; and phenyl glycidyl ether, which produced atrophic liver and kidney effects in rats. Ovarian toxicity and depression of hematopoesis have also been observed in laboratory animals for butadiene dioxide and vinylcyclohexene dioxide. Respiratory epithelium and nasal mucosa effects have been responses typical of irritation, such as flattening or destruction of epithelial cells.

Although all of the compounds described in this chapter were mutagenic to bacteria (excluding

epoxidized glycerides) as well as positive in other *in vitro* genotoxicity assays, not all have produced genotoxicity in *in vivo* studies. Ethylene oxide was positive in the mouse micronucleus assay and mouse dominant lethal assay. In contrast, propylene oxide, although positive in all the *in vitro* assays in which it was tested, was negative in all of the *in vivo* mammalian assays where propylene oxide was administered via the relevant inhalation route. These negative mammalian studies include a mouse micronucleus assay (although positive by IP injection of high doses), mouse sperm cell analysis, and a rat dominant lethal assay. In addition, propylene oxide failed to cause chromosomal changes (SCE and chromosomal aberrations) in monkey lymphocytes following chronic exposures to 300 ppm. Other compounds showing positive or equivocal effects *in vitro* but negative effects *in vivo* are styrene oxide, and many of the glycidyloxy compounds used in epoxy resin formulations.

There has been no evidence of teratogenicity for glycidyl ethers or olefin oxides, except ethylene oxide (EO), when tested by oral or inhalation exposure in conventional developmental toxicity studies. Fetal toxicity has been observed at maternally toxic doses for ethylene oxide, propylene oxide by inhalation in rats, and 1,2-epoxybutane by inhalation in rabbits. No evidence for fetal toxicity, in some instances even at maternally toxic doses, has been observed for phenyl glycidyl ether by inhalation in rats, 1,2-epoxybutane by inhalation in rats, or propylene oxide or styrene oxide by inhalation in rabbits. Additionally, repeated intravenous infusion of ethylene oxide was teratogenic in mice. Inhalation of extremely high levels of EO (600–1200 ppm compared to the ACGIH-recommended 8-h TWA–TLV of 1 ppm) in mice at the time of fertilization or early zygote development has led to fetal deaths or malformations in some survivors. However, no teratological effects have been demonstrated by inhalation exposures up to 150 ppm in rats or rabbits.

A number of these epoxide compounds have been found to be carcinogenic in rodents, although there has been no clear epidemiologic evidence for cancer in the workplace. In rats and/or mice, many epoxy compounds produce a carcinogenic response in the tissues of first contact. These compounds include ethylene oxide, butylene oxide, propylene oxide, styrene oxide allyl glycidyl ether, phenyl glycidyl ether, and neopentyl glycol diglycidyl ether. A few of them, such as ethylene oxide, butadiene dioxide, and vinylcyclohexene dioxide, have produced tumors at sites other than the "portal of entry."

Epoxy Compounds—Olefin Oxides, Aliphatic Glycidyl Ethers and Aromatic Monoglycidyl Ethers

Epoxy Compounds—Aromatic Diglycidyl Ethers, Polyglycidyl Ethers, Glycidyl Esters, and Miscellaneous Epoxy Compounds

John M. Waechter, Jr., Ph.D., DABT, Gauke E. Veenstra, Ph.D.

Introduction

The principal focus of this chapter is on the epoxy compounds frequently encountered in industrial use as uncured epoxy resins. These resins are marketed in a variety of physical forms from low-viscosity liquids to tack-free solids and require admixture with curing agents to form hard and nonreactive cross-linked polymers. They are in demand because of their toughness, high adhesive properties (polarity), low shrinkage in molds, and chemical inertness.

It is the uncured resins that are of main interest to toxicologists, for a well-cured resin should have few or no unreacted epoxide groups remaining in it. The toxicology of the curing agents is not treated in this chapter. They are most frequently bi- or trifunctional amines, di- or tricarboxylic acids

and their anhydrides, polyols, and compounds containing mixed functional groups, such as aminols and amino acids, as well as other resins containing such groups (1).

Some of the other epoxide compounds described in this chapter are used as reactive diluents in epoxy resin mixtures; others are of commercial importance for their multiple uses in the synthesis of other compounds (specifically, epichlorohydrin). As reactive diluents, monomeric epoxides are added to epoxy resins to reduce viscosity and modify the handling characteristics of the uncured materials. The epoxide functionalities of these diluents react with the resin curing agents in the same manner as the resin to become part of the finished polymer. Epoxy resins have found application as protective coatings, adhesives for most substrates (metals included), caulking compounds, flooring and special road paving, potting and encapsulation resins, low-pressure molding mixtures, and binding agents for fiber glass products. Uncured, they are used as plasticizers and stabilizers for vinyl resins.

Epoxy resin coating formulations can generally be limited to one of three forms: solution coatings, high-solids formulations, and epoxy powder coatings. Solid epoxies are used in coating applications, as solid solutions or heat-converted coating. Solution coatings are often room-temperature applications, and typically there is little potential for vapor exposure. The potential clearly exists for skin contact during application of coatings of this type. Heat-converted coatings are usually applied and cured by mechanical means and exposure to vapors or contact with skin is minimal.

Solid resins are used for other applications such as electrical molding powders and decorative or industrial powder coatings. For applications of this kind, exposure to vapors and dust can occur and is greatest during formulating and grinding.

Considering that epoxides can react with nucleophiles, particularly basic nitrogens, one might expect the epoxides to react with cellular biomolecules such as glutathione, proteins, and nucleic acids, and indeed this has been demonstrated for some of these epoxide compounds. The nature and magnitude of these interactions with these biomolecules is most likely related to the toxicity and observed for any given molecule in this class of compounds. However, the potential for any epoxide to react with cellular nucleophilic biomolecules is dependent on several factors, including the reactivity of the particular epoxide, the dose and dose rate, as well as the molecular weight, and solubility, these latter two influencing access to molecular targets within the cell. In addition, the efficiency of metabolism via epoxide hydrolase or other metabolic routes of detoxication may significantly influence the toxicologic potential and potency of these materials.

Epoxide hydrolase activity is widely distributed throughout the body, but it is organ, species, and even strain variant (2). The liver, testes, lung, and kidney have considerable epoxide hydrolase activity; the activities in the skin and gut, however, are considerably lower. In this regard it should be noted that mouse tissues have a much lower level of EH activity than does human tissue; in fact, at least two strains of mice, C57BL/6N and DBA/2N, have no EH activity in their skins (3). Therefore, it may be questioned if toxicity or treatment-related effects observed in dermal mouse studies are relevant for hazard evaluation. Epoxy compounds may also be metabolized by the cytoplasmic enzyme glutathione-*S*-transferase, which converts epoxides to 2-alkylmercapturic acids. This enzyme because it is in the aqueous phase, may play a minor role in the detoxification of large lipophilic epoxides, but is active against low-molecular-weight epoxides (4, 5). Due to differences in physio-chemical properties and the effectiveness and nature of the detoxification of these materials through metabolism, the toxicity of these compounds ranges from the highly active, electrophilic, low-molecular-weight mono- and diepoxides to the nontoxic and inert cured materials, which possess only a few epoxy groups per molecule.

In general, the acute toxicity of epoxy resin compounds as observed in laboratory animals can be considered low; oral and dermal LD_{50} values generally range from about 2000 to greater than 10,000 mg/kg in rodents; there are not marked differences in acute toxicity among the structurally

diverse categories of epoxy resin compounds. The acute toxicity of low-molecular-weight epoxides such as epichlorohydrin and glycidol is significantly greater (oral LD_{50} values range from 90 to about 500 mg/kg). Lung irritation following inhalation or gastrointestinal irritation following gavage has also been observed in animals. It is generally difficult to achieve acutely toxic levels of epoxy compounds by dermal exposure. Usually the irritating properties of epoxy liquids or vapors limit significant exposure to produce systemic toxicity.

Effects most commonly observed in animals have been dermatitis (either primary irritation or secondary to induction of sensitization), eye irritation, pulmonary irritation, and gastric irritation, which are typically found in the tissues that are the first to come into contact with the epoxy compound. In general, it appears that epoxy compounds of higher molecular weight (e.g., epoxy novolac resins and diglycidyl ether of bisphenol A) produce less dermal irritation than those of lower molecular weight. In some instances, liquid epoxy compounds splashed directly into the eye may cause pain and, in severe cases, corneal damage. Skin irritation is usually manifested by more or less sharply localized lesions that develop rapidly on contact, more frequently on the arms and hands. Signs and symptoms usually include redness, swelling, and intense itching. In severe cases, secondary infections may occur.

Workers show marked differences in sensitivity. Devices made from epoxy resins have produced severe dermatitis when not properly cured and when in prolonged contact with the skin (6). Skin irritation also has been reported from exposure to epoxy vapors (7). Most of the epoxy compounds have the ability to produce delayed contact skin sensitization, although there are notable exceptions, such as the advanced bisphenol A/epichlorohydrin resins. The higher molecular weight of these resins may be responsible for the absence of dermal sensitization (8, 9). Skin sensitization reactions can be elicited from much less agent than is required for a primary irritation response. Because this condition is difficult to treat, sensitized individuals may require transfer to other working areas. Particular attention should be paid to vapors and fine airborne dusts.

Animals exposed to vapors of epichlorohydrin have shown pulmonary irritation. Sequelae of this effect may include pulmonary edema, cardiovascular collapse, and pneumonia. However, this route of exposure is unlikely for many of these epoxy compounds owing to their low volatility. For the glycidyloxy compounds for which LC_{50}s have been determined, it appears that none of these compounds can be considered highly acutely toxic by the inhalation route.

For those epoxy compounds for which repeat dosing studies have been conducted, generally the liver, kidneys, respiratory epithelium or nasal mucosa (when inhalation was the route of exposure), and stomach (when given by gavage) appear to be the major target organs. Respiratory epithelium and nasal mucosa effects have been responses typical of irritation, such as flattening or destruction of epithelial cells. Disruption of hematopoesis, primarily leukopenia, has also been demonstrated in laboratory animals with a polyglycidyl ether of substituted glycerin and resorcinol diglycidyl ether, but similar changes have not been observed in workers as a result of occupational exposures. The testes have been found to a target organ for glycidol and epichlorohydrin. Glycidol was also embryotoxic in laboratory animals when administered by a route not relevant to occupational exposure (intra-amniotic injection). However, no developmental toxicity has been observed for any other compounds in this chapter where there are data available. In addition, a two-generation reproduction study in rats on the diglycidyl ether of bisphenol A also indicated that this material did not produce adverse effects on either male or female reproduction.

There is evidence in rats from a National Toxicology Program study that glycidol produces neurotoxicity (10), and this finding suggests that glycidyl esters, if metabolized to glycidol, could have this effect. However, glycidyl ethers have shown no evidence of neurotoxic effects in numerous acute or repeated dosing subchronic studies in rodents. A recently completed neurotoxicity study of diglycidyl ether of bisphenol found no evidence of neurotoxic effects in rats dosed dermally.

Generally, *in vitro* genetic toxicity testing of the epoxide compounds has resulted in positive (genotoxic) responses; the majority of the studies of genotoxic potential have been carried out using bacteria. These results are not surprising because many of these compounds have been tested in strains TA1535 and TA100 of *S. typhimurium* or in other gene mutation assays that are specifically sensitive to base-pair substitution, Metabolic activation was not required for most of the epoxides, which showed mutagenic in these tests. Many other *in vitro* assays examining both gene mutation and chromosomal effects have been employed to test the epoxy compounds, including assays in *E. coli*, yeast, Chinese hamster ovary cells (CHO/HPGRT), mouse lymphoma cells, and cultured human lymphocytes; the results have usually been mixed or positive. Fewer epoxy compounds have been tested using *in vivo* assays for genotoxic effects, although some have been extensively studied. Glycidol was positive in the *Drosophila* sex-linked recessive lethal assay and mouse micronucleus assay and produced chromosomal aberrations in the bone marrow of mice dosed orally or intraperitoneally. Glycidaldehyde was positive in the *Drosophila* sex-linked recessive lethal assay. In contrast, epichlorohydrin, also a low-molecular-weight epoxy compound, was negative in both the mouse micronucleus test following intraperitoneal administration and the mouse dominant lethal assay following oral or intraperitoneal administration, although it was positive in many of the *in vitro* assays. Another compound showing positive or equivocal effects *in vitro* but negative effects *in vivo* is the diglycidyl ether of bisphenol A.

Of the compounds in this chapter, four (resorcinol diglycidyl ether, epichlorohydrin, glycidaldehyde, and glycidol) were the subject of studies in which there was clear evidence of tumorigenic effects in rodents. Larger-molecular-weight glycidyloxy compounds such as castor oil glycidyl ether, the diglycidyl ether of bisphenol A, and advanced bisphenol A/epichlorohydrin epoxy resins have been negative in dermal bioassays. Epidemiology studies have not provided any evidence for an association between workplace exposure and cancer to any of the materials in this chapter.

Organic Peroxides
Jon B. Reid, Ph.D., DABT

Introduction
A review of the literature for these compounds has resulted in very little new information. Consequently, the content of this chapter is drawn heavily from the previous authors, including the tables. The only compounds where there has been publishing activity are: dibenzoyl peroxide,

methyl ethyl ketone peroxide, *t*-butyl hydroperoxide, isopropylbenzene hydroperoxide, and peroxyacetic acid. A recent review compared the skin tumor promoting activity of different organic peroxides in SENCAR mice (especially *t*-butyl peroxide, dicumyl peroxide, and also dibenzoyl peroxide) (1). Much of this literature is, however, irrelevant to health. The introduction presented in the previous edition is entirely correct and relevant.

Peroxides are highly reactive molecules due to the presence of an oxygen–oxygen linkage. Under activating conditions, the oxygen–oxygen bond may be cleaved to form highly reactive free radicals. These highly reactive radicals can be used to initiate polymerization or curing. Consequently, organic peroxides are used as initiators for free-radical polymerization, curing agents for thermoset resins, and cross-linking agents for elastomers and polyethylene. In some cases they can be used as antiseptic agents.

These materials must be handled and stored with caution. If free radicals are formed during storage in concentrated form, an accelerated decomposition could result, leading to the release of considerable heat and energy. It has been determined that decompositions of commercially available peroxides are generally low-order deflagrations rather than detonations (2).

There have been several investigations into the types of physical hazards represented by organic peroxides (2–5). These compounds may possess the combination of thermal instability, sensitivity to shock, and/or friction, as well as flammability. Organic peroxides tend to be unstable, with the instability increasing with greater concentrations. Because of their instability, many peroxides are stored/handled in inert vehicles (6). It has been shown by Tamura (3) that the ignition sensitivity and the violence of deflagration for each organic peroxide may have a tendency to increase with increasing active oxygen content among the same type of organic peroxide, with a few exceptions. The ignition sensitivity and the violence of deflagration for each type of organic peroxide may decrease in the following order, given the same active oxygen content: diacyl peroxides > peroxyesters > dialkyl peroxides > hydroperoxides (3).

Basically only acute health testing has been performed on organic peroxides. Exposures should be well controlled, primarily owing to the decomposition or deflagration hazard of the organic peroxide. The health data presented in Tables 84.1–84.9 were collected and furnished by the Organic Peroxide Producers Safety Division of the Society of the Plastics Industry to the previous authors of this chapter and are presented again in this edition. This represents an effort by industry to evaluate their products and provide that information to the public. Most of the information in the table has been previously published (7) in an industry bulletin.

The analytic method should also be specific for each organic peroxide. NIOSH has fully validated a high-performance liquid chromatography/ultraviolet light method for benzoyl peroxide (8). Very few of the other organic peroxides have fully validated analytic methods. One of the first conventional methods to determine concentrations of organic peroxides was the titration of iodine from sodium iodide. However, it was not specific for organic peroxides. The polarographic method came into use with the visible-recording polarograph because hydroperoxides could be distinguished from other peroxides. This method could identify the functional groups and also quantify mixtures. Di-*t*-butyl peroxide is an exception because it is not reduced polarographically (9).

Many analytical methods that have not been subjected to review by consensus standard organizations or regulatory agencies are in use. Some examples include gas chromatography (dialkyl peroxides such as di-*t*-butyl peroxide), high-pressure liquid chromatography (peroxyketals), and iodometric titration (peroxyesters, diacyl peroxides, hydroperoxides, and peroxydicarbonates). Some degree of selectivity in iodometric titrations may be obtained by variation of the reducing agent employed and the reaction conditions.

Organic Peroxides
Jon B. Reid, Ph.D., DABT

A. Peroxydicarbonates

Table 84.1. Toxic Properties of Peroxydicarbonates (7)[*]

Peroxydicarbonate	CAS No.	Oral LD_{50} (mg/kg)	Dermal LD_{50} (mg/kg)	Primary Skin Irritation[a]	Eye Irritation[a]	LC_{50}, ppm (mg/L)[b]	*Salmonella typhimurium* Assay
Diisopropyl peroxydicarbonate	[*105-64-6*]						
100%		2140		Mod. irritant	Ext. irritating		
30% in toluene		3720	2025	Ext. irritating	Mod. irritating		
45% in Soltrol 130		8500	1.7[c]	V. severe irritant	Irritant	Irritant gas	
45% in cyclohexane--benzene		6500	4.0[c]	V. severe irritant	Irritant		
Di-*n*-propyl peroxydicarbonate	[*16066-38-9*]						
100%		3400	>6800	Ext. irritating	Ext. irritating	>22.7 (>0.19) 1 h	
85% in methylcyclohexane		4600	3500	Ext. irritating	Ext. irritating	>1433 (>12) 1 h	
Di-*sec*-butyl peroxydicarbonate	[*19910-65-7*]						
100%		7600				172 ppm—no adverse effects (1 h)	
75% in odorless mineral spirits		>4640	Not toxic at 2000[d]		Irritant		
75% in Soltrol 130		9300	1200				
Di-(2-ethylhexyl) peroxydicarbonate	[*16111-62-9*]						
97% min			Not toxic at 2000[d]		Irritant

Organic Peroxides
Jon B. Reid, Ph.D., DABT

G. Sulfonyl Peroxides
75.0 Acetyl Cyclohexanesulfonyl Peroxide
75.0.1 CAS Number: [*3179-56-4*]

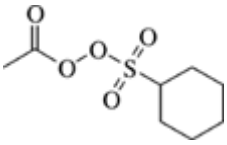
75.0.2 Synonyms: NA

75.0.3 Trade Names: NA

75.0.4 Molecular Weight: 222.2

75.0.5 Molecular Formula: $C_8H_{14}O_5S$

75.0.6 Molecular Structure:



75.1 Chemical and Physical Properties
75.1.1 General No information was located for this compound.
75.2 Production and Use
No information was located for this compound.
75.3 Exposure Assessment
75.3.1 Air No air collection method or analytic method was located for this compound.
75.4 Toxic Effects
The only toxicity data found for acetyl cyclohexanesulfonyl peroxide were as follows (7): It had an oral LD_{50} of >4640 mg/kg, a dermal LD_{50} of >2000 mg/kg, and was classified as an eye irritant. At a concentration of 29% in dimethyl phthalate, its oral LD_{50} was 1710 mg/kg.

An acute inhalation study was performed exposing 40 rats to 25, 50, 100, and 200 mg/L of this chemical. At the lowest concentration, 25 mg/L, bloody nasal discharge and congested lungs were noted. One death was noted. The LC_{50} was judged to be 58.3 mg/L with 95% confidence limits of 46–74 mg/L (159).

Glycols

Finis L. Cavender, Ph.D., DABT, CIH, Edward J. Sowinski, Ph.D., DABT, CIH

1 Introduction to Class of Chemicals

The glycols are hydrocarbons that have two hydroxyl groups attached to separate carbons in an aliphatic chain or alicyclic ring. They are used as antifreeze agents, cryoprotectants, solvent carriers, chemical intermediates, and vehicles in a number of chemical formulations. They vary from slightly viscous liquids to waxy solids, are soluble in water, alcohols, and ketones, and are insoluble in hydrocarbons (1–10).

They have low vapor pressures; therefore inhalation of vapors and aerosols is of little concern unless they are heated, agitated, or sprayed. They have little or no odor; thus only their irritancy at high concentrations is a warning property (11–15).

Because of the irritant properties and the potential for central nervous system (CNS) depression at high concentrations, the threshold limit value (TLV) for glycols is generally set as a ceiling limit. The chemical and physical properties of several of the more common glycols are given in Table 85.1 (1–15).

Table 85.1. Physical and Chemical Properties of Common Glycols (Diols)

Property	Ethylene Glycol	Diethylene Glycol	Triethylene Glycol	Propylene Glycol
CAS Number	[*107-21-1*]	[*111-46-6*]	[*112-27-6*]	[*57-55-6*]

Molecular formula	$C_2H_6O_2$	$C_4H_{10}O_3$	$C_6H_{14}O_4$	$C_3H_8O_2$
Molecular weight	62.07	106.12	150.1	76.1
Specific gravity (25/4°C)	1.11	1.12	1.125 (20/20° C)	1.033
Boiling point, °C (760 mmHg)	197.4	245	287.4	187.9
Freezing point, °C	–13.4	–8.0	–4.3	–31.0
Vapor pressure, mmHg (25°C)	0.06 (20°C)	<0.01	0.001	0.13
Refractive index (25° C)	1.432		1.456	1.431
Flash point, °F (o.c.)	240	290	330	215–225
Percent in saturated air (25°C)	0.017	0.0013 (20° C)	0.00013 (20° C)	0.038
1 ppm ⇔ mg/m^3 at 25°C and 760 mmHg	2.54	4.35	6.14	3.11
1 mg/l ⇔ ppm at 25°C and 760 mmHg	365.0	230.7	162.8	321.6

Glycols

Ethers of Ethylene Glycol and Derivatives
Rodney J. Boatman, Ph.D., DABT, James B. Knaak, Ph.D.

Introduction
A. Background
There are currently seven U.S. manufacturers of ethers and other derivatives of ethylene glycol (EG), diethylene glycol (DEG), and higher glycols. Five of them are members of the American Chemistry Council (ACC) Glycol Ethers' Panel (Table 86.1).

Table 86.1. U.S. Manufacturers of Ethylene Glycol Ethers and Derivatives

Manufacturing Company	Trade Name
The Dow Chemical Company[a]	Dowanol® solvent
Eastman Chemical Company[a]	Eastman® solvent
Ferro Corporation	
Olin Chemical Corporation	Poly-solv® solvent
Equistar Chemical Company[a]	
Shell Chemical Company[a]	Oxitol solvent® (ethers of EG) Dioxitol® solvent (ethers of DG)
Union Carbide Corporation[a]	Cellosolve® solvent (ethers of EG) Carbitol® solvent (ethers of DEG)

[a] Member of the American Chemistry Council, Ethylene Glycol Ethers Panel.

B. Production and Use
The glycol ethers most commonly encountered industrially are colorless liquids that have mild ethereal odors. Alkyl glycol ethers are manufactured in a closed, continuous process by reacting ethylene oxide with an anhydrous alcohol in the presence of a suitable catalyst. Depending on the

molar ratios of the reactants and other process parameters, the product mixtures obtained contain varying amounts of the monoethylene-, diethylene-, triethylene-, and higher glycol ethers. Typically, the products in these mixtures are separated and purified by fractional distillation. Ethylene-based glycol ether production capacity in 1996 was about 1500 million lb. In 1995, output of the butyl ether of ethylene glycol, the most widely produced glycol ether was about 413 million lb (1).

The miscibility of most of these ethers with water and with a large number of organic solvents makes them especially useful as solvents in oil–water compositions. Their relatively slow rate of evaporation also makes them useful as solvents and coalescing agents in paints (2). Other uses include inks, cleaners, chemical intermediates, process solvents, brake fluids, and deicers (2). The ethers of the higher glycols are used as hydraulic fluids. An estimate of the U.S. production and use of representative ethylene glycol ethers is presented in Table 86.2. Production of ethylene glycol ethers (total) in Western Europe amounted to 245 thousand metric tons in 1995 (1). Japanese production of ethylene glycol ethers (total) amounted to 59.5 thousand metric tons in 1995 (1). Lesser amounts of glycol ethers are also produced in Brazil, Canada, and Eastern Europe (1).

Table 86.2. Ethylene Glycol Ethers and Ether Acetates: Production Volumes and Uses i

Chemical	Company Trade Name	CAS Number	Production Volume (10^6 lbs)	Type of Consumer End Products	Consumer Products Volume (10^6 lbs)	Consumer Products (% of Production)	Consu Prod (App Wei %
Ethylene glycol monomethyl ether (EGME)	Methyl Cellosolve® Solvent Glycol Ether EM	[*109-86-4*]	15	None

[a] This information was compiled by the Chemical Manufacturers Association, Ethylene Glycol Ethers Panel.

C. Occupational Exposure

Occupational exposure to glycol ethers occurs dermally and by inhalation. Ingestion is not a concern in industrial exposure, although some cases of intentional ingestion of consumer products containing ethylene glycol ethers have been reported. Several review articles were recently published dealing with house painters' exposure to glycol ethers in water-based paints (3) and exposure of workers in the semiconductor industry to glycol ethers during manufacturing (4–12).

Analytical Methods

A number of analytical methods have been published that are suitable for detecting glycol ethers in environmental air samples (13). These methods rely principally on adsorption onto activated charcoal or other suitable material followed by desorption and gas chromatographic analysis. Lower limits of detection generally range from 0.1 to 2 ppm in air depending on the specific analytical method employed and on the gas sampling procedure used. Typical methods include NIOSH method 1403 (14) and OSHA method 83 (15). A typical example is an industrial hygiene monitoring method developed by Dow Chemical Company (16) that can analyze for nine airborne glycol ethers: ethylene glycol methyl ether (EGME), ethylene glycol ethyl ether (EGEE), ethylene glycol phenyl ether (EGPhE), ethylene glycol butyl ether (EGBE), diethylene glycol methyl ether (DGME), diethylene glycol ethyl ether (DGEE), diethylene glycol phenyl ether (DGPhE), diethylene glycol

butyl ether (DGBE), triethylene glycol methyl ether (TGME), and triethylene glycol phenyl ether (TGPhE), collected on charcoal or silica gel using an air pump. The procedure involves pulling air that contains the volatile glycol ethers through charcoal or silica gel adsorbent tubes for periods of time up to 8 h. The adsorbed glycol ethers are desorbed from charcoal using water/CS_2 and from silica gel using a 25/75% mixture of methanol/water. The aqueous layer is analyzed for glycol ethers by gas chromatography using a flame-ionization detector (GC-FID). A 3.3 ft × 2 mm i.d., glass column, packed with 5% SP-1000 on 60/80 mesh Carbopack B may be used for the analysis or the packed column may be substituted with a SPB-1000 (Supelco, Inc., Bellefonte, PA) capillary column (30 m × 0.53 mm i.d., 0.5 mm film thickness). Supelco (17) recommends using a Nukol® fused silica capillary column for glycols (15 m × 0.53 mm i.d., 0.5 mm film). Water can be directly injected into this column. The column may be used to separate free acids, phenols, glycol ethers, and glycols dissolved in water. Several other similar capillary columns would also be suitable for this analysis.

Eckel et al. (18) reported the presence of glycol ethers in groundwater samples from hazardous waste sites. These authors point out that the general-purpose USEPA methods (GC/MS) used for either volatile or semivolatile pollutants may underestimate the true amounts of glycol ethers in environmental samples. This is due to the inefficiency of either the common purge-and-trap or solvent extraction methods for isolating glycol ethers. These authors suggest that more appropriate techniques would involve direct aqueous injection, extractive alkylation or salting-out extraction with derivatization.

D. Pharmacokinetics, Metabolism, and Mechanism of Action

Pharmacokinetics—Absorption

Inhalation Glycol ethers as a class are polar solvents that have generally low volatility and higher boiling points than most comparable solvents. Respiratory retention of glycol ethers is high and accounts for 50 to 80% of inhaled amounts due to high blood/air partition coefficients (i.e., 34913 for EGME) in lungs. Inhalation of 5.13 ppm EGME at the Occupational Exposure Limit (OEL) concentration of 16 mg/m^3 for 8 h resulted in an uptake of 57 mg in human volunteers at rest (19). Work (50 W, 100 W, 150 W) results in an increase in respiratory volume and the inhalation and retention of substantially larger amounts of volatile glycol ethers (EGME, EGEE, and EGBE).

Dermal—Liquid Glycol ethers (neat) are absorbed by the dermal route, and 0.2 to 3% of topically applied EGME is absorbed by humans under occlusive conditions (area (27 cm^2) × concentration (1.0 g/cm^3) × K_p (28.9×10^{-4} cm/h) × time (10 h) = 780 mg absorbed; 780 mg/27000 mg applied × 100 = 2.9%) (19). The amount absorbed is determined by the exposed area, applied concentration, permeation constant (K_p), and total contact time. Microgram quantities are absorbed per cm^2 of skin per h from concentrations (mg/cm^3) normally encountered in the work place. For those glycol ethers that have been adequately tested, dermal administrations generally result in toxicities that are similar to those following oral administrations, but require higher equivalent dermal doses and longer periods of exposure. Skin penetration is determined primarily by the stratum corneum. The *in vitro* rates of permeability of a homologous series of glycol ethers through human stratum corneum have been summarized in Table 86.3. The methyl, ethyl, and butyl ethers of diethylene and triethylene glycol are absorbed to a lesser extent than the corresponding ethers in the ethylene glycol series (20, 21). An increase in either the chain length of the alkyl substituent or in the number of ethylene glycol moieties (ethylene oxide adducts) results in a decreased rate of percutaneous absorption. It can be seen that EGME is absorbed 131 times more rapidly than the triethylene glycol butyl derivative. Increased absorption of the lower molecular weight homologues is offset by an increased rate of evaporation from the skin, as indicated by the lower boiling points for these derivatives.

Table 86.3. Permeation of Glycol Ethers Through Human Epidermis *In Vitro*[a]

Glycol Ether	Mol. Wt.	Vapor Pressure (mmHg)	Boiling Pt. (°C)	Permeation Constant (cm/h × 10^4)	Relative Rate
Ethylene glycol series:					
Methyl ether	76	9.7	124	28.9	131
Ethyl ether	90	5.75	135	8.42	38
Butyl ether	118	0.88	171	2.14	9.7
Diethylene glycol series:					
Methyl ether	120	0.18	194	2.06	9.4
Ethyl ether	134	0.14	202	1.32	6.0
Butyl ether	162	0.043	230	0.357	1.6
Triethylene glycol series:					
Methyl ether	164	<0.01	249	0.34	1.5
Ethyl ether	178	<0.01	256	0.24	1.1
Butyl ether	206	<0.01	279	0.22	1.0

[a] Taken from Refs. 20 and 21.

Dermal-Vapor Glycol ethers are absorbed through skin in accordance with the following rate equation:

[TEXnical Error]

where C is the concentration gradient of the chemical in skin (g/cm^3), l is the thickness of the skin (cm), k_m is the partition coefficient of the chemical in skin (unitless), D is the diffusion coefficient (cm^2/h), and K_p is the permeability constant (cm/h). In the case of glycol ether vapors, skin/air partition coefficients need to be determined and used in the absorption equation to account for higher concentrations in skin due to partitioning. The equation is as follows for whole body exposure at the OEL for EGME of 16 mg/m^3 (5.13 ppm): area (18,000 cm^2) × concentration (16.0 × 10^{-6} mg/cm^3) × PC (11,734) × K_p (28.9 × 10^{-4} cm/h) × time (8 h) = 78 mg absorbed (19). The combined amount (135 mg) results in a dose of 1.9 mg/kg for a 70-kg person during an 8-h workday, assuming total body contact with vapors.

Pharmacokinetics—Distribution to Tissues

Regardless of the route of administration, glycol ethers are absorbed and distributed to tissues when administered to animals whose blood/air and skin/air partition coefficients for EGME are of the order of 34,900 and 11,700. Except for adipose tissue, measured tissue to blood partition coefficients

for glycol ethers and alkoxyacetic acid metabolites are generally near unity (11700/34900 = 0.335 for EGME skin/blood). See Table 86.4. Notable exceptions include EGME and methoxyacetic acid (MAA), which attain greater concentrations in developing embryos and embryonic fluids than in plasma, and EGBE, which has an increased affinity for lung and gastrointestinal tissue (22, 23).

Table 86.4. Tissue Partition Coefficients for EGME, EGEE, and EGBE and Alkoxyacetic Acid Metabolites

	Tissue Partition Coefficients					
	EGME[a]	MAA[a]	EGEE[b]	EAA[b]	EGBE[c]	BAA[c]
Blood/air	34,913	0.99	22,093	NA	7,965	NA
Liver/blood	1.02	1.26	1.0	1.1	1.46	1.30
Fat/blood	0.05	—	0.04	0.32	2.03	0.77
Poorly perfused/blood	0.93	—	0.94	0.05	0.64	1.31
Richly perfused/blood			1.1	1.06	1.46	1.30
Placenta/blood	1.20	1.05				
Extraembryonic fluid/blood	1.48	1.33				
Embryo/blood	1.52	0.94

Metabolism and Elimination
A general metabolic scheme for ethylene glycol monoalkyl ethers is summarized in Figure 86.1. Glycol ether acetates are rapidly hydrolyzed to their corresponding glycol ethers by carboxylesterases. This occurs in a variety of tissues, including blood and olfactory mucosa and as a result, both the toxicity as well as patterns of metabolic elimination are nearly identical for glycol ethers and their acetates. The parent glycol ethers are substrates for alcohol dehydrogenase (ADH) which catalyzes the conversion of their terminal alcohols to aldehydes. Further conversion by aldehyde dehydrogenase produces alkoxyacetic acids. The conversion by ADH and the resulting toxicity of the glycol ether can be blocked by pyrazole and other ADH inhibitors. Alcohol also inhibits this conversion. The higher molecular weight glycol ethers, (di- and triethylene glycol ethers), are believed to be poor substrates for ADH and are partially cleaved by the action of P-450 isozymes. Alkoxyacetic acids are significant if not major urinary metabolites of glycol ethers in both animals and humans and are the only toxicologically significant metabolites that have been detected *in vivo*. Although indirect evidence suggests that the aldehydes form under *in vivo* conditions, these have not yet been detected in whole animal studies. In animal studies, ethylene glycol has been

identified as a minor metabolite of glycol ethers. Sulfate and glucuronide conjugation of the parent glycol ethers has been reported as have the glycine (rodents) and glutamine (humans) conjugates of the alkoxyacetic acid metabolites. The formation of ethylene glycol under normal conditions of exposure is unlikely to contribute to the toxicity of glycol ethers. None of the other conjugates that have been identified has been associated with a toxicological response, and the formation of these is presumed to represent detoxification (24–26).

Glycol Ethers: Ethers of Propylene, Butylene Glycols, and Other Glycol Derivatives
Steven T. Cragg, Ph.D., DABT, Rodney J. Boatman, Ph.D., DABT

A. Ethers of Propylene Glycol

A.1 Background

There are currently five U.S. manufacturers of propylene glycol ether derivatives as shown in Table 87.1 (1). This table also contains a listing of the trade names used by these manufacturers for these materials.

Table 87.1. U.S. Manufacturers of Propylene Glycol Ethers and Tradenames

Manufacturer	Trade Name
Lyondell Chemical Company[a]	Arcosolv®
The Dow Chemical Company[a]	Dowanol®
Eastman Chemical Company[a]	Eastman®
Olin Chemical Corporation	Poly-Solv®
Union Carbide Corporation	Propasol®

[a] Members of the Chemical Manufacturers Association, Propylene Glycol Ethers Panel.

A.2 Production and Use

The ethers of mono-, di-, tri-, and polypropylene glycol are prepared commercially by reacting propylene oxide with the alcohol of choice in the presence of a catalyst. They also may be prepared by direct alkylation of the selected glycol with an appropriate alkylating agent such as a dialkyl sulfate in the presence of an alkali. When propylene oxide is used as the starting material, which is the case for most propylene glycol ethers, preparation under commercial conditions yields products that are mixtures of the a and b isomers. The a isomer consists of the ether linkage on the terminal hydroxyl group of propylene glycol; while the b isomer has the ether linkage on the secondary hydroxyl group, with the primary hydroxyl group unsubstituted. The a isomer is thermodynamically favored during synthesis from propylene oxide and the desired alcohol; thus, it constitutes the bulk of the resulting ether. By further manipulating the conditions of synthesis, the proportion of a isomer may be enhanced to constitute >99% of the end product. As explained later, this distinction is important regarding the toxicity of the propylene glycol ethers. The a and b isomers are shown below, where “R” represents the desired alcohol portion of the propylene glycol ether.

Glycol Ethers: Ethers of Propylene, Butylene Glycols, and Other Glycol Derivatives
Steven T. Cragg, Ph.D., DABT, Rodney J. Boatman, Ph.D., DABT

B. Ethers of Butylene Glycol

B.1 Source, Uses, and Industrial Exposure
The methyl, ethyl, and *n*-butyl ethers of butylene glycol considered herein are prepared by reacting the appropriate alcohol with so-called straight-chain butylene oxide, consisting of about 80% 1,2 isomer and about 20% 2,3 isomer in the presence of a catalyst. They are colorless liquids with slight, pleasant odors. The methyl and ethyl ethers are miscible with water, but the butyl ether has limited solubility. All are miscible with many organic solvents and oils; thus they are useful as mutual solvents, dispersing agents, and solvents for inks, resins, lacquers, oils, and greases. Industrial exposure may occr by any of the common routes.

C. Esters, Diesters, and Ether Esters of Glycols
C.1 Sources, Uses, and Industrial Exposure
The common esters and diesters of the polyols are prepared commercially by esterifying the particular polyol with the acid, acid anhydride, or acid chloride of choice in the presence of a catalyst. Mono- or diesters result, depending on the proportions of each reactant employed. The ether esters are prepared by esterifying the glycol ether in a similar manner. Other methods can also be used (142).

The acetic acid esters have remarkable solvent properties for oils, greases, inks, adhesives, and resins. They are widely used in lacquers, enamels, dopes, and adhesives to dissolve the plastics or resins. They are also used in lacquer, paint, and varnish removers.
C.2 Physical and Chemical Properties
All the esters and ether esters of organic acids are colorless volatile liquids. Generally the odors are mild, sometimes fruity, and they all have a bitter taste. See Tables 87.10 and 87.11 for additional properties.

C.3 Determination in the Atmosphere

The choice of methods for the determination of esters, diesters, and ether esters of various glycols vary with existing conditions. Gas chromatography would seem to offer the best means not only of resolving mixtures of vapors but also of identifying components. Mass spectrometry may also be used. Chemical methods such as proposed by Morgan (143) for esters or ether esters may be useful where spectroscopic equipment is not available.

C.4 Summary of Toxicology

Generally speaking, the fatty-acid esters of the glycols and glycol ethers, in either the liquid or vapor state, are more irritating to the mucous membranes than those of the parent glycol or glycol ethers. However, once absorbed into the body, the esters are hydrolyzed and the systemic effect is quite typical of the parent glycol or glycol ethers. Lepkovski et al. (144), in studies with higher fatty acids of glycols, concluded that the fatty acids were liberated and used nutritionally. Furthermore, they observed in rats that severe injury to the tubular epithelium of the kidneys occurred when the esters of ethylene glycol and diethylene glycol were administered, but not when equivalent amounts of fatty esters of propylene glycol, glycerol, ethyl alcohol, methyl alcohol, or the free fatty acids themselves were given. Shaffer and Critchfield (145), in studies with polyethylene glycol 400 monostearate, concluded that it was low in toxicity and also could be utilized nutritionally.

It should be noted that the nitric acid esters of glycols are highly toxic and exert a physiological action quite different from that of the parent polyols. These materials are covered in Section D of this chapter.

Table 87.12. Occupational Exposure Guidelines for Propylene Glycol Monoacrylate[a]

Regulatory or Expert Authority (Date)	Exposure Value	Comment/Notation
ACGIH (TLV) (1997)	TWA = 0.5 ppm	Skin

United Kingdom (OEL) (1993)	TWA = 0.5 ppm	Skin

[a] The OEL values set by Bulgaria, Colombia, Jordan, Korea, New Zealand, Singapore, and Vietnam are based on the ACGIH value.

D. Nitrate Esters of Ethylene and Propylene Glycols

The nitric acid esters of glycols are not typical of the esters or ether esters of organic acids and are considered separately in this chapter. They are used as explosives, usually in combination with nitroglycerin, to reduce the freezing point.

Industrial exposures of consequence are most likely to occur through the inhalation of vapors, but may also occur through contact with the eyes and skin. With the dinitrate, a serious hazard exists from absorption through the skin.

Synthetic Polymers

Bailus Walker, Jr., Ph.D., MPH, Laureen Burton, MPH

Introduction

Polymers are among the oldest chemicals known to humans. Since ancient times, natural polymers, including silk, wool, rubber, and cellulose, have been known and exploited. For a century and a half now, synthetic fibers, plastics, and modified natural polymers have been part of everyday life. The

early history of these materials is being documented, and new generations are being taught about their production and fabrication. In the United States, a number of institutions have been established to preserve and transmit knowledge of polymer technology. Natural polymers such as proteins occupy a central position in the architecture and function of living matter. Nucleic acid polymer, called deoxyribonucleic acid (DNA), automatically controls the formation of another nucleic acid, ribonucleic acid (RNA), that controls the formation of a specific protein. These natural polymers are increasingly important, especially in agriculture and medicine, and much has been written about them. They are not considered here.

Many of the general considerations discussed in the chapters on synthetic polymers in the fourth edition of *Patty's Industrial Hygiene and Toxicology* are still applicable. To update those portions that need alteration, literature since 1994 when the fourth edition was published has been searched using primarily the National Library of Medicine's Hazardous Substances Data Bank (HSDB) and ToxLine. Other sources including the polymer science literature were reviewed for useful information. However, there has been no intent to compile an exhaustive bibliography. References to the multiple dimensions of synthetic polymers are so numerous that it has been necessary to limit citations to those that are most useful to understanding and controlling the toxicological problems of polymers in the occupational environment.

The Polymer Industry

Perhaps no other aspect of the chemical industry has grown as rapidly as synthetic polymers. Each year since 1868 when cellulose nitrate was first introduced, new commercial polymers have been produced for a broad range of industrial and nonindustrial applications. Prominent examples include polyvinyl chloride which was introduced in 1927, ethyl cellulose in 1931, fluoropolymers in 1943, acrylonitrile-butadiene-styrene (ABS) in 1948, polypropylene in 1957, and polyisoprene in 1962.

In the 1970s and 1980s, engineering polymers made their mark by replacing traditional materials such as metals, rubber, automotive glass, electronics, and other materials. During the decade of the 1980s, the polymer industry's focus shifted to developing blends and alloys of existing polymers. In the 1990s, new products were rapidly developed, as manufacturers capitalized on developments in metallocene catalysis and other new chemistry. A manufacturer using metallocene catalysis transformed polystyrene—an amorphous, low melting point, relatively brittle plastic—into a tough crystalline material that has a melting point of 270°C, and employs the same styrene monomer. Medical and diagnostic containers are expected to benefit from another promising new cycloolefin copolymer, which is expected to be produced in large quantities by mid-2000. The copolymer's clarity, stiffness, and moisture and shatter resistance should make it attractive for pharmaceutical packaging, where moisture resistance is needed. It will also be useful in cut-produce packaging where the copolymer's high oxygen permeability is a desirable property.

Synthetic Polymers

Bailus Walker, Jr., Ph.D., MPH, Laureen Burton, MPH

Introduction to class of chemicals

Olefin Resins

Olefin is a class of unsaturated hydrocarbon, obtained by cracking naphtha or other petroleum fractions at high temperatures. The simplest members are ethylene, propylene, and butylene which are the starting points for certain resins.

The commercial development of polyethylene began in the 1930s and was followed by full-scale production of the major olefin resins during the 1940s and through the 1960s. Polyethylene and other olefins are closely related to paraffins. As a class, these resins have very low water absorption, moderate to high gas permeability, good toughness and flexibility at low temperatures, and relatively

low heat resistance. Environmental stress cracking is greater with polyethylene, whereas polypropylene is more susceptible to oxidation. Polyethylene cross-links on oxidation, whereas polypropylene degrades to form lower molecular weight products. Typical properties are given in Table 88.1.

Table 88.1. Physical Constants of Selected Polymers

Compound	CAS	Molecular Formula	Molecular Weight	Boiling Point (°C)	Specific Gravity	Melting Pt (°C)	Sol in Water (at 68F) mg/ml	Refractive Index (20° c)	V Pı (n
Polyethylene	[*9002-88-4*]	$(C_2H_4)_n$	28.054	—	0.92	130–145	—	1.51–1.54	
Polypropylene	[*9003-07-0*]	$(C_3H_6)_n$	42.080	—	0.89–0.94	160–171	—	1.49	
Polybutylene	[*9003-29-6*]	$(C_4H_8)_n$	56.107	—	0.87–0.95	124–135	—	—	

Toxicological Potential
Monomer residue has not been considered a problem. Ethylene, propylene, and 1-butene monomers act toxicologically as asphyxiant gases. Ethylene is a natural constituent of apples and other fruit and is used commercially to accelerate ripening of fruit. Low molecular weight additives or impurities may be of concern if significant migration of these materials into food or water is possible.

Synthetic Polymers—Olefin, Diene Elastomers, and Vinyl Halides
Bailus Walker, Jr., Ph.D., MPH, Laureen Burton, MPH

Introduction
Elastomers, also called rubber, can withstand considerably greater deformation than other materials and uniquely return essentially to their original shape even after substantial deformation. A familiar example is the behavior of a stretched rubber band after its release. All elastomers are composed of long macromolecular chains that assume a random coil conformation when undeformed (1). Deformation causes these coils to straighten out. Upon being allowed to relax, an elastomer returns essentially to its original shape because the chains reassume their random conformation.

The first elastomer identified, natural rubber, was described by Columbus as a ball that bounced. More practical early applications included primitive waterproof clothing and the rubber tires made for the carriage of Queen Victoria in 1846. Although the first specialty elastomers, polysulfides and polychloroprene, were commercialized in the 1930s, natural rubber was the major industry product until World War II, when styrene-butadiene rubber (SBR) and acrylonitrile-butadiene rubber (NBR) were established as important synthetic rubbers.

From these early beginnings, the elastomer industry grew rapidly to a global elastomer demand of 15 million metric tons in 1990 (2). The range and diversity of synthetic rubber becomes evident upon reviewing the Synthetic Rubber Manual (3) that describes both thermosetting elastomers (TSE) and thermoplastic elastomers (TPE).

TSE and TPE exhibit important similarities. The most useful properties are the result of their long molecular chains linking to one another to form a three-dimensional network. In TSE this network is linked together with essentially irreversible cross-links. Vulcanization is the process of forming these cross-links, most typically using sulfur as the cross-linking agent.

In contrast, the attachments between chains in TPE can be reversibly broken and re-formed by heating the TPE. This feature permits the direct recycling of scrap TPE by molding and other shaping processes. This is the principal difference in properties between TSE and TPE; the

irreversible sulfur links of TSE cause the polymer to break down when sufficiently heated, whereas the TPE can be reliably reprocessed.

TPEs are generally provided as pellets to rubber product manufacturers. Although additives might be incorporated into the pellets by the manufacturer (a process called compounding) of the final product, the TPE pellets are usually converted directly into products. This differs from typical practice with TSE.

TSE generally arrives at the rubber fabricators in bales. Ten or more ingredients might be added to the bale in heavy mixers before the compounded elastomer is shaped into a product and vulcanized. Schunk (4) has characterized the health hazards of many of these ingredients, including carbon blacks, mineral fillers, plasticizers, protective and cross-linking agents, and accelerators. Broadly considered, these health hazards can be considered in terms of the following:

1. monomers, solvents, and other materials used to prepare elastomers
2. storage and handling of elastomer (bales, pellets, and powder)
3. processing of elastomers, generally at high temperatures
4. finished rubber product

Health hazards in processing, and storage and handling elastomers are the dominant focus of this section; limited references will be made to the other two areas where appropriate.

Certain portions of the material refer to monomer toxicology and epidemiology because some of the monomers used in manufacturing elastomers remain at low levels in the polymer. A full discussion of the toxicity of monomers is beyond the scope of this chapter.

Table 89.1 lists some typical basic properties of certain elastomers. Properties within a given class of elastomers can vary significantly. For example, increasing acrylonitrile content in NBR reduces swelling of the NBR caused by some oils and solvents. Figure 89.1 gives comparative properties of various elastomers.

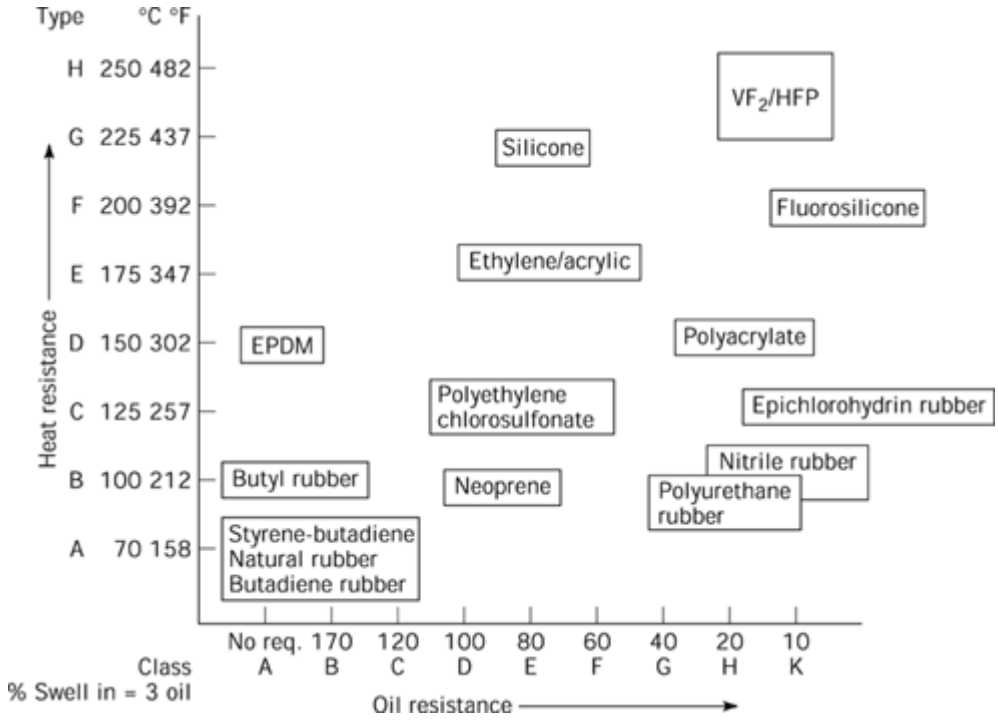

Figure 89.1. Heat and oil resistance of various elastomers (courtesy of D. H. Geschwind, DuPont Company, Inc., Polymer Products Department, Wilmington, Delaware.

Compound	CAS	Molecular Formula	Molecular Weight 68.118	Boiling Point (°C)	Specific Gravity

Most rubber is sold raw or uncured as a solid or liquid latex. The basic steps in the manufacture of some types of dry synthetic rubber are polymerization, coagulation, washing, and drying. The basic steps in producing a latex are polymerization, stabilization, and usually, concentration. A latex is defined as a stable aqueous dispersion that contains discrete polymer particles about 0.05 to 5 mm in diameter (5).

Emulsion polymerization systems contain water, monomer(s), initiator, and anionic or cationic surfactants. Solution polymerization with stereospecific catalysts involves reacting one or more monomers in an inert solvent; system conditions can be controlled to maximize a desired isomer arrangement in the polymer.

Antioxidants are generally added for shelf, processing, and in-service stability. Unsaturation of the components in the polymer chain correlates with sensitivity to oxidation. For example, among synthetic rubbers, butadiene and isoprene polymers are much more sensitive to oxidation than ethylene-propylene polymers. Natural rubber contains some natural antioxidants from rubber trees.

Vulcanization is usually done with sulfur, sulfur-containing compounds, or peroxides, but it may also be accomplished with other compounds that yield free radicals at curing temperature or by radiation. Various supplementary materials such as cure accelerators, cure retarders, or reinforcing agents are commonly part of the compounding recipe. Vulcanization ideally begins when the elastomer assumes its final shape in a mold. The elastomer type and its viscosity significantly affect molding behavior (6).

Analysis and Specifications

Measurements to determine the amounts of residual monomer have been of particular interest (7–9). Residual butadiene, acrylonitrile, and styrene can be determined in solid rubber to <1 ppm (by

weight, w/w) by headspace gas chromatography (9). Butadiene monomer in 0.1 g samples of latex can be measured by gas chromatography with a detection limit of 50 ppm (10). A gas chromatographic/mass spectrometric method to identify volatile materials released during simulated vulcanization at 160 to 200°C has been reported (11); the polymers tested were *cis*-polybutadiene, styrene-butadiene, and a blend of these two. Pyrolysis/mass spectrometry (samples <5 mg) has been used to distinguish among adhesives based on natural rubber, styrene-butadiene, and polychloroprene (12). More recent work has helped to unravel some of the complexities of ingredient–emission relationships through computerized analysis of emissions from vulcanized rubber (13).

Residual acrylonitrile in nitrile rubber reportedly varies from "nondetectable to something less than 100 ppm" (14). The concentration of chloroprene monomer is less than 1 ppm (w/w) in solid polychloroprene, but amounts as high as 5000 ppm have been reported in some latex samples (8).

Accepted practice in raw rubber manufacturing calls for quality control of the polymer within various specifications (usually +10%). Standards for these measurements are generally formulated by ASTM (15) or product-oriented organizations such as the Society of Automotive Engineers (16).

Elastomers that meet certain specifications are permitted in specific food-additive applications (17). Both natural rubber and polyisoprene are specifically identified among the elastomers permitted in rubber articles intended for repeated use. Natural rubber, natural latex, *cis*-1,4-polyisoprene, synthetic rubber, and rubber hydrochloride are specifically identified among the elastomers permitted in adhesives, sealing gaskets, paper, paperboards, and coatings. Styrene-butadiene, ethylene-propylene copolymer (and certain diene-containing terpolymers), acrylonitrile-butadiene copolymer, and chloroprene polymers are similarly permitted in specific applications. The components permitted in rubber articles intended for repeated use also include vinylidene fluoride-hexafluoropropylene copolymer that has a minimum number-average molecular weight of 70,000 and tetrafluoroethylene terpolymer that has a minimum number-average molecular weight of 100,000. Chlorosulfonated polyethylene is also permitted in certain food-contact or drinking water applications; specifications require that the chlorine content and the sulfur content not exceed 25 and 1.15% by weight, respectively, and that the molecular weight is in the range of 95,000 to 125,000. Permissible direct additive applications include the use of natural rubber, styrene-butadiene, and butyl rubber as masticatory substances in chewing gum base.

Reviews of analytical methods useful in assessing health and safety aspects of rubber processing and handling have been published biennially (18–21). These methods focus on many modern analytic techniques.

Toxicological Potential

Dry solid polymers usually contain less residual monomer (or solvent) than latex materials. The processing necessary to produce the dry product drives the residual monomer or solvent out of the resin, usually by heat.

Several reports address worker health problems in the rubber fabrication industry. For example, one study (22) suggests an association between the mortality risk of lung cancer and employment in operations involving reclaim, chemicals, and special products. Another study (23) showed that processing workers had increased mortality from leukemia, emphysema, and cancers of the stomach, large intestine, biliary passages, and liver. Other findings (24) demonstrated that men who were employed for at least 10 years experienced small increases in deaths from cancers of the large intestine, pancreas, and lung. Studies of cancer mortality in the British rubber industry found (25) an absence of any excess mortality from bladder cancer among men who entered the industry after January 1, 1951, possibly the result of removing putative bladder carcinogens from production processes in July 1949.

Industrial dermatitis from finished rubber products due to the various chemicals added during polymerization, curing, and processing is not uncommon (26–30). Mercaptobenzothiazole,

tetramethylthiuram disulfide, *N*-isopropyl-*N*'-*p*-phenylenediamine (IPPD), and related compounds are the most common offenders.

Elastomers degraded at high temperatures around 800°C can yield more toxic products than elastomers degraded at smoldering temperatures or gradually rising temperatures. This is to be especially so with nitrile-butadiene.

Workplace Practice and Standards

At ambient temperatures, the main concern with vulcanized polymer is possible effects from inhalation of dust generated in grinding operations and dermatitis in "rubber-sensitive" individuals. Operations that may generate dust should, as a minimum, be controlled within recommended limits for nuisance dusts (31). Dermatitis can usually be controlled only by avoiding either the specific materials that provoked the reaction or "rubber" in general. In some cases, avoiding occluded contact with the skin may eliminate dermatitis (32).

Depending on the particular polymer and type, unvulcanized rubber may require special handling because of the residual monomer or solvent content. Uncured chlorosulfonated polyethylene or other elastomers similarly prepared by dissolving an existing polymer generally contain residual solvent. Monitoring carbon tetrachloride from chlorosulfonated polyethylene, is desirable if bulk polymer is stored in warehouses with limited ventilation or if ventilation in the processing area is questionable. Ventilation adequate to protect against diffusion of the residual carbon tetrachloride should be adequate for any other vapors that may develop during normal curing operations.

Ammonia is added to NR (polyisoprene) latex to preserve it (33), and it may be released during processing. Handling of latex requires consideration of the toxic potential of the monomer(s), cosolvents, other ingredients, and also of the particular operation(s) involved to determine if monitoring the working environment is indicated. Standard operating procedures should include provisions for appropriate personal protective equipment and monitoring to ensure that exposures are well controlled where gross exposure is unavoidable, as in tank entry.

Polyvinyl alcohol	[*9002-89-5*]	Rats	ig	50g/kg	30 single doses	Minimal changes in liver and myocardial cells
Polyacrylonitrile	[*25014-41-9*]	Rat	ig	0.25 to 0.5	Daily doses for 6 months	Reversible changes in liver, kidney and thyroid
		Rats	ig	4.0		
Polyacrylamide	[*9003-05-8*]	Rats/dogs	ig	MTD[a]	Repeated oral administration for 2 years	No effect

[a] MTD = Maximum tolerated dose.

Synthetic Polymers—Olefin, Diene Elastomers, and Vinyl Halides
Bailus Walker, Jr., Ph.D., MPH, Laureen Burton, MPH

B. Vinyl Halides

The commercial polymers in this group contain chlorine atoms, fluorine atoms, or both in a few cases. In very diverse ways these halogens can be used to produce vinyl polymers that have such characteristics as increased resistance to water, oils, and solvents, plus other distinctive properties. The prototypes are polyvinyl chloride and polyvinylidene chloride. Polyvinyl chloride and its copolymers rank first in production/consumption volume among polymers in the United States and abroad. Their key attribute is low-cost versatility. Polyvinylidene chloride resins have an extremely regular, closely packed molecular structure that results in outstanding impermeability to water, oils, and gases (87, 88).

Polyvinyl Acetate, Alcohol, and Derivatives, Polystyrene, and Acrylics

Bailus Walker, Jr., Ph.D., MPH, , and Laureen Burton, MPH

A. A Polyvinyl Acetate, Alcohol and Derivative Polymers

Polyvinyl acetate, the most widely used vinyl ester, is noted for its adhesion to substrates and high cold flow. Polyvinyl acetate serves as the precursor for polyvinyl alcohol and, directly or indirectly, the polyvinyl acetals. Both polyvinyl acetate and polyvinyl alcohol are insoluble in many organic solvents but water sensitive. Polyvinyl acetate absorbs from 1 to 3% water, up to 8% on prolonged immersion (1). Polyvinyl alcohol absorbs 6–9% water when humidity conditioned and can usually be dissolved completely in water above 90°C, but it can also be insolubilized by chemical treatment. Table 90.1 gives data on properties for typical polymers.

Table 90.1. Physical Properties of Selected Polymers

Compound	CAS	Molecular Formula	Molecular Weight	Boiling Point (°C)	Specific Gravity	Melting Point (°C)
Polyvinyl acetate	[*9003-20-7*]	$(C_4H_6O_2)_n$	86,090	—	1.18	35
Polyvinyl acetate-butyl acrylate	[*25067-01-0*]	—	—	—	—	—
Polyvinyl acetate-1-ethylhexyl acrylate	[*25067-02-1*]	—	—	—	—	—
Polyvinyl acetate-ethylene	[*24937-78-8*] —	—	—	—	—	—
Polyvinyl alcohol	[*9002-89-5*]	$(C_2H_3OH)_n$	37,000–185053	—	1.3	228
Polystyrene	[*9003-53-6*]	$(C_8H_8)_n$	104.15	—	1.05	240
Polyacrylo-nitrile	[*25014-41-9*]	$(C_2H_3CN)_n$	100,000–150,000	—	1.07–1.53	317–340
Styrene-Acrylonitrile	[*9003-54-7*]	$(C_8H_8–C_3H_5N)_n$	100,000–400,000	—	1.06–1.08	—
Acrylonitrile	[*9003-56-9*]	—	60,000–200,000	—	1.02–1.07	—

Butadiene Styrene

Production and Processing

U.S. manufacturers currently sell polyvinyl acetate in emulsion form and polyvinyl alcohol as granules. Polyvinyl alcohol is processed into films and formulated with other materials into emulsion intermediates. Both polymers are typically used in aqueous systems.

Both polyvinyl acetate and polyvinyl alcohol meeting certain specifications are permitted in stated food contact applications such as packaging, coatings, and adhesives. Ethylene–vinyl acetate copolymers and ethylene–vinyl acetate–vinyl alcohol terpolymers [CAS # [*26221-27-2*] are similarly permitted in certain food contact applications. Polyvinyl acetate with a minimum molecular weight of 2000 is permitted as a synthetic masticatory substance in chewing gum base (2).

Toxicologic Potential

Monomer residue has not been considered a problem in end-use products. Latexes or solutions of polyvinyl acetate that are essentially intermediates may contain residual vinyl acetate, essential emulsifiers, or initiators (3). No detailed information is available on the amount of unreacted monomer in either polyvinyl acetate or polyvinyl alcohol resins (3).

Local sarcomas have been produced in rats with polyvinyl alcohol sponges, but implants of both polyvinyl alcohol and polyvinyl acetate in powder form did not produce tumors. IARC considered that additional studies would be required prior to evaluation of carcinogenic potential (3).

Inhalation and combustion toxicity have not been considered problems. This may be attributed to polymer structure and degradation characteristics as well as the nature of ordinary intermediate and end-use products.

Work Practices

With products formulated as solutions or emulsions, the potential for inhalation toxicity or skin reactions from residual monomer or additives may in some cases require evaluation. Recommended industrial hygiene procedures for dealing with nuisance dusts should provide adequate control for any dust hazards from solid forms of polymer. Spillage of these polymers can produce slipping hazards; spills should be cleaned up immediately to prevent falls.

Polyvinyl Acetate, Alcohol, and Derivatives, Polystyrene, and Acrylics
Bailus Walker, Jr., Ph.D., MPH, , and Laureen Burton, MPH

B. Polystyrene and Acrylics Polymers

Since the 1700s when Newman first isolated styrene by stream distillation from liquid ambar, a solid resin obtained directly from a family of trees native to the Far East and California, a substantial industry has developed for styrene-based products. Today, "styrene-based" plastics most commonly are polystyrene, successfully commercialized in 1938, plus the derivatives containing butadiene, acrylonitrile, or both. The derivatives containing acrylonitrile are also called "acrylonitrile polymers" or "nitrile polymers." Polystyrene is made in three different forms: crystal, impact, and expandable. Producers generally refer to the polystyrene market as including only crystal and impact grade. Expandable polystyrene—a foam product, with primary markets in construction and packaging—is a separate specialty product.

Structurally the acrylic polymers include those containing repeating units of acrylonitrile, acrylic acid, acrylates, methacrylates, and all the various derivatives. "Acrylic plastics" may imply only polymers of acrylic or methacrylic acid ester (29), among which the prototype is polymethyl methacrylate. The demand for sheet polymethyl methacrylate dates from World War II, when it was used for aircraft glazing (5).

Polyacrylonitrile is used primarily as fibers, commonly called "acrylic,"that have been formulated with varying amounts of comonomer. Processing may involve blending with other fibers. Dyeing may be done with either the yarn or woven fabric. "Polymeric acrylontrile" is a powder that can be hydrolyzed to form water-soluble polyacrylamides or cast as plastic or film from solvent.

The main copolymer types derived from both styrene and acrylonitrile are (*1*) styrene–acrylonitrile (SAN) copolymer resin and (*2*) acrylonitrile–butadiene–styrene (ABS), in which discrete butandiene particles are dispersed in a SAN copolymer matrix and then sold as pellets or powder. Temperatures described for ABS processing are in the 190–275°C range (30).

Acrylate and methacrylate esters are generally available from the manufacturer in granules or powder. Dyes, pigments, plasticizers, or ultraviolet absorbers may be added during processing. Commercial processing of polymethyl methacrylate per se uses three intermediate types of approach: the melt state for injection molding and extrusion; sheets, rods, and tubes that are mechined or welded; and monomer–polymer dough, primarily for dentures (5).

13.0 Ethyl Acrylate Polymer

13.0.1 CAS Number: [*900-32-1*]

The limited information in the literature focuses primarily on properties of the monomer, ethyl acrylate, described as a colorless liquid widely used in the production of polymers and copolymers. These polymers are for manufacturing textiles, latex paints, paper coatings, and specialty plastics. The monomer is an irritant of the skin, eyes, respiratory tract, and mucus membrane, and it is carcinogenic in experimental animals. The 2000 ACGIH threshold limit value (TLV) is 5 ppm, with a short-term exposure limit of 15 ppm (86).

Synthetic Polymers—Cellulosics, Other Polysaccharides, Polyamides, and Polyimides

Finis L. Cavender, Ph.D., DABT, CIH

Introduction

Natural polymers are biological macromolecules and are as old as life itself. The natural polymers include such diverse materials as proteins, polypeptides, polysaccharides, DNA, wood, wool, and silk. The word *polymer* is derived from the Greek words *poly*, or many, and *meros*, or parts. This chapter will focus on cellulose and it derivatives, polyamides such as nylon, and polyimides.

Synthetic Polymers—Cellulosics, Other Polysaccharides, Polyamides, and Polyimides
Finis L. Cavender, Ph.D., DABT, CIH

A. Cellulosics

"Cellulose plastics are produced by the chemical modification of cellulose. Raw cellulose is not a thermoplastic: it does not melt. Cellulose is a substance that forms the cell walls of many trees and plants. Raw cellulose can be made into a fiber or film, but it must be chemically modified to produce a thermoplastic" (1).

1.0 Cellulose

1.0.1 CAS Number: [*9004-34-6*]

1.0.2 Synonyms: Regenerated cellulose, rayon, cellophane, and cellulose, microcrystalline

1.1 Chemical and Physical Properties

1.1.1 General Cellulose is a white substance that is practically insoluble in water and other solvents. It can be dissolved in zinc chloride, ammoniacal copper hydroxide, or caustic alkali with carbon disulfide (2). The specific properties of the many types of rayon vary widely (3). Rayon is readily blended with other fibers. Rayon can contribute pleasing texture and touch quality, moisture absorbency, or strength. Cellophane is noted for clarity, crisp hand, and dimensional stability. Coatings of nitrocellulose or saran reduce moisture and oxygen permeability; polyethylene or ionomer coatings reduce heat loss. Both rayon and cellophane can be highly flammable (4). See Tables 91.1–91.3.

Table 91.1. Limiting Oxygen Indices and Ignition Temperatures for Various Polymers[a]

		Ignition Temperature (°C)	
Polymer	**Range of Limiting Oxygen Indices[b]**	**Flash Ignition**	**Self-Ignition**
Wood	22.4–25.4	228–264 (white pine shavings)	260
Cotton	18.6–27.3	230–266	254
Cayon	18.7–19.7		
Cellulose acetate	16.8–27	305	475
Cellulose nitrate		141	141
Wool	23.8–25.0		
Nylon 66 fabric	20–21.5		
Nylon 6 fabric	20–21.5		
Polyethylene terephthalate fabric	20–21		

[a] Summarized from Ref. 4. Additional ignition temperatures are summarized in Table 91.2.

[b] The limiting oxygen index can also be expressed in terms of the volume of oxygen in the atmosphere, where *n* is a decimal.

Synthetic Polymers—Cellulosics, Other Polysaccharides, Polyamides, and Polyimides

B. Polyamides and Polyimides

The synthetic polyamides and polyimides are all step-growth or condensation polymers. As a group, they are considered performance polymers, whereas the chain growth or addition polymers include the typical commodity polymers of polyethylene, polyvinyl chloride, and polystyrene as well as the high-performance fluoropolymers. Polyamides are linked with the word nylon, the first major synthetic polyamide. Nylon was developed as a fiber in the 1930s and as a plastic in the 1940s. Polyamide polymers also include protein fibers such as wool and silk that have been commercially important for several millenia (4). These natural protein fibers are not discussed in this section.

Nylon is a generic term for a synthetic aliphatic polyamide of well-defined structure and certain typical properties either as a fiber (62) or as a plastic (63) The name system reflects the chemical structure and preparation. Nylons 66, 610, and 612 are all prepared from a six-carbon diamine and a 6-, 10-, or 12-carbon dibasic acid, respectively. [The names can also be written in the style nylon 6/6, nylon 6.6, or nylon 6,6 to reflect the two-monomer origin; the simpler style of nylon 66—always "six six," or "six ten" for nylon 610—is usually preferred (28).] Nylons 6, 11, and 12 are prepared from an amino acid or derivative thereof with 6, 11, or 12 carbons, respectively. Nylon 66 was developed in the United States and nylon 6 was developed abroad (37), but both are now found worldwide. As a group, the nylons are tough, strong, abrasion resistant, and resistant to alkalies, hydrocarbons, ketones, and esters (63, 64).

Aromatic polyamides such as Nomex were formerly called nylon (65), but aramid is now the official generic classification of the U.S. Federal Trade Commission and the International Standards Organization. Aramid denotes a long-chain synthetic polyamide fiber in which at least 85% of the amide linkages are attached directly to two aromatic rings, whereas nylon now indicates that less than 85% of the amide linkages are so attached (66). Aromatic polyamide fibers typically have many desirable properties of nylon fibers plus improved heat resistance and strength (67).

Polyimides are a completely synthetic class of polymers developed as a variation on polyamides to provide increased resistance to high temperature (68). Aromatic polyimides have exceptional heat resistance. Conventional tensile strength has been measured up to 500°C (69). Thermoplastic varieties, or those that become rubbery rather than melt at the glass-transition temperature of approximately 310°C (70), retain high strength at almost 300°C. Table 91.5 summarizes some typical physical properties. Figure 91.1 compares the performance of selected aramid and nylon fibers with other types in a standardized test.

Synthetic Polymers, Polyesters, Polyethers, and Related Polymers
Steven T. Cragg, Ph.D., DABT

1 Overview

Commercial use of polyester resins dates from the early twentieth century, when alkyd resins were first used in surface coatings (1). The polyesters are found today as fibers, films, laminating resins, molding resins, and engineering plastics. The high-molecular-weight polyethers are known primarily as engineering plastics (an exception is high-molecular-weight polyoxyethylene, a water-soluble packaging polymer), as are the polysulfides and the polysulfones. Table 92.1 gives some basic properties.

Table 92.1. Selected Properties of Some Polyesters, Polyethers, and Related Polymers[a]

A. Polyesters			
Property	**Polyethylene Terephthalate**	**Polybutylene Terephthalate**	**Polycarbonate of Bisphenol A**

Melting temperature (°C)	254–284; 256 (commercial PET); 271 (highly crystalline PET)	221–232	215–230
Glass-transition temperature (°C)	69. 67, amorphous; 81, crystalline; 125, crystalline and oriented	17–80; 22–43; unfilled, 50	145–149
Service temperature (° C)	–60 to +150	Can be used for prolonged periods of time at 120–140°C. Embrittlement by hydrolysis on long-term aging at 60–85° C under humid conditions	135 maximum
Density	1.33 (amorphous) 1.45 (crystalline)	1.31–1.32	1.20
Refractive index, n_D	Film: amorphous, 1.5760; crystalline and biaxially oriented, 1.64		1.585
Moisture absorption 0.8%, immersion	0.55%, 24-h immersion of commercial films; 0.8%, immersion in water at 25°C for 1 wk	0.08%, 24-h immersion at 23°C	0.2% in air at 60% relative humidity
Moisture regain (fiber)	0.4%, commercial value and normal conditions		
Solvents	Crystalline: choralhydrate, phenol, phenol tetrachloroethane, (1:1 vol.), nitrobenzene, DMSO (hot)	“Complex phenols” such as *o*-chlorophenol	Methylene chloride and chloroform; less soluble in tetrachloroethane, trichloroethylene, dichloroethane, tetrahydrofuran, dioxane, cyclohexanone, dimethylformamide. Swells in benzene, chlorobenzene, acetone, ethyl acetate, carbon tetrachloride
Nonsolvents/relatively unaffected by	Crystalline: hydrocarbons, chlorinated hydrocarbons, aliphatic alcohols,	Very resistant to most chemicals	Hydrocarbons, styrene, carbon tetrachloride, acetone, lower esters.

	ketones, carboxylic esters, ethers.		
Decomposes	Strong acids and bases, particularly when hot. Hydrolyzes slowly in water at elevated temperature (fibers with ~20% loss in strength after 1 week at 100°C, without measurable loss in strength after several weeks at 70°C		Hot alcoholic alkalies, amines, and other organic bases; surface attack by aqueous alkali. Hydrolyzes in water >600°C (can withstand relatively short exposures)

B. Polyethers

Property	**Polyoxymethylene**	**Polyoxyethylene**	**Polyphenylene Oxide**
Melting point (°C)	175–200		298 (as poly-*p*-phenylene oxide); 261–272 [as poly (2,6-dimethyl-*p*-phenylene oxide]
Glass-transition temperature			105–120 (phenylene oxide-based resin)
Density	1.40–1.42 for molded parts, range to 1.56 for special grades of resin		1.314 (as poly-2,6-dimethyl-*p*-phenylene oxide); 1.408 (as poly-*p*-phenylene oxide)
Refractive index, n_D	1.489–1.553	1.51–1.54	
Water absorption, 24 h (%)	0.02–0.3		0.006
Solvents	At elevated, temperature; benzyl alcohol, phenol, chlorophenols, aniline, formamide, DMF, *y*-butyrolactone, bromobenzene, diphenylether	Benzene, chloroform, carbon tetrachloride, alcohols, cyclohexanone esters, DMF, water (cold), aqueous, K_2SO_4 (0.45 *M* above 35°C); (swells in dioxane).	Poly(oxy-2,6-dimethyl-1,4-phenylene)[b] amorphous, a-pinine (hot); crystalline, benzene, toluene, chloroform chlorobenzene poly(oxy-1,3-phenylene)[c] benzene, biphenyl, 3-pentanol, phenyl ether, pyridine, benzophenone, nitrobenzene,

			DMF, DMSO
Nonsolvents/relatively unaffected by	Aliphatic hydrocarbons, lower alcohols, diethyl ether, lower esters	Aliphatic hydrocarbons, ethers, water (hot)	poly(oxy-2,6-dimethyl-1,4-phenylene).[d] Amorphous, a-pinene (cold), methanol, ethanol; crystalline, a-pinene (hot), methanol, ethanol, nitromethane poly (oxy-1,3-phenylene).[b] methanol
Decomposes	Alkalies with pH > 9; acids with pH < 1 (extended contact)		

C. Polyphenylene Sulfide and Polysulfones

Property	**Polyphenylene Sulfide**	**Polysulfone of Bisphenol A**	**Polyethersulfone 200P**
Melting point (°C)	~285–295		
Glass-transition temperature (°C)	97	~190	230 (other polysulfones ranging to 315)
Density	1.440; 1.34, unfilled; 1.64, 40% glass	1.24	
Refractive index, n_D		1.633	
Water absorption	0.02, unfilled; 0.01, 40% glass		
Solvents	Biphenyl, dimethyl-*p*-terphenyl, chloronaphthalene, some other solvents at elevated temperature	Chlorinated hydrocarbons, dimethylformamide, *N*-methylpyrrolidone; swells in dimethyl sulfoxide	
Nonsolvents/relatively unaffected by	At reflux temperature:toluene, pyridine, phenyl oxide, phenyl sulfide	Inorganic acids, alkalies, aliphatic alcohols	
Decomposes		Concentrated sulfuric acid (dissolves with degradation)	

[a] From Ref. 2a

[b] "Phenylene-oxide based resin" may soften or dissolve in certain halogenated or aromatic

hydrocarbons. If an application requires such exposure, stressed samples should be tested under operating conditions (10).

1.1 Production and Processing

Production data for the general categories are listed in Table 92.2. Processing techniques vary widely and are discussed in the appropriate subsection.

Table 92.2. Production of Certain Synthetic and Natural Polymers

	Dry Weight Basis	
Polymer	**1000 lb**	**1000 kg**
A. U.S. Production of Plastics, Resins, and Elastomers (1990)		
Thermoplastic resins[a]		
Low-density polyethylene	7,254,891	3,291,693
Linear low-density polyethylene	3,893,252	1,766,448
High-density polyethylene	8,339,360	3,783,739
Polypropylene	8,310,409	3,770,603
Acrylonitrile–butadiene–styrene (ABS)	1,161,855	527,157
Styrene–acrylonitrile (SAN)	135,173	61,331
Polystyrene	5,021,090	2,278,172
All other styrene-based resin	1,189,204	539,566
Nylon	558,307	253,315
Polyvinyl chloride	9,095,534	4,126,830
Polyvinyl acetate	987,190	447,908
Other vinyl/vinylidene resins[c]	211,560	95,989
Thermoplastic polyester[d]	1,878,629	852,373
Engineering resins[e]	1,382,806	627,407
Acrylic[b]	1,507,031	683,771
Other thermoplastic resins	781,856	354,744
Total thermoplastic resins	51,708,147	23,461,046
Thermosetting resins[a]		
Epoxy	499,321	226,552
Polyester (unsaturated)	1,221,160	554,065
Urea–formaldehyde	1,495,531	678,553
Melamine–formaldehyde	201,986	91,645
Phenolic and other tar acid resins[f]	2,946,276	1,336,786
Polyurethane[g]	2,951,818	1,339,300
Alkyd[b]	769,238	349,019
Furfuryl type resins[b]	14,035	6,368
All other thermosetting resins[b]	152,488	69,187
Total thermosetting resins	10,251,853	4,651,475

Synthetic elastomers[h] (include latex)	Metric tons
Styrene–butadiene	852,851
Polybutadiene	403,388
Nitrile	562,261
Ethylene–propylene	255,537
Other synthetic elastomers (includes polychloroprene, polyisoprene, and butyl rubber but excludes polyurethane rubber)	
Total	2,620,535

B. World Production of Certain Textile Fibers (1990)[i]

	1000 Metric tons
Natural fibers	
Raw cotton	18,714
Raw wool	1,964
Raw silk	66
Total	20,744
Percent of world total = 54	
Man-made fibers except olefin and textile glass	
Rayon and acetate	2,846
Acrylic and modacrylic	2,326
Nylon and aramid	3,765
Polyester	8,621
Certain other noncellulosic fibers	157
Total	17,715
Percent of world total = 46	

[a] Adapted from data in Society of the Plastics Industry, "Monthly Statistical Report—Resins, Full Year 1990, Production and Sales & Captive Use of Thermosetting & Thermoplastic Resins" issued by the SPI Committee on Resin Statistics as compiled by Ernst & Young; other data reported in SPI *Facts and Figures of the U.S. Plastics Industry*, 1991 Edition; and data in *Synthetic Organic Chemicals*, USITC Publ. 2470, U.S. International Trade Commission, Washington, DC, 1991. SPI data are used where available. Data reported to the USITC do not necessarily coincide with those reported to the SPI because of differences in both the reporting instructions and the coverage of certain resins.

[c] Includes only polyvinyl butyral, polyvinyl formal, and polyvinylidene.

[d] Does not include polyester for film and tape.

[e] Engineering resins include acetal, granular fluoropolymers, polyamide-imide, polycarbonate, modified polyphenylene oxide, polyphenylene sulfide, polysulfone, polyether imide, and liquid crystal polymers, (ABS and nylon resins are listed separately.)

[b] As reported in *Synthetic Organic Chemicals*, USITC Publication 2470, December 1991.

[f] Material is reported on a "gross weight" or "as sold" basis including the weight of water and other liquid diluents.

[g] Polyurethanes are derived from starting materials isocyanates (TDI/MDI) and polyols (polyether polyester). Raw materials reported to the SPI sold in the United States for conversion into polyurethanes provide the basis for these data.

[h] The term *elastomers* may be defined as substances in bale, crumb, powder, latex, and other crude forms that can be vulcanized or similarly processed into materials that can be stretched at 68°F to at least twice their original length and, after having been stretched and the stress removed, return with force to approximately their original length (*Synthetic Organic Chemicals*, USITC Publ. 2470, U.S. International Trade Commission, Washington, DC, 1991).

Production figures are based on the *RMA Industry Rubber Report*, December 1990, and are reprinted by permission of the Rubber Manufacturers Association, Washington, DC.

[i] As listed in *Fiber Organon*, 62(6), June 1991. Data are reprinted by permission of the Fiber Economics Bureau, Inc., Roseland, NJ. "The silk and man-made fiber data are on a calendar-year basis, while the figures for cotton and wool are on a seasonal basis."

1.2 Specifications and Test Methods

Clearance for certain food contact applications with many of these materials has been obtained under Title 21 of the Code of Federal Regulations (2). Those specifically listed include polyethylene terephthalate, polybutylene terephthalate, polycarbonate, polyoxymethylene, polyoxyethylene derivatives, polyphenylene sulfide, and polysulfone. Specifications concerning mechanical and other types of performance depend on end use.

1.3 Toxicologic Potential

Industrial hygiene concerns with these polymers depend on the type of resin in use. Chemicals released in significant quantities may include (*1*) styrene during the fabrication of unsaturated polyester resins and in any subsequent release of styrene, (*2*) other volatile products generated at elevated temperatures or in fires, and (*3*) dust or particulate generated in the manufacturing and processing of polyester fibers. The use of styrene in polyester resins that are fabricated into glass-reinforced plastics can provide the greatest intensity of exposure to styrene in workplace situations (3–5). Toxic vapors can also be released by solvent systems, particularly at elevated temperatures, and during fabrication of engineering resins. For example, the processing of polyoxymethylene (acetals) in a poorly ventilated space may release biologically significant amounts of formaldehyde into the adjacent atmosphere.

Sulfur-containing engineering resins typically have a high resistance to thermal deterioration but may yield hydrogen sulfide or sulfur dioxide if heated to decomposition temperatures.

Inhalation tests in rats indicate no particular hazard to humans from particles of commercial polyester fiber but suggest that sufficient inhalation of cyclic ethylene terephthalate trimer dust may produce a granulomatous tissue response. Both types of particles produced a nonspecific inflammatory tissue response when first introduced into the lungs (6). This initial response was transitory and was not followed by collagen formation or any development of fibrosis. However, small particles of crystalline cyclic ethylene terephthalate trimer dust produced more prominent foreign body giant cell reactions than small polyester fiber particles. The latter, formed during high-speed processing by abrasive fracture of the surface of commercial fiber, produced a modest response consisting mostly of macrophages; the large nonrespirable particles produced artifactual foreign body granulomas.

1.4 Synthetic Fibers and Human Responses

Prior to 1950, "textile dust" was essentially the dust of cotton and other natural fibers. Harmful health effects were particularly identified with the inhalation of the dusts of raw cotton, flax, and hemp in the workplace. Today, the production and use of synthetic fibers is comparable to that of natural fibers (Table 92.2). No conclusive evidence links the manufacturing or processing of synthetic fibers with any serious health effects.

Except for cotton and other byssinogenic dusts, relatively few epidemiologic studies that involve exposure to organic fibers have been conducted. Three studies that consider exposure to polyacrylonitrile fiber, rayon, or an unidentified synthetic fiber, respectively, do so in the context of a comparison to cotton. Valic and Zuskin (7) report a mild reduction of ventilatory capacity in 1975 Yugoslav textile workers exposed to polyacrylonitrile fibers, including 30 with previous exposure to cotton and 77 with previous exposure to hemp; however, this response did not appear to be dose related. Tiller and Schilling (8) found an insignificant change in ventilatory capacity (less than 1%) among 26 English rayon workers, 13 of whom had been previously exposed to cotton. Another British report (9) describes a decreased prevalence of bronchitis among workers in two spinning mills using "man-made" fiber compared to workers in 14 cotton mills.

Several clinical reports record the symptoms or test results of affected textile workers but do little to

clarify the origin of these observations. The significance of these reports outside the immediate environment is difficult to determine and quite likely limited. Pimentel et al. (10) describe seven patients in Portugal with a history of exposure to various textiles during the manufacturing process. The seven patients were variously affected with asthma, extrinsic allergic alveolitis, chronic bronchitis with bronchiectasis, spontaneous pneumothorax, or pneumonia. All had worked with one or more synthetic fibers; five had also worked with wool and/or cotton. The terminal patient identified as Case 3 had been exposed to the dust of "wool, cotton, synthetic fibers" over approximately a quarter-century and had apparently continued work with fibers for some 3 years after a hospital admission for progressive breathlessness upon exertion 8 years earlier. Many fibers were found in fibrotic tissue and some were identified as polyester. However, the mere presence of particles in the respiratory tract cannot be considered pathological. Each day, the average person inhales some 20,000 L of air laden with particles, many of which are deposited on the alveolar surface (11).

Bouhuys (12) points out that this report of case histories (13) suffers from lack of control biopsy samples, specific exposure data, and information on the nature and size of the populations at risk. A later report by Pimentel et al. (14) describes two patients with unusual "sarcoid-like granulomas" of the skin that the authors attributed to acrylic or nylon fibers, respectively; one of the patients also had respiratory tract lesions that were considered similar to those described in the first report. Unfortunately, this second report does not remedy the deficiencies of the first report.

Two Finnish investigators (13) cite the first Pimentel et al. study and also fail to give exposure data when reporting the results of several inhalation challenge tests in textile workers. Neither group provides specific evidence to support its implication of an immunogenic phenomenon.

These clinical reports pay little or no attention to the dimensional characteristics of the inhaled fibers as distinct from the chemical nature of the polymer in question. Both size and shape are important factors in biologic responses to durable fibers—particularly carcinogenicity (see Section 1.4). Work with fibrous glass indicates that short fibers (<8 mm long) have negligible carcinogenic potential, but fine-diameter fibers (<1.5 mm) that are long (>8 mm) appear to increase in carcinogenic potential as their length increases (15) The synthetic organic fibers used in textiles are generally larger in diameter than this apparently critical 1.5-mm diameter (16).

1.5 Workplace Practices and Standards

No specific standards are known that pertain to ordinary industrial use of the finished polymeric products. Fabrication of the raw polymers or use of the prepolymers may release volatile materials and require appropriate industrial hygiene measures. Possible fire hazards should be considered when large amounts of these polymers are present in a given area, particularly with prepolymers of unsaturated polyester that contain appreciable amounts of flammable solvent or styrene.

In general, exposure to particles of polymeric fibers should be minimized by appropriate industrial hygiene measures for the control of exposure to insoluble organic dust. Particles of fiber dust should not be considered harmless but rather as particles that can—like particles of any dust—have biologically significant consequences if inhaled in gross concentrations. The presence of oligomers or other impurities may require evaluation in specific workplace situations.

The Textile Research Institute has provided a current review (16) on methods for collecting and measuring the particle sizes of respirable dust with special emphasis on dusts of importance to the fiber and textile industries.

1.6 Fire and Toxicity of Smoke

These polymers generally are not used in materials of construction, interior finish, or furnishings. They have had little or no study with respect to their smoke toxicity upon burning.

Synthetic Polymers, Polyesters, Polyethers, and Related Polymers
Steven T. Cragg, Ph.D., DABT

2 Linear Terephthalate Polyesters
All high-molecular-weight polyester polymers of commercial significance as fibers or films are derived from dimethyl terephthalate (or terephthalic acid). The basic structure is polyethylene terephthalate or its copolymers. Poly-1,4-cyclohexylenedimethylene terephthalate has also been used, but to a much more limited extent.

Polybutylene terephthalate is known as an engineering resin. The two fiber-forming terephthalates can also be adapted for this purpose as homopolymers or copolymers (1).
2.0 Polyethylene Terephthalate and Polyester Fibers
2.0.1 CAS Number: [*25038-59-9*]

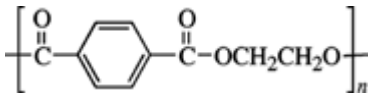
2.0.2 Synonyms: NA

2.0.3 Trade Names: NA

2.0.4 Molecular Weight The molecular weight of commercial polymers has been given as 15,000–20,000 M_n and 20,000–30,000 M_w (24). Farrow and Hill (25) describe M_n in the range of 10,000–50,000, the latter figure representing fibers used particularly for industrial applications.

2.0.5 Molecular Formula: NA

2.0.6 Molecular Structure:



2.2 Production and Use
2.2.1 Structure, Synthesis, and Processing of Polyester Fiber As noted above, the basic structure in most polyester fiber is polyethylene terephthalate.

The structure of the end groups has been described as mainly hydroxyethyl ester with a small number of carboxyl end groups (17). The Federal Trade Commission defines a polyester fiber as “a manufactured fiber in which the fiber-forming substance is any long chain synthetic polymer composed of at least 85 percent by weight of an ester of a dihydric alcohol and terephthalic acid” (18).

Most polyester fiber is composed primarily of a polyethylene terephthalate. Other fibers are derived from polycyclohexylenedimethylene terephthalate (17). Other variations include terephthalate-substituted isophthalate copolymers that provide enhanced dyeability (19, 20).

Polymerization has two basic steps (1, 17, 19): (*1*) reaction of ethylene glycol with terephthalic acid (esterification) or dimethyl terephthalate (alcoholysis) to produce oligomeric hydroxyethyl terephthalate, ranging from dimer to pentamer; (*2*) polycondensation of this oligomeric mixture to the desired molecular weight and removal of the excess glycol and by-products.

Commercial polyester fibers are prepared by melt spinning. The extruded melt is forced into filamentary streams that are formed into spun filaments and then drawn to fibers, either in a separate drawing step or in combination with spinning (19).

Two impurities are “normally” present in polyester fibers (17). Ethylene glycol used in the synthesis

may be converted to diethylene glycol, and the corresponding ether group may be present to a slight degree (1–3 mol%) in the polyester. Cyclic trimer is present to the extent of <1.5% in the polymer or in the fiber derived from it. Part of this trimer may be removed during dyeing or reprecipitate on the fiber.

"Snow" deposits that can develop on the surfaces of high-speed friction twist texturing machines (21) are aggregates of irregular polymeric particles ("skin" particles that describe the outermost layer of the individual fibers) rather loosely held together by finish oils. Analyses of these deposits average approximately half polymer, half finish. Generally the polymeric particles have the melting point and molecular weight characteristics of polyethylene terephthalate and should not be confused with cyclic trimer. "Snow" appears to be the result of local yarn heating caused by friction. Optimal control of yarn and process variables can reduce the level of snow generation.

2.2.2 Structure and Processing of Film The basic structure in most of these films is again polyethylene terephthalate. Polycyclohexylenedimethylene terephthalate can also be used (22, 23). These films can be prepared by quenching (solidifying) extruded polymer to the amorphous state and then reheating and stretching the sheet approximately threefold in each direction at 80–100°C. Orienting the film and then annealing it under restraint at 180–210°C can raise the crystallinity to 40–42% (1).

2.2.3 Properties and Applications Fabrics made of polyester fibers are noted for their strength, wrinkle resistance, and resistance to moisture at ordinary temperatures. Weathering resistance is good and superior to that of the polyamides (24); resistance to sunlight is inferior to that of the acrylics. Polyester fibers blend well with cotton or wool, and blends with cotton for clothing are easily the largest single end use (25). Industrial uses of polyester fibers include rubber reinforcing material, filter cloths, sieve cloths, and marine applications such as fishing nets or tarpaulins.

Polyethylene terephthalate film in its oriented crystalline state ranks among the strongest of the thermoplastics. Properties vary widely among the different types and subtypes, but its basic advantages are its toughness, durability, excellent flex life, resistance to most organic solvents and mineral acids, very low moisture retention, and general absence of plasticizers (26). Applications include magnetic tape, X-ray and other photographic film, electrical insulation (metallized for capacitors), food packaging, and boil-in-bag food pouches. Polyethylene terephthalate can also be blow-molded to prepare bottles (1). Additional properties are listed in Table 92.1.

2.4 Toxic Effects

2.4.1 Oral Toxicity Several 90-d feeding tests have been conducted. In a series of tests with films intended for food packaging, polyethylene terephthalate (27) and heat-treated polyethylene terephthalate (28) were fed to rats and dogs. The dietary level was 10% in all cases. No clinical, nutritional, hematologic, urinary, biochemical, or pathological evidence of toxicity was observed. Chloroform extracts of powdered resin produced no adverse effects when administered to rats in oral doses as high as 10 g/kg in an acute test and 400 mg/kg in a 90-d test (29).

2.4.2 Skin Contact As with acrylic and nylon fabrics, clinical experience over the past several decades indicates that the basic polyethylene terephthalate fiber is essentially innocuous when applied to the skin. Tests conducted by the Schwartz–Peck procedure with a 2-wk rest period (30, 31) showed no sensitization but occasional irritation reactions consistent with occlusion. Fabric made from textured yarn (false twist) has also caused some slight reactions that appeared to be related to mechanical irritation from the rough edges formed during draw texturing and to increasing denier per filament (32). Several recent tests conducted by a modified Shelanski repeated insult patch test procedure (33, 34) or a modified Draize repeated insult patch test procedure (35) were entirely negative. These procedures are described in Ref. 36.

Like acrylic fiber, 100% polyester knit fabric is low in free formaldehyde content; 15 samples of American clothing contained ≤30 ppm free formaldehyde (37), formaldehyde not attributable to the intrinsic fiber. Samples of polyester/cotton fabrics showed in some cases a relatively high level of

free formaldehyde.

2.4.3 Inhalation Toxicity, Thermal Degradation, and Related Data Insufflation tests have been conducted with the cyclic ethylene terephthalate trimer dust (38) and also with the polyester "skin" particles (39) released from some types of filament yarns during high-speed processing (see preceding). Under examination by a light microscope, the particles of trimer dust were refractile and varied in size from 1 to 7 mm; many particles were 1 to 3 mm. The dust was brilliantly birefringent under polarized light. Forty rats were given intratracheal injections of 0.25 mL of a 1% trimer dust suspension in 0.9% saline; three other groups of rats received injections of the same volume of a 10% suspension of quartz dust in saline, a 1% suspension of quartz dust in saline, or the saline diluent alone. Rats were killed serially in groups of five at 2, 7, 28, 91, 183, and 371 d after dosing. The remaining 10 rats of each group (or less if some died) were killed at 2 yr after treatment.

The injected trimer dust was found to be scattered in the alveoli adjacent to the respiratory bronchioles. Rats that were killed 2 d after exposure showed extensive acute peribronchiolar pneumonia from the dust accumulation. This reaction was much more intense than that observed after a 2-wk series of 10 4-h exposures to 0.4 mg/L trimer dust (mass median diameter = 5.9 ± 1.1 mm, histologically visible particles mostly <2 mm). The lungs of rats so inhaling trimer dust showed a nuisance dust cell reaction after the tenth exposure with significant reduction of dust-laden macrophage cells 2 wk later (6).

At 1 wk after exposure the inflammatory exudate had disappeared and a small number of minute dust-laden granulomas developed. The granulomas were readily detected under polarized microscopic examination. Dust particles a few micrometers or less in diameter were directly surrounded by foreign body giant cells and lymphocytes. Some dust particles had been transported from the lung to the tracheal lymph nodes. The number of granulomas appeared to be somewhat less at 1 yr and was further diminished at 2 yr, although a few active foreign body granulomas were still evident at this time. No fibrogenic activity was evident in the granulomas or in the dust-laden macrophages of the tracheobronchial lymph nodes.

The pulmonary reactions from the quartz-treated groups were quite different. Two years after treatment at the 2.5-mg dose level, the dust was almost entirely eliminated from the lungs and normal architecture was observed. At the 25-mg dose level, quartz lesions were characterized by silicotic nodule formation with progressive collagenization.

The polyester fiber "skin" particles appeared irregularly constricted and sausagelike when examined under a light microscope and were brilliantly birefringent in polarized light (39). Size varied from 1 to 1000 mm in length and 1 to 40 mm in width.

Forty rats given an intratracheal injection of 0.25 mL of a 1% suspension of these particles were maintained on the sacrifice schedule described for the trimer dust. The long nonrespirable particles were found in the small bronchi and terminal bronchioles, whereas shorter fibers were trapped in the respiratory bronchioles and adjoining alveoli. On the second day after exposure, the inflammatory reaction consisted of bronchitis, bronchiolitis, and peribronchial pneumonia. At 1 wk, the inflammatory reaction had disappeared; the test material was retained in the foreign body giant cells or macrophages, but no significant tissue reaction was observed. The intensity of the reaction progressively decreased at 1-mo, 6-mo, 1-yr, and 2-yr observations. At 2 years, large nonrespirable particles were retained in the terminal air passages while small respirable particles had been mostly removed by the lung clearing mechanism. No evidence of collagen formation, fibrosis, or significant alteration of the lung stromal architecture was observed.

Combustion toxicity tests (Table 92.1) show no unusual hazard from the products evolved from polyester compared to those from other fabrics similarly tested. Thermal degradation at approximately 300°C yields primarily acetaldehyde, whereas somewhat higher temperatures yield carbon monoxide (40–51).

2.4.4 Carcinogenic Potential/Cytotoxicity/Implant Studies Many studies have been conducted with implants of polyethylene terephthalate, mostly in a form described as mesh or velour but also as sutures or powder. Polyethylene terephthalates have often been favored on the basis of minimal toxicologic response, durability, and mechanical properties (52; see also 53–55). Sutures of this fiber have been preferred by some investigators (20) but not others (59). Athough relatively inert, polyethylene terephthalate fiber is subject to slow degradation in body fluids (58, 59).

Particulate polyethylene terephthalate showed little cytotoxicity when tested in rats (60, 61). Two instances have been reported in which a prosthetic graft made from this polymer was associated with tumor development in humans (62, 63); pore size between the polymeric strands was identified as a determining factor in the second case. Vascular prostheses should be knitted with the largest possible pores to promote connective tissue organization and blood supply within the knitted structure of the prosthesis (59). A Russian report states that subcutaneous implants of polyethylene terephthalate "fibers" were resorbed in humans after an average interval of 30 yr (64).

Polyethylene terephthalate has been fabricated into sutures in filamentary form (e.g., for corneal surgery) and into supporting ligature in sheet form (e.g., for hernias) in biomedical implants. Several studies have examined the types and rates of complications resulting from use of polyethylene terephthalate as opposed to other prosthetic materials (65–69). The polyesters made from polyethylene terephthalate polyesters had higher rates of infection, fistula formation, and hernia failure than materials made from polypropylene mesh (68). Biomedical implants made from polyethylene terephthalate also may cause an inflammatory response due to increased adhesion of fibrinogen to the material; this may be related to the type of weave used in the material as well as any intrinstic property of the polyester (69). Tissue compatibility may be improved to reduce the likelihood of thrombosis and inflammation by impregnating the polyester with agents that reduce fibrinogen or lymphocyte adhesion (70). The continuing use of polyethylene terephthalate as permanent prosthetic implants points to the low toxicity of these materials.

2.4.5 Biodegradation Human data as cited indicate that polyethylene terephthalate is slowly biodegradable.

3.0 Polybutylene Terephthalate

3.0.1 CAS Number: [*24968-12-5*], [*26062-94-2*], [*30965-26-5*]

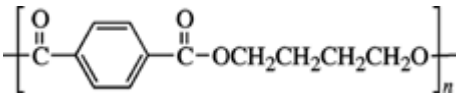
3.0.2 Synonyms: Polytetramethylene terephthalate and PBT

3.0.3 Trade Names: NA

3.0.4 Molecular Weight The low-molecular-weight polymers generally have M_n of 23,000–30,000 and M_w of 36,000–50,000. High-molecular-weight polybutylene terephthalate resins, which have preferable mechanical properties, have M_n of 36,000–50,000 and M_w of 60,000–90,000 (71).

3.0.5 Molecular Formula: NA

3.0.6 Molecular Structure:



3.1 Synthesis, Properties, and Applications

Polybutylene terephthalate can be made by the catalyzed condensation of 1,4-butanediol with either terephthalic acid or more frequently dimethyl terephthalate (71, 72).

Polybutylene terephthalate has a relatively low glass-transition temperature (see Table 92.1) and crystallizes at a rapid rate; molding cycles are very short. These resins are noted for their low coefficients of friction and are resistant to abrasion. They can be readily glass reinforced. Typical applications include exterior parts in the automotive and related fields and connectors and fuse cases in the electrical and electronic industries. Polybutylene terephthalate materials are also used in appliances, pump housings, and impellers (71). Polybutylene terephthalate has been approved for use by the FDA as a material that may contact food (21CFR 177.1655) and it is used in biomedical implants.

3.4 Toxic Effects

3.4.1 Oral Toxicity Polytetramethylene terephthalate (i.e., polybutyleneterephthalate) with a M_w of 45,000–85,000 has been fed at dietary levels up to 5%, to rats for 148 d, and to dogs for 90 d (73). At the 5% level both male and female dogs showed a somewhat enhanced food intake, but otherwise no untoward effects were observed. Analysis of urine from rats and dogs fed the 5% dietary level revealed no evidence of free or combined terephthalic acid at the detection limit of 1 mg/mL; it was therefore concluded that <0.003% of the daily intake of polytetramethylene terephthalate was absorbed from the gastrointestinal tract and then eliminated via the urine. The investigators reasoned that if the 2.5% level of polymer intake was considered an acceptable no-effect level, and the likely maximum was 1.8 mg extractable material from the polymer migrating into the total food intake, the safety factor would be in excess of 10,000.

3.4.2 Inhalation Toxicity and Thermal Degradation Data Cartier et al. (74) report a case of asthma in a 39-year-old male who developed cough, dyspnea, sweating, and tremors 2–3 wk after starting a job where he was exposed to a variety of chemicals. Challenge with heated polyester fiber would initiate an asthmatic episode.

Reported data indicate no unusual inhalation toxicity of the pyrolysis/combustion products of polybutylene terephthalate per se (75–78). Flame-retarded samples may exhibit additional toxic properties; rats inhaling vapors from some but not all brominated samples heated to simulate processing temperatures developed slightly enlarged livers.

3.4.3 Implant Studies Polybutylene terephthatate is used in a variety of biomedical implants similar to polyethylene terephthalate. It seems to have fewer coagulation, inflammatory, or rejection complications than the latter polyester. The plasma coagulation system, as measured by thrombin activation markers such as fragment 1 + 2 and fibrinopeptide A, was activated when polybutylene terephthalate was incubated *in vitro* with the coagulation system but not as great as polyethylene terephthalate (79). When used as an artificial ligament in Wistar rats, polybutylene terephthalate was less rejected than polyethylene terephthalate (Teflon was most inert) (80). As a copolymer with poly (ethylene oxide hydantoin), polybutylene terephthalate, used as an alloplastic tympanic membrane substitute, was assessed in rats for periods up to 1 yr (81). This copolymer was better accepted than a similar implant fabricated from Estane 5712 F1 polyether urethane, routinely used for this procedure, and much better than an implant made of polypropylene oxide. Minimal macrophages and foreign-body giant cells were present, but fibrous tissue and bone growth into the implant were acceptable. The continued use of polybutylene terephthalate in biomedical implants highlights the low toxicity of this polymer.

3.5 Elastomeric Polyester

This term has been used to describe a random copolymer of polybutylene terephthalate and polybutylene ether glycol. These polyester elastomers have strength comparable to many thermoplastics plus a rubberlike extensibility (82). A variety of polymers have been used in biomedical implants, indicating low toxicity, including biodegradable nerve guidance channels (83), replacement arteries (84), and biodegradable artificial skin (85).

Synthetic Polymers, Polyesters, Polyethers, and Related Polymers
Steven T. Cragg, Ph.D., DABT

4 Unsaturated Polyester Resins
Polyester resins comprise a large group of polymers and may include both these resins and the alkyds discussed in Section 4.
4.1 Properties
4.1.1 Molecular Weight, Properties, and Applications The molecular weight for uncured resins has been given as 7,000–40,000 (24). When used in polyester–glass laminates, the cured resins are noted for their good strength and rigidity, low density, toughness, and translucency. They can be formulated to be fire retardant and generally have superior heat resistance compared to most rigid thermoplastics available in sheet form.

Propylene and diethylene glycol are often used to influence the rigidity or flexibility of the resin. With phthalate–fumarate resins, increasing propylene glycol content increases hardness but may cause a reduction in tensile and flexural strength. Diethylene glycol can make the polyester more flexible and also more susceptible to water absorption. Dibromoneopentyl glycol, tetrabromophthalic anhydride, and chlorendic acid (anhydride) are used for fire retardancy. Chlorendic acid (anhydride) and propoxylated bisphenol A are used for chemical resistance.

Generally, unsaturated polyester resins are classified as either general purpose or specialty polyester resins (88). General-purpose resins are widely used in the so-called “open mold” processes (hand lay-up/spray-up) to produce a wide range of products including boats, truck components, furniture, and applications that do not require the premium performance of higher-cost grades of polyester resin. Specialty polyesters are chemically tailored to meet the requirements of a wide range of applications including flexibilized polyesters, electrical-grade polyesters, heat-resistant polyesters, low flame/low smoke, translucent polyesters, and low shrink/low profile.
4.2 Production and Use
4.2.1 Structure, Synthesis, and Processing Thermosetting, unsaturated polyester resins are made in several steps (1, 24, 86). A saturated dihydric alcohol is generally condensed with both a saturated and an unsaturated dicarboxylic acid. The alcohol used in the prepolymer is almost always a glycol such as ethylene, propylene, butylene, diethylene, or neopentyl or dipropylene glycol. The use of ethylene glycol is limited because unsaturated polyester resins made from it have poor solubility in styrene. Polyhydric alcohols are sometimes used to provide strength and chemical resistance. Maleic acid (anhydride) and fumaric acid are the usual unsaturated acids, although itaconic or mesaconic acid may be used to give flexibility. Phthalic anhydride is the most widely used saturated acid component; however, isophthalic and adipic acids have common use.

The prepolymer (or first-stage resin) is dissolved in a vinyl monomer, usually styrene, with appropriate inhibitors; the product may be supplied as a syrup containing 20–50% monomer (vinyl toluene, methyl methacrylate, diallyl phthalate, or other monomers can be used) (87). To add strength to the cured resin, glass fiber can be added as reinforcement (other fibers such as aramid, boron, carbon, nylon, polyester, polyethylene can also be used) (88). Curing is by free-radical polymerization of styrene monomer with the unsaturated acid residues of the resin. An organic peroxide is used as an initiator. Benzoyl peroxide is frequently used for elevated temperature curing; methyl ethyl ketone peroxide or cyclohexane peroxide can be used with a cobalt accelerator at room temperature.

Products of high quality often require a relatively high percentage of unsaturation in the polymeric chain. This can result in resins that during the curing process produce high temperatures that must be controlled to prevent explosions. Styrene-containing unsaturated polyesters polymerize with time at ambient temperatures.

Maximum mechanical strength may not be attained until more than a week after curing. Unsaturated polyester may remain undercured, soft, and, in some cases, tacky, if freely exposed to air during this

period.

4.4 Toxic Effects

4.4.1 Skin Reactions The finished, completely polymerized products are not considered dermatologic hazards (89), although there has been one case report of an 8-month-old child who developed contact sensitivity to cured unsaturated polyester resin in a limb prosthesis (90). Exposure to the uncured unsaturated polyester resin systems used in manufacturing have been associated with outbreaks of dermatitis during the 1960s (91, 92), but this was less common during the 1970s (89, 93). However, dermatitis can readily become a major problem in plants with poor industrial hygiene practices (94). The incompletely hardened macromolecular resin was considered the main causative agent in 17 dermatitis cases cited in a 1962 Czech report (95).

The dermatitis is reported as caused mostly by primary irritation but occasionally by sensitizing agents (92, 96–98; see also Ref. 89). Reactions are eczematous and more frequent on the backs of the hands, wrists, and forearms. The suggested patch test concentration for the unsaturated polyester resin is 10% in acetone. Malten (99) discusses several earlier studies (including Ref. 94), rates the sensitizing capacity of the polyester resin system low, and calls attention in this connection to a test with volunteers exposed to benzoyl peroxide that induced a 40% incidence of sensitization.

Kanerva et al. (100), reported two cases of hand and face contact sensitization in two car repair workers using an unsaturated polyester resin filler putty. The sensitizing agent was determined to be diethylene glycol maleate. Tarvainen et al. (101) found that some workers may react to the hardened glue of unsaturated polyester resins after becoming sensitized. These researchers also identified diethylene glycol maleate as the putative agent responsible for sensitization with this unsaturated polyester system. Irritant dermatosis of the hands in workers using unsaturated polyester resins may also be of a nonallergic origin (102).

4.4.2 Inhalation and Thermal Degradation As indicated earlier, styrene is frequently used as a cross-linking monomer in the preparation of unsaturated polyester products. Potential exposure to styrene during processing is generally considered to present the most serious inhalation hazard associated with polyester resin. Styrene invariably evaporates when the resin surface is exposed to the atmosphere during molding operations, and without proper control, operators may be exposed to unacceptable levels of vapors (103). When products are manufactured in open molds typical of boat manufacturing, as much as 10% of the styrene can volatilize into the workplace air (104). Overall exposure to styrene monomer in seven representative U.S. plants in the fiberglass plastic boat industry ranged from 2 to 183 ppm; mean exposures for the primary job categories ranged from 44 to 78 ppm (3); see also Refs. 4, 105, 106, and 107. A Scandinavian report indicates that workers can be exposed “to a styrene concentration typically ranging from 20 to 300 ppm” (5). A French study (108) conducted under model laboratory conditions indicates that a standard-type resin released the equivalent of 4.3 mg styrene/cm^2 surface in 4 h, whereas a resin with reduced potential for evaporation of styrene yielded 0.7 mg/cm^2.

Other studies of boat manufacturing facilities report average exposures during work shifts typically did not exceed the then current OSHA PEL of 100 ppm (99, 109); however, those exposures did exceed the current PEL of 50 ppm. Studies of other hand lay-up and spray-up operations also report typical exposure levels below the then-current 100 ppm PEL (110–112). In 1989, OSHA reduced the 8-h TWA PEL for styrene from 100 to 50 ppm. In the rule making, OSHA noted that, with the exception of hand lay-up and spray-up operations in the boat building industry, the 50 ppm PEL could be achieved with engineering and work practice controls. OSHA found, for these boat-building and similar large scale lay-up operations, that employers must use respiratory protection in combination with engineering controls and work practices to achieve these limits (113). The PEL for styrene has since been increased to 100 ppm.

Fiberglass particles released during processing may be coated with a mixture of resins and finishes. Lim et al. (94) report finding minute amounts of trivalent and hexavalent chromium on fiberglass

samples collected during walk through plant surveys.

When exposed to fire, both conventional and fire-retarded formulations of unsaturated polyester resins typically yield copious amounts of smoke because the major decomposition product is usually styrene, which burns with a very smoky flame (86). Resins based on alkyl and particularly acrylate monomers may produce less smoke (114). Tests conducted by German investigators indicate that products evolved from pyrolysis in the 330–400°C range or above may be lethal to rats. Carbon monoxide can be released in biologically significant amounts but is not necessarily the cause of death. Additional details can be found in Refs. 114–117.

4.4.3 Cyto-/Genotoxicity Furniture workers exposed to unsaturated polyester resins showed increased frequencies of sister chromatid exchanges in their circulating lymphocytes compared to controls (118). Frequencies were higher than for nonexposed smokers. The specific agent responsible for the increase was not identified.

Synthetic Polymers, Polyesters, Polyethers, and Related Polymers

5 Alkyd Resins
Commercial production of alkyd resins was begun in the 1920s, and by the 1940s they had become the backbone of the coatings industry, widely used in paints, varnishes, lacquers, baking enamels, and other surface coatings. In 1973, consumption of alkyd resins peaked—they constituted about one-third of all synthetic resins used in coatings. Now they comprise about one-fourth (119).

Because of environmental concerns for the solvents typically associated with these resins and the better performance of latex paints aimed at the consumer architectural coatings market, their use has declined and will continue to do so. However, they are one of the more versatile binders with potential for modification for use in high-solids coatings, an attribute that will make them important for some time to come.
5.1 Production and Chemical Characteristics
Alkyd resins are condensation polymers formed from esterification reactions. However, they differ from other polyesters that are unsaturated and thermosetting in that they are modified with a triglyceride oil or the fatty acids of that oil. They are the reaction products of a polybasic acid, a polyhydric alcohol, and a monobasic fatty acid or oil. The name alkyd is derived from a combination of alcohol and acid (120).

The most commonly used polybasic acids are the anhydrides of dicarboxylic acids, with phthalic anhydride being by far the most important. Pentaerythritol is the most commonly used polyhydric alcohol; others used frequently include glycerol, trimethylol-propane, and trimethylolethane. When oils are used as starting materials, alcoholysis from a polyol, glycerol being very common, must first be carried out to form the monobasic fatty acid. This reaction is often catalyzed by a very small quantity of basic compounds such as lithium hydroxide. Currently, most alkyd resins are manufactured using the solvent process that refluxes the solvent and the reactants until the completion of the reaction. The final product is usually let down or thinned with a solvent or diluent to a 50% or more solids content in solution.

The fatty acid moiety determines whether the alkyd is drying or nondrying. Unsaturated fatty acids in the alkyd undergo oxidation in air and cross-link or “dry.” The cross-linking is catalyzed by “driers,” usually metallic soaps added during the paint formulation stage. Alkyds without these unsaturated groups are nondrying and are usually used as plasticizers with other resins. Sometimes monobasic acids other than fatty acids are used as starting materials to make “oil-free” alkyds (e.g.,

rosin acids) or to terminate an alkyd chain [e.g., *p*(*tert*-butyl)benzoic acid].

Alkyds may be modified chemically by combining them with other molecules. Vinyl modification is common and occurs by grafting such molecules as styrene, vinyltoluene, and acrylic esters to the unsaturated groups in the resin chain via free-radical initiation. Alkyd resins may also be modified by alkoxypolysiloxanes, phenolics, polyamides, and diisocyanates. Alkyd resins may also be mixed with other resins to obtain the desired properties. They are commonly added to nitrocellulose lacquers.

By varying the starting materials, the modifiers, and/or the polymers with which they are blended, they may be "designed" for a wide variety of uses. Vapor emissions and hazards from solvents may also be minimized by making an alkyd resin water reducible. This is accomplished by creating an emulsion or introducing groups into the resin to make it water soluble.

Exposure to the ingredient dicarboxyic acid precursors, phthalic, trimellitic, and maleic anhydrides, was evaluated in a retrospective cohort study of alkyd resin workers (121). This study found that exposures in alkyd resin production facilities were generally low in recent years at levels below the TLVs for these anhydrides capable of causing occupational asthma. Another similar study in a cushioned flooring manufacturing plant showed similar low exposures (122).

5.4 Toxic Effects

Little information exists on the toxicity of the alkyd resins themselves. It is quite common to perform no toxicity tests at all on new alkyd resins for two reasons. First, they are almost always encountered as part of formulations that contain other chemicals assumed to present greater hazards. Thus exposure is controlled by limiting the exposure to the other chemicals. Second, the precursors to alkyd resins and any residual monomers are considered to be far more toxic than these large molecules, most of which exceed 1000 molecular weight.

Aside from the solvents, the dibasic acids used as starting materials for the basic alkyd resins present the greatest hazards during the manufacturing process. Phthalic anhydride, along with other low-molecular-weight anhydrides, is a known irritant and has been identified as a sensitizer, with a potential for respiratory sensitization. The EPA has identified carboxylic acid anhydrides as a category of concern for potential pulmonary sensitization and may require testing for new chemicals containing this group during the premanufacture notification review process (123). (These groups are not present in the resin owing to esterification.) Yokota et al. (124) recently have reviewed prevention of occupational allergy due to these anhydrides. The chain terminator, *p*-(*tert*-butyl) benzoic acid, has been identified as a potential reproductive toxin. The toxicity of such ingredient monomers, stabilizers, plasticizers, catalysts, and other performance enhancing chemicals that may be present as precursors or residuals, is dealt with in other chapters of this treatise.

Chemical modifiers such as styrene, acrylic esters, and diisocyanates present health hazards, including irritation and sensitization potential, unique to these chemicals during the manufacturing process (125). The hazards associated with the solvents used to manufacture the resin are also associated with the processing and use of the resin and the coatings formed from it. Small amounts of residual monomers (usually well below 1% by weight) remain in the resin and may present a potential for exposure during their use. Release of monomers (e.g., phthalic anhydride) may be of concern during heat-accelerated curing processes such as baking.

Toxic combustion products usually are not a problem. Most of these resins contain only carbon, hydrogen, and oxygen, and they are contained, owing to their customary use, in thin films, making less of a contribution to the combustion products than the substrates and other materials in the environs. Protective measures aimed at solvents and other attendant chemicals encountered during the manufacturing, processing, and use of alkyd resins should protect against any hazards from the resins themselves, residual monomers, or low-molecular-weight species. Additional protection may be required when handling raw materials such as acid anhydrides, styrene, and acrylic esters, for the manufacturing operation.

5.5 Additives
Other substances may be used as modifiers or additional ingredients, including phenolic resins, epoxy resins, styrene, cobalt naphthenate, lead soaps, and fire retardants. Additives are used to resist mildew and ultraviolet light. Curing or cross-linking is accomplished by air oxidation of the unsaturated groups (24, 86).

Synthetic Polymers, Polyesters, Polyethers, and Related Polymers
Steven T. Cragg, Ph.D., DABT

6 Allyl Polymers
The term *allyl resin* typically refers to unsaturated polyester cross-linked with an allyl-type monomer, such as allyl alcohol, rather than styrene. Such resins are notable for their retention of electrical properties under conditions of high temperature and high humidity. "Allyl molding compounds" may refer to "nonpolymeric" substances used in the preparation of thermoset moldings. Those in widest commercial use are the monomers and prepolymers of diallyl phthalate and diallyl isophthalate (126). Another self-polymerizing monomer, CR-39 (CAS # [*142-22-3*]; a.k.a., diethylene glycol *bis*(allyl carbonate) or diallyl diglycol carbonate), is used for lenses and optical devices because of its light weight and resistance to impact, scratch, and abrasion.

CR-39 monomer is a colorless, slightly volatile liquid (molecular weight 274) prepared from diethylene glycol chloroformate and allyl alcohol (127). A peroxide catalyst (typically, benzoyl peroxide, isopropyl percarbonate, cyclohexyl percarbonate) is dissolved at about 3% by weight in the diallyl glycol carbonate and then the liquid is polymerized first to a gel and then to a fusible solid.

The monomer is known to be an irritant. Skin contact during the polymerization process may result in a rapidly developing, irritant dermatitis with an incidence as high as 70%. Dermatitis frequently appears to result from direct contact with the liquid monomer. Some cases would appear to be traceable to residual monomer or other ingredient(s) in partially polymerized polymer because "adherence of the polymer to the molds is often associated by the workers with the irritant nature of the resin" (127). The National Fire Protection Association ranks the health hazard for this monomer as a 1 (slightly toxic) (128).

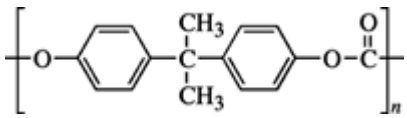
7 Polycarbonate Resins
7.1 Chemical and Physical Properties
Polycarbonate resins are characterized by water-white clarity and high impact resistance. They are extremely tough and rigid and have good electrical insulation characteristics (1, 86).

7.1.1 Structure Thousands of polycarbonates have been prepared since polycarbonate was first introduced in the late 1950s. Approximately 99% of the polycarbonate sold is the polycarbonate of bisphenol A with the basic structure



7.1.2 Properties The properties of polycarbonates are dramatically affected by the comonomers, molecular weight, end groups and branching agents. BPA polycarbonate homopolymer has a T_g of 145–150°C. Polycarbonate is typically amorphous. The polymer has a polymer decomposition temperature as measured by thermal gravimetric analysis in nitrogen of ~510°C. The polymer is soluble in solvents such as chloroform, methylene chloride, and tetrachloroethane. Other nonchlorinated solvents include pyridine, *m*-cresol, and phenol. Polycarbonates are insoluble in water, alcohol, organic acids, and hydrocarbons (130). The resin swells in various aromatic solvents, ketones, and esters.

7.2 Production and Use

7.2.1 Preparation Aromatic polycarbonates are prepared by the condensation of a bisphenol with a carbonic acid derivative. Commercially, the bisphenol is typically 4,4'-hydroxyphenylpropane (BPA), and the carbonic acid derivative is normally phosgene. Other comonomers can be added to tailor the properties of the resin to specific applications. In addition, various monofunctional compounds are added to control the molecular weight of the resin.

The interfacial polymerization process is the most widely used method in the manufacture of polycarbonates and polycarbonate copolymers. Two variations of the process have been described in the literature (129).

In the standard interfacial process, the bisphenol, chain terminator, catalyst, organic solvent, water, and caustic are charged into a stirred reactor followed by the addition of phosgene. The sodium salt of BPA is generated in the aqueous phase and allowed to react with phosgene in the organic phase in the presence of a catalyst. The catalyst is typically a tertiary amine. In this process, the phosgene reacts with the sodium salt of BPA to form BPA chloroformates. Concurrently, the catalyst facilitates the reaction of phenoxide with the chloroformates to form high polymer. The molecular weight of the resin is controlled by chain terminators, typically monofunctional phenols, carboxylic acids, or acid chlorides.

In the second process the tertiary amine catalyst, and in some cases the terminator, are not added in the first step. Without the catalyst present, the reaction of phenoxide with the chloroformate end group is suppressed resulting in the formation of BPA chloroformates and chloroformate oligomers. After the chloroformates are formed, the terminator and the tertiary amine are added. The amine catalyzes the condensation of the phenoxides with the chloroformates affording high polymer. This process has been claimed to produce resin with less carbonate functionality.

In both processes, after the reaction is complete, the organic phase is separated from the aqueous phase and washed free of catalysts and salts. Isolation of the polymer can be accomplished by antisolvent precipitation, spray drying, and devolatization using an extruder (129).

7.2.2 Additives A variety of additives are added to polycarbonate to enhance its properties, its retention of properties, and/or its processability. These include the following:

- UV stabilizers (typically benzotriazoles)
- Thermal stabilizers [such as phosphonites, phosphites, and organosilicon compounds (131–133)]
- Epoxides for increased hydrolytic stability (134)
- Release agents [typically, long-chain carboxylic acids and esters (135, 136)]

Other commercially significant additives and fillers include the following:

- Fire-retardant agents such as brominated polycarbonate copolymers (137) organic sulfonates (138–141), and finely dispersed fluoropolymer

- Glass fiber
- Blowing agents, such as 5-phenyltetrazole (142) or henyldihydrooxadiazinone (143), for use in foamed polycarbonate

7.2.3 Processing 7.2.3.1 Injection Molding Although polycarbonate has been processed in most common injection molding machines, in-line reciprocating screw machines are preferred. Melt temperatures of 280–350°C and mold temperatures of 80–120°C are typically recommended for general-purpose grades.

7.2.3.2 Extrusion Film, sheet, multilayer sheet, profiles, tubes, and rod stock can be manufactured using high-viscosity polycarbonate resin in extrusion processes. Melt temperatures of 230–260°C are typically recommended.

7.2.3.3 Thermoforms Polycarbonate sheet can be thermoformed. The sheet must be dried at 80–110° C prior to forming. Typical forming temperatures are 175–205°C.

7.2.3.4 Blow Molding Blow molding of branched polycarbonate has been extensively used to manufacture a wide variety of items from baby bottles to 5-gal water bottles. Typically, the non-Newtonian rheological properties obtained with branched resin are needed for blow-molding applications.

7.2.3.5 Applications Applications include medical equipment, beer pitchers, automotive lenses and trim extrusions, drapery fixtures, door and window components, furniture, and plumbing. Foamed polycarbonate is used in major automotive components such as a one-piece bus seat frame. Sheet glazing products that conform to specifications for safety glazing and burglar resistance may be used in schools, off-highway installations, and security facilities. Coated thin-gauge sheet has been used for protective eyewear and business machines (144). Registration of fast-neutron-induced recoil and (*n, a*) tracks in polycarbonate foils provides a sensitive means of dosimetry (145). Polycarbonate resins are approved for use with foods by the FDA (21 CFR 177.1580).

7.4 Toxic Effects

7.4.1 Toxicologic Information Polycarbonates in general are not considered primary eye irritants. When polycarbonate products, in finely divided form, were placed into the eyes of rabbits, slight transient redness or discharge occurred, consistent with the expected slightly abrasive nature of the resin particles (146).

Polycarbonates are not considered primary skin irritants. The Draize skin primary irritation score (rabbit) for polycarbonate resins, in finely divided form, for a 24-h exposure is 0. These resins are not expected to be skin sensitizers based on results of modified Buehler guinea pig sensitization. The dermal LD_{50} (rabbit) is estimated to be greater than 2 g/kg (146).

The estimated acute oral LD_{50}(rat) is greater than 5 g/kg (147). Bisphenol-A polycarbonate has been found to be physiologically inert when fed to rats at a level of 6% in food (148).

In acute inhalation tests, laboratory rats were exposed to processing fumes at concentrations exaggerating those that would likely occur in workplace situations. No deaths or signs of toxicity, except transient irritancy in some cases, were noted during the 6-h fume exposure tests. There were no distinct or consistent treatment-related tissue or organ changes noted in gross necropsies (149).

Recently, bisphenol A has been implicated as an environmental “endocrine disruptor” or chemical that interferes with normal endocrine metabolism by mimicking estrogen. Brotons et al. (150) reports finding the “xenoestrogen” bisphenol A in foods from cans lined with a polycarbonate resin. However, other studies that have evaluated the migration potential of bisphenol A from polycarbonate indicate that degradation of polycarbonate and consequent migration of bisphenol A is minimal. Specifically, a study using FDA worst-case extraction procedures found no

migration/extraction of bisphenol A from several polycarbonate formulations (151). Bisphenol A was found not to migrate from 24 different brands of polycarbonate baby bottles following sterilization by steam, alkaline hypochlorite, or washing in an automatic diswasher at 65°C with detergent (152).

Toxicologic aspects of plastic combustion products are very complex. This is due mainly to the fact that it is very difficult to simulate real-world environments under controlled conditions. Depending upon a variety of factors, the qualitative and quantitative nature of chemicals present in the combustion product mixtures will vary. Factors contributing to toxicity of real-life fires include increase of carbon monoxide and carbon dioxide, decrease of oxygen, and the presence of irritant gases. The primary effects from fires are asphyxia due to oxygen deficiency, poisoning from carbon monoxide, heat damage to tissues, and irritation of the respiratory tract by combustion gases (see Section 1.5). A study using rats as models found that combustion products from polycarbonate resins induce rapid sensory irritation of the upper respiratory tract. Rapid recovery also occurred following termination of exposure (153). Another study on toxicity of plastic products using eight different plastic resins found that combustion products from polycarbonate were among the least toxic relative to the other resins (154). Polycarbonates manufactured with the flame retardant tetrabromobisphenol A should not present an additional toxicological hazard during manufacturing since this compound has low acute or chronic toxicity (155). Its combustion toxicity has not been assessed. When polycarbonate products were manufactured with a flame-retardant metallic covering film, combustion toxicity products were no worse than for noncoated polycarbonate (156).

7.4.2 Plastic Processing Fumes The chemical composition of processing fumes of polycarbonates, like any other plastic materials, depends greatly on product formulation. In general, processing fumes from polycarbonates processed at recommended processing conditions may include trace levels of phenol, alkylphenols, and diarylcarbonates. Polycarbonate treated with brominated fire retardants may also evolve small traces of hydrogen bromide. Products formulated with polyfluorocarbon additives may evolve hydrogen fluoride and fluorocarbon compounds in the resulting processing fumes. Thermal emissions from impact-modified polycarbonate resins may also include styrene and acrylates, depending on the impact modifier used in its formulation.

In some instances, additives containing certain heavy metal compounds may be present. These ingredients are essentially bound in the plastic matrix and are unlikely to contribute to workplace exposure under recommended processing conditions.

Processing fumes may cause irritation to the eyes, skin, and respiratory tract, and in cases of severe overexposure, nausea and headaches. Fumes from plastic thermal processes may condense on processing equipment, ventilation systems, and other surfaces. These greaselike processing fume condensates can cause irritation and injury to skin. Use of proper personal protection while cleaning or handling these condensates should be observed.

When polycarbonate was machined using either hot-gas welding or laser cutting techniques, significant particulate was formed compared to polymethyl methacrylate polymer or polyethylene terephthalate (157, 158).

7.4.3 Exposure Controls and Personal Protection A continuous supply of fresh air to the workplace sufficient to replace that used to remove processing fumes through local exhaust systems is necessary for proper operation of these systems. Processing fume condensate may be a fire hazard and toxic; it must be removed periodically from exhaust hoods, duct work, and other surfaces. Persons performing such tasks must be provided appropriate personal protection including face protection and respirators. Ventilation requirements must be locally determined to limit exposure to materials at their point of use.

8 Polyethers
8.0 Acetal Resins—Polyoxymethylene
8.0.4 Molecular Weight Most manufacturers supply a number of different molecular-weight resins. The Mw of some commercial polyoxymethylenes has been reported in the range from 20,000 to 110,000 (1). In general, increasing molecular weight leads to increased toughness, and increased melt viscosity. Table 92.3 provides an example of the effect of molecular weight on properties. Coupled with low density (as compared to metal) and ease of fabrication, acetals are used as replacements for metal in many applications (1).

Table 92.3. Effect of Molecular Weight on Impact Properties of Acetal Homopolymer*

Approximate M_n	Notched Izod (ft-lb/in)[a]	Tensile Impact (ft-lb/in^2)[b]
65,000	2.4	170
40,000	1.4	100
30,000	1.3	70

* *Source*: Ref. 2a
[a] Method: ASTM D256.
[b] Method: ASTM D1822.

8.0.6 Molecular Structure Acetal resins [*9002-81-7*] are also known as polyformaldehyde and polyoxymethylene. Polyoxymethylene heart valve biopolymeric materials may be found in the biomedical literature with the name Delrin [*9085-38-5*]. Although paraformaldehyde [*30525-89-4*] also is a polymer of formaldehyde, this material has repeating units of 8–100 according to Hawley's Condensed Chemical Dictionary (159) and should not be considered the same as the larger polyformaldehyde resins discussed here. Unlike the larger, more refined polyoxymethylene polymers, paraformaldehyde may be highly irritating and an allergic sensitizer, perhaps due to large amounts of residual free formaldehyde (160, 161). High-molecular-weight acetal resins are highly crystalline, resulting in excellent retention of properties and dimensions and predictable behavior. Because of these notable features of metal-like stiffness, resistance to fatigue, and resistance to organic solvents, they are referred to as engineering resins.

The dominant structural repeat unit of acetal resins is

or formaldehyde. Acetal homopolymers consist entirely of these repeating units, with acetate and caps to provide stability. In acetal copolymers, the structural regularity of—OCH_{2-n} is interrupted after approximately 65 units (n = 65) by a comonomer unit derived from ethylene glycol, 1,4-butylene glycol, or diethylene glycol. The purpose of including comonomer units is to provide depolymerization stoppers. The inclusion of the comonomer units also reduces the inherent crystallinity, affecting the strength and rigidity of the resin. Reduction of properties is generally

compensated to some extent by addition of nucleating agents.

8.1 Properties

Typical properties of the intermediate molecular weight, probably the most widely sold grades of acetal resins, are listed in Table 92.4. Again, owing to the highly crystalline nature, acetals have excellent solvent resistance. However, all acetals are attacked by strong acids; copolymer resins in general are resistant to strong bases.

Table 92.4. Properties of Typical Acetal Resins at 23°C

Property	Method	Acetal[a]
Tensile strength	ASTM D638	8,800–10,000 psi
Elongation at break	ASTM D638	40–50%
Flexural modulus	ASTM D790	375,000–400,000 psi
Melting point		165–175°C
Specific gravity	ASTM D792	1.41–1.42 g/ml

[a] Range accounts for both homopolymer and copolymer values.

Acetals in contact with steel generally produce less friction than acetals with other metals, and acetals used with nylon are usually preferable to either alone (1). Most manufacturers also sell resins modified with various additives, including fluoropolymer fibers for reduced friction and wear, glass fiber for increased modulus and strength, and toughener to increase impact resistance.

8.2 Production and Use

Acetal resins are manufactured from monomeric formaldehyde or from its cyclic trimer, trioxane. Homopolymers are manufactured from highly purified anhydrous formaldehyde (1, 162). One process for making these resins starts with aqueous formaldehyde. The manufacture of polymers with useful molecular weights (typical M_w are 25,000–80,000 with M_w/M_n~2) requires very high-purity monomer. Thus the concentration of chain transfer agents such as water and methanol must be reduced to very low levels. All acetal homopolymers are believed to be manufactured by anionic polymerization. To ensure good thermal stability, the homopolymers are end capped with acetate end groups. Esterification with acetic anhydride or other anhydrides can be conducted at 130–200°C with sodium acetate as a catalyst.

Most copolymers are manufactured from trioxane by cationic polymerization. Like the formaldehyde used for making homopolymers, the trioxane must also be highly purified to be able to produce copolymer resins of useful molecular weights. (M_n of 15,000–40,000, with M_w/M_n~3–80). Because the "as-polymerized" copolymer resins contain unstable ends, the polymer is typically stabilized by thermal or hydrolytic degradation back to depolymerization-stopping comonomer units.

Acetal resins may be readily processed on conventional injection molding, blow molding, and extrusion equipment, provided that overheating is avoided. Overheating can lead to the production of formaldehyde gas and a serious or even dangerous buildup of pressure. Gas pressure created by decomposition can rapidly become extremely high when processing machines are not properly vented. A shotgun-like reaction (blow-back) from a pellet hopper was reported to develop within a few minutes after failure of one of three heating zone circuits (163). Recommended control measures (164, 165) include (*1*) the use of vented feed screw and proper design of injection nozzle, (*2*) preventive maintenance and replacement of worn gaskets and valves, (*3*) automatic heat regulation and monitoring of excess temperature conditions by an audible alarm or warning device in direct view of the operator, (*4*) a standby water cooling device not dependent on the main electrical system, and (*5*) personnel instruction.

8.4 Toxic Effects

8.4.1 Oral Toxicity and Skin Contact Ninety-day feeding tests have been conducted with two different types of polyoxymethylene (96+ and 99% active ingredient, respectively, both with M_w of 25,000–30,000). Rats in groups of 40 and dogs in groups of 4 were fed a 10% dietary level of each test polymer with Alphacel® cellulose as a control (28). One or two rats died in each of the two test groups; one death was also observed in the corresponding control group. No deaths occurred among any of the dogs. No changes attributable to the test polymer were evident in behavior and appearance, body weight, food consumption, ophthalmoscopy, and hematologic, biochemical, or urinalysis studies. No gross or microscopic lesions or variation in organ weight attributable to treatment were observed in any of the animals.

Skin irritation and sensitization tests with 1-in disks of polyoxymethylene extruded sheeting were conducted by the Schwartz–Peck procedure (36). In another study with a 10-d rest period, on a panel of 212 volunteers (166), some mild or moderate erythema consistent with occlusion was observed at the 6-d reading, but otherwise no reactions were observed. The panel included one subject known to be sensitive to urea–formaldehyde who showed no reaction through 4 d after removal of the test polymer.

8.4.2 Inhalation Toxicity and Thermal Degradation Data A massive single 6-h dust inhalation exposure (47 mg/L nominal concentration) caused emphysema and atelectasis in rats. Fumes evolved at temperatures as low as 150°C, in sufficient quantity, can be lethal to animals that are exposed for 4 h. Both formaldehyde and carbon monoxide have been identified in the effluent evolved at elevated temperatures. More details can be found in Refs. 168–171.

8.4.3 Cytotoxicity/Implant Studies Many studies have evaluated the long-term efficacy and biocompatability of heart valves manufactured from Delrin, a highly refined polyoxyethylene, in humans (172–180). Other than mechanical wear, sometimes manifesting as distortions in the shape of the valve as a result of cavitation and other hemodynamic stresses, no toxicity and little evidence of rejection have been reported in heart-valve patients for periods as long as 20 yr. Delrin, used as a bone substitute in a rabbit model, was less inert than titanium inducing foreign body reactions (181). Polyoxyethylene (Delrin) was more cytotoxic than polyvinyl chloride, inhibiting cell growth in the continuous cell line, L-929, as measured by cell density, total protein, total per cell, protein fraction of cells in mitosis and other parameters (182).

8.4.4 Injection Studies Rats receiving intraperitoneal injections of an unstated concentration of dust suspension showed granulomas with some scarring when examined 90 d later (183). In another study 40 mg/kg was administered to male guinea pigs. One animal died due to pneumonia and infection. The other four animals survived the 32-d observation period. At sacrifice, peritoneal nodules consisting of the polymer surrounded by grant cells were found in all animals. The nodules showed no inflammation and were typical of the reaction caused by an inert, insoluble material (184).

9.0 Polyoxyethylene

Polyoxyethylene is available as high- or low-molecular-weight polymer.

9.0.4 Molecular Weight One group of low-molecular-weight polyoxyethylenes range from liquids to waxy solids, with a molecular weight up to 10,000. High-molecular-weight resins have a molecular weight described as ≥100,000 (16) and ranging up to 4,000,000 (185).

9.0.6 Molecular Structure: The generic structure is

9.1 Properties and Applications

Even the high-molecular-weight resins are water-soluble thermoplastic polymers that can be extruded as films. They can be used in packaging for food, as textile sizes, and for the reduction of

hydrodynamic friction.

9.4 Toxic Effects

9.4.1 Acute Toxicity Polyoxyethylene polymers (a.k.a, polyethylene glycols or PEGs) with molecular weights below 10,000 have very low acute oral toxicity with LD_{50}s generally above 5,000 mg/kg and often above 10,000 or even 20,000 mg/kg (160). Even intraperitoneal and intravenous LD_{50}s often are above 5,000 mg/kg (160). In an older report (185), solutions of 0.1% commercial material killed rats when first administered intravenously at a dosage of 3 mg/kg (0.3 mL). This may have been due to clumping of cells and death from embolism. Subsequent injection of this concentration after shearing the polymer in an Osterizer did not kill rats receiving 40 mg/kg (4 mL). Few dermal LD_{50}s were found for polyethylene glycols of any molecular weight. Those found generally were greater than 5,000 mg/kg with no deaths reported at the highest dose tested (160).

Primary irritation testing of a variety of low-molecular-weight PEGs in rabbits reveals minimal irritation of eyes or skin (160, 161). PEG 400 (molecular weight = 400) has been used to wash human eyes as a 50% aqueous solution (160). Low-molecular-weight polyoxyethylenes were found to be nonsensitizing in patch tests. Low-molecular-weight PEGs have parasympathomimetic properties (160).

9.4.2 Repeat-Dose Toxicity Polyoxyethylene (PEG 400) was administered to Fischer 344 rats by daily gavage 5 d/wk for 13 wk at doses of 0, 1, 2.5, or 5 mL/kg/d (186). No changes were noted in mortality, clinical chemistries, or hematology. High-dose animals showed a slight decrease in body weights. Mid- and high-dose groups exhibited loose stools. All treatment groups consumed water in excess of controls in a dose-related manner. Kidney weights were slightly increased, but histopatholgy revealed no lesions. A functional difference was seen in kidney function evidenced by increased urinary *N*-acetyl-b-D-glucosaminidase, vascular cell findings, and bilirubin levels. Animals allowed to recover for 6 wk showed no kidney changes.

Rats were exposed to aerosols of polyoxyethylene (PEG 3350) at concentrations of 0, 109, 567 or 1008 mg/m^3, 6 h/d, 5 d/wk for 2 wk (187). No effect was noted on clinical signs, ophthalmology, clinical chemistries, urinalyses, or gross pathology. Body weight gains in males of both groups were statistically decreased but with no associated dose–response effect. Lung weights of both sexes were increased, and histopathology revealed some macrophage-filled alveoli. No histological lesions were found in other tissues.

Polyoxyethylene with a mean molecular weight of 4,000,000 was fed to rats for 90 d at dietary levels averaging 8.0 and 18.4 g/kg/d (188). These rats showed changes, rated minor, in the liver and kidney. Two-year tests with rats fed at dietary levels averaging up to 2.76 g/kg/d and dogs fed at dietary levels in the range of 0.6 g/kg/d showed no detectable effect. Testing with a ^{14}C sample revealed no significant absorption of the polymers *per se* from the gastrointestinal tract of the rat or dog. The content of glycols and polyglycols in the tagged sample was considered sufficient to account for all the radioactivity found in the urine (0.72 and 1.1% of the dose administered to 20 rats and 1 dog, respectively).

9.4.5 Reproductive Toxicity Facial malformations have been reported in the offspring of mice but not rats where pregnant mice were dosed orally with 0.5 and 0.7 mL/kg/d on days 6–17 of gestation, and rats were dosed orally with 1.5–5 mL/kg/d on days 6–14 or 11–16 (188). Maternal toxicity was evident in rats but not mice. Offspring of mice exhibited marked facial and thoracic skeletal defects. In the rabbit, PEG 300 and 400 caused maternal toxicity at daily oral doses of 2 mL/kg during organogenesis but no adverse effects on the fetus (189). Gupta et al. (190) reported no malformations in soft or skeletal tissue in either rats or rabbits (10 dams/group) treated daily during organogenesis with oral doses of 1 mL/kg (rats) or 2 mL/kg (rabbits).

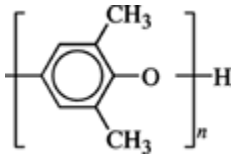
9.4.6 Human Clinical Use Review of the biomedical literature reveals many studies where polyoxyethylene polymers have been evaluated for efficacy and adverse effects when used as vehicles for medications and as oral or rectal colonic cleansers prior to colonoscopies. The continued use of polyoxyethylene polymers of diverse molecular weights points toward the low toxicity of this family of polymers.

10.0 Polyphenylene Oxide-Based Resin

Polyphenylene oxide can be blended with crystal polystyrene (PS) in all proportions, forming an alloy with a single glass-transition temperature. The higher the PS content, the lower the heat distortion temperature of the material and the easier the alloy to process. These alloys can be brittle and must be further modified to improve toughness by the addition of rubber impact modifiers. In practice, polyphenylene oxide–PS resin blends are also compounded with many additives, including stabilizers and fire retardants. The resulting resins are cream colored and have excellent melt flow. Alloys of polyphenylene oxide can be modified with glass or carbon fibers and a variety of mineral fillers to improve rigidity, tensile strength, and static dissipative properties. This resin family can be filled to high levels with combinations of fiber and mineral fillers to provide high-modulus, controlled shrinkage resins.

10.0.1 CAS Numbers: [*9041-80-9*], [*25134-01-4*]

10.0.6 Molecular Structure:



10.1 Physical and Chemical Properties

Polyphenylene oxide is a thermoplastic resin made from phenolic monomers. Commercially available resins are based on 2,6-dimethylphenol (a.k.a., 2,6-xylenol) and are produced by oxidative polymerization in the presence of an amine catalyst.

Polyphenylene oxide homopolymers have a relatively high T_g (above 212°C) and are very difficult to process (191). At normal processing conditions (300–350°C), melt flow is very stiff, and special precautions must be taken to minimize oxidation.

The blendability of polyphenylene oxide and PS in all proportions provides the capability of producing materials with a wide variety of physical properties and heat resistance. Products are available over the 75–175°C heat distortion range (192). Because both polyphenylene oxide and polystyrene are hydrophobic in nature, the resulting alloys are characterized by low moisture absorption; this, in turn, results in very good electrical properties over a wide range of temperature and humidity.

These resin blends have relatively low coefficients of thermal expansion. In fact, glass-reinforced resins have nearly the same coefficient of thermal expansion as that of metals, such as aluminum.

Alloys of polyphenylene oxide and PS are amorphous materials and can be chemically attacked by a number of organic solvents. These resins will soften or dissolve in many halogenated and aromatic hydrocarbons. Several alloys, however, have been developed to provide improved chemical resistance. These blends are based on polyphenylene oxide and crystalline polymers, such as nylon. Polyphenylene oxide provides excellent heat resistance and toughness, and the crystalline resin provides chemical resistance. These types of blends have utility in the automotive industry, where chemical resistance to compounds such as oils and gasoline is needed in addition to good heat resistance at relatively high temperatures.

10.2 Production And Use

Polyphenylene oxide–PS resins can be processed by standard injection molding, extrusion, blow molding, and structural foam molding. Processing temperatures vary, depending on resin grade, from 230 to 320°C. These resins are easily foamed either by chemical heat-activated blowing agents or by physical injection of inert volatile gases.

Major applications of polyphenylene oxide–PS blends include automotive interiors, such as instrument panels and seat backs; automotive exteriors, such as wheel covers, mirror housings, and rear spoilers; and electrical applications such as fuse boxes and connectors. Other applications include telecommunications and business machines. For telecommunications and computer and business equipment applications, these resins are available with varying levels of flame retardants to meet a wide range of applications: computer housings, card frames, keyboard bases, printer housings, and so on. High-modulus grade resins also find applications in chassis for copiers and laser printers. Examples of home appliance applications include power tools, hair dryers, pump housings, and portable mixers (193). These resins also find extensive use in food contact applications in cookware and food packaging. In food contact applications, these resins offer great improvements over polystyrene in heat resistance for microwave food packaging.

10.4 Toxic Effects

Polyphenylene oxide is not considered a primary eye irritant. In a primary eye irritation study, polyphenylene oxide produced mild and transient irritation in albino rabbits (194). Within 1 h of instillation, redness of the conjunctivae and chemosis was observed, but had resolved by 48 h.

Polyphenylene oxide is not considered a primary skin irritant or a skin sensitizer. Polyphenylene oxide was nonirritating when applied dermally (500 mg/site) to rabbits for 4 h and examined for 3 d following removal (194). Polyphenylene oxide did not cause delayed contact hypersensitivity in guinea pigs given three weekly 6-h epicutaneous applications of a 100% concentration of polyphenylene oxide and challenged 2 wk later with a final application to a naive site (195).

Estimated acute oral exposure LD_{50} (rat) is greater than 5 g/kg. No mortality or signs of toxicity were reported in a group of five male and five female Sprague–Dawley rats given polyphenylene oxide acutely at 5000 mg/kg (146). In two other acute oral toxicity studies in rats, up to 15 g/kg produced no mortality or signs of toxicity (196, 197).

A no observed adverse effect level (NOAEL) for repeated inhalation of polyphenylene oxide powder is estimated to be 7 mg/m^3. In a 13-wk repeated inhalation study, a group of Fischer 344 rats (10 of each sex/group) receiving 1, 7, or 50 mg/m^3 of polyphenylene oxide dust for 6 h/d, 5 d/wk for 2 wk had no treatment-related mortality, clinical signs of toxicity, significant body weight or food consumption differences, or changes in hematology and clinical chemistry parameters (198). Gross and microscopic examination in the 50-mg/m^3 group revealed an exposure-related localized toxicity in the lungs and regional lymph nodes, consisting of a significant increase in lung weights and lung to body weight ratio and a mild, acute/chronic pulmonary inflammation and thymic/peribronchial lymph node histiocytosis. These symptoms were still apparent in the high-exposure group following a 13-wk recovery period.

Groups of 30 male and 30 female rats fed 1.0, 5.0, and 10% of polyphenylene oxide in the diet for 22 mo had no treatment-related mortality, clinical signs of toxicity, body weight differences, changes in clinical chemistry parameters, or apparent gross or microscopic alterations (12). Beagle dogs fed 1.0, 5.0, and 10.0% of polyphenylene oxide in the diet for 2 yr developed no treatment-related changes in mortality or physical parameters, and there were no alterations noted upon gross or histopathological examination (199).

Polyphenylene oxide is not a mutagen by the Ames assay. Several samples of polyphenylene oxide were negative in the *in vitro* Ames *Salmonella*/microsome plate test with and without activation at concentrations up to 2500 mg/plate (200, 201).

10.4.1 Exposure to Processing Fumes In acute inhalation tests, laboratory rats were exposed to processing fumes at concentrations exaggerating those that would likely occur in workplace situations. During the exposure periods (6-h duration) signs of eye and nasal irritation were observed. These signs of irritation disappeared shortly after the animals were removed from the exposure chamber. No deaths or signs of toxicity were noted during the fume exposure period. There were no distinct or consistent treatment-related tissue or organ changes noted in gross necropsies (202).

10.4.2 Exposure to Combustion Products The toxicologic aspects of plastic combustion products are very complex. This is mainly because it is very difficult to simulate real-world environments under controlled conditions. Depending on a variety of factors, the qualitative and quantitative nature of chemicals present in the combustion product mixtures will vary. Factors contributing to toxicity of real-life fires include increase of carbon monoxide and carbon dioxide, decrease of oxygen, and the presence of irritant gases. The primary effects from fires are asphyxia due to oxygen deficiency, poisoning from carbon monoxide, heat damage to tissues, and irritation of the respiratory tract by combustion gases.

Some older studies have attempted to elucidate the pyrolysis products of polyphenylene oxide and compare the toxicity of combustion products from this polymer and natural fibers. Under varying fire generation conditions, carbon monoxide, carbon dioxide, and particulates were major combustion products of polyphenylene oxide (203, 204). Bucci et al. attempted to characterize the lung histopathology of mice exposed to the pyrolysis products of several synthetic polymers, including polyphenylene oxide (205). Except for the lungs, no histopathology was evident in major organs from survivors 2 wk after exposure. In the lungs, extensive damage was found 2 wk post-exposure, but damage was too extensive to distinguish differences among polymers. Hilado et al. found that a modified polyphenylene oxide were less toxic than cellulosic materials, based on time of death (206). Based on time to incapacitation, however, synthetic polymers were more toxic. A fire-retarded polyphenylene oxide produced carbon monoxide less rapidly than non-fire-retarded synthetic polymers or natural materials (207). The authors of this study concluded that qualitatively identifying chemicals produced from pyrolysis should be the goal of such studies rather than ranking the toxicity of various polymers or natural materials. These results should be interpreted with caution since, as stated previously, the conditions of fire generation may profoundly influence the formation rates of toxic combustion species.

10.4.3 Plastic Processing Fumes Processing fumes from polyphenylene oxide and its blends, like any other plastic materials, depend highly on product formulation. In general, processing fumes from polyphenylene oxide processed under recommended conditions may include trace levels of alkylphenols, aliphatic amines and aldehydes, dimethylcyclohexanone, and toluene. Polyphenylene oxide/polystyrene blends may evolve styrene, styrene dimers, toluene, aliphatic amines, aldehydes and alcohols, ethylbenzene, and 4-vinylcyclohexene. Polyphenylene oxide/polystyrene blends flame retarded with triarylphosphate esters also evolve triarylphosphate esters and phenol. Products formulated with polyfluorocarbon additives may evolve hydrogen fluoride and fluorocarbon compounds in the resulting processing fumes. In some instances, additives containing certain heavy metal compounds may be present. These ingredients are essentially bound in the plastic matrix and are unlikely to contribute to workplace exposure under recommended processing conditions.

Processing fumes may cause irritation to the eyes, skin, and respiratory tract, and in cases of severe overexposure, nausea and headaches. Fumes from plastic thermal processes may condense on processing equipment, ventilation systems, and other surfaces. These grease-like processing fume condensates can cause irritation and injury to skin. Use of proper personal protection while cleaning or handling these condensates should be observed.

10.4.4 Exposure Controls and Personal Protection A continuous supply of fresh air to the workplace together with removal of processing fumes through exhaust systems is recommended. Processing

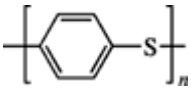
fume condensates may be a fire hazard and toxic; it should be removed periodically from exhaust hoods, duct work, and other surfaces using appropriate personal protection. Ventilation requirements must be locally determined to limit exposure to materials at their point of use.

Synthetic Polymers, Polyesters, Polyethers, and Related Polymers
Steven T. Cragg, Ph.D., DABT

11 Sulfur Polymers
The main commercial polymers are polyphenylene sulfide and the polysulfones.
11.0a Poly(p-phenylene sulfide)
11.0.1a CAS Number: [*53027-72-8*], [*9016-75-5*]

11.0.2a Synonyms: Poly(thio-1,4-phenylene)

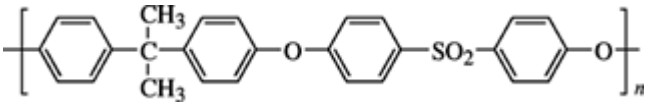
11.0.6a Molecular Structure:



11.0.b Polysulfone of Bisphenol A

11.0.1b CAS Number: [*25135-51-7*]

11.0.6b Molecular Structure:



Other polysulfones, such as polyether sulfone and polyaryl sulfone, that exist as powders differ in the types of linkage between aromatic rings and vary in their properties accordingly.
11.1a Synthesis, Properties, and Applications of Polyphenylene Sulfide
This polymer has been manufactured commercially by reacting *p*-dichlorobenzene and sodium sulfide, apparently in *N*-methylpyrrolidone (as cited in Ref. 208). Heating under oxygen cures the product to form a fine white powder, apparently linear. The white, lightly crystalline polymer discolors on heating in air to form a brown product, presumably cross-linked. Polyphenylene sulfide is known for thermal and chemical resistance, toughness, and flexibility. Additional properties are summarized in Table 92.1 (209).

Polyphenylene sulfide molded parts can be used in submersible and centrifugal pumps, computer housings, and telecommunications. Coatings of this polymer often utilized for chemical resistance in industrial process operations (210).
11.1b Synthesis, Properties, and Applications of Polysulfone
For commercial products an aryl ether can be treated with sulfonyl chloride in the presence of catalysts to give sulfone groups (polysulfonylation) or sulfones can be treated with phenolates to give ether groups (polyetherification). The structures made by one route are usually not made by the other, although some can be made by either process. All polysulfones have excellent creep resistance. They are stable to oxygen and thermal degradation and are flame resistant. Their toughness is affected by the inclusion of bulky side groups in the polymer structure or deviations

from the all-*para* orientation of groups linking the aromatic rings (208, 211). See Table 92.1 for additional data.

11.4 Toxic Effects

Several experimental tests indicate that products evolved at elevated temperatures can be rapidly toxic to mice. Thermal degradation of polyphenylene sulfide may yield hydrogen sulfide; the sulfur of polysulfone is typically evolved as sulfur dioxide. See Table 92.1. Additional details may be found in Refs. 40 and 212–216.

Ground fiberglass-reinforced polyphenylene sulfide (CAS# [*9016-75-5*]) was fed to rats in their diets at concentrations of 0, 0.5, 2.75, or 5% for 6 mo. A small number of high-dose rats exhibited yellow staining of the anogenital region. Red or black staining was noted in some rats around the eyes and masses on the neck. No changes were noted in behavior or hematology, and clinical chemistries revealed a transient elevation in blood urea nitrogen and a decrease in SGOT in the two highest-dose groups. No gross lesions were evident at necropsy, and organ weights were normal (217).

Highly refined polysulfone has been used as membranes in kidney dialysis machines and other biomedical applications with little toxicity.

Polyurethanes, Miscellaneous Organic Polymers, and Silicones
Steven T. Cragg, Ph.D., DABT

Overview

The toxicity of the polymers discussed in this chapter may be generally attributed to the residual monomers, catalysts, and other additives present rather than the polymer *per se*. The cured polymer itself may be of high molecular weight and, consequently, more or less toxicologically inert.

Carefully manufactured, highly refined polymers contain few residual toxic chemicals. However, some of the polymers discussed in this chapter, at least in some applications, go through an intermediate stage consisting of "prepolymers" (sometimes referred to as "resins") that react further to achieve their final, cured form. An example is a polyurethane system for making foam cushions. To manufacture polyurethane foam for cushions, workers combine diisocyanate molecules with a polyol prepolymer. Such "systems" inherently have more potential for exposure of workers if not the general public to toxic monomers or other reactive chemicals. The exposure potential of glues, paints, and coatings may extend more broadly to the consumer. Thus, examination of the toxicity of the polymers discussed in this chapter focuses on monomers and prepolymers. This is not always so. Some of polymers in this chapter are used in biomedical devices or in a way that puts them in intimate contact with humans. Here, the issue of biodegradation becomes important because of potential toxicity from breakdown products of the polymer, or rejection may ensue if the polymer is incompatible with the surrounding tissues.

Polyurethanes, Miscellaneous Organic Polymers, and Silicones
Steven T. Cragg, Ph.D., DABT

A. Polyurethanes

Polyurethanes are an extremely complex class of polymers (1) that are essentially ester-amide derivatives of carbonic acids (2). They were first developed commercially about 1937–1941 as nylon-like fibers (3, 4). Today they exist as foams, elastomers, coatings, adhesives, and elastomeric fibers. A major concern of the polyurethanes, polymers and silicones is the toxic health effects not only during manufacture, but also during installation, use and combustion of these materials. The exposed populations, the chemicals and types of exposure may vary considerably. This information is provided when it is available.

Polyurethanes, also called polyurethans, urethanes (these compounds should not be confused with urethane gas, a chemical used as an anesthetic), and polycarbamates, are polymers that have a urethane linkage in the polymer backbone, which is derived from the condensation of an isocyanate group and an alcohol group. A typical polyurethane may contain aliphatic and aromatic hydrocarbon moieties, linked as esters, ethers, or amides (5). Polyurethanes can be prepared by reacting bischloroformates with diamines or by other techniques, but are most commonly made by reacting isocyanates with polyhydroxy compounds. These reactions characteristically involve polycondensation by the addition of hydrogen across the carbon–nitrogen double bond of the isocyanate group (6). The term "polyurethane" now generally includes all of the complex polymers formed from diisocyanates and polyols (3).

1.0 Polyurethane

1.0.1 CAS Number: [*9009-54-5*]

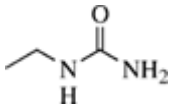
1.0.2 Synonyms: Polyurethane; polyurethane foam

1.0.3 Trade Names: NA

1.0.4 Molecular Weight: 88.109

1.0.5 Molecular Formula: $[C_3H_8N_2O]_n$

1.0.6 Molecular Structure:



1.2 Production and Use
Polyurethane compounds are formed by reacting polyisocyanates with polyalcohols (or “polyols”).

The use of polyurethane is expanding worldwide and exceeded 11 billion lb in 1990. The United States accounted for about 29% of world use (11–13). In 1991, 51% of the U.S. market was in flexible foam, 26% in rigid foam, and 23% in elastomerics and other types. Production data for polyether and polyester polyols are given in Table 93.1. Toluene diisocyanate (TDI) and 4,4'-methylenebisphenyl diisocyanate (MDI) are the principal commercial aromatic diisocyanates. Commercial aliphatic diisocyanates include isophorone diisocyanate (IPDI), hexamethylene diisocyanate (HDI), methylene cyclohexyl diisocyanate, and naphthalene diisocyanate (NDI)

Polyurethanes, Miscellaneous Organic Polymers, and Silicones
Steven T. Cragg, Ph.D., DABT

B. Miscellaneous Organic Polymers
Miscellaneous organic polymers discussed in this section include phenolics, aminoplastics including urea formaldehyde and melamine-formaldehyde; furan polymers and resins; polyvinylpyrrolidone and polybenzimiadiazole.
Phenolics
The phenolics were the first completely synthetic class of resins developed commercially and are still a major product line (Tables 93.1 and 93.4). The term phenolic describes a resinous material produced by reacting a phenol or a mixture of phenols with an aldehyde. Phenol itself, or sometimes cresols, are usually combined with formaldehyde and occasionally with other aldehydes such as furfural (3). The resin has sometimes been associated with dermatitis that is traceable to the phenolic monomer component, the resin itself, or less frequently formaldehyde. Inhalant effects from dust or fumes during processing have also been reported. No toxicologically significant emission of volatile substances is has been connected with the cured resin. Phenol-formaldehyde is highly resistant to biological decay (124). Other common resins of this class include (*1*) *p-tert*-butylphenol-formaldehyde [*25085-50-1*], (*2*) bisphenol A/epichlorohydrin/formaldehyde [*28906-96-9*], and (*3*) aniline/phenol/formaldehyde [*24937-74-4*] copolymers.

Table 93.4. Some Commercial Polymers and Approximate Year of Introduction[a]

Date	Material	Typical Application
1868	Cellulose nitrate	Eyeglass frames, table tennis balls
1900	Viscose rayon	Lining in clothing, curtains, tablecloths
1909	Phenol–formaldehyde	Telephone handset, electrical insulators
1919	Casein	Knitting needles
1926	Alkyd	Exterior paint, electrical insulators,

	distributor caps
1927 Cellulose acetate	Toothbrushes, packaging film, lacquers
1927 Polyvinyl chloride	Wall coverings, pipe, siding, flooring
1929 Urea–formaldehyde	1,1,0,3.1631,0,0,0,0,0,0,5 Lighting fixtures, wood adhesives, electrical fixtures and parts
1931 Polychloroprene	Industrial hoses, wire and cable, footwear
1935 Ethyl cellulose	Flashlight cases, coatings
1936 Acrylic	Display signs, brush backs
1936 Polyvinyl acetate	Flashbulb lining, adhesives
1937 Styrene–butadiene copolymers	Tires, footwear, molded items
1938 Cellulose acetate butyrate	Packaging, tubing, lacquers
1938 Polystyrene	Kitchenware, toys
1939 Nylon	Fibers, films, gears
1939 Polyvinylidene chloride	Packaging film, paper coating
1939 Melamine–formaldehyde	Tableware
1942 Unsaturated polyester	Boat hulls
1942 Low-density polyethylene	Packaging film, squeeze bottles
1943 Silicone	Rubber goods, motor insulation
1943 Fluoropolymers	Industrial gaskets, coatings
1943 Polyurethane	Foam cushions, insulation, adhesives
1943 Butyl rubber	Tubeless tire liner, inner tubes
1945 Cellulose propionate	Pens and pencils
1947 Epoxy	Coatings, industrial equipment
1948 1,1,0,3.1631,0,0,0,0,0,0,5 Acrylonitrile–butadiene–styrene (ABS)	Pipe and fittings, luggage, appliances
1950 Polyacrylonitrile	Sweaters, knitwear, blankets
1950 Chlorosulfonated polyethylene	Automotive hoses, wire and cable
1952 1,1,0,3.1631,0,0,0,0,0,0,5 Polyethylene terephthalate (fiber grade)	Clothing, fiberfill, sailcloth
1954	Housewares, automotive trim
1956 Styrene–acrylonitrile (SAN)	Auto parts
1956 Acetal	High-temperature seals and gaskets
1957 Fluoroelastomers	Milk bottles
1957 High-density polyethylene	Safety helmets, carpet fiber, battery cases
1957 Polypropylene	Appliance parts
1958 Polycarbonate	Wire insulation, film
1959 Fluorinated ethylene propylene	Valves and fittings
1961 Chlorinated polyether	Tires, footwear, medical items
1962 Polyisoprene (high cis)	Tires, general-purpose rubber
1962 Ethylene propylene rubber	Bottles

1964 Phenoxy	Skin packaging moldings
1964 Ionomer	High-temperature moldings
1964 Polyphenylene oxide	High-temperature films, wire coatings
1964 Polyimide	Adhesives and coatings
1965 Ethylene–vinyl acetate	Electrical/electronic parts
1965 Polysulfone	Clear moldings
1965 Poly (4-methylpentene-1)	Electrical/electronic parts
1970 Thermoplastic polyester	Piping, film
1973 Polybutylene	Telecommunications
1974 Polyphenylene sulfide	Printed circuit boards
1974 Polyethersulfone	1,1,0,3.1631,0,0,0,0,0,0,5 Clothing, reinforcement/on tires and plastic composites
1975 Aromatic polyamides	Non-food packaging
1978 Nitrile barries resins	Extruded film
1982 Linear low-density polyethylene	Electrical/electronic parts
1983 Polyetherimide	Wire and cable
1984 Polyetheretherketone	Electrical/electronic parts
1985 Aromatic copolyester	Electrical/electronic parts
1988 Liquid crystal polymers	High temperature transparent
1988 Polymethylpentene	Packaging, electrical electronic, medical products

Falcetta, Eds., *Introduction to Polymer Science and Technology*, Copyright © 1977 by John Wiley and Sons, Inc., New York, and from *Facts and Figures of the U.S. Plastics Industry*, (1991 Edition) prepared annually by The Society of the Plastics Industry, Inc., Washington, D.C.

C. Silicones

Silicones or silicon hydrides of increasing chain length up to about Si_6H_{14} are known. Above this length however, the Si–Si chain becomes thermally unstable. Commercial silicone polymers contain the siloxane link Si–O–Si.

Organic Sulfur Compounds
Howard G. Shertzer, Ph.D.

A. Mercaptans

The toxicological mechanisms for organic mercaptans (RSH, also known as thiols or sulfhydryls) are based on their chemical and biochemical properties. They are best known for their strong odors, most notably in *Allium* vegetables (garlic, onion, leek, shallot), rotting foodstuff (cabbage, eggs) and as the characteristic odorant for natural gas.

Mercaptans are the essential functional chemical moiety for synthesizing other organosulfur

compounds. They are more acidic than the corresponding alcohols and readily form the reactive soft-nucleophilic thiolate anion (RS^-). The most significant difference between the chemistry of alcohols and mercaptans is the relative ease of mercaptan oxidation that produces (in order of oxidant strength) disulfides (RSSR'), sulfoxides (RSOR'), and sulfones (RSO_2R'). Thus, mercaptan oxidation tends to occur at the sulfur atom itself, whereas the oxidation of an alcohol usually increases the oxidation state of an adjacent carbon (as in the oxidation of organic alcohols to produce aldehydes or acids). Mercaptans are extremely important in fundamental biological processes. The thiol-containing amino acid cysteine is important in maintaining proper protein structure via disulfide bonds between two cysteine residues. Cysteine is also important in regulating genetic events in cells, including DNA replication, gene transcription, and protein translation. In addition, cysteine forms the reactive moiety of the intracellular antioxidant glutathione that helps maintain the highly reduced state of cells and protects cells from potentially toxic electrophiles and radicals that may originate from metabolism or from foreign sources (xenobiotics).

Mercaptans, it has long been known, react with several heavy metals, including mercury. The formation of insoluble mercury complexes is characteristic of this class of compounds and is the source of the name *mercaptan* (*mercurium captans*, capturing mercury). Although not in current use, the dithiol 2,3-dimercapto-1-propanol (BAL, dimercaprol, British anti-Lewisite CAS Number [*59-52-9*]) was developed to protect against arsenical war gases (including Lewisite) and has been used as an antidote for exposure to arsenic, mercury, and other heavy metals. Interestingly, mercaptans such as the intracellular antioxidant glutathione activate the environmentally and occupationally important heavy metal Cr^{6+} and also the economically important solvent methylene chloride to genotoxic products.

1.0 Methyl Mercaptan

1.0.1 CAS Number: [*74-93-1*]

1.0.2 Synonyms: Mercaptomethane; methanethiol; methylthioalcohol; methyl sulfhydrate; thiomethanol

1.0.3 Trade Names: NA

1.0.4 Molecular Weight: 48.10

1.0.5 Molecular Formula: CH_4S

1.0.6 Molecular Structure:

Organic Sulfur Compounds
Howard G. Shertzer, Ph.D.

B. Sulfides

Sulfides (RSR', also known as thioethers) are weak Lewis bases and are highly nucleophilic due to the lone pairs of electrons on sulfur. Sulfides are readily oxidized to sulfoxides (RSOR') and then to

sulfones (RSO_2R'). Sulfides tend to form insoluble complexes with heavy metal salts, such as mercuric chloride. Sulfides also react with alkyl halides to form the corresponding sulfonium halide salts ($R_3S^+X^-$). Sulfides readily form disulfides (RSSR') under mild oxidizing conditions, such as in the presence of iodine. The amino acid cysteine forms intramolecular and intermolecular protein disulfide bonds to maintain proper conformation essential for activity, such as enzyme-mediated catalysis. Protein cysteinyl residues also form mixed disulfides with glutathione (protein-cysteine-*SS*-cysteine-glutathione) during episodes of cellular oxidative stress and for gene regulation. A number of cellular enzymes (thiol isomerases and reductases) are involved in regulating the oxidation state of protein disulfides.

Organic Sulfur Compounds
Howard G. Shertzer, Ph.D.

C. Sulfones, Sulfoxides, Sulfonium chlorides, Sulfonates
The formation of sulfoxides, sulfones, and sulfonium chlorides from sulfides was discussed previously. Because sulfoxides contain sulfur in an intermediate oxidation state, they are readily oxidized to sulfones or reduced to the corresponding sulfides by mercaptans, hydroiodic acid, or tertiary phosphorus (R_3P^{3+}) compounds. Sulfones are not very reactive but can be reduced to sulfides by lithium aluminum hydride or sodium borohydride. Because of electron withdrawal by the sulfone substituent group, most reactions involving sulfones occur at the electropositive a-carbon.

Sulfonic acids (RSO_3H) are stronger acids than the corresponding sulfuric acids ($ROSO_3H$), but are weaker oxidizing agents. Therefore, these compounds are used industrially as acid catalysts. Aromatic sulfonic acids are typically produced by *p*-sulfonation of the corresponding hydrocarbon (e.g., toluene + $H_2SO_4 \rightarrow$ *p*-toluenesulfonic acid). Aliphatic sulfonic acids and their salts (sulfonates) can be produced by a variety of methods, including oxidation of the corresponding mercaptan (RSH), nucleophilic displacement of the corresponding alkyl halide (RX), or a radical-mediated addition to an alkene ($RCHCH_2$). An important industrial synthesis of phenols involves reacting benzenesulfonyl chloride or other aryl sulfonates with molten sodium hydroxide.

Combustion or contact with strong oxidizing materials (including high oxygen concentrations) may yield hazardous decomposition or oxidation products.

Organic Sulfur Compounds
Howard G. Shertzer, Ph.D.

D. Benzothiazole Derivatives
When heated to decomposition, compounds containing the benzothiazole moiety emit very toxic fumes of nitrogen and sulfur oxides, as well as cyanide gas.
1.0 Benzothiazole
1.0.1 CAS Number: [*95-16-9*]

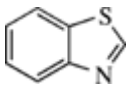
1.0.2 Synonyms: Benzosulfonazole; 1-thia-3-azaindene

1.0.3 Trade Names: NA

1.0.4 Molecular Weight: 135.2

1.0.5 Molecular Formula: C_7H_5NS

1.0.6 Molecular Structure:



1.1 Chemical and Physical Properties

Melting point (°C)	2
Boiling point	231
Specific gravity	1.238

1.2 Production and Use

Benzothiazole is an isolated intermediate used in synthesizing mercaptobenzothiazoles and substituted benzothiazole sulfenamides.

1.4 Toxic Effects

1.4.1 Experimental Studies 1.4.1.1 Acute Toxicity Following acute single doses benzothiazole is slightly to moderately toxic by both oral and dermal routes of administration. Oral LD_{50} values in the rat are 380 to 492 mg/kg. An oral LD_{50} for mice of 900 mg/kg has also been reported (82). Two dermal LD_{50} values in the rabbit have been reported: between 630 and 1000 mg/kg and between 126 and 200 mg/kg. Exposure of rats to a saturated vapor for 6 h did not cause toxicity or mortality. It is slightly irritating to rabbit skin and eye (Monsanto, Younger Laboratories, 1964 and 1976).

1.4.1.6 Genetic and Related Cellular Effects Studies No mutagenic activity was observed with or without metabolic activation in the Ames *S. typhimurium* or *S. cerevisiae* assays (Monsanto, Bionetics, 1976). A conflicting positive with *S. typhimurium* strain TA 1537 was reported with metabolic activation (117).

2.0 2-Mercaptobenzothiazole

2.0.1 CAS Number: [*149-30-4*]

2.0.2 Synonyms: 2(3H)-Benzothiazolethione; 2-benzothiazolyl mercaptan; benzothiazole-2-thione; MBT

2.2 Production and Use

2-Mercaptobenzothiazole is a cream to light yellow solid used as an accelerator in rubber vulcanization. It does not measurably hydrolyze over a 7-day period (Monsanto, ABC Laboratories, 1984).

2.4 Toxic Effects

2.4.1 Experimental Studies 2.4.1.1 Acute Toxicity The acute oral and dermal toxicities are low; LD_{50} values are >3800 mg/kg (rat) and >7940 mg/kg (rabbit), respectively (Monsanto, Younger Laboratories, 1975). An oral LD_{50} was also determined in rabbits and was in the range 7500 to 8750 mg/kg (Monsanto, Scientific Associates, 1974).

It was practically nonirritating in rabbit eye and skin irritation studies (Monsanto, Younger Laboratories, 1975). In a delayed contact sensitization assay in guinea pigs (modified Buehler), challenges from 0.5% and 2% petrolatum formulations elicited positive responses (118). A strong positive response was also reported in a Magnusson–Kligman guinea pig sensitization assay (119).

Dietary administration for 4 weeks to rats at levels of up to 2500 ppm reduced body weight increments in males at levels above 1500 ppm and in females at 2000 ppm and above. Increased liver weights were observed in all treated groups. 2-Mercaptobenzothiazole was administered by gavage (diluted in corn oil) to rats and mice of both sexes for 13 weeks at dosages up to 3000 mg/kg in rats and 1500 mg/kg in mice. Mortality was noted in rats at 3000 mg/kg and in mice at dosages of 750 mg/kg and above. Reduced body weight gains were noted in rats and mice at 750 mg/kg and above. Necrosis of the renal distal convoluted tubular epithelium was seen in rats at 3000 mg/kg (Monsanto, Monsanto Environmental Health Laboratory, 1988).

2.4.1.4 Reproductive and Developmental In a rat teratology study 2-mercaptobenzothiazole was administered to pregnant rats on days 6 to 15 of gestation at dosages of 300, 1200, and 1800 mg/kg. Signs of maternal toxicity were seen at 1200 mg/kg and above. There were some equivocal intergroup differences in postimplantation loss, but these are unlikely to be of toxicological significance. 2-Mercaptobenzothiazole was also administered to pregnant rabbits on days 6 to 18 of gestation at dosages of 50, 150, and 300 mg/kg. Signs of maternal toxicity were seen at 300 mg/kg. There were no indications of fetal or developmental toxicity at any dosage (Monsanto, Springborn Laboratories, 1991). In a two-generation reproduction study in rats, parental animals received diets that contained 2500, 8750, or 15,000 ppm from the premating period through gestation and weaning. Body weights of F1 pups were reduced at 8750 ppm and higher; similar effects were noted in all groups from day 14 of lactation in all treatment groups in the F2 generation. Reproductive indexes were unaffected by treatment at any level. Renal changes (pigmentation of proximal convoluted tubules and kidney weight increases) were seen at 8750 ppm and above in both the F0 and F1 animals. Hepatocyte hypertrophy in both sexes was seen at 8750 ppm and above in the F1 generation, which was accompanied by hepatomegaly at 8750 ppm and higher in males and at 15,000 ppm in females (Monsanto, Springborn Laboratories, 1981).

2.4.1.5 Carcinogenesis Some evidence of carcinogenicity was reported in male (increased incidences of preputial and adrenal tumors) and female F344 rats (increased pituitary and adrenal tumors). No increased tumor incidences were seen in either male or female B6C3F1 mice (Monsanto, 1993).

2.4.1.6 Genetic and Related Cellular Effects Studies 2-Mercaptobenzothiazole was not mutagenic in Ames *S. typhimurium*, *S. cerevisiae*, L5178Y mouse lymphoma, CHO/HPRT, mouse micronucleus, or dominant lethal assays (Monsanto, Bionetics, 1976; Monsanto, Pharmakon Research International, 1986; Monsanto, Litton Bionetics, 1986; Monsanto, Springborn Laboratories, 1991).

2.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization In an acute neurotoxicity evaluation in rats at dosages of 500, 1250, and 2750 mg/kg, responses to treatment were confined to nonspecific effects such as decreased motor activity, salivation, and decreased vocalization. Motor activity testing and a functional observation battery indicated that the responses were likely to be related to nonspecific effects (Monsanto, Bio-Research Laboratories, 1991).

2.4.2 Human Experience There was no evidence of primary skin irritation or delayed-contact skin sensitization following a repeated insult patch test in 50 human volunteers (Monsanto, Product Investigations, 1976). Skin sensitization reactions have been reported in humans repeatedly exposed to rubber articles containing 2-mercaptobenzothiazole (120). Positive reactions to 2-mercaptobenzothiazole or 2-mercaptobenzothiazole mixtures containing other sulfur rubber accelerators have also been reported (121, 122). Individuals that responded to 2-mercaptobenzothiazole often responded to other rubber additives, although similar cross-reactions were not seen by other investigators (123, 124).
3.0 **N**-Isopropyl-2-benzothiazolesulfenamide
3.0.1 CAS Number: [*10220-34-5*]

3.0.2 Synonyms: *N*-(1-methylethyl)-2-benzothiazolesulfenamide; *N*-isopropylbenzothiazol-2-sulfenamide
3.2 Production and Use

N-Isopropyl-2-benzothiazolesulfenamide is a solid material used as an accelerator in rubber vulcanization.
3.4 Toxic Effects
3.4.1 Experimental Studies 3.4.1.1 Acute Toxicity The acute oral and dermal toxicity is low; LD_{50} values are >7940 mg/kg (rat) and >7940 mg/kg (rabbit), respectively. Exposure of a group of six rats for 1 h to a nominal concentration of 200 mg/L did not cause any mortality (Monsanto, Younger Laboratories, 1975).

Slight eye irritation but no skin irritation were noted in rabbit irritation studies (Monsanto, Younger Laboratories, 1975).

Oral administration for 3 months to rats of both sexes at 0, 10, 50, 125, or 500 mg/kg/day reduced body weight gains in males at 500 mg/kg and increased liver weights in females at the same level. There was no other evidence of systemic toxicity, and microscopic examination of the livers from female animals did not provide any corroborative evidence for an adverse effect on the liver of females at the high dosage (Monsanto, Monsanto Environmental Health Laboratory, 1988).

3.4.1.6 Genetic and Related Cellular Effects Studies No evidence of genotoxicity was found in an Ames *S. typhimurium* assay with and without metabolic activation, an *in vitro* cytogenetics assay in Chinese hamster ovary cells with or without metabolic activation, or in an *in vitro* unscheduled hepatocyte DNA synthesis (UDS) assay (Monsanto, Stanford, Research Institute, 1986).

3.4.2 Human Experience Patch testing of a panel of 54 human volunteers using a 1% preparation demonstrated the material was not a primary skin irritant but one individual demonstrated a positive response for delayed contact sensitization. The material is considered to possess weak sensitization potential at this concentration (Monsanto, Product Investigations, 1986).
4.0 **N**,**N**-Diisopropyl-2-benzothiazolesulfenamide
4.0.1 CAS Number: [*95-29-4*]

4.0.2 Synonyms: *N*,*N*-Bis(1-methylethyl)-2-benzothiazolesulfenamide
4.1 Chemical and Physical Properties
It is completely hydrolyzed to mercaptobenzothiazole and isopropylamine during an 8-day period at pH 8.0; hydrolysis occurs more readily at lower pH values (Monsanto, ABC Laboratories, 1984).
4.2 Production and Use
It is a solid material used as an accelerator in rubber vulcanization.
4.4 Toxic Effects
4.4.1 Experimental Studies 4.4.1.1 Acute Toxicity The acute oral and dermal toxicity is low; LD_{50} values are 5700 mg/kg (rat) and >2000 mg/kg (rabbit), respectively. An oral LD_{50} value in mice was 3892 mg/kg (Monsanto, Bio/dynamics Inc., 1982).

Slight eye (mild, transient irritation of the conjunctiva) and slight skin (slight erythema and edema) irritation were observed in rabbit irritation studies (Monsanto, Bio/dynamics Inc., 1982).

Oral administration to rats of both sexes for 3 months at 0, 250, 500, or 100 mg/kg/day reduced body weight increments in males at 500 mg/kg and higher. Increased absolute and relative liver weights in both sexes at all dosages were related to hepatocellular hypertrophy. There was an accumulation of hyaline droplets in the renal tubular epithelium in males at all dosages. This finding was not present in females, but a brown pigment was present in the same cells in females at dosages of 500 mg/kg and above (Monsanto, Monsanto Environmental Health Laboratory, 1987).

4.4.1.6 Genetic and Related Cellular Effects Studies No evidence of mutagenicity was found in an Ames *S. typhimurium* assay or in *S. cerevisiae* (Monsanto, Bionetics, 1976). It was also negative in an *in vitro* unscheduled heptocyte DNA synthesis assay. An *in vitro* chromosomal aberration assay in Chinese hamster ovary cells was positive without metabolic activity but not when a source of

metabolic activation was included (Monsanto, SRI International, 1986). This positive result is not considered indicative of a clastogenic hazard when compared to a negative *in vivo* rat bone marrow cytogenetics assay following oral administration of 2850 mg/kg and bone marrow cell harvests at 6, 18, and 30 h after administration (Monsanto, Pharmakon Research International, 1987).

4.4.2 Human Experience Patch testing of a panel of 54 human volunteers using a 1% preparation in petrolatum indicated that the material was neither a primary skin irritant nor a delayed contact sensitizer (Monsanto, Product Investigations, 1986). Patch testing of humans previously demonstrated as sensitized to 2-mercaptobenzothiazole gave positive results, although the likely presence of impurities and inadequate documentation of sample quality and source render the validity of this result questionable (123).
5.0 **N-tert**-Butyl-2-benzothiazolesulfenamide
5.0.1 CAS Number: [*95-31-8*]

5.0.2 Synonyms: *N*-(1,1'-dimethylethyl)-2-benzothiazolesulfenamide
5.1 Chemical and Physical Properties
It is completely hydrolyzed to 2-mercaptobenzothiazole and *tert*-butylamine within a 25-h period at pH 7.0; the hydrolysis rate is slower at pH 9.0 (Monsanto, ABC Laboratories, 1984).
5.2 Production and Use
It is a solid material used as an accelerator in rubber vulcanization.
5.4 Toxic Effects
5.4.1 Experimental Studies 5.4.1.1 Acute Toxicity The acute oral and dermal toxicities are low; LD_{50} values are >6310 mg/kg (rat) and >7940 mg/kg (rabbit), respectively. Slight eye irritation and minimal skin irritation were defined in rabbit irritation studies (Monsanto, Younger Laboratories, 1973). A 25% solution in ethanol did not induce any delayed-contact sensitization reactions in a guinea pig sensitization (Buehler) assay (Monsanto, Pharmakon Research International, 1982).

Oral administration for 3 months to rats of both sexes at 0, 100, 300, or 1000 mg/kg/day reduced body weight increments in males at dosages of 300 mg/kg and higher. Liver and kidney weights were also increased in females at 1000 mg/kg, but there was no microscopic evidence of morphological change in these organs and the findings were not considered of toxicological significance (Monsanto, Monsanto Environmental Health Laboratory, 1982). A dust inhalation study of rats (6 h/day, 5 days/week) for 4 weeks at 0, 2.4, 29, and 84mg/m^3 elicited morphological effects on the liver and lymph nodes at 84mg/m^3 that were detected during microscopic examination (Monsanto, International Research and Development Corporation, 1978). Repeated daily dermal applications of 0, 125, 500, or 2000 mg/kg/day caused slight dermal irritation but no evidence of systemic toxicity (Monsanto, International Research and Development Corporation, 1979).

5.4.1.4 Reproductive and Developmental No maternal toxicity, fetal toxicity, or developmental toxicity were seen in rats following oral administration of 0, 50, 150, or 500 mg/kg/day to pregnant female rats on days 6 to 15 of gestation (Monsanto, International Research and Development Corporation, 1978).

5.4.1.6 Genetic and Related Cellular Effects Studies No evidence of mutagenicity was found in Ames *S. typhimurium*, *E. coli*, *S. cerevisiae*, or Chinese hamster ovary HPRT assays (125; Monsanto, Bionetics, 1978). Positive results were obtained in mouse lymphoma assays of L5178Y cells with metabolic activation (Monsanto, Bionetics, 1978). Cell transformation was noted at the highest concentration tested in BALB/3T3 cells, but significant cytotoxicity may confound the relevance of this finding (Monsanto, Monsanto Environmental Health Laboratory, 1993).

5.4.2 Human Experience Patch testing of a panel of 54 human volunteers using a 60% preparation in petrolatum indicated the material was not a primary skin irritant, but a strong delayed contact sensitization response occurred (Monsanto, Product Investigations, 1982). Patch testing of humans previously demonstrated to be sensitized to 2-mercaptobenzothiazole gave positive results, although

the likely presence of impurities and inadequate documentation of sample quality and source render the validity of this result questionable (123).
6.0 **N**-Cyclohexyl-2-benzothiazolesulfenamide
6.0.1 CAS Number: [*95-33-0*]
6.1 Chemical and Physical Properties
It is a pale, buff-colored powder or granule completely hydrolyzed within 25 h at pH 7.0 (Monsanto, ABC Laboratories, 1984).
6.2 Production and Use
N-Cyclohexyl-2-benzothiazolesulfenamide is used as an accelerator in rubber vulcanization.
6.4 Toxic Effects
6.4.1.1 Acute Toxicity The acute oral and dermal toxicities are low; LD_{50} values are 5300 mg/kg (rabbit) and >7940 mg/kg (rat), respectively (Monsanto, Younger Laboratories, 1973). It is slightly irritating to the rabbit eye (Monsanto, Younger Laboratories, 1973) and practically nonirritating to rabbit skin (Monsanto, Pharmakon Research International, 1982).

In a guinea pig delayed-contact skin sensitization assay (Buehler) using a 25% preparation in ethanol, no evidence of sensitization was found after challenge with the 25% solution. No evidence of comedogenicity was detected in rabbits when solutions in chloroform up to 10% were applied to the inner surface of the ears for 4 weeks (Monsanto, Pharmakon Research International, 1982).

Dermal application of up to 2000 mg/kg/day to intact and abraded skin of rabbits for 21 days did not elicit any evidence of toxicity (Monsanto, International Research and Development Corporation, 1979). Inhalation exposure of rats for 4 weeks (5 days/week) to dust concentrations of 4.3, 14.4, and 48.0 mg/m^3 caused microscopic lesions of the conjunctivas, lymph nodes, and spleen at 48 mg/m^3. Elevated aspartate aminotransferase activities at 14.4 mg/m^3 and above were not associated with any morphological abnormalities (Monsanto, International Research and Development Corporation, 1978). Administration to rats of diets that contained levels approximating 100, 250, 500, 1000, or 3000 mg/kg for 4 weeks reduced food intake and body weight gain at 500 mg/kg and higher; there was no other evidence of systemic toxicity (Monsanto, International Research and Development Corporation, 1979). Administration to rats by gavage for 5 weeks (5 days/week) of dosages up to 1.25 mg/kg/day reduced body weight gain and increased thyroid weights relative to body weight. There was no evidence of pathological change, so the thyroid weight finding may reflect reduced body weight gain (Monsanto, 1993).

superscript Excretion After a single oral dosage of 250 mg/kg of ^{14}C-labeled material 65 and 24% of the dose was excreted with in 3 days in the urine and feces, respectively. Biliary excretion over this period accounted for approximately 5% of the dose. There was no evidence of selective accumulation or concentration in any organs. The urinary metabolites were identified as cyclohexylamine and 2-mercaptobenzothiazole (129).

6.4.1.4 Reproductive and Developmental Oral administration to pregnant rats of dosages of up to 500 mg/kg on days 6 to 15 of gestation caused maternal toxicity at 500 mg/kg and concomitant reduction in fetal body weight; there were no teratological responses at this dosage. No maternal or fetal effects were noted at 300 mg/kg (Monsanto, International Research and Development Corporation, 1978). In a separate study, oral administration, of dosages of 50, 150 and 450 mg/kg to pregnant rats during organogenesis, produced maternal toxicity at the highest dosage and dose-dependent fetal toxicity (fetuses/litter and hydrocephalus) (126). These investigators found that the dosage of 450 mg/kg produced embryotoxicity, shown by increases in late resorptions and post implantation losses, decreased fetal body weight and length, and subcutaneous hemorrhage (127). In another study, dietary administration at dietary levels approximating dosages of 0.7, 7.1, 69.6, and 288.8 mg/kg to pregnant female rats on days 0 to 20 of gestation caused reduced maternal food intake and body weight gains at 288.8 mg/kg and a concomitant reduction of fetal body weight. Maternal body weight gain was also reduced at 69.6 mg/kg, although there were no effects on fetal body weight. No effects on pre- or postimplantation loss, litter size, or the incidence of

malformations or visceral or skeletal variations were reported (128).

6.4.1.6 Genetic and Related Cellular Effects Studies No evidence of mutagenicity either with or without metabolic activation was found in the Ames *S. typhimurium, E. coli*, or Chinese hamster ovary HPRT assays (Monsanto, Bionetics, 1976; Monsanto, 1993), the *S. cerevisiae* assay (Monsanto, Bionetics, 1976), or the L5178 mouse lymphoma assay (Monsanto, Bionetics, 1978).

6.4.2 Human Experience Occupational exposure reportedly causes irritation of the eyes, skin and upper respiratory tract. Patch testing of a panel of 51 human volunteers using a 70% preparation in petrolatum did not cause primary or cumulative irritation, but sensitization responses occurred in 5 of the 51 subjects (Monsanto, Product Investigations, 1982). The literature contains many reports of skin sensitization, but in most cases the patients were also sensitized to other components of the "mercapto mix" used for skin testing. Industrial experience indicates that this material is a weak sensitizer.
7.0 **N,N**-Dicyclohexylbenzothiazolesulfenamide
7.0.1 CAS Number: [*4979-32-2*]

7.0.2 Synonyms: *N,N*-dicyclohexyl-1-benzothiazolesulfenamide.
7.2 Production and Use
It is an off-white solid, a powder or pellet, that is used as an accelerator in rubber vulcanizing.
7.4 Toxic Effects
7.4.1 Experimental Studies 7.4.1.1 Acute Toxicity The material has low acute oral and dermal toxicities; LD_{50} values are >5000 mg/kg (rat) and >2000 mg/kg (rabbit), respectively. It was practically nonirritating in rabbit skin and eye assays (130); (Monsanto, Bio/Dynamics Inc., 1984). Using the Magnusson–Kligman maximization assay for delayed-contact cutaneous sensitization, it was concluded that it is not a skin sensitizer (Monsanto, International Research and Developmental Corporation, 1984).

7.4.1.2 Chronic and Subchronic Toxicity Administration to rats in the diet for 4 weeks at 2000 to 10,000 ppm caused a dose-related decrease in food consumption and body weight increments at all dietary concentrations. There was no evidence of any systemic toxicity based on evaluations of the cellular and chemical constituents of blood, organ weight analysis, or macroscopic pathology examinations (130); (Monsanto, Bio/Dynamics Inc., 1987). Administration to rats in the diet for 13 weeks at 2500 or 5000 ppm decreased food intake and reduced body weight increments at both dietary concentrations. There was no evidence of any systemic toxicity or microscopic pathology changes at either dietary concentration. The no-effect level on subchronic administration in the diet was 500 mg/kg diet (130; Monsanto, Monsanto Environmental Health Laboratory, 1988).

7.4.1.5 Carcinogenesis An increased incidence of sarcomas occurred at the site of subcutaneous administration of 20 g/kg body weight, administered as 1 g/kg body weight at irregular intervals during 413 days (130). However, there was no evidence for mutagenic or clastogenic effects in the Ames *S. typhimurium* assay, the Chinese hamster ovary HPRT assay, and an *in vitro* hepatocyte DNA repair (UDS) assay, or in an *in vivo* rat bone marrow chromosomal aberration assay after oral administration of a single 1000-mg/kg dose (130); (Monsanto, Pharmakon International, 1984; Monsanto, Hazelton Laboratories, 1984; Monsanto, 1993; Monsanto, SRI International, 1984).

Organophosphorus Compounds
Jan E. Storm, Ph.D

1.0 Introduction
Organophosphate pesticides are a highly diverse group of chemicals to which workers may be exposed during manufacture and formulation and during or after application for their intended uses (1, 2). They are all characterized by their ability to inhibit the enzyme acetylcholinesterase (AChE) that deactivates the neurotransmitter acetylcholine (ACh).

Compounds in this class are numerous and have been categorized in many ways according to the nature of the substituents. Gallo and Lawryk, for example, categorized them into four main categories (Groups I-IV) based on the characteristics of the leaving group (X) (1). Group I compounds, phosphorylcholines, have a leaving group that contains a quaternary nitrogen and are among the most potent organophosphates (e.g., Shradan). Group II compounds, fluorophosphates, have a fluoride leaving group and are also generally highly toxic (e.g., diisopropyl fluorophosphate). Group III compounds have leaving groups that contain cyanide or a halogen other than fluoride and are generally less potent than Groups I or II (e.g., Parathion). Group IV contains most of the organophosphates used as insecticides today. These compounds have alkoxy, alkylthio, aryloxy, arylthio or heterocyclic leaving groups and a wide variety of other substituents.

Another classification scheme is based on the nature of the atoms that immediately surround the central phosphorus atom and results in 14 different categories (2). According to this scheme, phosphates are the prototype for the entire class and are those compounds where all four atoms that surround the phosphorus atom are oxygen (e.g., dichlorvos, mevinphos). Sulfur-containing organophosphate compounds (phosphorothioates; phosphorothiolates; phosphorodithioates; phosphorodithiolates) are far more numerous than phosphates and include well recognized organophosphate insecticides such as parathion, diazinon, chlorpyrifos, etc. Other groups contain nitrogen (phosphoramides and phosphorodiamides), nitrogen and sulfur (phosphoramidothionates and phosphoramidothiolates), carbon (phosphonates and phosphinates), or carbon and sulfur (phosphonothionates, phosphonothionothiolates and phosphinothionates).

All aspects of organophosphate chemistry, toxicity, analysis, and exposure potential have been previously reviewed (1–9). Additionally information regarding the toxicity of this class of compounds has expanded greatly in recent years as a result of toxicity data supplied by registrants to the U.S. EPA's Office of Pesticides to support reregistration. These data are being made publically available by the U.S. EPA on their internet web site (9a). The following discussion draws heavily from recent reviews but also includes summaries of relevant toxicity data submitted to the U.S. EPA available when this chapter was completed. Due to space limitations detailed data reviews are

included here for only 30 organophosphate pesticides. Information on other pesticides registered or undergoing reregistration in the United States can be readily obtained from the previously mentioned website.

1.1 Production and Use

Organophosphates are the most widely used insecticides today; more than 40 are currently registered for use in the United States (3). They were the number one cause of symptomatic illnesses reported in 1996, according to the American Association of Poison Control Centers (3). The earliest organophosphates (e.g., schradan) were initially developed as war gases, and they have also been used as therapeutic agents, gasoline additives, hydraulic fluids, cotton defoliants, fire retardants, plastic components, growth regulators, and industrial intermediates (363). Their use as insecticides far exceed these uses.

Organophosphorus Compounds
Jan E. Storm, Ph.D

2.0 Azinphos-Methyl

2.0.1 CAS Number:

[*86-50-0*]

2.0.2 Synonyms:

Phosphorodithioic acid *O*,*O*-dimethyl-*S*-((4-oxo-1,2,3,-benzotirazin-3 (4*H*)-yl)methyl)ester; metiltriazotion guthion; Guthion, Gusation; S-(3,4-dihydro-4-oxobenzo[d][1,2,3]triazin-3-ylmethyl) *O*,*O*-dimethyl phosphorodithioate; Azinphos-Me; Gusathion; Methyl guthion; Guthion(R); Phosphorodithioic acid *O*,*O*-dimethyl *S*-[4-oxo-1,2,3-benzotriazin-3(4*H*)-yl)methyl] ester; phosphorodithioic acid *O*,*O*-dimethyl ester, *S*-ester with 3-mercaptomethyl-1,2,3-benzotriazin-4 (3*H*)-one; Bayer 17147; Cotnion-methyl; Gusathion M; Azimil; Bay; R 1582; Gusthion M; Gution; *O*,*O*-dimethyl *S*-(4-oxobenzotriazino-3-methyl) phosphorodithioate; *S*-(3,4-dihydro-4-oxo-1,2,3-benzotriazin-3-ylmethyl) *O*,*O*-dimethyl phosphorodithioate; azinophos-methyl; bay 9027; bay 17147; bayer 9027; 3-(mercaptomethyl)-1,2,3-benzotriazin-4(3*H*)-one *O*,*O*-dimethyl phosphorodithioate; carfene; cotneon; crysthion 21; crysthyon; DBD; *O*,*O*-dimethyl *S*-(benzaziminomethyl) dithiophosphaate; *O*,*O*-dimethyl *S*-(1,2,3-benzotriazinyl-4-keto)methyl phosphorodithioate; *O*,*O*-dimethyl *S*-(3,4-dihydro-4-keto-1,2,3-benzotriazinyl-3-methyl) dithiophosphate; dimethyl dithiophosphoric acid *N*-methylbenzazimidyl ester; *O*,*O*-dimethyl *S*-(4-oxo-3*H*-1,2,3-benzotriazine-3-methyl) phosphorodithioate; *O*,*O*-dimethyl *S*-(4-oxo-1,2,3-benzotriazino (3)-methyl) thiothionophosphatae; *O*,*O*-dimethyl *S*-4-oxo-1,2,3-benzotriazin-3(4*H*)-ylmethyl phosphorodithioate; gothnion; gusathion-20; gusathion 25; gusathion k; gusathion methyl; 3-(mercaptomethyl)-1,2,3-benzotriazin-4(3*H*)-one *O*,*O*-dimethyl phosphorodithioate *S*-ester; methylazinphos; *N*-methylbenzazimide, dimethyl dithiophosphoric acid ester; metiltriazotion; Beetle Buster; Ketokil No. 52; Crysthyon 2L; Dimethoxy ester of (4-oxo-1,2,3-benzotriazin-3(4*H*)-yl) methyl ester of dithiophosphoric acid; dimethyl *S*-((4-oxo-1,2,3-benzotriazin-3(4*H*)-yl)methyl) phosphorodithioate; dimethyl *S*-(3-(mercaptomethyl)-1,2,3-benzotriazin-4(3*H*)-one) phosphorodithioate; Methyl gusathion; Guthion (Azinphos-Methyl)

2.0.3 Trade Names:

Guthion®, Gusathion®, methyl Guthion, Azimil, Bay 9027, Bay 17147, Carfene

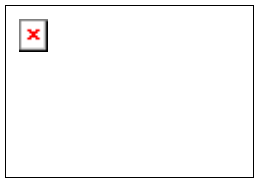
2.0.4 Molecular Weight:

317.34

2.0.5 Molecular Formula:

$C_{10}H_{12}N_3O_3PS_2$

2.0.6 Molecular Structure:



2.1 Chemical and Physical Properties

Pure azinphos-methyl is a white crystalline solid; the technical material is a brown, waxy solid.

Specific gravity	1.44 at 20°C
Melting point	pure 73–74°C; technical 65–68°C; unstable at temperatures higher than 200°C
Solubility	soluble in methanol, ethanol, propylene glycol, xylene, and other organic solvents: slightly soluble in water (33 mg/L)
Vapor pressure	$<3.8 \times 10^{-4}$ mmHg at 20°C

2.2 Production and Use

Azinphos-methyl is an insecticide used for control of pests on various fruits, melons, nuts, vegetables, field crops, ornamentals and shade trees. It is formulated as a liquid (20% active ingredient) and a wettable powder (20–50% active ingredient). Azinphos methyl is a restricted use pesticide.

2.3 Exposure Assessment

Absorption after dermal exposure constitutes the primary source of azinphos-methyl exposure (57a). Urinary alkyl phosphate metabolites of azinphos-methyl have been proposed as reliable markers of exposure regardless of the route of exposure (58–66).

2.4 Toxic Effects

2.4.1.1 Acute Toxicity Azinphos-methyl is a highly acutely toxic organophosphate that has oral LD_{50}s of 4–20 mg/kg, (242). The dermal LD_{50} for azinphos-methyl is 220 mg/kg in both males and females (64a). One-hour LC_{50} values in rats for azinphos-methyl are 310 to 396 mg/m^3. Four-hour LC_{50} values in rats are 107–155 mg/m^3 (61). An oral LD_{50} of 7 mg/kg and an LD_{01} of 4–5 mg/kg in male and female mice, respectively, demonstrated that the dose–lethality curve is very steep (62). At the LD_{50}, cholinergic signs occur within 4–6 minutes; death usually occurs within 10–30 minutes. Rats tolerated cumulative oral doses of up to five to ten times the LD_{50} given as daily doses of 0.5–2 mg/kg for 2–8 weeks demonstrating the lack of cumulative toxicity.

When 2, 6, or 12 mg/kg (males) and 1, 3, or 6 mg/kg (females) azinphos-methyl was given by gavage to rats, plasma and RBC cholinesterase inhibition occurred at the lowest dose tested (63). Brain cholinesterase inhibition and cholinergic effects occurred in males and females at 6 and 3 mg/kg, respectively. A high incidence of mortality (28% males and 83% females) was observed at the 6- and 12-mg/kg dose.

Azinphos-methyl did not cause acute delayed neurotoxicity in atropinized hens administered 0.1, 1.0, 10.0, 100.0 or 300 mg/kg in corn oil followed by a second dose at 21 days.

Azinphos methyl was judged to be a mild eye irritant, but nonirritating to the skin, and it did produce dermal sensitization in guinea pigs (242).

2.4.1.2 Chronic and Subchronic Toxicity A 90-dose LD_{50} was 10.5 mg/kg for rats fed ground chow that was contaminated with azinphos-methyl (196). Using the 90-dose LD_{50} and the single dose LD_{50} of 11.0 mg/kg (196), a “chronicity factor” (single-dose $LD_{50/90}$ dose LD_{50}) of about 1 was

calculated, indicating that azinphos-methyl did not have a cumulative effect.

When rabbits were treated dermally with 2, 4, 8 or 20 mg/kg azinphos-methyl for 6 h/day, 5 days/week, 15 times over three weeks, RBC cholinesterase activity was inhibited at 4 mg/kg/day and higher (242). Spleen and kidney weights increased in males and body weight gain decreased in females at this exposure level.

In rats fed diets that contained 15, 45, 90 (females), or 120 (males) ppm azinphos-methyl (about 0.9, 2.8, and 7.9 mg/kg/day (males) and 1.1, 3,2, and 7.0 mg/kg/day (females)) for 13 weeks, body weight gain decreased in both males and females fed 120 or 90 ppm, respectively (63). In males, 120 ppm (7.9 mg/kg/day) was associated with increased reactivity and autonomic cholinergic; no cholinergic signs were associated with 45 or 15 ppm. In females, 90 ppm (7.0 mg/kg/day) was associated with neuromuscular cholinergic signs and perianal staining; 45 ppm (3.2 mg/kg/day) was associated with increased reactivity and urine stains; no cholinergic effects were associated with the 15-ppm diet. Brain and RBC cholinesterase was inhibited at all dietary levels. In dogs given dietary levels of 0, 20, 50, 100, 200, or 400 ppm azinphos-methyl for 19 weeks, dose-related cholinesterase inhibition (whole blood) was observed at all dose levels. No information was provided on the occurrence of cholinergic effects.

In rats exposed to 0.195, 1.24, or 4.72 mg/m^3 azinphos-methyl aerosol for 6 h/day 5 days/wk, for 12 weeks, no effects occurred at the two lower exposure levels (242). Male rats exposed to 4.72 mg/m^3 showed lower body weight gain, and plasma and RBC cholinesterase inhibition (30–40%) occurred in both sexes exposed to 4.72 mg/m^3. Brain cholinesterase activity was not affected at any dose.

2.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Studies that showed that oral, intraperitoneal, inhalation, and intravenous LD_{50}s and LC_{50}s are equivalent on a milligram per kilogram basis indicate that azinphos-methyl is equally well absorbed following oral or inhalation exposures. Neither oral nor inhalation absorption has been quantified. However, a study in humans showed that about 70% of an intravenous dose was absorbed and excreted within 5 days (66). About 30% of the dose was excreted in the urine in the first 24 hours after exposure; 20% was excreted in the second 24 hours, and 11% was excreted in the third 24 hours. An i.v. elimination half-life of 30 hours was calculated.

Dermal absorption of azinphos-methyl can be considerable. Dermal absorption of azinphos-methyl was determined in rats exposed to 0.93, 9.3 and 93 mg azinphos-methyl/cm^2 as the wettable powder (equivalent to 0.056, 0.56, or 5.6 mg/kg) on their clipped dorsal skin (242). By 10 hours, 32%, 22%, and 24% of the applied doses respectively, remained on the skin, suggesting that absorption had been 68%, 78%, and 76% of the applied dose (uncorrected using intravenous absorption), respectively. To simulate worker exposure, the test site of rats exposed for 24, 72 and 168 hours was wiped with a moistened gauze pad after 10 hours of exposure. Maximum systemic absorption occurred 168 hours after exposure, and 42% 22% and 18% of the applied dose was recovered in urine, feces, carcass, and cage wash combined for the 0.056, 0.56 and 5.6 mg/kg doses, respectively. In humans, about 16% of an applied dermal dose (4 mg/cm^2 on ventral forearm) was absorbed within 5 days. About 5.5% of the applied dose was excreted in urine within the first 24 hours, 5% was excreted during the second 24 hours, and 3% was excreted during the third 24 hours (corrected using intravenous excretion).

By 72 hours after oral dosing of rats with azinphos-methyl, 92–109% of the dose had been excreted. Between 63–79% of the dose was eliminated in urine, and between 20–27% was eliminated in feces. The highest residual concentrations of dose occurred in the blood, kidney, live, lung, and brain.

Azinphos methyl requires metabolic activation to azinphos-methyl oxon by microsomal mixed-function oxidases to inhibit cholinesterase (67). However, hydrolytic deactivation of the active

metabolic is also very rapid (67). *In vitro* studies of azinphos-methyl metabolism indicate that metabolism of azinphos-methyl in rats proceeds largely through the actions of glutathione *S*-transferase and a mixed-function oxidase (242).

Cysteinyl methyl benzazimide sulfone (13–20% of the dose) and methyl sulfonly methyl benzazimide (14–20% of the dose) were the major urinary metabolites in rats given oral doses of azinphos-methyl (67). In feces, the methyl sulfonly methyl benzazimide, cysteinyl methyl benzazimide sulfoxide, desmethyl isoazinphos-methyl, azinphos-methyl oxygen analog, and methyl thiomethyl benzazimide were identified, but did not comprise greater than 5% of the administered dose. No azinphos-methyl or glucuronic or sulfate conjugates were found in urine or feces.

2.4.1.4 Reproductive and Developmental Azinphos-methyl did not cause developmental effects or fetotoxicity at maternally nontoxic doses when given to rats (0.5–2 mg/kg/day) or rabbits (1–6 mg/kg/day) during gestation, at maternally nontoxic doses (242).

In a two-generation reproductive study, rats were given diets that contained 5, 15, or 45 ppm azinphos-methyl (0.25, 0.75 or 2.25 mg/kg/day) (242). Increased dam mortality, decreased body weight of parental males and F1 males and females, and cholinergic signs (“poor condition”, convulsions) occurred among rats given 45 ppm. Reduced pup viability and lactation indexes (death between postnatal days 0–5 and 5–28) and decreased mean total litter weights at weaning on postnatal day 28 occurred among rats given 15 and 45 ppm. No adverse effects occurred among rats given 5 ppm. In a supplementary study, rats were given diets that contained 15 or 45 ppm azinphos-methyl (0. 43, 1.30 or 3.73 mg/kg/day (males); 0.55, 1.54, or 4.87 mg/kg/day (females)) for one year. The pup viability index (death of offspring during postnatal days 0–5) was reduced, and pup weights decreased at postnatal days 14 and 21 among the 15- and 45-ppm groups, but not the 5-ppm group. At 45 ppm, reduction in brain cholinesterase activity occurred in pups on postnatal days 5 and 28; a reduction in brain weight occurred on postnatal day 5 but not day 28.

2.4.1.5 Carcinogenesis In a 52-week study, dogs were given diets containing 5, 25, or 125 ppm azinphos-methyl (equivalent to 0.149, 0.688, or 3.844 mg/kg/day (males); 0.157, 0.775, or 4.333 (females)) (242). Mucoid diarrhea occurred in males given 25 ppm and in males and females that received 125 ppm. Both sexes given 125 ppm exhibited inhibition of plasma, RBC, and brain cholinesterase that began at week 4 of treatment and continued until week 52. In an earlier study, dogs given diets that contained 20 ppm azinphos-methyl for 36 weeks exhibited “irregular, slight” RBC cholinesterase depression, dogs given diets that contained 50 ppm for 15 months exhibited “slight to moderate” RBC cholinesterase inhibition, dogs given diets that contained 100 ppm exhibited “moderate” RBC cholinesterase inhibition; and dogs given diets that contained 150 ppm for 27 weeks followed by a diet that contained 300 ppm for 21 weeks exhibited “severe” (>75% inhibition) RBC cholinesterase inhibition (64). Cholinergic signs occurred only in dogs given 300 ppm.

When rats were given diets that contained 5, 15, and 45 ppm azinphos-methyl (equivalent to 0, 0.25, 075, and 2.33 mg/kg/day (males); 0.31, 0.96 and 3.11 mg/kg/day (females)) for up to 24 months, no cholinergic signs occurred, nor was clinical chemistry affected (242). There was, however, a marked inhibition of RBC, plasma and brain cholinesterase at 45 ppm, inhibition of RBC cholinesterase in males at 15 ppm, and, inhibition of RBC and plasma cholinesterase in females at 15 ppm. At 5 ppm, RBC cholinesterase decreased by 12% in male rats. When rats were fed a diet that had 50 ppm azinphos-methyl for 47 weeks followed by 100 ppm for 49 weeks, consistently depressed brain, plasma, and RBC cholinesterase activity occurred. When they were given a diet of 20 ppm for 97 weeks, depression of plasma and RBC cholinesterase activity occurred that decreased as the study progressed; exposure to diets of 2.5 or 5 ppm had no effect (64). Convulsions were seen in a “small number of female rats” (*sic*) (5/40) after increasing their dietary exposure from 50 to 100 ppm.

When azinphos-methyl was fed to mice at 0, 5, 20, or 40 ppm (about 0.79, 3.49, 11.33 (males); 0.98, 4.12, 14.30 (females)) for two years, no compound-related toxicity or evidence of cancer occurred

(242). However, up to 80% inhibition of plasma, RBC, and brain cholinesterase activity occurred in mice given 20 and 40 ppm. At 5 ppm, RBC cholinesterase was still slightly inhibited.

In a chronic bioassay, rats were fed diets that contained 78 or 156 ppm (males) or 62.5 or 125 pm (females) azinphos-methyl for 80 weeks, then observed for 34-35 weeks, and mice were fed diets that contained 31.3 or 62.5 ppm (males) or 62.5 or 125 ppm (females) for 80 weeks, then observed for 12–13 weeks (65). Body weight gain decreased in male rats and mice given either diet and in female rats or mice given the high dose diet. Signs of organophosphate intoxication (hyperactivity, tremors, dyspnea) occurred "in a few animals of both species" (*sic*) fed the higher dose diets. During the second year, cholinergic toxicity occurred at both dietary levels. An equivocal increase in the incidence of tumors of the pancreatic islets and follicular cells of the thyroid suggested, but did not provide sufficient evidence of, carcinogenicity in male rats. There was no increased incidence of tumors of any kind among mice.

2.4.1.6 Genetic and Related Cellular Effects Studies Azinphos-methyl with and without metabolic activation showed no evidence of mutagenicity in *Salmonella typhirium* (242). Azinphos-methyl was also negative in the reverse mutation induction assay with *Sacharomyces cerevisiae* and in the primary rat hepatocyte unscheduled DNA synthesis assay (242). In an *in vitro* cytogenetics assay using human lymphocytes, azinphos-methyl was clastogenic only with a metabolic activating system (242). However, a clastogenic effect was not observed in femoral marrow prepared from mice treated intraperitoneally with 5 mg/kg azinphos-methyl (242).

2.3.5 Biomonitoring/Biomarkers Among rats exposed dermally to 100, 200 or 400 mg azinphos-methyl on the shaved dorsal skin in the scapular region, there was a good correlation between dose and amount of dimethylthiophosphate in urine (69).

Studies of agricultural field workers exposed to azinphos-methyl have shown that they excrete dimethyl phosphate (DMP), dimethyl thiophosphate (DMTP), and dimethyl dithiophosphate (DMDTP) in urine (59, 60, 69–71). However, urinary metabolite excretion is not always well correlated with serum or RBC cholinesterase inhibition (60, 71).

2.4.2 Human Experience 2.4.2.2.1 Acute Toxicity A pilot who had spilled azinphos-methyl concentrate on his hands experienced visual disturbances, headache, tightness in the chest, abdominal cramps, nausea, vomiting, weakness and some excessive salivation (72).

2.4.2.2.2 Chronic and Subchronic Toxicity Work in orchards treated with azinphos methyl is associated with blood cholinesterase activity reductions of up to 70% (30% of pre exposure baseline) and that intake is primarily due to dermal exposures (70). It was estimated that workers who sprayed apple orchards (with solutions of 0.5 to 6 lb of 25% wettable powder per 100 gallons of water) were exposed to 0.05 to 2.55 mg/m^3 (average 0.64 mg/m^3) azinphos-methyl for periods of 15 to 45 minutes; workers responsible for filling tanks were exposed to 0.26 to 6.20 mg/m^3 (average 2.76 mg/m^3) azinphos-methyl for brief periods; and formulators were exposed to 1.07 to 9.64 mg/m^3, presumably for 8 hours/day. In all cases, dermal exposures exceeded inhalation exposure when quantified on a milligram per day basis. Serum cholinesterase activities were slightly depressed (78–91% of preexposure levels) after exposure, but no other effects were noted (73).

Orchardists who sprayed azinphos-methyl (wettable powder) were potentially exposed to an average concentration of 0.05 mg/m^3 (range 0.02–0.11 mg/m^3) based on air concentrations "measured near the spraymen during spraying operations," although inhalation exposures were probably significantly less than this because workers reportedly wore respirators. Dermal exposures were estimated at from 9 to 43 mg/kg. No evidence of serum or RBC cholinesterase inhibition was observed (57a). However, in another study of orchard workers, where exposures were primarily dermal (ranging up to 8,315 mg/hand wipe sample in thinners; up to 14,498 mg/sample on shirts of harvesters), median RBC cholinesterase activity declined by about 19% during a 6-week spraying season, and median

plasma activity fell by about 12% (60).

Workers engaged for 5 days in thinning a peach orchard after it was treated with azinphos-methyl, showed very slightly inhibited RBC cholinesterase activity (mean decrease of about 6% compared to baseline) and essentially no change in plasma cholinesterase activity. No symptoms associated with cholinesterase inhibition occurred. Daily urinary excretion of dimethyl phosphate (DMP) and dimethyl phosphorothionate (DMPT) increased in exposed workers, and daily mean DMP and DMTP excretion was highly correlated with the mean percentage decline in RBC cholinesterase activity from baseline (74).

No changes in plasma or RBC cholinesterase activities occurred in human volunteers given oral doses 4, 4.5 or 6 mg/day (0.06, 0.06 or 0.09 mg/kg/day) (75); 7, 8 or 9 mg/day (0.10, 0.11 or 0.13 mg/kg/day) (76); or, 10, 12, 14 or 16 mg/day (0.14, 0.17, 0.20 or 0.23 mg/kg/day) for 30 days (77).

2.5 Standards, Regulations, or Guidelines of Exposure

All azinphos-methyl liquids with a concentration greater than 13.5% are classified as restricted use pesticides by the U.S. EPA because of their high toxicity.

The ACGIH TLV for azinphos-methyl is 0.2 mg/m^3 and is associated with a skin notation (154). OSHA has established a PEL-TWA of 0.2 mg/m^3 with a skin notation, NIOSH has established a REL-TWA of 0.2 mg/m^3 with a skin notation, and most other countries have also established Occupational Exposure Limits of 0.2 mg/m^3 (e.g., Australia, Austria, Belgium, Denmark, Federal Republic of Germany, Netherlands, Philippines, Switzerland, Thailand, United Kingdom). Finland has established an OEL of 0.02 mg/m^3.

3.0 Chlorpyrifos

3.0.1 CAS Number:

[*2921-88-2*]

3.0.2 Synonyms:

(*O*,*O*-diethyl *O*-(3,5,6-trichloro-2-pyridinyl) phosphorothioate, Dursban; Lorsban; Dursban(R); chlorpyrifos-ethyl; Dowco 179; Pyrinex; phosphorothioic acid *O*,*O*-diethyl *O*-(3,5,6-trichloro-2-pyridinyl) ester; Brodan; Chloropyrifos; *O*,*O*-diethyl *O*-(3,5,6-trichloro-2-pyridyl) phosphorothioic acid; *O*,*O*-diethyl *O*-3,5,6-trichloro-2-pyridyl phosphorothioate; *O*,*O*-diethyl *O*-(3,5,6-trichloro-2-pyridinyl) phosphorothioic acid; 3,5,6-trichloro-2-pyridinol *O*-ester with *O*,*O*-diethyl phosphorothioate; chlorpyriphos-ethyl; detmol u.a.; dursban f; oms-0971; stipend; dursban 4E; chloropyriphos; killmaster; dursban 10cr; suscon; lorsban 50sl; coroban; terial 401; terial; danusban; durmet; *O*,*O*-diethyl *O*-(3,5,6-trichloro-2-pyridinyl) phosphorothioate; Dursban/Lorsban; Lorsban 4E-SG; Chlorpyrifos 4E-AG-SG; diethyl *O*-(3,5,6-trichloro-2-pyridyl) phosphorothioatae; diethyl *O*-(3,5,6-trichloro-2-pyridinyl) phosphorothioate; Dursban HF; Eradex; Pyrindol. 3,5,6-trichloro-, *O*-ester with *O*,*O*-diethyl phosphorothioate; Super I.Q.A.P.T.; Trichlorpyriphos

3.0.3 Trade Names:

Dursban®; Dowco 179®; ENT-27,311; Eradex®; Lorsban®; Pyrinex ®

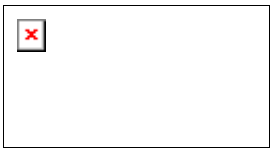
3.0.4 Molecular Weight:

350.57

3.0.5 Molecular Formula:

$C_9H_{11}Cl_3NO_3PS$

3.0.6 Molecular Structure:



3.1 Chemical and Physical properties
Pure chlorpyrifos is a white crystalline powder; technical chlopyrifos is an amber to white crystalline powder.

Specific gravity	1.398 g/cm^3 at 43.5°C
Melting point	42.5–43°C
Boiling point	decomposes at approximately 200°C
Vapor pressure	1.87×10^{-5} mmHg at 20°C
Solubility	soluble in most organic solvents; 0.00013 g/100 mL in water

3.1.2 Odor and Warning Properties Mild mercaptan odor due to diethyl disulfide in technical product.
3.2 Production and Use
Chlorpyrifos is a broad spectrum pesticide and acaracide that acts as a contact poison. Originally used to control mosquito larvae, it is no longer registered for this use. It has a wide range of applications on crops, lawns, ornamental plants, domestic animals, and a variety of building structures. Chlorpyrifos is available as 25% wettable powders, 1–10% granules, and emulsifiable concentrates of 2 and 4 lb/gal.
3.3 Exposure Assessment
Most exposures to chlorpyrifos are anticipated to be via inhalation of aerosols during its application; dermal absorption in humans is not significant (56, 199). Chlorpyrifos metabolism yields a unique urinary metabolite, 3,5,6-trichloro 2 pyridinol (TCP), which has been correlated to chorpyrifos exposure if analyzed within 48 hours of exposure (200, 201).
3.4 Toxic Effects
3.4.1.1 Acute Toxicity Chlorpyrifos is an organophosphate compound that has moderate toxicity and oral LD_{50}s of 80–250 mg/kg (64a, 202). Inhalation LD_{50}s of 78 and 94 mg/kg were calculated for female mice and rats, respectively, based on lethality observed after 60- to 180-minute exposures to aerosol concentrations of 5900 mg/m^3–7900 mg/m^3 (203). In female and male rats, 20 and 80% mortality occurred following 4-hour exposure to 5300 mg/m^3 chlorpyrifos, respectively, whereas no mortality occurred after exposure to 2500 mg/m^3 (56). A dermal LD_{50} of 202 mg/kg was reported in rats (64a). There is evidence that young animals are more sensitive than older animals; and that females are more sensitive than males to the lethal effects of chlorpyrifos (64a, 203a, 204).

Signs typically associated with organophosphate poisoning do not necessarily precede death caused by chlorpyrifos (203). “Apparent” (*sic*) tremors occasionally occurred in neonatal rats treated with a maximum tolerated dose (MTD) (45 mg/kg), but typical signs of a “cholinergic crisis” were not noted. Adult mice treated with a MTD (279 mg/kg) showed only slight to moderate signs of toxicity (e.g., diarrhea, fasciculations, lacrimation, slight tremors) (204). Cholinergic toxicity associated with sublethal exposure to chlorpyrifos was reflected only as mild diarrhea and hypoactivity evident only for the first two days following single s.c. injection of 279 mg/kg and not evident at all following repeated s.c. injections of 40 mg/kg (1×, 4 days, 16 days) (205, 206). Brain cholinesterase activity, however, was markedly depressed for at least 6 weeks following a single subcutaneous dose of 279 mg/kg and for at least 4 days following repeated subcutaneous doses of 40 mg/kg.

Prolonged cholinesterase inhibition occurred in rats given single subcutaneous injections of 0, 60, 125, or 250 mg/kg and examined up to 53 days later (207). Cholinergic toxicity was evident as a fine tremor in rats given 250 mg/kg but not 60 mg/kg (tremors in the 125 mg/kg group were not reported). Tremor intensity reached a peak in 9 days and returned to normal by 14 days after dosing. No overt signs of cholinergic toxicity occurred in rats treated with 0, 30, 60, or 125 mg/kg subcutaneously at any time from 1 to 35 days after dosing, although RBC cholinesterase activity was significantly inhibited in all groups (44). However, deficits in conditioned behavior occurred 2–16 days after dosing rats with 60, 125, or 250 mg/kg (207), and single oral doses of 12.5, 25, 37.5, or 50 mg/kg chlorpyrifos (or repeated doses of 12.5 mg/kg/day 5 days/week for eight weeks) caused significant deficits in response acquistition and performance measurements in a conditioned behavior task (208).

In rats given single oral doses of 20, 50, or 100 mg/kg chlorpyrifos by gavage, cholinergic signs peaked at 3½ hours in the 100-mg/kg group, were still present at 24 hours, and had disappeared by 72 hours after dosing (324). Only hypoactivity occurred in the 20-mg/kg group. When rats were given single oral doses of 10, 30, 60, or 100 mg/kg chlorpyrifos, no cholinergic effects occurred at 10 mg/kg, rats exhibited cholinergic signs at 30 mg/kg, tremors were also evident at 60 mg/kg, and cholinergic symptoms were present and severe at 100 mg/kg (43). The time of peak effect was always 3½ hours after dosing, and by 24 hours all symptoms had disappeared in the 30 mg/kg, but ataxia and hypoactivity were still evident in the 60- and 100-mg/kg group. Brain, plasma, and RBC cholinesterase inhibition were significantly and dose-dependently depressed at all dose including the 10 mg/kg group at both 3½ and 24 h. Thus, behavioral and biochemical effects of chlorpyrifos exposure were poorly correlated; and, behavioral signs showed recovery at 24 h whereas cholinesterase activity did not (43).

When rats were given 10, 50, or 100 mg/kg chlorpyrifos orally and observed 1, 8, and 15 hours later, cholinergic effects occurred only on day 1 in 100-mg/kg treated female rats (209). One female rat treated with 50 mg/kg had tremors, two exhibited incoordination, and one showed pronounced lacrimation. One male rat given 100 mg/kg exhibited only minimal tremor, and one male exhibited incoordination and lacrimation. Rats treated with 50 or 100 mg/kg were significantly hypoactive only on day 1. Thus, cholinergic effects were widespread at 100 mg/kg, minor at 50 mg/kg, moderated over a few days, and were more severe in females than males.

Responses of adult rats given single oral doses of 80 mg/kg were compared with those of 17-day-old rats treated with single doses of 15 mg/kg; these doses were equally effective in inhibiting cholinesterase (203a). Compared to adults, young rats showed similar behavioral changes and cholinesterase inhibition although at a fivefold lower dose. The onset of maximal effects was somewhat delayed, cholinesterase activity recovered more quickly, more extensive muscarcinic receptor down-regulation occurred, and no gender-related difference in sensitivity was noted.

Chlorpyrifos caused neurotoxicity, indicated by leg weakness. Onset was 3-18 days after dosing and lasted from 10–20 days when given subcutaneously to atropinized chickens at a dose of 200 mg/kg but not 100 mg/kg (64a).

3.4.1.2 Chronic and Subchronic Toxicity No treatment-related signs of toxicity, changes in body weight; or, in plasma, RBC, or brain cholinesterase activities occurred among rats exposed for 6 h/day, 5 days/week, 13 weeks, nose-only, to 72, 143, or 287 mg/m^3 chlorpyrifos (210). Nor was there any adverse effect at any exposure level based on urinalysis, clinical chemistry, hematology, gross pathological or histopathological evaluation.

When rats were exposed to 0.1, 1, 5, 15 mg/kg/day chlorpyrifos via the diet for 13 weeks, mild clinical effects (perineal soiling) were noted in females given 5 and 15 mg/kg/day (209). Plasma cholinesterase was significantly inhibited in males and females given 1 mg/kg or more, RBC cholinesterase was significantly inhibited in females given 1 mg/kg or more, and, brain

cholinesterase was inhibited in both males and females given 5 or 15 mg/kg. Motor activity of males and females given 15 mg/kg mildly decreased only at week 4 of exposure, and no treatment related differences were apparent subsequently, consistent with the occurrence of tolerance upon repeated exposure to chlorpyrifos.

Oral treatment of hens with 1, 5, or 10 mg/kg/day chlorpyrifos for 13 weeks did not induce neurotoxicity (1237).

3.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms There are no studies available that describe the pharmacokinetics of chlorpyrifos following inhalation exposure. However, absorption via inhalation was demonstrated indirectly in mice and rats who experienced lethality when exposed to 5900–7900 mg/m^3 aerosolized chlorpyrifos for 27–180 minutes (203). Indirect evidence of inhalation absorption in humans was provided in a study showing urinary excretion of diethyl phosphate chlorpyrifos metabolities by pesticide workers involved in treating structures with a spray emulsion of chlorpyrifos and vaponite (212).

Chlorpyrifos is well absorbed orally. Nearly 90% of orally administered chlorpyrifos was eliminated by rats in urine by 48–66 hours after dosing (201, 200a). The remaining 10% was eliminated in the feces. Chlorpyrifos was distributed especially to tissues involved in metabolism and excretion (liver and kidney), to tissues with considerable blood circulation (e.g., muscle, heart, lungs, spleen, testes, and bone), and to tissues high in lipids (e.g., fat and skin). It was eliminated nearly exclusively in urine (primarily as 3,5,6-trichloro-2-pyridinol phosphate). Elimination half-lives for liver, kidney, muscle, and fat were 10, 12, 16, and 62 hours, respectively, indicating considerable storage in fat.

About 72% of an oral dose of chlorpyrifos was absorbed (following a 1–2 hour delay), metabolized, and nearly completely eliminated (primarily as 3,5,6-trichloro-2-pyridinol (TCP)) in urine by male volunteers within 120 hours (199). Following either exposure route, chlorpyrifos was widely distributed and was eliminated from blood with a half-life of about 27 hours. In three individuals who ingested a concentrated solution of chlorpyrifos, its elimination was biphasic (276). An average elimination half-life for chlorpyrifos of 6 ± 2 hours in the initial elimination phase and of 80 ± 25 hours in a slower elimination phase was calculated.

Skin absorption of chlorpyrifos by humans is limited (56). In humans, less than 3% of a dermal dose of 5 mg/kg was absorbed (following a 22 hour delay) and was eliminated in urine within 180 hours (199). Considerable dermal absorption of chlorpyrifos has been reported in animals, although irritation and/or blistering from some high doses may have compromised the skin barrier. For example, 80–96% of a 22-mg/kg dermal dose was absorbed by goats by 12–16 hours after dosing and was distributed primarily to blood, liver, and fat, and lesser amounts were distributed to heart, gastrointestinal tract, and skeletal tissue (56, 57). About 60% of a dermal dose of chlorpyrifos (3–15 mM/5.6 cm^2) applied to rats was absorbed by 72 hours after dosing; young rats absorbed up to 90% of the applied dose. Eight hours after dermal treatment of mice with 1 mg/kg chlorpyrifos, about 74% of the dose was found primarily in urine and feces, carcass, blood, intestine, liver, and kidney, and an elimination half-life of 21 hours was estimated (213).

Chlorpyrifos is metabolized to chlorpyrifos oxon via cytochrome p450-dependent desulfuration (16, 215, 216). The oxon is rapidly hydrolyzed to 3,5,6-trichloro-2-pyridinol (TCP) via microsomal esterase (including paraoxonase and chlorpyrifos oxonase) (49, 217, 218) or via a nonenzymatic process (14, 215, 216). Alternatively, chlorpyrifos is dearylated to form diethyl thiophosphoric acid and TCP in a reaction also catalyzed by microsomal enzymes. TCP is a relatively unique metabolite of chlorpyrifos and it (or one of its conjugates) is almost exclusively (90%) excreted in the urine (200a, 201).

Chlorpyrifos oxon binds to and irreversibly inhibits acetylcholinesterase. However, the relative affinity of chlorpyrifos oxon for plasma and hepatic esterase exceeds that for acetylcholinesterase

(13, 14, 219). Moreover, chlorpyrifos oxon causes relatively greater and longer lasting inhibition of hepatic esterase *in vivo* compared to brain acetyklcholinesterase (13, 14, 219). Noncatalytic binding of chlorpyrifos oxon to hepatic and plasma esterase represents a significant detoxication mechanism because it prevents much hepatically generated chlorpyrifos oxon from entering the general circulation and target tissues (56). High rates of hepatic dearylation and esterase binding may represent protective factors but it should also be recognized that chlorpyrifos can be activated in extrahepatic tissues such as brain (219).

Comparative differences in the rates of hepatic esterase binding and rates of dearylation have been implicated as contributors to the greater sensitivity of female rats to chlorpyrifos toxicity compared to male rats, to the greater sensitivity of some tissues (e.g., brain) to chlorpyrifos compared to other tissues (17), to the greater sensitivity of young animals to chlorpyrifos toxicity compared to adults (18), and to the greater toxicity of parathion compared to chlorpyrifos (13, 15, 19, 221).

Although human chlorpyrifos oxonase has not been shown to exhibit clear genetic polymorphism as has been shown for paraoxonase (218, 222), a 13-fold variation in chlorpyrifos oxonase activity has been found in human serum (223–225).

3.4.1.4 Reproductive and Developmental No effects on reproduction, fertility indexes, or neonatal development were noted in two generations of rats fed diets that contained 0.1,1.0, and 5 mg/kg/day chlorpyriphos (211). Parental toxicity at the highest dose was accompained by a decrease in pup body weight and increased pup mortality in the F1 litters.

Chlorpyrifos was not fetotoxic to rats given 0, 0.1, 3.0, or 15 mg/kg/day chlorpyriphos by gavage on days 6 through 15 of gestation (211). When pregnant mice were given 0,1,10, or 25 mg/kg/day chlorpyriphos by gavage on gestation days 6 through 15, minor fetotoxic responses and skeletal variations were noted at 25 mg/kg/day, a dose that also caused severe maternal toxicity (589). Teratogenicity (exencephaly) was observed in one pup at 1 mg/kg/day, but was not noted at 10 or 25 mg/kg/day.

3.4.1.5 Carcinogenesis Neither rats maintained for 2 years nor dogs maintained for 1 or 2 years on diets that contained 0.01, 0.03, 0.1, 1, or 3 mg/kg chlorpyrifos showed signs of cholinergic toxicity or carcinogenicity at 12, 18, or 24 months (202). However, RBC cholinesterase activity was intermittently depressed among female rats given 0.1 mg/kg (at 30 and 365 days only) and was consistently depressed among male and female rats given 1 mg/kg and 3 mg/kg (202). Brain cholinesterase activity in rats was intermittently depressed in both sexes given 1 mg/kg (at 180 days and 547 days in females; at 365 and 730 days in males), and was consistently depressed in both sexes given 3 mg/kg. RBC and brain cholinesterase returned to normal levels within 7–8 weeks in a subset of exposed rats after they were switched to control diets. RBC cholinesterase activity was significantly depressed in dogs given 1 or 3 mg/kg diets from day 30 through 730. Brain cholinesterase activity in dogs exposed for 1 or 2 years was slightly depressed in the 3-mg/kg group (81–92% of control levels).

No evidence of cholinergic toxicity occurred in rhesus monkeys given 0.08, 0.40, or 2.0 mg/kg/day chlorpyrifos orally for six months, although plasma cholinesterase activity was reduced in all dose groups and RBC cholinesterase activity was reduced in the 0.40- and 2.0-mg/kg/day groups (220).

3.4.1.6 Genetic and Related Cellular Effects Studies Chlorpyrifos is genotoxic based on a recent review (56). Chlorpyrifos induced micronuclei in erythroblasts and caused cytogenetic effects in human lymphoid cells in a dose-related fashion (56). Chlorpyrifos produced significant increases in sister chromatid exchanges and caused X chromosome loss in *Drosophila melanogaster* and chromosomal aberrations and sister chromatid exchanges in spleen cells. Spindle poisoning and induction of micronuclei and polyploidy have been reported following chlorpyrifos exposure. Sex-linked recessive lethals have also been produced in *Drosophila melanogaster* by chlorpyrifos exposure, indicating that chlorpyrifos is genotoxic to both somatic and germ cells.

3.3.5 Biomonitoring/Biomarkers TCP is a unique urinary metabolite of chlorpyrifos. Variation in urinary TCP was investigated in termite control workers frequently involved in spraying chemicals in closed environments (226). Variation in the urinary TCP level corresponded to the termite control season and the length of the working period.

3.4.2 Human Experience 3.4.2.2 Clinical Cases Unconsciousness, cyanosis, wheezing, and uncontrolled urination and diarrhea occurred within 18 hours after an individual ingested an estimated dose of 300 mg/kg chlorpyrifos (227). In another suicide attempt, a 27-year-old male experienced extreme agitation, diaphoresis and excessive oral secretions, muscle weakness and fasciculations 14 hours after ingestion of an unknown amount of chlorpyrifos (228). RBC cholinesterase activity was within normal limits. He was administered atropine, pralidoxime, and ventilatory support, and symptoms resolved after 72 hours without permanent sequelae. In another case of chlorpyrifos poisoning, a woman presented with stupor, increased muscle tone, absence of superficial reflexes, and striking choreoathetotic movements of all limbs (229). Serum and RBC cholinesterase activities were markedly depressed (about 20 and 2% of normal, respectively). Atropine relieved the symptoms, and the patient was completely well one month later. A 5-year-old girl who ingested an unknown amount of Rid-A-Bug® which contains chlorpyrifos and a 3-year-old boy who experienced frothing at the mouth, coma, pinpoint pupils, nasal secretions, fasciculations of the eyelids, and twitching of the extremities after ingesting an unknown amount of Dursban®, survived through treatment with atropine and pralidoxime (230, 231). In the boy, a distal polyneuropathy developed 18 days later, but all symptoms were fully resolved by day 52.

An intermediate syndrome that required endotracheal intubation and intermittent positive pressure ventilation followed by vocal cord paralysis was reported in an individual who had recovered from a cholinergic crisis due to acute chlorpyrifos ingestion (232). Immediate and delayed toxicity was reported in eight individuals exposed to Dursban® presumably via inhalation and dermal contact as a result of its use as a commercial fumigant (233). Immediate symptoms included nausea, vomiting, and lightheadness in a worker after chlorpyrifos was inadvertently introduced into the workplace ventilating system, and headaches, nausea, and painful muscle cramps in a family of four after their house was sprayed with chlorpyrifos by an exterminator. About 4 weeks after initial exposure, the affected worker developed paresthesia in his feet, urinary frequency and pain in the suprapubic, groin, and thigh regions, and the affected family developed numbness and paresthesias especially in the legs which was accompanied by reported memory impairment. Nerve conduction studies were consistent with distal axonopathy. Delayed sensory neuropathies were also described in two women whose houses had been treated with chlorpyrifos 3–4 weeks earlier and in an exterminator who was exposed repeatedly to chlorpyrifos during a 6-month period (233). All symptoms resolved by 2 weeks–3 months after exposure stopped. No estimates of exposure or cholinesterase activity levels were provided.

A spectrum of common birth defects that involved central nervous system malformations, ventricular, eye, and palate defects, hydrocephaly, microcephaly; mental retardation; blindness; hypotonia; widely-spread nipples; and deformities of the teeth, external ears and external genitalia was described in four infants (two of whom were siblings) and attributed to maternal exposure to chlorpyrifos during the first trimester of pregnancy either in the home or at work (234, 235). However, no confirmation of exposure either through chlorpyrifos measurements or cholinesterase activities was provided nor was any estimate of dose attempted. Reports of an additional nine cases of birth defects that had the same or similar spectrum of effects associated with *in utero* chlorpyrifos exposure were provided to the EPA and reviewed by the Centers for Disease Control (CDC) (236). The EPA concluded that the cases did not support a finding of teratogenicity (236).

3.4.2.2.2 Chronic and Subchronic Toxicity The prevalence of selected illnesses and symptoms in 175 employees involved in producing chlorpyrifos for more than one day between 1 January 1977 and 31 July 1985 and in 335 individually matched controls were compared (237). Subjects were subdivided into three exposure groups (high, moderate, and low) on the basis of job title and air monitoring data.

Estimated TWA concentrations of chlorpyrifos were not provided by exposure group, but for all employees reporting ranged from 0.01 to 0.37 mg/m^3. Company medical records were examined for evidence of gastrointestinal tract and nervous symptoms. No significant differences in illness or prevalence of symptoms were observed between the exposed and unexposed groups or among the three exposure subgroups. The observation period was extended to 31 December 1994, and the study group size was increased to 496 potentially exposed employees and 911 controls in a follow-up study (238). High, moderate, low, and negligible exposures were defined as □0.2 mg/m^3 chlorpyrifos or high potential for dermal exposure, □0.03 mg/m^3 or moderate potential for dermal exposure, □0.03 mg/m^3 or low potential for dermal exposure, and □0.01 mg/m^3 or negligible dermal exposure, respectively. Employees were categorized into moderate, low or negligible exposure levels on the basis of plasma cholinesterase activities. Prevalence odds ratios for various nervous, respiratory, and digestive system symptoms were calculated by exposure as well as plasma cholinesterase inhibition, and no exposure-related effects were observed.

An increase in the frequency of blurred vision, flushing of skin, and decreased urination were reported by pet control employees who used chlorpyrifos within the previous three months (239). However, no estimates of chlorpyrifos exposure were obtained, and exposure was not confirmed with biomarkers of exposure.

Volunteers were treated with 0.014, 0.03 or 0.10 mg/kg/day chlorpyrifos by capsule for a total of 20 days at the low and mid-dose and for 9 days at the high dose (95). Treatment of the high-dose group was discontinued after 9 days due to a runny nose and blurred vision in one individual. Mean plasma cholinesterase in this group was inhibited by about 65%. No effect on RBC cholinesterase activity was apparent at any dose. No signs of toxicity were reported among human volunteers given daily oral doses of 0.014, 0.030, or 0.100 mg/kg chlorpyrifos for up to four weeks (210). Plasma cholinesterase inhibition was reported in the 0.100-mg/kg group, but RBC cholinesterase was reportedly unaffected at all exposure levels.

No signs of toxicity or depression in RBC acetylcholinesterase activity occurred among human volunteers given 0.5 mg/kg orally or 0.5 or 5 mg/kg dermally. Plasma cholinesterase activity was reduced to 15% of predose levels after the 0.5 mg/kg oral dose, but RBC cholinesterase activity was unchanged after this dose or the 5 mg/kg dermal dose (199).

3.5 Standards, Regulations, or Guidelines of Exposure

The EPA established a 24-hour reentry interval for crop areas treated with emulsifiable concentrate or wettable powder formulations of chlorpyrifos unless workers wear protective clothing. Chlorpyrifos is undergoing reregistration by the EPA (242).

The ACGIH TLV and the NIOSH REL-TWA for chlorpyrifos is 0.2 mg/m^3 with a skin notation (154). There is no OSHA TWA-PEL for chlorpyrifos. Most other countries have also established Occupational Exposure Limits of 0.2 mg/m^3 with skin notation for chlorpyrifos (e.g. Australia, Belgium, Denmark, Finland, France, Netherlands, Switzerland, and United Kingdom). NIOSH has also established a 0.6 mg/m^3 STEL for chlorpyrifos.

Organophosphorus Compounds

4.0.3 Trade Name:

Agridip; Asuntol®; Bay 21; Baymix®; Co-Ral®; ENT-17957; Meldane®; Muscatox®; Negashunt; Resitox®; Suntol, Umbethion

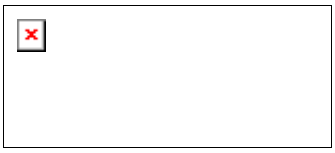
4.0.4 Molecular Weight:

362.8

4.0.5 Molecular Formula:

$C_{14}H_{16}ClO_5PS$

4.0.6 Molecular Structure:



4.1 Chemical and Physical Properties

Technical coumaphos is a colorless or white and tan powder. Coumaphos is stable under normal use conditions but hydrolyzes slowly under alkaline conditions

Specific gravity	1.47 at 20°C
Melting point	91–92°C
Boiling point	20°C at 1×10^{-7} mmHg
Vapor pressure	1×10^{-7} mmHg at 20°C
Solubility	soluble in acetone and diethyl phthalate; much less soluble in denatured alcohol and xylene; only slightly soluble in octanol, hexane and mineral spirits; insoluble in water

4.1.2 Odor and Warning Properties Slight sulfur odor.

4.2 Production and Use

Coumaphos is an organophosphate insecticide used to control anthropoid pests on beef cattle, dairy cows, goats, horses, sheep, and swine. Formulations include wettable powders, emulsifiable liquids, flowable concentrate, ready-to-use liquids, and dusts. Coumaphos is applied by aerosol can, dust bags, hand-held dusters, dip vats, high- and low-pressure hand-held sprayers, back rubber oilers, mechanical dusters, shaker can, and squeeze applicators (241). The EPA issued a Registration Standard for coumaphos in 1989 and a Reregistration Standard in 1996 (45). Currently 26

coumaphos products are registered (243).

4.4 Toxic Effects

4.4.1.1 Acute Toxicity Coumaphos is highly toxic and has an oral LD_{50} of 16–41 mg/kg in rats (64a). However, the EPA noted that the oral LD_{50} in male rats was >240 mg/kg and oral LD_{50} in female rats was 17 mg/kg (241). The dermal LD_{50} for coumaphos was previously reported as 860 mg/kg in rats (Gaines 1969) although EPA noted that the dermal LD_{50} was >2400 mg/kg in male and female rats (241). One-hour LC_{50}s of 1081 mg/m^3 and 341 mg/m^3 and 341 mg/m^3 were reported for male and female rats (241).

When male rats were given single oral doses of 250 mg/kg and female rats were given single oral doses of 17.5 mg/kg, cholinergic signs occurred and lasted for 12–13 days (242). RBC cholinesterase activity was depressed at 2 mg/kg in both sexes. When sheep were given 2 or 4 mg/kg/day coumaphos orally for 6 days, 4 mg/kg/day caused RBC cholinesterase inhibition and signs of cholinergic toxicity (*sic*); 2 mg/kg/day inhibited RBC cholinesterase but caused no apparent overt cholinergic toxicity (240). Treatment with coumaphos did not significantly alter the anticholinesterase effects of the second treatment 6 weeks later, suggesting no cumulative effect. Simultaneous treatment with coumaphos (4 mg/kg/day) and an intravenous dose of trichlorfon (insufficient to cause significant inhibition of RBC cholinesterase alone) resulted in an additive effect on RBC cholinesterase inhibition (240).

When rats were treated dermally for 2 or 5 days with 0, 2.5, 5, 10, 20, or 50 mg/kg/day coumaphos, no cholinergic toxicity was noted (241). Brain, plasma, and RBC cholinesterase activity, however, were depressed at 50 mg/kg after 2 days, and RBC and brain cholinesterase activity were depressed at 20 mg/kg/day after 5 days (241).

Coumaphos is a mild eye irritant, but is not irritating to the skin and is not a skin sensitizer; nor does it produce delayed neurotoxicity in hens (241).

4.4.1.2 Chronic and Subchronic Toxicity No signs of cholinergic toxicity were observed at any dose in rats fed diets that contained 0, 2, 5, or 10 ppm coumaphos for 13 weeks (about 0, 0.2, 0.5, or 1.0 mg/kg/day) (241). However, plasma cholinesterase was inhibited at 10 ppm (1 mg/kg/day), and RBC cholinesterase was inhibited at all dose levels. Brain cholinesterase was not inhibited at any time at any dietary level.

When rats were dermally treated with 2, 4, 20, or 100 mg/kg/day coumaphos for 21 days, cholinergic toxicity (muscle fasciculation, tremors) occurred at 20 or 100 mg/kg/day (241). RBC cholinesterase was inhibited at all doses, and brain cholinesterase was inhibited at 20 and 100 mg/kg. In another 21-day dermal study, when female rats were given 0, 0.1, 0.5, 1.1, or 2.1 mg/kg/day coumaphos, no signs of cholinergic toxicity were observed at any dose, although RBC cholinesterase was significantly inhibited at 1.1 and 2.1 mg/kg/day (242).

4.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Coumaphos is well absorbed orally. The plasma half-life for coumaphos following oral exposure ranges from 2–3 hours at 1.0 mg/kg and 3–5 hours at 15.0 mg/kg (241). Urinary excretion is rapid; and 63–87% of an administered dose was excreted within 24 hours, and 76–96% of an administered dose was excreted within 168 hours. Tissue residues were highest in fat, kidney, liver, and muscle. Seven days after rats were given single oral doses of about 1 mg/kg coumaphos, about 55% had been excreted in urine and about 24% has been excreted in feces (246). The remaining dose was distributed primarily to the liver, abdominal fat, skin, and kidney.

The fate of dermally applied coumaphos was examined in lactating goats given about 14 mg/kg coumaphos (243). During the 7 days after treatment, an average of <0.1, 4.7, and 1% of the administered dose was eliminated in milk, urine, and feces, respectively. When goats were killed

after 7 days, the highest coumaphos residues were in adipose tissue (mainly unmetabolized coumaphos) followed by the kidney and liver.

Coumaphos is extensively metabolized. The urine of rats treated orally with coumaphos contained five to eight metabolites, and the feces contained five to seven metabolites (242). The major metabolite is chlorferone (the hydroxylated leaving group). Coumaphos represented 0.1% of the urinary metabolites. Coumaphos represented 0.2% of the fecal metabolites when administered intravenously but approximately 15 to 55% of the fecal metabolites when given orally, suggesting that the process of oral absorption may slow metabolism.

4.4.1.4 Reproductive and Developmental Reproductive toxicity did not occur in rats fed diets that contained 1, 5, or 25 ppm coumaphos (0.07, 0.30, and 1.79 mg/kg/day (F_0 males) and 0, 0.08, 0.34, or 2.02 mg/kg/day (F_0 females)) during premating for two generations (241). Dose-dependent decreases in plasma and RBC cholinesterase activity occurred among rats fed 5 or 25 ppm. Brain cholinesterase was significantly inhibited in F_0 and F_1 females. In pups, plasma and RBC cholinesterase levels were inhibited at 25 ppm on lactation day 21 but not on lactation day 4.

No developmental effects occurred in offspring of rats given 1, 5, or 25 mg/kg/day coumaphos by gavage on gestation days 6 to 15 (242). Three rats in the 25-mg/kg/day group showed tremors, and two showed additional signs of cholinergic toxicity. No developmental effects occurred in rabbits given 0.25, 2.0, or 18.0 mg/kg/day coumaphos by gavage during gestation days 7 through 19 (242). Maternal toxic signs, including death and abortion, were observed in the 18-mg/kg/day group. When pregnant bovines were dermally treated with coumaphos at various stages of gestation by pouring it along the dorsal midline, there was evidence of increasing embryonic death rates or teratogenic effects (245).

4.4.1.5 Carcinogenesis There was no evidence of carcinogenicity at any dose in rats fed diets that contained 1, 5, or 25 ppm coumaphos (0.05, 0.25, or 1.22 mg/kg/day (males); 0.07, 0.36, or 1.70 mg/kg/day (females)) for two years (241). Body weight gain decreased in females given the 25-ppm diet (1.7 mg/kg/day). Plasma and RBC cholinesterase was inhibited in females given the 5- or 25-ppm diet (0.36 or 1.7 mg/kg/day) and in males given the 25-ppm diet (1.22 mg/kg/day). There was no evidence of carcinogenicity in another study when rats were given diets that contained 10 or 20 ppm coumaphos for 103 weeks (244). The only adverse effect observed was slightly decreased body weight gain in females given either the 10- or 20-ppm diet. No adverse effects of any kind were observed in mice given diets that contained 0, 10, or 20 ppm coumaphos for 103 weeks (241).

There were no treatment related effects other than cholinesterase inhibition in dogs given 1, 30, or 90 ppm coumaphos in the diet for one year (0.025, 0.775, or 2.295 mg/kg/day (males); 0.024, 0.7095, or 2.478 mg/kg/day (females)) (241). Plasma, RBC, brain, and ocular muscle cholinesterase activity levels were depressed in the 30- and 90-ppm fed dogs (0.775/0.7095 and 2.295/2/478 mg/kg/day).

4.4.1.6 Genetic and Related Cellular Effects Studies Coumaphos was not mutagenic in *S. typhimurium* with or without metabolic activation, was negative in a mouse micronucleus test, and was negative in a Pol A test on *E. coli* with and without metabolic activation (241).

4.4.2 Human Experience 4.4.2.2 Clinical Cases Six individuals suffered serious organophosphate poisoning after ingesting coumaphos mistakenly used as a food flavoring in two separate incidents (247). In the first incident, four adults developed symptoms of poisoning (nausea, vomiting, and abdominal pain) 1 hour after eating seafood flavored with coumaphos which had possibly been mistaken for monosodium glutamate. After 2 hours, obvious signs of cholinergic toxicity (sweating, urination, miosis, bronchorrhea, and hypersalivation) were apparent. One adult female died at home after about 3 hours; the remaining three adults were treated with atropine and pralidoxime and gradually recovered. In the second incident, a man and wife developed signs of organophosphate

poisoning (nausea, vomiting, diarrhea, abdominal pain, and blurred vision) after eating coumaphos-contaminated fried fish and recovered with atropine and PAM.
4.5 Standards, Regulations, or Guidelines of Exposure
The EPA classifies most formulations of coumaphos as General Use Pesticides. The formulations 11.6% EC and 42% flowable concentrate end-use products have been classified as Restricted Use Pesticides because they pose a hazard of acute poisoning from ingestion. No Occupational Exposure Limits were identified for coumaphos.

Organophosphorus Compounds

5.0 Demeton
5.0.1 CAS Number:
[*8065-48-3*]
5.0.2 Synonyms:
O,*O*-diethyl *O* (and *S*)-2-(ethylthio)ethyl phosphorothioate mixture; Systox; Bayer 8169; Demeton-o + Demeton-s; Demox; E-1059; phosphorothioic acid *O*,*O*-diethyl *O*-2-(ethylthio)ethyl ester, mixed with *O*,*O*-diethyl-*S*-2-(ethylthio)ethyl phosphorothioate; Denox; Systemox; phosphorothioic acid *O*,*O*-diethyl *O*-[2-(ethylthio)ethyl] ester mixture with *O*,*O*-diethyl *S*-[2-(ethylthio)ethyl] phosphorothioate; phosphorothioic acid *O*,*O*-diethyl *O*-[2-(ethylthio)ethyl] ester, mixed. with *O*,*O*-diethyl *S*-[2-(ethylthio)ethyl] phosphorothioate; demeton+; Demeton (O-isomer and S-isomer); diethyl *O*-(and *S*-)(2-(ethylthio)ethyl) phosphorothioate (mixed isomers); phosphorothioic acid, *O*,*O*-diethyl *O* (and *S*)-(ethylthio)ethyl esters; Demeton O(35%)+S(56%)
5.0.3 Trade Names:
Demox®; Mercaptofos®; Systox®; Bay 10756; Bayer 8169; ENT 17,295
5.0.4 Molecular Weight:
258.34
5.0.5 Molecular Formula:
$C_8H_{19}O_3PS_2$
5.1 Chemical and Physical Properties
Demeton is a light brown to pale yellow, oily liquid. Demeton is the common name for a mixture of *O*,*O*-diethyl-*O*-2-ethylthioethyl phosphorothioate (demeton-O) and *O*,*O*-diethyl-*S*-2-ethylthioethyl phosphorothioate (demeton-S) in a ratio of approximately 2:1. Demeton decomposes to toxic gases and vapors such as sulfur dioxide, phosphoric acid mist, and carbon monoxide. Contact with strong oxidizers may cause fire and explosions.

Specific gravity	1.18 at 20°C
Melting point	>–25°C
Boiling point	134°C at 2 mmHg
Vapor pressure	3.4×10^{-4} mmHg at 20°C (mixture)
Solubility	slightly soluble in water; soluble in most organic solvents

5.1.2 Odor and Warning Properties Pronounced mercaptan-like odor.
5.2 Production and Use
Demeton is a systemic insecticide effective against sap-feeding insects and mites. Before 1989 when it was discontinued by the manufacturer, it was available as emulsifiable concentrates of varying active ingredient content (1). Because demeton is no longer an active ingredient in any registered pesticide product, its registration has been canceled by the U.S. EPA (45).
5.4 Toxic Effects
5.4.1.1 Acute Toxicity Demeton is a highly toxic organophosphate compound that has oral LD_{50}s of

2–6 mg/kg (64a, 248, 249). The oral LD_{50} for the P–S isomer (demeton-O) in rats was 7.5 mg/kg and for the P–O (demeton-S) isomer was 1.5 mg/kg (250). The sulfoxide and sulfone metabolites of demeton are as lethal as demeton itself; they have oral LD_{50}s in rats of 1.9 to 2.3 mg/kg (251).

The dermal LD_{50}s are 8.2–14 mg/kg in rats, nearly equivalent to its acute oral toxicity (64a). However, formulation impacts the dermal toxicity of demeton. An equal volume of emulsifier changed the LD_{50} from less than 24 to 620 mg/kg, whereas dilution of the mixture to the strength used for spraying greatly increased the toxicity, so that a lethal dose was about 5 mg/kg (478).

A single 2-hour exposure to 18 mg/m^3 demeton was fatal within 50–90 minutes to all of a group of six rats (250). Rats exposed to 3 mg/m^3 demeton for 2 hours/day experienced "no signs of illness during the first exposure" (sic), tremors during the second exposure, lacrimation and more severe tremors during the third exposure, and mortality in 10 of 17 rats during the fourth exposure. Rats exposed to 3 mg/m^3 demeton for only 1 hour/day experienced no signs of intoxication after two days; mild tremors after 4 days; marked tremors, lacrimation, and 5% mortality (1/20) after 6 days; and 37% mortality (7/19) after 12 days. One and four-hour LC_{50} values of 175 and 47 mg/m^3 were obtained for rats (123).

Demeton was not associated with signs of organophosphate-induced delayed neuropathy when administered subcutaneously to atropinized chickens at doses that ranged from 5–80 mg/kg and were then observed for 30 days (190).

5.4.1.2 Chronic and Subchronic Toxicity When rabbits were given greens sprayed with demeton so that intake was 2.3, 1.5, 0.5, 0.1, or 0.07 mg/kg/day for 40, 30, 100, 98, and 94 days, respectively, no effects occurred in the 0.07- or 0.1-mg/kg/day groups, one of six rabbits fed 0.5 mg/kg/day died after 64 days, four of six rabbits fed 1.5 mg/kg died, and three of six rabbits fed 2.3 mg/kg/day died (250).

Rats fed diets that contained 50 ppm demeton containing 48% of the more potent P□O isomer (equivalent to 2.6 mg/kg) for 11–16 weeks exhibited cholinergic toxicity (fasciculations, weakness, tremors, lacrimation, and salivation) at 11 weeks, but by 16 weeks they were exhibiting no signs of cholinergic toxicity despite severe brain cholinesterase inhibition (253). No cholinergic signs were observed in rats given diets that contained 1, 3, or 20 ppm demeton for 11–16 weeks. When rats were given 0.4, 0.66, 0.9, and 1.89 mg/kg/day demeton by gavage for 65 days during a 90-day period, signs of cholinergic toxicity (hyperexcitability, tremors) occurred in rats given the two highest doses after 21 days (250). There was one death in the group fed 1.89 mg/kg.

In dogs given diets that contained 1, 2, or 5 ppm demeton (0.025, 0.047, or 0.149 mg/kg/day) for 24 weeks, plasma cholinesterase activity was maximally inhibited after about 12 weeks in dogs given the 5-ppm diet and after 16 weeks in dogs given the 2-ppm diet (193). RBC cholinesterase activity was unaffected by the 1- or 2-ppm diets and was slightly inhibited by the 5-ppm diet. When demeton and parathion were in the same diet at levels necessary for cholinesterase inhibition, the effects were additive (193). In an unpublished study submitted to EPA, overt cholinergic toxicity reportedly occurred in rats fed a diet that delivered 0.9 mg/kg/day demeton but not 0.7 mg/kg/day (95). In another unpublished study, cholinsterase inhibition (*sic*) reportedly occurred in female rats fed diets that contained 3 ppm demeton for 77–112 days but not in rats fed 1 ppm). Cholinergic effects evidently occurred at 20 ppm but not at 10 ppm (95).

5.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms The principal metabolic pathway for both the O- and S-isomers is oxidation of the 2-ethylthioether to sulfoxide and sulfone. In the case of demeton-O, a secondary pathway involves oxidation of P□S to P□O and subsequent oxidation to sulfoxide and sulfone (257). These oxidation products are more potent inhibitors of

acethylcholinesterase than the parent compound. Studies in mice are consistent with the notion that oxidation of the mercapto sulfur of the ethylmercaptoethyl portion of demeton and the P–O isomer to the corresponding sulfoxide and finally to the sulfone is an important metabolic pathway for demeton (258).

5.4.1.4 Reproductive and Developmental Administration of 7 or 10 mg/kg demeton to mice as a single intraperitoneal dose or as three consecutive doses of 5 mg/kg each between days 7 and 12 of gestation was embryo toxic, as evidenced by decreased fetal weight and slightly higher mortality of the young (254). Fetuses that had intestinal hernias were found at 16 but not at 18 days. The high dose (10 mg/kg) administered on days 8, 9, or 10 of gestation had no effect on litter size at birth or on the survival rate of the young.

Ducklings hatched from eggs innoculated with demeton at the rate of 0.01 mg/egg on day 13 of incubation had partial to complete loss of voluntary control of one or both hind legs. Some were excitable and ataxic. The difficulties gradually disappeared about 1 week after hatching, but the growth of treated ducklings remained retarded. Histological examination of the skeletal muscles revealed areas of degenerative change and other areas of marked regenerative activity (255, 256).

5.4.1.5 Carcinogenesis No published studies of the chronic toxicity or oncogenicity of demeton were identified. In an unpublished study submitted to the EPA, dogs were fed diets that contained demeton (all levels not specified) for 24 weeks (95). RBC cholinesterase was inhibited at a dietary concentration of 5 ppm (about 0.125 mg/kg/day), and plasma cholinesterase was inhibited at a dietary concentration of 2 ppm (about 0.05 mg/kg/day). A dietary level of 1 ppm (0.025 mg/kg/day) was without effect on either on either plasma or RBC cholinesterase. In another unpublished study submitted to EPA, cholinesterase (*sic*) was reportedly inhibited at 0.5 mg/kg/day but not at 0.15 mg/kg/day in rabbits that were given demeton orally for 106 days (95).

5.4.1.6 Genetic and Related Cellular Effects Studies Demeton was reportedly both positive and negative in *in vitro* tests of bacterial mutagenicity and negative in a sex-linked lethal mutation assay using *D. melanogaster* (545).

5.4.2 Human Experience 5.4.2.2 Clinical Cases Demeton has been associated with numerous deaths after high accidental and intentional exposures and from occupational exposures (1). Estimates of exposure are not available. A man who spilled 60 mL of concentrated liquid demeton on his thigh, then rinsed his thigh with water but continued wearing the pants, suddenly experienced nausea, vomiting and, weakness after about 9 hours, was treated with atropine, and recovered uneventfully (1).

Twelve of fourteen agricultural workers exposed to about 1 mg/m^3 demeton reportedly had lowered cholinesterase levels (*sic*) but displayed no clinical evidence of poisoning (*sic*) (259). In another study, air concentrations of up to 6 mg/m^3 were reportedly without clinical effect, although they were associated with reduced serum cholinesterase activity (259).

Eighteen different doses of demeton were evaluated in men who were given oral doses of demeton that began at 0.75 mg per day for 30 days (260). Doses of 4.5 to 6.375 mg/day (equivalent to about 0.06 to 0.09 mg/kg/day assuming a 70-kg body weight) produced average inhibition of plasma cholinesterase that was indistinguishable from normal variation. Doses of 6.75 mg/day (0.10 mg/kg/day) produced an average temporary inhibition of plasma cholinesterase, and a dose of 7.124 mg/day (0.10 mg/kg/day) produced an average of 40% inhibition by day 25. This dose was also associated with an average 16% inhibition of RBC cholinesterase inhibition. However, one of five test subjects had a marked decrease in plasma and RBC cholinesterase activities of 59% and 29%, respectively, after 24 days when given 4.125 mg/day (equivalent to 0.06 mg/kg/day). No clinical signs were observed or reported at any exposure level.

Three volunteers were exposed for two consecutive days to 9–27 mg/m^3 Metasystox (30% demeton-*S*-methyl, 70% demeton-*O*-methyl) while spraying with a hand-held nebulizer. Exposure lasted for 3 and 6 hours on the first and second days, respectively. Plasma and RBC cholinesterase activities measured up to 14 days after exposure did not show significant decreases (262).

5.5 Standards, Regulations, or Guidelines of Exposures

Demeton is not registered for use by the U.S. EPA. The ACGIH TLV for demeton is 0.11 mg/m^3 with a skin notation (154). The OSHA PEL-TWA is also 0.1 mg/m^3 with a skin notation. NIOSH established an IDLH of 10 mg/m^3 and REL-TWA of 0.1 mg/m^3 with a skin notation. Many other countries have also established Occupational Exposure Limits (OELs) of 0.1 mg/m^3 for demeton with a skin notation (Australia, Austria, Belgium, Denmark, Finland, France, Germany, India, The Netherlands, The Philippines, Switzerland, Thailand, and Turkey).

Organophosphorus Compounds

6.0 Demeton-**S**-methyl

6.0.1 CAS Number:

[*919-86-8*]

6.0.2 Synonyms:

Ethanethiol, 2-(ethylthio)-*S*-ester with *O*,*O*-dimethyl phosphorothioate; BAY 18436; Bayer 25/154; phosphorothioic acid *S*-[2-(ethylthio)ethyl] *O*,*O*-dimethyl ester; Metasystox (I); metasytox thiol; *S*-(2-(ethylthio)ethyl) *O*,*O*-dimethyl phosphorothioate; Methyl-*S*-Demeton

6.0.3 Trade Names:

Demetox®; DEP 836 349; Duratox®; Isometasystox®; Isomethylsystox®; Metaisoseptox®; Metaisosytox; Metasystox (I)®

6.0.4 Molecular Weight:

230.3

6.0.5 Molecular Formula:

$C_6H_{15}O_3PS_2$

6.0.6 Molecular Structure:

6.1 Chemical and Physical Properties

Demeton-*S*-methyl is an oily, colorless to pale yellow liquid. It is hydrolyzed by alkali and oxidized to the sulfoxide (oxydemeton-methyl) and sulfone (demeton-*S*-methylsulfone).

Specific gravity	1.21 at 20°C
Boiling point	74°C at 0.15 mmHg; 92°C at 0.2 mmHg; 102°C at 0.40 mmHg; 118°C at 1 mmHg
Vapor pressure	1.6×10^{-4} mmHg at 10°C; 4.8×10^{-4} at 10°C; 1.45×10^{-3} at 30°C; 3.8×10^{-3} mm Hg at 40°C
Solubility	soluble in water (3.3 g/L); readily soluble in most organic solvents (e.g., dichloromethane, 2-propanol, toluene); limited solubility in petroleum solvents

6.1.2 Odor and Warning Properties Unpleasant odor.

6.2 Production and Use

Demeton-*S*-methyl was first marketed in 1957. It replaced technical grade methyl demeton which had been introduced in 1954 and was a 70:30 mixture of *O*,*O*-dimethyl-*O*-ethylthioethyl phosphorothioate (demeton-*O*-methyl or O-isomer) and *O*,*O*-dimethyl-*S*-ethylthioethyl phosphorothioate (Demeton-*S*-methyl or S-isomer). Demeton-*S*-methyl is a systemic and contact insecticide and acaricide used to control aphids, red spider mites, whiteflies, leafhoppers, and sawflies on garden crops, fruit, and hops (155). It is applied as an emulsifiable concentrate formulation, mainly as a spray, and usually at a concentration of 0.025% active ingredient.

6.4 Toxic Effects

6.4.1.1 Acute Toxicity Demeton-*S*-methyl is an organophosphate that has high oral toxicity with oral LD_{50}s of 33–130 mg/kg (262). The toxicity of demeton-*S*-methyl is markedly increased when it is allowed to age and forms sulphonium derivatives (263) Intravenous and oral LD_{50}s for the sulfoxide and sulfone derivatives of demeton-*S*-methyl were 22–47 mg/kg and 32–65 mg/kg, respectively (261). Intraperitoneal LD_{50}s of 7.5 and 10 mg/kg were also reported for demeton-*S*-methyl, suggesting that oral absorption may be slightly limited and/or that bypassing first-pass hepatic metabolism enhances toxicity (262). Dermal LD_{50}s from 45 to 200 mg/kg, depending on formulation and duration of exposure, were reported for rats, indicating that dermal exposures are about as potent as oral exposures on a milligram per kilogram basis (262). Dermal application of 10 mg/kg to the backs of cats caused mild signs (*sic*); application of 20 or 100 mg/kg caused death (no other details provided) (IPSC 1997). Four hour LC_{50}s for rats were 210–500 mg/m^3 (545).

Demeton-*S*-methyl applied to the shaved skin of rabbits for four hours caused mild erythema and edema that disappeared after three days (262). No signs of eye irritation occurred in rabbits whose eyes were treated with a 0.5% aqueous solution of demeton-*S*-methyl, but an undiluted formulation caused severe lacrimation and miosis. Mild corneal opacity and discrete redness and edema of conjunctivae were observed that disappeared within about 7 days (262).

Demeton-*S*-methyl had skin sensitizing potential when assessed using the guinea pig mazimization test but did not have skin sensitizing potential when assessed using the Buehler epidermal patch test on guinea pigs (262).

6.4.1.2 Chronic and Subchronic Toxicity When groups of six rats were fed diets that contained 50, 100, or 200 ppm (aged) demeton-*S*-methyl (5, 10, and 20 mg/kg/day, respectively) for six months, cholinergic signs (slight tremors, fasciculations) occurred at 200 ppm during the first 5 weeks (263). Decreased body weight gain in the 10- and 20-mg/kg/day rats and decreased brain and RBC cholinesterase activities occurred at 5 ppm and higher.

6.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Demeton-*S*-methyl is completely absorbed and very rapidly eliminated following either oral or intravenous administration. Blood concentration decreased, and the half-life was about 2 hours during the first 6 hours and then about 6 hours for the next 48 hours following oral administration of demeton-*S*-methyl to rats. The half-life thereafter was even longer. The half-life of urinary elimination was 2–3 hours during the first 24 hours and 1.5 days thereafter. Elimination through feces and exhaled air was minimal and accounted for 0.5–2% and about 0.2% of the dose, respectively. Except for RBCs which tended to bind the demeton-*S*-methyl, it was distributed uniformly in various body tissues and organs. At 2, 24, and 48 hours after dosing, about 60%, 1%, and 0.5% of the administered dose, respectively, remained in the body. By 10 days, demeton-*S*-methyl was almost undetectable in most organs except in the RBCs (262).

The main metabolic route of demeton-*S*-methyl is oxidation of the side chain leading to the formation of the corresponding sulfoxide, oxydemeton methyl, and to lesser extent, after further oxidation, the sulfone (262). O-demethylation also occurs. Neither glucuronide nor sulfate conjugates have been identified (262).

6.4.1.4 Reproductive and Developmental Pup viability, lactation index, and body weight gain were reduced in F1 offspring when rats were fed a diet that contained 25 ppm demeton-*S*-methyl for two generations (202). Offspring of rats fed 1 or 5 ppm were unaffected. No compound-related malformation was found in animals of any of the treatment groups.

No alterations of physical appearance or behavior occurred in dams or fetuses from dams given 0, 0.3, 1, or 3 mg/kg demeton-*S*-methyl by gavage on days 6 to 15 of gestation (262). The numbers of live fetuses and resorptions, fetal weight, number of fetuses with malformations, and number of implants were comparable in all groups. No treatment-related visceral or skeletal abnormalities were observed (262). No abortions or increases in the numbers of implantations per day, preimplantation losses, postimplantation losses, resorptions, living and dead fetuses, or sex ratios occurred in rabbits given 3, 6, and 12 mg/kg/day demeton-*S*-methyl by gavage on gestation days 6 to 18. Diarrhea, decreased food consumption, and decreased fetal body weight occurred in the 12 mg/kg/day treated animals. There was no treatment-related increase in gross, skeletal, or visceral malformations (262).

6.4.1.5 Carcinogenesis When dogs were fed diets containing 1, 10, or 100 ppm (day 1–36) followed by 50 ppm (day 37-termination) demeton-*S*-methyl (equivalent to 0.036, 0.36, and 4.6 followed by 1.5 mg/kg/day), diarrhea and vomiting occurred at all levels (262). Multifocal slight/moderate atrophy and/or hypertrophy of proximal renal tubules also occurred in the high dose group. Plasma and RBC cholinesterase activity was reduced at 10 and 100 ppm, and, brain cholinesterase activity was reduced at 10 ppm.

There was no evidence of carcinogenicity in mice given diets with 1, 15, or 75 ppm demeton-*S*-methyl (0.24, 3.47, or 17.81 mg/kg/day (males); 0.29, 4.18, or 20.0 mg/kg/day (females)) for two years (271). Cholinergic signs were not observed at any level nor did mortality differ among groups. Plasma, RBC, and brain cholinesterase activity decreased in mice at 15 and 75 ppm. There was no evidence of carcinogenicity in rats given 1, 7, or 50 ppm demeton-*S*-methyl in their feed (0.05, 0.31, or 2.59 mg/kg/day (males); 0.06, 0.41, or 3.09 mg/kg/day (females)) for 24 months (262). Hair loss and diarrhea occurred more frequently at 50 ppm. Body weight was reduced in males at 7 ppm and in both males and females at 50 ppm. Plasma, RBC, and brain cholinesterase activites decreased in groups given the 7- or 50-ppm diet. Increased incidence of retinal atrophy and keratitis was observed in mice given the 50-ppm diet.

6.4.1.6 Genetic and Related Cellular Effects Studies Available information is insufficient to permit an adequate assessment of the genotoxic potential of demeton-*S*-methyl (262). Demeton-*S*-methyl did not induce DNA damage in the Pol test in *E. coli* with or without metabolic activation, but it did increase mutation rates in the Ames test and in the mouse lymphoma forward mutation assay with or without metabolic activation. In *in vivo* tests, no sister chromatid exchanges (SCEs) were found in the bone marrow of Chinese hamsters treated with high doses of demeton-*S*-methyl, and, bone marrow micronucleus and dominant lethal tests in mice treated with demeton-*S*-methyl gave negative results. However, chromosomal aberrations were found in the bone marrow of Syrian hamsters treated with a commercial formulation of demeton-*S*-methyl (262).

6.3.5 Biomonitoring/Biomarkers Urinary levels of the metabolite dimethyl phosphorothiolated potassium salt (DMPThK) and plasma and whole blood cholinesterase activities were monitored in agricultural workers exposed to demeton-*S*-methyl for 3 consecutive days (262). Exposed subjects were identified as either mixers, sprayers, or others not directly involved in handling the pesticide. Levels of DMPThK in urine from mixers had a medium (*sic*) value of 83 mg/liter and a range of 0–822 mg/liter (neither corrected for creatinine nor for urine volume); urine from sprayers had a mean value of 30 mg/liter (limit of detection) and a range of 0–208 mg/liter, and urine from other subjects not directly exposed had a mean value of 30 mg/liter and a range of 0–100 mg/liter. Whole blood cholinesterase activity was not affected by exposure, and plasma cholinesterase activity was slightly reduced compared to preexposure levels in mixers. No correlation was found between DMPThK levels and plasma cholinesterase activity (269).

6.4.2 Human Experience 6.4.2.2 Clinical Cases Six hundred seventy-three occupational cases of organophosphate poisoning, including three deaths, reportedly occurred in Egypt about 1 week after demeton-*S*-methyl began to be used for spraying cotton (265). Two children evidently accidentally exposed to demeton-*S*-methyl via inhalation while waiting for their father (a sprayman) to finish work, became unconscious for a few minutes. When aroused, they vomited and complained of abdominal colic. Another girl who evidently ate beans contaminated during spraying also vomited and suffered abdominal colic.

One woman attempted suicide by ingesting "1 or 2 mouthfuls" of Metasystox I (25% demeton-*S*-methyl). On admission to hospital she was comatose, sweating, salivating and had pinpoint pupils. Plasma and RBC cholinesterase activites were less than 10% of normal. She was successfully treated and released after 30 days at which time plasma cholinesterase values had returned to normal, but RBC cholinesterase activity was still below normal (262). In another suicide attempt, a 41-year-old pregnant woman was admitted to a hospital about 3.5 hrs after ingesting an estimated 12 g of methyl demeton. Upon admission, blood (*sic*) cholinesterase was 10% of normal. About 12 hours after admission, she became comatose and was treated with atropine, odoxime, haemoperfusion, and artificial ventilation. She recovered and was discharged 24 days later (262).

A man who had been an agricultural applicator for five years worked with demeton-*S*-methyl, mainly as a flagman in aerial spraying but also in preparing the spray and in cleaning containers after spraying. For about a month and half, he was potentially exposed for periods that varied from 20 minutes to 6¾ hours. Symptoms (headaches, nausea, dizziness) gradually increased in severity during the week and subsided during the weekend. Later, he developed anorexia and loss of ability to concentrate. At the end of 6 weeks, his symptoms became worse while he was driving a tractor applying disulfoton. After 2 hours, he became dissatisfied with his control of the machine and sought medical aid. Clinical findings were normal, but cholinesterase activity was low (266). The author concluded that the man had suffered from gradually worsening organophosphate poisoning primarily due to absorption of demeton-*S*-methyl through the skin (despite the use of required protective clothing) that began about 2–3 weeks after initial exposure.

Organophosphate poisoning following demeton-*S*-methyl exposure was described in six men engaged in packaging bulk loads of demeton-*S*-methyl concentrate (500 g/L) into one liter containers (267). The first poisoned worker experienced cholinergic symptoms (nausea, dizziness, weakness, difficult breathing, and diarrhea) after working 1 day filling containers; the second experienced symptoms (giddiness, nausea, weakness, sweating, and cramps) after 72 hours. The filling procedure was modified to decrease worker exposure by requiring more protective clothing and performing operations in a fume "cupboard," but a third worker experienced symptoms (nausea, abdominal cramps, and weakness) after working 2 days using the revised procedure. Plasma and RBC cholinesterase activities measured 15–30 days after exposure were below the lower limit of the normal range and did not completely recover to the normal range until 60 days after exposure. Chemical analysis of vapor in the fume hood and of residue on gloves and other clothing indicated that exposure had occurred primarily via dermal absorption that resulted from contamination of external and internal surfaces of gloves.

Six workers engaged in hop cultivation using Metasystox I (reported to contain demeton-*O*-methyl instead of demeton-*S*-methyl as the commercial name implies) were monitored. They sprayed up to 2400 liters of a 0.1% solution (in water) of the insecticide in 1 day. No significant inhibition of blood acetylcholinesterase was observed at the end of exposure or 1 or 2 days later. One subject, who was exposed twice, showed a 29% decrease in blood (sic) acetylcholinesterase after the second exposure. No cholinergic toxicity was observed in these workers (262).

In a group of men who sprayed cotton fields with demeton-*S*-methyl, signs and symptoms of cholinergic toxicity (gastrointestinal disturbances, dizziness, persistent general weakness and fatigue, respiratory manifestations, headache, sweating, salivation or lacrimation, tremors of outstretched

hands, intention tremors, ataxia, exaggerated superficial and deep reflexes, hiccough, and muscular fasciculations) occurred after 1–18 days of exposure, and the mean latency period was 3 days (265). Serum cholinesterase activity estimates were performed within 24 hours after the onset of symptoms in some patients and after the cessation of symptoms in some others. In most cases, they were repeated two to three times at various intervals up to 40 days from the onset of symptoms. In general, serum cholinesterase activity underwent a marked initial fall followed by a rise above normal levels after about 30–40 days (265).

6.5 Standards, Regulations, or Guidelines of Exposure

Demeton-*S*-methyl is not registered by the EPA for use. It is anticipated that most other national registrations for demeton-*S*-methyl were probably transferred soon after 1998 to oxydemeton-methyl (262). No Occupational Exposure Limits were identified for demeton-*S*-methyl. In the 2000 ACGIH TLVs, in the notice of intended changes, ACGIH proposes a TLV of 0.05 mg/m^3, for demeton-*S*-methyl.

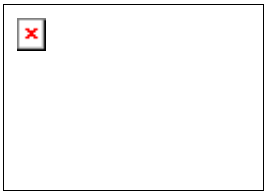
7.0.5 Molecular Formula:

$C_{12}H_{21}N_2O_3PS$

7.0.6 Molecular Structure:



7.1 Chemical and Physical Properties

Diazinon is a colorless liquid.	
Specific gravity	1.116–1.118 at 20°C
Boling point	83–84°C at 0.002 torr
Melting point	>120°C (dec)
Vapor pressure	1.4×10^{-4} mmHg at 20°C
Solubility	slightly soluble in water (0.004 g/100 mL); freely soluble in petroleum solvents; miscible with alcohol, ether, benzene, and similar hydrocarbons

7.1.2 Odor and Warning Properties Faint ester-like odor.
7.2 Production and Use
Diazinon is a nonsystemic insecticide used on a wide variety of agricultural crops such as rice, fruit trees, corn, tobacco, and potatoes and to control fleas and ticks. Various types of formulations are available, including dusts, emulsifiable concentrates, impregnated material, granules, microencapsulated forms, pressurized sprays, soluble concentrates, and wettable powders (55).
7.4 Toxic Effects
7.4.1.1 Acute Toxicity Diazinon is a moderately toxic organophosphate compound that has oral LD_{50}s of 250–466 mg/kg (64a). Oral LD_{50}s for an impure formulation were 76–108 mg/kg (Gaines, 1960). The dose–lethality curve is steep as illustrated by the observation that acute LD_{01}s are only 30–36% smaller than LD_{50}s (64a) and that an acute oral dose of 528 mg/kg was lethal to rats whereas a dose of 264 mg/kg was not (55). Dermal LD_{50}s were 455–900 mg/kg (64a, 268). The dermal LD_{50} for male rats of a sample allowed to completely crystallize in air for several weeks was 34 mg/kg, demonstrating that acute dermal toxicity increases significantly with an impure diazinon formulation (268). Onset of symptoms and death following acute exposures to diazinon occurs between 1 and 6 hours from oral exposures (81, 271) but may be delayed following dermal exposure by about 10 hours (272).

A 4-hour LC_{50} of 3500 mg/m^3 was reported for rats; a 4-h LC_{50} of 1600 mg/m^3 was reported for mice, and a 4-hour LC_{50} of 55,500 mg/m^3 was reported for guinea pigs (545). No deaths occurred among rats exposed to 2330 mg/m^3 diazinon for 4 hours in inhalation chambers and observed for 14 days, although decreased activity and increased salivation were noted (55).

No signs of organophosphate toxicity occurred in rats exposed to 0.05, 0.46, 1.57, or 11.6 mg/m^3 for 6 h/day, 5 days/week for three weeks (55). Serum cholinesterase activity decreased in females exposed to 0.46 mg/m^3 and higher and in males exposed to 1.57 mg/m^3 and higher; RBC acetylcholinesterase activity decreased in females exposed to 11.6 mg/m^3, and brain acetylcholinesterase activity decreased in females exposed to 1.57 and 11.6 mg/m^3.

Among male rats that were given single doses of 100, 200, or 400 mg/kg diazinon by gavage, cholinergic signs (lacrimation, salivation, miosis, hypoactivity, ataxia, increased landing foot splay, decreased tail-pinch response, tremors, chewing (smacking), and hypothermia) peaked at 4 hours in the 400-mg/kg group and were still present at 24 hours, but had disappeared by 72 hours after dosing (55). Cholinergic toxicity also occurred in the 200-mg/kg group, and only hypoactivity and decreased defecation occurred in the 100-mg/kg group. Among rats given single oral doses of 2, 132, 264, or 528 mg/kg diazinon, cholinergic signs (autonomic (smacking), neuromuscular (ataxia, abnormal gait)) occurred at 132 mg/kg and higher (55). Serum cholinesterase and RBC

acetylcholinesterase activity was reduced at all levels (55).

Diazinon was not neurotoxic in atropinized hens given 11.3 mg/kg twice orally, 21 days apart (55).

7.4.1.2 Chronic and Subchronic Toxicity No cholinergic toxicity occurred in rats fed diets that contained up to 1000 ppm technical diazinon for four weeks (82), in rats or mice fed diets that contained up to 1600 ppm for 13 weeks (87), in rats given diets that contained up to 25 ppm diazinon for up to 92 days (79, 80) or in rats fed diets, that contained up to 125 ppm diazinon for 15–16 weeks (81). Subchronic exposures in the 3- to 100-ppm range were associated with inhibition of RBC acetylcholinesterase activity, and exposures to 1000 ppm were associated with brain acetylcholinesterase inhibition (79–82). Six week exposures of rats to up to 180 mg/kg/day via their diet caused no cholinergic toxicity, although RBC acetylcholinesterase activity was inhibited at doses of 8 or 9 mg/kg/day (83). Thirteen-week exposures of rats to 168 or 212 mg/kg/day resulted in cholinergic signs (soft stools and hypersensitivity to touch and sound), although RBC acetylcholinesterase activity was inhibited at doses as low as 15 mg/kg/day (83).

No cholinergic toxicity occurred in dogs given diazinon via their diet (0.25, 0.75, or 75 ppm) for 12 weeks, although RBC acetylcholinesterase activity was inhibited for 6 weeks after termination of dosing to dogs given the 75-ppm diet (84). When dogs were given diets that contained 0.1, 0.5, 150, and 300 ppm diazinon for 13 weeks, cholinergic signs (emesis and diarrhea) occurred but were not dose-related (90). Significant reductions in RBC and brain acetylcholinesterase levels occurred in rats fed the 150-ppm diet.

7.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Absorption of diazinon following oral exposures is rapid and complete. Nearly 100% of orally administered diazinon was recovered in urine (70–80%) and feces (16–24%) within 168 hours in rats (98). Diazinon was not detected later than 2 days after a final repeated dose of diazinon, demonstrating that it does not accumulate in tissues (98). The biological half-life of diazinon was 12 hours. In dogs, absorption was at least 85% after a single oral dose (99). About 68% of an oral dose of diazinon was detected in urine 60 minutes after dosing in mice. In all cases, diazinon is widely distributed to tissues, especially adipose tissue, muscle, brain, and liver (101). Similar results were observed in dogs, guinea pigs, goats, sheep, and cows (55).

The pharmacokinetics of diazinon following inhalation exposure has not been studied. However, pharmacokinetic studies following intravenous administration of diazinon to dogs indicated rapid absorption and an elimination half-life of 6 hours (99). Recovery in urine was 58% of the administered dose after 24 hours and was primarily diethyl phosphoric and phosphorothioic acid. In rats given diazinon intravenously, plasma diazinon levels declined rapidly during the distribution phase and more slowly during the elimination phase and were characterized by an elimination half-life of about 6 hours (102). In another study that examined the toxicokinetics of diazinon in rats following oral and intravenous exposure, the elimination half-lives were 1.8 and 4.7 hours, respectively, suggesting that hepatic metabolism enhances elimination (102). In four rhesus monkeys dosed intravenously with 32 mg diazinon, about 56% was excreted in urine, and 23% was eliminated in feces after 7 days, accounting for about 70% of the total dose. Most of the dose was excreted in urine on day 1 (103).

Total dermal absorption of diazinon was estimated at about 3–4% of the dose applied to the forearm or abdomen (2 mg/cm^3) of humans during 7 days regardless of whether the vehicle was acetone or lanolin (103). Absorption measured in human skin placed in an *in vitro* diffusion cell was about 14%.

The metabolism of diazinon is complex. The primary pathways are desulfuration by cytochrome P450 enzymes to the metabolite diazoxon which then either binds to acetylcholinesterase and other esterases or is further metabolized to diethyl phosphoric acid and oxidative products such as 2-

isopropyl-4-methyl-6-hydropyrimidine (104, 105). Alternatively, diazinon is dearylated and hydrolyzed by cytochrome P450 enzymes to diethyl phosphorothioic and phosphoric acid and other oxidation products (e.g. 2-isopropyl-4-methyl-6-hydropyrimidine) which are excreted mostly in urine, although minor amounts of these metabolites and some unchanged diazinon have been detected in feces (98, 100, 104).

7.4.1.4 Reproductive and Developmental Diazinon did not cause adverse effects on fertility in rats fed 0.05 mg/kg/day diazinon in the diet for 60 days before weaning for four generations (89). No gross or histological treatment-related damage to reproductive tissues occurred in rats given up to 168 mg/kg/day (males) or 212 mg/kg/day (females) diazinon for 13 weeks (83), in rats given up to 10 mg/kg/day (males) or 12 mg/kg/day (females) for 98 weeks (86), or in dogs given up to 11 mg/kg/day for 13 weeks (90). In another study, testicular atrophy and arrested spermatogenesis were observed in one dog given 10 mg/kg/day and in all dogs given 20 mg/kg/day for 8 months via corn oil capsule (85).

No teratogenic or fetotoxic effects occurred in rabbits given 7–100 mg/kg/day diazinon by gavage during gestation (91, 92). Cholinergic signs occurred in dams given 30 mg/kg or more. In hamsters, no embryo- or teratogenicity occurred at doses up to 0.25 mg/kg/day during gestation, although cholinergic toxicity occurred in parents (diarrhea, salivation, and incoordination). In another study, however, diazinon caused an increased incidence of stillbirths in dogs given 1.2 or 5 mg/kg/day by gavage (85). In rats, doses greater than or equal to 70.6 mg/kg/day during gestation increased fetal resorptions when given on days 8 to 12 or 12 to 15; no effects occurred at doses less than 70.6 mg/kg/day (93). In another study, no differences were observed in litter size, fetal body weight, fetal brain weight, number of resorptions, or corpora lutea among rats given diazinon via peanut oil gavage at 0, 40, 50, 60, or 75 mg/kg/day on gestation days 7 through 19 (94).

Pregnant mice given 0, 0.18, or 9 mg/kg/day diazinon throughout gestation (18 days) gave birth to viable offspring, although pups exposed to 9 mg/kg grew more slowly than controls (590). Mature offspring of both treated groups displayed impaired endurance and coordination on rod cling and inclined place tests of neuromuscular function. Morphological abnormalities in brain occurred among offspring of dams exposed to 9.0 mg/kg/day.

7.4.1.5 Carcinogenesis No signs of cholinergic toxicity occurred in rats given diets containing 10 to 1000 ppm diazinon for 72 weeks or in dogs given up to 4.6 mg/kg/day diazinon via capsule 6 days/week for up to 46 weeks (82). Doses of 4.3 to 4.6 mg/kg/day, however, caused significant RBC cholinesterase inhibition in dogs after two week (82). Cholinergic signs (soft stools) occurred in dogs given 9.3 mg/kg by 30 days and excitability and tremors occurred in one dog given 25 mg/kg/day for 6 days. In dogs given 2.5, 5.0, 10.0, or 20.0 mg/kg/day diazinon by gavage for 8 months, cholinergic signs were observed in one dog given 10 mg/kg/day and emesis, fasciculation and mortality occurred in dogs given 20.0 mg/kg/day (85). No cholinergic toxicity occurred in pigs given 1.25 mg/kg/day for eight months; but cholinergic signs were observed pigs given 2.5–10 mg/kg/day (85).

No signs of cholinergic toxicity occurred in rats given diazinon via their diet at doses of 0.004, 0.06, 5, or 10 mg/kg/day (males) and 0.005, 0.07, 6, or 12 mg/kg/day (females) for 52 or 98 weeks (86). After 1 year, RBC acetylcholinesterase activity decreased in males given 5 and 10 mg/kg/day and in females given 6 or 12 mg/kg/day; brain acetylcholinesterase activity was unchanged in males but decreased in females given 6 or 12 mg/kg/day. During a 4-week recovery period, RBC acetylcholinesterase activity returned to normal in males, whereas that of females dosed at 12 mg/kg/day remained decreased; brain acetylcholinesterase activity returned to normal in females. Results were similar at 98 weeks.

Diazinon was not carcinogenic in rats or mice when they were given diets containing 400 or 800 ppm diazinon (rats) or 100 or 200 ppm diazinon (mice) for 2 years (87). However, clinical signs of hyperactivity were noted in low- (males) and high-dose (males and females) rats and in all dosed mice (*sic*). Bloating, vaginal bleeding, and vaginal discharge were also noted in the dosed female

rats.

No cholinergic, hematological, clinical chemistry, or histopathological signs occurred at any dose in monkeys given oral doses of 0, 0.05, 0.5, or 5 mg/kg diazinon 6 days/week for two years via gavage, although serum and RBC cholinesterase activities were inhibited in monkeys given 0.5 or 5 mg/kg/day (88).

7.4.1.6 Genetic and Related Cellular Effects Studies The genotoxicity of diazinon is equivocal. *In vitro* test results showed that diazinon was positive for gene mutations in the *S. typhimurium* test assay with metabolic activation and in the mouse lymphoma cell forward mutation assay without metabolic activation (55, 96). Diazinon was also positive for chromosomal aberrations in Chinese hamster cells with metabolic activation (55). But in other tests, diazinon was negative for gene mutations in the *S. typhimurium* test assay (97) and in the rec assay utilizing strains of *Bacillus subtilis* (55) both of which were conducted without metabolic activation. Tests for sister chromatid exchange in Chinese hamster V79 cells with and without metabolic activation (55) and for chromosomal aberrations in human peripheral blood lymphocytes (55) were also negative.

7.4.2 Human Experience 7.4.2.2 Clinical Cases Ingestion of diazinon causes typical organophosphate poisoning that varies in intensity with dose (107–109). Lethality followed adult ingestion of an estimated 293 mg/kg diazinon (110) and child ingestion of 20 mg/kg (111), although the latter estimate may have been complicated by the possible simultaneous ingestion of parathion and/or chlordane. A summary of 76 fatal cases of diazinon poisoning indicated a high incidence of miosis, froth from nose and mouth, acute pulmonary edema and congestion, acute ulcers, blood stained gastric contents, CNS hemorrhage, and evidence that death was due to asphyxiation (109). No estimates of exposure levels were provided.

Cholinergic symptoms (nausea, epigastric pain, headache, miosis and unreactive pupils, tachycardia) occurred in a woman who ingested an estimated 1.5 mg/kg diazinon (112). Severe toxicity (bradycardia, tachycardia, clonus, stupor, profuse diaphoresis, sialorrhea, miosis, hyperreflexia, weakness, dysdiadokinesis, abdominal pain, nausea, coma, twitching, restlessness, and bronchospasm) was reported in five individuals who intentionally ingested estimated doses of 240 to 986 mg/kg diazinon and recovered (113). Signs of organophosphate poisoning (profuse sweating, nausea, vomiting, and abdominal cramps) were reported in children who had eaten oatmeal contaminated with about 2.5–244 ppm diazinon (114). An earlier report indicated that oatmeal contaminated by home spraying with a 25% concentrate of diazinon caused organophosphate poisoning (nausea, vomiting, abdominal cramps, diaphoresis, muscular weakness, rolling eye movements, ataxia, and muscle cramps) in eight children from two different families (115).

A man died from cardiac arrest, despite atropine therapy, following inhalation exposure to a commercial insecticide formulation containing diazinon and malathion, but no estimate of exposure was provided (115a). Inhalation exposures to a diazinon spray used to kill cockroaches in an adjoining apartment were implicated in the organophosphate poisoning of twin infants (116).

Depressed serum cholinesterase activities were only sometimes accompanied by signs of cholinergic toxicity in individuals occupationally exposed to diazinon primarily via inhalation (117). However, cholinergic symptoms (headache, blurred vision, dizziness, fatigue, nausea, and vomiting) began within 15 minutes in mushroom workers exposed to diazinon when it was sprayed around the only entrance to a room in which they were working. Reduced serum and RBC cholinesterase activities also occurred within 48 hours, and serum cholinesterase activities remained depressed for 15 days (118). Based on comparison with stabilized cholinesterase measurements taken in affected individuals 15 days after exposure, the authors estimated that plasma cholinesterase activities had been inhibited by about 30–34% and RBC acetylcholinesterase activities had been inhibited by about 27–34%.

In another report that involved multiple routes of exposure, several family members experienced

diazinon poisoning (headache, vomiting, fatigue, and chest heaviness) associated with slightly depressed serum cholinesterase activities for several months after their home had been treated with diazinon (118a). Surface concentrations in the home ranged from 126 to 1051 mg/m^2, air concentrations were between 5 and 27 mg/m^3, and some clothing showed contamination (0.5 to 07 mg/g).

Dermal exposure to diazinon caused cholinergic signs (cyanosis, forthing at the mouth, drowsiness, nausea, vomiting, abdominal colic, diarrhea, tachpnea, miosis, and sinus tachycardia) in two female gardeners (119), but estimates of exposure were not available.

Exposure to diazinon via multiple routes was estimated at an average of 0.02 mg/kg/day in 99 workers exposed to diazinon granules 8 h/day for 39 days during an insecticide application program. Slight neurological functional deficits (postshift symbol-digit speed and pattern memory accuracy) were reported among the workers, but these effects were not statistically significant (120).
7.5 Standards, Regulations, or Guidelines of Exposure
Diazinon is under reregistration by the EPA (78).

The ACGIH TLV for diazinon is 0.1 mg/m^3 with a skin notation (154). The OSHA PEL-TWA and NIOSH REL-TWA are 0.1 mgm^3 with a skin notation. Most other countries have also established an Occupational Exposure Limit of 0.1 mg/m^3 for diazinon (Australia, Belgium, Denmark, Finland, France, Germany, India, The Netherlands, and the United Kingdom).

8.1 Chemical and Physical Properties

Dichlorvos is a colorless to amber, oily liquid. It hydrolyzes at a rate of 3% per day in saturated aqueous solution at room temperature; at high pH or in boiling water, it completely hydrolyzes in 1 hour. Dichlorvos decomposes to toxic gases and vapors (such as hydrogen chloride gas, phosphoric acid mist, and carbon monoxide)

Specific gravity	1.415 g/ml at 25°C
Boiling point	140°C at 20 mmHg; 221°C at 760 mmHg
Melting point	–60°C
Vapor pressure	0.012 torr at 20°C
Solubility	slightly soluble in water (1 g/100 mL at 20°C); miscible with aromatic and chlorinated hydrocarbon solvents and alcohols

8.1.2 Odor and Warning Properties Mild chemical odor.

8.2 Production and Use

Dichlorvos is used against a wide variety of insects in greenhouses, outdoor fruit and vegetable crops, and is also used in aquaculture to rid fish of various skin parasites. In addition, it is used to control severe internal and external parasite infestations in animals and humans (57). It is a available as soluble concentrates and aerosols and is also formulated with other pesticides.

8.4 Toxic Effects

8.4.1.1 Acute Toxicity Dichlorvos is an organophospahte that has high oral toxicity, oral LD_{50}s of 56–98 mg/kg in rats, and oral LD_{50}s 133–139 mg/kg in mice (57). Dose–lethality curves are steep; oral LD_{01}s are about one-half or less the LD_{50} value (62, 64a), and death occurs quickly within minutes. Cholinergic signs occurred within 7–15 minutes in dogs given a single oral dose of 11 or 22 mg/kg dichlorvos (62a). Three of 12 dogs given 22 mg/kg died within 10–155 minutes of treatment. Similar effects occurred when dogs were given 2–11 mg/kg dichlorvos intravenously, but death occurred slightly more rapidly, by 7 minutes in one case. When rats were given single oral doses of 0.5, 35, or 70 mg/kg dichlorvos by gavage, the 35- and 70-mg/kg groups exhibited cholinergic signs within 15 minutes after dosing (120a). Several animals in the 70-mg/kg group died. No signs of toxicity were apparent in any rats given 0.5 mg/kg or in any of the 35- or 70-mg/kg treated rats that survived 7 days after dosing (120a). Severe cholinergic signs occurred in dogs given 15–30 mg/kg/day for 12–24 days via corn oil capsule, and less severe cholinergic signs occurred in dogs given 1–10 mg/kg/day for 16–24 days (95). Doses of 0.1 mg/kg/day for up to 24 days had no effect.

Dermal LD_{50}s are 75–107 mg/kg in rats (64a). Cholinergic signs and death occurred in monkeys after a single 100 mg/kg dermal dose, after eight 50-mg/kg/day doses during 10 days, and after ten 75-mg/kg doses during 12 days, suggesting that dermal exposures may be cumulative (121).

Inhalation exposures are more potent on the basis of body weight than oral exposures (122). Four and one-hour LC_{50}s for dichlorvos in rats are 455 and 340 mg/m^3 (123). A saturated atmosphere of

dichlorvos (230–341 mg/m^3) caused deaths among rats after 7 to 62 hours (121). Rabbits are more sensitive than rats or mice to dichlorvos vapor. Deaths occurred in 9 of 16 rabbits exposed to 6.25 mg/m^3 and in 6 of 20 rabbits exposed to 4 mg/m^3 for 23 h/day for 28 days during gestation (37), whereas no deaths occurred in mice or rats exposed to the same concentrations. Even exposures up to 56 mg/m^3 for 14 days did not cause deaths in rats (124). No deaths occurred in mice exposed to 30–55 mg/m^3 for 16 hours (125) or in pregnant mice or rabbits exposed to 4 mg/m^3 for 7 h/day (126). No adverse effects occurred in rhesus monkeys exposed to 0.48, 2.3, 2.6, or 12.9 mg/m^3 for 2 h/day for 4 days, although RBC cholinesterase was inhibited in monkeys exposed to 12.9 mg/m^3 (127).

Delayed neuropathy occurred in chickens after 35 days treatment with 6.1 mg/kg/day dichlorvos; 3.1- and 4.4-mg/kg/day doses were ineffective (128). Two doses of 16.5 mg/kg dichlorvos 21 days apart to hens did not cause acute delayed neurotoxicity, although signs of cholinesterase inhibition were apparent shortly after dosing (120a).

In a guinea pig mazimization test, induction with dichlorvos by intradermal injection and topical application and subsequent challenge with topical dichlorvos solutions showed sensitization (129).

8.4.1.2 Chronic and Subchronic Toxicity A 90-day LD_{50} > 70 mg/kg was determined in rats fed dichlorvos in their diet for 90 days (196). Because this value was more than the single dose LD_{50} of 56 mg/kg, it was concluded that dichlorvos does not have a cumulative effect. When rats were given feed that delivered 0–360 mg/kg/day for 6 weeks, all rats that consumed 180 mg/kg or more died whereas none that consumed 90 mg/kg/day or less died (130). When mice were given feed that delivered 0–1080 mg/kg/day for six weeks, four of five females given 720 mg/kg/day died; all mice given 1080 mg/kg/day died (130).

Cholinergic signs occurred in dogs given 0.625 or 1.25 mg/kg/day dichlorvos by capsule for 70–90 days (65). RBC and brain cholinesterase activities were inhibited in dogs given 0.625 mg/kg/day. Ninety-day studies of dichlorvos in rats have shown that dietary levels up to 1000 ppm (about 70 mg/kg/day) do not result in overt cholinergic toxicity, although exposures to levels of 200 ppm or greater inhibit RBC cholinesterase (56, 57). Oral gavage studies show lower effect levels. Daily administration of 7.5 mg/kg/day or more to rats via gavage for 13 weeks is associated with cholinergic toxicity (131) as well as significant RBC and brain acetylcholinesterase inhibition. Daily administration of 160 mg/kg/day by gavage for 13 weeks caused death in mice (131) as well as significant RBC and brain acetylcholinesterase inhibition. Gavage doses up to 40 mg/kg/day had no effect.

8.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms At least 85% of an oral dose of dichlorvos is absorbed (145). Dichlorvos is well absorbed following inhalation exposure based on the occurrence of toxic symptoms associated with inhalation exposures and the detection of specific dichlorvos metabolites (dichloroethanol and dimethyl phosphate) in urine of individuals exposed to dichlorvos (137, 138). Excretion is very rapid based on the observation that dichlorvos could not be detected in the blood of two male volunteers immediately after exposure to dichlorvos vapor (145). An elimination half-life of 13.5 minutes was estimated based on dichlorvos concentration in rat kidney after 2 or 4 hours exposure to 5 mg/m^3 (145). In mice and rats given single oral doses of dichlorvos, 59–65% was eliminated in urine, 3–7% was eliminated in feces, 14–18% was eliminated as CO_2 by 4 days after dosing, and the vast majority was eliminated by 24 hours (138). Retained dichlorvos following either oral or inhalation exposures is high because it is incorporated into intermediary metabolism (139).

Dichlorvos binds to acetylcholinesterase forming dimethoxy-phosphorylated acetycholinesterase and dichloroacetaldehyde (140). Alternatively, it is metabolized (primarily in the liver but also in the

blood, adrenal, kidney, lung, and spleen) via two pathways (141). The major pathway is catalyzed by A-esterases and produces dimethyl phosphate and dichloroacetaldehyde (140). Dichloroacetaldehyde is converted to dichloroethanol which is then excreted as the glucuronide. Alternatively, dichloroacetaldehyde is dehalogenated and the carbon atoms are incorporated into normal tissue constituents via intermediary metabolism (137, 138, 141). The second minor pathway is catalyzed by glutahione-*S*-transferase and produced desmethyl dichlorvos and *S*-methyl glutathione. Subsequent degradation of desmethyl dichlorvos to dichloroacetaldehyde and monomethyl phosphate is catalyzed by A-esterases. *S*-methyl glutathione is broken down to methylmercapturic acid and excreted in urine. CO_2 is also the major metabolite following inhalation exposures. The major urinary metabolite following either oral or inhalation exposures is dichloroethanol glucuronide.

Dichlorvos is rapidly metabolized in human blood by A-esterases (142, 143). Unlike paraoxonse which exhibits polymorphism in the human population (144), dichlorvos A-esterase appears to be normally distributed. Half-lives for degradation of dichlorvos in whole blood after inhalation were 8.1 minutes for men and 11.2 minutes for women (145).

8.4.1.4 Reproductive and Developmental Several studies indicated that dichlorvos is not a reproductive or developmental toxin. No impairment of male fertility occurred in mice exposed to 30 or 55 mg/m^{3}dichlorvos for 16 hours or to 2.1 or 5.8 mg/m^3 for 23 hours daily for 4 weeks (37). However, estrus was delayed 10 days in female rats that were continuously exposed from birth to 2.4 mg/m^3 dichlorvos vapors from a Shell “No-pest Strip” (132). Number, viability, and growth rate were normal in offspring of swine fed up to 37 months on diets containing 200–500 ppm dichlorvos (133). No maternal or reproductive toxicity occurred in rats given dichlorvos for three generations at a dietary level of 0.1–500 ppm (about 0.005–25 mg/kg/day) (95).

No adverse effect on fetuses occurred when pregnant rats were given injections of 15 mg/kg dichlorvos on gestation day 11 (379), 0.1–21 mg/kg/day dichlorvos on gestation days 6 through 15 (95), or were exposed to 0.25–6.25 mg/m^3 dichlorvos vapor for 23 h/day on gestation day 1 through 20 (37). No adverse effect on fetuses occurred when pregnant mice were given the maximal tolerated dose of dichlorvos (60 mg/kg) on gestation days 6 through 15 or were exposed to 4 mg/m^3 dichlorvos vapor for 7 h/day (126). No adverse effect occurred on fetuses when pregnant rabbits were administered doses of 0.1 to 7.0 mg/kg/day dichlorvos by gavage on gestation days 7 through 19 (120a) or when rabbits were exposed for 23 h/day to 0.25 to 6.25 mg/m^3 dichlorvos vapor on gestation days 1 through 28 (37).

8.4.1.5 Carcinogenesis Dichlorvos was not carcinogenic when rats were exposed to 0.05, 0.48, or 4.70 mg/m^3 dichlorvos for 23 h/day, 7 days/week for up to two years (136). Nor were any cholinergic signs observed in any group. The EPA's Carcinogenicity Peer Review Committee (CPRC) considered this study sufficient evidence that dichlorvos does not cause cancer via inhalation (68).

Carcinogenicity was not observed in rats given diets of 0, 150, or 326 ppm dichlorvos (equivalent to doses of about 8–14 and 16–29 mg/kg/day) for 80 weeks and then observed for an additional 30 weeks (130). The results of this study, however, were questioned because of an extraordinarily high mortality rate in control rats. Therefore, the chronic toxicity and carcinogenicity of dichlorvos was reevaluated in rats dosed with dichlorvos by gavage at levels of 0, 4, or 8 mg/kg/day dichlorvos for 5 days/week for 103 weeks (131). Cholinergic signs of toxicity occurred and RBC acetylcholinesterase activity decreased in both groups. Significant increase in mammary gland neoplasms in females and a significant trend (not dose related) for mononuclear cell leukemia was observed in males. Peer review panels characterized these results as “some evidence” of carcinogenic activity in males and equivocal evidence” in females (131). EPA's CPRC concluded that increased incidence of leukemia in rats may not be biologically significant (68, 120a).

Carcinogenicity was not observed in mice given diets that delivered 57 or 114 mg/kg/day dichlorvos for 80 weeks (130). However, a positive trend for squamous cell papilloma and carcinomas of the forestomach was observed in mice given 10–40 mg/kg/day dichlorvos by gavage for 5 days/week for 102 weeks (131). Significantly decreased RBC acetylcholinesterase activity was also observed at all levels. Peer review panels characterized these results as "some evidence" of carcinogenicity in male mice and "clear evidence" in female mice (131). However, the relevance of forestomach tumors to humans is questionable. Carcinogenicity was not reported in male or female mice given 58 or 95 mg/kg/day or 56 or 102 mg/kg/day, respectively, in their drinking water for 2 years (95). However, there was a dose-related decrease in absolute and relative weight of the gonads of males, and testicular atrophy increased in males given the high dose (95 mg/kg/day). The absolute and/or relative weight of the pancreas also decreased in treated females.

When dogs were given dichlorvos by capsule for 52 weeks at doses of 0, 0.1, 1.0, or 3.0 mg/kg/day, one male in the 3.0 mg/kg/day group exhibited cholinergic toxicity only at week 33 (57). RBC cholinesterase was inhibited at doses of 0.1 mg/kg/day and higher, and brain cholinesterase was inhibited in the 1.0-mg/kg/day (males only) and 3.0-mg/kg/day groups.

8.4.1.6 Genetic and Related Cellular Effect Studies Dichlorvos is not genotoxic when tested in *in vivo* system but is generally genotoxic or mutagenic in *in vitro* test when metabolizing enzymes are not present (57). Dichlorvos increased the frequency of chromosomal damage and micronucleus formation in Chinese hamster ovary cells; induced sister chromatid exchange, chromosomal aberrations, and transformation in cultured rat tracheal epithelial cells; induced DNA single-strand breaks in isolated rat hepatocytes; and caused increases in cell transformation of hamster embryo cells (134).

Dichlorvos was negative in the sex-linked lethal mutation test in *Drosophila*. However, increased mutations and chromosomal abnormalities occurred in flies given dichlorvos-contaminated food. Dominant lethal mutations did not occur in mice given an intraperitoneal dose or oral doses of 5 or 10 mg/kg dichlorvos or in mice exposed to dichlorvos via inhalation (30 or 55 mg/m^3). No chromosome damage occurred in mice given drinking water containing 2 mg/L dichlorvos for 7 weeks, no aberration in chromosomal structure or number occurred in bone marrow cells of mice given intraperitoneal injections of dichlorvos for 2 days, and no chromosomal abnormalities occurred in mice exposed to 64–82 mg/m^3 dichlorvos for 16 h or to 5 mg/m^3 for 21 days (134). There is a report that intraperitoneal injection of mice with lethal (LD_{50}, ½ LD_{50}) amounts of dichlorvos causes chromosomal aberrations in bone marrow (146). However, the usefulness of this study in predicting *in vivo* genotoxicity has been challenged because of the toxic dose administered (134). In other *in vivo* studies, an increase in the percentage of hair follicles that contained nuclear aberrations occurred in mice 24 hours after a single dermal dose of dichlorvos (134a) and an increase in the incidence of micronuclei occurred in cultured skin cells from mice given a single dermal dose of dichlorvos (135).

It has been suggested that dichlorvos is not genotoxic *in vivo*, despite its methylating ability, because the phosphorus atom of the molecule is a stronger electrophile than the methyl carbons. Hence, *in vivo*, dichlorvos is much more likely to react with A-type esterases, serum cholinesterase, or acetylcholinesterase than with DNA (57, 134).

8.3.5 Biomonitoring/Biomarkers The major metabolites of dichlorvos, dimethyl phosphate, and the glucuronide conjugate of dichloroethanol, are rapidly excreted in urine and could conceivably be used to monitor acute dichlorvos exposure. However, because other organophosphates, naled and trichlorphon, are metabolized to dichlorvos, exposure to them would have to be ruled out before a definitive exposure of dichlorvos could be made.

8.4.2 Human Experience 8.4.2.2 Clinical Cases Death has followed accidental or intentional ingestion of liquid dichlorvos or cake-like baits containing both malathion and dichlorvos (504).

Two workers in Costa Rica died after splashing a concentration formulation of dichlorvos on their bare arms and failing to wash it off (504). Persistent contact dermatitis has also been reported following skin contact with dichlorvos (148).

RBC acetylcholinesterase activity marginally decreased in one of two dichlorvos applicators exposed to an estimated level of 0.02 mg/m^3 for about 25.5 minutes and 0.028 mg/kg/hr dermally (149). RBC acetylcholinesterase activity was reduced in some residents exposed to an estimated level of 0.2 mg/m^3 dichlorvos for about 15.8 hours, and some residents complained of headache (149). Average air concentrations of 0.13 mg/m^3 resulting from the use of resin strips in residences had no effect on RBC acetylcholinesterase activity (149a). Airbone levels of dichlorvos that caused slight to moderate RBC cholinesterase depression were 0.7 mg/m^3 averaged over 1 year in factory workers who produced dichlorvos vaporizers (149b). No significant change in RBC acetylcholinesterase activity occurred in babies exposed to an estimated 0.05 to 0.16 mg/m^3 dichlorvos for 18 h/day for 5 days (150).

Exposure of men to 0.1 to 0.3 mg/m^3 dichlorvos in 39 half-hour periods during 14 days had no effect on RBC, plasma cholinesterase, or physiological function (151). When the intensity of exposure was kept the same but the frequency of exposure increased to 96 half-hour exposures during 21 days, plasma cholinesterase activity slightly decreased, and when exposure concentration was increased to 0.4 to 0.5 mg/m^3, plasma cholinesterase activity significantly decreased. RBC cholinesterase activity was unaffected under any exposure conditions. No cholinergic signs or RBC acetylcholinesterase inhibition occurred in men exposed to average dichlorvos concentrations of 0.49 or 2.1 mg/m^3 for 1 or 2 hours on 4 consecutive days in a simulated aircraft cabin (127).

No cholinergic signs or RBC acetylcholinesterase inhibition occurred in men given 1- to 2.5-mg doses of dichlorvos via two corn oil capsules daily for up to 28 days (152) or in men given 0.9 mg dichlorvos three times a day for 21 days (152a). No adverse clinical signs or RBC acetylcholinesterase inhibition occurred in men given two oral doses of 35 mg dichlorvos (0.5 mg/kg/day), 12 or 15 daily doses of 21 mg dichlorvos (0.3 mg/kg/day), or 21 daily doses of 7 mg/kg dichlorvos (0.1 mg/kg/day) (120a). When the same individuals were given 70 mg dichlorvos for 14 days, however, RBC acetylcholinesterase was significantly inhibited. Cholinergic toxicity did not occur in volunteers given single oral doses of dichlorvos in slow release polyvinyl resin pellets ranging from 0.1 to 32 mg/kg, despite the fact that RBC acetylcholinesterase was dose-dependently inhibited because it was maximal at 24 mg/kg (153). Repeated daily administration of 8 to 38 mg/kg for 7 days caused cholinergic toxicity and dramatically decreased RBC acetylcholinesterase activity, so the experiment was terminated in most subjects in less than 7 days.

Six of 59 males and 9 of 48 females in an occupational study of flower growers showed positive reactions on patch testing of dichlorvos for an overall rate of 14%. Twelve of 18 subjects who had positive skin patch test reactions to triforine (1,4-bis (2,2,2-trichlor-1-formamidoethyl)piperazine) also showed positive reactions to dichlorvos (129).

8.5 Standards, Regulations or Guidelines of Exposure

Dichlorvos is undergoing reregistration by the EPA (9a). The ACGIH TLV for dichlorvos is 0.9 mg/m^3 with a skin notation (154). The OSHA PEL-TWA and NIOSH REL-TWA are 1 mg/m^3 with a skin notation. Most other countries have established OELs of 0.1 ppm as well (Republic of Egypt, Australia, Austria, Belgium, Denmark, Finland (1 mg/m^3) (Jan. 93), France, Germany 0.11 ppm (1 mg/m^3), Hungary STEL 0.2 mg/m^3 (Jan. 93), India, The Netherlands, The Philippines 1 mg/m^3 (Jan. 93), Poland 1 mg/m^3 (Jan. 93), Russia 0.2 mg/m^3 (Jan. 93), Switzerland, Thailand, United Kingdom 0.1 ppm (0.92 mg/m^3).

9.0.3 Trade Name:
Bidrin®; Carbicron®; Ektafos®
9.0.4 Molecular Weight:
237.21
9.0.5 Molecular Formula:
$C_8H_{16}NO_5P$
9.0.6 Molecular Structure:

9.1 Chemical and Physical Properties
Pure dicrotophos is an amber liquid; the commercial grade which consists of 85% E-isomer is brown in color. Dicrotophos is stable when stored in glass or polyethylene containers up to 40°C but decomposes after 31 days at 75°C or after 7 days at 90°C. Dicrotophos emits toxic fumes of phosphorus and nitrogen oxides when heated to decomposition.

Specific gravity	1.216 at 15°C; 8.6×10^{-5} mmHg at 20°C
Boiling point	440°C at 760 mmHg
Vapor pressure	1×10^{-4} mmHg at 20°C
Solubility	slightly soluble in xylene, kerosene, and diesel fuel; miscible with water, acetone, alcohol, 2-propanol, and other organic solvents

9.1.2 Odor and Warning Properties A mild ester odor.
9.2 Production and Use
Dicrotophos was introduced in 1956 as a systemic and contact organophosphorus insecticide effective against sucking, boring, and chewing pests and is recommended for use on coffee, cotton, rice, pecans, and other crops. It is also used to control ticks and lice on cattle (155). Dicrotophos is available as 24% and 85% concentrates, as 40% and 50% emulsifiable concentrates, water-soluble concentrates, and ultra low volume formulations (155).

9.4 Toxic Effects

9.4.1.1 Acute Toxicity Dicrotophos is an organophosphate that has high oral toxicity and oral LD_{50}s of 16–21 mg/kg (64a). The dermal LD_{50} of dicrotophos is 42–43 mg/kg in rats (64a) and 225 mg/kg in rabbits (155). A 4-hour LC_{50} of 90 mg/m^3 and a 1-hour LC_{50} of 610–910 mg/m^3 was reported for rats (545).

9.4.1.2 Chronic and Subchronic Toxicity Cholinergic toxicity did not occur in rats fed diets that contained 0, 15, or 150 ppm dicrotophos for 4 weeks, although whole blood and plasma cholinesterase activites were markedly inhibited at both dose levels (156).

9.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms The oral, intraperitoneal, and intravenous LD_{50}s for dicrotophos are equivalent (ranging from 9–17 mg/kg), indicating that it is essentially completely absorbed orally. Experimental studies show it is well absorbed via other routes of exposure as well.

After 6 hours, 65% of a subcutaneously injected dose (10 mg/kg) was excreted, and after 24 hours, 83% was excreted in the urine alone (159). Similar results were obtained in other studies of rats and other species (160).

Dicrotophos is metabolized in part to monocrotophos, and the concentration of monocrotophos in tissues may be higher than that of the parent compound a few hours after administration, as reflected by analysis of rat urine and goat milk (1). Residues of both compounds are dissipated almost entirely within 24 hours, as indicated by a rapid decrease in unhydrolyzed metabolites in urine or milk.

Hydrolysis of the vinyl phosphate bond of dicrotophos and/or its oxidative metabolites (monocrotophos) to produce dimethyl phosphate is the predominant metabolic reaction (159). The proportion of dimethyl phosphate in the urine of rats increases rapidly after dosing and reaches 50% of all metabolites present in less than 4 hours and more than 80% in 20 hours. During this interval, there is a correspondingly rapid decrease in the excretion of the parent compound and its oxidation products. Desmethyl dicrotophos and inorganic phosphate are also found in minor concentrations in the urine of treated rats (159). Dimethyl phosphate has been confirmed in the urine of an individual who accidentally ingested dicrotophos (161).

9.4.1.4 Reproductive and Developmental When rats were fed diets that contained 2, 5, 15, or 50 ppm dicrotophos (0.1, 0.25, 0.75, and 2.5 mg/kg/day) for two generations, decreased pup survival was observed at 5 ppm (95). Other effects (weakness, emaciation, and CNS effects) were seen at 50 ppm. No effects occurred at 2 ppm.

No morphological anomalies occurred in offspring of pregnant mice given intraperitoneal injections of 1, 2, 4, or 7.5 mg/kg dicrotophos on gestation day 11, 13, or days 10–12 (157). In other mice, a dose of 5 mg/kg/day on gestation days 8 though 16 did not change the developmental patterns of brain acetylcholinesterase or choline acetyltransferase in offspring through day 42, even though this dose on day 11 reduced embryonic or fetal acetylcholinesterase to 1.8% of control levels (157). The fetal brain enzyme level returned to normal by day 19 following dosing of the mother on days 8 through 16 of gestation.

9.4.1.5 Carcinogenesis When rats were fed dicrotophos in their diets at concentrations of 0, 1, 10, or 100 ppm for two years, there were no detectable effects at the 1-ppm concentration (95). Plasma cholinesterase was inhibited at 1 ppm (95). At 10 and 100 ppm, decreased body weights and reduced cholinesterase (RBC, plasma, brain not specified) activities occurred. Dogs given dicrotophos in their diets at 0, 0.16, 1.6, or 16 ppm for two years showed some instances of slightly excessive salivation (95). At 16 ppm, both plasma and RBC cholinesterase activity was decreased.

9.4.1.6 Genetic and Related Cellular Effects Studies Dicrotophos is considered mutagenic on the basis of its similarity in structure to monocrotophos and the observation that it induced increases in sister chromatid exchanges in cultures of Chinese hamster ovary cells (158).

9.4.2 Human Experience An individual who inhaled a spray that contained dicrotophos and was being used to control mosquitoes in the home developed organophosphate poisoning (162). Upon hospital admission, he had abdominal cramps, nausea, vomiting, and diarrhea; the next day he exhibited increased sweating, salivation, dyspnea, coarse tremor of both legs, and generalized weakness. Plasma and RBC cholinesterase activities were nonexistent. The patient responded to atropine and pralidoxime. However, on the sixth day, respiratory paralysis occurred (typical of "intermediate syndrome"), and he required an artificial respirator for 5 days. He was discharged on day 22. In another case, a 52-year-old man accidentally drank a solution that contained dicrotophos in turpentine (163). He was brought to the hospital where he was treated effectively with atropine and pralidoxime chloride, but he required assisted respiration for more than a week.
9.5 Standards, Regulations, or Guidelines of Exposure
Dicrotophos is undergoing reregistration by the EPA (9a). Dicrotophosis a Restricted Use Pesticide (RUP) which can be purchased and used only by certified applicators. Some specific state restrictions may apply. The ACGIH TLV for dicrotophos (intended change in the 2000 TLVS is 0.05 mg/m^3) and monocrotophos is 0.25 mg/m^3 with a skin notation (154). The NIOSH TWA-REL is also 0.25 mg/m^3 with a skin notation.

10.1 Chemical and Physical Properties

Dioxathion is a nonvolatile, chemically stable, dark amber liquid.

Specific gravity	1.257 at 26°C
Melting point	–20°C
Boiling point	60–68°C
Solubility	insoluble in water; soluble in aromatic hydrocarbons, alcohols, ethers, esters and ketones

10.2 Production and Use

Dioxathion is the common name for an organophosphate product that contains 70% cis and trans (1:2 ratio) isomers of 2,3-*p*-dioxanedithiol *S,S*-bis-(*O,O*-diethyl phosphorodithioate) as the principal ingredient (164). It was formely used in the United States on citrus, grapes, walnuts, and stone fruits. It was also used to control ticks, lice, and horn flies on cattle, goats, hogs, horses, and sheep when sprayed or dipped. Until 1989, when its manufacture and use in the United States was discontinued, dioxathion was available as a 25% wettable powder and a 48% emulsifiable concentrate (1, 155).

10.4 Toxic Effects

10.4.1.1 Acute Toxicity Dioxathion is an organophosphate compound that has moderately high oral toxicity and oral LD_{50}s of 23–64 (64a, 164). An intraperitoneal LD_{50} of 30 mg/kg was obtained for rats suggesting (by comparison with the oral LD_{50} of 23 mg/kg) that dioxathion is well absorbed orally. The oral LD_{50} for dogs is 10–40 mg/kg. The dermal LD_{50} for dioxathion is 63–235 mg/kg in rats and 85 mg/kg in rabbits (64, 545). One-hour LC_{50} values of 1398 and 340 mg/m^3 were reported for rats and mice (164). The acute symptoms of dioxathion are typical of other organophosphates, but the rate of onset is "somewhat slower" (164).

When dogs were given 0.25, 0.80, 2.5, or 8.0 mg/kg/day dioxathion by capsule for 5 days/week for two weeks, those given 8.0 mg/kg/day developed signs of cholinergic toxicity (diarrhea, hypersalivation, termors, ataxia, and depression) (*sic*). Doses of 0.8 mg/kg/day and higher significantly inhibited plasma cholinesterase, and doses of 2.5 and 8.0 mg/kg/day significantly inhibited RBC cholinesterase (164).

Dioxathion showed additive or less than additive toxicity when administered in equitoxic ratios with 15 other anticholinesterase insecticides. However, when dioxathion was administered 4 hours before malathion, potentiation as great as 5.4-fold was observed (164).

When rats were given single intraperitoneal injections of 4, 8, or 16 mg/kg, liver and plasma carboxylesterase activities were 19–55%, RBC cholinesterase activity was 76%, and, brain cholinesterase activity was 96% of control in rats given 4 mg/kg/day dioxathion (165). Thus dioxathion more effectively inhibits carboxylesterases than acetylcholinesterase. A similar tendency of dioxathion to inhibit carboxylesterases to a greater extent than acetylcholinesterase was observed when enzymatic activity was examined in rats fed diets that contained 4, 10, 20 or 40 ppm dioxathion for 7 days (165). Brain acetylcholinesterase was unaffected at any level, and RBC cholinesterase was significantly inhibited at 20 and 40 ppm; however, liver carboxylesterases were significantly inhibited at all levels. Further, rats given diets that contained 4 or 10 ppm dioxathion were more susceptible than untreated rats to inhibition of brain cholinesterase by a single 100- or 200-mg/kg dose of malathion (165).

When 75 mg/kg dioxathion was given subcutaneously to rats, they displayed muscular fibrillation at 2 hours and convulsions at 4 to 8 hours (166). Symptoms of organophosphate poisoning continued several days before recovery. Oral administration of dioxathion to rats at 5 mg/kg/day for up to 21 days resulted in plasma, RBC, and brain cholinesterase inhibition within 1 day (166).

Dioxathion produced mild, transient conjunctivitis but no transient or permanent corneal damage when 0.1 mL was instilled into the eyes of rabbits (164).

Dioxathion did not produce neurotoxicity in surviving hens that received single oral doses of 10–1000 mg/kg or subcutaneous doses of 25–200 mg/kg, even though the higher rates killed some of the birds (164). However, a slightly larger subcutaneous dose, 320 mg/kg, in hens protected by atropine produced a temporary neurotoxic effect that lasted 3–31 days (164).

10.4.1.2 Chronic and Subchronic Toxicity When rats were fed diets that contained 100 or 500 ppm dioxathion for 1–13 weeks, a dietary level of 500 ppm caused marked food refusal and loss of body weight within the first week (164). Female rats given 100 ppm (about 7.5 mg/kg/day) showed hyperexcitability and slight tremor, but males remained well. Both sexes showed marked inhibition of brain, plasma, and RBC cholinesterase activity. In another study, rats were fed diets that contained 1, 3 or 10 ppm dioxathion for 13 weeks. A dietary level of 10 ppm (0.78 mg/kg/day) produced no inhibition of brain cholinesterase but significantly reduced plasma and RBC cholinesterase activity. Dietary levels of 3 and 1 ppm (0.22 and 0.077 mg/kg/day) did not alter brain, plasma, or RBC cholinesterase activity (164).

No adverse effects occurred in dogs given 0.013, 0.025, or 0.075 mg/kg/day dioxathion for 5 days/week for 90 days via capsule (164).

10.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Dioxathion is well absorbed orally or dermally. Rats treated orally with dioxathion for 10 consecutive days excreted dioxathion primarily in the urine (about 50% of daily administered dose) and to a lesser extent in the feces (about 20% of daily administered dose) (166). Rats given 25 mg/kg of different components of the technical product excreted about 36–45% in the urine and about 6 to 25% in the feces, depending on the component administered, by 48 hours. Hydrolytic products identified in the urine included diethyl phosphoric, phosphorothioic, and phosphorodithioic acids. When rats were given 25 mg/kg dioxathion and sacrificed after 48 hours, fat had “appreciable” (*sic*) amounts of the dose. When rats were given 5 or 10 mg/kg dioxathion for several days, the maximum level in fat (0.6 ppm) was reached within 3 days and held constant through 21 days.

The metabolism of dioxathion was examined in rats treated orally and in rat liver microsomes (168). Both the trans, and cis, isomers were rapidly and extensively metabolized by rat liver microsomes in the presence of NADPH (indicating the involvement of microsomal oxidases) and by rats *in vivo* to the corresponding oxons and dioxon. The compound also underwent oxidative O-deethylation and hydroxylation of the ring resulting in ring cleavage and the loss of both phosphorus moieties. The more toxic cis isomer was metabolized more rapidly to form oxon and dioxon and also to form CO_2 from the ethoxy group (168). Of the dose administered, 80–87% was excreted by 96 hours in urine and most of this occurred in the first 24 hours. Unmetabolized dioxathion appeared in feces.

10.4.1.4 Reproductive and Developmental In a three-generation study, rats were fed diets containing 0, 3, or 10 ppm dioxathion (167). There were no measurable abnormalities among either parental animals or their progeny.

10.4.1.5 Carcinogenesis No evidence of carcinogenicity was observed in rats or mice given diets that contained dioxathion for 78 weeks and then observed for an additional 33 or 12–13 weeks, respectively (585). Time-weighted average dietary concentrations were 180 and 90 ppm for male rats, 90 and 45 ppm for female rats, 567 and 284 ppm for male mice, and 935 and 467 ppm for

female mice.

10.4.1.6 Genetic and Related Cellular Effects Studies Dioxathion was positive in the *Salmonella* assay and in cultured Chinese hamster ovary (CHO) cells for the induction of sister-chromatid exchanges but was negative in the mouse lymphoma assay and in cultured CHO cells for the induction of chromosomal aberrations (65).

10.4.2 Human Experience 10.4.2.2 Clinical Cases A 5-year-old boy, who ingested about three-quarters of a teaspoon of a 21% dioxathion formulation intended to be diluted for use as a flea dip (about 57 mg/kg) when it was mistaken for cough medicine, vomited and exhibited profuse diarrhea (169, 170). Within 2 hours, the child was mentally dull and unable to stand; he had shallow rapid respirations, muscle fasciculations, tearing, and miosis. After 12 hours of appropriate treatment, he recovered.

Volunteers were given 0.075 mg/kg/day dioxathion in divided doses three times/day, 7 days/week via capsule for 4 weeks. After 4 weeks, two of the subjects continued on this dose; other subjects received 0.150 mg/kg/day, and, the other six continued to receive 0.075 mg/kg/day dioxathion, but also received 0.150 mg/kg malathion. A dose of 0.075 mg/kg/day produced no effect on plasma or RBC cholinesterase activity. There was a slight inhibition of plasma cholinesterase activity in subjects that received 0.015 mg/kg/day. There was no effect on RBC cholinesterase activity and no clinical effect. Plasma cholinesterase measurements showed slight but statistically uncertain decreases when dioxathion was administered daily for 60 days at a rate of 0.075 mg/kg/day and malathion was given at a rate of 0.15 mg/kg/day simultaneously for the last 30 of these days (164).
10.5 Standards, Regulations, or Guidelines of Exposure
All registrations and tolerances for dioxathion have been revoked by the EPA (78). The ACGIH TLV for dioxathion is 0.2 mg/m^3 (154). NIOSH has recommended a REL-TWA of 0.2 mg/m^3 with a skin notation. Most other countries have occupational Exposure Limits of 0.2 mg/m^3 with a skin notation for dioxathion (Australia, Belgium, Denmark, France, The Netherlands, Switzerland, United Kingdom).

11.0.4 Molecular Weight:
274.38
11.0.5 Molecular Formula:
$C_8H_{19}O_2PS_3$

11.0.6 Molecular Structure:

11.1 Chemical and Physical Properties

Pure disulfoton is a colorless oil that has low volatility and water solubility. The technical product is yellow.

Specific gravity	1.144 at 20°C
Boiling point	108°C at 0.01 mmHg
Vapor pressure	0.00018 torr at 20°C
Solubility	insoluble in most organic solvents; slightly soluble in water (25 mg/L)

11.2 Production and Use

Disulfoton is an organophosphate insecticide effective against aphids, leafhoppers, thrips, spider mites, and coffee leaf miners. It is used on cotton, tobacco, sugar beets, corn, peanuts, wheat, ornamentals, potatoes, and cereal grains. Disulfoton is used to treat seeds and is applied to soils or plants as an emulsifiable concentrate and in granular or pelletized forms.

11.4 Toxic Effects

11.4.1.1 Acute Toxicity Disulfoton is a highly toxic organophosphate that has oral LD_{50}s of 2.3–12.7 mg/kg for rats, mice, and guinea pigs (54, 64a). Dermal LD_{50}s are 3.6–20 mg/kg for rats, demonstrating a relatively high dermal toxicity (64a). Two of two rabbits died after dermal application of 10 mg/kg/day disulfoton that lasted 6 hours, whereas no rabbit similarly treated with 0.4 or 2.0 mg/kg/day for five days died. Treatment of rabbits five days/week for three weeks with 0.4, 0.8, 1.0, 1.6, 3.0, or 6.5 mg/kg resulted in marked cholinergic toxicity following 6.5 mg/kg, cholinergic signs and significant RBC and brain cholinesterase inhibition following 3.0 mg/kg, slight but significant RBC cholinesterase inhibition following 1.0 or 1.6 mg/kg, and, no cholinesterase inhibition following 0.4 or 0.8 mg/kg (171).

One-hour LC_{50}s values for disulfoton aerosol for rats are 290 mg/m^3 and 63 mg/m*3* for males and females, respectively; four-hour LC_{50} values are 60 mg/m^3 and 15 mg/m^3 for males and females, respectively (178). Repeated inhalation exposures are more lethal than single exposures. When female rats were exposed to disulfoton 4 h/day for 5 days, the LC_{50} was between 1.8 and 9.8 mg/m^3 (sic) (178).

Symptoms caused by acutely toxic levels of disulfoton are similar to those caused by other organophosphates and develop beginning about 30 minutes after exposure, depending on dose. Time of death depends on dose; it generally occurs within 48 hours at lethal doses but is sometimes delayed by several days for doses near the LD_{50} (172).

When rats were given single gavage doses of 1.5 and 5.2 mg/kg (males) and 0.76 and 1.5 mg/kg (females) disulfoton, cholinergic toxicity developed within 0–3 days and resolved by day 4 after treatment (178). RBC cholinesterase was inhibited in mid- and high-dose females and in high-dose males. Tolerance to the cholinergic toxicity of disulfoton occurs upon repeated, subtoxic exposures. Male rats given 2.0 or 2.5 mg/kg/day disulfoton for 1–14 days exhibited cholinergic signs whose severity diminished with repeated dosing (173, 174). When rats were given 3.5 mg/kg/day for 3–4 days, clinical cholinergic signs were more severe than those exhibited by rats pretreated with 2.5 mg/kg/day for 6 days and then given 3.5 mg/kg/day for 6 more days (173, 174). Thus, rats pretreated with 2.5 mg/kg/day became tolerant to even higher doses of disulfoton. After 3 days on a diet that provided 1 mg/kg/day disulfoton, rats developed severe cholinergic signs that diminished

markedly during a 62-day period despite the fact that brain and diaphragm cholinesterase activity was depressed at day 6 and remained depressed throughout the study (173).

Inhalation exposure of rats to 0.02 mg/m^3 disulfoton for 6 h/day, 5 days/week for three weeks did not cause any signs of cholinergic toxicity (171). Exposure to 0.1 to 0.5 mg/m^3 resulted in behavioral changes linked to inflammatory changes in the respiratory system, and exposure to 3.1 or 3.7 mg/m^3 caused cholinergic symptoms (muscle tremors, convulsions, increased salivation, dyspnea). Five of ten females exposed to 3.7 mg/m^3 died after three to twelve exposures, and three of twenty females exposed to 3.1 mg/m^3 died after eight to fifteen exposures. No deaths occurred in males at any exposure level. RBC cholinesterase was significantly inhibited at 0.1 mg/m^3 or more, and brain cholinesterase was significantly inhibited at 0.5 mg/m^3 in females and 3.7 mg/m^3 in males. In another 21-day study, rats exposed to 0.006, 0.07, or 0.7 mg/m^3 disulfoton showed no compound-related mortality or clinical signs of toxicity in any group. However, RBC cholinesterase was significantly inhibited at 0.7 mg/m^3. Brain cholinesterase activity was unaffected.

Neuronal degeneration was evident in some hens administered disulfoton (30 mg/kg) twice 22 days apart (95)

11.4.1.2 Chronic and Subchronic Toxicity The mortality rate was 20% in rats given daily intraperitoneal injections of 1.0 mg/kg/day disulfoton and 100% in rats given 1.2 or 1.5 mg/kg/day for 60 days (172). After the first two doses of 1.0 mg/kg, rats displayed cholinergic signs immediately after each dose for up to 7 or 10 days. Then the rats began to recover in spite of daily treatment. Intraperitoneal doses of 0.25, 0.5, and 1.0 mg/kg produced rapid dose-related inhibition of brain and serum cholinesterase that persisted throughout the entire study period, even though cholinergic signs disappeared (175).

Disulfoton caused no cholinergic clinical signs, or adverse effects on mortality, ophthalmology, feed consumption, or body weight gain in rats exposed to 0.018, 0.16, or 1.4 mg/m^3 for 6 h/day, 5 days/week for 13 weeks (178). However, RBC, brain and plasma cholinesterase activities were significantly inhibited in rats exposed to 1.4 mg/m^3.

No adverse effects occurred in rats fed diets that contained 1, 2, 4, 5, 6, 10, or 16 ppm disulfoton (0.1, 0.2, 0.5, or 1.0 mg/kg/day) for 13 or 16 weeks, other than decreased body weight gain at 16 ppm and urine stains in females at 4 ppm (63, 171). However, RBC, brain, plasma, and tissue (submaxillary gland) cholinesterase activity was significantly inhibited in females given 2 ppm or more and in males given 5 ppm or more. In mice fed diets that provided 0.63–0.71 mg/kg/day disulfoton, cholinesterase was inhibited in all tissues, although the tissues were not specified (176). No-effect levels were 0.13–0.14 mg/kg/day.

Dogs fed diets that contained 1, 2, or 10 ppm disulfoton for 12 weeks exhibited no signs of toxicity, although plasma and RBC cholinesterase activity were significantly inhibited in dogs given 2 or 10 ppm (171).

11.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Disulfoton is rapidly absorbed after oral exposure. An average of 80–84%, 6–8%, and 9% of a single oral dose of disulfoton was eliminated by rats in urine, feces, and expired air, respectively, in the 10 days following exposure that accounted for 96–100% of the administered dose (171). The rate of excretion was significantly lower in females—males eliminated one-half the dose in 4–6 hours, whereas females required 30–32 hours. Another experiment showed that 72 hours after an oral dose of disulfoton to rats, about 97% was eliminated in urine, 2% was eliminated in feces, and less than 1% remained in the body (171). Similar results were obtained at 12 hours in rats given 15 consecutive doses of disulfoton. There was no accumulation of disulfoton in the body. Tissue and blood levels of disulfoton peaked at 6 hours

and were highest in liver followed by kidney, plasma, fat, whole blood, skin, muscle, and brain. However, on a percentage of dose basis, female livers contained a much greater amount of disulfoton than males (34% vs. 10% at 6 hours; 3% vs. 9% at 12 hours), possibly indicating slower metabolism and accounting for longer elimination in females.

Dermal absorption of 0.85, 8.5, or 85 mg/cm^2 of a disulfoton formulation ranged from 39–44% of an applied dose applied to the skin (15 cm^2) of rats (178). There was no concentration-dependent effect; the majority of absorption occurred within the first hour, and, the majority of the absorbed dose (66–91%) excreted was found in the urine.

Disulfoton is rapidly metabolized via oxidation to sulfoxides and sulfones, oxidation to oxygen analogs, and/or hydrolysis to produce a corresponding phosphorothionate or phosphate (54). Metabolism is accompanied by inhibition of microsomal enzymes (183).

In humans exposed to disulfoton, sulfones (disulfoton sulfone and demeton *S*-sulfone) were detected in blood (104), and diethyl phosphate (DEP), diethyl thiophosphate (DETP), diethyl dithiophosphate (DEDPT), and diethyl phosphorothiolate were detected in urine (184). Similar metabolic products were detected in the urine of rats and mice administered disulfoton intraperitoneally or orally and in liver homogenates of treated rats (54).

The oxidation reactions are toxification reactions that create metabolic products that bind to cholinesterase. In an oral study of rats, the metabolites, disulfoton sulfoxide, disulfoton sulfone, demeton-*S*-sulfoxide, and demeton *S*-sulfone caused mortality and signs of toxicity at lower doses than disulfoton itself (171a). The hydrolytic reactions create more polar products that are eliminated in the urine and therefore are detoxification reactions.

11.4.1.4 Reproductive and Developmental Two-generation reproductive studies indicates that diets that contained 3 or 9 ppm disulfoton have adverse reproductive effects; diets that contained 0.5–2 ppm do not (242). Adverse outcomes among rats fed 9-ppm diets include decreased body weight gain during pregnancy and lactation; decreased number of implantations; decreased litter size, weights and viability; and decreased brain cholinesterase activity in F1a pups. Adverse outcomes among rats fed 3 ppm disulfoton include decreased litter size, weights, and viability in the F2 generation. Cholinergic signs were evident in rats fed 9 ppm; decreased brain cholinesterase activity occurred in rats fed a 0.5-ppm diet or more. Reproductive effects were also reported in a study in which male and female rats were given 0.5 mg/kg/day disulfoton for 60 days before and/or during mating. Two-fifths of the treated females failed to become pregnant (182).

There was no indication of a teratogenic effect in any rats given 0, 0.1, 0.3, or 1.0 mg/kg/day disulfoton via gavage on gestation days 6–15 (171). Significant depressions of RBC cholinesterase activity occurred in dams given 0.3 and 1.0 mg/kg/day. A significant increase in the incidence of incomplete ossification of the sternebrae was observed in fetuses at 1.0 mg/kg/day which was considered an effect of growth retardation due to maternal toxicity. There was no evidence of teratogenicity or embryo toxicity in rabbits given 0, 0.3, 1.0, or 3.0 mg/kg/day disulfoton (95). The highest dose was lowered to 2.0 and later to 1.5 in some but not all of the high-dose animals due to severe toxic responses and mortality.

11.4.1.5 Carcinogenesis There was no evidence of carcinogenicity or any other adverse effect among rats fed diets that contained 1 or 2 ppm disulfoton for 104 weeks or 0.5 ppm for 80 weeks followed by 5 ppm for 24 weeks (242). Females fed 5 ppm, however, exhibited significantly inhibited plasma and brain cholinesterase. Rats fed diets that contained 10, 25, or 50 ppm disulfoton for 178 days had significantly inhibited brain cholinesterase activities but exhibited no signs of cholinergic toxicity (177). There was no evidence of carcinogenicity in rats given feed that contained 0, 1, 4, or 16 ppm disulfoton, (0.05, 0.2, and 0.1 mg/kg/day) (178). Females given the 16-ppm diet had a 40% mortality rate during the last week of the study compared with a 12% mortality in controls, and both sexes

given the 16-ppm diet exhibited cholinergic signs and increased relative brain weight. There was an increased incidence of optic nerve degeneration in males given the 4-ppm diet and in females given the 4- or 16-ppm diet. Increased incidences of mucosal hyperplasia and chronic inflammation of the forestomach occurred in females given 16 ppm. Cystic degeneration of the Harderian gland occurred in male rats given 16 ppm and in female rats given 4 ppm. Corneal neovascularization was significantly increased in rats given 16 ppm. RBC and brain cholinesterase activity was inhibited in rats given 1 ppm.

There was no evidence of cancer in mice fed diets that contained 0, 1, 4, or 16 ppm disulfoton for 99 weeks (171). Nor was there any adverse effect on behavior, feed consumption, hematology, or organ weights. Significant depression of RBC, plasma, and brain cholinesterase activity occurred in mice fed diets that contained 16 ppm (equivalent to 2–2.5 mg/kg/day).

Dogs did not exhibit cholinergic signs, opthalmoscopic changes, hematological or clinical chemical changes, or any evidence of carcinogenicity when given diets that contained 0.5 or 1.0 ppm disulfoton for two years (equivalent to 0.03 or 0.14 mg/kg/day) (242). Nor was RBC cholinesterase activity inhibited. RBC cholinesterase activity was inhibited in dogs after five months exposure to □0.5 mg/kg/day given by capsule and when they were fed diets that contained disulfoton at a dose of 0.06 mg/kg/day for 40 weeks (242). Moderate inhibition of RBC cholinesterase occurred in dogs given diets that contained 5.0 ppm for 69 weeks (equivalent to about 0.7 mg/kg/day). Brain cholinesterase was not inhibited in dogs given a 0.5- or 1.0-ppm diet for two years but was markedly inhibited in dogs given diets that contained 2.0 ppm or more.

Ocular effects (myopia and astigmatism) associated with degenerative changes in the ciliary muscle cells occurred after 12 months in dogs given □0.63 mg/kg/day disulfoton for two years (128, 179). The myopia became progressively worse until dosing ceased. Necrosis and atrophy of the optic nerve and retina was observed in dogs given disulfoton (0.5–1.5 mg/kg/day) for 2 years (180). However, no ophthalmological effects occurred in dogs given diets that contained 0.5, 4, or 12 ppm disulfoton (0.015, 0.1, or 0.3 mg/kg/day) for 1 year (181). Dogs given the 4-ppm diets “demonstrated intermediate toxicity” (*sic*), and those given the 12-ppm diet “demonstrated systemic toxicity near the Maximum Tolerated Dose” (*sic*). RBC cholinesterase was significantly inhibited in females given 4 and 12 ppm, corneal cholinesterase was significantly depressed at 4 and 12 ppm in both sexes, retinal cholinesterase was significantly inhibited at 4 ppm in females in 12 ppm in males, and ciliary body cholinesterase was significantly inhibited at 12 ppm in both sexes.

11.4.1.6 Genetic and Related Cellular Effects Studies The genotoxicity of disulfoton in *in vitro* assays has been reviewed and was mainly negative (54). Positive results for reverse mutation occurred in single assays with LT-2 or TA1535 stains of *S. typhimurium* without activation but not in several other assays with or without activation (54). Similarly, both positive and negative results for reverse mutation have been reported in *E. coli* and *S. cerevisiae* (54). Disulfoton was negative of gene conversion, mitotic crossing over and recombinants, and for DNA damage in *S. cerevisiae* with or without activation but was positive in an assay for chiasmatic frequency (genetic recombinants), mitotic index, chromosomal aberrations, and pollen fertility in barley (54).

Disulfoton was positive or weakly positive for sister chromatid exchange in Chinese hamster ovary cells in some studies, but negative in others; negative for HGPRT mutations in Chinese hamster ovary cells with or without activation; positive for forward mutations in mouse lymphoma cells for unscheduled DNA synthesis in human lung fibroblasts, and for growth inhibition and increased protein synthesis in human HeLa cells; and negative for chromosomal aberrations in human hematopoietic cell lines and for alterations of DNA or RBA synthesis in human HeLa cells (54).

11.3.5 Biomonitoring/Biomarkers The presence of disulfoton and/or its metabolites in urine is a reliable biomarker for disulfoton exposure. At 2–10 days post exposure, 30–84% of an oral dose can be accoun-ted for in the urine of animals. Although precise relationships between disulfoton exposure and urinary DEP have not been established, DEP is considered a relatively sensitive

biomarker for exposure to disulfoton and other diethyl organophosphate esters (54).

11.4.2 Human Experience 11.4.2.2 Clinical Cases A 30-year-old man was found dead after consuming an unknown amount of disulfoton, as evidenced by the presence of disulfoton in urine and blood (186). A 75-year-old woman who ingested an unknown quantity of disulfoton as Di-Syston (5%, granular) experienced severe organophosphate poisoning from 3.5 hours to 11 days, characterized first by vomiting and diarrhea, followed by nausea, fasciculations, and then confusion, miosis, and cardiac arrhythmias. She recovered after 28 days (186a). A farmer who had worn disulfoton-contaminated gloves for several days developed signs of disulfoton toxicity (weakness, fatigue, and cyanosis) and had to be hospitalized (187).

The inhalation exposure potential of wet and dry mix procedures used to prepare disulfoton fertilizer mixtures were compared by measuring disulfoton on special filter pads used in place of the usual outer absorbent filter pads that cover the filter cartridges of respirators worn by workers (31). Dermal exposure was measured by attaching layered gauze absorbent pads to various parts of the body or clothing and allowing workers to be exposed for a timed period of work. Air exposures during dry mix operations averaged 0.633 mg/m^3 1–5 meters from the work station and, during wet mix operations, averaged 0.06 mg/m^3 1–5 meters from the work station. Dermal exposures averaged 2.0 mg/h and 0.09 mg/h during dry and wet mix operations, respectively. RBC cholinesterase values for dry mix workers were reportedly depressed by about 23% after 9 weeks of work, but it was not clear whether these measurements were from workers wearing respirator or not—which would have decreased the anticholinesterase effect.
11.5 Standards, Regulations, or Guidelines of Exposure
Disulfoton is undergoing reregistration by the EPA (178). The ACGIH TLV for disulfoton is 0.1 mg/m^3 with a skin notation (154). NIOSH has recommended a REL-TWA of 0.1 mg/m^3 with a skin notation. Most other countries also have Occupational Exposure Limits of 0.1 mg/m^3 (Australia, Belgium, Denmark, France, The Netherlands, Switzerland, and the United Kingdom).

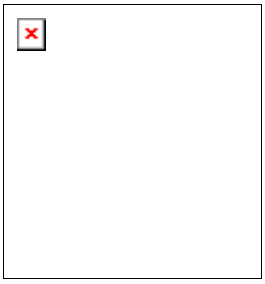
12.0.5 Molecular Formula:

$C_{14}H_{14}NO_4PS$

12.0.6 Molecular Structure:



12.1 Chemical and Physical Properties

EPN is a noncombustible, light yellow solid or brown crystalline substance. Contact of EPN with strong oxidizers may cause fires and explosions. Toxic gases and vapors (e.g., oxides of sulfur and nitrogen, phosphoric acid mist, and carbon monoxide) may be released when EPN decomposes.

Specific gravity	1.268 at 25°C
Melting point	36°C
Boiling point	215 at 5 mmHg
Vapor pressure	0.0003 torr at 100°C
Solubility	soluble in acetone, alcohols, ether, toluene; slightly soluble in water

12.2 Production and Use

EPN was introduced in 1949 for use as a nonsystemic insecticide and acaricide. It was used primarily on cotton to control the boll weevil and lepidopterous pests and was available as a 45% emulsifiable concentrate, as granules, and in combination with other insecticides (188). EPN is no longer registered for use in the United States (45).

12.4 Toxic Effects

12.4.1.1 Acute Toxicity EPN is an organophosphate compound that has high oral toxicity and oral LD_{50}s of 14.5–91 mg/kg for rats (64a). Oral doses of 2–75 and 2–50 mg/kg technical EPN were fatal to female and male dogs, respectively (277). Oral and intraperitoneal LD_{50}s for the mouse were 12.2 and 8.4 mg/kg, respectively, and an oral LD_{50} for the dog was 20 mg/kg (545). EPN was about five times more potent in young rats compared to adult rats; the intraperitoneal LD_{50} in 23-day-old rats was 8 mg/kg, whereas it was 33 mg/kg in adults (189). Dermal LD_{50}s were 25–230 mg/kg in rats (64a). A dermal LD_{50} for the rabbit was 30 mg/kg (529), and the lethal range for dermal exposure to EPN for rabbits was 30–150 mg/kg (277). The only acute inhalation toxicity value available for EPN is a 1-hour LC_{50} of 160 mg/m^3 that was reported for rats (545).

The magnitude of brain, plasma, and RBC cholinesterase activity inhibition and its rate of recovery in rats was determined following a sublethal dose of 25 mg/kg EPN (38). Maximum brain cholinesterase inhibition occurred 4–24 hours after exposure and recovered to normal by 2 weeks, maximum plasma cholinesterase inhibition occurred at 4 hours and recovered by 72 hours, and maximum RBC inhibition occurred at 24 hours and recovered by 4 weeks (the same rate at which new rat RBCs are formed) (38).

Adult, atropinized hens treated subcutaneously with doses of EPN equivalent to the hen subcutaneous LD_{50} (60 mg/kg) developed leg weakness immediately after dosing that persisted for more than 48 hours and occurred in addition to cholinergic symptoms (140). Only 3 of 21 animals that exhibited leg weakness survived. In another study, EPN produced neurotoxicity when administered subcutaneously to atropinized hens at doses of 40 mg/kg or more, but not at doses of

20 mg/kg. Although this effect was prompt in onset and lasted as little as 6 days in some hens, it persisted for more than 330 days in others (64a). High, lethal, single oral exposures (65–100 mg/kg) also caused delayed neuropathy in atropinized hens (191). Delayed neurotoxic ataxia was also observed in mice following oral dosing. A sublethal oral dose (20 mg/kg) produced an irreversible neurotoxic ataxia in mice after 29 days (192).

EPN potentiates malathion toxicity and is itself potentiated by malathion. Oral LD_{50}s for EPN and malathion given by gavage to rats were 65 and 1400 mg/kg, respectively. When given together at approximately equitoxic doses (about a 25:1 malathion: EPN ratio), a tenfold potentiation was observed. The LD_{50} for malathion was 167 mg/kg and for EPN was about 6.6 mg/kg (193, 194). Similarly, when single doses of EPN were administered to dogs, 200 mg/kg was fatal, and 50–100 mg/kg caused moderate to severe symptoms; however, when EPN was administered simultaneously with as little as 100 mg/kg malathion (<10% of the malathion LD_{50}), 2 mg/kg EPN caused 100% mortality.

Potentiation, it is believed, results from inhibition of the hydrolytic detoxification of malathion by EPN (194a, 195). The rate of malaoxon detoxification in liver was 10 to 80% inhibited in rats given single injections of 0.5 to 1.5 mg/kg EPN and was 29 to 95% inhibited in rats fed diets containing 5 to 100 ppm EPN for 2 weeks compared to controls. In this study, the LD_{50} of malathion was 550 mg/kg 1 hour after an intraperitoneal injection of 1.5 mg/kg EPN, compared to 1100 mg/kg in untreated controls.

Neither brain, plasma, or RBC cholinesterase inhibition occurred in rats maintained on a dietary level of 5 or 25 ppm EPN (about 0.25 and 1.25 mg/kg/day) for 8 or 2 weeks, respectively (38). When rats were given diets that contained 0, 100, 300, or 600 ppm (males) (equivalent to 5, 15, or 30 mg/kg/day) or 0, 35, 100, or 300 ppm (females) (equivalent to 2, 5, or 15 mg/kg/day) EPN for 30 days (279), “transitory nervous manifestations” (*sic*) (excitability, tremors) were noted and mortality occurred in the 600- (males) and 300-ppm (females) groups. Body weight gain decreased in the 300- (males) and 100-ppm (females) groups. The authors noted that comparable studies of rats fed the commerical 35% formulation gave consistent results.

12.4.1.2 Chronic and Subchronic Toxicity In rats fed ground chow contaminated with EPN for 90 days and then observed until death, a calculated 90-dose LD_{50} was 12 mg/kg/day (196). Using the 90-dose LD_{50} and the single dose LD_{50} of 7.7 mg/kg previously obtained, a “chronicity factor” (single dose $LD_{50/90}$-dose LD_{50}) of 0.64 mg/kg was calculated, indicating that EPN does not exhibit a cumulative toxic effect.

Cholinesterase activity declined in all organs and tissues in rats after being fed diets that contained 75 ppm EPN for 1 month (154). When rats were fed diets that contained 0.2, 1, 5, or 25 ppm EPN (0.01, 0.05, 0.25, or 1.25 mg/kg/day) for 1, 3, 6, or 13 weeks, cholinesterase activity in the brain was unaffected, although there was a dose-related inhibition of aliesterase activity in both liver and serum at dietary level of 1 ppm and above (197, 285). When rats were given diets, that contained up to at least 125 ppm, the effects noted at 125 ppm (6.25 mg/kg/day) included decreased plasma and brain cholinesterase activity, decreased female growth and decreased RBC, hemoglobin, and hematocrit in both sexes (95). At 25 ppm (1.25 mg/kg/day), RBC cholinesterase was significantly inhibited. At 5 ppm (0.25 mg/kg/day), no adverse effects were noted (95).

When dogs were treated orally with repeated doses of up to 3.0 mg/kg/day EPN, decreased RBC and brain cholinesterase activity; decreased red blood cells, hemoglobin, and hematocrit in both sexes; and pancreatic acinar cell atrophy in two males were recorded (95). Administration of 1.0 mg/kg/day had no adverse effect. No other details were provided in the study summary (95).

Potentiation of cholinesterase inhibition occurs when subchronic exposure is to EPN and malathion simultaneously (194). When rats were fed diets that contained 25 ppm EPN for 8 weeks, a small but significant inhibition of RBC cholinesterase was observed, whereas when 25 ppm EPN was fed simultaneously with 500 ppm malathion, RBC cholinesterase inhibition was marked. (500 ppm malathion alone had no effect on RBC acetylcholinesterase activity.) Similarly, when dogs were fed diets that contained 20 or 50 ppm EPN for 12 weeks, RBC cholinesterase activity marginally decreased (5 ppm had no effect), whereas diets that contained 3, 20, or 50 ppm EPN combined with 8, 100, or 250 ppm malathion (levels which did not inhibit RBC cholinesterase), respectively, markedly inhibited RBC cholinesterase (193).

12.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms EPN is readily absorbed following either oral or dermal exposure. In rats, following a single oral dose of 1.5 mg/kg EPN, about 61–68% of the dose was excreted in urine and 7–21% of the dose was excreted in the feces (279). Metabolism was essentially complete because urinary excretion of metabolites totaled 60–68% of the total dose; the corresponding fecal values were 6.7–17.2% (279). The plasma half-life was approximately 33.6 hours in males and 38.6 hours in females. In rats given 0.72 or 0.072 mg/kg EPN three times at 24-hour intervals, 14 and 26% of the dose was excreted as *p*-nitrophenol in urine (280). EPN was not detectable in blood at any time after the final dose but was detectable in adipose tissue (0.06 ppm) only on day 3.

It has been argued that the toxicokinetics and metabolism of EPN plays a major role in the development and expression of neuropathy. When a rat was preconditioned for 21 days on a diet that contained 450 ppm EPN, only traces of the dose remained in body tissues after 72 hours (280). Thus, EPN was practically completely metabolized and eliminated in rats. Two EPN-conditioned hens that received 2.5 mg/kg EPN for 21 days and two unconditioned hens excreted 94–100% of a single oral, nonneurotoxic 4-mg/kg dose within 72 hours of administration. No significant difference was apparent in the dose excreted from conditioned or unconditioned chickens. Small amounts of EPN remained in body tissues; only trace amounts were found in the brain and spinal cord. By contrast, a single oral neurotoxic dose of 50 mg/kg EPN was slowly metabolized and excreted by chickens. Only 65% of the dose was eliminated during the 72 hour test. Excreta extract contained the same five metabolites found in the rat. Thus, the 50-mg/kg dose may have exceeded the metabolic capacity of the liver to detoxify EPN (280). Based on these data, half-lives for EPN were 1.1 days for a single oral 17.3-mg/kg dose in male rats, 1.8 days for a single oral 4-mg/kg dose in chickens, and 3.5 days for a single oral dose of 5 mg/kg in chickens (280).

In cats, EPN was readily absorbed when a single dose of 20 mg/kg was dermally applied as reflected by disappearance of EPN from the application site (281). Most of the absorbed dose was excreted in urine (29.9%); 3.2% was recovered in the feces. In cats given daily dermal doses of 0.5 mg/kg EPN for 10 days, 62% of the total dose was eliminated in the urine. Thus, the metabolism and toxicokinetics of EPN in the cat are intermediate between those in the rat and in the chicken. Similarly to the rat, EPN is excreted as polar metabolite, mostly in the urine. As in the chicken, however, EPN is persistent in cat tissues, especially in nervous tissues. The finding that the cat is ten times less sensitive than the chicken to subchronic dermal exposure to EPN may be explained by the relatively rapid metabolism and elimination of EPN in the cat. (The extensive metabolism of EPN in the rat compared to (the chicken or) the cat might be explained by the presence of a higher level of cytochrome P-450 in rat liver microsomes than in the chicken or in the cat.)

EPN undergoes oxidative toxication through desulfuration that is catalyzed by microsomal oxidases (282) and detoxication through hydrolytic removal of *p*-nitrophenol (280, 283). Moreover, has been shown that the rate of hydrolytic detoxication of EPN more closely correlates with sex and age differences in EPN toxicity than the rate of toxication (20). The nitro group can be further reduced to an amino group by enzymes in the livers of mammals, birds, and fish and in the kidneys, spleens, hearts, lungs, and RBCs of mammals. The resulting amine is a weak inhibitor of cholinesterase but the importance of this reduction for detoxication *in vivo* is unknown 283. Activation and degradation of EPN is not restricted to the liver. *In vitro* studies have shown that rat brain also possesses

activation and degradation capability (284).

Overall, metabolism evidently reduces the toxicity of EPN, maybe even to a greater extent than for parathion or methyl parathion. The intraperitoneal LD_{50} was 7.3 mg/kg in untreated rats and 75 mg/kg in phenobarbital-treated rats, whereas for parathion and methyl parathion, these values were 2.5 and 7.3 mg/kg and 7.0 and 8.0 mg/kg, respectively (197).

12.4.1.4 Reproductive and Developmental EPN was administered via gavage once daily to mice (1, 3, 6, or 12 mg/kg) on days 6 through 16 of gestation (278). EPN, at dose levels up to those that were maternally lethal (12 mg/kg), did not produce fetotoxicity, fetal lethality, or teratogenicity (591).

12.4.1.5 Carcinogenesis No evidence of carcinogenicity occurred in rats fed EPN at levels of 50, 150, or 450 ppm (males) or 0, 25, 75, or 255 ppm (females) for two years (277). Dietary levels of 450 ppm (males) and 225 ppm (females) caused intermittent tremors and slight retardation of growth. Rats given the highest dietary level had depressed growth from the start of EPN feeding. Other groups of rats tolerated oral dosages up to 10 mg/kg/day. There was no indication of increasing mortality with increasing doses of EPN, although the mortality by the end of the two year study was high (86–98%).

12.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization Delayed neurotoxicity was produced in hens given daily oral doses of 0.01, 0.1, 0.5, 1.0, 0.5, 5.0, or 10.0 mg/kg EPN for 90 days and observed for 30 days (274). Hens treated with 5 mg/kg or more were atropinized to protect them from acute cholinergic toxicity. The clinical condition of most ataxic hens deteriorated during the 30-day observation period following the end of dosing, and the severity of effects dependend on the size of the daily ingested dose. Hens given small doses showed only ataxia, but those treated with large doses progressed to paralysis and died. Hens treated daily with 0.01 mg/kg EPN showed no abnormality in gait or behavior. In a study summarized by EPA, when adult hens were dosed orally at 0.01, 0.1, 0.5, 1.0, 2.5, or 5.0 mg/kg/day for 90 days, organophosphate type delayed neurotoxicity (ataxia) was seen at doses of 2.5 and 5.0 mg/kg/day but not at lower doses (95). Histopathologically observed damages to the nervous system was seen at doses of 0.1 mg/kg, but not at 0.01 mg/kg/day.

When EPN was applied dermally at doses of 0.01 to 10 mg/kg to the necks of hens for 90 days, all hens given 2.5 to 10 mg/kg EPN developed signs of cholinergic poisoning despite treatment with atropine (269). All hens given EPN, except those that received the 0.01 mg/kg dose, developed signs of delayed neurotoxicity, such as ataxia, paralysis, and death. All doses of EPN, except for the 0.01 mg/kg/day dose, caused degeneration of axons and myelin in the spinal cord.

Delayed neurotoxicity was produced in cats following the administration of a single dermal dose of 22.5, 45, 112.5, or 225 mg/kg (0.2 to 5.0 times the dermal LD_{50} of 45 mg/kg) or repeated daily doses of 0.5, 1.0, or 2.0 mg/kg EPN (269). Single dermal doses of 9.0 mg/kg and repeated dermal doses of 0.1 mg/kg were without effect. Therefore, the cat is about ten times less sensitive than the hen to EPN-induced delayed neurotoxicity.

When dogs were given 2.8 to 5.0 mg/kg EPN orally for up to a year, the first symptoms were vomiting and diarrhea, followed by gait disturbances and weight loss; histopathological changes in the nervous system were noted (275). Male sheep treated orally with 1 mg/kg/day EPN for 180 days showed no clinical signs of neurotoxicity, no histological changes in tissues, and no remarkable neurotoxic esterase (NTE) measurements (214).

12.4.2 Human Experience 12.4.2.2 Clinical Cases In one case, ingestion of an estimated 200 mL of 50% EPN resulted in coma, miosis, sweating, bloody stools, pulmonary edema, and death despite treatment with pralidoxime and atropine (286). In another case, a 500 mL suspension that contained EPN was obtained from the gastrointestinal tract of a 46-year-old farmer who died following generalized convulsions and cardiorespiratory arrest (287). Signs and symptoms of EPN poisoning

may persist for years after acute or chronic exposure due to permanent nerve damage; symptoms of nerve damage being and may be irreversible at the time of severe acute exposure (294).

Applicator personnel were monitored during aerial and ground applications of EPN to cotton in Mississippi and Arizona. Respiratory exposures based on an 8-hour work day averaged 11 mg for pilots, 15 mg for loaders, and 39 mg for ground applicators. Respiratory exposure of flagmen, monitored during a complete application cycle, averaged 317 mg/8 hours. Mean 8-hour dermal exposures were 2.1 mg for pilots, 6.3 mg for loaders, 117.7 mg for flagmen, and 7.5 mg for ground applicators (185).

Neither plasma nor RBC cholinesterase activity was affected among five volunteers given 3 mg EPN/day by capsule (about 0.04 mg/kg/day) for 32 days, nor were any clinical effects observed or reported (294). No significant effect on plasma or RBC cholinesterase activity occurred when the dose was increased to 6 mg EPN/day (0.0857 mg/kg/day) for 47 days, nor were any clinical effects observed or reported (294). When the dose was further increased to 9 mg EPN/day (about 0.13 mg/kg/day) for 56 days, plasma cholinesterase activity that began 2 weeks after first administration of EPN was depressed and continued to be depressed at 3 weeks after dosing stopped. RBC cholinesterase activity inhibition was similar to that of plasma but did not occur as soon. However, in a later study, when five other volunteers were given 6 mg EPN/day (0.086 mg/kg/day) plus 16 mg malathion/day for 44 days, both RBC and plasma cholinesterase were significantly depressed (288).

12.5 Standards, Regulations, or Guidelines of Exposure

EPN is not registered for use in the United States. The ACGIH TLV for EPN is 0.1 mg/m^3 with a skin notation (154). The OSHA PEL-TWA is 0.5 mg/m^3 with a skin notation. The NIOSH REL-TWA is 0.5 mg/m^3 with a skin notation.

Organophosphorus Compounds
Jan E. Storm, Ph.D

13.0 Ethion

13.0.1 CAS Number:

[*563-12-2*]

13.0.2 Synonyms:

O,O,O′,O′-Tetraethyl-*S,S′*-methylene di(phosphorodithioate; *O,O,O′,O′*-tetraethyl *S,S′*-methylene bis phosphorodithioate; Diethion; Ethanox; Ethiol; FMC 1240; Hylemox; Niagra 1240; Rhodiacide; Rhodocide; RP-Thion; *O,O,O,O*-tetraethyl *S,S*-methylene bisphosphorodithioate; Nialaten; Nialate (R); ethyl methylene phosphorodithioate; *O,O,O′,O′*-tetraethyl *S,S′*-methylenediphosphorodithioate; bis[S-(diethoxyphosphinothioyl)mercapto]methane; *S,S*-methylene *O,O,O′,O′*-tetraethyl phosphorodithioate; Ethion 8; phosphorodithioic acid, *S,S′*-methylene *O,O,O′O′*-tetraethyl ester; Bis (diethoxyphosphinothioylthio)methane; Embathion; Ethodan; Ethopaz; Fosfatox E; Fosfono 50; Itopaz; KWIT; methanedithiol, *S,S*-diester with *O,O*-diethyl phosphorodithioate; methylene *O,O,O′,O′*-tetraethyl phosphorodithioate; tetraethyl *S,S′*-methylene bis(phosphorodithioate)

13.0.3 Trade Names:

Nialate®; Bladan; Embathion, Ethanox Ethodan, Fosfatox E; Fosfono 50; Hylemax; Hylemox Itopax, Niagara 1240; Soprathion

13.0.4 Molecular Weight:

384.48

13.0.5 Molecular Formula:

$C_9H_{22}O_4P_2S_4$

13.0.6 Molecular Structure:

13.1 Chemical and Physical Properties

Pure ethion is a colorless liquid. Ethion emits toxic fumes of oxides of sulfur and phosphorous when heated to decomposition. It is subject to acid and base hydrolysis, and undergoes oxidation in air slowly

Specific gravity	1.220 at 20°C
Melting point	–12° to –13°C
Boiling point	decomposes above 150°C
Vapor pressure	1.5×10^{-6} mm Hg at 25°C
Solubility	slightly soluble in water; readily soluable in most organic solvents, including acetone, xylene, chloroform, and methylated naphthalene

13.1.2 Odor and Warning Properties The technical material has a very disagreeable odor.

13.2 Production and Use

Ethion is a preharvest, topical insecticide used primarily on citrus fruits, deciduous fruits, nuts, and cotton. End-use product formulations for citrus consist of emulsifiable concentrates (EC) that contained 9–82% active ingredient. Applications are made using ground boom or air blast equipment. High-pressure and low-pressure hand wands along with backpack sprayers are used for spot treatment. It is also used as a cattle dip for ticks and as a treatment for buffalo flies. Ethion is marketed as a 25% wettable powder; 2%, 3%, and 4% dusts; 5% granules; and various oil solutions and combinations with other materials (296).

13.4 Toxic Effects

13.4.1.1 Acute Toxicity Ethion is an organophosphate that has relatively high oral toxicity and oral LD_{50}s for rats of 21 to 191 mg/kg (64). Dermal LD_{50}s for rats are 62 to 838 mg/kg (Gaines 1969; 242). For rabbits, the dermal LD_{50} was 915 mg/kg (IPCS 1986). A 4-hour LC_{50} of 864 mg/m^3 for ethion in rats has been reported and in studies submitted to EPA, 4-hour LC_{50}s of 2310 mg/m^3 and 450 mg/m^3 were obtained for male and female rats, respectively (155, 296).

When goats were given single intravenous injections of 2, 5, or 10 mg/kg ethion, only those given 5 or 10 mg/kg displayed cholinergic toxicity (291). All doses decreased RBC cholinesterase activity that lasted for about 4 days and recovered by 8–10 days.

Ethion was slightly irritating to rabbit eye and skin but did not cause dermal sensitization in guinea pigs (296). In a study submitted to EPA, ethion was negative in an acute neurotoxicity test using hens (296).

13.4.1.2 Chronic and Subchronic Toxicity When dogs were given diets that contained 0.5, 2.5, 25, or 300 ppm ethion for 90 days, cholinergic toxicity and body weight gain and food consumption decreased among dogs given 300 ppm (equivalent to about 6.9 or 8.25 mg/kg/day) but not 25 ppm (about 0.71 mg/kg/day). Brain and RBC cholinesterases were inhibited at 25 and 300 ppm, respectively (296).

When rabbits were treated dermally for 21 days with 0, 1.0, 3.0, 25, or 250 mg/kg/day ethion, RBC and brain cholinesterase activity were inhibited at all doses (296). Cholinergic signs were not noted.

Erythema and desquamation at the application sites occurred at 25 and 250 mg/kg. Inhibition of brain cholinesterase was again observed when rabbits were treated dermally for 21 days with 0, 0.1, 0.25, 0.8, 1.0, 3.0, or 25 mg/kg/day (296).

13.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms About 80% of an oral dose to goats was excreted (in urine (64%), feces (14%), and milk (2%)) within 14 days and about 55% was excreted within the first 96 hours (291). Less than 5% of the dose was absorbed unchanged, consistent with the hydrolysis of organophosphate due to ruminal microflora. About 20% of a dermal dose of ethion (100 mg/kg) applied to goats was absorbed during 14 days. Following intravenous treatment of goats with 2 mg/kg ethion, unchanged ethion was rapidly eliminated (effective half-life of 2 hours) demonstrating the large role of ruminal microflor metabolism. Metabolized, ethion was distributed primarily to liver, kidney and fat. Tissue elimination was relatively fast the first 3 days but slow during the third and fourth weeks after dosing. The half life was about 2 weeks. Seventy-seven percent of the dose was recovered after 2 weeks in urine (55%) and feces (22%). At least five major metabolites were identified in the urine. Regardless of route of exposure, ethion was extensively bound to plasma proteins.

In humans given an intravenous dose of ethion, 38.4% of the dose was excreted in the urine by 5 days (66). About 15% of the administered dose was excreted in the first 12 hours, 9.5% in the second 12 hours, and 7.6% over the next 24 hour period. The elimination half-life was estimated at 14 hours. After topical administration of 4 mg/cm^2 to the forearm, about 3.3% of the applied dose was excreted by 5 days.

13.4.1.4 Reproductive and Developmental In a three-generation study in which rats were given diets that contained 2, 4, or 25 ppm ethion, no adverse effects on reproduction occurred at any dose (296). In rats given 2.0, 0.6, or 2.5 mg/kg/day ethion by gavage on gestation days 6–15, maternal toxicity (hyperactivity) and developmental toxicity (delayed ossification of pubes) occurred only at 2.5 mg/kg/day (242). In rabbits given 0, 0.6, 2.4, or 9.6 mg/kg/day ethion by gavage on gestation days 6–18, maternal toxicity (weight loss, reduced food consumption, and orange colored urine) occurred at 9.6 mg/kg/day; developmental toxicity was not observed (296).

13.4.1.5 Carcinogenesis When dogs were given diets containing 0.5, 1, 2, 20, or 100 ppm ethion (about 0.01, 0.03, 0.05, 0.5, or 2.5 mg/kg/day) for one year, cholinergic signs were not noted in any group (296). At 20 ppm, RBC cholinesterase was inhibited in females, and, at 100 ppm, both brain and RBC cholinesterase activities were (296). When rats were fed diets containing 0, 2, 4, or 40 ppm ethion (about 0.1, 0.2, and 2.0 mg/kg/day) for 24 months, the only effect was reduction in serum cholinesterase activity at 40 ppm (178). No evidence of carcinogenicity was observed. No evidence of carcinogenicity or other adverse effects occurred in mice fed diets containing 0, 0.75, 1.5, or 8.0 ppm (about 0.11, 0.22, or 1.2 mg/kg/day) ethion for 2 years (296).

13.4.1.6 Genetic and Related Cellular Effects Studies Ethion is not mutagenic. Ethion did not cause mutations in the Ames test with or without metabolic activation, did not cause chromosomal aberrations in an *in vivo* cytogenetic test in rats, did not increase unscheduled DNA synthesis in an *in vitro* test with rat hepatocytes, and did not cause mutation in a recombinant/conversion assay using *S. cerevsiae* (296). However, there is also a report that ethion was mutagenic in an *in vivo* (mouse bone marrow) and *in vitro* (Chinese hamster lung cells) micronucleus test (289) and a report that ethion induces chromosomal aberrations when administered to chicks (290).

13.4.2 Human Experience Six male adult human volunteers were given ethion via capsule according to the following sequential dosing regime: (1) 0.05 mg/kg/day for 21 days, (2) 0.075 mg/kg/day for 21 days, (3) 0.10 mg/kg/day for 21 days, (4) 0.15 mg/kg/day for 3 days, and (5) recovery for 19 days (296). RBC cholinesterase activity, averaged across subjects, was not inhibited at any dose level. Signs of overt cholinergic toxicity occurred in one subject on days 19–21 of 0.05 mg/kg/day dosing (headache, blurred vision, lightheadedness, and dizziness) and on day 1 of 0.075 mg/kg/day dosing.

Signs of overt cholinergic toxicity (partial blindness, lightheadedness) also occurred in another subject on the first day of receiving 0.075 mg/kg/day for 0.15 mg/kg/day. EPA concluded that these results suggested a cumulative effect of ethion when administered at a dose of 0.05 mg/kg/day or higher.

13.5 Standards, Regulations, or Guidelines of Exposure

Ethion has been reregistered for use by the EPA. The ACGIH TLV for ethion is 0.4 mg/m^3 with a skin notation (154). There is no OSHA PEL-TWA. The NIOSH REL-TWA is 0.4 mg/m^3 with a skin notation. Other countries generally have the same standard (Australia, Belgium, France, The Netherlands, and Switzerland).

Organophosphorus Compounds

14.0 Fenamiphos

14.0.1 CAS Number:

[*22224-92-6*]

14.0.2 Synonyms:

Bay SRA 3886; Nemacur; ethyl 4-(methylthio)-*m*-tolyl isopropylphosphoramidate; Nemacur(R); (1-methylethyl)phosphoramidic acid ethyl 3-methyl-4-(methylthio)phenyl ester; isopropylphosphoramidic acid, 4-(methylthio)-m-tolyl ethyl ester; ethyl 3-methyl-4-(methylthio) phenyl (1-methylethyl)phosphoramidate; isopropylamino-*O*-ethyl-(4-methylmercapto-3-methylphenyl)phosphate; 1-(methylethyl)-*O*-ethyl-*O*-(3-methyl-4-(methylthio) phenylphosphoramidate; nemacur p; phosphoroamidic acid, isopropyl-, 4-(methylthio)-*m*-tolyl ethyl ester

14.0.3 Trade Names:

Bay SRA 3886; Nemacur®

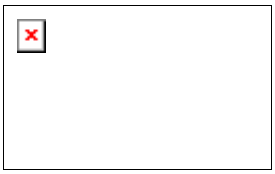
14.0.4 Molecular Weight:

303.4

14.0.5 Molecular Formula:

$C_{13}H_{22}NO_3PS$

14.0.6 Molecular Structure:



14.1 Chemical and Physical Properties

Pure fenamiphos is a colorless crystal; technical fenamiphos is an off-white to tan, waxy solid. Fenamiphos is stable under most normal use conditions but is subject to hydrolysis under alkaline conditions

Melting point	49.2°C (pure); 40°C (technical)
Density	1.15 g/cm^3 at 20°C
Vapor pressure	7.5×10^{-7} mmHg at 30°C; 4.7×10^{-5} mmHg at 20°C
Concentration in saturated air	0.001 ppm (0.01 mg/m^3) at 30°C
Solubility	soluble in most organic solvents; soluble in water (approximately

400 mg/L)

14.2 Production and Use

Fenamiphos is used as a selective nematocide and insecticide to control nematodes, thrips, beetles, aphids, and root borers on terrestrial food crops and nonfood sites (297). It is applied by a variety of methods including broadcast, row, drench, and irrigation before or at planting time or to established plantings.

14.4 Toxic Effects

14.4.1.1 Acute Toxicity Fenamiphos is a highly toxic organophosphate that has oral LD_{50}s of 2–100 mg/kg for rats, mice, rabbits, dogs, and guinea pigs (61 292–294). Analytical preparations of fenamiphos are slightly more toxic than technical preparations (295). Intraperitoneal LD_{50}s are equivalent to oral LD_{50}s indicating high oral absorption (61, 292). Dermal LD_{50}s were 72–225 mg/kg for rats and rabbits (292, 296). Rabbits dermally treated with 0, 0.5, 2.5 or 10 mg/kg/d fenamiphos for 6 h/day for 21 consecutive days showed slight erythema of abraded skin that lasted 3–6 days, and inhibition of RBC and brain cholinesterase occurred at doses of 2.5 and 10 mg/kg/day. Cholinergic effects were not reported at any dose (297).

One- and 4-hour LC_{50}s and 110–175 mg/m^3 and 91–100 mg/m^3, respectively, were reported (298). When 4-hour exposures were repeated for 5 days, the LC_{50} was >28 mg/m^3 but <100 mg/m^3, indicating a cumulative effect (299). No-effect levels for RBC cholinesterase inhibition were 28 mg/m^3 (males) and 4 mg/m^3 (females) for RBCs. Male and female rats exposed to 0.03, 0.25, or 3.5 mg/m^3 fenamiphos aerosols 6 hours/day for 5 days/week for 3 weeks showed no overt cholinergic symptoms or changes in physical appearance, behavioral patterns, body weights, hematology, clinical chemistry, urinalysis, gross pathology, or organ weights (299). RBC and brain cholinesterase were unaffected at any level.

When rats were given single oral doses of 0.4, 1.6, or 2.4 mg/kg fenamiphos, four males and one female that were given 2.4 mg/kg died within 30 minutes of dosing (300). Cholinergic effects occurred among rats given 1.6 or 2.4 mg/kg, were maximum about 25 minutes after dosing, and were relatively quickly reversed. All treatment-related effects had completely resolved by 7 days after dosing. RBC cholinesterase activities were inhibited among rats given 1.6 or 2.4 mg/kg, and brain cholinesterase was not affected in any group.

There was no evidence of delayed neurotoxicity in atropinized hens that were treated with single doses of 12.5 mg/kg fenamiphos, in atropinized hens treated with 25 mg/kg twice at an interval of 3 weeks, or, in unprotected hens treated with up to 50.0 mg/kg and observed for 21 days (301).

Fenamiphos was only slightly irritating (caused mild erythema) when applied to skin of rabbits and was mildly irritating to the eye of rabbits (297). Fenamiphos did not cause either contact dermatitis or “tuberculin type allergy” in a guinea pig sensitization study (302).

14.4.1.2 Chronic and Subchronic Toxicity Repeated intraperitoneal injections of 1 mg/kg/day fenamiphos for 60 days caused no mortality in rats, although brain and tissue cholinesterase activity was inhibited (198). Administration of 2 mg/kg/day fenamiphos for 60 days resulted in 40% and 100% mortality by 30 and 60 days, respectively, as well as significant brain and tissue cholinesterase inhibition.

No cholinergic signs or decreases in brain or RBC cholinesterase activity occurred in rats given diets that contained fenamiphos at 0, 0.36, 0.60, or 1.0 ppm for 14 weeks (approximately 0.02, 0.03, or 0.05 mg/kg/day) (297). When rats were given fenamiphos via diets that contained 0, 4, 8, 16, or 32 ppm (about 0.2, 0.4, 0.8, and 1.6 mg/kg/day) for 90 days, cholinergic signs occurred in rats given only the 32-ppm diet (297). RBC cholinesterase was inhibited in rats given 8 ppm or more. When rats were fed diets that contained 0, 1, 10, or 50 ppm fenamiphos (equivalent to about 0, 0.1, 0.7,

3.3–4.0 mg/kg/day) for 13–14 weeks, treatment-related cholinergic signs (muscle fasciculations) occurred only in high-dose females during weeks 1–3; no cholinergic signs occurred in males (303). There were no adverse ophthalmic findings. Decreases in RBC cholinesterase activity occurred in the 10- and 50-ppm group in males and in all treated groups in females, were evident at 4 weeks, and, remained at about the same level for 13 weeks. A no-observed-effect level for RBC cholinesterase inhibition extrapolated from the data was 0.4 ppm for females (approximately 0.032 mg/kg/day). No effect on brain cholinesterase was observed.

When dogs were given diets that contained 18 ppm or more for 3 months, overt cholinergic toxicity occurred (303a). No adverse effects were observed at dietary levels of 16 ppm or less (equal to about 0.45 mg/kg/day). RBC cholinesterase was inhibited in dogs fed diets that contained 2 (females only), 5 (females only), 6, 10, or 18 ppm. No adverse effects of any kind and no inhibition of RBC cholinesterase occurred in dogs given diets that contained 0 or 0.5 ppm fenamiphos for six months (equivalent to 0 and 0.01–0.02 mg/kg/day) or in dogs given diets that contained up to 1.7 ppm fenamiphos (equivalent to 0.04 mg/kg/day) for 100 days (304, 305).

14.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms About 93–95% of an oral dose of fenamiphos was absorbed by rats and excreted by 12–15 hours after treatment (309). Forty-eight hours later, residues in tissues were greatest in liver and kidney; less in fat, gastrointestinal tract, and heart; and minimal in brain and muscle. Similar results were obtained in a whole body autoradiographic study of rats treated orally with fenamiphos which showed that oral absorption was virtually complete, distribution volume was low, and excretion was rapid and nearly complete by 8 hours after dosing (310). Pretreatment of rats for 14 days before treatment with fenamiphos did not alter absorption, distribution, or elimination patterns. Distribution following oral doses was rapid in brain, and plasma and concentrations in brain exceeded concentrations in plasma by about 1.3-fold to twofold (311). Concentrations in brain and plasma were highest 0.5 hours after dosing and declined; a and b half-lives in the brain were 2 and 100 hours, respectively, and a and b half-lives in plasma were 17.5 and 212 hours, respectively. Oral absorption of fenamiphos sulfoxide was equally rapid in pigs and reached maximum blood concentrations 2 hours after a 0.9-mg/kg dose (312). Fifty-seven percent of the administered dose was excreted within 5 hours and 90% was recovered after 48 hours. Tissue residues were minimal; only liver and kidney contained residues >0.1 ppm.

In vitro dermal absorption of fenamiphos by human and rat skin accounted for 0.42–9.95% of the applied dose and was 2.07 ± 0.33 mg/cm^2/h (human) and 3.15 ± 0.40 mg/cm^2/h (rat) (313). Dermal absorption of a granular formulation was considerably less (0.01–0.03 mg/cm^2/h) and dermal absorption of a liquid formulation was considerably more (13.0 ± 1.87 mg/cm^2/h (human) and 49.0 ± 2.69 mg/cm^2/h (rat) during 24 hours.

The major metabolic pathway for fenamiphos is oxidation and formation of the sulfoxide and sulfone analogs. Loss of the isopropyl and probably the isopropyl amine moieties are also likely. Subsequent hydrolysis, conjugation, and excretion in urine gives nonorganosoluble compounds whose molecular weights are 400–800. Rats treated intravenously or orally with fenamiphos excreted fenamiphos phenols in different stages of oxidation at the sulfur atom and their respective sulfuric acid conjugates (276).

In pigs given fenamiphos sulfoxide orally, excreted metabolites were primarily conjugated phenols of the sulfoxide and sulfone. The metabolic pathway was hydrolysis and/or oxidation followed by conjugation.

14.4.1.4 Reproductive and Developmental No treatment-related endocrine effects, reproductive effects, or clinical signs occurred in adults or pups given diets that contained 0, 2.5, 10, and 40 ppm fenamiphos (about 0, 0.2, 0.6–0.7, and 2.8–3.2 mg/kg/day) for two generations. Among rats fed the 40-ppm diet, F1 pups experienced decreased body weight gain during lactation, F0 and F1 females had lower body weights during lactation, terminal body weights significantly decreased in adult rats,

and absolute and relative ovary weights significantly decreased. RBC cholinesterase was significantly inhibited in adult rats fed the 10-ppm diet and in 4 day old pups fed the 10-ppm diet. Brain cholinesterase was significantly inhibited in adult rats fed the 40-ppm diet but was not inhibited in 4- or 21-day-old pups fed any dietary concentration. No adverse reproductive outcomes occurred in rats given diets that contained 0, 3, 10, or 30 ppm fenamiphos (equivalent to about 0, 0.15, 1.0, and 1.5 mg/kg/day) (276). Reduced body weight gain occurred only in the F2b generation males of the 30-ppm group.

No adverse developmental outcomes occurred among offspring of rats given fenamiphos at dose levels of 0, 0.3, 1.0, and 3.0 mg/kg by gavage on gestation days 6 through 15 (276). Dams in the 3-mg/kg group exhibited cholinergic signs of toxicity within 30 minutes after dosing, and two dams in this group died. No treatment-related maternal effect were seen at lower doses.

Fenamiphos was not fetotoxic or embryotoxic at any dose in rabbits treated orally on gestation day 6–18 with 0.1, 0.3 or 1.0 mg/kg/day fenamiphos (242). However, chain fusion of sternebra was found in five fetuses in the 1.0-mg/kg/day group and was higher than controls. The authors concluded that this may have been a treatment-related abnormality. When rabbits were given 0, 0.1, 0.5, and 2.5 mg/kg/day fenamiphos by gavage on gestation days 6–18, neither visible nor measurable treatment-induced effects were observed in dams given 0.1 or 0.5 mg/kg day (276). However, 2.5 mg/kg/day produced frank maternal toxicity, evidenced by four treatment-induced deaths, decreased body weight gains, and decreased food consumption. There were no treatment-related effects in mean numbers of corpora lutea; in numbers of live or dead fetuses, litter size, or sex ratio, or in the numbers of live or resorbed fetuses. However, preimplantation loss was elevated in the 2.5-mg/kg/day group, and, in addition, the mean live pup weight was slightly reduced. Except for one malformation observed in the high-dose group, no other fetal visceral anomalies were observed.

14.4.1.5 Carcinogenesis There was no evidence of carcinogenicity or adverse effects of any kind in dogs given a diet that contained 0.5, 1, 2, 5, and 10 ppm fenamiphos for 2 years (about 0.01, 0.025, 0.05, 0.125, or 0.250 mg/kg/day), although RBC cholinesterase activities were inhibited at 2 ppm (312a). When dogs were fed diets that contained 1, 3, or 12 ppm fenamiphos (about 0, 0.030, 0.08, and 0.3 mg/kg/day), no adverse effects of any kind occurred, except for mild anemia (decreased RBC counts, hemoglobin, hematocrit) among dogs given the 12-ppm diet (304). RBC cholinesterase activity was inhibited in dogs given 3- or 12-ppm diets, and brain cholinesterase activity was inhibited in dogs given 12-ppm diets.

There was no evidence of carcinogenic effect in rats maintained on a diet that contained 3, 10, or 30 ppm fenamiphos for two years (about 0.2, 0.67, and 2.0 mg/kg/day) (306). In the 30-ppm group, mild symptoms that reflected cholinergic toxicity were observed temporarily, and mortality in female rats increased slightly. The 3-and 10-ppm diets did not cause evident adverse effects of any kind. There was no evidence of carcinogenicity or ophthalmologic effects in rats fed diets that contained 0, 2, 10, or 50 ppm fenamiphos for 2 years (equivalent to about 0, 0.1, 0.5–0.6, or 2.4–3.4 mg/kg/day) (307). RBC cholinesterase was significantly inhibited in the 10- and 50-ppm groups. Brain cholinesterase was marginally inhibited in the 50-ppm group. Females that consumed the 50-ppm diet exhibited an increase of rough coats and alopecia “associated with stress due to severe cholinesterase inhibition” (*sic*). No other compound-related effect occurred.

There was no evidence of carcinogenicity or other adverse effect in mice given diets that contained 0, 2, 10, or 50 ppm fenamiphos for 20 months (equivalent to doses of about 0, 0.2, 1.0, and 5.0 mg/kg/day), except that mice that received 50 ppm had reduced body and organ weights, and absolute brain weights decreased at 2 ppm or more (147).

14.4.1.6 Genetic and Related Cellular Effects Studies Fenamiphos was negative in Ames tests using *S. typhimurium* with and without metabolic activation, and negative in a preincubation reverse mutation test with a tryptophan mutant strain of *E. coli* with and without mammalian metabolic activation (276). In a forward mutation assay using Chinese hamster cells (CHO), fenamiphos

induced an increase in the mutant frequency in an initial test conducted without metabolic activation. However, the response was not dose-dependent and could not be reproduced in two subsequent repeat assays. Therefore, the authors concluded that fenamiphos is not mutagenic in the CHO/HGRPT forward mutation assay. Fenamiphos did not induce an increase of sister chromatid exchange in Chinese hamster V-79 cells (308).

In a micronucleus test, there was no evidence of any mutagenic effect of fenamiphos. Nor was there any deleterious influence on erythrocyte formation as measured by the ratio of polychromatic to normochromatic erythrocytes. Fenamiphos did not have a mutagenic effect in a dominant lethal test using mice (276).

Increased chromosomal aberration rate was observed in cultures of human lymphocytes, but only in the cytotoxic range. Therefore, this evidence of mutagenicity is considered equivocal (276).

14.4.2 Human Experience No published reports of human poisonings as a result of fenamiphos exposure were identified. However, the EPA noted that "fenamiphos has been implicated in a handler poisoning incident which resulted in hospitalizing the worker" (276).

Potential inhalation and dermal exposures to fenamiphos were estimated over 2 to 4-hour periods for six mixer-loaders or applicators involved in treating agricultural soil (1 lb a.i./acre). Inhalation exposures (measured using personal air pumps attached to the collar) were less than the detectable level of 0.001 mg/h; dermal exposures (measured using cloth patches and by collecting hand wash water) were substantially higher and ranged from about 93 to 667 mg/h (314).

14.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV for fenamiphos is 0.1 mg/m^3 with a skin notation (154). There is no OSHA PEL-TWA for fenamiphos. The NIOSH REL-TWA is 0.1 mg/m^3 with a skin notation. Most other countries also have an Occupational Exposure Limit of 0.1 mg/m^3 with a skin notation (Australia, Belgium, Denmark, France, The Netherlands, and Switzerland).

Organophosphorus Compounds

15.0 Fensulfothion
15.0.1 CAS Number:
[*115-90-2*]
15.0.2 Synonyms:
(*O*,*O*-Diethyl-*O*-4(methylsulfinyl)phenyl)-phosphorothioate Dasanit; Bay 25141; S767; phosphorothioic acid *O*,*O*-diethyl *O*-[methylsulfinyl)phenyl] ester; Dansanit; Fonsulfothion; Terracur P; Daconit; Agricur; Chemagro 25141; diethyl *O*-(4-(methylsulfinyl)phenyl) phosphorothioate; DMSP; phenol, p-(methylsulfinyl)-, *O*-ester with *O*,*O*-diethyl phosphorothioate
15.0.3 Trade Names:
Dasanit®; Terracur R®
15.0.4 Molecular Weight:
308.35
15.0.5 Molecular Formula:
$C_{11}H_{17}O_4PS_2$
15.0.6 Molecular Structure:

15.1 Chemical and Physical Properties

Fensulfothion is a yellow, oily liquid. Fensulfothion is oxidized readily to the sulfone and apparently isomerizes readily to the *S*-ethyl isomer

Specific gravity	1.202 at 20°C
Boiling point	138–141°C at 0.01 mmHg
Solubility	soluble in most organic solvents except aliphatics; slightly soluble in water (approximately 160 mg/100 mL)

15.2 Production and Use

Fensulfothion was introduced in 1957 as a systemic and contact insecticide and nematicide for use against free living and root knot nematodes. Until 1990 when its manufacture and use was discontinued, it was available as an emulsifiable concentrate, a wettable powder, a dust, and as granules (1, 155).

15.4 Toxic Effects

15.4.1.1 Acute Toxicity Fensulfothion is an organophosphate compound that has high oral toxicity and oral LD_{50}s are 1.8–10.2 mg/kg for rats (64a, 315). Intraperitoneal LD_{50}s are 1.5–5.5 mg/kg, indicating that fensulfothion is well absorbed from the gastrointestinal tract. Dermal LD_{50}s are 3.5–30.0 mg/kg (64a, 315). A 1-hour LC_{50} of 113 mg/m^3 and a 4-hour LC_{50} of 29.5 mg/m^3 were reported for rats (123). Following either oral or intraperitoneal doses, the onset of poisoning is rapid, and symptoms appear within 15 minutes, although death may be delayed. When lethal doses were given, death usually occurred within 2 hours, but after sublethal doses, the symptoms often persisted for 3 or 4 days (315).

Fensulfothion may have potentiating characteristics. An ordinarily harmless dose (550 mg/kg) of the anesthetic tricaine caused loss of righting ability in all rats and 20% mortality when it was given 1 hour after administering 2.5 mg/kg fensulfothion, a dose that inhibited carboxylesterase(s) but had no overt toxic effect (316a).

Fensulfothion did not produce neurotoxicity when given orally or intraperitoneally at doses up to 50 mg/kg to chickens protected by atropine and 2-PAM (1).

15.4.1.2 Chronic and Subchronic Toxicity When rats were given 0.25, 0.5, or 0.75 mg/kg/day fensulfothion via intraperitoneal injection for up to 60 days, all rats given 0.75 mg/kg died within 5 days, 1 of 5 rats given 0.5 mg/kg died by day 60, and no rats given 0.25 mg/kg died within 60 days (315).

15.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Fensulfothion is well absorbed orally as reflected by the similarity of oral and intraperitoneal LD_{50}s.

Based on findings for other phosphorothioates, it can be concluded that fensulfothion undergoes desulfuration to the corresponding oxygen analog to exert an anticholinesterase action (315). Indeed, the intraperitoneal LD_{50} of the oxygen analog in female rats was 1.2 mg/kg, equivalent to the 1.5 mg/kg observed for the parent compound. The thioether linkage of fensulfothion may also undergo oxidation to the sulfone derivative. The intraperitoneal LD_{50} of the oxygen analog sulfone was 0.9 mg/kg in female rats.

15.4.1.4 Reproductive and Developmental Some female mice given a diet that contained 5 ppm fensulfothion died before mating (316). There was no effect on reproduction, gestation, or the lactation index of the survivors, except a slight reduction in the lactation index of third-generation pups. A level of 1 ppm had no effect. A slight nonsignificant increase of minor skeletal abnormalities occurred in rabbits that received fensulfothion during pregnancy at 0.10 mg/kg/day; no effect occurred on 0.05 mg/kg/day (316).

15.4.1.5 Carcinogenesis When rats were provided diets that contained 1, 5, or 20 ppm fensulfothion, mortality increased in male rats given the 5- and 20-ppm diets, and body weight gain was depressed in both sexes given the 20-ppm diet (316). Plasma, RBC, and brain cholinesterase activities in females were “detectably” (*sic*) inhibited in rats given the 1-ppm diet (about 0.053 mg/kg/day).

When dogs were provided diets that contained 1, 2, or 5 ppm fensulfothion for 2 years, reduced food consumption, severe weight loss, and signs of cholinergic poisoning were initially evident in dogs given the 5-ppm diet, although food consumption increased and lost body weight was regained after the second month (316). Slight, temporary cholinergic effects and a slight reduction of cholinesterase (*sic*) occurred in dogs provided the 2-ppm diet, but not the 1-ppm diet (316).

15.4.1.6 Genetic and Related Cellular Effects Studies Fensulfothion did not increase the incidence of sister chromatid exchanges in V79 cells, nor did it induce cell cycle delay (308).

15.4.2 Human Experience 15.4.2.2 Clinical Cases Fensulfothion caused death by the following morning of a 34-year-old farmer who had applied fensulfothion to potato plants during the day. Autopsy indicated that death was due to pulmonary edema and blood cholinesterase activity which was far below normal (1). Death also occurred to a 5-year-old child who resided in a home 6 days after about 12,000 mg of fensulfothion was applied to about 10 m^2 of surface in two rooms (1). Other members of the family suffered nausea, vomiting, disorientation, diarrhea, and abdominal pain. Combined dermal and oral exposure led to severe poisoning characterized first by vomiting and weakness and by coma the next morning for a 7-year-old girl who had been playing with an empty fensulfothion container (1).

Fensulfothion poisoning from its accidental ingestion was recently reported in a family of four (317). Fensulfothion was misidentified as pepper and applied to the family's fish dinner. Shortly after the meal family members experienced nausea, vomiting, abdominal pain, and weakness. Two members had bradycardia, hypotension, and seizures. They were treated with atropine, artificially ventilated, and eventually recovered.

15.5 Standards, Regulations, or Guidelines of Exposure

Fensulfothion is not registered for use in the U.S. (145). The ACGIH TLV for fensulfothion is 0.1 mg/m^3 (154). There is no OSHA PEL-TWA. The NIOSH REL-TWA for fensulfothion is 0.1 mg/m^3. Most other countries also have an OEL of 0.1 mg/m^3 with a skin notation for fensulfothion (Australia, Belgium, France, The Netherlands, and Switzerland).

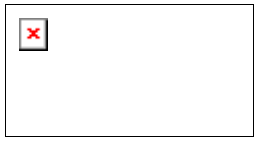
16.0.6 Molecular Structure:



16.1 Chemical and Physical Properties

Fenthion is a yellow to tan, oily liquid

Specific gravity	1.250 at 20°C
Melting point	7.5°C
Bioling point	87°C at 0.01 mmHg (pure); 105°C at 0.01 mmHg (commercial grade)
Vapor pressure	3×10^{-5} torr at 20°C; (technical) 2.1×10^{-6} mmHg at 20°C)
Solubility	soluble in organic solvents; nearly insoluble in water (56 mg/L)

16.1.2 Odor and Warning Properties Fenthion has a slight garlic odor.

16.2 Production and Use

Fenthion is used primarily for livestock dermal treatments and mosquito control in residential areas. Direct dermal treatments to livestock are by spot treatment and pour-on treatment; ear tags are used for dairy and beef cattle. Mosquito control (adulticide) applications are to residential areas in Florida by ultra low volume spray (aerial and ground application) and by thermal fog (ground application) (317a).

16.4 Toxic Effects

16.4.1.1 Acute Toxicity Fenthion is an organophosphate compound that has moderate oral toxicity and oral LD_{50}s of 215 to 615 mg/kg for rats, mice, and rabbits (64a, 317a). Deaths occurred 1–4 days postdosing (315, 318). Dermal LD_{50}s are 330–963 mg/kg for rats and rabbits (45, 64, 318, 319). Deaths occurred 2–5 days postdosing. The signs of poisoning following oral or dermal exposure develop over a period of hours but then persist for several days (318, 320).

One-hour exposure to 243 mg/m^3 fenthion caused no mortality in mice, but 20 and 40% mortality in

female and male rats, respectively. One-hour LC_{50}s for rats range from, >1125 to 2400 mg/m^3, and, 4-hour LC_{50}s range from 454–2400 mg/m^3 (123, 321). When 4-hour exposures were repeated for 5 days, the LC_{50} was reduced to approximately 212 mg/m^3 for males and to between 55 and 212 mg/m^3 for females (321). Acute exposures of 209 mg/m^3 resulted in deaths in 2/20 female rats and ataxia and tremors in both sexes (322, 323).

Lethal doses of fenthion, when given in fractions on successive days, are lower than they are when given as a single dose, indicating cumulative toxicity. There was 75% mortality in female rats given 50 mg/kg via gavage for 5 days (about one tenth the LD_{50}) and 100% mortality in female rats given 100 mg/kg for 5 days (about one sixth the LD_{50}) (318). The dermal LD_{50} for a dose applied on 5 consecutive days was 73 mg/kg/day, whereas the single-dose dermal LD_{50} was 500 mg/kg. Daily intraperitoneal doses of 10 mg/kg for 60 days caused no mortality, but doses of 20 mg/kg caused 80% mortality by 30 days, doses of 40 or 50 mg/kg caused 100% mortality by 10 days, and, a dose of 100 mg/kg caused 100% mortality by 5 days (315).

When rats were given single oral doses of 0, 20, 75, or 150 mg/kg fenthion, cholinergic signs occurred in all groups that peaked at 1.5 hours and persisted for at least 24 hours (324). When rats were given single oral dose of 0, 1, 50, or 125 mg/kg (males) and 0, 1, 75, and 225 mg/kg (females) fenthion, clinical signs of acute cholinergic toxicity occurred in mid- and high-dose rats of both sexes (325). RBC and brain cholinesterase activities were inhibited in the mid- and high-dose males and in the low-, mid- and high-dose females. A no-effect level for RBC cholinesterase of 0.7 mg/kg was derived from these data.

Dogs given a single oral dose of 220 mg/kg fenthion exhibited cholinergic signs, that disappeared by 5 days after dosing (326). RBC cholinesterase was inhibited 20 minutes after exposure, increased to pre-exposure levels by 3–12 hours after exposure, but then decreased again below control levels from 24 hours to 30 days after dosing.

One of the relatively unique toxic effects associated with fenthion is acute ocular toxicity (327). Four days after single intramuscular doses of 0.005, 0.05, 0.5, or 5.0 mg/kg fenthion, electroretinograms (ERG) in rats were supernormal (*sic*) 4 days after a dose of 25 mg/kg, the ERG was normal; and 4 days after a 100-mg/kg dose, the ERG was subnormal (327–329). Retinal acetylcholinesterase was unaffected 4 days after 0.005- or 0.05-mg/kg doses but decreased after doses of 0.5–100 mg/kg (327–329). Further study indicated that supernormal ERG changes associated with 5 mg/kg peaked at 10 days and returned to normal by two months, supernormal ERG changes associated with 25 mg/kg peaked at four days then became subnormal and recovered by two months, and ERGs associated with 50 mg/kg remained subnormal for at least 66 days (327). Single acute intraperitoneal doses of 100 mg/kg fenthion were associated with retinotoxicity and characterized by inhibition of retinal cholinesterase and temporary down-regulation of muscarinic receptors in the retina (330).

Fenthion is not considered as an eye or dermal irritant and does not cause dermal sensitization (317a).

16.4.1.2 Chronic and Subchronic Toxicity Rats fed a daily diet that contained 300 ppm fenthion for approximately 30 days showed symptoms of organophosphate intoxication (331). When rats were given diets that contained 5, 10, 20, or 250 ppm fenthion (equivalent to daily doses of about 3, 5–6, 11–12, and 100–138 mg/kg/day) for 4 weeks, symptoms of cholinergic poisoning were mild and transient and occurred only in the 250-ppm group (318). Brain cholinesterase activities in rats from all groups were significantly inhibited. Among rats fed 0.25, 0.5, 2.5, or 5.0 mg/kg/day fenthion for 12 weeks, cholinergic signs occurred in those fed 2.5 or 5 mg/kg (331a). RBC cholinesterase activity was significantly inhibited in rats fed 0.5 mg/kg or more, and tissue cholinesterase (heart, liver) was significantly inhibited in female rats fed 0.25 mg/kg/day or more and male rats fed 0.50 mg/kg/day

or more. when rats were fed diets that contained 0, 2, 25, or 125 ppm fenthion for 13 weeks (equivalent to 0, 0.13–0.17, 1.6–2.2, and 8.5–12.6 mg/kg/day, clinical cholinergic signs and a dose-related decrease in RBC and brain cholinesterase activities occurred in rats given the 25- or 125-ppm diet (317a). There were no treatment-related opthalmologic findings. When mice were fed diets that contained 0, 50, and 100 ppm fenthion for approximately (*sic*) 5 weeks, no cholinergic signs were observed in any group, but marked RBC and brain cholinesterase inhibition occurred in mice at all treatment levels (333).

When rats were exposed to 0, 1, 3, or 16 mg/m^3 fenthion aerosol for 6 h/day, 5 days/week for 3 weeks, females in the two higher group exhibited behavioral disturbances (*sic*) (334). Male rats tolerated these exposures without clinical symptoms. RBC and brain cholinesterase activity were inhibited in both sexes at 3 mg/m^3.

When rabbits were dermally treated with 5, 50, or 100 mg/kg fenthion for 6 h/day, 5 days/week for 3 weeks, no cholinergic effects occurred (317a). Inhibition of RBC cholinesterase in males and inhibition of brain cholinesterase in females occurred only at the highest dose. Dermal treatment of rabbits with 150 mg/kg according to the same paradigm caused cholinergic signs and significant RBC and brain cholinesterase inhibition (317a). When shaved (one-half abraded) rabbits were dermally treated with 5 or 25 mg/kg fenthion applied as a dilute solution in Cremophor for 21 days, RBC and brain acetylcholinesterase were inhibited at 5 mg/kg/day (317a).

16.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Fenthion is quickly absorbed in the digestive tract, and lung, and skin and is hydrolyzed either unchanged or after enzymatic oxidation. Elimination occurs via urine and feces within 3 days. In lactating cows, fenthion was readily distributed to and eliminated in milk (350).

Peak concentrations of fenthion in milk occurred 18 or 8 hours after dermal or intramuscular exposure, respectively, and by 14–20 days after treatment accounted for 1.1% and 2.2% of the dermal or intramuscular dose, respectively. Fenthion was rapidly degraded and eliminated primarily in the urine. Following topical administration of fenthion of lactating cows, 45–55% was excreted in urine, 2–2.5% was eliminated in feces, and 1.5–2% was eliminated in milk during a period of 4 weeks (350). EPA estimated that dermal absorption would be about 20% of an applied dose (317a) based on a comparison between cholinesterase inhibition no-effect levels in rabbits treated dermally or orally which were 1 mg/kg/day and 5 mg/kg/day, respectively.

The delayed and prolonged effect from a single dose of fenthion suggests that a large portion of a dose is stored and then slowly released to be metabolized (318). Fenthion (and/or fenthion metabolites) is lipid-soluble, and there is evidence that it readily accumulates in the body. In a postmortem analysis following ingestion of fenthion, greater concentrations of fenthion were detected in human organs and fat than in blood (351).

It has been proposed that the sulfoxide and sulfone of the thioether of *fenthion* are produced before P□S to P□O oxidation takes place (352, 353). Both of these compounds given orally to rats are more toxic than fenthion itself, and their effects occur more rapidly than after fenthion. However, neither compound actively inhibits acetylcholinesterase, so presumably these compounds are oxygenated to forms that readily inhibit acetylcholinesterase (318).

16.4.1.4 Reproductive and Developmental Decreased epididymal weight, decreased fertility, increased maternal weight gain during premating, decreased weight gain during gestation, decreased pup weight gain during lactation, and inhibition of brain acetylcholinesterase occurred in rats given a diet containing 100 ppm fenthion (about 5 mg/kg/day) for two generations (317a). Cytoplasmic vacuolation of the epithelial ductal cells of the epididymis and inhibition of RBC acetylcholinesterase occurred in parents and offspring fed 14 ppm (about 0.7 mg/kg/day). Diets that contained 1 or 2 ppm fenthion had no adverse reproductive effect. When mice were given water that

contained 60 ppm fenthion (delivering doses of between 9.5–10.5 mg/kg) for five generations, there was no consistent effect on mating success, although treated mice exhibited longer periods to produce first litters in the first three generations and pup survival and growth decreased in the second, third, and fourth generations (254).

A slightly higher rate of resorptions occurred among rats given 18 mg/kg/day fenthion by gavage on gestation days 6–16 (317a). Adverse developmental effects did not occur in rats given 1 or 4.2 mg/kg/day. Cholinergic signs and decreases in body weight gain also occurred in the 18-mg/kg/day dosed pregnant rats. RBC and brain acetylcholinesterase were inhibited at 1 mg/kg/day and higher. Fetal brain acetylcholinesterase was also inhibited in the high-dose group at day 20. In rabbits given 0, 1, 2.75, or 7.5 mg/kg/day fenthion by gavage on gestation days 6 through 18, a slight increase in resorptions occurred in the 2.75- and 7.5-mg/kg/group, and increases in unossified metacarpals occurred in the 7.5-mg/kg/day group. Dams exhibited "soft stools" at 2.75 mg/kg/day, a weight gain decrease at 7.5 mg/kg/day, and inhibition of brain and RBC acetylcholinesterase at both 2.75 and 7.5 mg/kg/day (317a).

16.4.1.5 Carcinogenesis There was no cholinergic toxicity, lens opacification, clinical chemistry effects, or hematotoxicity among rhesus monkeys that received a daily oral dose of 0.02, 0.07, or 0.2 mg/kg via corn oil gavage for 2 years (317a). However, RBC acetylcholinesterase had a threshold for inhibition at 0.07 mg/kg/day (frequent inhibition at this level up to 39% for the first 3 months of the study). More consistent inhibition was noted at 0.20 mg/kg/day.

When dogs were fed diets containing 0, 2, 5, or 50 ppm fenthion (equivalent to about 0.06, 0.3, and 1.2 mg/kg/day) for 1 year, no signs of cholinergic toxicity occurred at any dose, although the 50-ppm dose caused marked inhibition of RBC and brain cholinesterase (335). No carcinogenicity or other toxicity occurred among dogs given diets containing 0, 3, or 10 ppm fenthion for 104 weeks or among dogs given diets that contained 30 ppm from week 1 to week 64, 60 ppm from week 65 to week 67, and 60 ppm from week 68 to week 104 (317a). However, RBC cholinesterase was inhibited at 10 ppm and higher in males and at 30 ppm and higher in females; brain cholinesterase was inhibited at 30 and 60 ppm. No cholinergic signs, tumors, or other toxicity occurred in dogs given diets that contained 0, 2, 10, or 50 ppm fenthion for 1 year (336). RBC cholinesterase activity was inhibited at 10 or 50 ppm, and brain cholinesterase was inhibited at 50 ppm.

When rats were fed diets that contained 0, 2, 3, 5, 25, or 100 ppm for 1 year, the 100-ppm diet caused decreases in body weight gain, increased mortality and inhibition of RBC, brain and submaxillary gland cholinesterase; the 25-ppm diet increased mortality in female rats and inhibition of RBC, brain, and submaxillary gland cholinesterase; the 5-ppm diet inhibited RBC cholinesterase; and the 3-ppm diet had no effect (335). No gross or microscopic lesions were observed in any group hemosiderosis in the spleen of rats fed 100 ppm. No carcinogenicity, cholinergic toxicity, hematoxicity, or alterations in clinical chemistry occurred in rats given diets that contained 3, 15, or 75 ppm fenthion (about 0.2, 1.0, or 5.0 mg/kg/day) for 24 months (586). However, the 75-ppm diet decreased body weight gain in males and slightly increased mortality in both sexes, and the 15-and 75-ppm diets significantly inhibited RBC cholinesterase in both sexes. There was no evidence of carcinogenicity in rats fed diets that contained 5, 20, or 100 ppm fenthion (about 0, 0.02–0.03, 0.8–1.3, and 5.2–7.3 mg/kg/day) for 2 years (336). However, clinical cholinergic signs, retinal degeneration, and posterior subcapsular cataract formation were observed in the 100-ppm groups; and electroretinograms were flat or suppressed in females given the 20- or 100-ppm diet. Significant RBC and brain acetylcholinesterase inhibition occurred at 5 ppm.

Subnormal ERGs occurred by 3 months and disappeared completely by 1 year among rats injected subcutaneously with 50 mg/kg fenthion once every 4 days for 1 year. Significant histopathology was evident in the retina that included disappearance of the retinal pigmentary epithelial layer, the outer nodes, inner nodes and outer granular layer, and photoreceptor cells (327, 328, 329, 337). ERGs were also extinguished and retinal degeneration was extensive in rats treated subcutaneously with 50 mg/kg twice a week for 1 year (327).

There was no evidence of carcinogenicity in rats or in female mice given fenthion in the diet at 10 or 20 ppm for 103 weeks and then observed for 0–2 additional weeks (338). Doses were 0.49 and 0.98 mg/kg/day for rats and 1.3 and 2.6 mg/kg/day for mice. Some cholinergic signs were noted at both doses in rats and mice. No evidence of carcinogenicity, cholinergic toxicity, hematotoxicity, or other toxicity was seen in mice given diets that contained 0, 0.09, 0.9, 4.6, or 25 ppm fenthion (equivalent to 0, 0.03, 0.4–0.5, 1.95–2.25, and 9.42–10.23 mg/kg/day) for 102 weeks (317a). RBC and brain cholinesterase inhibition was significant at a dietary level of 25 ppm.

16.4.1.6 Genetic and Related Cellular Effects Studies *In vitro* tests of fenthion (339–342) and *in vivo* tests in mice (343, 344) showed no mutagenic effect of fenthion. Fenthion was negative in the dominant lethal mutation assay in male mice (345, 346) and negative or weakly clastogenic at acutely toxic doses in the mouse micronucleus test (347). Among rats treated with two oral doses of 54 mg/kg fenthion (one-fourth LD_{50}) 21 hours apart, there was a fivefold increase in hepatic and brain lipid peroxidation and a 3.5-fold increase in hepatic single-strand DNA breaks (348). Increased numbers of single chromatid gaps and breaks were detected in human lymphocytes incubated in variable concentrations of 98% technical grade fenthion (349).

16.4.1.7 Other: Neurological, Pulmonary, Skin Sensitization Fenthion caused neurotoxicity that lasted from 3 to 10 days when given subcutaneously at a dose of 25 mg/kg to atropinized chickens (64). The lowest lethal dose was 40 mg/kg, indicating that neurotoxicity occurred at a sublethal dose. Atropinized hens treated with 40 mg/kg (orally) or 200 mg/kg (dermally) two times 21 days apart and observed for a total of 42 days showed no behavioral or histopathological signs of delayed type neuropathy (317a). Additionally, no evidence of pathological changes in the structure of brain or peripheral nerve indicative of delayed type neuropathy were observed in hens treated orally by gavage with 0, 084, 1.7, or 3.2 mg/kg/day for 90 days (317a).

16.4.2 Human Experience 16.4.2.2 Clinical Cases A 26-month-old male experienced abdominal pain and vomiting for 8–18 hours after dermal (and possibly oral) exposure of a flea killer that contained fenthion. About 42 hours after exposure, he experienced respiratory arrest accompanied by miosis, hyperactive bowel sounds, pulmonary edema, and diminished muscle tone and reflexes. Therapy with atropine, 2-PAM, and ventilation saved his life, and he recovered about 32 days after exposure (1). A 71-year-old farmer who was estimated to have ingested about 83 mg/kg fenthion suffered nausea, was hospitalized unconscious after 13 hours, and died 4 days later. A 40-year old individual who drank as estimated 25 mg/kg fenthion was unconscious for about 4 days but survived (1). In another attempted suicide, a 44-year-old man was thought to have ingested 310 mg/kg fenthion. He showed only a few mild signs of poisoning when hospitalized 3 hours after ingestion. However, he experienced two relapses in spite of adequate drug therapy and required tracheotomy during recovery (1).

Fenthion blood levels and plasma cholinesterase activity were followed in a 41-year-old male who ingested an unknown amount of fenthion and died after 7 days (354). Blood fenthion concentration was 0.27 mg/L on admission (20 hours after ingestion) but rapidly increased to 0.78 mg/L coincident with worsening cholinergic symptoms. Even after 5 days, fenthion blood concentration still varied within the 0.2–0.3 mg/L level. In another case of fenthion poisoning, a 43-year-old man ingested about 30 mL of Lebaycid, corresponding to about 18 g fenthion (355). Signs of cholinergic toxicity were seen 31 hours after ingestion at which time RBC acetylcholinesterase were totally inhibited. The relatively long half-life of fenthion was illustrated in another case report of a woman who experienced severe poisoning after ingesting fenthion in a suicide attempt. A fat biopsy obtained 22 days after ingestion, after recovery from an acute cholinergic phase of poisoning but before experiencing a delayed intermediate type syndrome, indicated fat residues of about 0.15 ppm fenthion. By day 31 when all symptoms had been resolved, fat residues had decreased to zero.

Neurological symptoms that ranged from occasional tingling and numbness of the hands and feet to

multiple shooting pain, back pain, numbness, and generalized muscle weakness were reported by five employees in a veterinary hospital who routinely used topical applications of a 20% fenthion solution on dogs and took no precautions to avoid dermal contract (356, 357). When the use of fenthion was discontinued, the symptoms stopped.

The characteristics of an intermediate syndrome (respiratory insufficiency, weakness of muscles, innervated by cranial nerves and weakness of proximal limb muscles) were described in four cases of fenthion poisoning (two of the people died) that occurred 2–6 days following resolution of an acute cholinergic crises and which lasted 5–18 days (358). Unusual transient dystonic movements also occurred in two of these cases. Symptoms that comprised an "intermediate syndrome" (i.e., weakness of external ocular, facial, neck, proximal limb, and respiratory muscles) and extrapyramidal signs (dystonia, rest tremor, cog-wheel rigidity, and choreoathetosis), occurred from 4 to 40 days after acute poisoning with fenthion, and resolved after 1 to 4 weeks in survivors were described in six cases of people who ingested 15–60 mL of fenthion (359).

Several publications report an association between an increased incidence of adverse visual effects (myopia and a visual disease syndrome termed "Saku" disease) and agricultural use of organophosphates, including fenthion, in Japan. The recently reviewed studies vary in quality and usefulness, but nevertheless suggest that the association is probable (327). However, only one study is available that suggests a specific link between fenthion exposure and ocular toxicity. In this study, neurological function, visual acuity, refraction, color vision, and the condition of the fundus oculi were assessed in 79 individuals who worked 5–6 h/day spraying an aqueous suspension of fenthion and were compared to equivalent observations of 100 control subjects (327). Macular changes (hypopigmentation, irregularity of background pigmentation, and dull foveal relex) were evident in 15 (19%) workers and in 3 (3%) control subjects. Other visual symptoms reported in workers who had macular change included visual impairment, reduced visual acuity, abnormal color vision, and constriction of visual fields. Pathological myopia (associated with "Saku") disease was not observed.

Symptoms reported among thirty-one workers who sprayed aqueous suspensions of fenthion (100 mg in 100 L water) by a hand-operated sprayer for 5–6 hours/day, 6 days/week included headache (56%) giddiness (44%), eye irritation (20%), anorexia and paresthesia (11%), but no signs specific for cholinergic toxicity (360). On neurological examination, two subjects had loss of ankle reflex, and one had coarse tremors. Additionally, subtle subclinical effects on psychometric tests and event related potentials were observed. However, no estimate of exposure was provided.

Fenthion administered to human volunteers at dose levels of 0.02 or 0.07 mg/kg daily for up to 4 weeks produced no physical signs or symptoms; no alterations in clinical chemistry, hematology or urinalysis; and no inhibition of RBC cholinesterase activity (361).

16.5 Standards, Regulations, or Guidelines of Exposure

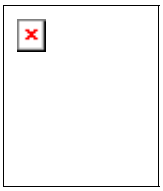
Fenthion has been reregistered for use by the EPA. The ACGIH TLV for fenthion is 0.2 mg/m^3 with a skin notation (154). There is no OSHA PEL-TWA or NIOSH REL-TWA for fenthion. Other countries have Occupational Exposure Limits of 0.2 mg/m^3 for fenthion (Australia, Belgium, Germany, and Japan); others have OELs of 0.1 mg/m^3 (Denmark, The Netherlands, and Switzerland).

Organophosphorus Compounds
Jan E. Storm, Ph.D

17.0 Fonofos

17.0.1 CAS Number:

[*944-22-9*]
17.0.2 Synonyms:
(*O*-ethyl-*S*-phenyl ethylphosphonodithioate; *O*-ethyl *S*-phenyl ethyldithiophosphonate; Ethyl *S*-phenylethylphosphonothiolthionate; Diphonate; Fonophos; *O*-ethyl *S*-phenylethylphosphonothiolothionate; ethylphosphonodithioic acid *O*-ethyl *S*-phenyl ester; Dyfonate II; N-2790; *O*-ethyl *S*-phenylethylphosphonodithioate; Stauffer N-2790; ethyl *s*-phenyl ethylphosphonodithioate; Dyphonate
17.0.3 Trade Names:
Dyfonate®; Difonate; Dyphonate
17.0.4 Molecular Weight:
246.32
17.0.5 Molecular Formula:
$C_{10}H_{15}OPS_2$
17.0.6 Molecular Structure:



17.1 Chemical and Physical Properties
Fonofos is a light yellow liquid.

Specific gravity	1.154 at 20°C
Boiling point	130°C at 0.1 mmHg
Flash point	>94°C, closed cup
Vapor pressure	0.00021 torr at 25°C
Solubility	very slightly soluble in water (13 mg/L at 20°C); miscible with organic solvents such as kerosene, xylene, and isobutyl ketone

17.1.2 Odor and Warning Properties Pungent, mercaptan-like odor.
17.2 Production and Use
Fonofos was introduced in 1967 for use as a soil insecticide to control corn borers, rootworms, cutworms, symphylans (garden centipedes), wireworms, and other soil and foliar pests. It is formulated as an emulsifiable concentrate and as granules. Registration of fonofos in the U.S. has been voluntarily cancelled.
17.4 Toxic Effects
17.4.1.1 Acute Toxicity Fonofos has high oral toxicity, and oral LD_{50}s are 3–18.5 mg/kg for rats (64a). Cholinergic signs and death occur rapidly after lethal exposure (364). The oral LD_{50} for a racemic mixture of fonofos was 14 mg/kg, which was less than the oral LD_{50} of 32 mg/kg for the $(S)_p$ isomer but greater than the oral LD_{50} of 9.5 mg/kg for the $(R)_p$ isomer (362). The acute i.p. LD_{50} for the fonofos racemic mixture was 4.8 mg/kg, suggesting an overall detoxification role of first-pass hepatic metabolism. The dermal LD_{50} for rats is 147 mg/kg and for guinea pigs is 278 mg/kg (363). Application of 0.5 ml undiluted fonofos to the skin of rabbits caused on dermal irritation, but all animals died within 24 hours (154). The 4-hour LC_{50} of fonofos for rats is 900 mg/m^3, and the 1-hour LC_{50} is 460 mg/m^3 (363).

Technical fonofos (0.1 mL) instilled into the eye of albino rabbits caused death during the first 24 hours after administration of the chemical, but local eye irritation was negligible (363).

17.4.1.2 Chronic and Subchronic Toxicity Dietary feeding of fonofos of groups of dogs for 14 weeks indicated a no-observed effect level of 8 ppm (approximately 0.2 mg/kg) (120a).

17.4.1.3 Pharmacokinetic, Metabolism, and Mechanisms Fonofos is well absorbed orally. After a single oral dose of fonofos, 98% was excreted in the urine (91%) and feces (7.4%) of rats within 96 hours. Prior exposure to fonofos did not change in excretion pattern. Tissue residues were very small and had virtually disappeared by day 16 (365). Similar results were obtained in white mice given the enantiomer of fonofos orally (365a). Fifty percent of the most toxic isomer and 95% of the less toxic isomer where eliminated within 96 hours.

Fonofos is first oxidized by microsomal enzymes to the oxon and also, by a different reaction, to *O*-ethyl-ethylphosphonothioic acid (ETP) and thiophenol. The oxon, in turn, is hydrolyzed to *O*-ethyl-ethylphosphoric acid (EOP) and thiophenol (366, 367). The oxon is not found *in vivo* due to its rapid hydrolysis (368). The other metabolites were much less toxic than the parent compound.

17.4.1.4 Reproductive and Developmental No adverse effects were noted on overall reproductive performance at either level among the parental animals or on the numbers, well-being, or integrity of the offspring among rats fed 10 or 31.6 ppm fonofos for three generations (95).

EPA noted a fetotoxic no-observed-effect level of 1.58 mg/kg/day in rats and a fetotoxic no-observed-effect level and lowest observed effect level of 2 and 6 mg/kg/day, respectively, in mice (95, 364).

17.4.1.5 Carcinogenesis There was no evidence of carcinogenicity when fonofos was given in the diet to rats for 105 weeks (95). This study produced a no-observed-effect level of 10 ppm (0.5 mg/kg/day) for brain acetylcholinesterase inhibition and a lowest observed effect level of 1.58 mg/kg/day based on RBC cholinesterase inhibition (95).

There was no evidence of carcinogenicity in dogs that were fed 0, 0.2, 1.5, and 12 mg/kg/day fonofos via their diet for 2 years (95). No compound-related effects were observed at 0.2 mg/kg/day; moderate (*sic*) inhibition of RBC cholinesterase, increased liver weight, tremors, lacrimation, and salivation occurred at 1.5 mg/kg/day; and, these symptoms plus microscopic lesions of the small intestines and liver occurred at 12 mg/kg/day.

17.4.2 Human Experience Four members of a family were poisoned by pancakes mistakenly made with fonofos instead of flour; one family member died (368a). Soon after eating the pancakes, one family member developed nausea, vomiting, salivation, and sweating and was taken to a hospital where she suffered cardiorespiratory arrest. She was resuscitated and transferred to a medical center where she was artificially ventilated, exhibited muscle fasciculations, low blood pressure, pinpoint pupils, and profuse salivary and bronchial secretions. Treatment continued and she was eventually released 2 months later. Gallo and Lawryk (1) noted that, although not reported in the original paper, three other members of the family were poisoned by the pancakes, and one of them died. A fifth family member who may have mixed the batter, but did not eat pancakes, remained well.

17.5 Standards, Regulations, or Guidelines of Exposure

The registration of fonofos has been voluntarily cancelled in the United States and tolerances are being revoked. The ACGIH TLV for fonofos is 0.1 mg/m^3 with a skin notation (154). The NIOSH REL-TWA for fonophos is 0.1 mg/m^3 with a skin notation. Most other countries also have Occupational Exposure Limits of 0.1 mg/m^3 for fonophos (Australia, Belgium, France, and Switzerland).

Organophosphorus Compounds

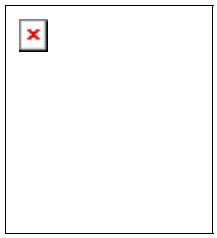
18.0 Malathion
18.0.1 CAS Number:
[*121-75-5*]
18.0.2 Synonyms:
(*O*,*O*-Dimethyl dithiophosphate of diethyl mercaptosuccinate; *O*,*O*-dimethyl-*S*-(1,2-dicarbethoxyethyl)-phosphorodithioate; diethyl [(dimethoxyphosphinothioyl)thio]butanedioate; Maldison; *O*,*O*-dimethyl phosphorodithioate ester of diethyl mercaptosuccinate; [(Dimethoxyphosphinothioyl)thio]butanedioic acid diethyl ester; mercaptosuccinic acid diethyl ester *S*-ester with *O*,*O*-dimethyl phosphorothioate; insecticide no. 4049; phosphothion; Cythion; dicarboethoxyethyl *O*,*O*-dimethyl phosphorodithioate; *O*,*O*-dimethyl *S*-(1,2-dicarbethoxyethyl) dithiophosphate; *O*,*O*-dimethyl *S*-(1,2-dicarbethoxyethyl)phosphorodithioate; diethyl mercaptosuccinate, *O*,*O*-dimethyl phosphorodithioate; 1,2-di(ethoxycarbonyl)ethyl *O*,*O*-dimethyl phosphorodithioate; chemathion; emmatos; karbofos, kop-thion; malagran; malamar; MLT; sadofos; *S*-(1,2-bis(carbethoxy)ethyl) *O*,*O*-dimethyl dithiophosphate; *S*-1,2-bis(ethoxycarbonyl)ethyl *O*,*O*-dimethyl dithiophosphate; calmathion; carbetox; carbethoxy malathion; carbetovur; celthion; cinexan; compound 4049; detmol ma; *S*-(1,2-di(ethoxycarbonyl)ethyl) dimethylphosphorothiolothionate; diethyl (dimethoxyphosphinothioylthio)succinate; diethyl mercaptosuccinate, *O*,*O*-dimethyl dithiophosphate, *S*-ester; diethyl mercaptosuccinate, *O*,*O*-dimethyl thiophosphate; diethyl mercaptosuccinate *S*-ester with *O*,*O*-dimethylphosphorodithioate; diethyl mercapatosuccinic acid *O*,*O*-dimethyl phosphorodithioate; *O*,*O*-dimethyl-*S*(1,2-bis(ethoxycarbonyl) ethyl)dithiophosphate; *O*,*O*-dimethyl-*S*(1,2-dicarbethoxyethyl) thiothionophosphate; *O*,*O*-dimethyl *S*-1,2-di(ethoxycarbonyl)ethyl phosphorodithioate; *O*,*O*-dimethyldithiophosphate diethyl mercaptosuccinate; phosphorodithioic acid, *O*,*O*-dimethyl ester, *S*-ester with diethyl mercaptosuccinate; Malaspray; dicarbethoxyethyl-*O*,*O*-dimethyldithiophosphate; diethyl mercaptosuccinic acid, *S*-ester of *O*,*O*-dimethyl phosphorodithioate; dimethyl dithiophosphate of diethyl mercaptosuccinate; dimethyl phosphorodithioate of diethyl mercaptosuccinate; Ethiolacar; Etiol; Cleensheen; Lice Rid
18.0.3 Trade Names:
Carbophos; Extermathion; Forthion; Fosfothion; Fyfanon; Malacide;Malatox; Maldison; Mercaptothion
18.0.4 Molecular Weight:
330.36
18.0.5 Molecular Formula:
$C_{10}H_{19}O_6PS_2$
18.0.6 Molecular Structure:



18.1 Chemical and Physical Properties
Malathion is a noncombustible, yellow to deep brown liquid. Malathion is rapidly hydrolyzed at pH>7 or >5 and is stable in aqueous buffered pH 5.6 solutions. It can corrode iron, steel, tinplate,

lead, and copper. It is a solid below 37°C.

Specific gravity	1.23 at 25°C
Melting point	2.85–3.7°C
Density	1.23 at 25°C
Boiling Point	156-157°C at 0.7 torr
Solubility	slightly soluble in water (145 ppm); completely soluble in alcohols, esters, ketones, ethers, aromatic solvents, and hexane, limited solubility in petroleum oils

18.1.2 Odor and Warning Properties A mild skunk-like odor.

18.2 Production and Use

Malathion is a broad-spectrum insecticide and one of the earliest organophosphate insecticides developed. It is used to control sucking and chewing insects on fruits, vegetables, and ornamental plants. It is also used to control mosquitos, flies, household insects, animal parasites, and head and body lice.

18.4 Toxic Effects

18.4.1.1 Acute Toxicity Malathion is an organophosphate compound that has low acute toxicity and rat oral LD_{50}s are generally in the 1,000–12,500 mg/kg range, depending on the formulation and gender tested (64, 268). An intraperitoneal LD_{50} of 750 mg/kg was reported, showing that route of exposure markedly impacts toxicity (369). This was also illustrated in a study where oral and intraperitoneal LD_{50}s in mice were 1025 and 420 mg/kg, respectively (370). Following lethal oral doses, maximal symptoms are often delayed for several hours, but death generally occurred within 2 days after poisoning (369). Technical grade malathion is more toxic than the pure product. Oral LD_{50}s for rats of 65% technical grade malathion, 90% technical grade malathion and 99% undiluted malathion were 369, 1156, and 5843 mg/kg, respectively (370). Commercial preparations of malathion vary in their toxicity due to the presence of impurities which bind to and inhibit acetylcholinesterase and also the carboxylesterase that detoxifies malathion (371–373).

A precise dermal LD_{50} for malathion has not been identified. The dermal LD_{50}s for rats for a 57% emulsifiable concentrate was greater than 4444 mg/kg (64a, 268). In rabbits, single dermal doses of up to 4 ml/kg 90% technical malathion or the 25% wettable powder caused no overt signs of toxicity, except for temporary irritation at the site of application (370). However, mortality occurred after four daily applications of 0.5 or 1 mL/kg/day and after two daily applications of 2 mL/kg. In each case, symptomology was characteristic of acute organophosphate poisoning (370).

An acute inhalation LC_{50} for malathion is not available, although a 4-hour LC_{50} of >5200 mg/m^3 has been reported (155). However, an intravenous LD_{50} of 50 mg/kg was reported in rats (373a) which is at least 20 times smaller than reported oral LD_{50}s. In dogs, an intravenous dose of 100 mg/kg resulted in immediate and profuse salivation and tremors (370). In a 5-hour exposure of mice of 7 mg/L 95% technical grade malathion (7000 mg/m^3), there were no signs of cholinergic toxicity and no deaths (203).

Overt toxicity has rarely been identified following single, sublethal exposures to malathion, although they cause RBC and brain cholinesterase inhibition. RBC cholinesterase activity maximally decreased in rats 45 minutes after an intraperitoneal dose of 300 mg/kg (370). Repeated daily intraperitioneal doses of 300 mg/kg produced a cumulative inhibitory action on cholinesterase activity of brain, submaxillary gland, and serum in rats so that after 5 days, activities were about 30, 50, and 25% of control, respectively (369). Rats could not tolerate longer periods of treatment.

Repeated administration of 200 mg/kg also progressively decreased cholinesterase activity of the brain and submaxillary gland.

An important characteristic of malathion acute toxicity is its potentiation by other organophosphates. When malathion and EPN were administered to rats separately, LD_{50}s were 1400 and 65 mg/kg, respectively. However, when malathion and EPN were administered simultaneously at a ratio of about 25:1, oral LD_{50}s were reduced to 167 and 7 mg/kg, respectively (184). The onset of symptoms for individual compounds was slow, and death usually occurred several hours after administration. However, when given together at or near the LD_{50}, symptoms developed much more rapidly, and death usually occurred within 1 hour. In dogs, oral doses of 2000 or 4000 mg/kg malathion alone were not fatal; however, when EPN was given simultaneously (2 or 5 mg/kg) with malathion, doses of 50, 100, and 200 mg/kg were lethal (184). Potentiation of malathion toxicity is due to the inhibition of carboxyesterase by EPN (and other organophosphates), an enzyme important in detoxifying of malathion (as well as the more toxic metabolic product malathion, malaoxon) (165, 374).

Evidence that malathion causes a paralytic type of neurotoxicity was observed in hens given 100 mg/kg or more malathion subcutaneously and observed for up to 30 days (190). Neurotoxicity, reflected by the occurrence of leg weakness that lasted for 4–14 days, occurred in atropinized chickens given single, subcutaneous doses of 100 mg/kg malathion (64a). Atropinized rats were given 600, 1000, or 2000 mg/kg malathion (88% pure) via oral gavage and were observed for signs of delayed neuropathy at 14–21 days; only the 2000-mg/kg dosed rats showed signs of gait alterations indicative of delayed neuropathy (375).

18.4.1.2 Chronic and Subchronic Toxicity Mortality was 20, 60 and 100%, respectively, among rats given 100, 200 or 300 mg/kg/day malathion intraperitoneally for 60 days (369). Rats fed lentil diets that contained 0.95 or 6.51 ppm malathion (equivalent to about 0.06 and 0.44 mg/kg/day) exhibited no signs of cholinergic toxicity (376). However, both exposure levels were associated with increased blood urea nitrogen and increased white blood cells, and the 0.44-mg/kg/day group had decreased serum cholinesterase activity. Brain and RBC cholinesterase activity were unaffected. Similarly, mice fed soybean seeds contaminated with 7 ppm malathion of 75 days exhibited no signs of cholinergic toxicity and no effect on RBC cholinesterase activity (376).

There is evidence that malathion is a sensitzer. In a field study, 3% of workers involved in spraying malathion for mosquito control and 5% of poultry ranchers who had used malathion for at least one season showed positive reactions when malathion (95%) was applied under adhesive tape to the skin of the upper arm and allowed to remain in place for 2 days (406). In another study of ten subjects who had reported skin reactions to malathion bait, none had a reaction to patch testing of malathion. Only one exhibited a positive reaction to the bait and another had irritant reactions to both bait and malathion (407).

18.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Approximately 90% of ingested malathion is relatively slowly absorbed and excreted in urine (1, 106, 389). Six hours after an oral dose of malathion, 75% remained in the stomach, 8% was in the small intestine, and 7% was in saliva. Thus a very small amount had been absorbed. Similar results were obtained in rats fed a lentil diet contaminated with malathion (376). After 48 hours, about 35% of the dose was excreted in urine; 45% in feces, 1.5% in exhaled air, and tissues contained about 9%. In rats given malathion orally, it is distributed to blood, adipose tissue, muscle, liver, and brain and then eliminated from these tissues at half-lives of 1.4, 2.4, 3.7, 19.4, and 17.6 days, respectively (101, 388).

Absorption of malathion via inhalation is expected to be high and elimination via urine extremely rapid and nearly complete based on pharmacokinetic studies following intravenous dosing. Among male volunteers, approximately 90% of an intravenous dose of malathion was excreted in urine within 5 days and the an elimination half-life was 3 hours (66). Thirty minutes following intravenous

administration of malathion to rats most had been distributed to tissues; liver, small intestine, lung, urinary tract, and kidney accumulated extremely high levels (389). Distribution pattern at 1 and 2 hours were similar.

In mice, 25% of a 1-mg/kg dermal dose of malathion was absorbed within 60 minutes, and 67% of the dose was absorbed by 8 hours (213). Distribution of malathion was equal in liver and blood; slightly greater in urine, feces, and expired air; and greatest in the rest of the carcass at 60 minutes. By 8 hours, 30% of the dose had been excreted, 30% remained in the carcass, and about 2.5% was distributed to lungs, kidney, bladder, stomach, intestine, liver, and blood. Whole body autoradiography of rats treated dermally with a single dose of malathion indicated that after 8 hours most of the dose was equally distributed between the application site (28%), remaining skin (29%), and the small intestine and urinary bladder (23%) (389).

Among human volunteers, about 8% of an applied malathion dermal dose of 4 mg/cm^2 was absorbed by 120 hours after application to the ventral forearm (66). *In vitro* absorption by human skin was about 9% from an aqueous ethanol solution and about 0.6 to 4% from cotton sheets to which malathion had been added (389a).

Malathion is either oxidized in the liver to malaoxon by microsomal cytochrome P450 enzymes or to monoacids by a microsomal carboxyesterase. Malaoxon is the toxic metabolite of malathion that binds and inhibits acetylcholinesterase and leads to the typical cholinergic sequelae associated with organophosphate poisoning. The other products of malathion and malaoxon metabolism are detoxification products. Malaoxon is also subject to hydrolysis and carboxyesterase (105, 390, 391). There is evidence that the linkage at P–S is enzymatically broken by another cytosolic esterase as well (*A*-esterase) and forms *O*,*O*-dimethyl phosphorothioate (390). There is some evidence the monoacids can then be S-methylated, and that the C–S bond of either malaoxon or malathion can be further hydrolyzed (392, 393).

The rate of malathion desulfuration is not as critical as the rate of hydrolysis by carboxyesterase or hydrolysis of the C–S bond, both of which are detoxication reactions, in determining the toxicity of malathion (393). Female rats that are more sensitive to malathion toxicity have relatively lower levels of liver carboxylesterase activity (394). Further, pretreatment of mice with the microsomal inducer phenobarbital failed to decrease the mouse intraperitoneal LD_{50} (i.e., failed to increase the toxicity) of malathion, whereas it did decrease the i.p. LD_{50} of dimethoate which is not subjected to detoxification reactions as extensive as those for malathion (391). Additionally, oral LD_{50}s for rats and three strains of mice were significantly correlated with their carboxyesterase titer in liver and plasma (371). Carboxyesterase activity (also termed hydrolase B) occurs in mouse, rat, and human liver microsomal preparations and it has been shown, is markedly inhibited by a common impurity of malathion, isomalathion (372). This inhibition is associated with the potentiation of malathion toxicity (395a). Finally, it is believed that malathion and/or malaoxon inactivate carboxyesterase, so that additional dose of malathion are less effectively detoxified. This contributes to the phenomenon whereby pretreatment with malathion increases the toxicity of subsequent doses (374).

No polymorphism of carboxylesterase was detected in 12 human livers, but the range of individual activity toward malathion was about 10-fold (395). In humans, carboxyesterase is expressed only, in the liver, whereas in rodents, carboxyesterase is expressed in the serum and liver. This could provide a basis for a greater sensitivity of humans to malathion compared to rodents, although that has not been adequately explored.

18.4.1.4 Reproductive and Developmental Viability and growth decreased in fetuses of rats fed diets that contained about 4000 ppm technical grade (95%) malathion (240 mg/kg) for 5 months (377). Pregnant rats on protein-deficient or protein-adequate diets given 500 mg/kg/day malathion orally on gestation days 6, 10, and 14 showed decreased maternal weight gain, a decreased number of implantations and live fetuses, and decreased brain acetylcholinesterase activity (392a). Protein

deficiency enhanced an effect of malathion on fetal crown to rump and tail length, fetal body weight, and retardation of skeletal ossification. No detectable increases in the number of resorptions, fetal size, and external or visceral anomalies occurred in rabbits given malathion (70%) at 100 mg/kg by gavage on gestation days 7 through 12 (378).

Pregnant rats given 600 or 900 mg/kg malathion via intraperitoneal injection on gestation day 11 showed signs of maternal toxicity but did not produce malformed or low birth weight pups (379). Malathion caused a dose-dependent inhibition in brain acetylcholinesterase activity in dams and pups among rats given 138, 276, and 827 mg/kg/day malathion via intraperitoneal injection on gestation days 6 through 13 (380).

18.4.1.5 Carcinogenesis No cholinergic toxicity or inhibition of whole blood cholinesterase activity occurred in rats fed diets that contained 100 or 200 ppm (2.5 or 6.25 mg/kg/day) for 8 weeks (194). However, when the diet contained 25 ppm (0.625 mg/kg/day) EPN, as well as 500 ppm malathion, whole blood cholinesterase was significantly inhibited. No cholinergic signs occurred in dogs fed diets that contained 25, 100, or 250 ppm malathion for 12 weeks, but RBC cholinesterase was significantly inhibited in dogs fed 250 ppm (194). In rats fed 100, 1000, or 10,000 ppm 65% technical malathion, 90% technical malathion, or 99%+ malathion in the diet (equivalent to about 6, 60, or 600 mg/kg/day) for 2 years, cholinergic toxicity was not described, but among rats given the more toxic 65% and 90% technical products, RBC and brain cholinesterase activities were inhibited in the 1000- and 10,000-ppm groups and were unaffected in the 100-ppm group (370).

There was no evidence of carcinogenicity in rats given diets that contained 4700 or 8150 ppm (about 270 mg/kg and 466 mg/kg) for 80 weeks and observed for an additional 33 weeks, in rats given diets that contained 2000 or 4000 ppm malathion (about 115 mg/kg/day and 230 mg/kg/day) for 103 weeks, or in rats given diets that contained 500 or 1000 ppm malaoxon for 103 week (482). There was no evidence of carcinogenicity in mice given diets that contained 8,000 or 16,000 malathion (about 800 and 1600 mg/kg/day) for 80 weeks and observed for an additional 14 or 15 weeks (482). During the second year, clinical signs including alopecia, rough and discolored coats, poor food consumption, hyperexcitability, and abdominal distension occurred with increasing frequency in dosed animals. A few animals appeared hyporeactive, and some had hunched appearances. During weeks 71 to 79, five high-dose females exhibited generalized body tremors.

18.4.1.6 Genetic and Related Cellular Effect Studies Mammalian *in vivo* and *in vitro* studies of technical or commercial grade malathion and its metabolite malaoxon show a pattern of induced chromosomal damage, as measured by increased chromosomal aberrations, sister chromatid exchanges, and micronuclei (381, 382), as well as increased mutations (383, 384). Purified (>99%) malathion gave weak or negative results in cytogenetic assays. Technical malathion was generally negative in mammalian gene mutation assay, but malaoxon was positive. Studies of human lymphocytes indicated that *in vitro* incubation with malathion increased the frequency of DNA mutations (383, 384). Malathion were positive in a modified SOS microplate assay in which the induction of b-galactosidase in *E-coli* PQ37 was used as a qualitative measure of genotoxic activity (385).

Dermal exposure caused cytogenetic damage in test animals at doses near those that produce positive results by intraperitoneal injection (381). Workers involved in a Mediterranean fruit fly aerial spraying eradication program in California in the early 1990's exhibited no increase in micronuclei formation or mutation frequency assessed by the glycophorin A (GPA) assay (386, 387). However, a significant increase in micronuclei occurred in whole blood cultures and in human lymphocytes at dose levels that also caused cytotoxicity and strong inhibition of proliferation (386, 387).

18.4.2 Human Experience 18.4.2.2 Clinical Cases There have been many reports of organophosphate poisoning from the intentional or accidental ingestion of malathion (1). There are a few reports of poisoning from dermal exposure of children that occurred when their hair was washed with a 50% solution of malathion to eliminate lice. Poisoning following inhalation exposures have

been reported but were probably confounded by simultaneous ingestion (1). Cholinergic symptoms appear rapidly from minutes to 3 hours following ingestion, but may be delayed by 12–14 hours after dermal exposure.

Estimates of lethal doses of malathion obtained from case study reports range from 68 to 3855 mg/kg (1). Actual estimates of ingestion obtained from reports of poisonings where the quantity was approximately known indicated that a life-threatening dose is 500–1000 mg/kg (371). Doses associated with serious but sublethal toxicity have ranged from approximately <1 mg/kg (in a two-year-old boy) to 357 mg/kg (396).

Large-scale occupational poisoning by malathion occurred among sprayers, mixers, and supervisors involved in a mosquito control program that used a water-wettable powder formulation of malathion (397). An estimated 2810 cases of poisoning including five deaths were recorded during the peak month of the epidemic. Symptoms and clinical histories were consistent with organophosphate intoxication and the most severe illness were associated with the formulation that contained high levels of isomalathion and other contaminants. Exposures were primarily dermal and estimates ranged from 1 to 200 mg/cm^2. Respiratory exposure was estimated to considered less important—peak air concentrations measured during spraying were about 1.5 mg/m^3. RBC cholinesterase decreased at the end of the workday in workers, who used the two formulations that contained 2–3% isomalathion, but not in workers who used the uncontaminated formulation.

An intermediate-type syndrome characterized by weakness of proximal limb muscles, cranial nerve palsies, and respiratory depression has sometimes followed initial acute symptoms associated with malathion poisoning (1). Typical of a case that showed such delayed symptoms is that of a woman who experienced a typical cholinergic crisis about 1 hour after ingesting 300 mL malathion. She was successively treated with atropine and pralidoxime iodide but suffered a “relapse” characterized by diaphoresis, miosis, mental confusion, and respiratory dysfunction 47 hours later (398). Measurements of plasma and RBC cholinesterase activities in this patient suggested that they were 26–38% and 28–40% of normal, respectively for the 15 days following malathion ingestion. Initial plasma concentrations were quite high in this patient, and an elimination half-life of 7.6 hours was determined suggesting to the authors that because of its lipophilicity, malathion may have been retained in adipose tissues and then was released more slowly into circulation, causing the delayed effects.

No signs of cholinergic toxicity have been reported as a result of the aerial spraying of malathion to control mosquitos or the Mediterranean fruit fly (399, 400, 405). However, chronic dose rates calculated from spraying to eradicate the Mediterranean fruit fly in California were quite low—about 0.001–0.246 mg/kg/day via dermal contact, about 0.01 to 0.1 mg/kg/day via inhalation, and about 0.030–0.080 mg/kg/day via ingestion of backyard vegetables (401). Average and upper bound estimates of environmental levels of malathion during aerial spraying derived from mass deposition rates and air monitoring in affected areas were 0.09 and 0.2 mg/m^3 in air immediately after spraying, 22 and 52 mg/m^2 on outdoor surfaces, 3.8 and 9.6 mg/g in plants, and 1.5 and 3.5 mg/g in soil. Estimated average and upper bound estimates of malaoxon levels were 0.04 to 0.110 mg/m^3 in air, 0.15 and 0.46 mg/m^2 on outdoor surfaces, 0.03 and 0.08 mg/g in plants, and, 0.01 and 0.03 mg/g in soil (402).

To test the safety of malathion in controlling lice, the bodies and clothing of thirty-nine men were dusted five times a week for 8–16 weeks with talcum powder that contained 0, 1%, 5%, or 10% malathion. Complaints about odor and skin irritation were roughly proportional to dosage. No change in blood cholinesterase activity was found, except occasionally with 10% powder (403).

Exposure to malathion via dermal contact and inhalation was estimated in six entomologists who were exposed to windborne aerosols of malathion drifting downwind from generators as they moved

along pastures where they were working (404). Measures of respiratory exposure were made using midget impingers at the breathing zones of the entomologists, by measuring malathion in absorbent filters in cartridge type respirators, and by measuring atmospheric concentrations. Dermal exposures were estimated from malathion contained in cotton gloves and absorbent cellulose surface patches placed in various locations on the skin. Estimates of total dermal exposures during a two week period ranged from 0.5–1.3 mg/kg (0.05–0.13 mg/kg/day assuming two 5-day weeks), and estimates of respiratory exposures ranged from 0.2–0.3 mg/kg (0.02–0.03 mg/kg/day assuming two 5-day weeks). Average air concentrations of malathion were 0.5 to 4 mg/m^3 although they ranged as high as 56 mg/m^3. None of the men exposed during the study exhibited any cholinergic clinical signs or inhibition of plasma or RBC cholinesterase activity.

18.4.2.3.4 Reproductive and Developmental No association was found between malathion exposure and spontaneous abortion, intrauterine growth retardation, stillbirth, and most categories of congenital anomalies in a cohort of 7450 pregnancies potentially exposed to malathion applied aerially to control the Mediterranean fruit fly (405).

Five men given gelatin capsules delivering 8, 16, or 24 mg/malathion each day (equivalent to roughly 0.11, 0.23, or 0.34 mg/kg/day) for 32, 47 or 56 days, respectively, experienced no cholinergic toxicity (294). RBC cholinesterase activity was not affected in either the 8- or 16-mg/day group, but it was inhibited by exposure to 24 mg/day.

No adverse symptoms or inhibition of RBC cholinesterase occurred among volunteers exposed to dust containing 1, 5, or 10% malathion five times/week for 8 weeks (403). The estimated maximum dosage received was about 224 mg/day or 3.2 mg/kg/day.

Groups of four men received two 1-hour exposures to aerosols that contained variable amounts of malathion in unventilated rooms on each of 42 consecutive days (408). Based on the decreased weight of the aerosol containers used to spray the exposure rooms, malathion air concentrations were estimated at 0.15 g, 0.60 g, or 2.4 g of malathion per 1000 ft^3—which is equivalent to about 5, 21, and 85 mg/m^3 malathion. No cholinergic toxicity occurred during the study, nor was RBC cholinesterase activity reliably depressed in any of the exposed subjects.
18.5 Standards, Regulations, or Guidelines of Exposure
Malathion is undergoing reregistration by the EPA (154). The ACGIH TLV for malathion is 10 mg/m^3 with a skin notation. The OSHA PEL-TWA is 15 mg/m^3 total dust with a skin notation. The NIOSH REL-TWA is 10 mg/m^3 with a skin notation. Other countries have Occupational Exposure Limits of 15 mg/m^3 (Austria, Germany, The Philippines, Thailand, and Turkey), 10 mg/m^3 (Egypt, Australia, Belgium, Finland, France, Japan, The Netherlands, and Switzerland), or 5 mg/m^3 (Denmark). In Poland the TWA is 1 mg/m^3, STEL 10 mg/m^3 (1998), and in Russia the STEL is 0.5 mg/m^3 (Jan. 93).

Organophosphorus Compounds
Jan E. Storm, Ph.D

19.0 Methyl Parathion
19.0.1 CAS Number:
[*298-00-0*]
19.0.2 Synonyms:
Axophos; *O*,*O*-Dimethyl *O*-(*p*-nitrophenyl) phosphorothioate; Parathion-methyl; phosphorothioic acid *O*,*O*-dimethyl *O*-(4-nitrophenyl) ester; *O*,*O*-dimethyl *O*-*p*-nitrophenyl thiophosphate; dimethyl parathion; Metaphos; E 601; Penncap-M; Metafos; dimethyl 4-nitrophenyl phosphorothionate;

dimethyl *p*-nitrophenyl monothiophosphate; *O*,*O*-dimethyl O-(*p*-nitrophenyl) thionophosphate; dimethyl *p*-nitrophenyl thionophosphate; *p*-nitrophenyldimethylthionophosphate; Dalif; nitrox 80; nitrox; wofatox; bay e-601; folidol-80; Metaphor; parathion methyl homolog; dimethyl *O*-*p*-nitrophenyl thiophosphate

19.0.3 Trade Names:

Bladan M®; Metron®; Nitrox®; Dalf®; Diithion 63; Ketokio 52; Foidol-M®; Metacide®; Metron®; Seis-Tres 6-3; Metaspray 5E; Paraspray 6-3

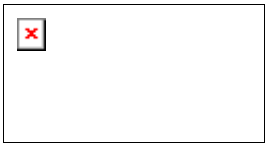
19.0.4 Molecular Weight:

263.23

19.0.5 Molecular Formula:

$C_8H_{10}NO_5PS$

19.0.6 Molecular Structure:



19.1 Chemical and Physical Properties

Pure methyl parathion is a white crystalline solid. The technical grade product contains about 80% methyl parathion and is a brown liquid. Methyl parathion is hydrolyzed by alkaline materials; may react with strong oxidizers; decomposes rapidly above 100°C (creating an explosion hazard) and may release fumes of dimethyl sulfide, sulfur dioxide, carbon monoxide, carbon dioxide, phosphorus pentoxide, and nitrogen oxides

Specific gravity	1.36 at 20°C
Melting point	37–38°C
Boiling point	143°C at 1.0 mmHg
Vapor pressure	0.5 torr at 20°C
Solubility	soluble in water (0, 005 g/100 mL) ethanol, chloroform, aromatic and aliphatic solvents

19.1.2 Odor and Warning Properties Rotten egg or garlic ordor (technical product); odor threshold 0.012 ppm.

19.2 Production and Use

Methyl parathion is a broad-spectrum insecticide and acaracide used to control boll weevils and many biting or sucking insect pests on cotton, field vegetables, rice, fruit trees, alfalfa, soy beans, forest trees, and aquatic food crops. It is also used for mosquito control. Methyl parathion is generally applied to the leaves or aerial portion of the crop by either aircraft or ground spray equipment (53). Methyl parathion is available as an emulsifiable concentrate or microencapsules (155). Methyl parathion may be formulated in combination with other pesticides (53).

19.3.5 Biomonitoring/Biomarkers Immediately after exposure, the concentration of methyl parathion in serum is the most specific biomarker for exposure (409). Urinary concentrations of two metabolites of methyl parathion, *p*-nitrophenol and dimethyl phosphate, may also indicate exposure to methyl parathion. However, they are not unique to methyl parathion. *p*-Nitrophenol is also a breakdown product of parathion, and alkylphosphates are metabolic products of a number of organophosphates (410, 411).

19.4. Toxic Effects

19.4.1.1 Acute Toxicity Methyl parathion is highly toxic and has oral LD_{50}s of 8–24 mg/kg for rats

(64, 268, 252, 412). Dermal LD_{50}s are 6–67 mg/kg (268). Dermal LD_{10}, LD_{50}, and LD_{90}s of 506, 566, and 632 mg/kg for rats indicate a very steep dose–lethality curve (413). One-hour and 4-hour LC_{50}s of 200–287 mg/m^3 and 120 mg/m^3, respectively, were reported for rats. A 4-hour LC_{50} of <163 mg/m^3 and a 4-hour LC_{50} of 135 mg/m^3 were reported for rats for the 80% technical formulation (243). On a milligram per kilogram basis, methyl parathion via intravenous injection was up to eight times more potent than via oral gavage indicating detoxification via first-pass hepatic metabolism (414, 415). Generally, lethal doses cause death quickly within one hour.

An intraperitoneal LD_{50} of 4 mg/kg was reported for adult rats (248, 416, 417), but is <1 mg/kg and <4 mg/kg in neonatal and 12 to 13-day-old rats, respectively, showing enhanced susceptibility of young animals of methyl parathion toxicity. Subcutaneous maximum tolerated doses (MTD, the highest dose that causes no mortality) of 8 and 18 mg/kg were reported for neonate and adult mice, respectively (204).

Among rats given single oral doses of 0, 0.025, 7.5, 10 (males only), or 15 mg/kg (females only) methyl parathion, cholinergic toxicity occurred at doses of 7.5, 10, or 15 mg/kg (243). Neuropathology (focal demyelination) was also evident at these levels.

Methyl parathion caused neurotoxicity, indicated by leg weakness, that lasted from 3–28 days after dosing when given subcutaneously to atropinized chickens at a dose of 64 mg/kg, but not at a dose of 32 mg/kg (64). This shows that methyl parathion may cause a delayed neuropathy but only at doses substantially above a lethal dose and is consistent with a study submitted to EPA in which hens were given an oral dose of 215 mg/kg (243). No signs of ataxia typical of delayed neurotoxic effects were seen in treated hens, nor were neural degenerative changes observed histologically.

Immunotoxicity was observed in mice that were treated with a single oral dose of 9 mg/kg or with 0.9 or 0.4 mg/kg/day, 5 days/week for 4 weeks with the industrial product used to produce Wofatox 50 (60% methyl parathion) and that were immunized with sheep red blood cells (418). Significant increases in the number of splenic plaque forming cells (PFC) occurred among mice treated acutely with 9 mg/kg or repeatedly with 0.9 mg/kg, but not among mice treated repeatedly with 0.4 mg/kg. Immunotoxic effects were also observed in rabbits given diets that contained doses of 0.6 mg/kg/day, but not 0.2 mg/kg/day (419), and in rats given 1.25 mg/kg/day (420).

19.4.1.2 Chronic and Subchronic Toxicity Repeated oral exposure of rabbits to methyl parathion (1.78 mg/kg/day for 28 days) was associated only with decreased body weight gain and slightly decreased plasma acetylcholinesterase activity by day 21 (421).

Cholinergic signs were not noted in rats given 0, 0.5, 1, 1.5, 2, or 2.5 mg/kg/day methyl parathion via their diet for 7 weeks followed by a 1-week observation period (421a). One female died in each of the 0.5-, 1.5- or 2-mg/kg groups, and two females died in the 2.5 mg/kg group; no deaths occurred in males. When methyl parathion was given to rats in the diet at 0, 2.5, 25, or 75 ppm (about 0, 0.12–0.16, 1.24–1.55, and 4.46–5.15 mg/kg/day) for 90 days, fourteen females and one male fed 75 ppm died by 4 weeks (243). Subjects fed 75 ppm also exhibited a variety of hematologic and clinical chemistry effects. Rats fed the 25- or 75-ppm diet exhibited inhibited RBC and/or brain cholinesterase activity. When parathion was given to rats in the diet at 0.5, 5, or 50 ppm (about 0.029–0.037, 0.295–0.365, or 3.02–3.96 mg/kg/day for 13 weeks, cholinergic toxicity and RBC and brain cholinesterase inhibition occurred (243). Among rats fed the 5-ppm diet, RBC cholinesterase inhibition occurred. No treatment related neuropathy was observed at any dose.

When mice were given 0, 2.6, 5.2, 7.8, 10.4, 13, 16.2, 32.5, or 65 mg/kg/day methyl parathion via their diet for 7 weeks followed by a 1-week observation period (421a), the only clinical signs noted were rough hair coat and arched back, but all males in the 32.5- and 65-mg/kg/day group died as did all females in the 65-mg/kg/day group. When methyl parathion was given to mice in the diet at 0, 10,

30, or 60 ppm (about 0, 2.1–2.5, 6.5–8.6, and 13.5–16.3 mg/kg/day) for 90 days, body weight decreased, absolute brain weight increased, and testes weight decreased in males given 60 ppm (243). In females fed the 60-ppm diet, brain and ovary weight decreased; in females fed the 30-ppm diet, only ovary weight decreased; no other adverse effects were recorded.

There was no evidence of cholinergic toxicity in rabbits given dermal doses of 0, 1, 5, 10, or 100 mg/kg/day methyl parathion for 21 days, although RBC cholinesterase was inhibited in rabbits given 10 or 100 mg/kg/day (243). Slight erythema and edema occurred in females at all doses. Rats exposed to methyl parathion via dermal application of 2 mg/kg/day for 30 days experienced cholinergic toxicity and 40% lethality. Treatment was associated with severe liver injury, severe renal tubular injury, and Purkinje cell necrosis, as well as a decrease in brain and RBC cholinesterase activity.

No cholinergic signs or treatment-related effects on clinical chemistry, hematologic, or urinalytic parameters occurred in dogs exposed to 0, 0.30, 1.0, or 300 mg/kg/day methyl parathion via the diet for 13 weeks (243). Dogs given 3 mg/kg/day exhibited decreased brain and RBC cholinesterase activity, and, dogs given 1 mg/kg/day exhibited decreased RBC cholinesterase activity. No adverse effects occurred in dogs given 0.3 mg/kg/day. When dogs were treated with methyl parathion in the diet at 0, 0.03, 0.3, or 3.0 mg/kg/day for 13 weeks, two high-dose males exhibited emaciation, dehydration, and thin appearance (242). RBC and brain cholinesterase activity were inhibited in high-dose males and females.

Dogs fed diets that provided 0.03, 0.1, or 0.3 mg/kg/day methyl parathion for 1 year exhibited no adverse effects at any dose other than decreased RBC cholinesterase activity at all doses (243). Cholinergic toxicity, thymic lymphoid depletion, and decreased RBC and brain cholinesterase activity occurred in dogs given 4.0 mg/kg/day via the diet for 1 year. Only decreased RBC and brain cholinesterase activity occurred in dogs given 3.5 mg/kg/day, and only decreased RBC cholinesterase activity occurred in dogs given 1.0 mg/kg/day (243). No effects occurred in dogs given 0.3 mg/kg/day, and no treatment-related effects on survival, food efficiency, hematologic and urinalytic findings, ophthalmoscopic findings, intraocular pressures, or electroretinograms occurred in any dogs at any dose (243).

When methyl parathion was given to rats via diets containing 0, 0.5, 2.5, 12.5, and 50 ppm (about 0, 0.02–0.03, 0.11–2.5, 0.53–0.70, and 2.21–3.09 mg/kg/day) for one year cholinergic signs, neuropathology (in peripheral nerve preparations), and decreased RBC and brain cholinesterase activity occurred in rats given 50 ppm (243). Among rats fed the 12.5 ppm diet, RBC and brain cholinesterase was significantly inhibited. No ocular effects were observed at any dietary level.

19.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Absorption, distribution, and elimination of methyl parathion via either oral or inhalation exposure is rapid and extensive. Eighty-five percent of an oral dose of methyl parathion was eliminated by mice in urine by 72 hours (425). Similarly, oral methyl parathion was rapidly absorbed by rats and guinea pigs. Concentrations in blood and brain were maximal in about 1–3 hours, and it was nearly completely eliminated in urine (mostly as dimethyl phosphoric and dimethyl phosphorothioic acid) by 7 days (415). Absorption following intravenous or oral dosing of dogs with methyl parathion was 63–78% and 80–95%, respectively, and urinary elimination was rapid and extensive. Bioavailability after oral exposure was much lower (6–30%) than after intravenous exposure due to extensive metabolism and a high extraction ratio in the liver, as well as extensive serum protein binding (426, 427). Maximum serum concentrations after oral exposure occurred 2–9 hours after dosing. Following intravenous injection of dogs with methyl parathion, serum concentrations initially declined rapidly and then more slowly, and the apparent volume of distribution exceeded total body water, indicating distribution to peripheral tissues (427). The mean terminal serum half-life was 7.2 hours, although one dog had a half-life of 16.4 hours. Similar results were obtained in rats and guinea pigs treated intravenously with methyl parathion—absorption, distribution, and elimination were rapid and complete (428).

Following oral exposure, methyl parathion is distributed to blood, liver, adipose tissue, muscle, and brain (429). Distribution coefficients were highest in adipose tissue 8 days after exposure (0.99), in liver 20 days after exposure (0.17), and in brain 16 days after exposure (0.35), but they were always <1.0, indicating no long-term accumulation of methyl parathion in tissues. Concentrations of methyl parathion are maximum 12 days after exposure in blood and liver and 8 days after exposure in adipose tissue and brain. Half-lives of elimination were 15 days for blood, 13 days for adipose tissue, 15 days for liver, and 15 days for brain (429).

Methyl parathion is oxidatively desulfurated to methyl paraoxon or dearylated to dimethyl thiophosphorothioic acid and *p*-nitrophenol via cytochrome p450 enzymes (20, 416, 417). Alternatively, methyl parathion is hydrolyzed to form *O*-methyl-*O*-*p*-nitrophenyl thiophosphate by esterase (termed A-esterase). Methyl paraoxon can also be dearylated to dimethyl phosphoric acid and *p*-nitrophenol or hydrolyzed to *O*-methyl-*O*-*p*-nitrophenyl phosphate. All of these oxidative and hydrolytic products are excreted in urine (425), except methyl paraoxon that is rarely detected in tissues. These metabolic conversions occur primarily in the liver but also occur in the lung and brain (13, 21, 434–436).

Methyl paraoxon binds to and irreversibly inhibits acetylcholinesterase. Noncatalytic, stoichiometric binding to other esterase (aliesterases) in liver and plasma also occurs, however, and may represent a significant detoxification mechanism because it may reduce the amount of methyl paraoxon that leaves the liver and/or blood to enter target tissues (14, 21, 435). Binding to hepatic and plasma esterase may not be as significant a detoxification mechanism for methyl parathion as it is for parathion and chlorpyrifos, however, because the affinity of methyl paraoxon is considerably greater for brain acetylcholinesterase than for hepatic esterase. The reverse is true for parathion and chlorpyrifos (14). Thus, even though methyl paraoxon has a lower affinity for acetylcholinesterase than paraoxon, the relatively weaker protection afforded by the aliesterases could allow lethal levels of the hepatically generated methyl paraoxon to reach the nervous system (14).

Differences in the relative rats of toxification and detoxification reactions of methyl parathion contribute to differences in its toxicity compared to other organophosphates, as well as to differences in toxicity between sexes and among different ages (20). For example, female rats, who are slightly less sensitive to the toxicity of methyl parathion than males, metabolized less methyl parathion to methyl paraoxon than male rats in *in situ* perfused liver (21). Age-related differences in the oral LD_{50} also correlated with rates of detoxification pathways of methyl paraoxon rather than with rates of direct metabolism of methyl parathion (417). Differences in the relative rates of toxification and detoxification also contribute to interspecies differences in toxicity. However, the primary factor that accounts for interspecies differences is species-specific differences in the affinity of acetylcholinesterase for methyl paraoxon (20, 437, 438).

19.4.1.4 Reproductive and Developmental When rats were fed diets that contained 0.5, 5.0, and 25 ppm methyl parathion (0.04, 0.4, and 2 mg/kg/day) for two generations, no treatment-related histopathological effects occurred, nor were there any effects on reproductive parameters, except for maternal weight gain at 25 ppm which decreased significantly in both generations during lactation (243). Reproductive effects, however, occurred in male mice given 0, 9.4, 18.8 and 75.0 mg/kg by gavage (422). Treated animals showed a dose-related increase in the percentage of abnormal sperm. Because there was no appreciable change in testis to body weight ratio and because greater damage was induced when cells were treated as spermatocytes, the authors concluded that methyl parathion acts as a germ cell mutagen. Reproductive effects were also reported in rats treated intraperitoneally with 2.5, 3.5, 4.0, and 5.0 mg/kg methyl parathion (423). Treatment with 4.0 or 5.0 mg/kg caused a significant decrease in ovarian weight and the number of healthy follicles but no change in atretic follicles. The number and duration of estrous cycles was significantly affected at 3.5 mg/kg and higher.

When pregnant rats were given 0.3, 1.0 or 3.0 mg/kg/day methyl parathion via gavage on gestation

days 6 through 15, developmental toxicity (increased postimplantation loss and embryonic resorptions, decreased fetal body weight, and delayed ossification) occurred at 3.0 mg/kg/day, but this dose was also maternally toxic (243). Pregnant rats given 1.5 mg/kg/day methyl parathion via gavage on gestation days 6 through 15 exhibited cholinergic toxicity, decreased body weight gain, and an increased number of fetal resorptions (243). When rabbits were given 0.3, 1.0, 3.0, or 5.0 mg/kg/day methyl parathion on gestation days 6 to 18, no maternal or developmental toxicity occurred, other than RBC cholinesterase inhibition at all doses 243.

Pregnant rats given 5, 10, or 15 mg/kg and pregnant mice given 20 or 60 mg/kg methyl parathion via intraperitoneal injection on gestation days 12 and 10, respectively, showed signs of toxicity at all doses (592). Some of the severely affected animals that were treated with the highest dose died. There were no fetotoxic effects in rats. The mice, however, showed more lethality and external malformations (cleft palate) at the highest dose (60 mg/kg). Among pregnant rats given 4.0 mg/kg methyl parathion on gestation days 9 or 15 or 6.0 mg/kg on gestation day 9 via intraperitioneal injection, marked RBC cholinesterase inhibition and some deaths occurred within 30 minutes after injection of 6 mg/kg (424). Embryos of both treated groups had diminished cerebral cortical cholinesterase activity, but there were no effects on fetal mortality or fetal weight and no gross anomalies or developmental defects occurred at either dose.

19.4.1.5 Carcinogenesis Methyl parathion was not carcinogenic in rats or mice given 0, 1, or 2 mg/kg/day (rats) or 0, 4.5–8, or 9.7–16.2 mg/kg/day (mice) methyl parathion via their diet for 2 years (421a). Methyl parathion was not carcinogenic in mice given diets containing 0, 1, 7, or 50 ppm methyl parathion (0, 0.2–0.3, 1.6–2.1, and 9.2–13.7 mg/kg/day) for 2 years, although RBC and brain cholinesterase were decreased in mice given 7 or 50 ppm (243). Nor was methyl parathion carcinogenic when diets that contained 0, 0.5, 2, 5, 10, or 50 ppm methyl parathion were given to rats for 2 years (equivalent to 0.02–0.03, 0.09–0.14, 0.21–0.26, 0.46–0.71, and 2.6-5.0 mg/kg/day) (243). Cholinergic symptoms, hematologic effects, bilateral retinal degeneration, posterior subcapsular cataract, decreased body weight, increased food consumption, and some deaths occurred in rats given 50 ppm. Brain and RBC cholinesterase activity were inhibited in males given the 10- or 50-ppm diets and in females given the 50-ppm diet; RBC cholinesterase activity was inhibited in females given the 10-ppm diet. At 5 ppm, cholinergic toxicity was apparent in one female, hematologic effects were apparent in males only, and RBC cholinesterase activity decreased slightly. Neurological changes (in particular sciatic nerve degeneration) were pronounced in rats that received 50 ppm, and lesions in 5-ppm treated rats were considered significant.

19.4.1.6 Genetic and Related Cellular Effects Studies Assays for mutagenicity of methyl parathion using prokaryotic systems have been both positive and negative. Methyl parathion was both positive and negative in *S. typhimurium* with or without metabolic activation, negative in *S. cerevisiae* for reverse mutation and gene conversion, negative for reverse mutation but positive for 5-methyl tryptophan resistance in *E. coli*, positive for mitotic recombination in *S. cerevisiae* (53, 243); positive for DNA damage in *S. typhimurium* and *E. coli*, and negative for unscheduled DNA synthesis in cultured human lung fibroblasts (53, 408a).

Increases in sister chromatid exchange were observed in Chinese hamster ovary cells with metabolic activation but not in Chinese hamster V79 cells, cultured human lymphoid cells, or lymphoma cells without metabolic activation (53).

Methyl parathion was negative in a mouse dominant lethal assay in which mice were fed diets that contained methyl parathion for 7 weeks, and a dominant lethal effect was not observed in mice given methyl parathion in drinking water for 7 weeks (53).

Increased percentages of lymphocytes that had chromosomal breaks were not found among workers from a pesticide factory that manufactured methyl parathion, but chromosomal aberrations were detected in lymphocytes of individuals who were acutely intoxicated by methyl parathion via oral ingestion, inhalation, or dermal contract (53).

19.4.2 Human Experience 19.4.2.2 Clinical Cases Numerous cases of death and serious toxicity have been reported following acute oral exposure to methyl parathion or following a combination of acute dermal and inhalation exposure (439). Minimal lethal doses were in the range of about 5–10 mg/kg (53).

The degree of RBC acetylcholinesterase inhibition was reported in several cases of combined parathion and methyl parathion poisoning (440). Levels of RBC acetylcholinesterase activity on the day of maximum depression, which ranged from day 1 to day 9 after poisoning, ranged from about 1 to 31% of normal values. This is consistent with RBC cholinesterase activity determined in a pesticide applicator who complained of headache, light headedness, increasing malaise, insomnia, anorexia, and decreased sexual drive, that was 13% of normal (441).

Seven children displayed signs of organophosphate poisoning (lethargy, increased salivation increased respiratory secretions, pinpoint pupils, and respiratory arrest) following their apparent exposure to methyl parathion as a result of its inappropriate use as an insecticide indoors. Significant residues of methyl parathion were found in water used for drinking, orange drink mix, and indoor air (441a). Two of the children died. Upon admission to the hospital, plasma and RBC cholinesterase activities ranged from 20–70% and from 0–26% of normal, respectively.

The occurrence of symptoms consistent with an "intermediate syndrome" began 1 to 3 days after recovery from an acute cholinergic crisis precipitated by ingestion of parathion and methyl parathion (442–444). Symptoms compatible with a diagnosis of an "intermediate syndrome" were respiratory paresis, external ophthalmoparesis, ptosis, proximal limb and neck flexor muscle weakness, and absent or depressed tendon reflexes. Plasma and RBC cholinesterase activities were <5% and <15% of control values, respectively, for as long as this syndrome persisted, and the authors noted that this degree of severe cholinesterase inhibition was not observed in individuals who recovered from a cholinergic crisis without subsequently experiencing this type of syndrome.

Dermal exposure to an estimated 0.06 or 0.11 mg/kg methyl parathion on arms and hands did not result in cholinergic effects in two entomologists who entered a cotton field two hours after it was sprayed with methyl parathion, although RBC cholinesterase activities were markedly depressed in both individuals (432).

Methyl parathion air concentrations ranged from 1–30 mg/m^3 and concentrations from surface wipe samples ranged from 50–980 mg/100 cm^2 in 64 residences that had been sprayed with methyl parathion within the previous 31 days. Although absorption of methyl parathion was evident by the presence of *p*-nitrophenol in the urine of 142 individuals who lived in the affected residences, no adverse clinical effects were reported.

No cholinergic toxicity of RBC or plasma cholinesterase inhibition occurred after two male volunteers ingested 2 mg/day (0.03 mg/kg) methyl parathion for 5 days or 4 mg/day (0.06 mg/kg) for 5 days 1 to 8 weeks later. Nor were clinical signs of cholinergic toxicity apparent among other volunteers who participated in a metabolic study of methyl parathion and were given a single dose of approximately 0.06 mg/kg methyl parathion (410).

Neurological signs did not occur among men who ingested daily doses of methyl parathion that ranged from 1 to 19 mg during a 30-day period. Nor were there any uniform changes in plasma or RBC cholinesterase levels reported at any of these doses (260). By increasing the concentrations of methyl parathion administered to the same experimental population and using the same protocol, a dose that inhibited RBC cholinesterase activity by 55% in one of five subjects was 24 mg/day (76). Assuming that this individual weighed 70 kg, this would be equivalent to about 0.3 mg/kg/day. This dose and higher levels of 28 and 30 mg/day (equivalent to about 0.4 mg/kg/day) did not result in any overt clinical signs of cholinergic toxicity (76, 78).

In a study where methyl parathion (and several organophosphate pesticides) were tested for the frequency of irritant or allergic contact dermatitis in 652 subjects, one subject (described as a farmer who had occupational hand dermatitis) exhibited allergic contract dermatitis (445).

19.4.2.2.3 Pharmacokinetics, Metabolism, and Mechanisms Rapid absorption, metabolism, and elimination of methyl parathion occurred in human volunteers given single oral doses of methyl parathion for 5 consecutive days (410). Metabolites detected in urine 24 hours after dosing included *p*-nitrophenol and dimethyl phosphate. Excretion of the primary metabolite, *p*-nitrophenol, was 60% complete in 4 hours, 86% complete in 8 hours, and 100% complete by 24 hours. Urinary excretion of dimethylphosphate followed a similar pattern and was essentially complete by 24 hours after ingestion.

Absorption of methyl parathion following combination dermal and inhalation exposures was demonstrated in a series of field studies of cotton field workers who reentered a field sprayed with methyl parathion. Urinary *p*-nitrophenol and serum methyl parathion were detected up to 12 hours after exposure, confirming that absorption of methyl parathion had occurred (409, 430, 431). Based on methyl parathion residues measured on skin, dermal exposure were probably much less than 0.1 mg/kg, and based on measured air concentrations, (<0.2 mg/m^3) inhalation exposures probably resulted in absorbed doses much less than 0.02 mg/kg (409, 430, 431). Dermal absorption of 0.06 to 0.11 mg/kg methyl parathion adsorbed on forearms and hands of entomologists (combined with likely inhalation exposure) who worked in a cotton field 2 hours after it was treated with an ultra low volume spray was demonstrated by a concurrent, marked (40% decrease) inhibition of RBC cholinesterase activity (432).

About 5% of an applied dose of a commercial preparation of methyl parathion (*sic*) penetrated human cadaver skin placed in an *in vitro* diffusion cell during a period of 24 hours, whereas only about 1% of an applied dose of methyl parathion in acetone penetrated during 24 hours (433).
19.5 Standards, Regulations or Guidelines of Exposure
Methyl parathion is undergoing reregistration by the EPA for use as a restricted pesticide (154). The ACGIH TLV for methyl paration is 0.2 mg/m^3 with a skin notation. There is no OSHA PEL-TWA for methyl parathion. The NIOSH REL-TWA is 0.2 mg/m^3 with a skin notation. Most other countries have Occupational Exposure Limits for methyl parathion of 0.2 mg/m^3 (Australia, Belgium, Denmark Finland, France, The Netherlands, Switzerland, and the United Kingdom) or 0.1 mg/m^3 (Hungary, Poland, and Russia).

Organophosphorus Compounds

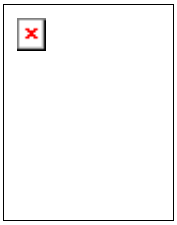
20.0.5 Molecular Formula:

$C_7H_{13}O_6P$

20.0.6 Molecular Structure:



20.1 Chemical and Physical Properties

Mevinphos is a pale yellow to orange liquid. The commercial product is a mixture of cis and trans isomers; the cis isomer is also referred to as the alpha or E isomer, and the trans isomer is also referred to as the beta or Z isomer. The cis isomer (which is ten times more toxic than the trans isomer) comprises about 60% of the commercial material (445a). Mevinphos is corrosive to black iron, drum steel, stainless steel, and brass. Mevinphos is hydrolyzed in water at pH 11 and has a half-life of 1.4 hours; as the pH is reduced, the rate of hydrolysis is also reduced, so the half-life in water at pH 6 is 120 days.

Specific gravity	1.25 at 20°C
Melting point	21°C (cis); 6.9°C (trans)
Boiling point	325°C at 760 torr
Vapor pressure	2.9×10^{-3} torr at 21°C (trans)
Flash point	79.44°C, open cup
Solubility	miscible with water, acetone, and benzene; slightly soluble in aliphatic hydrocarbons

20.1.2 Odor and Warning Properties Weak Odor.

20.2 Production and Use

Mevinphos was initially registered as a pesticide in the United States in 1957 and was classified as a Restricted Use Pesticide in 1978 (297). It was formulated as a ready-to-use liquid and concentrate and applied to foliage using aerial, boom spray, and airblast equipment to control aphids, mites, thrips, and lepidopterous larvae on a wide variety of crops. Largely as a result of a high incidence of human poisonings, mevinphos is no longer registered for use in the United States (297).

20.4 Toxic Effects

20.4.1.1 Acute Toxicity Mevinphos is an organophosphate that has extremely high oral toxicity and

has LD_{50}s of 3.4–6.8 mg/kg for rats and mice (64a). The dermal LD_{50} is 4.2–4.7 mg/kg for rats, and 33.8 mg/kg for rabbits (64a, 446). In a comparative study, the oral LD_{50} for female rats was 6.0 mg/kg compared to the intraperitoneal LD_{50} of 1.5 mg/kg (446). Intraperitoneal, oral, intravenous, and subcutaneous LD_{50}s were 2.5, 12.3, 0.6, and 1.2 mg/kg, respectively, indicating that mevinphos is less toxic when administered via "hepatic" routes (intraperitoneal and oral) than via "peripheral" routes (intravenous and subcutaneous) (122). This suggests that the process of oral absorption and/or first-pass metabolism by the liver slightly decreases the acute toxicity of mevinphos. One-hour LC_{50} values are 9.8–92 mg/m^3 (155, 448).

Poisoning following oral or intraperitoneal exposure is rapid. Moderate cholinergic signs occur within 5 to 10 minutes. Peak toxicity occurs within 15 to 30 minutes, lasts about 10 minutes, and most deaths occur in 45 minutes. Symptoms develop faster following intraperitoneal exposure. Signs of distress occur in 1 minute, and death usually occurred in 10 minutes or less (446).

Mevinphos does not cause delayed neuropathy in the hen (448).

20.4.1.2 Chronic and Subchronic Toxicity To assess the potential for cumulative toxicity, rats were given intraperitoneal injections of 10, 25, or 50% of the intraperitoneal LD_{50} (1.5 mg/kg) for 5 days/week for 17 to 22 days (446). Cumulative effects were not evident because the only sign observed was slight trembling of the head in rats that received 50% of the LD_{50} immediately after injection. No deaths occurred in any group.

When rats were fed diets that contained 0, 6.3, 12.5, 50, or 100 ppm mevinphos (about 0, 0.5, 1.0, 4.0, or 8.0 mg/kg/day) for 60 days all rats fed 100 ppm died within 3 weeks (446). Rats in all dosed groups showed slight tremors. In another study, rats were fed diets that contained 0, 0.3, 2, 5, 25, 50, 100, or 200 ppm (about 0, 0.02, 0.16, 0.4, 2.0, 4.0, 8.0, or 16 mg/kg/day) for 13 to 18 weeks or a diet that contained 150 ppm for 5 weeks followed by a diet that contained 300 ppm for 2 weeks and a diet that contained 400 ppm for 6 weeks (447). Cholinergic signs were "minimal" (*sic*) at 25 ppm and increased progressively with increasing dietary level; signs were not reported in rats given the 5-ppm diet. Additionally, nonspecific, diffuse, toxic degeneration of the liver and renal tubular epithelium and degeneration of the epithelial cells that line ducts and acini of the exocrine glands occurred. RBC cholinesterase activity progressively decreased during the experimental period in rats fed diets that contained 2 ppm mevinphos or more. Brain cholinesterase was inhibited in rats fed diets of 25 ppm mevinphos or more.

When dogs were fed diets that contained 0, 0.3, 1.0, 2.5, 5.0, 75, or 200 ppm mevinphos (about 0, 0.0075, 0.025, 0.0625, 0.125, 1.875, or 5 mg/kg/day) for 14 weeks, cholinergic signs occurred in dogs given the 75- and 200-ppm diets (447). Dogs fed the 2.5- or 5-ppm diet had inhibited RBC cholinesterase activity. The 1-ppm diet had no effect on RBC cholinesterase activity. Brain cholinesterase activity was inhibited in dogs given 7.5 or 200 ppm.

20.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms The similarity of LD_{50} values and the rapid occurrence of cholinergic signs regardless of route of exposure indicates that mevinphos is well absorbed via all relevant routes of exposure. Indeed, approximately 94% of an orally administered dose to rats was absorbed, and dermal absorption of mevinphos in the rats was reportedly approximately 16.8% of an applied dose (448).

In the first 24 hours, 18% of an orally administered dose of mevinphos was excreted in the urine, at 76% was excreted in expired air. Mevinphos was distributed to all human organs within 45 minutes of ingestion of a lethal dose.

Mevinphos is rapidly hydrolyzed *in vivo* in humans to dimethyl phosphate which subsequently

appears in the urine (449–451). In two cases of occupational mevinphos poisoning, peak urinary dimethylphosphate concentrations occurred within 12 hours of exposure, and elimination in urine was essentially complete within 50 hours of initial exposure (449). Initial urine concentrations of dimethyl phosphate in mevinphos-poisoned individuals wee 4.7 and 4.0 mg/L. Total excretion of dimethyl phosphate, it was estimated, was equivalent to 7.7 or 9.2 mg mevinphos. These findings are similar to that observed in two mevinphos poisonings where urine concentration of dimethyl phosphate at hospital admission was about 5 mg/L (411).

20.4.1.4 Reproductive and Developmental Mevinphos did not cause reproductive toxicity in rats fed a diet that contained mevinphos for two generations (448). Other studies indicated that no developmental toxicity occurred in rats or rabbits when they were administered mevinphos during gestation (448). No other details were provided.

20.4.1.5 Carcinogenesis No evidence of carcinogenicity was reported in chronic mice and rat studies (No other details were provided) (448).

A no-observed-effect level for inhibition of RBC cholinesterase in a chronic dog study was 0.025 mg/kg/day (448). A 1-year no-observed-effect level for inhibition of brain cholinesterase activities in rats was 0.025 mg/kg/day (lowest observed effect level = 0.35 mg/kg/day); and, a 2-year no-observed-effect level for clinical signs in rats was also 0.025 mg/kg/day (448). No other details were provided.

20.4.1.6 Genetic and Related Cellular Effects Studies Mevinphos was mutagenic with or without metabolic activation in *S. typhimurium* and in an assay with Chinese hamster ovary cell (448). Mevinphos with or without metabolic activation also caused chromosomal aberrations in Chinese hamster cells *in vitro* but did not increase unscheduled DNA synthesis (448).

20.4.2 Human Experience 20.4.4.2 Clinical Cases Initial symptoms of organophosphate poisoning (nausea, vomiting) occurred between 1 to 2 hours in a worker exposed while spraying greenhouse carnations and a worker exposed while cleaning out a spray bottle. Initial symptoms in both cases were followed by blurred vision, fasciculations, weakness, and miosis. Hospitalization occurred about 10 or 3 hours after exposure, respectively, at which time RBC and plasma cholinesterase activities were about 10% of normal laboratory values (449). The estimated intake of mevinphos based on quantification of dimethyl phosphate in urine was 7.7 and 9.2 mg which would be about 0.1 mg/kg, assuming a 70-kg body weight.

Widespread poisoning, apparently due mostly to dermal contact, occurred among nineteen farm workers who worked in a cauliflower field that had been sprayed 4 hours earlier with a mixture of mevinphos and phosphamidon (451a). Within minutes of beginning work, workers developed blurred vision and headache, followed by nausea, weakness, vomiting, abdominal pain, and dizziness; two workers collapsed, one into unconsciousness. Sequential determinations made during a 4-week period of recovery indicated the plasma and RBC cholinesterase activities had initially been inhibited by an average of 66% and 32%, respectively. Plasma and RBC cholinesterase activities in poisoned individuals returned to normal levels by about 57 and 66 days after poisoning, respectively (118). In another case of occupational poisoning, twenty-nine workers who were packing and cutting lettuce in a field 2 hours after it had been sprayed with mevinphos experienced eye irritation, headache, visual disturbances, dizziness nausea, vomiting, weakness, chest pain or shortness of breath, skin irritation, pruritis, eyelid fasciculation, arm fasciculation, excessive sweating, and diarrhea (118). Sequential determinations made during a 2-week period of recovery indicated that plasma and RBC cholinesterase activities had initially been inhibited by an average of 16% and 6% respectively.

Another case of widespread occupational mevinphos poisoning was that of twenty-six men who worked in nineteen different apple orchards where mevinphos was used to control apple aphids (454). Twenty-three of the workers who were exposed during mixing/loading or application of

mevinphos experienced nausea, vomiting, dizziness, visual disturbances, muscle weakness, abdominal pain, headache, sweating, and salivation. Seven workers were hospitalized; four required intensive care. RBC cholinesterase activity was depressed to at least 25% below the lower limit of normal in affected workers.

Among cases of accidental poisoning by dermal contact, six children were poisoned after wearing mevinphos-contaminated trousers that had been sold as "damaged goods" (452); a 17-year-old boy experienced delayed mevinphos poisoning, which appeared 2 days after initial contact, as a result of continued wearing of contaminated clothing (453); and an orchardist experienced typical signs of anticholinesterase poisoning 10 hours after mevinphos was applied as a patch test at a dose estimated at 14 mg/kg (312). In other cases, a farmer was poisoned after his boots were accidentally filled with mevinphos solution, and four formulators experienced symptoms of cholinesterase inhibition up to 48 hours after their last contact with mevinphos (450, 451).

Severe poisoning characterized by unconsciousness, pinpoint pupils, profuse sweating, and salivation and accompanied by acute pancreatis was reported for a 37-year-old woman who intentionally ingested 200 mL mevinphos (454a).

The predominant role of dermal absorption of mevinphos in occupational settings was illustrated in a study of greenhouse workers in Finland (454b). Inhalation exposure was measured during 2 days after application of mevinphos to greenhouse plants by measuring mevinphos in green house air. Workers' dermal exposure was measured with patch and hand-wash samples. Greenhouse air concentrations in breathing zones ranged from about 0.04 mg/m^3 (detection limit) to 11.4 mg/m^3 after spraying or use of automatic foggers that resulted in maximum inhalation doses up to about 0.002 mg/kg/day. Intake from dermal exposure would have been considerably more: up to 298 mg/hr mevinphos was determined by measuring mevinphos in hand-washing water from one worker and up to 20 mg/hr mevinphos was determined using patch samples. An additional study of these workers showed that decreases in plasma and RBC cholinesterase activity correlated well with estimated dermal exposure to mevinphos reflected in hand-wash water concentration (455).

Five male volunteers were given various doses of mevinphos daily for 30 days (456). A dose of 1.0 mg/day (about 0.01 mg/kg/day) had no effect during the test period, but RBC acetylcholinesterase activity decreased by as much as 17% in two subjects during the 30-day posttest period. Doses of 1.5, 2.0, or 2.5 mg/day inhibited RBC cholinesterase in all subjects. None of these doses affected plasma cholinesterase activity. No cholinergic signs were directly related to treatment, although loose stools were occasionally reported.

Mean reductions in RBC cholinesterase and plasma cholinesterase activities of 19% and 13%, respectively, occurred in eight volunteers who ingested 0.025 mg/kg/day mevinphos for 28 days (456a, 472). No signs or symptoms of organophosphate intoxication were detectable, and no changes in standard clinical chemistry parameters, other than the reductions in cholinesterase activities, were observed at this dose.

20.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV for mevinphos is 0.09 mg/m^3 with a skin notation (154). The OSHA PEL-TWA is 0.1 mg/m^3 and the NIOSH REL-TWA is 0.1 mg/m^3.

Organophosphorus Compounds
Jan E. Storm, Ph.D

21.0 Monocrotophos

21.0.1 CAS Number:

[*6923-22-4*]
21.0.2 Synonyms:
(*E*)-dimethyl 2-methylcarbamoyl-1-methylvinyl phosphate; (*E*)-*O*,*O*-dimethyl-*O*-(1-methyl-3-oxo-1-propenyl) phosphate, phosphoric acid, dimethyl (*E*)-1-methyl-3-(methylamino)-3-oxo-1-propenyl ester; Biloborn; Nuvacron; Phosphoric acid (E)-dimethyl 1-methyl-3-(methylamino)-3-oxo-1-propenyl ester; dimethyl 1- methyl-3-(methylamino)-3-oxo-1-propenyl phosphate; phosphoric acid, dimethyl 1-methyl-3-(methylamino)-3-oxo-1-propenyl ester, (*E*); Corophos; Monocil; Parryfos; dimethoxyphosphinyloxy-*N*-methyl-*cis*-crotonamide; dimethyl phosphate ester of 3-hydroxy-*N*-methyl-*cis*-crotonamide; hydroxy-*N*-methyl-*cis*-crotonamide dimethyl phosphate; phosphoric acid, dimethyl ester, ester with 3-hydroxy-*N*-methylcrotonamide
21.0.3 Trade Names:
Azodrin®; Monocron®; Nuvacron®
21.0.4 Molecular Weight:
223.16
21.0.5 Molecular Formula:
$C_7H_{14}NO_5P$
21.0.6 Molecular Structure:

21.1 Chemical and Physical Properties
Monocrotophos is a reddish brown solid.

Melting point	54–55°C; 25–30°C
Boiling point	125°C at 0.005 mmHg
Vapor pressure	7×10^{-5} mmHg at 20°C
Solubility	soluble in water, acetone, and alcohol; very slightly soluble in kerosene and diesel fuel

21.1.2 Odor and Warning Properties Possesses a mild ester odor.
21.2 Production and Use
Monocrotophos was introduced in 1965 and used as a systemic and contact organophosphorus insecticide and acaricide to control a variety of sucking, chewing, and boring insects and spider mites on cotton, sugarcane, peanuts, ornamentals, and tobacco (155). All registrations for monocrotophos have been cancelled in the United States but it is available in other countries as a soluble concentrate or an ultralow volume spray.
21.4 Toxic Effects
21.4.1.1 Acute Toxicity Monocrotophos is an organophosphate that has high oral toxicity and oral LD_{50s} of 17–20 mg/kg for rats (164a). Intraperitoneal, oral, intravenous, and subcutaneous LD_{50}s for monocrotophos were 8.9, 14.3, 9.2, and 8.7 mg/kg, respectively, for mice, indicating that it is equally potent whether exposure is via an "hepatic" (intraperitoneal and oral) or "peripheral" (intravenous and subcutaneous) route (122). Regardless of route of exposure, lethality occurs rapidly within 5 minutes. Dermal LD_{50}s are 112–129 mg/kg for rats and 270–354 mg/kg for rabbits (64a, 457). A 4-hour LC_{50} of 100 mg/m^3 and a 1-hour LC_{50} of 163–176 mg/m^3 have been reported (458).

Among mice given single oral doses of 1, 2, or 4 mg/kg monocrotophos, reduced locomotor activity occurred at 1 mg/kg and deficits in performance on a rotating rod occurred at 4 mg/kg (459). Among rats given single oral doses of 0, 2, 4, or 6 mg/kg monocrotophos, hypothermia occurred at all levels

(459). Cholinergic signs occurred in rats given 6–9 mg/kg/day for 1, 3, 7, 11, or 16 days, but only until 4 to 9 days; signs were absent after 10–11 days. Repeated exposure of rats to 4.5 or 6 mg/kg/day for 16 days also caused overt cholinergic toxicity that diminished by the seventh day of exposure and illustrated accomodation to lowered cholinesterase activity. All rats given three doses of 0.45, 0.85, 1.75, or 3.5 mg/kg/day monocrotophos on alternate days exhibited mild cholinergic signs (461).

Rabbits treated dermally with 20 or 40 mg/kg/day monocrotophos for 6 h/day, 5 days/week for 3 weeks exhibited no clinical signs of toxicity (458). Monocrotophos was not irritating to eyes or skin and was not sensitizing under conditions of current standard tests in rabbits and guinea pigs (458).

Two single doses of 6.7 mg/kg monocrotophos 3 weeks apart were fatal in nine of fourteen atropinized hens (458). The hens that survived two doses did not develop signs of delayed neurotoxicity during an observation period of 3 weeks after the second dose.

Decreased body weight and reduced brain, RBC, and plasma cholinesterase activities occurred in rats given diets that contained 8 ppm monocrotophos (about 0.6 mg/kg/day) for 8 to 13 weeks (458). Body weight gain decreased in rats given diets that contained 45 or 135 ppm and blood and brain cholinesterase were inhibited in rats given diets that contained 1.5 ppm for 12 weeks (458). Mild tremors occurred in dogs given diets that contained 135 ppm, for less than 9 weeks and blood and brain cholinesterase were inhibited in dogs given 15 ppm for 13 weeks (458). In rats treated with 0.3, 0.6, or 1.2 mg/kg/day monocrotophos by gavage for 90 days, brain and whole blood cholinesterase were inhibited at all levels (458).

21.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Monocrotophos is well absorbed orally and rapidly excreted. Sixty-three to 85% of an oral dose of monocrotophos was excreted in the urine of rats within 12–48 hours; the majority appeared within the first 6 hours (466). By 96 hours, 82%, 3%, and 6% of the dose was eliminated in urine, feces and expired air, respectively (466). An additional 5% of the dose appeared in feces within 48 hours. Most of the excreted dose in urine was present as water-soluble hydrolytic products (e.g., dimethyl phosphate), and the remainder was the parent compound or the *N*-hydroxymethyl amide analog of monocrotophos (160).

Human volunteers given a single intravenous injection of monocrotophos rapidly excreted 67 ± 5% of the dose in the urine within 4 to 8 hours. The elimination half-life was about 20 hours (66). When monocrotophos was applied dermally (4 mg/cm^2) to the forearm, 14± of the dose was found in the urine within 120 hours. When covered with a vaporproof film for 72 hours, 33% of the applied dose was absorbed.

The metabolism of monocrotophos involves three different reactions: N-demethylation, O-demethylation, and cleavage of the vinyl phosphate bond. Cleavage of the vinyl phosphate bond is the primary pathway resulting ultimately in excretion of resultant degradation products and conjugates in urine (466). Metabolism is not necessarily complete because significant amounts of unmetabolized monocrotophos are also excreted in urine and feces.

21.4.1.4 Reproductive and Developmental Rats given diets that contained 10 ppm monocrotophos for two generations had lower body weights, decreased male mating index, lengthened gestation periods, fewer litters, reduced viability and lactation indices, and decreased pup weights in both generations (458). Those given diets that contained 3 ppm had lower pup weights in the second generation, and those given 0 or 0.1 ppm exhibited no adverse reproductive or developmental effects.

When rats were given 0.3, 0.6 or 1.2 mg/kg/day monocrotophos by gavage for two weeks before mating and throughout gestation and lactation, average birth weight and crown–rump length decreased in the 1.2-mg/kg/day group, but this dose was also maternally toxic. No fetotoxicity

occurred among rats given 0.1, 0.3, 1, or 2 mg/kg/day by gavage on gestation days 6 through 15 in the absence of maternal toxicity which occurred at 1 mg/kg/day (458). No fetotoxicity occurred among rabbits given 0.1, 1, 3, or 6 mg/kg/day by gavage on gestation days 6 through 18 in the absence of maternal toxicity which occurred at 3 mg/kg/day (458).

21.4.1.5 Carcinogenesis No carcinogenicity or other adverse effects occurred in mice given diets that contained 1, 2, 5, or 100 ppm monocrotophos (about 0.15, 0.30, 0.75 or 1.5 mg/kg/day) for 2 years, other than inhibition of RBC and brain cholinesterase at all levels (458). No carcinogenicity or other adverse effects occurred in rats given diets that contained 0.01, 0.03, 0.1, 1, 10, or 100 ppm (equivalent to 0.001, 0.002, 0.005, 0.05, 0.5, or 5 mg/kg/day) other than reduced weight gain at 10 ppm and higher, and RBC and brain cholinesterase inhibition at 1 ppm and higher (458).

No carcinogenicity or other adverse effects occurred in dogs given diets that contained 0.16, 1.6, or 16 ppm monocrotophos (about 0.004, 0.04, or 0.4 mg/kg/day) for 2 years, other than inhibition of RBC cholinesterase at 16 ppm and brain cholinesterase activity at 100 ppm (458).

21.4.1.6 Genetic and Related Cellular Effects Studies Monocrotophos is consistently mutagenic in *in vitro* test systems (458). It was positive in the Ames assay (458a). A dose- and incubation-time-dependent increase in the frequency of chromosomal aberrations occurred in human lymphocytes incubated with monocrotophos. The incidence of sister chromatid exchanges also increased in a dose- and time-dependent manner.

In vivo studies also indicate that monocrotophos is mutagenic. Significant increases is chromatid breaks occurred in bone marrow cells of rats given monocrotophos (462). Chromosomal aberrations in bone marrow cells increased in rats treated orally with monocrotophos (463). Monocrotophos caused somatic mutations and also induced sex-linked recessive lethal mutations among *D. melanogaster* fed contaminated diets (464). In chicks, monocrotophos increased the occurrence of micronuclei in erythrocytes of bone marrow and peripheral blood when administered once daily for 30 days (465).

21.4.2 Human Experience 21.4.2.2 Clinical Cases Death followed ingestion of an estimated dose of 1200 mg monocrotophos by a woman (about 20 mg/kg assuming 60 kg body weight). The highest concentrations of monocrotophos were found in brain and lung, followed by blood, kidney, and liver (467). Accidental ingestion has also resulted in coma, but patients have recovered without sequelae after prolonged hospitalization (468). A 19-year-old man splashed about 570 mL monocrotophos on his bare chest and arms. He initially experienced no symptoms but within 28 hours he vomited and experienced muscular weakness, chest pain, and blurred vision. Later, he experienced blackouts and intervening lucid intervals. By 38 hours, he could not stand and experienced dry retching, sweating, and confusion. He was hospitalized, treated, and discharged from the hospital 10 days later (469).

Monocrotophos is one of a group of organophosphate compounds associated with the “intermediate syndrome” that is characterized by sudden respiratory distress, proximal limb muscle weakness, and motor cranial nerve palsies that occur 1 to 4 days after acute poisoning. In one case, an individual was poisoned when a bottle containing monocrotophos was thrown at his head and broke, creating a laceration and spilling liquid over his head and face (470). After 6 to 7 hours, he experienced nausea, vomiting, abdominal pain, miosis, fasciculations, and excessive sweating. He was successfully treated with atropine and pralidoxime, but on the fourth day he developed respiratory distress with cyanosis and bradycardia along with weakness of limbs. He was artificially ventilated and eventually recovered. In another case, a male who had ingested monocrotophos and been treated with atropine and pralidoxime developed respiratory distress after 70–80 hours and required ventilatory support (471). He had bilateral facial paresis and weakness of the neck muscles and proximal limb muscles. Fasciculations were seen in the limbs. Deep tendon reflexes were absent in the upper limbs but were normal in the lower limbs. He gradually improved and was discharged after 16 days. In another report, an “intermediate syndrome” was described in an individual who ingested monocrotophos in a suicide attempt and in a worker who was poisoned while spraying monocrotophos (358). In both

cases, a well-defined cholinergic phase was followed after 24–96 hours by respiratory difficulty and cranial nerve weakness which lasted 16 to 18 days.

Exposures to monocrotophos experienced by farmers during the spraying of cotton fields were roughly estimated at between 0.007 and 0.02 mg/kg/day based on concentrations of dimethyl phosphate excreted in urine during a 24-hour period after exposure. No overt symptomology was recorded, and RBC cholinesterase activity was unaffected (472a).

Volunteers who had worked for 5 hours in cotton fields treated with monocrotophos either 48 or 72 hours earlier showed no signs of organophosphate poisoning and no RBC cholinesterase inhibition (409).

When groups of volunteers were given oral monocrotophos at 0.0036 and 0.0057 mg/kg/day for 1 month, plasma cholinesterase was reduced, but RBC cholinesterase activity was not changed (472). Signs or symptoms of cholinergic toxicity that could be ascribed to monocrotophos were not reported in the volunteers.

21.5 Standards, Regulations, or Guidelines of Exposure

All registrations of monocrotophos in the United States have been cancelled, and tolerances are being revoked. The ACGIH TLV for monocrotophos is 0.25 mg/m^3 with a skin notation (154). There is no OSHA PEL-TWA for monocrotophos. The NIOSH REL-TWA is 0.25 mg/m^3.

Organophosphorus Compounds

Jan E. Storm, Ph.D

22.0 Naled

22.0.1 CAS Number:

[*300-76-5*]

22.0.2 Synonyms:

Dimethyl-1,2-dibromo-2,2-dichloroethyl phosphate; Ortho 4355; Bromochlorphos, dimethyl-1,2-dibromo-2,2-dichlorethyl; Dibrom; phosphoric acid 1,2'2-dibromo-2,2-dichloroethyl dimethyl ester; Alvora; Bromex; Dibromfos; 1,2-dibromo-2,2-dichloroethyl dimethyl phosphate; dimethyl *O*-(1,2-dibromo-2,2-dichloroethyl) phosphate; Hibrom

22.0.3 Trade Names:

Bromchlophos®; Bromix®; Dibrom®

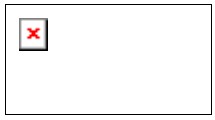
22.0.4 Molecular Weight:

380.79

22.0.5 Molecular Formula:

$C_4H_7Br_2Cl_2O_4P$

22.0.6 Molecular Structure:



22.1 Chemical and Physical Properties

Pure naled is a white solid; the technical form is 60% pure, and it is usually obtained as a liquid. Naled is completely hydrolyzed (90% to 100%) within 48 hours at room temperature in the presence of water. It is degraded by sunlight and should be stored in lightproof containers.

Specific	1.96 at 25°C (technical)

gravity	
Melting point	26°C (pure)
Boiling point	110°C at 0.5 torr (technical)
Vapor pressure	0.002 torr at 20°C; 2×10^{-4} mmHg at 20°C
Solubility	practically insoluble in water; slightly soluble in aliphatic solvents; very soluble in aromatic and oxygenated solvents

22.1.2 Odor and Warning Properties Has a slightly pungent odor.

22.2 Production and Use

Naled is a liquid insecticide and acaricide used to control mosquitoes and insects on many field crops, on plants in greenhouses, and in mushroom cultivation. It is formulated as a soluble concentrate/liquid (85% a.i.), an emulsifiable concentrate (36–58% a.i.), liquid ready to use (1–35% a.i.), ultra low volume (1–35% a.i.), dust (4% a.i.), and an impregnated collar (7–15% a.i.) Dichlorvos is frequently an impurity of technical naled.

22.4 Toxic Effects

22.4.1.1 Acute Toxicity Naled is an organophosphate that is moderately toxic and has oral LD_{50s} of 92 to 375 mg/kg for mice and rats (62, 64a, 203). Dermal LD_{50}s of naled are 800 mg/kg for rats and, 360–390 mg/kg for rabbits (64a). A 4-hour LC_{50} of 190–200 mg/m^3 was reported for rats (471a).

When rats were given a single oral dose of 25, 100, or 400 mg/kg naled, the 400-mg/kg dose produced mortality and transient decreases in body weight gain (471a). Rats of both sexes given 100 or 400 mg/kg and females given 25 mg/kg showed marked cholinergic effects. No treatment-related neurological effects were observed 7 or 14 days after treatment at any dose level.

When rats were exposed to 3.4, 7.2, or 12.1 mg/m^3 naled for 6 hours/day, 5 days/week for 3 weeks, a dose-dependent inhibition of brain, RBC, and plasma cholinesterase occurred at all concentrations (473).

Hens treated with atropine sulfate and pralidoxime and then given two acutely toxic doses of naled 21 days apart showed clinical signs of neurotoxicity but no locomotor ataxia characteristic of delayed neurotoxicity (471a). However, axonal degeneration in the spinal cord increased in naled-treated hens.

Naled caused severe eye and dermal irritation in rabbits and was weakly positive in a skin sensitization test in guinea pigs (471a).

22.4.1.2 Chronic and Subchronic Toxicity When rats were exposed to 0.2, 1, or 6 mg/m^3 naled for 6 hours/day, 5 days/week, exposure to 6 mg/m^3 resulted in cholinergic signs of toxicity (471a). Brain cholinesterase was inhibited at 6 mg/m^3, and RBC cholinesterase was inhibited at 1 and 6 mg/m^3.

When rats were fed diets delivering 0, 0.25, 1, 10, 100 mg/kg/day naled for 28 days, cholinergic effects occurred at 10 mg/kg/day, but not at lower doses (471a). When rats were exposed to naled by dermal application of 1, 20, or 80 mg/kg/day naled for 6 hours/day, 5 days/week for 28 days, the two highest doses were irritating to the skin (471a). Exposure to 20 and 80 mg/kg/day also produced systemic toxicity. Body weight gain by males was depressed, RBC and brain acetylcholinesterases were inhibited at 20 and 80 mg/kg/day, liver and adrenal weights of 80-mg/kg treated females increased, and mild renal effects were observed.

When 0.4, 2.0, or 10.0 mg/kg/day naled was given to rats by gavage for 90 days, cholinergic effects

occurred in three of ten high-dose females (471a). No other clinical effects occurred in either sex at any other dose level.

23.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms No data quantifying absorption after oral, inhalation, or dermal exposures to naled are available, but absorption via all routes of exposure is expected to be nearly equal based on the relatively low oral and dermal LD_{50}s and inhalation LC_{50}s reported.

O,*O*-Dimethyl-2,2-dichlorovinyl phosphate (dichlorvos) is a metabolite of naled as are other hydrolytic products such as methyl phosphates (mono- and di-), *O*-methyl 2,2-dichlorovinyl phosphate (desmethyl dichlorvos), and inorganic phosphate (471a). Three metabolites were identified were in an *in vitro* study using the rat liver homogenates, dichlorvos, dichloroacetaldehyde, and bromodichloroacetaldehyde (471a).

Metabolism of naled to dimethyl phosphate was demonstrated indirectly in individuals who were outdoors during aerial spraying with a naled and temephos mixture for mosquito control (1). Urinary dimethyl phosphate concentrations increased from a maximum of 0.06 ppm to a maximum of 0.50 ppm within 3 hours after spraying.

22.4.1.4 Reproductive and Developmental When rats were given 2, 6, or 18 mg/kg/day naled by gavage for two generations, body weight gain was depressed at 18 mg/kg/day for F_0 males and at all dose levels for F_1 males (471a). Reproductive indexes were unaffected in both generations. Survival of pups was reduced at 18 mg/kg/day in the F_1 and F_{2b} generations, and a consistent pup weight consistently decreased during lactation in both generations.

When naled was given to pregnant rats at doses of 2, 10, or 40 mg/kg/day by gavage on gestation days 6 through 19, 40 mg/kg/day was maternally toxic produced cholinergic signs, and reduced weight gain. No developmental toxicity occurred at any dose. There was a marginal effect on resorptions at 40 mg/kg/day, but, because this dose was also maternally toxic it was not considered significant (471a). When pregnant rats were treated orally with 25 to 100 mg/kg naled on gestation days 6 through 15, no adverse teratogenic effect was evident (471b). No maternal or developmental toxicity occurred in rabbits given 0.2, 2, or 8 mg/kg/day naled by gavage on gestation days 7 through 19, although mild cholinergic signs occurred in adults at 2 mg/kg/day.

22.4.1.5 Carcinogenesis When dogs were given 0.2, 2.0, or 20 mg/kg/day naled by gavage for one year, cholinergic signs, increases in mineralization of spinal cord, and mild testicular degeneration in males occurred at 2 and 20 mg/kg/day (471a). RBC and brain cholinesterase activities were depressed at these same dose levels. Anemia also occurred at 2 and 20 mg/kg/day, and RBC count, hemoglobin, and hematocrit were reduced. At 20 mg/kg/day, liver and kidney weights increased but were unaccompanied by histopathological changes.

There was no evidence of carcinogenicity among rats given 0.2, 2, or 10 mg/kg/day naled by gavage for 2 years, although there was a reduction in brain and RBC cholinesterase activity at 2 or 10 mg/kg/day (471a).

Cholinesterase activity of rats treated at 0.2 mg/kg/day was unaffected. Cholinergic signs occurred on isolated occasions after dosing in four females given 10 mg/kg/day; no other adverse effects were observed at any dose.

There was no evidence of carcinogenicity when mice were administered 3, 15, or 75 mg/kg/day naled by gavage for 89 weeks (471a). The high dose was reduced to 50 mg/kg/day after 26 weeks due to cholinergic signs and high mortality. The only other treatment-related finding was a slight reduction in weight gain by males that showed a dose-related trend at the middle- and high-dose

levels. Cholinesterase activity was not determined.

22.4.1.6 Genetic and Related Cellular Effects Studies Naled was positive for gene mutation in the *S. typhimurium* reverse mutation assay but did not induce DNA damage in a *rec*-type repair test with *Proteus mirabilis* strains PG713 (*rec*-, *hcr*-) and PG273 (wild-type) (471a). The mutagenicity of naled is due to the direct alkylating ability of the parental molecule and to mutagenic metabolites (e.g., dichlorvos) generated by enzymatic splitting of the side chain. Glutathione-dependent enzymes in the S9 mix eliminate the mutagenic activity of naled completely (474).

Naled exhibited no potential to induce mutations in an *in vivo* gene mutation study (mouse spot test) that used mice given 3, 20, or 150 mg/kg/day naled by gavage on gestation days 8 to 12 (471a).

Naled produced no nuclear anomalies in a mouse bone marrow micronucleus assay in mice and had no clastogenic effect in an *in vivo* cytogenetic study in which rats were given naled by gavage (471a).

22.4.2 Human Experience Acute symptoms following accidental or intentional poisoning by naled include typical cholinergic signs that disappear after 2 days (475).

Dermal exposures to naled caused residual papular dermatitis on the arm, glazing on the skin of the cheek, mild irritation of the neck skin, and a maculopapular eruption of the abdomen that caused a contact sensitization type dermatitis (476). Dermatitis was also caused by picking flowers sprayed with naled. In another case, contact dermatitis was reported in an aerial applicator who had used naled (477).

22.5 Standards, Regulations, or Guidelines of Exposure

The 90% technical product of naled is currently registered with EPA and is undergoing reregistration. The ACGIH TLV for naled is 3 mg/m^3 with a skin notation (154). The OSHA PEL-TWA and NIOSH REL-TWA is 3 mg/m^3 with a skin notation.

Organophosphorus Compounds

23.0 Parathion

23.0.1 CAS Number:

[*56-38-2*]

23.0.2 Synonyms:

O,*O*-Diethyl *O*-*p*-nitrophenyl phosphorothioate; DNTP; Ethyl parathion; ethyl parathion; parthion; Foliclal; Fostox; Rhodiatox; diethyl *p*-nitrophenyl monothiophosphate; SNP; E 605; ac 3422; Etilon; phoskil; deoxynucleoside 5'-triphosphate; Parathion-E; Aqua 9-Parathion; phosphorothioic acid *O*,*O*-diethyl-*O*-(4-nitrophenyl) ester; diethyl *p*-nitrophenyl thiophosphate; *O*,*O*-diethyl-*O*-(*p*-nitrophenyl) thionophosphate; diethylparathion; *p*-nitrophenol *O*-ester with *O*,*O*-diethylphosphorothioate; AAT; AATP; acc 3422; American Cyanamid 3422; Aralo; B 404; bay e-605; bayer e-605; bladan f; compound 3422; corothion; corthione; danthion; ecatox; fosfive; fosova; fostern; genithion; kolphos; kypthion; lirothion; murfos; nitrostygmine; niuif-100; nourithion; oleofos 20; oleoparathion; Orthosphos; panthion; Paramar; paramar 50; parathene; Parawet; pestox plus; pethion; phosphemol; phosphenol; phosphostigmine; RB; stathion; strathion; sulfos; T-47; thiophos 3422; TOX 47; vapophos; diethyl *para*-nitrophenol thiophosphate; diethyl 4-nitrophenyl phosphorothionate; diethyl *p*-nitrophenyl thionophosphate; drexel parathion 8E; E 605 F; e 605 forte; ekatin wf & wf ulv; ekatox; ethlon; folidol e605; folidol e & e 605; folidol oil; fosfermo; fosfex; gearphos; lethalaire g-54; oleoparaphene; OMS 19; PAC; Pacol; Paradust; rhodiasol; rhodiatrox; selephos; sixty-three special e.c.; soprathion; super rodiatox; vitrex; penncap e; thiomex; tiofos; Viran; Durathion;

Thionspray No. 84; diethyl *O*-*p*-nitrophenyl phosphorothioate; Fosferno 50; Niran; *O*,*O*-diethyl-*O*-*p*-nitrophenylthiophosphate

23.0.3 Trade Names:

Paraphos®; Alkron®, Alleron®, Aphamite®, Etilon®, Folidol®, Bladan® (Registered); Fosferno®, Niram®, Parapos®, Rhodiatos®

23.0.4 Molecular Weight:

291.27

23.0.5 Molecular Formula:

$C_{10}H_{14}NO_5PS$

23.1 Chemical and Physical Properties

Parathion is a pale yellow liquid. Parathion is stable in acids but hydrolyzes readily in alkaline solutions. It slowly decomposes in air to paraoxon. At temperature above 120°C, parathion decomposes and may develop enough pressure to cause containers to explode. Thermal decomposition may release toxic gases such as diethyl sulfide, sulfur dioxide, carbon monoxide, carbon dioxide, phosphorus pentoxide, and nitrogen oxides.

Specific gravity	1.26 at 25°C
Melting point	6°C
Boiling point	375°C at 760 mmHg
Vapor pressure	3.78×10^{-5} torr at 20°C
Solubility	very slightly soluble in water (20 ppm); completely soluble in esters, alcohols, ketones, ethers, aromatic hydrocarbons, and animal and vegetable oils; insoluble in petroleum ether, kerosene, and spray oils

23.1.2 Odor and Warning Properties Faint odor of garlic at temperatures above 6°C.

23.2 Production and Use

Parathion is a broad-spectrum pesticide and acaracide with a wide range of applications on many crops against many insect species. In 1992 the U.S. Environmental Protection Agency (EPA) cancelled all uses of parathion on fruit, nut, and vegetable crops. The only uses continued are those on alfalfa, barley, corn, cotton, sorghum, soybeans, sunflowers, and wheat (477a).

23.4 Toxic Effects

23.4.1.1 Acute Toxicity Parathion is a highly toxic organophosphate compound that has oral LD_{50s} of 1–30 mg/kg for rats, mice, and guinea pigs (62, 64, 268). Dermal LD_{50s} for rats are 7–21 mg/kg (64, 268). Approximate lethal dermal doses to the rabbit ranged from 150 to 2800 mg/kg, depending on the formulation applied (252). A 4-hour LC_{50} of 32 mg/m^3 was reported for rats (123). Two-hour exposures to 3–4 mg/m^3 of a spray of commercial parathion were lethal to the female rat (252). Death occurs rapidly at lethal oral or inhalation exposures. In dermal exposures, death is often delayed, and in rabbits an “intermediate-type syndrome” occurred characterized by paralysis that affect the muscles of the neck and the extensor muscles of the forelegs (“foot drop”) (252).

Intraperitoneal LD_{50}s were 3–7 mg/kg for adult rats and mice, but 1 mg/kg for neonates (Benke and Murphy 1975); and subcutaneous maximum tolerated doses (MTD, the highest dose that causes no mortality) of 2 and 18 mg/kg were reported for neonate and adult mice, respectively (204), suggesting that immature animals are more sensitive to parathion than mature animals.

When rats were given 0, 2, 4, or 7 mg/kg parathion by gavage, tremors, ataxia, and 10% mortality occurred in the 7-mg/kg group, whereas only decreased tail-pinch responsivity occurred in the 2-

mg/kg group (324). When rats were given single oral doses of 0, 0.025, 0.5, 2.5, or 10.0 mg/kg/day, mortality, cholinergic toxicity, and decreased RBC and brain cholinesterase activity occurred in males given 10 mg/kg/day (477a). Males given 2.5 mg/kg had only decreased RBC cholinesterase activity. One female given 2.5 mg/kg died, and another in this group exhibited cholinergic effects and inhibition of RBC and brain cholinesterase. The time for peak effect was 4 hours and partial to full recovery occurred by 14 days.

Single-dose oral exposure to 6 mg/kg parathion caused deficits in passive avoidance learning in mice and depression in brain and RBC acetylcholinesterase activity after 0.5 h; subcutaneous exposures to 1, 2, or 4 mg/kg/day for 6 days had no effect on this type of behavior, despite a decrease in brain and RBC acetylcholinesterase activity (479). Response rates for schedule controlled behavior decreased in rats given 0.75 or 1.0 mg/kg paraoxon (the active metabolite of parathion) intraperitoneally for 3 days, but not in rats given 0.05 mg/kg. All levels of exposure, however, caused marked inhibition of brain cholinesterase (39). Similarly, among rats given 1.5, 2.5, and 4.5 mg/kg/day every other day, no sign of cholinergic toxicity occurred on days 1–5, 7–13, and 15–21, respectively, despite inhibition of brain cholinesterase (40). Rats given single oral doses of 2, 3.5, or 5 mg/kg parathion showed altered conditioned taste aversion behavior even though brain cholinesterase activities were inhibited only at 3.5 and 5 mg/kg (479a). Monkeys given a single oral dose of 2.0 mg/kg showed cholinergic toxicity, whereas monkeys given 1.5, 1.0, or 0.5 mg/kg did not (480). Performance of a visual discrimination task, however, was disrupted at 1.0 mg/kg and was associated with inhibition of blood acetylcholinesterase activity (480).

23.4.1.2 Chronic and Subchronic Toxicity A calculated 90-dose LD_{50} was 3.1–3.5 mg/kg/day for rats given feed that contained parathion for 90 days and then observed until death (196). Using the 90-dose LD_{50} and the single-dose LD_{50} of 3–4 mg/kg, a "chronicity factor" (single-dose LD_{50}/90-dose LD_{50}) of about 1 was calculated, indicating that parathion is not expected to exhibit a cumulative toxic effect.

A diet that contained 125 ppm parathion (15.4 mg/kg/day) given to rats for 15 weeks caused severe illness, growth suppression and death, as well as severe RBC and brain cholinesterase inhibition (481). Exposure to a diet that contained 25 ppm (2.4 mg/kg/day) had no toxic effect, but RBC and brain cholinesterase activities were depressed (81). Cholinergic toxicity did not occur among rats fed diets that contained 0.05, 0.5, or 5.0 ppm parathion (about 0.005, 0.05, or 0.5 mg/kg/day) for 84 days; however, RBC cholinesterase was inhibited in the 0.05- and 0.5-mg/kg/day groups. Brain cholinesterase activity was unaffected at any exposure level. In a subchronic neurotoxicity study, rats given feed that delivered 0.05, 1.25, 2.5, or 5.0 mg/kg/day showed a RBC cholinesterase inhibition at the lowest dose tested (477a).

When rats and mice were given diets containing 5, 10, 20, 40, 80, 160, 320, 640 (mice only), or 1280 (mice only) ppm parathion for 6 weeks and then observed for two additional weeks, diets of 80 ppm or more were associated with decreased body weight and increased mortality in rats, and diets of 320 ppm or more were associated with decreased body weight and increased mortality in mice (479b). Diets that contained 5 to 40 ppm had no effect on rats, and diets that contained 5 to 160 ppm had no effect on mice.

When dogs were given 0.02, 0.08, or 8 mg/kg/day parathion via gelatin capsule, 7 days/wk for 6 months, no cholinergic signs or ocular toxicity occurred at any dose (483). However, RBC and retinal cholinesterase activities were intermittently depressed in dogs given 8 mg/kg/d.

23.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Absorption of parathion is rapid and complete following oral exposure. Based on the plasma concentration–time curve in rabbits given 3 mg/kg parathion orally, a and b elimination rate constants are about 5 ± 2 and 0.7 ± 0.1 hr^{-1}, respectively, and the b elimination half-life is about 1 ± 0.3 h (494). Urinary excretion was rapid, accounted for 46% and 85% of the administered dose 3 and 6 hours after exposure, respectively, was

directly correlated with levels of parathion in plasma (494). Maximum cholinergic effects following oral exposure were slightly delayed compared to i.v. administration, and occurred 30–90 minutes after oral dosing. Similar results were observed in dogs given 10 mg/kg and in mice given 1 mg/kg parathion orally (106, 426).

Rapid absorption and elimination of parathion following oral exposure was confirmed in human volunteers given single oral doses of 1–2 mg parathion for 5 consecutive days (410). Metabolites detected in urine 24 hours after dosing included *p*-nitrophenol, diethylphosphate, and diethyl thiophosphate. Excretion of the primary metabolite, *p*-nitrophenol, was 60% complete in 4 hours, 86% complete in 8 hours, and was directly correlated with exposure. Urinary excretion of diethyl phosphate was more prolonged and reached maximum rates 4 to 8 hours after ingestion.

Absorption, distribution, and elimination are also rapid and complete following inhalation, as evidenced by results of studies where parathion was given intravenously. This is a route of exposure whose distribution and excretion characteristics are similar to those of inhalation because it allows parathion to bypass the extensive "first-pass" metabolic effect of the liver. In humans, 46% of an intravenous dose was excreted in urine by 120 hours, and an elimination half-life of 8 hours was determined (66). Intravenous administration of parathion to dogs demonstrated high serum protein binding, a very high liver extraction ratio (82–97%), rapidly decreasing serum levels, rapid excretion of 85–92% of the dose in urine by 14 hours, and a plasma half-life of 8.5 to 11.2 hours (427, 493). In atropinized rats, parathion was rapidly distributed to tissues (brain, fat, and liver) and eliminated from blood following intravenous administration; the elimination half-life was 3.4 hours (493). Absorption, distribution, and elimination were also rapid in rabbits given intravenous doses of parathion (494). The plasma concentration–time curve followed a three-compartment kinetic model, two very rapid distribution phases followed by a final slower disposition phase that had a b elimination half-life of 5 ± 3 h. Maximal cholinergic effects, including one death, occurred 10–20 minutes after injection. In 8-week-old pigs, parathion had distributed to plasma, kidney, liver, lung, brain, heart and muscle, and about 82% of the dose had been eliminated in urine by 3 hours after dosing, (495). Urinary excretion of metabolites was much lower in newborn (1–2 days old) and neonatal (1-week-old) pigs administered the same dose, and parathion tended to accumulate in newborn and neonatal tissues to a much greater extent than in the 8-week-old pigs, providing a possible partial basis for the apparent sensitivity of developing mammals to parathion (204, 417).

Dermal absorption of parathion is extensive and has been the major cause of occupational disease. In one study, humans absorbed about 20–30% of a dermally applied emulsion of parathion (approximately 2.5 mg) after 300 minutes (496), from 0.1 to 2.8% of parathion dermally applied using an absorbent pad in another (497), and 10% of an applied dose of 4 mg/cm^2 in acetone in another (66). In another study, 5 grams of 2% parathion dust was placed on the right hand and forearm of a volunteer for 2 hours, after which the hand and arm were thoroughly washed, and urinary *p*-nitrophenol (the major parathion metabolite) was monitored for 40 hours (498). Dermal absorption was indicated by increases in urinary *p*-nitrophenol that peaked after 5–6 hours and decreased to very low levels within 40 hours. Marked differences in dermal absorption depending on the anatomic site of exposure were observed among six men who were dosed with 4 mg/cm^2 ^{14}C parathion in thirteen different locations and requested not to wash the site of application for 24 hours (499). After 5 days, the following percentages of applied dose had been absorbed from each anatomic site tested: forearm: 9%; palm: 12%; ball of the foot: 14%; abdomen: 18%; back of the hand: 21%; jaw angle: 34%; postauricular area: 34%; forehead: 36%; axilla: 64%; and scrotum: 102%. Maximum rates of absorption occurred 1–2 days after exposure but were still significant 5 days after exposure.

Location-specific absorption rates were observed in pigs in an experiment that showed that absorption rates ranged from 30–50% occluded skin to 8–25% for nonoccluded skin, depending on the site of application (500). Times of maximum excretion were 8–13 h for occluded skin and 12–17 h for nonoccluded skin. Rats treated dermally with 1.7–2.0 mg/kg (44–48 mg/cm^2) parathion

reached steady state and absorbed 1.4% of the applied dose within 1 hour and 57–59% of the applied dose during a period of 168 hours (501). The skin absorption rate was 0.33 and 0.49 mg/h/cm^2, and the permeability constant was 7.5×10^{-3} and 1.0×10^{-2} cm/h for males and females, respectively. Absorbed parathion was rapidly distributed to heart, liver, and kidneys. Elimination half-times were 39.5 and 28.6 h for males and females, respectively. Mice absorbed nearly 100% of a 1-mg/kg dose of parathion from 1-cm^2 area on their shaved backs by 2 days after treatment (213). Eight hours after treatment nearly 50% of the absorbed dose was excreted in urine, and the rest was distributed primarily to intestine, liver, blood, stomach, kidney, lungs, fat, ear, spleen, and bladder.

Once absorbed, parathion is widely distributed regardless of the route of exposure. Distribution coefficients are highest in the liver (4.1–20.8) and adipose tissue (1.3–2.9) but also exceed one in the brain (1.0–1.4) and muscle (1.5–1.9), indicating retention of parathion by these tissues (101). Maximum concentrations in all tissues is reached 10–20 days after dosing. Extensive distribution of parathion to the liver was demonstrated in mice following intraperitoneal, subcutaneous, oral, or dermal exposure (106, 213, 436, 502) and in pigs following i.v. exposure (495). This is consistent with its rapid hepatic metabolism and high affinity for hepatic esterase (13, 220). Placental transfer has been demonstrated *in vitro* using term perfused human placentas (503).

Parathion is converted to paraoxon by cytochrome P450 enzymes (primarily CYP3A4, but possibly also CYP1A2 and CYP2B6 (48, 504). Binding to other cytochromes also occurs (e.g., CYP3A2, CYP2C11) and is accompanied by their inactivation (48, 504). Alternatively, parathion is dearylated to form diethyl phosphorothioic acid and *p*-nitrophenol in a reaction catalyzed by microsomal enzymes or hydrolyzed by paraoxonase (also termed A-esterase) to form *O*-ethyl-*O*-*p*-nitrophenyl thiophosphate (13). Paraoxon can also be dearylated to diethyl phosphoric acid or hydrolyzed to *O*-ethyl-*O*-*p*-nitrophenyl phosphate. *p*-Nitrophenol, the primary dearylation metabolic product formed from parathion, is eliminated in the urine and quantifying it provides an index of parathion exposure (154). These metabolic conversions occur primarily in liver, but also in the lung and brain (435, 436, 504, 505), and a significant "first-pass" metabolic effect in skin has been demonstrated (506).

Paraoxon binds to and irreversibly inhibits acetylcholinesterase. Binding to other hepatic and plasma esterases also occurs, however, and represents a significant detoxication mechanism because it prevents much of the hepatically generated paraoxon from entering the general circulation and target tissues (13, 14). Comparative differences in the rates of hepatic esterase binding, as well as rates of dearylation, have been implicated as contributors to the greater sensitivity of female rats to parathion toxicity compared to male rats (15, 19, 221), to the greater sensitivity of some tissues (e.g., brain) to parathion toxicity compared to other tissues (17), and, to the greater sensitivity of young animals to parathion toxicity compared to adults (18). Differences in the relative rates of parathion desulfuration, dearylation, hydrolysis, and esterase binding probably also contributes to interspecies differences in sensitivity to parathion toxicity; however, the primary factor that accounts for interspecies differences appears to be species-specific differences in the affinity of acetylcholinesterase for paraoxon (218, 437, 438, 507).

Interindividual differences in paraoxonase activity may contribute to interindividual differences in human sensitivity to parathion because this enzyme is polymorphic in the human population. Its expression is determined by two codominant alleles that represent high and low activity (218, 222, 508). Individuals whose paraoxonase activity is low might be expected to detoxify relatively less of an absorbed dose of parathion and therefore experience greater toxicity than individuals whose paraoxonase activity is high, although that has not been demonstrated. The low-activity phenotype is apparently more common than the high-activity phenotype. In a Southeast Asian population, 4–18% of individuals expressed the high-activity form (508). In another population, 6% were homozygous for high activity, 42% were homozygous for low activity, and 53% were heterozygous (222). Differences in baseline levels of plasma cholinesterase activity may also contribute to interindividual differences in sensitivity. Plasma cholinesterase activity in pregnant women was about 76% of the activity in nonpregnant women, and the plasma cholinesterase activity of renal patients was about

77% of normal (509).

23.4.1.4 Reproductive and Developmental No adverse reproductive outcomes occurred in rats given feed that contained 1, 10, or 20 ppm parathion (0.05, 0.5, or 1.0 mg/kg/day) for two generations (477a). The only developmental effect observed was reduced body weight and body weight gain in pups fed the 20-ppm diet. However, excess mortality occurred among pups of second-generation rats when given diets that contained 10 ppm parathion once per (486). To further explore these findings, six additional second-generation exposed females were mated with two second-generation exposed males, and six second-generation exposed females were mated with a single second-generation control male. Only four of the twelve females produced litters. Survival of pups was 27% in litters from females mated to the exposed males, and 38% in litters mated to the control male. Thus parathion interfered with both reproductive success and developmental viability.

When rats were given 0, 0.25, 1.0, or 1.5 mg/kg/day parathion on gestation days 6 through 19, mortality occurred and body weight gain decreased in 1.5-mg/kg doses dams (477a). No fetotoxic effects were observed at any dose. When rabbits were given 0, 1, 4, or 16 mg/kg/day parathion via gavage on gestation days 7 through 19, mortality occurred and body weight gain decreased in 16-mg/kg dosed dams (477a). A decrease in litter size also occurred at the 16-mg/kg dose. Conception and litter size were not affected in wild rabbits given two oral 8-mg/kg doses of parathion 30 days apart, although brain acetylcholinesterase activity was reduced, and dosed animals had lower perirenal and kidney fat weights (487).

Intraperitoneal injection of pregnant mice with 4, 8, 10, 11, or 12 mg/kg parathion on gestation days 12, 13, and 14 caused increased resorptions and a reduction in fetal weight at doses of 8 mg/kg and higher. The highest dose was associated with 90% fetal mortality. At 4 mg/kg, fetal body weight was reduced, although the incidence of resorptions was normal (488). Intraperitoneal injection of 10 mg/kg parathion on gestation days 8, 9, and 10 had no impact on fetal weight. Intraperitoneal injection of pregnant rats with 3 or 3.5 mg/kg parathion on gestation day 11 produced increases in resorptions, decreased fetuses/litter, and reductions in fetal and placental weight (123). However, this treatment was also associated with maternal toxicity. Subcutaneous injection of pregnant rats for 4 days during the first, second, or third trimester of gestation resulted in inhibition of brain acetylcholinesterase in dams, but not in pups. However, all pups of parathion-treated rats displayed delays in development of the righting reflex (489).

Altered electrocardiographic patterns (decreased heart rates) occurred in 24-day-old progeny of spontaneously hypertensive strain rats given oral doses of 0.01, 0.1, or 1.0 mg/kg/day parathion from day 2 of pregnancy through day 15 of lactation (490). Dose-related decreases in acetylcholinesterase activity and muscarinic agonist binding occurred in the cerebral cortexes of 21- and 28-day-old rat pups treated subcutaneously with either 1.3 or 1.9 mg/kg/day parathion on postnatal days 5–20 (490a). Slight alterations also occurred in the development of memory; however, no deficits in the development of most reflex behaviors occurred. Acetylcholinesterase activity and muscarinic agonist binding also decreased in the hippocampi of 12-day-old rat pups treated subcutaneously with 0.882 mg/kg/day parathion on postnatal days 5–20 (491). Additionally, cellular disruption and necrosis occurred in the hippocampi of 21-day-old treated pups. When neonatal rats were given subcutaneous injections of 0.5, 1.0, 1.5, or 2.0 mg/kg parathion on postnatal days 8–20, doses of 1.0 mg/kg/day or more caused decreases in body weight gain, mild tremor, brain acetylcholinesterase inhibition decreases in muscarinic receptor density, and mortality (492).

23.4.1.5 Carcinogenesis Cholinergic toxicity was not observed in dogs given feed that delivered parathion doses of 0, 0.01, 0.03, or 0.10 mg/kg/day for 12 months (477a). RBC cholinesterase activity was intermittently depressed at all doses; brain cholinesterase activity was decreased only in dogs given 0.03 mg/kg/day. When dogs were orally dosed by capsule with parathion at 0, 0.0024, 0.079, or 0.7937 mg/kg/day for 6 months, only dogs given 0.7937 mg/kg/day had decreased RBC and brain cholinesterase activity.

There was no evidence of carcinogenity in rats given feed that contained 10, 25, or 50 ppm parathion for 64–88 weeks or in rats given 50 (about 3 mg/kg/day) or 100 ppm (about 6 mg/kg/day) parathion for 104 weeks (370, 484). Rats fed the 100-ppm diet occasionally showed peripheral tremors and irritability during the first few weeks, but were normal later. At 50 ppm no adverse effects occurred. However, when rats were given food that contained 10, 20, 50, 75 or 100 ppm parathion once a day for 1 year, those given food containing 75 or 100 ppm experienced serious poisoning and lethality, so that exposures were discontinued (486). Excess mortality occurred at 50 ppm and higher by 1 year. No signs of poisoning occurred in either the 20-ppm or 10-ppm groups.

No evidence of carcinogenity occurred when mice were fed diets that contained 80 or 160 ppm parathion (equivalent to about 12 and 23 mg/kg/day) for 62–80 weeks and were observed for an additional 9–28 weeks (479b). Cholinergic toxicity occurred at both exposure levels. However, when rats were fed diets that averaged 23–32 and 45–63 ppm parathion (delivering doses of 1.3 or 2.6 mg/kg/day) for 13–67 weeks and observed for 9–28 additional weeks, there was an increased incidence of adrenal cortical adenomas and carcinomas in the high-dose group. Cholinergic toxicity occurred at both doses. Based on these results, the NCI concluded that the evidence for carcinogenicity was equivocal in rats (479b). Noting that the exposure duration of these experiments was less than lifetime, that adrenal cortical adenomas sometimes spontaneously arise in aged rats, and that most tumors were adenomas rather than carcinomas, the International Agency for Research on Cancer (IARC) concluded that these data provided inadequate evidence to evaluate the carcinogenicity of parathion in animals (485). No evidence of carcinogenicity occurred in another study when rats were maintained on diets that contained 0, 0.5, 5.0, and 50.0 ppm parathion for 100 (males) and 120 (females) weeks (477a).

23.4.1.6 Genetic and Related Cellular Effects Studies Parathion was negative in the *rec*-assay (differential killing assay utilizing H17 *rec*+ and M45 *rec*– strains of *Bacillus subtilis*) and the *E. coli Pol*-assay without metabolic activation (485). In a large number of tests, it did not induce gene mutations in *E. coli, S. typhimurium, Serratia marcescens, S. cerevisiae*, or *Schizosaccharomyces pombe* with or without metabolic activation (485).

p-Nitrophenol, a metabolite of parathion, was not mutagenic to *S. marcescens* or *S. typhimurium* G46 in a mouse host-mediated assay following i.p. administration of 75 mg/kg (485). *p*-Nitrophenol, but not parathion, induced mitotic gene conversion in *S. cerevisiae*. Paraoxon reportedly in two abstracts was weakly mutagenic to *S. typhimurium* TA98 and TA1538 without metabolic activation (485) and induced lethal mutations in mice treated with 0.3 mg/kg (485).

No excess of sex-linked recessive lethal mutations was induced in *D. melanogaster* by parathion. Negative results have also been reported for the induction of unscheduled DNA synthesis by parathion in WI38 human fibroblasts, with or without uninduced mouse liver microsomal fractions (485). No dominant lethal mutation was induced in mice fed parathion for 7 weeks at 62.5, 125, or 250 mg/kg of diet or following a single i.p. injection (485).

Radiolabeled metabolites of ^{14}C parathion bound to DNA *in vitro* in the presence of a rat liver microsomal metabolizing system (485).

23.4.2 Human Experience 23.4.2.2 Clinical Cases Parathion is a potent cholinergic poison in humans. Upon oral exposure, initial symptoms of poisoning usually occur within 1–2 h. Massive oral exposures can cause death within 5 minutes (33). Estimates of lethal parathion exposures in adults range from 120–900 mg (about 2–13 mg/kg assuming a 70-kg body weight), but are much lower in children and range from 0.1–1.3 mg/kg (1). The heightened sensitivity of children to parathion is illustrated by instances in which parathion-contaminated food was eaten by people of different ages, but death occurred mainly or exclusively among children (1, 510). Research has suggested that the sensitivity of young animals to parathion is due, at least in part, to their relatively lower levels of detoxifying enzyme activity compared to adults (18).

RBC cholinesterase activities among fifty-one mild-to-moderately poisoned individuals averaged 58–64% of normal levels, although some individuals showed essentially no cholinesterase inhibition (18). RBC cholinesterase activities among seven severe-to-fatal poisoning cases averaged 14–29% of normal levels, and all affected individuals exhibited marked depression. Clinical symptoms in all moderately and severely poisoned individuals were thoroughly documented and were characterized especially by gastrointestinal signs (abdominal pain, anorexia, diarrhea, nausea, and vomiting), fatigue, malaise, miosis or visual disturbances, headache, diarrhea, and respiratory difficulty. Giddiness, ataxia, drowsiness, paresthesia and loss of consciousness also occurred.

Occurrence of symptoms consistent with an "intermediate syndrome" began 2 days after recovery from an acute cholinergic crisis precipitated by ingestion of parathion. Symptoms included acute respiratory paresis, severe nystagmus, weakness in proximal limb muscles, and depressed tendon reflexes. Symptoms occurred in the absence of muscarinic signs, lasted for approximately 3 weeks, and were not influenced by atropine. Five instances of "intermediate syndrome" were also reported in individuals who ingested or inhaled a combination of methyl parathion and parathion (442, 443). In two reports, an intermediate syndrome was reportedly followed by axonal polyneuropathy in individuals who were severely poisoned by ingesting parathion (511).

Parathion levels in air during various operations in a parathion manufacturing plant ranged from 0.2–0.8 mg/m^3 during 6-month period. During this same period, repeated measurements were made of RBC cholinesterase activity in thirteen workers. Although there were no preexposure baseline levels of cholinesterase activity against which to compare these levels, activities markedly increased 5 months after parathion manufacture ceased, suggesting that parathion exposure had markedly depressed them in the first place (512).

Several studies simply reported depressions in cholinesterase activity associated with different work environments. Field workers or pilots involved in spraying parathion on agricultural fields have had cholinesterase activities that ranged from 60–70% of baseline and RBC activities from 30–50% of baseline (509, 513, 514).

In a poorly described report, oral intake of 0.07 mg/kg produced no clinical signs of toxicity; 0.1 mg/kg produced uneasiness, warmth, tightness of the abdomen, frequent urination, and a 12% depression in whole blood cholinesterase activity; and 0.4 mg/kg resulted in increased peristalsis, tightness of the chest, and 47% cholinesterase activity inhibition in whole blood (515).

Ten male volunteers given 0.003, 0.010, 0.025, and 0.050 mg/kg/day parathion in capsules sequentially for 3 days at each dose exhibited no signs or symptoms of toxicity at any dose. RBC cholinesterase levels were monitored before, during, and after exposure and showed no effect (516). In another study, five men given 3.0, 4.5, 6.0, or 7.5 mg/day (0.04, 0.06, 0.08, or 0.10 mg/kg/day) for up to 30 days exhibited no clinical signs. RBC cholinesterase activity decreased in three individuals to 63, 78, and 86% of their preexposure levels. RBC cholinesterase activity in all individuals recovered to preexposure levels by 37 days after exposure stopped (260). No inhibition occurred in lower doses. Women given 7.2 mg/day (0.1 mg/kg/day assuming a 60-kg body weight) orally for 5 days/week for 6 weeks exhibited no clinical signs, a 16% decrease in RBC cholinesterase activity, and a 33% decrease in whole blood cholinesterase activity (517), and men given 1 or 2 mg/kg orally for five days (0.01 or 0.03 mg/kg/day assuming a 70-kg body weight) exhibited no clinical signs and no change in RBC cholinesterase activity (410).

RBC and plasma cholinesterase activity was measured and correlated with urinary *p*-nitrophenol excretion for 112 hours following dermal exposure in an individual covered with 2% parathion dust and placed in a rubberized suit for 7–7½ hours (518). No signs or symptoms of toxicity were observed. Maximum depression of plasma and RBC cholinesterase activity occurred 12–24 hours from the start of exposure but did not exceed 56 or 16% depression, respectively (518). Based on

measurements of *p*-nitrophenol excretion, the authors estimated that 18.2 mg parathion had been absorbed over a period of 103 hours (514), which is equivalent to about 0.06 mg/kg/day, assuming a 70-kg body weight.

To assess parathion toxicity and cholinesterase inhibition following inhalation exposures, a single volunteer was exposed to vapors generated from technical parathion (*sic*) spread over a 36 in^2 area and heated to 105–115°F for 30 minutes/day for 4 days (515). No signs of toxicity were observed by day 4 of exposure, although RBC cholinesterase activity was 71% of preexposure baseline activity. Based on measurements of 24-hour urinary *p*-nitrophenol excretion, the authors estimated that 2.5 mg parathion had been absorbed each day during the 4-day period, an amount equivalent to about 0.04 mg/kg/day, assuming a 70-kg body weight. This is consistent with the occupational study noted before in which RBC cholinesterase activities rebounded 5 months after cessation of exposure to about 0.03 mg/kg/day (512).

23.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV for parathion is 0.1 mg/m^3. The OSHA PEL-TWA is 0.1 mg/m^3 with a skin notation. The NIOSH REL-TWA is 0.05 mg/m^3 with a skin notation. Most other nations have Occupational Exposure Limits of 0.1 mg/m^3 (Australia; Belgium, Denmark, Finland, France, Germany, Japan, The Netherlands, The Philippines, Switzerland, Thailand 0.11 mg/m^2, Turkey, and the United Kingdom) or 0.05 mg/m^3 (Hungary and Russia).

Organophosphorus Compounds
Jan E. Storm, Ph.D

24.0 Phorate

24.0.1 CAS Numbers:

[*298-02-2*]

24.0.2 Synonyms:

(*O*,*O*-Diethyl (*S*-ethylmercaptomethyl) dithiophosphate; *O*,*O*-diethyl (*S*-ethylthiomethyl) phosphorodithioate; phosphorodithioic acid *O*,*O*-diethyl *S*-[(ethylthio)methyl] ester; *O*,*O*-diethyl *S*-(ethylthio)methyl phosphorodithioate; *O*,*O*-diethyl *S*-ethylmercaptomethyl dithiophosphate; American Cyanamid 3911; EI 3911; CL 35,024; diethyl *S*-((ethylthio)methyl) phosphorodithioate

24.0.3 Trade Names:

Granatox®; Rampart®; Thimet®; Timet®

24.0.4 Molecular Weight:

260.40

24.0.5 Molecular Formula:

$C_7H_{17}O_2PS_3$

24.0.6 Molecular Structure:

24.1 Chemical and Physical Properties

Technical phorate is a colorless to light yellow clear liquid. Phorate is stable at room temperature; it is hydrolyzed in the presence of moisture and by alkalis.

Specific gravity	1.17 at 25°C
Melting point	–43.7°C

Boiling point	125° to 127°C at 2 mmHg
Vapor pressure	0.00084 mmHG at 20°C; 6.380×10^{-4} mmHg at 25°C
Saturated vapor pressure	11.8 mg/m^3 (1.1 ppm) at 20°C
Solubility	insoluble in water, miscible with carbon tetrachloride, dibutyl phthalate, 2-methoxyethanol, dioxane, xylene, and vegetable oils

24.1.2 Odor and Warning Properties Skunk-like odor.

24.2 Production and Use

Phorate is a systemic and contact insecticide and acaracide registered for use on corn, sugar beets, cotton, brassicas, and coffee. It is available as a 2 to 95% emulsifiable concentrate and in granular form at 6.5% to 20% active ingredient although it is currently only used in granular formulation (1). Phorate is not registered for greenhouse or indoor uses. Phorate can be applied by aircraft and ground equipment; only one application per season is allowed for most uses, although two applications are allowed for irrigated cotton, sorghum, peanuts, and sugar beets.

24.4 Toxic Effects

24.4.1.1 Acute Toxicity Phorate is an organophosphate that has extremely high oral, dermal and inhalation toxicity and oral LD_{50}s of 1–4 mg/kg, dermal LD_{50}s of 2–9 mg/kg, and a 1-hour LC_{50} of 11–60 mg/m^3 (64a, 518a).

There are no data on primary eye or dermal irritation or on the primary dermal sensitization properties of phorate. However, the high acute toxicity of phorate would make the conduct of these types of experiments problematic (518a).

No signs of delayed neurotoxicity occurred in hens treated with two LD_{50} doses (14.2 mg/kg) of phorate 21 days apart (518a).

24.4.1.2 Chronic and Subchronic Toxicity When rats were given diets that contained 0, 0.22, 0.66, 2, 6, 12, or 18 ppm phorate (about 0, 0.01, 0.03, 0.1, 0.3, 0.6, or 0.9 mg/kg/day) for 90 days, mortality and reduced body weight gain occurred at 12 and 18 ppm. RBC cholinesterase activity inhibition occurred at 2 ppm and higher (518a). When dogs were given capsules that delivered 0, 0.01, 0.05, 0.25, 1.25, or 2.5 mg/kg/day for 6 days/week for 13–15 weeks, dogs given 1.25 or 2.5 mg/kg/day showed typical signs of organophosphate poisoning and subsequently died (518a). RBC cholinesterase was inhibited in dogs given 0.25 mg/kg/day or more.

24.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Phorate is well absorbed both orally and dermally, as evidenced by the low oral and dermal LD_{50}s. About 77% of an oral dose was excreted in the urine of rats within 24 hours, and 12% was excreted in the feces (518a). Rats given oral phorate at 2 mg/kg or six daily oral doses at 1 mg/kg/day eliminated up to 35% of the dose in urine and up to 6% in feces in 6 days. Rats treated at the rate of 1 mg/kg/day for 6 days excreted only 12% in the urine and 6% in the feces within 7 days (319). The major hydrolytic products that appeared in urine were *O*,*O*-diethylphosphoric acid (17%), *O*,*O*-diethyl phosphorothioic acid (80%), and *O*,*O*-diethyl phosphorodithioic acid (3%).

Rats metabolize phorate to the corresponding sulfoxide and sulfine and produce the phosphorothiolic and phosphoric acids that appear in urine (518a).

Metabolites of phorate were quantified in daily urine specimens obtained from employees of a pesticide formulating plant (184). The predominant alkyl phosphates found in urine were diethyl phosphate, diethyl phosphorothiolate, and diethyl thiophosphate.

24.4.1.4 Reproductive and Developmental Pup survival and pup body weight decreased among rats given diets that contained 4 or 6 ppm phorate (equal to about 0.4 and 0.6–0.7 mg/kg/day) for three generations (518a). No adverse developmental or reproductive effects occurred when rats were fed diets that contained 1 or 2 ppm phorate (equal to about 0.1 or 0.2 mg/kg/day) for three generations. Slight reductions in lactation and viability indexes occurred in the second generation of mice fed diets that contained 3 ppm phorate (equal to about 0.45 mg/kg/day) for three generations (518a). No reproductive effects occurred in mice fed 0.6 or 1.5 ppm (equal to about 0.09 or 0.23 mg/kg/day).

Neither fetotoxicity nor adverse developmental effects independent of maternal toxicity occurred in progeny of rats given 0.1, 0.125, 0.2, 0.25, 0.3, 0.4, or 0.5 mg/kg/day phorate via gavage on gestation days 6 to 15 (518a). Decreased fetal weights and increased incidence of skeletal variation occurred at 0.4 mg/kg/day, and enlargement of the fetal heart occurred at 0.5 mg/kg/day, but both of these doses were also associated with maternal cholinergic signs and mortality. Similarly, a marginal increase in resorptions occurred in rats exposed to 1.94 mg/m^3 phorate for 1 hour/day on gestation days 7 through 14, but this exposure also caused maternal phorate poisoning (518a). Exposures to 0.15 or 0.40 mg/m^3 phorate for 1 hour/day on gestation days 7 through 14 had no maternal or fetal effect.

Neither fetotoxicity nor adverse developmental effects occurred in rabbits given 0.15, 0.5, 0.9, or 1.2 mg/kg/day phorate on gestation days 6 to 18 (518a).

24.4.1.5 Carcinogenesis When dogs were given phorate via capsules at doses of 0.005, 0.01, 0.05, or 0.25 mg/kg/day for 1 year, slight body tremors, marginal inhibition of body weight gain, and RBC and brain cholinesterase inhibition occurred in males given 0.25 mg/kg/day (518a).

No evidence of carcinogenicity occurred in rats given diets that contained 0, 1, 3, or 6 ppm phorate (equal to about 0, 0.05, 0.15, or 0.3 mg/kg/day) for 2 years (518a). RBC and brain cholinesterase inhibition occurred at exposures of 3 and 6 ppm. No evidence of carcinogenicity or other adverse effects occurred in mice given diets that contained 0, 1, 3, or 6 ppm phorate (equal to about 0, 0.15, 0.45, and 0.9 mg/kg/day) for 78 weeks, other than a slight decrease in body weight gain in females that were fed 6 ppm (518a).

24.4.1.6 Genetic and Related Cellular Effects Studies Phorate was negative for mutagenicity in *S. typhimurium*, in *E. coli*, and at the HGPRT locus in cultured Chinese hamster ovary (CHO) cells with or without metabolic activation (45). Phorate was negative in a mitotic recombination assay with *S. cerevisiae* D3 with and without metabolic activation (45). Preferential toxicity assays in DNA repair proficient and deficient strains of *E. coli* and *B. subtillis* were negative (518a).

Phorate was negative for chromosomal aberrations in a dominant lethal test in mice and did not cause chromosomal aberrations in mammalian (rat) bone marrow cells (518a).

An unscheduled DNA synthesis (UDS) assay in human fibroblasts did not show a mutagenic respone (518a).

24.4.2 Human Experience Poisoning as a result of handling phorate-treated cotton seed led to coma, pinpoint pupils, blood-tinged, frothy sputum, and occasional convulsions in a worker (Hayes, 1963). The next day, RBC cholinesterase activities were 49% of normal. Treatment continued until day 15, at which time RBC cholinesterase activity was 24% of normal. In another study, 60% of a group of 40 workers engaged in formulating 10% phorate granules experienced cholinergic symptoms (514). Exposure levels were not reported.

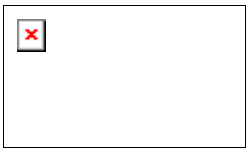
In a pesticide formulating plant where phorate concentrations ranged from 0.07 to 14.6 mg/m^3, two workers experienced cholinergic toxicity (520). After appropriate treatment, recovery was prompt and uncomplicated.

24.5 Standards, Regulations, or Guidelines of Exposure

Phorate is undergoing reregistration by the EPA. The ACGIH TLV for phorate is 0.05 mg/m^3 (154). The NIOSH REL-TWA is 0.05 mg/m^3 with a skin notation and a 15-minute STEL of 0.2 mg/m^3. Most other countries have Occupational Exposure Limits of 0.05 mg/m^3 (Australia, Belgium, Denmark, France, The Netherlands, Switzerland, and the United States).

Organophosphorus Compounds
Jan E. Storm, Ph.D

25.0 Ronnel
25.0.1 CAS Number:
[*299-84-3*]
25.0.2 Synonyms:
O,*O*-Dimethyl *O*-(2,4,5-trichlorophenyl)phosphorothioate: dimethyl trichlorophenyl thiophosphate; Trichlorometaphos; Blitex; Dermafos; dimethyl(2,4,5-trichlorophenyl)phosphorothionate; dimethyl *O*-(2,4,5-trichlorophenyl)thiophosphate; Gesektin K; Moorman's medicated RID-EZY; Nankor; phenol, 2,4,5-trichloro-, *O*-ester with *O*,*O*-dimethyl phosphorothioate; Remelt; *O*,*O*-dimethyl *O*-(2,4,5-trichlorophenyl) phosphorothioate; Rovan; Trichlorometafos; Fenclofos
25.0.3 Trade Names:
Fenchlorophos®; Ectoral®; Etrolene®; Korlan®; Nankor®; Trolene®; Viozene®
25.0.4 Molecular Weight:
321.57
25.0.5 Molecular Formula:
$C_8H_8Cl_3O_3PS$
25.0.6 Molecular Structure:



25.1 Chemical and Physical Properties
Ronnel is a white, noncombustible powder

Specific gravity	1.48 at 25°C
Melting point	41°C
Boiling point	decomposes; 97° at 0.013 mbar
Vapor pressure	0.0008 torr at 25°C
Solubility	practically insoluble in water; very soluble in acetone, carbon tetrachloride, ether, methylene chloride, toluene, and kerosene

25.2 Production and Use
Ronnel was introduced in 1954, and until 1991 when all registered uses of ronnel in the United States were cancelled by the EPA. It was used as an oral or contact insecticide to control insects that affect cattle. It has also been used as a systemic antiparasitic in humans (1).
25.4 Toxic Effects
25.4.1.1 Acute Toxicity Ronnel is an organophosphate that has low oral toxicity and oral LD_{50}s of 1250–2630 mg/kg for rats and mice, >500 mg/kg for dogs (larger doses caused emesis), 640 mg/kg

for rabbits, and 3140 mg/kg for male guinea pigs (41, 64a). In rats given single oral doses of 250, 500, or 1000 mg/kg ronnel by gavage, RBC acetylcholinesterase was unaffected 24 hours after dosing (41).

A specific dermal LD_{50} could not be determined but was larger than 5000 mg/kg for rats (64a). The rabbit dermal LD_{50} was 1600 to 2000 mg/kg (445a). When ronnel was dermally applied to rabbits under an impervious cuff for 24 hours, one of twelve died at a dose of 1000 mg/kg, six of twelve died at a dose of 2000 mg/kg, and eight of eight died at a dose of 4000 mg/kg (41).

No cholinergic effects occurred in rats given 25, 50, 100, or 200 mg/kg ronnel via intraperitoneal injection, although brain and RBC cholinesterase were inhibited at the 200-mg/kg dose (165). Plasma carboxyesterases were markedly inhibited even at the 25-mg/kg dose. Similar effects occurred in cows given 100 mg/kg via gelatin capsule (521).

When rats were given diets that contained 5, 10, or 30 ppm ronnel for 30 days or, 10, 30, 100, 300, or 500 ppm ronnel for 7 days, adverse cholinergic effects were not reported, and only the rats fed 300- or 500-ppm diets (equivalent to about 0.5, 1.0, 3.0, 10.0, 30.0, or 50.0 mg/kg/day) for 7 days exhibited significantly inhibited brain and RBC cholinesterase (165). Other esterases, however, were significantly inhibited in all rats except those fed 5-ppm diets. Overall, plasma and liver carboxyesterases were about ten times more sensitive to ronnel inhibition than brain or RBC cholinesterase. Moreover, 30-ppm diets had no effect on brain or RBC cholinesterase activity regardless of whether exposures were for 7 or 30 days, suggesting that ronnel lacks a cumulative effect. However, though the 30-ppm diet for 7 days did not inhibit brain cholinesterase, it increased the degree of cholinesterase inhibition produced by a challenge dose of malathion. The percentage inhibition of brain cholinesterase produced by 200 mg/kg malathion was three times as great as expected on the basis of additive effects in ronnel-fed rats.

A small (unspecified) amount of ronnel powder placed in the eye of a rabbit caused slight discomfort and a transient conjunctival irritation that disappeared in 48 hours (41). “A very slight hyperemia of the skin” was produced in rabbits whose skin was treated ten times during 14 days with ronnel under a gauze bandage (519).

25.4.1.2 Chronic and Subchronic Toxicity Albino rats that received 328 and 164 mg/kg ronnel developed cholinergic signs of poisoning within 2 weeks. Some of the rats died. No signs were observed in rats that received 16.4 and 8.2 mg/kg (522).

Among steers given diets that contained 0, 44, 88, or 176 ppm ronnel (equivalent to about 0, 1, 2, or 5 mg/kg/day), growth was promoted and thyroid function was altered (increased plasma T4) only in the 176-ppm group—no other effects were reported (523).

Repeated dermal exposure to ronnel apparently cured generalized demodicosis in eighteen of twenty dogs treated for 5–20 weeks, although it also caused lethal organophosphate poisoning in one of twenty (524).

25.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms In rats given three acute oral doses of about 18.6 or 186.5 mg/kg/day ronnel 24 hours apart, approximately 14 and 8% of the dose was eliminated in urine as the alkyl metabolites dimethyl phosphoric acid and dimethyl phosphorothioic acid, and 41 and 47% of the dose was eliminated as 2,4,5-trichlorophenol within 48 hours of the last dose. On the third day of dosing, ronnel was distributed to body fat (370 ppm) but by the eighth day the concentration dropped significantly (0.40 ppm) (280). Maximum concentrations in fat occur after 12 hours, and residues at 7 days are equivalent and persist longest in subcutaneous and mesenteric fat, followed by spleen, kidney, and liver.

25.4.1.4 Reproductive and Developmental Ronnel treatment did not alter the number of total

implants, live fetuses, dead fetuses, resorptions, or fetal weight in pregnant rats given 0, 400, 600, or 800 mg/kg ronnel via gavage on gestation days 6 through 15 (525). However, increases in the incidence of extra ribs were observed in fetuses from dams given 600 or 800 mg/kg.

When pregnant rabbits were given oral doses of 0, 12.5, 25, and 50 mg/kg ronnel on gestation days 6 through 18, an increase in malformed fetuses occurred in the 12.5- and 50.0-mg/kg group, an increase in fetuses that had malformations in the cardiovascular system occurred in the 50-mg/kg treated group, and fetuses that had cerebellar hypoplasia increased in the 25.5- and 50.0-mg/kg group (526).

25.4.1.5 Carcinogenesis A single female dog given 25 mg/kg ronnel for 11 months reportedly experienced no adverse effects, although RBC and brain cholinesterase activity were below normal (41). Dogs given 0.3, 1, 3, or 10 mg/kg ronnel via their diet for 1 year exhibited no adverse effects, although RBC cholinesterase activity was inhibited in dogs given 10 mg/kg.

No evidence of carcinogenicity, cholinergic toxicity, or adverse effects were seen in dogs given diets that contained 15, 45, or 150 ppm ronnel (equivalent to daily doses of 1, 3, or 10 mg/kg/day) for 2 years (587). Neither brain nor RBC cholinesterase activities were inhibited.

There was no evidence of carcinogenicity in rats fed diets that delivered doses of 0.5, 1.5, 5, 15, or 50 mg/kg/day ronnel for 2 years (41). Among rats given 50 mg/kg/day, there was some evidence of slight granular degeneration or cloudy swelling of the parenchymal cells of the liver and cloudy swelling and vacuolation of renal tubular epithelium of the kidney. RBC and brain acetylcholinesterase were inhibited at 15 or 50 mg/kg/day.

25.4.2 Human Experience There was no indication of sensitization among thirty men and twenty women given three patch applications of ronnel per week for 3 weeks and then challenged 2 weeks after the last application (41).

Five of twenty-one patients treated orally for creeping eruptions (larva migrans) with ronnel at 10 mg/kg/day for 5 or 10 days, reported nausea, weakness, blurred vision, and/or serpiginous ulcers (527). After ronnel was discontinued, the side effects spontaneously disappeared.

Nausea, headaches, and irritations of the throat and facial skin were occasionally reported by veterinarians who treated group infestations in cattle with pour-on applications of ronnel or other organic phosphorus pesticides (famphur, coumaphos, fenthion, trichlofon) in poorly ventilated areas. Neither plasma nor RBC cholinesterase activities were reduced in these cases, although correlations between specific exposures and cholinesterase measurements appeared imprecise. In support of this, alkyl phosphate metabolites were only occasionally found in the urine at the same times at which blood was drawn for cholinesterase determinations (528).

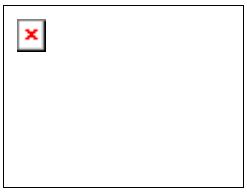
25.5 Standards, Regulations, or Guidelines of Exposure

Ronnel is no longer registered by the EPA for use (EPA, 1998). The ACGIH TLV for ronnel is 10 mg/m^3 (154). The OSHA PEL-TWA is 15 mg/m^3. The NIOSH REL-TWA is 10 mg/m^3. Most other countries have Occupational Exposure Limits for ronnel of 10 mg/m^3 (Australia, Belgium, Denmark: 5 mg/m^3 (Jan 93), Russia: STEL 0.3 mg/m^3 (Jan 93), France, The Netherlands, The Philippines, Switzerland, and the United Kingdom).

Organophosphorus Compounds
Jan E. Storm, Ph.D

26.0 Sulfotepp

26.0.1 CAS Number:
[*3689-24-5*]
26.0.2 Synonyms:
Tetraethyl dithionopyrophosphate; tetraethyl dithiopyrophosphate; tetraethyl dithiopyrophosphate; tetraethyl pyrophosphorodithionate; thiodiphosphoric acid tetraethyl ester; Bladafum; Dithione; thiopyrophosphoric acid, tetraethyl ester; ASP-47; bay-g-393; bayer-e 393; bis-*O*,*O*-diethylphosphorothionic anhydride; bladafun; dithiodiphosphoric acid, tetraethyl ester; dithiofos; dithiophos; di(thiophosphoric) acid, tetraethyl ester; dithiotep; E393; ethyl thiopyrophosphate; lethalaire g-57; pirofos; plant dithio aerosol; plantfume 103 smoke generator; pyrophosphorodithioic acid, tetraethyl ester; pyrophosphorodithioic acid, *O,O,O,O*-tetraethyl ester; sulfatep; Tedtp; *O,O,O,O*-tetraethyl dithiopyrophosphate; tetraethyl thiodiphosphate; Dithio Insecticidal Smoke; dithiopyrophosphoric acid, tetraethyl ester; thiopyrophosphoric acid ($[HO)_2P(S)]_2O$), tetraethyl ester
26.0.3 Trade Names:
Dithion®; Dithiophos®; Sulfotepp®; TEDP; Thiotepp®
26.0.4 Molecular Weight:
322.30
26.0.5 Molecular Formula:
$C_8H_{20}P_2S_2O_5$
26.0.6 Molecular Structure:



26.1 Chemical and Physical Properties
Sulfotepp is a pale yellow, noncombustible liquid.

Specific gravity	1.196 at 25°C
Boiling point	136–139°C
Vapor pressure	0.00017 torr at 20°C
Solubility	slightly soluble in water (25 mg/L); soluble in alcohol and most organic solvents

26.1.2 Odor and Warning Properties Possesses a garlic odor.
26.2 Production and Use
Sulfotepp is registered for use in greenhouses only as a fumigant formulation to control aphids, spider mites, whiteflies, and thrips (529a). It is formulated as impregnated material in smoke generators (canisters) containing 14 to 15% active ingredient. Smoke generators are placed in greenhouses and then ignited using inserted sparklers to generate a thick white smoke for fumigation.
26.4 Toxic Effects
26.4.1.1 Acute Toxicity Sulfotepp is extremely toxic following oral, dermal or inhalation exposures. Oral LD_{50}s are 5–13.8 mg/kg for rats (529, 530). Oral LD_{50} values are 21.5–29.4 mg/kg for mice; 25 mg/kg for rabbits, 3 mg/kg for cats, and 5 mg/kg for dogs (530). In rats, maximum acetylcholinesterase inhibition occurred 24 hours after an oral dose, was greater in RBCs than in plasma, and returned to normal after 7 days (530). Intraperitoneal LD_{50}s are about one-half oral LD_{50}s for mice and rats, suggesting delayed oral absorption and/or an overall detoxifying role for the liver. Rat dermal LD_{50}s of 65 and 262 mg/kg have been reported (530). A rabbit dermal LD_{50} of

20 mg/kg has also been reported. One-hour and 4-hour LC_{50}s for rats were 160–330 mg/m^3 and 38–59 mg/m^3, respectively. One-hour and 4-hour LC_{50}s for mice were 155 mg/m^3 and 40 mg/m^3, respectively. Typical symptoms of organophosphate poisoning were observed, and animals died in 24 hours (530). Following any route of exposure, symptoms occur within 1 hour and death occurs within 24 hours; surviving animals completely recover in 1–4 days.

Sulfotepp applied to the skin of rabbits at 0.4 gm for a period of 24 hours produced no noticeable effects on the skin (530). When sulfotepp was instilled into a rabbit eyes, the conjunctiva reacted slightly but returned to normal within 24 hours (530).

Nonatropinized and atropinized hens that received single oral doses of sulfotepp that ranged from 10 to 50 mg/kg body weight exhibited no signs of ataxia or paralysis of extremities during a 4-week observation period (530).

26.4.1.2 Chronic and Subchronic Toxicity When rats were exposed to 0, 0.89, 1.94, and 2.83 mg/m^3 sulfotepp aerosols for 6 hours/day, 5 days/week for 12 weeks, no changes in appearance, behavior, or body weight gain occurred at any dose. RBC acetylcholinesterase was not inhibited at any dose; however, plasma cholinesterase activity was inhibited in rats exposed to 2.83 mg/m^3. Absolute and relative lung weights of females exposed to 2.83 mg/m^3 were significantly higher than those of controls due to edema. No effects were observed at sulfotepp concentrations less than 2.83 mg/m^3 (530).

When rats were fed diets that contained sulfotepp at concentrations of 0, 5, 10, 20, and 50 ppm for 3 months, plasma cholinesterase activity was significantly reduced in female rats at 20 and 50 ppm and in male rats at 50 ppm. RBC acetylcholinesterase activity was significantly reduced in both sexes at 20 and 50 ppm (530). The highest dietary concentration tested for 12 weeks that was reportedly without symptoms in rats was 60 ppm; 180 ppm produced both illness and histological change (529).

When dogs were given diets that contained 0, 0.5, 3, 15, or 75 ppm sulfotepp (equivalent to about 0, 0.014, 0.11–0.12, 0.55–0.57, or 2.75–3.07 mg/kg/day) for 13 weeks, food consumption and body weight gain decreased at 75 ppm (529a). Plasma cholinesterase activity was inhibited at 3 ppm or higher, whereas RBC cholinesterase was inhibited at 15 ppm sulfotepp or higher. Occasional diarrhea and vomiting occurred in dogs at 15 ppm and were common in dogs at 75 ppm. RBC and plasma cholinesterase activity was inhibited at 75 ppm, and plasma cholinesterase was inhibited at 3 ppm and more. Brain cholinesterase was unaffected at any dose.

26.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms There are no available data on the absorption, distribution, elimination, or metabolism of sulfotepp. However, based on what is known about other organophosphates, it is likely to be well absorbed via all routes of exposures, rapidly oxidatively desulfurated to oxon derivatives, and/or hydrolyzed to dimethyl thiophosphoric acid or diethyl phosphoric acids.

26.4.1.4 Reproductive and Developmental No embryo toxic or teratogenic effects occurred in rats given 0.1, 0.3, or 1.0 mg/kg/day sulfotepp by gavage on gestation days 9 to 15 (593). No embryo toxic or teratogenic effects occurred in rabbits given 0.1, 1.0, or 3.0 mg/kg/day on gestation days 6 to 18 (533).

26.4.1.5 Carcinogenesis No signs of carcinogenicity or other adverse effects occurred at any dose level in mice or rats given diets that contained 0, 2, 10, or 50 ppm (equivalent to 0, 0.29, 1.43, or 7.14 mg/kg/day (mice); 0.13, 0.67 or 3.33 mg/kg/day (rats)) sulfotepp for 2 years (531). There were no signs of toxicity other than inhibition of plasma and RBC cholinesterase at 50 ppm.

26.4.1.6 Genetic and Related Cellular Effects Studies Sulfotepp was mutagenic in *S. typhimurium* strain TA1535 with metabolic activation (78). However, sulfotepp was not mutagenic to *S. typhimurium* strains TA100, TA98, TA1537, and TA1535 with or without metabolic activation (534, 535). A micronucleus test in rats was negative (536). A dominant lethal assay, in which sulfotepp was administered orally to mice, was also negative (537).

26.4.2 Human Experience Two men suffered from acute poisoning when spraying a mixture of sulfotepp and tetraethylpyrophosphate which had decomposed from diazinon. Symptoms were similar to those observed from organophosphorus insecticide poisonings (nausea, vomiting, burning eyes and blurred vision, difficulty breathing, headache, muscle twitching in arms and legs, and weakness). Blood cholinesterase activity showed a marked reduction but recovered 20 days after the poisoning incident in one individual and 28 days in the other individual (538).

In a review of available epidemiological information on sulfotepp EPA described an instance where a greenhouse worker experienced symptoms of organophosphate poisoning (headache, nausea, diarrhea, vomiting, cough, dizziness, sweating, fatigue, abdominal pain, anxiety, muscle aches, chest tightness, drowsiness, restlessness, shortness of breath, and excessive salivation) when applying the compound.

Skin lesions have been reported during the spraying of sulfotepp.
26.5 Standards, Regulations, or Guidelines of Exposure
Sulfotepp is undergoing reregistration by the EPA. The ACGIH TLV for sulfotepp is 0.2 mg/m^3 with a skin notation. The OSHA PEL-TWA for sulfotepp is 0.2 mg/m^3 with a skin notation; the NIOSH REL-TWA for sulfotepp is 0.2 mg/m^3 with a skin notation.

Organophosphorus Compounds

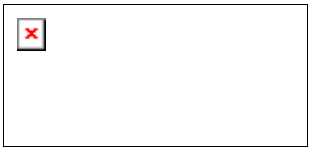
27.0 Sulprofos
27.0.1 CAS Numbers:
[*35400-43-2*]
27.0.2 Synonyms:
O-Ethyl *O*-(4-(methylthio)phenyl)-*S*-propyl phosphorodithioate; BAY NTN 9306; Phosphorodithioic acid *O*-ethyl *O*-[4-(methylthio)phenyl] *S*-propyl ester; merdafos; *O*-ethyl *O*-(4-(methylthio)phenyl) *S*-propyl phosphorodithioate; *O*-ethyl *O*-[4-(methylthio)phenyl]phosphorodithioic acid *S*-propyl ester; Bolstar 6; *O*-ethyl *O*-(4-methylthiophenyl) *S*-propyl dithiophosphate; Heliothion; ethyl *O*-(4-(methylthio)phenyl) *S*-propyl phosphorodithioate; Morpafos
27.0.3 Trade Names:
Bolstar®; Helothion®
27.0.4 Molecular Weight:
322.43
27.0.5 Molecular Formula:
$C_{12}H_{19}O_2PS_3$
27.0.6 Molecular Structure:



27.1 Chemical and Physical Properties
Sulprofos is a tan colored liquid that hydrolyzes in basic conditions and is stable in acid or neutral conditions.

Specific gravity	1.20 at 20°C
Melting point	<–50°C
Boiling point	125°C at 0.0075 torr (pure active ingredient) (155°C at 0.1 mmHg)
Vapor pressure	<7.88 torr at 20°C (6.3×10^{-7} mmHg at 20°C)
Solubility	soluble in organic solvents; slightly soluble in water (310 mg/L at 20°C)

27.1.2 Odor and Warning Properties Possesses a sulfide or phosphorus-like odor.
27.2 Production and Use
Sulprofos is a selective organophosphate used to control foliar lepidopterous, dipterous, and hemipterous insects Registration of sulprofos in the United States was voluntarily cancelled by the registrant in 1997.
27.4 Toxic Effects
27.4.1.1 Acute Toxicity Sulprofos is a moderately toxic organophosphate via oral, dermal or inhalation exposure. Oral LD_{50}s are 65–275 mg/kg and 107–304 mg/kg for female and male rats, respectively (539). Intraperitoneal LD_{50}s for male and female rats are 305 and 224 mg/kg, respectively, indicating that sulprofos is well absorbed orally (539). Oral LD_{50}s are 1831 and 1617 mg/kg in male and female mice, respectively (539). Dermal LD_{50}s are 5491 and 1064 mg/kg in male and female rats, and dermal LD_{50}s are 820 and 994 mg/kg in male and female rabbits, respectively (539). A 4-hour LC_{50} >4130 mg/m^3 and a 1-hour LC_{50} >3840 mg/m^3 were reported for rats; a 4-hour LC_{50} of >490 mg/m^3 was reported for mice and hamsters (539). Five 4-hour exposures of rats to 37, 94, or 259 mg/m^3 sulprofos caused cholinergic signs and inhibition of RBC and plasma cholinesterase activities.

In rats given single doses of 0, 29, 71, or 206 mg/kg sulprofos, cholinergic signs occurred in females at all dose levels and in males at the two higher doses (539). RBC cholinesterase activity was inhibited at all doses. No lesions were seen at necropsy or during histopathological examination of skeletal muscles, peripheral nerves, and tissues from the central nervous system. Following single oral exposures, the no-observed-effect-levels for plasma and brain cholinesterase inhibition were 7.5 and 30 mg/kg, respectively, in male rats (a no-observed-effect level for RBC cholinesterase inhibition was not identified). The lowest observed effect levels for plasma, RBC, and brain cholinesterase inhibition were 15, 30, and 90 mg/kg, respectively. In female rats, no-observed-effect levels for plasma, RBC, and brain cholinesterase inhibition were 4.5, 8.5, and 17 mg/kg, respectively. The lowest observed effect levels for plasma, RBC, and brain cholinesterase inhibition were 8.5, 17, and 50 mg/kg, respectively (539). In female dogs, no-observed-effect levels for plasma and RBC inhibition were 1 and 10 mg/kg, respectively. A lowest observed effect level for plasma inhibition was 5 mg/kg, but a lowest observed effect level for RBC cholinesterase inhibition was not identified. Inhibition was most severe within the first 24 hours after the acute oral dose, and brain cholinesterase was less affected than plasma and RBC cholinesterase (539).

A combination of sulprofos and malathion caused a fivefold potentiation of acute oral toxicity in rats, based on oral LD_{50}s (539). Similarly, a simultaneous dosing of sulprofos and azinphos-ethyl yielded a threefold potentiation of toxicity (539).

In rats exposed to 6, 14, or 74 mg/m^3 sulprofos aerosol for 6 hours/day, 5 days/week for 3 weeks, cholinergic signs (“general health impairment”, trembling) occurred only at 74 mg/m^3 (539).

Exposures of 6 or 14 mg/m^3 reportedly had no detrimental effects on behavior, physical appearance and growth rate, hematology, clinical chemistry, urinalysis, macroscopic pathology, or histopathology. Plasma, RBC, and brain cholinesterase activities were inhibited in males exposed to 74 mg/m^3 and in females exposed to 14 or 74 mg/m^3.

When rats were given 0.1, 1.0, and 10 mg/kg/day sulprofos by gavage for four weeks, the only parameters affected were dose- and time-dependent depressions of plasma, RBC, and brain cholinesterase enzymes (539). Plasma cholinesterase activity was inhibited in the 1.0-mg/kg/day group, and RBC and brain cholinesterase activity were inhibited in the 10-mg/kg/day group. No other treatment-related changes were seen in weight gain, blood chemistry urinalysis, gross pathology, or histopathology.

Sulprofos was not an eye or dermal irritant when tested in rabbits and did not cause dermal sensitization in guinea pigs (539).

Hens given antidote doses of pyridine-2-aldoxime methiodide and atropine sulfate followed by two doses of 65 mg/kg sulprofos (the LD_{50} for the hen) 3 weeks apart exhibited no ataxia or paralysis, nor any changes in the histopathological examinations of brain, spinal cord, or sciatic nerves. There was no evidence of delayed neurotoxicity (539).

27.4.1.2 Chronic and Subchronic Toxicity When groups of twenty male and female Sprague–Dawley rats were fed diets that contained 10, 30, 100, or 300 ppm (0.54–0.65, 3.0–3.5, and 15–17 mg/kg/day) for 90 days, reduced body weight gain occurred in females given the 300-ppm diet (539). Plasma cholinesterase activity was depressed at 30 ppm and above in both sexes. RBC cholinesterase activity was depressed at 100 ppm in males and 30 ppm in females. Brain cholinesterase activity was depressed in both sexes at 100 ppm and higher. No other effects were noted in blood parameters, urine parameters, or pathology examinations.

In rats fed diets that contained 0, 9, 47, or 226 ppm sulprofos (equivalent to 0, 0.54–0.65, 3.0–3.5, or 15–17 mg/kg/day) for 90 days, cholinergic signs occurred only in rats given the 226-ppm diet (539). Brain cholinesterase activity was inhibited at 226 ppm, RBC cholinesterase was inhibited at 47 and 226 ppm, and plasma cholinesterase was inhibited at 9 ppm (females only). No treatment-related effects were seen during gross pathology or histopathological examination of skeletal muscle, peripheral nerves, eyes, and tissues from the central nervous system.

In dogs given diets that contained 0, 10, 20, or 200 ppm (equivalent to 0, 0.26–0.32, 0.52–0.64, 5.2–6.4 mg/kg/day) for 90 days, diarrhea and regurgitation occurred at 200 ppm (539). Reduced body weights, and decreased plasma, RBC, and the brain cholinesterase activity also occurred at 200 ppm, as well as thickening of the small intestinal wall; decreased liver, kidney, brain and lung weights (males only); increased brain and liver weights, relative to body weight; increased relative lung weights (females only); and increased relative heart weights (males only). Plasma and RBC cholinesterase were also inhibited at 20 ppm. No treatment-related effects were seen in ophthalmic examinations.

No changes occurred in blood or urine parameters, behavior, clinical signs, food consumption, body weights, organ weights, mortality, or in necropsied tissues in mice given diets that contained 0, 2.5, 5, 100, 200, or 400 ppm (equivalent to 0, 0.38–43, 0.76–0.86, 15.2–17.2, 30.4–34.4, or 60.8–68.8 mg/kg/day) for 10 months (539). At 5 ppm and higher, plasma and RBC cholinesterase were inhibited and, at 200 ppm and higher.

27.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Sulprofos is rapidly and nearly completely absorbed following oral exposures. In rats, more than 98% of an oral dose of sulprofos was eliminated within 48–72 hours after dosing (539). Rats that received one 11-mg/kg dose or ten 10-mg/kg doses of sulprofos during 15 days also excreted >96% of the dose (or last dose) within 24

hours. The primary route of excretion was through the urine, and less than 11% was excreted in the feces. Conjugated and nonconjugated phenol accounted for 11% of the administered dose, conjugated phenol sulfide accounted for 33–36% of the administered dose, and conjugated phenol sulfone accounted for 41–45% of the administered dose (539). Tissues and organs retained □2% of the dose; the highest residues were in the fat, ovaries, skin, and liver. Less than 1% of the dose was expired as CO_2 or volatile organic compounds from any exposure. A previous study had demonstrated that female Sprague–Dawley rats dosed at 10 mg/kg excreted >92% within 24 hours (540).

Pigs rapidly excreted an oral dose of sulprofos. More than 95% of the dose was excreted in urine by 24 hours. The major urinary excretion metabolites were the conjugated phenol, free and conjugated phenol sulfoxide, and free and conjugated phenol sulfone. Maximum blood levels occurred 4 hours posttreatment, at which time tissue levels were <0.01 ppm, except for 0.27- and 0.53- ppm levels in liver and kidney, respectively. Traces of sulprofos and its sulfoxide were found in the omental fat (539). All tissue residues were <0.05 ppm of sulprofos equivalents at 48 hours posttreatment (539).

Sulprofos is involved in a series of oxidation reactions that may result in replacing the thiono sulfur with oxygen and/or the addition of first one and then two oxygen atoms to the thioether sulfur. The phosphorous-O-phenyl ester of sulprofos and any of these materials may be hydrolyzed to the free phenols, which are then conjugated and eliminated, usually in the urine. The oxidation of the thioether sulfur to its sulfoxide is catalyzed by microsomal flavin-contain monooxygenase (352, 541). The major sulprofos metabolites are phenol, phenol sulfoxide, phenol sulfone, and their conjugates. Sulprofos sulfoxide, sulprofos sulfone, O-analog and O-analog sulfone were also identified in pigs, goats and cows but not in the rat or hen (539, 540).

27.4.1.4 Reproductive and Developmental No adverse effects on reproduction or development occurred in three generations of rats given diets that contained 0, 30, 60, or 120 ppm sulprofos (539). Third-generation parents of both sexes given the 120-ppm diet had decreased plasma and RBC cholinesterase activity, and third-generation female parents had decreased brain cholinesterase activity. Mean body weights of all treated F1a offspring were lower at weaning, but this was not evident in subsequent litters or additional generations.

No treatment-related reproductive or teratogenic effects were seen in rats given 0, 3, 10, or 30 mg/kg/day sulprofos by gavage on gestation days 6 through 15 (539). At 30 mg/kg/day, signs of maternal toxicity included clinical signs, reduced food consumption, and lower body weights. Fetal body weights were also reduced at the 30-mg/kg/day level. No maternal toxicity, embryo toxicity, or teratogenic effects occurred in rats given 0, 1, 3, or 10 mg/kg/day sulprofos on gestation days 6 through 15 (539). No developmental effects occurred in rabbits given 0, 3, 10, or 30 mg/kg/day sulprofos on gestation days 6 through 18 (539). The 30-mg/kg/day dose was maternally toxic and caused mortality, decreased weight gain, diarrhea, drowsiness, occasional salivation, and "proneness" (*sic*).

27.4.1.5 Carcinogenesis No evidence of carcinogenicity or overt cholinergic toxicity occurred in rats given diets that contained 6, 60, or 250 ppm sulprofos (0.28–0.27, 2.46–2.74, or 10.25–11.43) for 2 years (539). Plasma, RBC, and brain cholinesterase were inhibited at 250 ppm; only plasma and RBC cholinesterase were inhibited at 60 ppm. There were no other differences in behavior, physical condition, mortality, other blood chemistry parameters, hematology, urine parameters, gross pathology, or histological findings for any treatment level other than decreased absolute and relative male kidney gonad weights at 250 ppm.

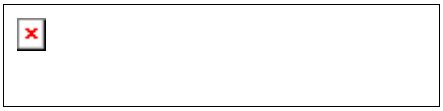
There was no evidence of carcinogenicity or overt cholinergic toxicity in dogs given diets that contained 10, 100, or 150 ppm sulprofos (0.23–0.24, 2.99–3.82, and 4.49–5.73 mg/kg/day) for 2 years (539). Plasma, RBC, and brain cholinesterase activities were inhibited at 100 ppm.

There was no evidence of carcinogenicity or other adverse effects in mice given diets that contained 2.5, 25, 200, and 400 ppm sulprofos (0.28–0.32, 2.8–3.2, 22.4–24.8, and 44.849.6 mg/kg/day) for 22 months (539). No changes were observed in food consumption, body weights, clinical signs, or mortality. Plasma and RBC cholinesterase activities decreased at dietary levels of 25 ppm, and brain cholinesterase activity decreased at 400 ppm (females only).

27.4.1.6 Genetic and Related Cellular Effects Studies Sulprofos is neither mutagenic nor genotoxic. Sulprofos was negative in the reversion assay using *S. typhimurium* with or without metabolic activation, in the CHO/HGPRT mutation assay, in the Pol DNA repair test using *E. coli*, and did not increase the incidence of sister chromatid exchange in Chinese hamster ovary cells (308, 539). Sulprofos was negative in the micronucleus test and in a dominant lethal test using mice (539).
27.5 Standards, Regulations, or Guidelines of Exposure
Registrations for sulprofos have been cancelled by the EPA, and all tolerances are being revoked (www.epa.gov/opsrd1/op/status.htm accessed 10/99). The ACGIH TLV for sulprofos is 1 mg/m^3 (154). There is no OSHA PEL-TWA. NIOSH REL-TWA is 1 mg/m^3. Most other countries have Occupational Exposure Limits of 1 mg/m^3 for sulprofos (Australia, Belgium, Denmark: 1 mg/m^3, France, The Netherlands, and Switzerland).

Organophosphorus Compounds
Jan E. Storm, Ph.D

28.0 Temephos
28.0.1 CAS Number:
[*3383-96-8*]
28.0.2 Synonyms:
O,*O*,*O*′,*O*′-Tetramethyl-*O*,*O*′thiodi-*p*-phenylene phosphorothioate; Temephosn; Abate; *O*,*O*′-(thiodi-4,1-phenylene)phosphorothioic acid *O*,*O*,*O*′,*O*′-tetramethyl ester; *O*,*O*′-(thiodi-4,1-phenylene)bis (*O*,*O*′-dimethylphosphorothioate); phosphorothioic acid, *O*,*O*′-(thiodi-4,1-phenylene) *O*,*O*,*O*′,*O*′-tetramethyl ester; Tempephos; *O*,*O*,*O*′,*O*′-tetramethyl *O*,*O*′-(thiodi-4,1-phenylene)phosphorothioate; temefos; Abaphos; Tetrafenphos; tetramethyl *O*,*O*′-thiodi-*p*-phenylene phosphorothioate
28.0.3 Trade Names:
Abate®; Abathion®; Biothion®; Difenthos®; Difos®; Nephis 1G®; Swebate®
28.0.4 Molecular Weight:
466.46
28.0.5 Molecular Formula:
$C_{16}H_{20}O_6P_2S_3$
28.0.6 Molecular Structure:



28.1 Chemical and Physical Properties
Pure temephos is a white crystalline solid; technical grade temephos (90–95% pure) is a brown, viscous liquid.

Melting point	30°C
Solubility	insoluble in hexane or water; soluble in toluene, ether, dichloroethane, carbon tetrachloride, and acetonitrile

Reactivity	undergoes hydrolysis at high or low pH
Specific gravity (technical)	1.3
Vapor pressure (technical)	7.17×10^{-8} mmHg at 25°C

28.2 Production and Use

Temephos is a nonsystemic larvicide used to control mosquitoes, chironomid midges, blackflies, biting midges, moths, and sandflies. It is used on crops to control cutworms, thrips, and lygus bugs and on humans as a 2% powder to control body lice. Temephos is formulated as emulsifiable concentrates (10, 43, or 50%), wettable powders (50%) or granules (1). It can be applied by fixed-wing aircraft, helicopter, handheld sprayers, power backpack blowers, and by spoon.

28.4 Toxic Effects

28.4.1.1 Acute Toxicity Temephos has low acute oral, dermal, and inhalation toxicity. Oral LD_{50}s are 1226–13,000 mg/kg for rats and mice although an LD_{50} value of 444 mg/kg was reported to EPA (42, 64a, 539a). Rats showed typical signs of organophosphate poisoning (*sic*) when given single oral doses of temephos as low as 500–750 mg/kg. Death of rats usually occurred after 6–7 days and after 3 days in mice. In rats given a single oral dose of 8600 mg/kg, brain acetylcholinesterase inhibition was maximum on day 3 and showed partial recovery by day 7 after dosing (542).

The dermal LD_{50} for rats was >4000 mg/kg (larger doses could not be practicably applied) (42). Systemic toxicity was apparent after a much lower dermal exposure of 1200 mg/kg (1). The dermal LD_{50} in rabbits is 970–1850 mg/kg (539a). A 4-hour LC_{50} of >1300 mg/m^3 for rats was reported to EPA (539a). Air concentrations of 40 and 12.9 mg/m^3 temephos were reported as single and repeated exposures that led to cholinesterase inhibition in rats (1).

Rabbits given 100 mg/kg/day temephos for 5 days experienced organophosphate poisoning (*sic*) as well as significant RBC acetylcholinesterase inhibition (Gaines et al., 1967). Rabbits given 10 mg/kg/day for 35 days experienced significant RBC acetylcholinesterase inhibition but no signs of organophosphate poisoning. Guinea pigs were apparently resistant to temephos and showed no signs of organophosphate poisoning when given 100 mg/kg for 5 days.

When rats were given single oral doses of temephos and malathion equivalent to one-eighth the LD_{50}, a fourfold potentiation of acute toxicity occurred (42). Further, when groups of rats were given drinking water that contained 5 or 30 ppm temephos for 7 days followed by single acute intraperitoneal doses of 400 mg/kg malathion, the degree of malathion-induced brain and tissue (submaxillary gland) cholinesterase inhibition was significantly enhanced (373).

Temephos is only very slightly irritating to the eye and skin and is not a skin sensitizer (539a).

Hens given single subcutaneous doses of 1000 mg/kg temephos developed immediate leg weakness that lasted for about 26 days and died; hens given 500 mg/kg also developed immediate leg weakness that lasted for about 15 days but survived (42). All hens given temephos in their diet at concentrations of 1000 or 2000 ppm died after 30–43 days. When hens were given a diet of 500 ppm (about 15.5 mg/kg/day) no deaths occurred and leg weakness developed, but only after 30 days; when given a diet of 250 ppm, no leg weakness occurred (42).

28.4.1.2 Chronic and Subchronic Toxicity Rats given 100 mg/kg temephos by gavage for 44 days showed “typical symptoms of organophosphate poisoning” (*sic*) after three doses and inhibition of RBC acetylcholinesterase (42). Gradual recovery from symptoms occurred while dosing progressed even though the degree of RBC acetylcholinesterase activity continued to decrease. Overt cholinergic toxicity was not evident in rats given 10 mg/kg/day, even though they also showed inhibition of RBC acetylcholinesterase. Neither overt toxicity nor RBC cholinesterase inhibition

occurred among rats given 1 mg/kg/day.

All ten rats fed a diet that contained 2000 ppm temephos (150 mg/kg/day) developed organophosphate poisoning and RBC cholinesterase inhibition, and eight died between days 5 and 10 (42). No rats fed diets that contained 2, 20, or 200 ppm temephos exhibited organophosphate poisoning, although rats given the 200 ppm diet exhibited a progressive inhibition of RBC acetylcholinesterase. RBC inhibition was not evident in rats given the 20- or 2-ppm diets.

Dogs given drinking water that contained 10 or 50 ppm temephos (0.6–0.8 or 3–4 mg/kg/day) for 129 days did not exhibit overt signs of cholinergic toxicity. However, RBC acetylcholinesterase activity in dogs given 3–4 mg/kg/day was significantly inhibited.

When rats were given diets that contained 2, 6, 18, or 350 ppm temephos (0.1, 0.3, 0.9, or 17.5 mg/kg/day) for 92 days, no adverse effects of any kind (clinical signs, opthalmology, food consumption, clinical chemistry and hematology, gross or microscopic changes) occurred in any group except decreased body weight gain in females and decreased liver to body weight ratio in males fed the 350-ppm diet (539a). RBC acetylcholinesterase was significantly inhibited in rats fed either the 18- or 350-ppm diets. Brain acetylcholinesterase activity was not significantly inhibited at any dose level. When rats were fed diets that contained 0, 6, 18, or 54 ppm temephos for 90 days, RBC acetylcholinesterase activity decreased in the 18- and 54-ppm group (539a).

28.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Oral absorption of temephos is limited. Thirty-six to 65% of a single oral dose given to rats in sesame oil was recovered unchanged in feces (543). There are no studies available on inhalation, dermal, or intravenous absorption.

Peak plasma concentrations of temephos occurred 5 to 8 hours after intubation of rats and guinea pigs with temephos (543). All but traces of absorbed temephos were eliminated in urine and feces in rats. The parent compound and small quantities of its sulfoxide metabolite were found primarily in adipose and gastrointestinal tissues. In feces and fat, temephos was mostly unchanged. Temephos appeared in rat urine as at least 13 urinary metabolites, including primarily 4,4'-thiodiphenol, 4,4'-sulfinyl diphenol, and 4,4'-sulfonyl dipheno ester conjugates. The elimination half-life was estimated at about 10 hours (543).

Although temephos clearly inhibits acetylcholinesterase, it is a much more effective inhibitor of liver carboxylesterases. When rats were given single oral doses of temephos, the dose giving 50% inhibition for three liver carboxylesterases was three to eighteen times smaller than that for RBC cholinesterase and eight to forty-five times smaller than that for brain cholinesterase (373). Carboxylesterase activity was still 30–80% of control by 10 days after dosing, suggesting its relatively slow recovery. This relationship was also apparent when rats were repeatedly exposed to temephos in drinking water. When rats were given drinking water that contained 0, 1, 3, or 5 ppm temephos for 8 weeks, RBC, brain and tissue (submaxillary gland) cholinesterase activity were unaffected, whereas liver carboxylesterases were significantly inhibited by week 2, even among 1-ppm treated rats.

28.4.1.4 Reproductive and Developmental When rats were given diets that contained 500 ppm temephos (25 mg/kg/day) throughout mating, gestation, parturition, and lactation, there was no effect on the number of litters produced, litter size, the viability of young, or the incidence of congenital deficits (42, 539a). However, the RBC acetylcholinesterase activity of dams and healthy 21-day-old offspring decreased. No adverse reproductive or developmental effects occurred among rats fed diets that contained 0, 25, and 125 ppm temephos (equivalent to 0, 1.25, and 6.25 mg/kg/day) for three generations (539a).

No maternal or developmental toxicity occurred in rabbits given 0, 3, 10, or 30 mg/kg/day or 12.5, 35, or 50 mg/kg/day temephos orally during days 6 through 18 of gestation, although rabbits given 50 mg/kg/day exhibited decreased body weights (539a).

28.4.1.5 Carcinogenesis EPA noted a chronic dog study (period of exposure not specified) in which significant inhibition of plasma and RBC cholinesterase occurred at dietary exposures equivalent to 12.5 mg/kg/day but not at 0.46 mg/kg/day (539a).

No evidence of carcinogenicity or other treatment-related effects occurred in rats fed a diet that contained 0, 10, 100, or 300 ppm temephos (equivalent to about 0.5, 5.0, or 15 mg/kg/day) for 2 years (539a).

28.4.1.6 Genetic and Related Cellular Effects Studies Weakly mutagenic effects of temephos were noted in one bacterial strain (EXTOXNET). Additional tests on rabbits and on other strains of bacteria have shown that the compound is nonmutagenic.

28.4.2 Human Experience Adverse effects were not reported among residents in the West Indies or among applicators when indoor and outdoor walls of residence and potable water were treated with temephos to control mosquitoes (1). Topical treatment with 34 to 57 g/person (about 486 to 814 mg/kg) of a 2% formulation of temephos in pyrax powder for lice control was considered both safe and effective (1).

Twenty-eight human volunteers were given daily doses of temephos in milk at an initial rate of 2 mg/day (equivalent to about 0.03 mg/kg/day) which was doubled every 3 or 4 days for a period of 4 weeks, reached the highest daily dose of 256 mg/man (about 3.7 mg/kg/day) for 5 days (544). Higher doses were impractical to administer because of an obnoxious taste. Separate volunteers were given a constant dose of 64 mg/man (about 0.9 mg/kg/day) temephos for 4 weeks. At no time were clinical symptoms reported or observed at any of the doses administered, nor was there any effect on plasma or RBC cholinesterase. The concentration of temephos in the men's urine was proportional to the dose, and temephos could still be detected at a greatly reduced concentration 3 weeks after dosing stopped.

28.5 Standards, Regulations, or Guidelines of Exposure

Temephos is undergoing reregistration by the EPA (78). The ACGIH TLV for temephos is 10 mg/m^3 (154). The OSHA PEL-TWA for temephos is 15 mg/m^3 total dust and 5 mg/m^3, respirable fraction. The NIOSH REL-TWA is 10 mg/m^3 (total dust) 5 mg/m^3, respirable. Other countries have Occupational Exposure Limits of 10 mg/m^3 (Australia, Belgium, France, The Netherlands, and Switzerland). 0.5 mg/m^3, Russia.

Organophosphorus Compounds

29.0 TEPP

29.0.1 CAS Number:

[*107-49-3*]

29.0.2 Synonyms:

Diphosphoric acid tetraethyl ester; ethyl pyrophosphate; tetra- phosphoric acid tetraethyl ester; tetraethyl pyrophosphate; Nifost; Vapotone; Tetron; Killax; Moropal; Tetraethyl ester diphosphonic acid; *O*,*O*,*O*′,*O*′-tetraethyl pyrophosphate; diphosphoric acid tetraethyl ester; bis-*O*,*O*-diethylphosphoric anhydride; pyrophosphoric acid, tetraethyl ester; fosvex; hexamite; kilmite 40; lethalaire g-52; lirohex; mortopal; Nifos; tetraethyl diphosphate; tetrastigmine; tetron-100

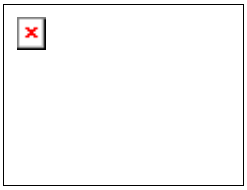
29.0.3 Trade Names:

Bladan®; Fosnex®; Grisol®; HETP®; Killex®; Kilmite®; Nifos T®; Pyfos®; Tetraspa®

29.0.4 Molecular Weight:

290.20

29.0.5 Molecular Formula:
$C_8H_{20}O_7P_2$
29.0.6 Molecular Structure:



29.1 Chemical and Physical Properties
TEPP is a clear to amber hydroscopic liquid that decomposes at 170–213°C and evolves ethylene. The commercial product is 40% TEPP.

Specific gravity	1.185 at 20°C
Boiling point	124°C at 1 torr
Vapor pressure	1.5×10^{-4} torr at 20°C (saturates in air at 0.20 ppm)
Solubility	miscible with water and most organic solvents except petroleum oils; hydrolyzes in water to form mono-, di- and triethyl orthophosphates; the resulting solutions are corrosive to metals

29.2 Production and Use
TEPP was introduced in 1943 as a nonsystemic aphicide and acaricide used to control aphids, spiders, mites, mealy bugs, leafhoppers, and thrips. It is commercially available as a 0.66–1.2% dust, an emulsifiable concentrate (10–40%), and as a solution in methyl chloride to be used as an aerosol (1, 155).
29.4 Toxic Effects
29.4.1.1 Acute Toxicity TEPP is an organophosphate compound that has extremely high oral toxicity and oral LD_{50}s of 1–2 mg/kg (38, 64a). A dermal LD_{50} for the male rat was 2.4 mg/kg (Gaines 1969). A 1-hour LC_{50} of 23.5 mg/m^3 and a 4-hour LC_{50} of 6.75 mg/m^3 were reported for rats (123). An intraperitoneal LD_{50} of 0.65 mg/kg was reported for rats, indicating that it is well absorbed orally; and an intravenous LD_{50} of 0.3 mg/kg was reported for rats (545). Similar results were obtained in mice—oral, dermal, intraperitoneal, and intravenous LD_{50}s in mice were 3, 8, 0.83, and 0.20 mg/kg, respectively (545). In all cases, the mechanism of death was peripheral inhibition of cholinesterase in the muscles, leading to respiratory paralysis, anoxia, and terminal convulsion.

29.4.2 Human Experience 29.4.2.2 Clinical Cases Many deaths have resulted from accidental and intentional contact with TEPP. In Japan, by 1959, TEPP had caused eight poisonings during spraying, eighteen by other accidents, and 101 by suicide attempts, ninety-nine of which were successful (1). In one case, one mouthful (*sic*) of TEPP was reported to have led to complete collapse in less than 5 minutes and death shortly afterward (1).

A pilot who spilled TEPP concentrate directly on his leg while adding it to the spray tank of his plane experienced serious poisoning (blurred vision, weakness, lightheadedness, followed by vomiting, unconsciousness, cyanosis, and frothing of foamy material from the nose and mouth) within one hour (1). He was successfully treated at a hospital and released after 50 hours. Another pilot who was covered with a spray solution containing TEPP when the hopper in his plane ruptured, collapsed almost immediately and died within 2 days despite aggressive treatment with atropine and pralidoxime (546). In another case, a 6-year-old boy died after aspilling TEPP concentrate over the

front of his pants from the groin to the knees (1).

Severe poisoning (characterized by excessive salivation, breathlessness, coughing, staggering, frequent urination, and defecation) occurred among cows when a pasture was sprayed with a 1% dust of TEPP during a thermal inversion. Two cows collapsed, convulsed, and died. The owners of the cows also experienced coughing and shortness of breath (547).

In studies to evaluate the effectiveness of TEPP in treating glaucoma, a 0.01–0.0125% solution produced definite miosis in 20–30 minutes that usually lasted 24 hours (548, 549). A 0.05% solution produced maximal miosis in 20–40 min, and some pupillary constriction remained for 2 days. In addition to miosis, ciliary spasm developed and lasted 12–18 h, but there was no significant change in ocular tension. A 0.1–0.2% solution produced maximal miosis in 7–20 minutes, and it lasted more than 2–3 weeks. The higher concentration also produced twitching of the eyelids, moderate spasms of accommodation for near vision, and aching of the eye and supraorbital area. There was no change in intraocular pressure. In several glaucoma patients, 0.05–0.1% TEPP effectively lowered tension, but in two cases it was actually raised (548–550).

A maintenance dose of 8–12 mg/day TEPP (about 0.1–0.2 mg/kg/day) given in two or three divided doses by mouth was effective in treating myasthenia gravis in atropinized patients (557). Intramuscular or intravascular administration of 1 mg TEPP or more (about 0.0143 mg/kg) resulted in rapid depression of plasma cholinesterase and RBC acetylcholinesterase. Approximately four times as large a dose was required to produce a similar effect when the compound was administered orally. (From a graph presented in the study, an intramuscular dose of about 0.5 mg (about 0.007 mg/kg) reduced plasma cholinesterase and RBC acetylcholinesterase to about 20% and 75% of control, respectively.) Thus, a no-effect level for RBC acetylcholinesterase inhibition following intramuscular administration is probably <0.007 mg/kg. Maximum depression of plasma cholinesterase occurred within 1 hour of dosing, and the maximum depression of RBC acetylcholinesterase occurred within 2 hours of dosing, regardless of the route of administration. Overt cholinergic symptoms (anorexia, vomiting, swearing, salivation, giddiness, uneasiness, headache, abdominal cramps, diarrhea, etc.) occurred after a single parenteral dose of 5 mg, after 3.6 mg for 2 days, or after 2.4 mg for 3 days. Similar results were obtained following oral dosing of 7.2 mg every 3 hours, three to five times. When symptoms appeared, they usually began suddenly about 30 minutes after the last dose of TEPP. In this same study, an average dose of 41 mg TEPP administered during a period of 5 hours or more was effective in reaching maximal or near maximal strength in eleven patients who had moderately severe and severe myasthenia gravis (550a). The average daily amount for maintaining strength was 16 mg orally in two or three divided doses. The difference that distinguished the dose of TEPP that produced a maximal increase in strength with a minimum of side effects, the dose that produced very little effect, and the dose that produced prohibitive side effects (including increased weakness) was very narrow (2–4 mg higher or lower than the optimum).

In another study of myasthenia gravis, patient's daily doses between 13 and 17 mg/day in two or three divided doses were effective (552). These authors also noted that the difference between the dose required to produce a maximal response and the dose that produced toxicity was remarkably small and ranged from 0.5 to 3 mg.

29.5 Standards, Regulations, or Guidelines of Exposure

The ACGIH TLV for TEPP is 0.05 mg/m^3 with a skin notation (154). The OSHA PEL-TWA for TEPP is 0.05 mg/m^3 with a skin notation. The NIOSH REL-TWA is 0.05 mg/m^3 with a skin notation.

30.0 Terbufos
30.0.1 CAS Number:
[*13071-79-9*]
30.0.2 Synonyms:
(*S*-(((1,1-Dimethylethyl)thio)methyl)-*O*,*O*-diethyl phosphorodithioate; AC 92100; phosphorodithioic acid *S*-[(tert-butylthio)methyl] *O*,*O*-diethyl ester; Contraven; *S*-*tert*-butylthiomethyl *O*,*O*-diethyl phosphorodithioate; *O*,*O*-diethyl *S*-(((1,1-dimethylethyl)thio)methyl) phosphorodithoic acid; phosphorodithioic acid, *O*,*O*-diethyl *S*-[1,1-dimethylethyl)thio]methyl ester; ST 100
30.0.3 Trade Names:
Counter®; Counter 15G®; ENT 27920
30.0.4 Molecular Weight:
288.42
30.0.5 Molecular Formula:
$C_9H_{21}O_2PS_3$
30.0.6 Molecular Structure:

30.1 Chemical and Physical Properties
Terbufos is a clear, slightly brown liquid that hydrolyzes under alkaline conditions

Specific gravity	1.105 at 24°C
Melting point	–29.2°C
Boiling point	69°C at 0.1 mmHg
Vapor pressure	3.2×10^{-4} mmHg at 25°C
Solubility	Soluble in acetone, aromatic hydrocarbons, chlorinated hydrocarbons, alcohols

30.2 Production and Use
Terbufos is an organophosphate insecticide/nematicide that is applied as a granular formulation (15 and 20% active ingredient) by soil incorporation, during planting, or postemergence to terrestrial food and feed crops. Crops treated are corn, grain, sorghum, and sugar beets. Aerial/broadcast treatment is not registered (552a).
30.4 Toxic Effects
30.4.1.1 Acute Toxicity Terbufos is an organophosphate insecticide that has extremely high acute oral toxicity and oral LD_{50}s of 1.3–9.2 mg/kg for rats, mice, and dogs (552a). “Severe” signs of toxicity (tremors, shallow breathing, motionless crouching, and loss of righting reflex) occurred among deer mice given single oral doses of 1.69 or 2.48 mg/kg terbufos by gavage; mortality was 33% among mice given 1.69 mg/kg and 63% among mice given 2.48 mg/kg. Deaths occurred between 0.4 and 70 hours after dosing, and 90% of mice died between 2 and 9 hours after treatment.

The dermal LD_{50} for terbufos in rabbits is 0.8 to 1.1 mg/kg (552a). Dermal LD_{50}s of 123 mg/kg and 71 mg/kg were reported for rats for a formulated product in which terbufos is mixed with clay, and dermal LD_{50}s of 566 mg/kg and 238 mg/kg were reported for a formulated product in which terbufos is mixed with polymer granules (552a).

Rats inadvertently supplied with bedding contaminated with about 30 ppm terbufos developed cholinergic signs (muscle fasciculations, severe depression, exophthalmus, and ptyalism) that progressed rapidly to death (553). Exposures were most likely primarily dermal but could also have been via ingestion and inhalation. When terbufos was inadvertently mixed into cattle feed (so that

doses were about 7.5 mg/kg), all heifers exposed died (554). Cows that received about one-tenth this dose (0.75 mg/kg) developed signs typical of ogonophosphate poisoning (554). The cows most "severely affected" (*sic*) had whole blood cholinesterase activity that averaged 0.9% of controls, and, cows that were "moderately affected" had whole blood cholinesterase activity that averaged 20% of controls. Inhibition continued for at least 30 days following ingestion of contaminated feed.

Mortality and cholinesterase activity depression (plasma, RBC, or brain not specified) occurred in rats exposed to 0.0394 mg/m^3 (552a). No other details were provided. In another study, rats were exposed to 0, 0.01, 0.02, 0.05, or 0.1 mg/m^3 terbufos for 8 h/day, 5 days/week for two weeks. Significant reductions in RBC cholinesterase activities occurred at 0.05 mg/m^3 (552a). No adverse effects occurred when rats were exposed to about 0.01, 0.025, 0.05, or 0.10 mg/m^3 terbufos for 8 h/day 5 days/week for 3 weeks, although RBC and brain cholinesterase activity decreased at the highest dose (552a).

No signs of cholinergic toxicity or depression of RBC or brain cholinesterase activity occurred at any dose in dogs given 0, 0.00125, 0.005, or 0.015 mg/kg/day terbufos by oral capsule for 28 days (552a). Decreases in RBC and brain cholinesterase activity occurred in rats given dermal doses of 5, 10, or 25 mg/kg/day (equivalent to 1, 2.5, or 6.75 mg/kg/day active ingredient) for 6 h/day, 5 days/week for 4 weeks (552a). A dermal dose of 2 mg/kg/day had no effect.

In primary eye and primary dermal irritation studies in rabbits, all animals died within 24 hours after dosing with 0.5 ml or less of terbufos (552a). No dermal sensitization study has been performed due to the acute lethality of terbufos.

Terbufos was not neurotoxic when administered to hens in a single oral dose of 40 mg/kg in an acute delayed neurotoxicity study (552a). Nor did acute delayed neuropathy occur in hens treated orally or dermally with terbufos (128).

30.4.1.2 Chronic and Subchronic Toxicity Mesenteric and mandibular lymph node hyperplasia occurred in rats given 0.05 mg/kg/day terbufos, and liver weight and liver extramedullary hematopoiesis increased in rats given 0.025 or 0.05 mg/kg/day terbufos via their diet for 13 weeks (552a).

30.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms A metabolism study of rats indicated that 83% of a single administration of 0.8 mg/kg terbufos was excreted in the urine in the form of metabolites and 3.5% in the feces during 168 hours. No terbufos accumulated in tissues (552a).

30.4.1.4 Reproductive and Developmental No adverse reproductive effects occurred in rats given 0.0125 or 0.05 mg/kg/day terbufos for three generations (552a). When rats were given diets that contained 0, 0.5, 1, or 2.5 ppm terbufos for three generations, those fed 2.5 ppm (0.2 mg/kg/day) showed decreased pregnancy rate and male fertility and decreased body weight gain and lower pup weights during lactation (552a). No maternal or developmental effects occurred among rats fed 1 ppm (about 0.08–0.09 mg/kg/day).

Early fetal resorptions, the number of litters that had two or more resorptions, and postimplantation losses increased among rats given 0.2 mg/kg/day terbufos dose by gavage on gestation days 6 through 15 (552a). No adverse developmental effects occurred in rats given 0.05 or 0.1 mg/kg/day. A slight reduction in fetal body weight and an increase in resorptions occurred among rabbits given 0.5 mg/kg/day by gavage on gestation days 7 through 19 (552a). No adverse developmental effects occurred in rabbits given 0.05, 0.1, or 0.25 mg/kg/day.

30.4.1.5 Carcinogenesis No signs of cholinergic toxicity occurred at any level in dogs given 0, 0.015, 0.06, 0.09, or 0.12 mg/kg/day terbufos via capsule for 1 year (552a). However, initial higher doses of 0.24 and 0.48 mg/kg/day had been reduced after the first 6–8 weeks due to cholinergic-related

behavioral signs, reduced food consumption and weight gain, depressed hematology parameters, and gross changes of congestion, edema and necrosis in the gastrointestinal tract. RBC and brain cholinesterase activities were inhibited in dogs given 0.09 and 0.12 mg/kg/day.

No adverse cholinergic effects occurred in rats fed diets that contained 0.125, 0.5, or 1.0 ppm terbufos for 1 year (0.007–0.009, 0.028–0.036, and 0.055–0.071 mg/kg) (552a). Brain cholinesterase activity was reduced among rats given the 1-ppm diet. There was no evidence of neoplastic activity among rats given diets that delivered doses of 0, 0.0125, 0.05, or 0.1 mg/kg/day (which was raised to 0.2 mg/kg/day at week 6, to 0.4 mg/kg/day at week 12, and reduced back to 0.2 mg/kg/day at week 16) for 2 years (552a). Mortality and exopthalmia increased in rats given 0.05 mg/kg/day. RBC cholinesterase inhibition occurred at all doses, and brain cholinesterase inhibition occurred at the 0.05-mg/kg/day dose and higher.

When dietary doses of 0, 0.45, 0.9, or 1.8 mg/kg/day were administered to CD-1 mice for 18 months, mortality and reduction in weight gain increased at the highest dose (552a). There was no evidence of neoplastic activity.

30.4.1.6 Genetic and Related Cellular Effects Studies Terbufos was positive in a dominant lethal study using rats (552a). However, it was not mutagenic in a variety of other studies tested to cytotoxic levels. Terbufos was negative in the Ames reversion assay with *S. typhimurium* and *E. coli* strains and in the CHO/HGPRT assay (552a). Terbufos did not cause structural chromosomal aberrations in Chinese hamster ovary cells in culture or in an *in vitro* cytogenetics assay in rats, was negative in the rat hepatocyte primary culture/DNA repair test, and did not alter DNA repair in *S. typhimurium* and *E. coli* strains (552a).

30.4.2 Human Experience Among eleven farmers who applied a formulated terbufos product while planting corn, dermal exposure (assessed using gauze patches) was estimated at an average of 72 mg/h, and respiratory exposure (assessed using personal monitoring pumps) was estimated at an average of 11 mg/h (range 2.8–27.4 mg/h). Exposure duration averaged 7.4 hours. No alkyl phosphates were detected in urine, and no significant depression of RBC cholinesterase activity occurred. Assuming an 8 hour day, 100% absorption, and a 10-m^3/day inhalation rate, a respiratory dose of 11 mg/hr would be achieved by exposure to roughly 0.009 mg/m^3 terbufos. Thus, this study suggests a human no-observed-effect level □0.009 mg/m^3 (551).
30.5 Standards, Regulations, or Guidelines of Exposure
Terbufos is undergoing re-registration by the EPA. There is no ACGIH TLV, OSHA PEL-TWA, or NIOSH REL-TWA for terbufos.

31.0.3 Trade Names:

Dylox®; Dipterex®; Proxol®; Neguvon®

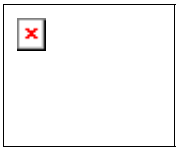
31.0.4 Molecular Weight:

257.44

31.0.5 Molecular Formula:

$C_4H_8Cl_3O_4P$

31.0.6 Molecular Structure:



31.1 Chemical and Physical Properties

Pure trichlorfon is a white crystalline solid

Specific gravity	1.73
Melting point	83–84°C
Boiling point	100°C
Vapor pressure	7.8×10^{-6} mmHg at 20°C
Solubility	readily soluble in dichloromethane, 2-propanol; soluble in toluene; nearly insoluble in *n*-hexane; slightly soluble in water (1–5 g/100 ml at 21°C)

31.2 Production and Use

Trichlorfon is used to control a wide variety of lepidopteran larvae, white grubs, mole crickets, sod webworms, leaf miners, stink bugs, ants, and other nuisance pests on outdoor turf and ornamentals; to indoor control flies, ants and roaches; for mound treatment for harvester ants; and to control cattle grubs and cattle lice. It is available as a soluble powder, granules, or bait. For turf, ornamental, or nursery use, it is applied via mechanical or hand-held sprayers, spreaders (for granular formulations), or irrigation systems; for indoor or outdoor perimeter use, it is applied as a soluble powder in water through hand-held sprayers or is applied as the solid; and for livestock, it is poured on from a cup or dipper (554a).

Trichlorfon (termed metrifonate when used therapeutically) has also been widely used as an antihelminthic to treat schistosomiasis (558) and has been extensively investigated as a treatment for Alzheimer's disease (556, 557).

31.4 Toxic Effects

31.4.1.1 Acute Toxicity Trichlorfon is a moderately toxic organophosphate compound that has oral LD_{50}s of 136–630 mg/kg for rats and 727–866 mg/kg for mice (62, 64a). The dermal LD_{50} for trichlorfon was more than 2000–2800 mg/kg (64a, 81). Thus trichlorfon is considerably less potent

on a body weight basis via dermal contact than via ingestion. Four-hour LC_{50}s of 533–1300 mg/m^3 have been reported for rats (123). Death occurs unusually quickly—within 5–15 minutes after dosing (81, 558a). If animals survive, recovery is equally quick and occurs within a few hours.

The single acute oral dose that causes 50% inhibition (ED_{50}) of brain, RBC, and plasma cholinesterase activities in 3-month-old rats was determined and compared to ED_{50}s for dichlorvos, the major *in vivo* nonenzymatic breakdown product of trichlorfon. The oral ED_{50} values for trichlorfon were 90 mg/kg for brain and 80 mg/kg for RBC and plasma cholinesterase, whereas the oral ED_{50} values for dichlorvos were 8 mg/kg for brain and 6 mg/kg for RBC and plasma cholinesterase (559). Thus, trichlorfon is one-tenth to one-fifteenth as potent a cholinesterase inhibitor as dichlorvos.

When rats were given single oral doses of 10, 30, and 100 mg/kg trichlorfon, the 100-mg/kg dose of trichlorfon caused salivation, tremor, diarrhea, ptosis, flat body, decreased body temperature, and decreased pentylenetetrazole seizure threshold, whereas the 30- or 10-mg/kg doses did not (560).

Trichlorfon is unusual among organophosphate pesticides in that several animal studies have demonstrated a beneficial effect of acute low doses of trichlorfon on certain behaviors in rats. For example, in old rats, improvements in spatial reference memory function in the water maze and in passive avoidance learning occurred after acute oral treatment with 10–30 mg/kg trichlorfon (561, 562). Performance in another behavioral task (Morris water escape) was optimally improved among young adult rats given 10–30 mg/kg trichlorfon or 0.03 mg/kg dichlorvos, the breakdown product of trichlorfon (563), and among rats given 3–30 mg/kg trichlorfon (564). Higher acute doses (80 mg/kg) were required to significantly increase the concentration of cortical acetylcholine and to improve “object recognition” in aged rats—a 30 mg/kg dose had no effect on these measures even though it caused significant acetylcholinesterase inhibition (565). Acute oral treatment with trichlorfon (5–15 mg/kg) has also ameliorated deficits in certain behaviors (water maze performance; passive avoidance tasks) caused by scopolamine or lesions of the basal forebrain (566).

Trichlorfon was moderately irritating to the eye and was a moderate contact allergen in the skin (554a).

31.4.1.2 Chronic and Subchronic Toxicity Trichlorfon does not have a cumulative effect. Repeated intraperitoneal doses of 50 mg/kg/day trichlorfon (about one-fourth of the i.p. LD_{50}) for a period of 60 days had no effect on mortality. But repeated doses of 100 mg/kg/day (about one-half LD_{50}) produced 40% mortality by 60 days, and repeated doses of 150 mg/kg produced 100% mortality by 60 days (558a).

Cholinergic toxicity was not observed among rats fed diets that contained 1, 5, 25, or 125 ppm (equivalent to doses of 0.088, 0.39, 2.4, or 11.3 mg/kg/day) for 1 to 13 weeks (81). When rats were given diets that contained 100, 500, or 2500 ppm trichlorfon (about 6–7, 31–35, and 165–189 mg/kg/day) for 13 weeks, cholinergic toxicity and inhibition of RBC and brain cholinesterase activities occurred in male rats given 2500 ppm, and RBC and brain cholinesterase inhibition occurred in females given 500 or 2500 ppm (63).

No signs of cholinergic or other toxicity were seen in dogs fed 42 mg/kg/day trichlorfon for 6 days/week for 3 months (1) or in dogs given diets that contained 50, 200, or 500 ppm trichlorphon for 12 weeks (84). The dietary level of 500 ppm (about 10.5 mg/kg/day) inhibited RBC cholinesterase activity (84).

No cholinergic toxicity occurred when trichlorfon was administered dermally to rabbits for 15 days (4 days/week for 3 weeks) at doses of 0, 100, 300, or 1000 mg/kg/day, although RBC cholinesterase

activity was inhibited at 300 mg/kg but not at 100 mg/kg/day (554a).

There is no evidence that trichlorfon causes delayed neuropathy. Hens that received acute subcutaneous doses of 100 or 300 mg/kg trichlorfon showed no visible sign of acute neurotoxicity. Brain, spinal cord, and plasma cholinesterase activities were significantly inhibited, but no significant reductions of neurotoxic esterase activity in these tissues were observed. Subcutaneous doses of 100 mg/kg trichlorfon every 3 days for a total of six doses caused little or no sign of overt neurotoxicity. No inhibition of spinal cord or brain NTE occurred. When trichlorfon was given to hens at doses of 0, 3, 9, or 18 mg/kg/day for 90 days, there were no overt indications of response characteristic of delayed neurotoxicity, although, histologically, a slight effect on nervous tissue, characterized as axonal degeneration was present in hens that received 18 mg/kg/day (554a).

31.4.1.3 Pharmacokinetics, Metabolism, and Mechanisms Trichlorfon is rapidly and completely absorbed via oral exposure and is extremely rapidly metabolized and excreted. Once absorbed following a 133 mg/kg oral dose, trichlorfon was not detected, but dichlorvos (a nonenzymatic breakdown product of trichlorfon) was distributed primarily in blood, adipose tissue, muscle, and liver. Peak concentrations occurred 1,7,7, and 7 days after exposure, respectively. Dichlorvos was undetected at 20 days. Calculated half-lives in blood, adipose tissue, muscle, and liver were 7, 11, 10, and 12 days, respectively (388).

Trichlorfon and dichlorvos levels were followed in plasma and RBCs of seven individuals given single oral doses of 7.5–10 mg/kg trichlorfon repeated after 2 weeks for treating schistosomiasis (574). The relationship of dichlorvos to trichlorfon in plasma and RBCs was about 1%. A biphasic curve for the elimination of trichlorfon in Plasma developed; the first phase had a half-life of 0.4 to 0.6 hours, and the second phase had a half-life of about 3 hours. Clearance of trichlorfon was primarily due to formation of dichlorvos.

Regardless of whether rats were given single or repeated oral doses or single intravenous doses of trichlorfon, 80–90% of the dose was excreted within 24 hours. The major route of excretion was via the urine, followed by feces and expired air. About 1 to 2% of the dose was found in the tissues after 96 hours.

Several groups of investigators examined the pharmacokinetics of trichlorfon in humans in conjunction with assessing its efficacy as a treatment for schistosomiasis and Alzheimer's disease. These studies confirmed that trichlorfon (and its decomposition product dichlorvos) is very rapidly absorbed and cleared in humans. After acute oral treatment of healthy male volunteers with a 2, 5, 7.5, or 12 mg/kg dose of trichlorfon (metrifonate), the maximum blood concentration of trichlorfon was obtained between 12 minutes and 2 hours and the half-life in blood was about 2 hours (575, 576). The concentrations of dichlorvos, the nonenzymatic breakdown product of trichlorfon, closely followed those of trichlorphon at a constant ratio of about 1 to 100. The concentrations of trichlorfon were detectable up to 8 hours, but those of dichlorvos had fallen below the level of detection by then. Both plasma and RBC cholinesterases were readily inhibited and were still low after 24 hours—none of the volunteers complained of side effects (and the half-life of the breakdown product, dichlorvos, was about 3.8 hours).

Pharmacokinetic analysis of both trichlorfon and dichlorvos in blood on the first and sixth day of a 21-day treatment regimen indicated that, regardless of maintenance dose (0.25 to 1.0 mg/kg/day), the half-lives of elimination were the same (about 2 or 3 hours for metrifonate and dichlorvos, respectively). This confirms that there was little or no accumulation of either of these compounds from long-term administration (556). Blood concentrations of dichlorvos were approximately 2% of the parent (trichlorfon) compound concentrations.

The predominant metabolic pathway that involves cleavage of the P–C phosphonate bond that generates trichloroethanol and dimethyl phosphate which are then excreted in urine (576a). Quantitatively minor pathways of metabolism include demethylation (to dimethyl trichlorfon) and

(nonenzymatic) dehydrochlorination to dichlorvos which is rapidly metabolized to dichloroethanol and dimethyl phosphate which are then excreted in urine. Trichlorfon itself does not act significantly as a cholinesterase inhibitor, but induces cholinesterase inhibition through its hydrolytic degradation product, dichlorvos (559).

31.4.1.4 Reproductive and Developmental When rats were fed diets that contained 0, 300, 1000, or 3000 ppm for three generations, 3000 ppm (about 150 mg/kg/day) caused a marked decrease in the pregnancy rate and early deaths in pups, 1000 ppm (about 50 mg/kg/day) caused reduced numbers of pups per litter and weight of individual pups, and 300 ppm (about 15 mg/kg/day) had no detectable effect on reproduction. There was no indication of teratogenesis, even at dosages that were highly toxic (1). When rats were fed diets that contained 0, 150, 500, or 1750 ppm (about 0, 15, 50, and 175 mg/kg/day) for two generations, pulmonary and renal lesions in the F1 generation and adverse reproductive outcomes (dilated renal pelvises in F1 pups and decreased F1 pup weight on days 7 and 21) occurred at 1750 ppm (554a).

Decreases in brain and RBC cholinesterase activities and an increased incidence of abortion occurred among rabbits given 35 or 110 mg/kg/day trichlorfon by gavage on gestation days 6 through 18 (554a). Increased numbers of resorptions, decreased fetal body weights (males), and delayed ossification occurred among rabbits given 110 mg/kg/day. Decreased cholinesterase activity (*sic*) and reduced ossification of skulls, vertebrae, and sternebrae in fetuses occurred among rats fed diets that contained 2500 ppm trichlorfon (equivalent to 45 mg/kg/day) on gestation days 6 through 15 of gestation (554a). Dietary exposures of 500 or 1125 ppm (about 102 or 227 mg/kg/day) had no adverse effect.

Trichlorfon was teratogenic when given to pregnant CD rats by gavage at 480 mg/kg/day on gestation days 6 through 15, but not when given only on gestation days 8 or 10 alone. Signs of cholinesterase inhibition occurred in dams after each dose. Teratogenic responses (increased fetal death and stunted and malformed fetuses) also occurred in hamsters after administration of 300 or 400 mg/kg/day on gestation days 7 through 11, but not after 200 mg/kg/day. Embroyotoxicity, but not teratogenicity, occurred after administration of 400 mg/kg/day only on day 8 of gestation. In mice, there was a significant increase in the incidence of cleft palate following treatment with 600 mg/kg/day on gestation days 10 through 14 and on days 12 through 14 (567).

Congenital ataxia and tremor occurred in piglets of sows treated with trichlorfon between days 45 and 63 of pregnancy (1). Usually all of the piglets in any given litter were affected, and many died. Autopsy revealed marked cerebellar and spinal hypoplasia. Retrospective study showed that the smallest dose capable of causing this effect was 56 mg/kg. In another study, cerebellar hypoplasia occurred in piglets from sows treated with 60 mg/kg on day 55 or on days 55 and 70 of gestation (568). Similar cerebellar lesions were observed in guinea pigs treated with trichlorfon during prenatal development. Dose–response studies showed that 100 mg/kg trichlorfon given to guinea pigs on 3 consecutive days during days 40–50 of gestation resulted in offspring that had brain hypoplasia, ataxia, and tremors (569). When trichlorfon (125 mg/kg/day) or dichlorvos (15 mg/kg/day) was administered to guinea pigs between day 42 and 46 of gestation, offspring exhibited severe reductions in brain weight that was most pronounced in the cerebellum, medulla oblongata, thalamus/hypothalamus, and quadrigemina (570).

31.4.1.5 Carcinogenesis When trichlorfon was administered to monkeys via Tang orange drink at doses of 0, 0.2, 1.0, or 5.0 mg/kg/day for 6 days/week for 10 years, RBC and brain cholinesterase activities decreased in those given 0.2 mg/kg/d. Monkeys given 5.0 mg/kg/day exhibited decreased body weight, anemia, and transitory signs of cholinesterase inhibition (pupillary constriction, muscle fasciculation, and diarrhea; females only) (554a).

There were no effects on mortality or body weights nor was there any cholinergic toxicity in dogs given diets that contained 0, 50, 250, 500, or 1000 ppm (equivalent to 0, 1.25, 6.25, 12.5, or 25 mg/kg/day, respectively) for 1 year (554a). There was mild to moderate enlargement of the spleen

in dogs fed the 1000-ppm diet, as well as congestion of the spleen and lymphoid atrophy and foci of inflammatory liver cells. Dogs given the 500- or 1000-ppm diet exhibited decreases in RBC cholinesterase activity. When dogs were fed diets that contained 0, 50, 200, 800, or 3200 ppm for 4 years, dogs fed the 50-ppm diet were unaffected; dogs fed the 200-ppm diet had depressed RBC cholinesterase activity; dogs fed the 800- or 3200-ppm diet had depressed RBC cholinesterase activity, reduced food intake, retarded body weight gain, and increased mortality; and, dogs fed the 3200-ppm diet also exhibited tremors, cramps, and salivation (588).

When rats were fed diets that contained 0, 50, 100, 200, 250, 400, 500, or 1000 ppm for 17–24 months, no treatment-related effects occurred in those fed 50 to 250 ppm (588). Serum cholinesterase activity was depressed in rats fed 500 ppm trichlorfon, and serum, RBC, and tissue (submaxillary gland) cholinesterase activities were depressed in rats fed 1000 ppm trichlorfon. Histopathological results that suggested the occurrence of mammary tumors, the absence of primary follicles and primitive ova, and necrotizing arteritis in rats fed 400, 500, and 1000 ppm; and tubular and roblastomas, focal aspermatogenesis, decreased growth rats, and decreased survival in rats fed 1000-ppm were equivocal (345). However, in another study, when rats were fed diets that contained 0, 50, 250, 500, or 1000 ppm trichlorfon for 24 months, no treatment-related effects other, than whole blood cholinesterase depression at 1000 ppm occurred (588). There was no increase in incidence of either benign or malignant tumors, including mammary tumors. Nor was there any indication of cystic atrophy, tubular hyperplasia in the ovaries, or aspermatogenesis.

When rats were fed diets that contained 0, 100, 300, 1514 (males), or 1750 ppm (females) trichlorfon (equivalent to about 0, 4.4–5.8, 13.3–17.4, and 75–94 mg/kg/d) for 24 months, the females given 1750 ppm exhibited rough hair coats, granular kidneys, foci in lungs, decreased body weight gain, and anemia, but no evidence of oncogenicity (554a). The males given 1514 ppm exhibited paleness and hunched backs, thickened enlarged duodenum, thickened, granular nonglandular stomachs, decreased body weight gain, anemia, and an increase in the incidence of benign pheochromocytomas and mononuclear cell leukemia. The EPA Office of Pesticide Programs (OPP) Carcinogenicity Peer Review Committee, however, concluded that these lesions were not compound-related.

When rats were fed diets that contained 2500 ppm trichlorfon (equivalent to 129–159 mg/kg/day), they exhibited signs of cholinergic toxicity, decreased body weight and body weight gain, decreased RBC parameters (hematocrit, hemoglobin, RBC count and MCV), hypercholesterolemia, increased serum hepatic enzymatic (SAP, AST, ALT, GGT) activity, and decreased brain and RBC cholinesterase activity. Nonneoplastic lesions included duodenal hyperplasia, gastritis, pulmonary hyperplasia and inflammation, nasolacrimal inflammation, hepatocellular hyperplasia and vacuolation, chronic nephropathy, and dermal lesions. There was an increase in the incidence of alveolar/bronchiolar adenomas in males, renal tubular adenomas in males, and alveolar/bronchiolar carcinomas in females that were not statistically significant, but the EPA noted that they were outside the historical control range for these types of tumors. There was no compound-related increase in the incidence of either benign pheochromocytomas or mononuclear cell leukemia (554a).

Cholinergic signs and inhibition of brain and RBC cholinesterase activities occurred in all mice given diets that contained 0, 300, 900, or 2700 ppm trichlorfon (equivalent to 0, 45, 135, and 405 mg/kg/day) for 24 months (554a). Mortality in female mice was significantly related to dose. There was an increase in lung tumors in low- and mid-dose females, but not in high-dose females. Therefore, the EPA OPP Carcinogenicity Peer Review Committee concluded that the tumors were not dose-related and trichlorfon was not carcinogenic in this study.

31.4.1.6 Genetic and Related Cellular Effects Studies Trichlorfon is sometimes mutagenic in *in vitro* systems (554a). In gene mutation assays with *S. typhimurium*, trichlorfon was weakly mutagenic at toxic concentrations with or without activation (554a). Trichlorfon produced base-pair substitution mutations in *S. typhimurium*, although mutagenic activity decreased in the presence of S9 (594). Trichlorfon was not mutagenic with or without activation in one gene mutation assay with *S. cerevisiae* (554a).

In other bacterial or prokaryotic assays, trichlorfon was positive for DNA damage and repair in *S. typhimurium* but was negative in relative toxicity assays with *E. coli* and *B. subtilis* strains (554a). In a DNA damage and repair study conducted with *S. Cerevisiae*, trichlorfon was positive for mitotic recombination with and without S9 activation (554a). In a recombinant DNA study, trichlorfon did not inhibit the growth of *Bacillus subtilis* (554a).

The genotoxity of trichlorfon in mammalian cells has also been equivocal. Trichlorfon induced significant increases in mutation frequencies with or without activation in an *in vitro* cytogenetic study in mammalian cells (type not specified) (554a). Trichlorfon was inactive in inducing unscheduled DNA synthesis in rat hepatocytes up to levels of severe cytotoxicity (554a). At cytotoxic levels of 1000 mg/mL, trichlorfon was associated with a marginal but significant increase in sister chromatid exchange in Chinese hamster ovary cells (1). Trichlorfon was clastogenic in human lymphocytes in the absence of S9 activation (554a) and also reportedly induced sister chromatid exchange in human lymphocytes. In other studies, trichlorfon reportedly slightly increased the frequency of chromosomal abnormalities in cultured human lymphocytes (571).

Under physiological conditions, trichlorfon alkylates DNA (through its conversion to dichlorvos which is more easily demethylated), and an increased rate of chromosomal aberrations in bone marrow cells of Syrian hamsters and mice treated with trichlorfon has been observed. In mice that received a single dose of trichlorfon, liver DNA adducts increased maximally 6 hours after dosing, were substantially reduced 24 hours after dosing, and were undetectable by 48 hours after dosing (584a). Increases in sister chromatid exchanges occurred in the bone marrow of mice treated 24 hours earlier with 120 mg/kg, but not with 30 or 50 mg/kg trichlorfon (584). Some researchers have obtained positive effects in dominant lethal mutation tests with mice (595), but some have not (571). No chromosomal aberrations occurred in the bone marrow or spermatogonia of mice treated with acute doses of 100 mg/kg trichlorfon, and dominant lethal mutations did not significantly increase in mice given 5 ppm trichlorfon for 5 days/week for 7 weeks (571).

Significant and persistent increases (lasting at least 180 days after exposure) in aneuploidy in lymphocytes of individuals who attempted suicide by using trichlorfon (Ditriphon-50) were reported (572). Trichlorfon also produced aneuploidy in genetically engineered human lymphoblastoid cell lines (573).

31.4.2 Human Experience 31.4.2.2 Clinical Cases Trichlorfon has been associated with numerous cases of accidental or incidential poisonings (1, 572). Gallo and Lawryk (1) reviewed 379 cases of trichlorfon poisoning and found that in some cases (3%), acute poisonings were accompanied by "mental disturbance" (described as loss of memory and problem-solving ability, delirium, depression and anxiety, psychomotor stimulation, hallucinations, and paranoid delusions); and in other cases (21%), poisoning was accompanied by a delayed type polyneuropathy. It is not clear, however, whether these symptoms were due to trichlorfon itself or to some contaminant in the ingested material. Estimates of dosages associated with poisonings suggested that ingestion of 40 mg/kg causes light to moderate poisoning, ingestion of 80–700 mg/kg causes severe poisoning, and ingestion of 30,000–90,000 mg/kg causes death (1).

Trichlorfon-contaminated fish was implicated as the cause of a cluster of congenital abnormalities that occurred in a Hungarian village in 1989–1990 (584a). Eleven of fifteen live births, were affected by congenital abnormalities (four with Down's syndrome) and six were twins. Examination of this group along with two negative control groups (mothers and their children born in the same village in 1987–1988, and mothers and children born in 1989–1990 in a nearby village) and a positive control group (mothers and their children who had congenital abnormalities from the same village) indicated that all mothers of affected children had eaten "contaminated" fish during pregnancy, whereas only about one-third of mothers from all control groups combined had. Other potential causes for the cluster, such as known teratogens, familial inherited disorders, and consanguinity were excluded as contributing causes. The "contaminated" fish were obtained from a pond which had been heavily

treated with trichlorfon to eradicate parasites. The content of trichlorfon in fish was 0.15 to 0.26 mg/kg and, it was estimated was as high as 100 mg/kg.

In a poorly described study, air concentrations of trichlorfon (dipterex) and blood cholinesterase activity were monitored among employees who worked in a trichlorfon (dipterex) packing facility in China (577). Estimates of mean 8-hour time-weighted average air concentrations (aerosol or dust not specified) ranged from about 0.2 to 0.6 mg/m^3 estimated dermal exposure (mainly to face, neck, and hands a 44 cm^2 area) ranged from about 0.4 to 7.2 mg/cm^2, and blood cholinesterase activity decreased to about 23% of preexposure baseline levels after about 2-month's work. The occurrence of overt cholinergic effects was evidently not examined. Unfortunately, specific types of exposures were not thoroughly described, and it was not possible to distinguish between the relative contribution of inhalation and dermal exposures to an internal dose.

Trichlorfon has been widely used as an antihelminthic (1, 578). The formulations of trichlorfon that have been used for treating people infested by worms have frequently produced mild, rapidly reversible side effects (560). The dose ordinarily employed is 5 to 15 mg/kg given orally three times at intervals of 2 weeks. (555, 579). When used as an antihelminthic, a total dose as high as 37.7 mg/kg produced very mild poisoning, and dose of 10 mg/kg/day had no untoward effects. However, mild poisoning was reported among other persons when they received daily doses as low as 5 mg/kg/day for 12 days. A single dose at the rate of 10 mg/kg was tolerated (1).

Trichlorfon has been proposed as a treatment for Alzheimer's disease based on its ability to elevate brain levels of acetylcholine because of its relatively long lasting inhibition of acetylcholinesterase. Clinical trials in Alzheimer's disease patients suggest that maintaining RBC cholinesterase activity at levels that are 40–60% of predose baseline through daily dosing with trichlorfon can significantly improve “cognitive ability” (557, 580). Effective therapeutic doses were a 2 mg/kg/day loading dose for 2 weeks followed by a maintenance dose of 0.65 mg/kg/day. This regimen yielded significant RBC cholinesterase inhibition and “mild and transient” cholinergic adverse effects that were primarily gastrointestinal. Lower doses—a 0.5 mg/kg/day loading dose for 2 weeks followed by a 0.2 mg/kg/day maintenance dose—significantly inhibited RBC cholinesterase activity but did not affect other outcome measures.

In a 21-day study, Alzheimer's disease patients received loading doses of 1.5, 2.5, 4.0, or 4.0 mg/kg/day for 6 days followed by maintenance doses of 0.25, 0.40, 0.65, or 1.0 mg/kg/day, respectively, for 15 days (556). After 21 days of treatment, RBC acetylcholinesterase inhibition occurred at all doses. In another study designed to evaluate the safety and tolerability of relatively high loading doses followed by lower maintenance doses and to determine the maximum tolerated dose of trichlorfon, groups of probable Alzheimer's disease patients were administered either 2.5 mg/kg/day for 14 days followed by 4.0 mg/kg/day for 3 days, then 2.0 mg/kg/day for 14 days or 2.5 mg/kg/day for 14 days followed by 1.5 mg/kg/day for 35 days (581). RBC acetylcholinesterase inhibition occurred in all groups. Moderate to severe cholinergic effects (muscle cramps, abdominal discomfort, headache, muscle weakness, generalized moderate to severe muscle cramps, weakness, inability to resume daily activities, and coordination difficulties) occurred in six of eight patients given the higher doses (4.0 mg/kg/day for 3 days and 2.0 mg/kg/day for 14 days); mild to moderate cholinergic effects (gastrointestinal disturbances, muscle cramps, and lightheadedness/dizziness) occurred among patients given the lower maintenance dose (1.5 mg/kg/day).

In some cases, weekly rather than daily dosing has been used. When doses were 2.5, 5, 7.5 and 15 mg/kg/week, no side effects occurred at 2.5 mg/kg, but did occur in patients who received 15 mg/kg (582). Nausea, vomiting and diarrhea were most commonly reported. Sixteen patients had electroencephalographic (EEC) abnormalities. When a weekly dose of about 5 mg/kg was given for 3 or 4 weeks followed by a weekly dose of 2.1 mg/kg for up to 6 months, adverse effects were reported as “mild and transient” (583). When patients were given 2 mg/kg/day trichlorfon for 5 days and 0.95 mg/kg on day 6, followed by 2.9 mg/kg weekly, adverse effects were uncommon (583).

31.5 Standards, Regulations, or Guidelines of Exposure
Trichlorphon is undergoing reregistration by the EPA. There is no ACGIH TLV, OSHA PEL-TWA, or NIOSH REL-TWA for trichlorphon.

Organophosphorus Compounds

Toxicological Effects of the Physical Agents
David H. Sliney, Ph.D.

Introduction
The toxicological approach has been shown to have benefit when deriving human exposure limits, or threshold limit values (TLVs) for physical agents. However, some adjustments must necessarily be made to the approach followed by chemical toxicologists. Also, the philosophies relating to the control of exposure may be quite different. Concepts such as "routes of entry" must be modified. Target organs differ and dosimetric concepts vary from agent to agent.

There are over 700 chemical substances that have had TLVs assigned by the American Conference of Governmental Industrial Hygienists (ACGIH) (1–2). Many other chemicals have been studied. Toxicologists, industrial hygienists, and occupational physicians are generally well trained to recognize the hazards of different classes of chemicals, their route of entry, sampling techniques, and control measures. The toxicological literature is extensive, and the ACGIH Documentation for all these substances is both extensive and widely available (2). However, when one approaches the several physical agents, most toxicologists, industrial hygienists, and physicians appear to feel somewhat uneasy and less than fully informed. Noise is perhaps one exception, as most of these specialists have had some exposure to the subject. Mention magnetic fields, lasers, whole-body vibration, infrared, or other physical agents, and most health scientists must search for a book. Fortunately, there are only a few physical agents with which to be concerned. The ACGIH Physical Agents TLV Committee has identified only 16 physical agents for which TLVs could be established since that Committee was initiated in 1966. Hazard assessment, measurement and evaluation, and engineering controls for each physical agent may differ considerably. If one examines the physical agents TLVs, one is struck by the variation in the physical quantities and units to describe, measure, and assess the hazard. Indeed, rather different technologies apply to different agents. Specialists exist in each technology who are expert in assessing those hazards, but are frequently not expert in the hazards and terminology of other technologies. The detailed information relating to each physical agent is generally found in separate texts.

Industrial hygienists and occupational health professionals worldwide routinely make use of PELs, TLVs, MACs, and toxicological data for chemicals. Industrial hygienists are very familiar with the use and the special notations for different classes of chemical substances. However, when it comes to the evaluation and control of potential hazards from physical agents, the beginner is frequently astonished by the seeming complexity—with different terminologies for different human exposure limits, the different types of engineering technologies, the various restrictions, and the specialized mathematical formulas. Some occupational health professionals complain that even the TLVs and basic technical data for many physical agents are overly complex. They feel that too many specialized mathematical expressions are used and are not readily understood by the average health and safety professional. Others also question whether the exposure guidelines and controls could not be simplified or made more readable.

These concerns are understandable when one recognizes that physics, biophysics, and engineering disciplines are applied most heavily in studies of any physical agent; whereas chemistry, biochemistry, and biological disciplines are fundamental to the studies of the chemical agents. The different approaches in dealing with chemical agents also appear when one examines occupational exposure limits, such as the ACGIH TLV list. If one examines an entry in the chemical substances TLV list, a single line of print is normally sufficient to present the TLV for a single substances. With large groupings of the chemical substances, similar toxicological approaches, similar methods of analysis, and similar methods of controls can apply. Broad statements can be made about each grouping of chemical substances. By contrast, a listing for a physical agent may require several pages to present. A physical agent may act uniquely on one organ or tissues, and these vary with each physical agent. Different physical quantities and units often apply, and different spatial and time dependencies are typical for each agent. Entire books and lengthy standards have been written about each physical agent (3–17).

Toxicological Effects of the Physical Agents
David H. Sliney, Ph.D.

Emission Limits and Exposure Limits
Two fundamental approaches can be taken to control the hazards of a physical agent: control the exposure or control the emission. Product safety standards exist for most physical agents that place the weight of responsibility upon the manufacturer to control emissions from the physical equipment. The product safety standards make use of *emission limits*. The alternative approach places the primary responsibility on the industrial hygienist or health physicist to make use of *human exposure limits* such as TLVs to aid in risk assessment in the workplace and control potentially hazardous exposure (Fig. 96.1). The manufacturer employs product safety measures (engineering controls) to limit emissions and warning labels and product information (administrative controls) to minimize risks. The occupational health specialist can use engineering controls, personal protective equipment, and administrative measures to minimize risk. If the manufacturer cannot completely eliminate hazardous emissions, then the occupational health specialist must evaluate the hazards for a particular operation and recommend appropriate control measures.

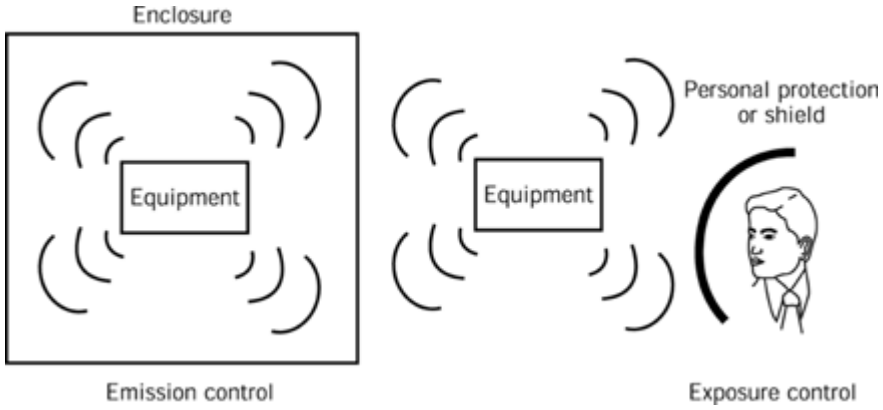

Figure 96.1. The two different approaches to reduce hazards from physical agents: at the source through emission controls or at the worker with exposure controls.

Depending upon the physical hazard and the field of technology, one approach to controlling hazards generally dominates. For example, in the control of hand/arm vibration and whole-body vibration, manufacturer product safety standards play the most important role, although vibration isolation devices such as specialized gloves may also play a role. Optical radiation hazards are frequently dealt with by the product safety approach through lamp safety standards and laser safety standards, but not all lamps and lasers can meet the safe category (e.g., “Class 1 laser product” or “Exempt” lamp), and user controls are required (18–20).

Toxicological Effects of the Physical Agents
David H. Sliney, Ph.D.

Categories Of Physical Agents
When considering physical factors upon health, it is useful to first set out broad categories. The broadest categories are: mechanical, thermal, radiation, and static (or slowly varying) electric and

magnetic fields. Mechanical factors are vibration, noise, and ultrasound. Radiation includes radiant energy across the entire electromagnetic spectrum from power-frequencies of 50 and 60 cycles per second (hertz, Hz) to high-energy gamma rays. Table 96.1 summarizes these physical factors. Within each broad category are subcategories as shown in the table. The physical terminology, measurement methods, and controls vary significantly between each category and these can vary even within a broad category. Figure 96.2 explains the spectrum of frequencies.

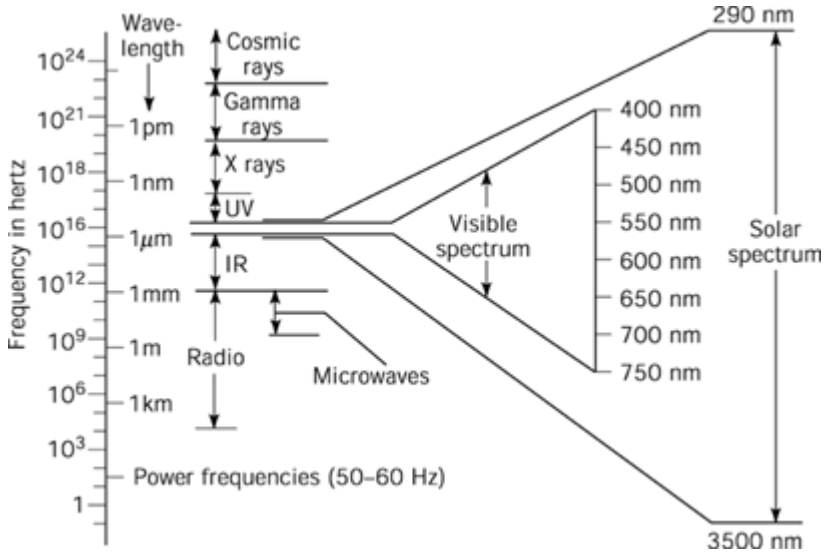

Figure 96.2. The electromagnetic spectrum. Dividing lines are approximate.

Table 96.1. Categories of Physical Agents of Concern

Category of Physical Factor	Dosimetric Concept	Terms and Units
Mechanical Ultrasound Audible noise Infrasound	Airborne power and energy: pressure levels in air	Sound pressure level (SPL) expressed as logarithmic (dB) levels referenced to 10 dyn/cm^2
Whole-body vibration Segmental (hand/arm) vibration	Energy or power conducted by mechanical structures	Transducer
Thermal Heat Cold	Measures of heat exchange of body with environment	Air temperature modified as WBGT air temp./humidity modified by wind
Electromagnetic radiation Ionizing	Absorbed dose 5/kg	Ionization in air (Sv) or absorbed dose (Gy)
Nonionizing Ultraviolet	Radiant power, energy per unit area transferred as electromagnetic waves in free space	W/cm^2 (irradiance or power density)

Visible (light) Infrared Radio frequency (includes microwaves)		J/cm^2 (irradiance exposure or energy density)
Static and slowly varying fields		
Electric fields	Electric field potential across two points in space	Volts/m
Magnetic fields	Magnetic flux concentration	Amperes/m and teslas (T)

Toxicological Effects of the Physical Agents

Extrapolation from Animal to Human

For some physical agents, animal research has not been the focus for research studies. Clinical and epidemiological data have been relied on heavily. The application of a toxicological approach to deriving human exposure limits has not generally been applied to all physical agents, but is aptly illustrated by examining the approach followed in deriving laser limits. Human exposure limits for laser radiation are based upon experimental ocular injury studies. The limits are derived by committees of ophthalmic and occupational health experts through a review of all available threshold data and an understanding of mechanisms of laser/tissue interaction. A major point of discussion in this derivation process relates to the level of uncertainty of the threshold of injury. An indication of the level of uncertainty relates to the slope of the transformed dose–response curve, or the "probit plot" of the data. The most important point on the probit plot is the exposure, which represents a 50% probability of injury: the ED_{50}. It is this value that is frequently referred to as the "threshold," even though some experimental damage points exist below this "threshold." The slope is related to the reciprocal of one standard deviation of the normal distribution of experimental data, and thus it reflects not only natural biological variation, but also the impact of experimental errors. The class of damage mechanism will also alter the steepness of the probit plot. When the steepness is less, it may indicate problems in conducting the experiment. The techniques of probit analysis come from toxicology, and certain inherent assumptions are carried over to laser safety studies.

An analysis of any number of example data sets reveals that the slope in most experiments could not be explained by biological variation alone. This type of critical analysis is essential in deriving exposure limits. For example, if the slope is not very steep, as with some retinal injury studies, the probit curve may suggest that at one-tenth the ED_{50} energy value, there might be a 0.1% risk of injury—a risk generally not acceptable in the laser safety community. Yet, from fundamental biophysical principles, this result could be shown clearly to be flawed. If the ED_{50} energy corresponds to a retinal temperature elevation of 15°, an energy of 10% of the ED_{50} must correspond to 1.5° (10% of the ED_{50} temperature elevation), which could not produce photocoagulation. This aptly illustrates that any derivation of human exposure limits for laser-induced injury requires one to estimate the true biological variation and separate this from the added experimental errors, which reduces the probit slope.

Analysis of reported experimental data indicates that the thermal and thermoacoustic damage mechanisms apparently have an intrinsic slope of approximately 1.15 to 1.2. However, experimental threshold data from retinal studies give slopes that are often much greater (e.g., 1.5–1.7), which is really not surprising. The enormous difficulty of seeing a minimally visible lesion and focusing the laser beam to produce the nearly diffraction-limited image leads to this greater spread of data and shallower slopes. If a probit curve is applied to the derivation of human exposure limits, it should have a slope of 1.2 or less with the ED_{50} point shifted to a lower value.

Toxicological Effects of the Physical Agents
David H. Sliney, Ph.D.

Mechanisms of Action
The interaction of physical energy with biological tissues varies greatly, and this variation accounts for some of the differences in the quantities and units required to assess the potential hazards from the different agents. The interaction can be systemic as in the case of heat and cold stress or organ-specific as in the cases of optical energy focused on the retina of the eye or airborne mechanical energy damaging structures within the car. Cellular response can be very important in the case of ionizing radiation and some photochemical effects from ultraviolet radiation.

To study biological effects and potential hazards of any physical agent, one must examine the possible means of coupling energy into tissue and the mechanisms of interaction with biological tissue. There are many parallels that may be drawn between the different physical agents. In all cases, researchers must examine how power and energy in the environment reaches sensitive biological tissues, the interaction mechanisms at cellular, tissue, and organ level, the biological response as a function of time physical parameters (wavelength, frequency, exposure duration), the time course of biological responses, injury thresholds, the natural means that are employed by biological tissues or organisms to defend against damage from overexposure, and possible subsequent biological repair.

The sensory organs—notably the eyes and ears—and skin are the most typical “routes of entry” of the physical energy which may cause harm. The most sensitive structures vulnerable to damage by physical energy are the sensory structures of the inner car (hair cells) and the sensory cells of the retina of the eye. The means to specify the action of this energy can vary. It may be possible actually to measure, or at least calculate, the power or energy concentration at these target cells. The external levels of acoustic or optical power and energy that result in these internal concentrations depend upon the transmission of the energy by the outer structures of the eye (cornea, aqueous, lens, and vitreous) or the ear (outer ear and transfer structures as the tiny bones of the middle ear). For mechanical energy (acoustic and vibration), one may determine the impedance of energy-transfer structures at different acoustic frequencies; for optical energy, one may determine the spectral transmission at different wavelengths of the ocular media.

Toxicological Effects of the Physical Agents
David H. Sliney, Ph.D.

Dosimetric Concepts
Several physical factors may be relevant to specify dose. Unfortunately, since the biological effects for each physical agent varies, the relevant dosimetric quantities and units vary. For electromagnetic radiation, the same dosimetric concepts may actually have different names because of different

conventions in sister fields of engineering or physics. For example, the incident power in watts per surface area (e.g., W/cm^2 or W/m^2) is termed "irradiance" in the optical spectrum (100 nm to 1 mm in wavelength) and power density in the radio-frequency (RF) region. To add further confusion, geometrical factors sometimes play a role. For example, slightly different radiometric concepts are used in the optical spectrum that have the same units: "fluence rate" has the same units as "irradiance," but includes power equally from all angles without a cosine correction and includes backscatter through the surface area. Unfortunately, not all scientists working in one discipline are rigorous in their use of these physical quantities and develop slightly different conventions, leading to confusion in conducting a review of the literature.

Each physical agent is frequently evaluated by specialists of that one agent, who study the biological effects and potential hazards and have differing conventions for examining damage at the cellular or organ level and expressing their results. In occupational health, one typically finds some specialists who routinely apply the exposure limits and are familiar with the special technology and techniques of hazard evaluation and control. This has led to the criticism that the limits are indeed too complicated or difficult to apply if they require an expert to apply. Furthermore, the presentation of the exposure limits are often succinct (as in the ACGIH TLV booklet), and a generalist feels that insufficient information is provided. The documentation for any ACGIH TLV contains a description of the biological effects of the agent, the relevant research studies and the rationale for the derivation of the TLV. Further clarification about the measurement and applications can also be included, but the TLV booklet presentation will be flawed if it does not provide the necessary caveats in the application of the limits and provide sufficient information for knowledgeable practitioners having training in that agent to apply the TLV.

Toxicological Effects of the Physical Agents
David H. Sliney, Ph.D.

Selected Industries and the Physical Agents Commonly Found

Construction	heat and cold stress, noise, and perhaps vibration and solar ultraviolet radiation.
Meat packing	cold stress
	Laser company or physical/chemical research facility lasers
Metallurgy	heat-stress, UV, laser, RF, or cold stress.

Common airborne sampling procedures and basic instrumentation may cover a large number of chemical substances, but there are many different types of instruments and sampling procedures (specifying exposure geometry, etc.) used for physical agents. For lasers one might need five different instruments to cover all of the conditions covered by the TLV (e.g, pulsed, continuous-wave, ultraviolet, visible or infrared, etc.).

Radio-frequency may apply to many different frequency bands of a single physical agent over a wide spectrum where measurement techniques differ. One can imagine many separate TLVs for small increments of the spectrum; hence the length of the TLV cannot be short without leading to ambiguity and confusion.

Toxicological Effects of the Physical Agents

Conclusions

Occupational health specialists require knowledge of the potential hazards, existing exposure limits, and control technology. Expertise in the physical agents is widespread, but diffused, since different technologies apply to different physical agents. Providing understandable guidance for control of hazards to health from physical agents is not an easy task. Currently available exposure limits and emission limits are generally scientifically well stated, sound and complete, and hopefully not misleading. For example, most of the wording in the ACGIH physical-agent TLVs has been carefully crafted over decades of review and from experience with incidents of misinterpretation, confusion, etc. Hence, the call to "simplify" the TLVs without recognizing these factors should be carefully studied. Perhaps the extensive efforts put into the seemingly lengthy and highly technical physical agent TLVs and related standards explain why they have been used in international standards and have been adopted by other countries. An expert committee of European scientists recommended the adoption of a number of physical agent ACGIH TLVs in the European Community a few years ago.

Cold Stress and Strain
Harry Mahar, Ph.D., CIH

1 Introduction

The human body has the thermoregulatory capacity to maintain its body temperature within about 1° C of normal (i.e., 37°C) under a variety of external environmental temperatures. When the body's heat loss to the environment is greater than its ability to maintain its internal homeostatic temperature, the body undergoes cold strain in response to the external cold temperature stress. Prolonged exposure to any temperature less than normal body temperature to which the body's thermoregulatory capacity cannot accommodate may result in cold-related injuries to tissues or cause other systemic changes, including hypothermia and death. Those injuries may involve local tissue damage that results when the tissue actually freezes (e.g., frostbite) or that can result from nonfreezing conditions in tissue sufficient to cause temporary or permanent vascular damage (e.g., chilblain, immersion foot). Heat loss sufficient to overcome the body's thermoregulatory mechanisms can produce a critical drop in the body's deep-core temperature and eventually hypothermia and death.

Exposure to cold stress may also produce physiological or metabolic changes or shifts in endocrine systems, affect judgment or behavior, or exacerbate existing medical conditions (e.g., cardiovascular disease). For acute exposures, the body's response to cold stress is a function of the rate of heat loss, the temperature to which the individual is exposed, and the duration of exposure. For chronic exposures which produce subtle endocrine and metabolic shifts, the diurnal or seasonal (e.g., circannual) periodicity of that exposure may be more important than the environmental temperature to which the person is exposed. In assessing the impacts of exposures to cold stress, one should differentiate between normal changes that result as the body accommodates to that stress (homeostatic response mechanisms) and actual damage or disruption that result when the body's homeostatic response mechanisms are exceeded.

Cold Stress and Strain
Harry Mahar, Ph.D., CIH

2 Prevalence
Most regions of the globe have environmental temperature fluctuations, seasonally or diurnally, that are sufficiently extreme to produce cold-related injury in unprotected persons. High-latitude areas (e.g., circumpolar regions) of the world in particular experience prolonged and severe periods of deep freezing temperatures, although sufficiently cold temperatures will occur in midlatitude and subtropical climates to produce cold-stress-related exposure risks.

Cold-related injuries are not exclusively freezing injuries, and in fact can occur at environmental air temperatures of ~10°C, whereas continuous immersion in water at temperatures only a few degrees below normal body temperature eventually will produce hypothermia. Morbidity and mortality statistics suggest that cold-related injuries are geographically widespread and appear more dependent on other co-factors than on the actual environmental temperature. Those statistics also suggest that cold stress does not appear to be a substantial occupational risk but rather more of a public health issue. From 1979 through 1992, the annual, age-adjusted death rate in the United States for hypothermia was 0.3 per 100,000, with approximately half of all hypothermia deaths occurring among persons aged 65 years or greater (1). In a survey of 428 cases of civilian accidental hypothermia in the United States, a majority of the cases occurred in urban settings, with 16% occurring in Florida (2). During 1991–1995 in Alaska, 327 persons were hospitalized for cold-related injuries, 46% of which were for hypothermia and 42% for frostbite of the foot (3). In 20% of all the cases, the individual sustained the injury while working. Occupations in which cold stress is an occupational risk include those industries involving outdoor work in cold or cold and wet environments (e.g., commercial fishing, recreational industries, underwater diving, construction and maintenance, military operations, transportation) or work in artificially cold environments (e.g., cold storage/freezer operations). In the nonoccupational setting, individuals pursuing outdoor sport and recreational activities in cold climates are at risk, in one survey accounting for over 50% of all clinical cases of frostbite injuries reported (4). From a public health perspective, cold stress appears to contribute to increased morbidity and mortality from a number of existing medical conditions such as ischemic heart disease and respiratory disease (5). Cold stress affects the elderly, infirm, or indigent (1) or those with personality disorders or substance-abuse problems more frequently or more severely than the average adult population (3, 4).

Cold Stress and Strain
Harry Mahar, Ph.D., CIH

3 Physiological Response to Cold Stress
In homeothermic organisms, the body's temperature, specifically the temperature of the deeper core, is in dynamic equilibrium with the external environment, where internal heat production is balanced against heat loss to the environment. This balance is sustained by the integration of heat production from normal metabolic function (M) and from energy produced during work (W) with the heat exchange due to evaporation (E), convection (C), conductance (K), and radiation (R) and can be expressed in basic thermodynamic principles as:

$$S = M + W \pm E + C + K + R$$

where S represents heat storage in the body and can be a positive (heat gain) or negative (heat loss) term. Both convection (C) and evaporation (E) may have a respiratory component (C_{resp}, E_{resp}) that reflects heat transfer via respiration. These values can be either positive or negative depending upon

the environmental conditions. In normal circumstances, heat is transferred from the human body to the surrounding environment, and the body's core temperature is maintained within about 1°C of the normal body temperature (~38°C) without undue physiologic strain. In humans exposed to environmental conditions colder than body temperature, heat loss will occur, typically via radiation or evaporation. Although a number of factors are involved, a generic representation of heat loss in air or in water is provided in Fig. 97.1.

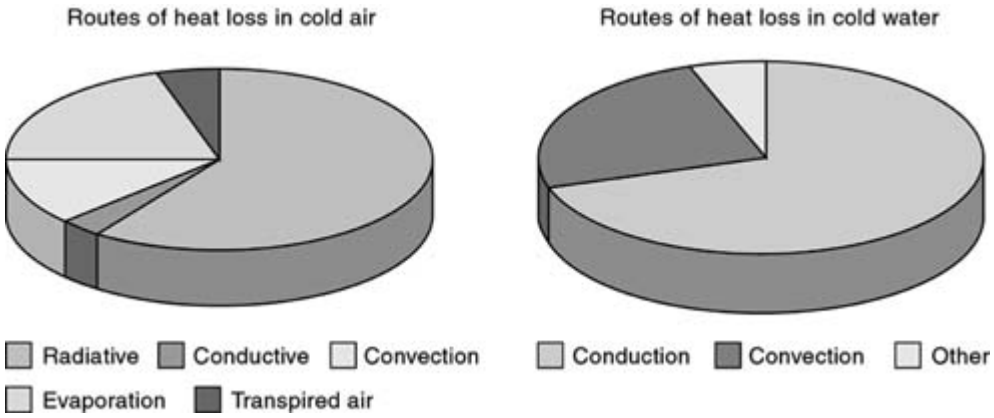

Figure 97.1. Typical routes of heat loss for humans in cold air or in cold water. Adapted from Herington and Morse (7), Toner and McArdle (10), and Danzl et al. (11).

Environmental conditions and the amount of insulating clothing worn will have a significant effect on those heat transfer values, and conductive or convective heat loss mechanisms may predominate under certain circumstances, particularly cold and wet conditions. Movement of cooler air across exposed body surfaces will increase convective heat loss, and forms the basis for the concept of wind chill (6). Clothing provides insulation between the body and the environment, reducing convective and conductive heat losses, but wet clothing provides considerably less insulation than dry, increasing the rate of heat loss up to five fold via those mechanisms (7). Because water has a higher thermal capacity than air, heat transfer from a warm body immersed in cooler water may be from 25 to 70 times greater than in air at comparable temperatures (7, 8). Thermal strain during exposure to cold air is less than immersion in water at comparable temperatures because of the differences in cooling rates (9), but the consequences of continuous exposure in air can be as severe.

An immediate thermoregulatory control mechanism is modulated through the autonomic nervous system, while a delayed control mechanism is modulated by the endocrine system. The hypothalmus acts as the body's temperature control center, regulating both the immediate and delayed control mechanisms based on input from temperature receptors found predominantly in the skin but present in other organs as well.

3.1 Immediate Thermoregulatory Control

Heat loss from the human body to the surrounding environment is a two-phase process. It first involves transfer of heat from the central core to the body's surface, and then from the surface to the surrounding environment. Although some of that heat loss is retarded by the insulating capacity of the tissue, the majority of the heat is transferred by means of the circulatory system. The normal physiologic response to cold stress is (*1*) to retard heat transferred by the circulatory system by constriction of the peripheral blood vessels to reduce blood flow and (*2*) to replace any heat lost to the environment by increasing metabolic heat production, as is indicated conceptually in Fig. 97.2.

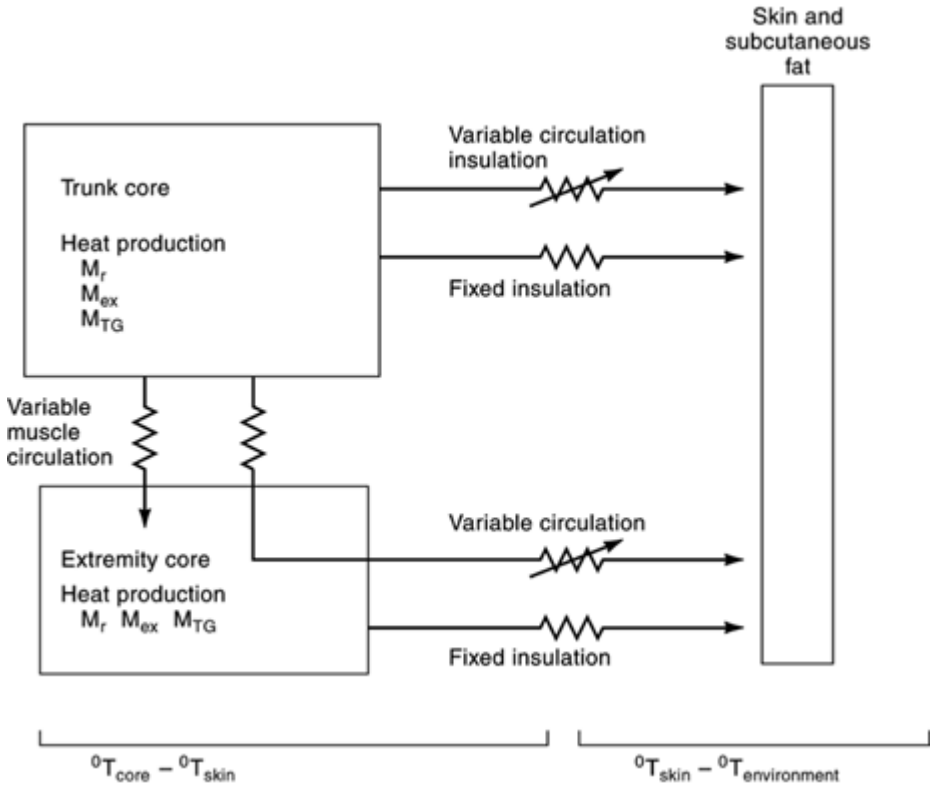

Figure 97.2. Physiologic components of heat transfer. Adapted from Toner and McArdle (10) and Bullard and Rapp (12).

Metabolic heat production may arise from the resting metabolism (M_r), exercise metabolism (M_{ex}), or from thermogenesis (M_{tg}). Transfer of heat between body compartments becomes a function of circulatory output, which is variable, conductive heat transfer from the site of metabolism through the overlying tissue to the surface, and the temperature differential between the compartments and the surrounding air or water ($[T_{core} - T_{skin}]$, $[T_{skin} - T_{environment}]$). Subcutaneous and deep body fat can be major factors in determining the rate of internal and external heat transfer, since thermal resistivities (insulation capacity) of fat are two to five times higher than for skin or muscle (13, 14). The benefits of body fat in maintaining core temperature during immersion in cold water (9, 15–17) and in cold air (18, 19) have been demonstrated in a number of independent studies.

Vasoconstriction of the peripheral blood vessels, particularly in the extremities, provides the primary line of defense against heat loss to the environment. When regional blood flow is reduced, skin temperature drops and begins to approach the temperature of the surrounding environment, thereby increasing the insulating capacity of the skin. This drop in skin temperature is not uniform throughout the body, with greater temperature reductions noted in the extremities and less in the torso areas (21, 22). Heat loss from the body is affected by the change in regional blood flow and the presence of subcutaneous fat, particularly when this vasoconstriction restricts blood flow to tissues underlying these insulating fat layers. In the extremities, a second vasomotor response to cold occurs, cold-induced vasodilation, which alternates with vasoconstriction. This cycling between vasoconstriction and vasodilation, termed the *hunting reaction* (23), provides periodic re-warming of those tissues (thus delaying the onset of freezing injuries) but at the expense of overall body temperature reduction (due to transient increased blood flow at the surface). There appears to be general agreement that as the core temperature is reduced below about 32–35°C, cold-induced vasodilation is reduced and eventually eliminated (10).

Other factors that affect the rate of convective heat transfer from a body immersed in cold water or air include the surface area-to-mass ratio of the body; the temperature differential of the body and

surrounding fluid; and the stability of the boundary layer at the skin-water (or air) interface. In general, as the surface area-to-mass ratio increases, the greater the observed heat transfer (9). The thin boundary layer of water or air at the surface of the skin acts as insulation, because as that layer is heated above ambient, heat conduction through this warmer boundary layer is reduced. Any disruption to this boundary layer increases heat loss, whether that disruption results from air or water currents past the skin surface or is induced by body movement during exercise (24, 25). This suggests that for a body immersed in cold water, any movement (e.g., swimming) removes this insulating boundary layer and exacerbates heat loss (10, 26). The heat produced during the physical movement, (i.e., metabolic heat from exercise) is rapidly lost causing a net loss of body heat to the environment.

Increases in metabolic heat production can allow the body to compensate for any heat lost to the environment and attempt to maintain core temperature. This metabolic capacity is determined by a number of factors, including body size, composition (e.g., muscle mass), nutritional state, endocrine system status, age, and race. Heat production can arise from the resting or basal metabolism (M_r), or metabolic heat from exercise (M_{ex}) or shivering thermogenesis (M_{tg}), as noted in Fig. 97.2, all of which can be expressed in terms of maximum aerobic power or oxygen uptake, V_{O2max} (27, 28). For short-term exposures to cold stress, the resting or basal metabolic rate does not change significantly; so heat production is primarily from muscle contraction during exercise (M_{ex}) or involuntary shivering (M_{tg}). In human infants and some other mammalian species, there may be a nonshivering thermogenesis associated with the aerobic metabolism of brown adipose tissue, but that does not appear to occur in human adults (10, 29). The resting metabolic rate may change over time (e.g., seasonally) as a result of delayed thermoregulatory mechanisms mediated by the endocrine system (30–32).

The increase in metabolic heat production from muscle contraction during exercise and/or shivering varies with the severity of the cold stress as the body attempts to replace the heat lost to the environment. Shivering may contribute up to ~50% of an individual's V_{O2max} during immersion in cold water (28) and somewhat less in cold air (33). While exercise or shivering increases heat production, the increased blood flow to the muscles also facilitates heat loss; so there may be a net loss of body heat in cold water. In contrast, exercising while exposed to cold air provides an effective means of maintaining thermal balance, since convective and conductive heat losses are less than in water. For an unclothed person at rest immersed in cold water or air, there is a critical environmental temperature below which an increase in energy metabolism (i.e., M_{tg}) is noted as the body attempts to replace heat lost to its surroundings. This critical temperature of the surrounding air or water can be correlated to the insulating capacity of the skin and subcutaneous fat deposits (expressed as skinfold thickness). As the body core temperature drops below 35°C, tissue metabolic rates decline with decreasing body temperature (34), accelerating the drop in body core temperature and the onset of hypothermia. Because of this decline in metabolic rate, 35°C is generally considered that body core temperature threshold below which the cold-stressed individual cannot recover without outside intervention.

The increased cardiac output needed to sustain this oxygen transport to the muscles in support of higher metabolic rates results from an increase in stroke volume rather than an increase in heart rate (35). The substrate source to fuel this increased metabolic activity appears to be an increase in carbohydrate and lipid oxidation, rather than protein oxidation (36, 37). Substrate mobilization and utilization appear to be the limiting factors in sustaining prolonged increases in exercise or shivering thermogenesis (37), along with the lactate threshold of exercising muscles (38). Therefore, muscle fatigue appears to be the most significant factor in hypothermia incidents where prolonged exposure to even mildly cold conditions was involved (39). It has been demonstrated that fit subjects also have more efficient thermoregulatory abilities against cold stress than unfit subjects because of an improved sensitivity of the thermoregulatory system (40).

3.2 Delayed Thermoregulatory Control

Two major hormonal mechanisms affect human cold tolerance. During cold exposures there is an immediate release of catecholamines (e.g., norepinephrine, dopamine), which activate the sympathetic nervous system to reduce heat loss via peripheral vasoconstriction and shift substrate utilization toward fatty acid metabolism for heat production. The hypothalamic–pituitary–thyroid axis provides the second hormonal control mechanism for regulating physiologic response to cold stress, with thyroid hormones (particularly triiodothyronine, or T_3) being the most influential (30). Whereas the catecholamines appear to act during the acute stages of cold exposure, the thyroid hormones are the primary mechanism for adapting to chronic cold exposures, such as those resulting from seasonal temperature changes or from the relocation of individuals from temperate to polar climates. These thyroid hormones stimulate a general increase in metabolic rate by increasing the activity of the enzyme sodium–potassium adenosine triphosphatase (Na–K ATPase), thereby decreasing the efficiency of mitochondrial oxidative phosphorylation (30, 41). This stimulation of T_3 kinetics (and its precursors) is noted initially within 2 wk of chronic cold exposure and eventually equilibrates within a 4–6-mo time period. This phenomenon has been characterized as the Polar T_3 Syndrome (42, 43).

Studies have shown an increase in energy requirement (up to 40%) for persons relocating from a midlatitude, temperate climate to a colder, high-latitude, polar climate (44). Some of this increase can be accounted for by an increase in resting metabolic rate or by a reduction in the efficiency of muscle activity at a predetermined workload (45) brought about by the stimulation of Na–K ATPase. These changes have been correlated with thyroid hormone levels, particularly T_3 in skeletal muscles, and are similar to other conditions involving thyroid hormone excess (46). This delayed hormonal response to cold stress has been demonstrated in populations exposed to chronic cold environments as well as in occupational groups intermittently exposed to cold conditions during normal work shifts (47) or in experimental subjects exposed to repeated short-duration cold exposures (48, 49). Changes in thyroid hormone levels resulting from prolonged habitation in Antarctica have been correlated with increased total serum cholesterol and high-density lipoprotein (HDL) cholesterol, a response consistent with other medical conditions of thyroid hormone imbalance (50). Changes in thyroid hormone levels have also been correlated with increased depressive symptoms and reductions in cognitive performance characteristic of Winter-Over Syndrome found in persons spending the austral winter in research stations in Antarctica (51).

Cold Stress and Strain
Harry Mahar, Ph.D., CIH

4 Adaptation

Humans can adapt to continuous or intermittent cold stress through a variety of mechanisms, usually related to the individual characteristics of the subjects (e.g., diet, fitness level, body fat) and the duration and severity of the cold stress. Physiologically, these adaptations can be characterized as (*1*) metabolic, where there is an alteration in metabolic heat production; (*2*) insulative, where there are improvements in heat conservation through more effective peripheral vasoconstriction; or (*3*) hypothermic, where a lower core body temperature than normal is tolerated before shivering occurs.

These physiological adaptations have been demonstrated in aboriginal peoples residing in high-latitude environments (e.g., Eskimos, Lapps) or in areas with significant diurnal temperature variations (e.g., Australian Aborigines, Kalahari Bushmen) (52–56). These types of adaptations have also been demonstrated in individuals intermittently exposed to cold stress in the occupational setting or in experimentally manipulated environments.

Longitudinal studies carried out in breath-hold divers in Korea subjected to repeated underwater dives in cold (~10°C) water have demonstrated all three adaptations—metabolic, insulative, and hypothermic (57–60). During the winter months, these divers developed an approximately 35% increase in basal metabolic rate over nondiving controls, apparently due to increased uptake of thyroid hormone in tissues (61). Studies of fishermen who immerse their hands repeatedly in cold water have demonstrated an insulative response locally in the cold-exposed hands. These fishermen developed a more rapid cycling of the vasoconstriction and vasodilation response in the cold-exposed hands and were able to maintain motor function in the hands in the cold water without a drop in body temperature that one might expect with increased peripheral vasodilation (62, 63). This insulative-type adaptation has also been hypothesized to occur in individuals working in Antarctica for an austral winter season who were able to sustain significant experimental cold challenges (e.g., standard cold air tests) without a concomitant drop in body core temperature (64). It is not clear whether these responses were due to insulative adaptations or reflected a change in energy balance resulting from delayed thermoregulatory controls mediated through the endocrine system.

Note that the type of cold adaptation that develops (i.e., metabolic, insulative, or hypothermic) is closely related to the cold stress to which the individual is exposed and the characteristics of the subjects (e.g., diet, age, physical fitness level, body fat content). As a result, different individuals exposed to the same environmental conditions may develop different adaptation approaches to accommodate to that stress.

Short exposures to severe cold may elicit different adaptive responses than prolonged exposures to moderate cold (65). Deacclimatization occurs over time, usually over a comparable time scale as was needed to produce the adaptation initially, but it may take several years to disappear completely, as was demonstrated in Korean breath-hold divers (57, 66). These adaptation responses to cold stress appear to confer a survival advantage to some aboriginal populations and to provide a modest benefit to certain cold-stressed groups.

Because anthropometric differences (body size, surface-to-mass ratio, fat composition) between individuals account for most of the variability in response noted in populations exposed to cold stress, it is difficult to define the magnitude of the contribution of adaptation processes to maintaining thermal balance. However, these adaptations provide only small improvements in body heat conservation compared to other heat-conserving alternatives such as the use of protective clothing; so their benefit in protecting the individual from cold stress should not be overstated. Short-term acclimatization to cold stress does not appear to convey as significant a physiological advantage as the acclimatization to heat stress that is observed in individuals exposed repeatedly to heat-stress conditions.

The delineation between the physiological changes indicative of normal adaptive response to cold stress (where the individual is accommodating the stress without long-term injury or detriment) and the physiological changes indicative of actual injury may be difficult to establish clearly in some instances. It is not uncommon for an individual's skin or core temperature to be lowered during exposure to cold stress without the individual sustaining any long-term damage or significant physiological strain. For example, individuals wintering in Antarctica and who have had an opportunity for adaptation may demonstrate a reduction in average body core temperature of more than a degree Centigrade with no long-term detrimental sequelae. On the other hand, a one-degree reduction in body core temperature in an individual exposed to an acute cold stress may indicate an excessive rate of heat loss in that individual and possible impending hypothermia.

5 Cold-Related Injuries

Direct tissue injuries resulting from acute exposures to cold stress can be categorized into several groupings, the most common being freezing cold injuries (where the affected tissues are frozen) and nonfreezing cold injuries (where the affected tissues never freeze but sustain damage from the cold stress). Examples of freezing cold injuries include frostbite and its less severe precursor, frostnip. Nonfreezing cold injuries include cold urticaria, chilbain and its more severe form pernio, trenchfoot, and immersion foot. Typically, freezing cold injuries occur when the environment is sufficiently cold and dry for the exposed tissue actually to freeze, whereas nonfreezing injuries occur in cold (but not freezing) and wet or moist/humid conditions, often as immersion in cold water. Nonfreezing cold injuries are time/temperature dependent—the warmer it is, the longer the time required to produce damage. Some nonfreezing injuries can occur at environmental temperatures as high as 16°C (60°F), but may take many hours or days to develop. Freezing cold injuries are usually determined by the rate of heat loss, and may manifest themselves within seconds or minutes.

Hypothermia is a condition associated with a lowering of body core temperature below which normal thermoregulatory and physiological functions are disrupted. The condition is not associated with specific tissue damage *per se*, as is frostbite or pernio, and can occur in association with either freezing or nonfreezing injury scenarios. Hypothermia may be produced in either cold/wet or cold/dry conditions, and may occur in what are considered warm conditions. For example, individuals can be immersed in water only a few degrees below normal body temperature and lose heat to the environment, eventually becoming hypothermic.

In chronic cold stress, shifts in thyroid hormone production and uptake have been demonstrated and are considered part of the normal adaptation process. Decreases in immune function, sperm function, and testicular cancer have been associated with cold stress. There are other sequelae from cold stress that do not demonstrate frank pathology but nonetheless might be considered injuries. Decrements in performance and work capacity, cognitive function, and mood disturbances are examples.

5.1 Nonfreezing Cold Injuries

5.1.1 Chilblain Chilblain is a recurrent localized erythema and swelling caused by exposure to cold (67, 68). The condition typically occurs on the hands and feet and occasionally on the ears and face in children. The affected area becomes red and swollen, with blistering and ulceration in the more severe cases, and is accompanied by a burning and itching sensation. The injury appears to result from repeated vasodilation and constriction with localized histamine release in the affected tissues (7, 69). It is produced by exposure to cold [anywhere from just above freezing up to 16°C (60°F)] and damp conditions, usually over long periods of time (i.e., many hours). Such environmental conditions frequently exist within rubberized boots and footwear, where the humidity can be high. Seasonally recurring chilblains on the hands (e.g., “milkers' chilblains” in dairy farmers) can occur, often aggravated by sunlight (70). Persons with poor peripheral circulation are predisposed to chilblain and may exhibit the condition after exposure to only moderately cold temperatures. Chronic chilblain occurs repeatedly in cold weather and disappears in warm weather, and can persist is some individuals for many years. Other predisposing conditions include Raynaud's syndrome and collagen-vascular diseases such as systemic lupus erythematosus (7, 71).

5.1.2 Pernio Pernio is a more severe form of chilblains, where the affected skin areas become necrotic and may slough off, leaving painful lesions that are slow to heal. The depth of the injury is dependent on the duration of exposure. As with chilblain, persons with certain existing conditions (e.g., Raynaud's syndrome, lupus erythematosus, and other skin lesions) are more susceptible. Persons with anorexia nervosa, with its attendant altered thermoregulation and hyperactive peripheral vascular response to cold, may also be at increased risk (72). It is difficult to establish precisely the environmental conditions of temperature, humidity, and duration of exposure that lead to the development of chilblains or perniosis, since many sufferers have existing conditions predisposing them to problems. However, exposure to moderately cold (but not freezing) temperatures, coupled with humid or wet microenvironments for hours may be sufficient to produce the condition. Recurrent pernio can be particularly painful to individuals upon re-exposure to cold conditions.

5.1.3 Trenchfoot and Immersion Foot Trenchfoot and immersion foot are comparable injuries, the former caused by exposure to cold/moist environments and the latter caused by immersion in cold water. Both can occur at temperatures from just above freezing to about 10°C (50°F), particularly if the individual is immobile or is wearing constricting footwear, with an exposure time in excess of 12 h (longer for the warmer temperatures). Pathology is indistinguishable between the two conditions, and is a result of ischemia and anoxia from prolonged vasoconstriction of the blood vessels. Injury shows a clear time–temperature relationship. Such nonfreezing injuries are cumulative and include vascular damage, tissue atrophy, peripheral neuropathy, blistering and ulceration of tissue, and possibly gangrene (7, 67, 69, 73–75). Peripheral nerve damage seems to favor large myelinated fibers (76, 77) and the distal portions of the nerve at the nerve fiber–receptor junction (78). Persistent pain, particularly on re-exposure to cold, is common in persons recovering from trenchfoot injury. Prior trenchfoot sufferers may develop Raynaud's syndrome, an abnormal maintenance of vasoconstriction in the fingers and toes (67). Individuals with poor peripheral circulation appear predisposed to developing trenchfoot, with one study suggesting up to 60% of the normal population base to be at risk (79).

5.2 Freezing Cold Injuries—Frostbite and Frostnip

Frostbite, and its less severe precursor frostnip, develops when tissues freeze, and can evolve slowly over several hours or rapidly (within minutes). Such freezing occurs when the body is unable to maintain sufficient warmth in the affected tissues because the rate of heat loss exceeds the capacity of the body to reheat the area through vasodilation. Freezing cold injuries can be subdivided into superficial (limited to the skin and adjacent subcutaneous tissues) and deep frostbite. Tissue damage is due to the direct effects of ice crystal formation in the tissues, the effects of vascular stasis and accompanying tissue anoxia, and the loss of integrity of the vascular system (7, 67). As the tissue freezes, ice crystals form in the extracellular spaces, dehydrating the adjacent cells and disrupting the cell membranes. During rapid freezing, ice crystals may form intracellularly, producing more extensive tissue damage. As blood flow in the cooling tissues is reduced by vasoconstriction and lowered temperature, oxygen tension is lowered, and diffusion rates into surrounding tissues decrease, combining to produce anoxia in the more distant tissues. Tissue freezing causes endothelial cell damage in the microvasculature, with destruction of the vessel walls, as well as plugging of the lumen of the vascular tree and capillary beds with cellular debris and fibrin, so that tissue healing after thawing is difficult because of the vascular destruction (67, 80, 81). Cell types differ in their susceptibility to frostbite, with nerve, muscle, and bone tissues more sensitive than skin.

The rate of heat loss in the tissue exposed to cold stress is an important determinant in cold injury (82). For exposed skin, air movement across the skin surface increases heat loss above that lost by the temperature differential alone. This concept of “wind chill factor,” originally derived from empirical measurements (6), can be used to predict the onset of frostbite in skin exposed to cold, dry air under various wind speed conditions. Ophthalmic injuries have occurred, particularly freezing of the cornea, in individuals who force their eyes open in high windchill conditions (e.g., snowmobiling, cross-country skiing) (80). Exposed skin in contact with cold metal objects may freeze very quickly because of the high conductive heat loss, although those types of injuries tend to be superficial rather than deep frostbite injuries. Evaporative heat loss during skin exposure to supercooled liquids may cause almost instantaneous frostbite.

Certain host factors may predispose individuals to frostbite injuries. Drugs that impair thermoregulation or vasodilation, alcohol, diabetes mellitus, peripheral vascular disease, and previous cold injury predispose individuals to frostbite injury (7, 83). Attenuated or abolished cold-induced vasodilation (i.e., “hunting reaction”) or persistent vasoconstriction of peripheral blood vessels evident in Raynaud's syndrome or cold-induced white finger disease make individuals susceptible to frostbite injuries (84–86). Dermatologic conditions that increase heat loss through the skin may increase the individual's risk of developing frostbite (11).

Cold Stress and Strain
Harry Mahar, Ph.D., CIH

6 Hypothermia
Hypothermia is defined as a drop in body core temperature to 35°C (95°F) or lower. It occurs when the body continually loses heat to the environment and is unable to maintain normothermic core body temperature through available mechanisms of heat production (e.g., basal metabolism, exercise, shivering) and heat conservation. When the body's core temperature drops below about 35°C, it becomes difficult or impossible for the individual to recover on his own, and outside intervention is required for survival. Environmental conditions that increase the rate of heat loss (e.g., high wind chill; cold and wet conditions; water immersion) are particularly dangerous, as are situations where the individual is unable to sustain metabolic heat production (e.g., muscle fatigue, malnutrition, forced inactivity). Typical routes of heat loss by the body have been described earlier (refer to Fig. 97.1). Environmental temperatures do not need to be below freezing to cause hypothermia; in fact, cool temperatures coupled with rain and moderate wind conditions create significant hypothermic risks.

As the body begins to cool and lose water from cold diuresis, the circulating blood volume decreases along with a concomitant increase in blood viscosity and peripheral resistance. Cardiac arrhythmias develop, leading eventually to ventricular fibrillation and asystole. Respiratory rate gradually decreases with progressive cooling, along with tidal volume proportional to the drop in metabolic demand. At a core temperature of about 32°C, the respiratory rate becomes insufficient to remove CO_2, and respiratory acidosis occurs (11, 67). As the body cools there is a decrease in cerebral metabolism and a general depression of central nervous system (CNS) function. Cerebral blood flow is reduced 6–7% for every 1°C reduction in body temperature between 35°C and 25°C (7). Temperature-dependent enzyme systems present in the brain may be more sensitive to temperature than in other organs, where colder temperatures seem to be better tolerated. On initial chilling of the body, a significant volume of urine is voided (i.e., cold diuresis), an apparent response to the hypervolemia induced by vasoconstriction (87). Renal circulation is decreased as the core temperature decreases, with about 50% of the normal flow when the body is cooled to 28–30°C. Many of these physiologic responses to hypothermia are so predictable that intentionally induced hypothermia is routinely used in certain surgical procedures to manipulate organ and system functions to the patient's advantage.

Mild hypothermia may occur frequently in individuals, often insidiously. Because normal body temperatures are restored eventually, with no long-term sequelae developing, these hypothermic incidents often are ignored. Underwater divers, in particular, are at risk of this insidious hypothermia when making repetitive dives in water only a few degrees below normal body temperature because body heat can be transferred to the surrounding water so rapidly. In addition, if water is only a few degrees below body temperature (e.g., ~28°C), normal heat conservation responses may not be triggered to respond to the cold stress, but the body will gradually cool to a little below 35°C without noticeable discomfort or shivering (88). Individuals progress through the sequential stages of hypothermia during cold-water immersion as they do during exposure to cold air but tend to pass through those stages more rapidly because of the increased rate of heat transfer from the body to the environment. Cold-induced diuresis is increased more than threefold during cold-water immersion compared to thermally neutral water and appears greater than produced during cold air exposure, apparently due to the affects of “hydrostatic squeeze” in submerged tissues (89).

Without monitoring the individual directly, it is difficult to predict when hypothermia will occur in a person exposed to specific cold conditions, since host factors, activity level, environmental conditions, and clothing all influence its progression. Body morphology, particularly subcutaneous fat deposits, is a prime determinant in defining the rate of heat loss to the environment. Conditions that influence metabolic heat production (such as endocrine diseases, age, and nutritional status), or

thermoregulation (such as anorexia nervosa or diabetes mellitus), affect one's susceptibility to hypothermia. Conditions that influence heat loss, such as certain dermatological diseases (e.g., psoriasis, eczema) or burns will affect susceptibility. Certain drugs and alcohol can increase heat loss or impair thermoregulation. Environmental conditions that increase the rate of heat loss to the environment, such as wind speed or water immersion, will exacerbate the hypothermic situation. Conversely, insulating clothing that retards heat loss to the environment will reduce the risk of hypothermia under cold or freezing conditions. Table 97.1 summarizes the clinical presentations of hypothermia.

Table 97.1. Clinical Signs of Progressive Hypothermia

Core Temperature (°C)	(°F)	Clinical Signs
37	98.6	Normal body temperature (±0.6°C)
35	95.0	Maximum shivering occurs (M_{tg}; see text)
34	93.2	Victim conscious, progressive disorientation; rewarming may require intervention, cerebral blood flow decreases (6–7% per °C reduction)
33	91.4	Ataxia, disorientation
32	89.6	Respiratory rate decreases to ~75% of normal; respiratory acidosis occurs
31	87.8	Involuntary shivering may cease
30	86	Cardiac arrhythmia develop; renal circulation reduced to ~50% of normal; cardiac output reduced
29	85.2	Progressive loss of consciousness; pulse and blood pressure difficult to obtain
28	82.4	Ventricular fibrillation probable with rough handling; cerebral blood flow ~50% of normal
27	80.6	Voluntary motion ceases; reflexes absent
26	78.8	Victim seldom conscious; major acid–base disturbances
25	77	Ventricular fibrillation may occur spontaneously; cerebral blood flow ~30% of normal
24	75.2	Pulmonary edema probable; significant hypotension
22	71.6	Maximum risk of ventricular fibrillation; oxygen consumption reduced 75%
20	68	Lowest temperature for resumption of cardiac electromechanical activity
18	64.4	Asystole
16	60.8	Coldest adult hypothermia victim to recover
9	48.2	Coldest therapeutic hypothermia patient to recover

Cold Stress and Strain
Harry Mahar, Ph.D., CIH

7 Other Effects of Cold stress

Exposure to cold stress, either as a short-term, acute exposure, or as a result of chronic exposure, including seasonal weather changes, may cause other conditions than those already mentioned. Decrements in performance or work capacity, cognitive function, endocrine function, immunological responses, and respiratory system changes, along with potential carcinogenic or reproductive impacts and general malaise, have been associated with acute or chronic exposure to cold stress.

7.1 Manual Performance/Work Capacity

Performance of manual tasks, particularly those requiring dexterity, has been shown to deteriorate the longer the individual is exposed to cold stress or the more severe the cold exposure. As regions of the body cool in response to cold stress, muscle tissues also cool, and with that cooling comes a decrease in maximal aerobic power, as measured by V_{O2max}. For example, a reduction in muscle temperature from 39.3°C to 35.1°C produced a 15% decrease in V_{O2max} (90). Aerobic power is a function of the rate of ATP splitting, whose velocity constant is temperature dependent (91), so as the muscle mass cools, the rate of ATP splitting is reduced. In addition, a reduced body temperature also reduces cardiac output, thereby limiting available oxygen to the muscle tissues (36, 90, 92). In cold-water immersion studies (at 10°C), forearm grip strength dropped approximately 1.8% per minute after 5 min of exposure (93). The ability to perform complex manual tasks is also affected by cold. Fine motor control may be lost when skin temperatures of the hand reach 12–16°C, and tactile sensitivity lost at about 8°C (94). However, the rate of cooling, particularly to the deeper tissues of the hand and arm, rather than actual skin temperature, may be a better predictor of such performance degradation (95, 96). The impacts of cold stress on manual performance depend on the tasks to be performed, with greatest impact on those tasks requiring fine motor skills, rapid finger movement, or joint flexibility.

7.2 Cognitive Function

Exposure to cold stress, especially when sufficient to cause mild or severe hypothermia, has been associated with reductions in cognitive functions, including short-term memory, quantitative or discrimination skills, and judgment or decision-making. This decrement in cognitive functions becomes particularly important when individuals are becoming hypothermic and fail to recognize it or are unable to take the proper steps to remedy the situation before the situation becomes extreme.

The effects of cold stress on cognitive functions include decrements in performance of tasks requiring vigilance, memory (particularly short-term memory), and rapid and accurate judgments under time constraints. Negative effects on memory and recall (97) and on more complex mental performance (98) have been associated with reductions in body core temperature of 2–4°C. Decrements in reaction time, tracking efficiency (e.g., visual-motor coordination), and time estimation have also been associated with cold stress (98). Cognitive impairment, as measured by standardized delayed matching-to-sample (DMTS) tasks, has been associated with acute cold stress and attributed to the effect of cold on short-term, or working memory (99).

A variety of physiological stresses, (87) including cold exposure, disrupt the sustained release of central nervous system catecholamines (i.e., norepinephrine and dopamine), which are needed for maintaining neurotransmitter release. It has been hypothesized that the inability of these neurons to sustain normal levels of release during acute cold exposures could be responsible for the observed deficits in cognitive function and working memory (100). The administration of supplemental tyrosine, a necessary precursor for catecholamine biosynthesis, appeared to allow for the continued biosynthesis of those neurotransmitters during cold exposure, preventing a cold-induced memory deficit as measured by the DMTS tasks. It is unclear whether the effects of less extreme cold stress—that is, exposure to moderate or short-duration cold exposures that are not sufficient to cause a reduction in body core temperature or a significant release of catecholamines—cause a measurable effect on these higher-order cognitive functions (101). Preliminary reports suggest the possible

effects of chronic cold exposures (e.g., seasonal residence in Antarctica) on cognitive function, memory, and mood and the role thyroid hormones may play in the process. Within the first several months of Antarctic residence, memory declined by about 13% in individuals but could be restored in those taking thyroxine supplements, whereas the placebo group's memory levels remained depressed throughout the remainder of the Antarctic winter (102).

7.3 Endocrine Function

The endocrine system plays a role in the physiological response to cold stress, providing immediate thermoregulatory control via the sympathetic nervous system and a delayed thermoregulatory response via the hypothalamic–pituitary–thyroid axis. The immediate release of catechloamines during acute cold exposure, primarily norepinephrine and dopamine, affect peripheral vasoconstriction and shift substrate utilization toward fatty acid metabolism for heat production. During prolonged exposure to cold environments (e.g., seasonal changes), the thyroid hormones, particularly triiodothyronine or T_3, stimulate an increase in the basal metabolic rate to accommodate long-term adaptation to the cold stress. This hypothermic cold adaptation begins to develop within several weeks of cold exposure, even though only the hands and face may be directly exposed to the outdoor temperature (48). Both the short-term catecholamine release and the delayed T_3 increase are normal physiological responses to cold stress and are not considered detrimental. However, the asymptomatic compensatory increase in thyroid hormone levels is suggestive of a partially corrected subclinical hypothyroidism condition (50), which may be indicative of subgroups within the general population potentially sensitive to cold stress. Altered baseline thyroid hormone levels, particularly T_3 levels, appear to be associated with resident populations in high Arctic latitudes when compared to reference populations in warmer climates (103) and may indicate a genetic adaptation to the circumpolar environment (104).

7.4 Respiratory System Reactions

Heat loss through respiratory gas exchange can be a significant contributor to body heat loss (~30%), particularly during periods of high ventilation rates. Inhalation of cold air can lead to a number of acute and chronic respiratory problems. Bronchospasms and brochorrhea (excess fluid in the airways) have been experienced in underwater divers breathing cold (0–7°C) compressed breathing gas in thermoneutral water, with the symptoms resolving if the gas was warmed (i.e., 23–32°C) and humidified (105). Exercise- and cold-induced asthma produces airway narrowing and increased airway resistance. The immediate airway response (within 5–15 min poststimulus) is thought to be due to rapid removal of heat and moisture from the respiratory tract, while a late-phase response (4–10 h poststimulus) in some individuals seems to be triggered by chemical mediators, possibly histamine (106, 107). Exposure to cold air (–23°C) increases the number of inflammatory cells in the lower broncho-alveolar airways in healthy subjects and has been implicated in the development of a chronic asthmalike bronchoconstriction noted in healthy subjects exercising in cold conditions (108). The initial onset of high-altitude pulmonary edema (HAPE) and other respiratory conditions brought on by heavy exertion and high ventilatory rates in cold air (e.g., “frosting” of the lungs) may be a result of cold-induced bronchorrhea. Chronic effects, such as “Eskimo lung,” similar to chronic obstructive pulmonary disease (COPD), occurs in individuals chronically subjected to hard physical exertion in severe cold. Although the disease may have a complex etiology, the increase in pulmonary arterial pressure and pulmonary hypertension produced from recurrent episodes of heavy exertion in cold conditions seems to establish the disease (106).

7.5 Immunological Responses

Studies of seasonal or temporary (up to one year) residents in Antarctica have suggested that changes to cell-mediated and humoral immunity may occur. It is not clear whether these changes are a result of cold or isolation stresses or the relative absence of other environmental immunological triggers, but the diminished immune function occurs within the first month of arrival in Antarctica (109, 110). However, year-long periods of isolation in Antarctic research stations have not resulted in enhanced susceptibility to respiratory infections (111, 112). Acute cold exposures have an immunostimulating effect that may be related to circulating norepinephrine levels (113).

7.6 Carcinogenesis

Cold stress has not been linked to carcinogenicity except in the case of testicular cancer. The normal extra-abdominal position of the testes makes it difficult for the body to maintain appropriate

temperatures within the scrotal sac during environmental temperature fluctuations without the benefit of protective clothing. Such testicular temperature variations have been associated with a reduction in spermatogenesis, sperm count and motility, and an increase in abnormal sperm morphology (114, 115). Several retrospective epidemiological studies have suggested an association between high and low environmental temperatures and an increase in testicular neoplasms (116, 117). However, there is an absence of data linking actual testicular tissue temperature to these adverse outcomes, and the association between environmental cold stress and testicular cancer remains statistical in nature.

7.7 General Health Complaints

Intermittent exposure to moderate cold stresses (e.g.,–5 to 15°C) in the work environment has been associated with a number of general health complaints and the exacerbation of existing conditions that may be influenced by cold exposures. Work in refrigerated food processing facilities, for example, has been associated with general discomfort, respiratory problems, rheumatic complaints, and back and joint pain (118, 119). Rapid-onset Raynaud's syndrome or cold-induced white finger has been linked to the repetitive vasoconstriction response to cold exposure, and is exacerbated in the presence of hand vibration or high grip forces (86, 118). In a number of situations involving moderate cold exposures, there is a high prevalence of nonspecific symptoms or health complaints and reports of general thermal discomfort that are not correlated reliably with specific environmental conditions (e.g., air temperature, air movement, surface temperatures). Although these effects have not been established unequivocally, they occur with such regularity to suggest a possible risk to health or worker performance.

Cold Stress and Strain
Harry Mahar, Ph.D., CIH

8 Combined Effects with Other Physical Stresses

Prolonged cold exposure has been associated with higher prevalence rates of several musculoskeletal disorders, in particular vibration-induced white fingers and nonspecific cumulative trauma disorders often evident in refrigerated meat and poultry processing facilities. Vibration-induced white finger, or secondary Raynaud's phenomenon, also is common in forestry occupations in cold climates and appears to be associated with not only vibration but also grip forces exerted on the vibrating implement (120). It is thought that the repeated vasoconstriction in the extremities associated with cold exposures exacerbates the development of vibration-induced white finger, an acknowledged occupational disease of multifactorial origin.

The prevalence of noise-induced hearing loss appears to increase when accompanied by cold exposure, and the time-to-onset of the disease may be more rapid (118, 120).

Cold Stress and Strain
Harry Mahar, Ph.D., CIH

9 Control of Cold Stress

In evaluating whether exposure to cold stress in a particular situation is detrimental and should be discontinued, one must focus on the particular end point of concern. Most current regulations or standards have been established to influence survival (e.g., hypothermia) or to prevent the development of adverse physiological effects (e.g., frostbite, chilblain). Conversely, certain guidelines or standardized industry practices have been developed to maintain or enhance performance of manual tasks or to maintain or improve subjective comfort levels. This distinction between discomfort versus frank physiological damage must be kept in mind when comparing

particular industrial standards or regulations—if the end points of concern are not comparable, then any comparison of permissible exposures to cold stress will be inappropriate. One must also keep in mind whether particular indices of cold exposures are normal physiological responses to the stress. For example, it is normal for the body's core temperature to fluctuate within certain temperature ranges as the body accommodates to the heat lost to the surrounding environment. There are minimal physiological impacts so long as that thermoregulatory capacity is not exceeded. However, if an exposure standard is based on the assumption of maintaining thermoneutrality in a given exposure situation (i.e., no net reduction in body temperature), then one is ignoring the capacity of the body to accommodate to that cold stress. At some point, perceived comfort and work performance may be impacted, but without the individual experiencing adverse health impacts.

Cold Stress and Strain
Harry Mahar, Ph.D., CIH

10 Exposure Standards

Regulations or standards defining acceptable cold-stress situations rely on one or a combination of approaches to control cold stress. Those traditional approaches include behavior (e.g., modifying work rates, adjusting clothing ensembles), use of insulating clothing to reduce heat loss, limiting the time of exposure to the cold environment, and by providing localized or general heating within the area. A summary of the prevalent national or international exposure guidelines are provided below.

10.1 ACGIH Threshold Limit Value

The American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value (TLV) (121) for cold stress is a series of exposure limits intended to (*1*) prevent body core temperature from falling below 36°C (i.e., hypothermia) and (*2*) protect against cold injuries to the extremities. Whole body and extremity cooling is based on the wind chill index (WCI), a derivation of the concept of the wind chill (6), and is intended to protect exposed skin from freezing by limiting exposure times. A modification of that index (not included in the TLV), the "apparent temperature" (122), incorporates additional meteorological parameters beyond temperature and wind speed that influence heat loss to the environment (e.g., relative humidity, solar radiation). The TLV also addresses conductive heat loss through cold objects. The TLV focuses on prevention of hypothermia and freezing cold injuries, but does not address directly nonfreezing cold injuries or chronic impacts of cold stress.

10.2 ISO TR 11079

The International Standards Organization (ISO) Technical Report 11079 utilizes the IREQ index (i.e., "insulation required") to maintain body heat balance based on clothing, metabolic heat load, and environmental conditions (111). Under the prescribed conditions, if the IREQ cannot be met to maintain "comfort" (i.e., thermoneutral) or "just acceptable" (i.e., minimal), then maximum exposure times to the cold stress can be established to maintain thermoneutrality. The IREQ provides a useful approach to whole body cooling in indoor and outdoor environments, but does not address extremity cooling to any significant degree. A family of related ISO standards define how metabolic heat production, ergonomics, and physiological strain are quantified (124–127).

10.3 British Standard 7915

The British Standards Institute (BSI) has developed guidance for managing cold stress and discomfort in indoor work environments (air temperature <12°C) (128). Assessment methods include the wind chill index, the IREQ index, and other models for predicting heat loss to the environment and the perception of thermal stress.

10.4 DIN 33 403-5

The German Standards Institute (also known as DIN) utilize the IREQ index to develop a standard for indoor work environments (from –50°C to 15°C, in five ranges). Based on these environmental parameters, insulating clothing requirements are defined, along with ergonomic recommendations for reducing cold strain.

Existing standards or guidelines tend to focus on acute, whole-body exposures and do not emphasize contact with cold surfaces, chronic effects of cold exposure (e.g., endocrine system disruptions), or concomitant exposures with other stressors. In addition, there are few physiological indices of impending damage that are defined well enough to benefit from routine physiological monitoring of the individual, as is done in heat stress environments. Given the individual variability in response to cold stress, such monitoring would be effective in minimizing the prevalence of cold stress in the occupational environment.

Heat Stress
Thomas Adams, Ph.D.

1 Introduction
This chapter's goal is to provide useful, interesting, and up-to-date information about the way people respond to acute and chronic heat stress. It also presents some groundwork about biological control systems, how heat is produced and stored in the body, and how it is exchanged with the environment. This background is necessary to understand the many complex and interactive phenomena associated with heat stress and with the challenges of heat strain.
1.1 Heat is a Unique Stressor
It is important to recognize the uniqueness of heat as a form of energy to understand issues of heat stress and strain and to see its special role in human welfare. No other potentially endangering energy, for example, is produced by the body itself, none other is so essential for life, and none other is the thermodynamic destiny in entropy for all other forms of energy.

No form of energy other than heat so directly affects life processes. Humans normally function in only a narrow range of deep body temperature (1, 2). Not more than a degree Fahrenheit, or so, deviation in brain temperature, sometimes not even that much, shows its effects in altered perceptions and behavior. We tread a narrow thermodynamic path from infancy to interment; hypothermia and cold injury are on one side, and heat strain and hyperthermia are on the other. Many personal and environmental circumstances unrelentingly persist in trying to unbalance us thermally. The path has about the same width for humans as for most other mammals. We all seek about the same degree of stability between about the same thermal limits. Body temperature for most mammals is about 99 ± 2.5°F (37 ± 1.5°C), even though it changes temporarily for an individual by as much as 5°F (2.8°C) because of loads from exercise and thermal exposure.

It is not always easy to spot the sources of heat danger or to gauge their effects. Heat-induced disabilities come from net heat gain from the environment and also from that produced by metabolic activity, which alone can be crippling and lethal. Danger levels for most energy and molecular environmental stressors are predictable for everyone, but they are not for heat. It is not hard, for example, to define a “threshold limit value” and safe exposure levels for gamma and ultraviolet radiations, sound intensity, and exposures to concentrations of specific chemicals. A toxic level for one person is just about as endangering as it is for someone else. It is quite different for heat.

The effects of heat stress must be seen in a different way. One level of environmental heat exposure and rate of heat production from work or exercise may be comfortably, safely and easily tolerated by one person, yet be uncomfortable, disabling, and potentially lethal for another, even though they work side by side at comparable tasks. Solving the complex problems of human thermal safety requires more than just measuring the intensity of contributing environmental factors. It requires additional analyses of a person's internal and external thermal environments and body heat distribution and also of many unique personal characteristics (3, 4).
1.2 Evaluating Heat Stress and Strain
Situations that challenge human thermoregulation must be surveyed at two levels. One is a need to look at the conditions of heat stress, the other must evaluate the level of heat strain. Heat stress and strain are functionally related, of course, but one does not predict the other.

Heat stress is quantified by measurements of a person's internal and external thermal environments. For example, measurements of air temperature, ambient relative humidity, air velocity, infrared radiant heat sources and sinks, emissivities and temperatures of clothing and nearby objects, heat production from work or exercise, conductive and convective thermal energy transfer coefficients of skin and clothing surfaces, thermal insulation of clothing and tissue, water vapor permeability of clothing, and related factors provide important, defining characteristics of heat stress. They do not, however, give any information about a person's competency for remaining thermally stable and safe under these conditions. Measures of heat stress provide no information about someone's level of heat strain. Personal danger comes directly from the level of heat strain and only secondarily from the intensity of heat stress.

Each person's level of heat strain is unique, and it also changes from moment to moment, even for the same, unchanging level of heat stress. Heat strain is defined by a person's total body heat content, deep body temperature, cardiovascular and peripheral vascular competencies and reserves, systemic arterial blood pressure, brain blood flow, ability to sweat, lean body mass, whole body hydration, circulating blood volume, hematocrit, blood viscosity, body fluid distribution and storage, whole body osmolarity, medication status and history, physical fitness, and other related personal factors. Because these are as precisely defined for each of us as are our fingerprints, no two people bear the same burden of heat strain, even when similarly exposed to the same level of heat stress (5–9).

Distinguishing between factors of heat stress and human heat strain is essential. It is naive, dangerous, and potentially lethal to consider that measuring only factors of heat stress, no matter how completely and precisely, or using one's own thermal comfort is any reliable gauge for another person's level of heat strain (10–12). Evaluating human heat strain is a complex but interesting detective story. Lessons learned are applicable to issues of the workplace, and they are also pertinent to each of us personally, to our family members, and to all life forms on the planet.

1.3 The Role of Heat in Life Processes

Heat is essential for life. It is a prime catalyst for biochemical reactions that support it. Each life form survives on its own, sometimes narrowly defined, thermal environmental niche. The range of thermal adaptation for all forms of life, however, is large (2a, 13). Some organisms survive in nearly freezing ocean water; others tolerate extreme temperatures near hot vents in the ocean floor. Some live only in polar regions; others inhabit exclusively equatorial zones. None other than humans, though, has extended its range of tolerable thermal environments so broadly. Though we are bare-skinned, comparatively puny, and generally vulnerable primates, we have, nonetheless, drawn from psychosocial and intellectual reserves to survive everywhere on the planet and extraterrestrially, as well. Stripped of these adaptive strategies, though, our species would not survive for long outside a narrow, paraequatorial zone. Most of us would not even make it there. It is astonishing that our ancestors prospered.

Humans share with other mammals and with birds, too, the ability to regulate physiological responses through complex, precise, and rapidly responding neurophysiological reflexes to support a nearly constant internal body temperature (14). We are the so-called “warm-blooded” animals (homeotherms). Other species do not do this. They are the so-called “cold-blooded” animals (poikilotherms). Yet, they depend on a narrow range of body temperature, too, but achieve it in a different way. Mammals and birds regulate physiological responses to achieve thermal stability, but other animals depend on adjusting physical activity and selecting appropriate habitats. Neither group uses exclusive strategies. Both share many adaptive and response techniques.

It does not take much close inspection before the distinctions between “cold-blooded” and “warm-blooded” animals blur. Under some conditions, as in states of torpor and hibernation, “warm-blooded” animals abandon tight thermoregulation and become thermally labile. Some “cold-blooded” animals, like species of deep-sea fishes, also use metabolic and cardiovascular strategies to regulate body temperature above that of their environment. Although they are in general use, the designations of homeothermy and poikilothermy are crude at best.

There is another nomenclature that discriminates better. “Endotherms” are those animals that regulate body temperature at a nearly constant level. Mammals and birds are in this category. Other animals, so-called “heterotherms,” keep a nearly stable body temperature when they are active. Many flying insects are in this group. So-called “ectotherms” depend more on environmental sources of heat to keep body temperature elevated, as do many reptiles and lizards (13a).

Not surprisingly, heat stress has challenged our species ever since we appeared. It has been documented before the Christian Era, has biblical references, and has determined the fates of armies and civilizations throughout history (15). It is alleged to have killed as many as 11,000 people in a heat wave in China in the eighteenth century and more recently contributed to the disability and deaths of more than a thousand people in the southwestern United States in 1980 (16). Hardly a year goes by that new records are not set for heat's dangers.

Although elderly and socially isolated people who have preexisting medical disorders are most vulnerable to heat strain (17), no one escapes the pressures of heat stress. It challenges physical abilities and also performance quality as well (18–21). It influences many daily activities, including such subtle skills and judgments as those involved in vigilance when operating a motor vehicle (22).

The name of the survival game for humans is to keep total body heat content and deep body temperature between narrow limits while facing a wide range of environmental thermal loads and deficits and producing considerable heat by physical activity (23–26). Seeing how we do this requires knowing some basics of physiological regulation and biological control systems. The next section introduces them.

Heat Stress
Thomas Adams, Ph.D.

2 Physiological Regulation and Control—The Basics
More than a century ago, biologists and physicians began to describe physiological processes in terms of controlled, dependent variables (27). A couple of centuries before that, however, the mechanics of self-limiting societal events were known and discussed. The word, “control,” in fact, came into English about this time to imply that one thing working against another establishes stability in their relationship (“control” = “contra”, indicating “against”, and “role” implying function).

The idea that dynamic interplay between or among opposing forces provides stability was recognized in human affairs long before this important principle was ever applied to life processes. When it was, though, it brought an important new way of conceptualizing, investigating, and describing them. In the middle of the nineteenth century, biologists who considered life events in terms of established equilibria and controlled functions introduced the concept of “homeostasis.” Homeostasis (“homeo”—same; “stasis”—state) implies a static balance of fixed forces or events (Fig. 98.1A). They almost got it right. Biological process are established by control systems, but they are not homeostatic.

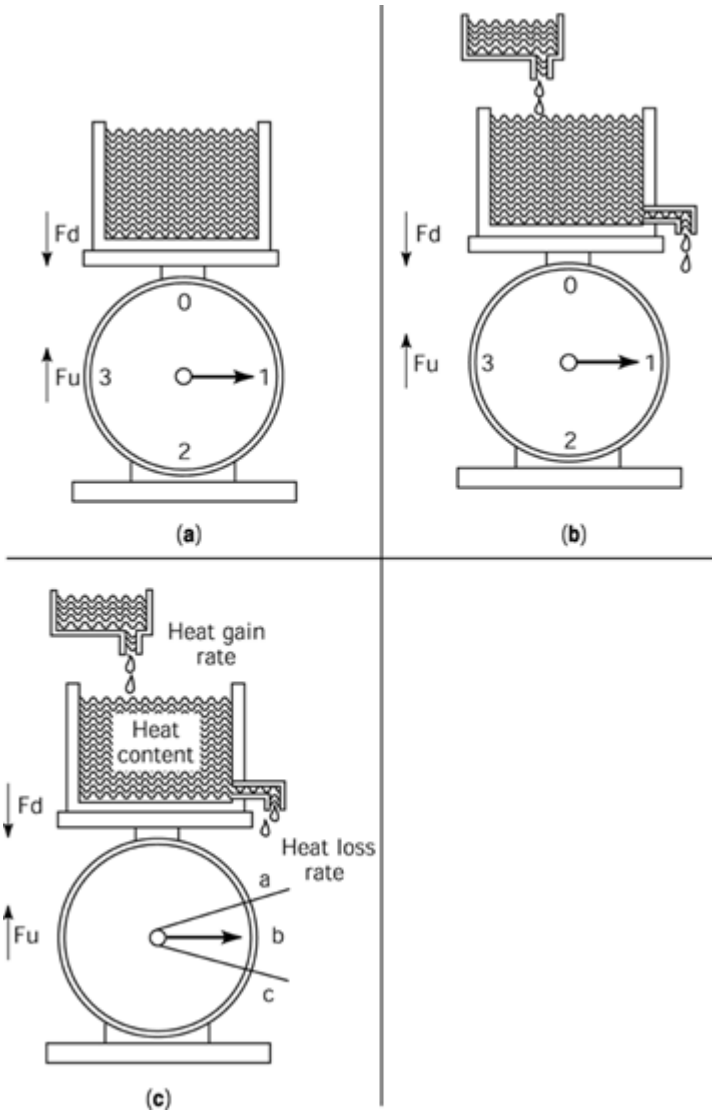

Figure 98.1. A. When a container of water holds a constant mass, its downward gravitational force (Fd) is matched by an upward force (Fu) from a spring in the scale. This system remains in homeostatic equilibrium because two, opposing, equal, and unchanging forces are in balance. B. Adding water at the same rate it leaks from a container establishes a balance between two dynamic phenomena, and the system remains in a steady state. C. A thermal steady state is established when heat is gained at the same rate that it is lost. Transient inequities are tolerated as long as body heat content remains in a normothermic range (b). Hyperthermia (c) develops when heat gain exceeds heat loss. Hypothermia (a) results from the opposite circumstance.

Although the idea of homeostasis was important in directing biologists' thoughts at the time, it is inappropriate for describing life processes. None is homeostatic in the sense that an equilibrium is ever achieved for it. All life processes are steady states. A steady state is a dynamic balance of rate processes (Fig. 98.1B). Stability of blood pressure, acid–base status, body weight, posture, body temperature (Fig. 98.1C), and all other physiological phenomena are steady states (28–30). There are differences in input and output rates among physiologically controlled processes, but all are balanced, dynamic events (30), as are those in psychological processes, too (31–33).

The gain and loss rates for body functions are ever changing, but in normal, good health they are juggled to yield a steady state. Bone mass, for example, changes more slowly than the partial pressure of oxygen in blood, but each is a controlled steady state—one changes over months and years; the other changes breath to breath. It is common for us to seek medical help when one or more of our controlled biological steady states go awry. We expect physicians, in a sense, to serve as

biological control system engineers to diagnose malfunctions in our physiological control systems and to set them right therapeutically (34–36).

2.1 General Control System Principles

Even a first-order understanding of how control systems function is important for interpreting the phenomenon of body temperature regulation and seeing how it responds under heat stress. There is a simple way to envision the basic relationships among elements in a controlled system. The familiar process for keeping room temperature in an acceptable range is an easy to understand example (Fig. 98.2).

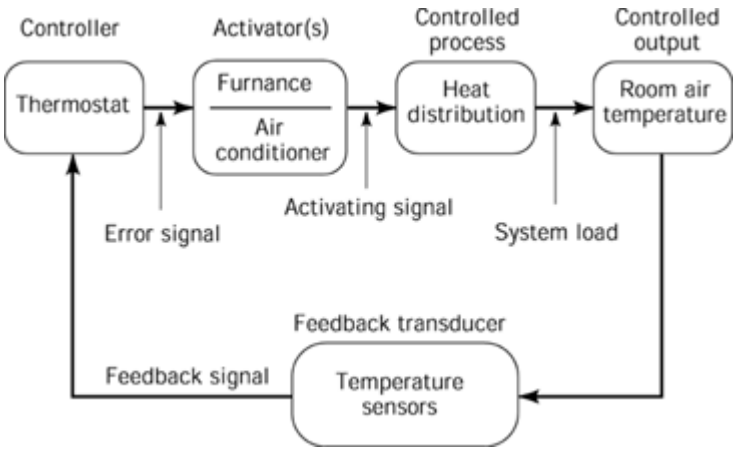

Figure 98.2. A model depicting interactions among control system elements for regulating room temperature. All components share information sequentially, so the control loop is "closed." Were any one disconnected, the control loop would be "open," and the system would not regulate.

A change in outside air temperature presents a "system load" (Fig. 98.2) to the stability of room temperature and causes it to rise or fall. Temperature sensors (usually in a wall-mounted unit) provide electrically encoded information ("feedback signal") about room temperature to a thermostat ("controller"). If room air temperature is outside a control zone limit, an "error signal" triggers either a furnace or an air conditioner ("activators") to bring heat into, or remove it, from the room. These controlled actions affect room temperature in the direction opposite to the feedback signal that triggered the response. The controlled process described in Figure 98.2, for example, would cause room temperature to go up, if the system load caused it to fall initially, and vice versa. This feature of the control system shows that it has "negative feedback." Negative feedback is an essential characteristic for any control system that regulates a dependent variable within a control zone limit.

There is a difference between the concepts of "control" and "regulation" in the context of interactive systems. A "control system" is one that has the basic five elements that sequentially share information (Fig. 98.2). If the control system operates with negative feedback, it achieves regulation. Some control systems, however, operate with "positive feedback." They do not regulate. Instead, they force the "controlled output" function to a limit, but they are still control systems. Coughing, sneezing, vomiting, ejaculation, parturition, urination, and defecation are examples. A diagram, like the one in Figure 98.2, would describe how these neurophysiologically controlled processes operate, but its analysis would reveal that the control system operates with positive feedback to empty a body cavity, not to regulate by its contents at some level negative feedback. The tickle at the back of the throat, for example, leads to contractions of nearby muscles and reflex salivation. These responses enhance the irritation and make the throat tighten all the more. The initial stimulus produces a response that increases the stimulus strength that, in turn, elevates the response. The end result is a cough to dislodge the irritant. Then, the control system remains silent.

2.2 The Control System for Body Temperature

How body temperature is regulated (Fig. 98.3) is less familiar than the process for stabilizing room temperature (Fig. 98.2), yet each system shares the same basic control system elements and each

functions similarly as do all other regulating control systems (30).

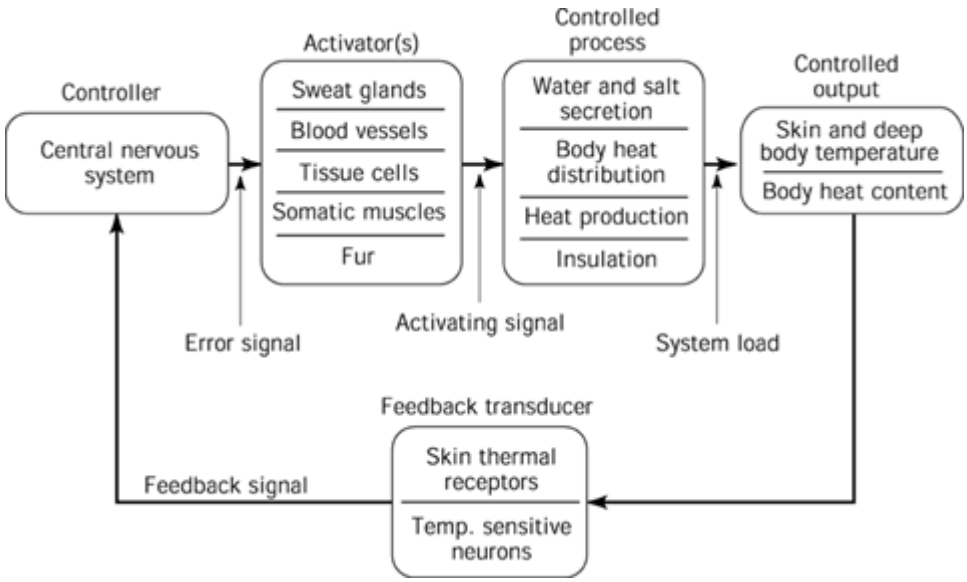

Figure 98.3. Deep body temperature and total body heat content are regulated within controlled limits through a closed-loop, negative-feedback control system that recruits many organ systems and physiological functions. This diagram shows only basic relationships and greatly oversimplifies the many complex ones required for thermoregulation.

Whole body exposures to thermally stressing environments and exercise impose system loads (Fig. 98.3) that affect the body's heat content and temperature. The body's thermal status is monitored and transduced by millions of thermal receptors that are widely distributed throughout the skin. The skin, the body's largest organ, covers about twenty square feet (1.86 m^2). The neurophysiological feedback transduction process encodes absolute levels of skin temperature, but more exquisitely, their rate of change, into frequency-modulated action potentials. Each action potential lasts only a few milliseconds, but there is a constant stream of them conducted afferently on sensory nerves. Thermal sensory receptors respond to little more than a rate of change in skin temperature of only about a few thousandths of a degree Fahrenheit (or Celsius) per second. The action potentials themselves are conducted at rates as fast as hundreds of miles per hour from the thermally stimulated skin site into the central nervous system.

Body temperature is protected by the responses of many thermal receptors in a large area of skin, and the control system (Fig. 98.3) is updated almost on a millisecond interval. Normally, this marvelous process continues uninterruptedly without conscious control and without error for a lifetime, even in the face of continuously changing, sometimes life-challenging thermal loads (36).

Skin thermal receptors provide feedback signals (Fig. 98.3) through synaptic connections with other nerve cells at millions of sites in the spinal cord, midbrain, cerebral cortex, and elsewhere, but most influentially in a small section of the hypothalamus, especially its anterior portion. The anterior hypothalamus is an unpaired structure that in humans lies just behind and at the level of the eyes and midway between the ears. It is no larger than about the size of a pea in an adult. This small mass of brain tissue plays a most important role for all homeotherms in controlling body temperature. It serves a highly complex controller function (Fig. 98.3), but it is also sensitive itself to temperature, although it has no thermal receptors, nor does any other part of the central nervous system.

Temperature affects nerve cells in the central nervous system by altering their transfer functions for processing action potentials. It changes the ratio between the rate at which they receive input information and the rate at which they send it to other nerve cells, tissues, and organs. Responses to

thermal stimuli at the skin, along with the temperature level of the brain itself, determine together how thermoregulation is achieved.

If body thermal stability is challenged by a cold environment, for example, frequency-modulated action potentials are generated as “error signals” (Fig. 98.3) by cells in the central nervous system to reduce convective heat transfer inside the body. This is done by reducing blood flow to the skin and to other peripheral tissues by vasoconstricting their arteriolar blood supplies. Appropriate “activating signals” (Fig. 98.3) also trigger reflex contractions in somatic muscle to produce heat by shivering and reorient fur and feather shafts so that they trap more air, thereby increasing thermal insulation. The net protective effect is to increase metabolic heat production and reduce body heat loss. In most cases, this preserves body heat content.

If a person's thermal stability is challenged by a warm environment or exercise, “error signals” (Fig. 98.3) cause peripheral blood vessels to dilate which increases convective heat transfer to the skin and heat loss from it. Sweat glands are also activated to bring water to the skin surface where heat is lost when it evaporates. Heat defenses in other homeotherms involve salivation and respiratory reflexes that increase airflow over wetted nasal, pharyngeal, and buccal surfaces. The net protective effects of reflex responses to heat stress are to deliver heat at a faster rate to the skin and increase its rate of dissipation. In most circumstances, this reduces body heat content.

For responses to either heat or cold stress, body temperature regulation is protected through a complex, nonlinear, closed-loop control system that has negative feedback (Fig. 98.3). Although there are differences among species in the physiological tools that they use for thermal stability, they all use about the same basic control system.

2.3 Characteristics of Controlled Processes

2.3.1 Time Functions Whether it is the stabilization of room temperature (Fig. 98.2) by a simple control system or body temperature by a highly complex and sophisticated one (Fig. 98.3), both are steady states (Fig. 98.1) earned through the controlled interaction of dynamic processes. Understanding their time-varying qualities gives important additional insight into their functions (Fig. 98.4).

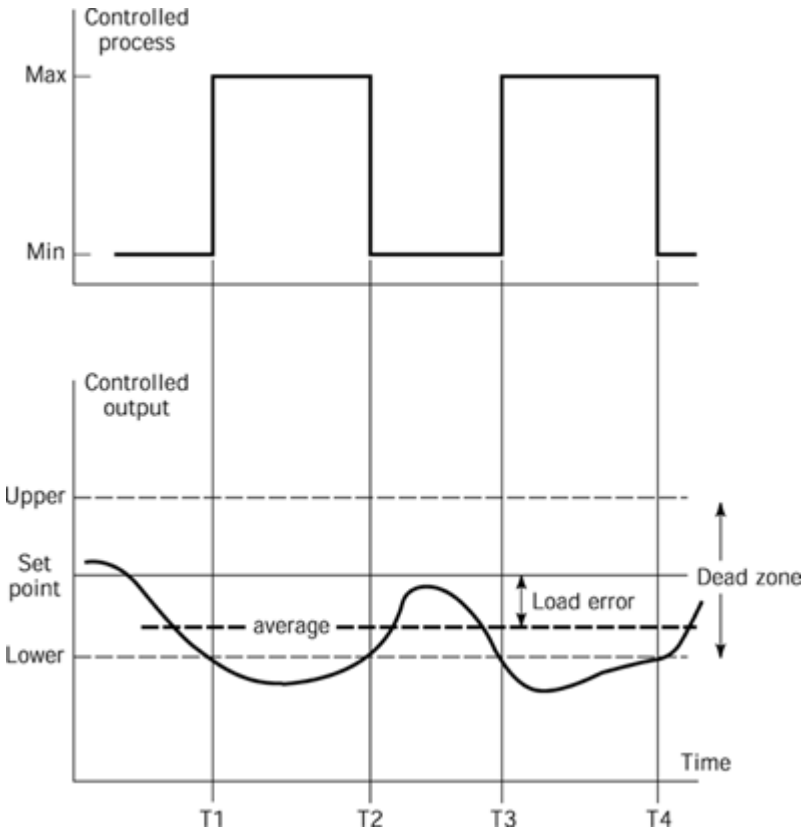

Figure 98.4. The controlled process for an “on-off” control system remains at a low level, as long as the controlled output remains in a “normal” range (the “dead zone”), whose center is its optimum value (the “set point”). When the controlled output drifts outside the dead zone (T1 and T3), the controlled process turns on. Once the controlled variable is again in a “normal” range, the controlled process turns off (T2 and T4). For a closed-loop control system with negative feedback, these interactions lead to regulation of the controlled output.

Air temperature in most homes is controlled by a relatively simple, closed-loop, negative-feedback control system (Fig. 98.2) that turns a furnace or an air conditioner on and off (“Controlled Process;” Fig. 98.4) to keep room temperature in an acceptable range near the optimum temperature set by the owner. The preferred temperature is shown typically by the manually adjusted red arrow on the thermostat. No control system, though, operates with infinite precision. Some variation in whatever is being regulated is to be expected. Were the thermostat set at 75°F (“set point”), for example, few people would complain if the furnace did not turn on until room temperature fell to 73°F. Similarly, room temperature might rise to 78°F before the air conditioner turned on. Typical of all control systems, there is a “dead zone” around an optimum setting (the “set point”) in which the controlled process is silent (Fig. 98.4). Only when the controlled variable drifts outside the dead zone are appropriate controlled processes started.

2.3.2 Load Error There is another expectation for the normal operation of a control system, whether it is one that controls room temperature, body temperature, or some other physical or physiological variable. When a control system operates under a load (“system load”; Fig. 98.2), the controlled variable does not vary around the system's set point (Fig. 98.4), but typically cycles to one side of it in the direction of the load. The system shows a “load error.” The average room temperature for a home on a cold day in the winter, for example, might be 74°F, even though the thermostat is set at 75°F. On a hot day in the summer, the average room temperature might be 76°F with no change in thermostatic setting. The larger the “system load” (Fig. 98.2), the larger the “load error” (Fig. 98.4), and vice versa.

Physiologically regulated processes also show load errors. Total body heat content, for example, will be lower for people who successfully respond to a cold stress, than it will be when they respond to a heat stress. Psychological processes show similar characteristics. Who has not felt a “little out of sorts” and “not feel like themselves” when under emotional stress? The imposition of challenging personal circumstances and events takes them a little further away from the “normal” personality “set point” that they usually try to maintain. Similarly, when things are going especially well, it is not unusual to feel a little better than we do on most other days.

2.3.3 Gain “Gain” defines how a change in the output of a control system varies in relationship to a change in its input. This is commonly seen as the ratio between a change in the system's “controlled output” (Fig. 98.3) and a change in its “feedback signal.” Gain adjustments are usually made at the level of the system's controller. There is high gain in the control system when there is a larger output than usual for the same level of input. There is low gain when there is a smaller output than usual for the same input.

Even in general physical examinations, physicians typically assess patients' gain for many of their physiological control systems. Seeing the change and rate of change of the eye's pupil in response to a bright light (input), for example, is one way to determine how the central nervous system (controller) is processing action potentials to control the iridial muscle (output). Sluggish or incomplete responses indicate low gain. A quickly developing pinpoint pupil shows high gain, compared to a normal rate and amount of pupillary constriction. Police make similar tests of reflex gain, sometimes even at the roadside, to evaluate suspected drug and alcohol effects on postural, pupillary, speech and other physiologically controlled processes.

Tapping a tendon or a muscle with a reflex hammer (input) to elicit a “tendon (or knee) jerk

reflex" (output) also reveals important information about central and peripheral nervous system control functions. A weak, slow, or incomplete movement of the leg suggests slowed, low gain reflex muscle control. A greater than expected, exaggerated kick of the leg shows high gain for the associated control system on that day, assuming that the stimulus was the same for each test.

Drugs like barbiturates and alcohol, that depress central nervous system action, reduce reflex gain. Lethal overdoses reduce it so far that respiratory, neurophysiological, and cardiovascular control system functions cease. Drugs, like caffeine, cocaine, and nicotine, that enhance central neural functions increase reflex gain. Central nervous system gain changes are also due to tumors, diseases like multiple sclerosis, infections of the brain or spinal cord, injuries, and any number of other events. They all show reflex gain changes in clinical tests that are easy and routine procedures, yet which reveal valuable information.

2.3.4 What is a "Normal" Value for a Regulated Variable? Understanding features of the "dead zone" is important in evaluating a control system's operation. There is no other rational way to distinguish between normalcy and pathology in the way it works. In the same way that it is impractical to define a "normal" room temperature, it is impossible to define a "normal" systemic arterial blood pressure, body weight, height, body temperature, behavior, personality, or other dependent variable. It is possible, however, to delimit an acceptable range of values for a controlled process in terms of its dead zone. A working definition for "normal" then depends on maintaining the control system's output in a dead zone (Fig. 98.4), but not necessarily at a specific set point. For this reason, laboratory analyses of body fluids, like blood and urine, show ranges of "normal" values for concentrations of sodium, potassium, chloride, and other ions, as well as for cholesterol, glucose, albumin, creatinine, and other molecules.

Police analyze dead zones more than set points when they evaluate driving behavior. Imagine, for example, the view from a hovering helicopter monitoring a car's position as it moves down the road. Not only will the vehicle's speed be noted, but so will its position on the highway. Little attention will be given to whether the car follows precise set points (optimum speed and movement down the exact middle of the traffic lane), but deviations from dead zones (going too slow or too fast or deviating from the left and right limits of the traffic lane) certainly will attract attention. Experienced officers take into account the effects of load error on speed and road position as the car goes around curves and up and down hills. Citations will document deviations of a driver's controlled behavior from acceptable dead zones of vehicle speed and position, but not from their set points. The narrower these dead zones, of course, the tighter the traffic regulation required in that community.

2.3.5 Thermoregulatory Control The many simultaneously operating biological control systems that regulate body temperature are much more complicated, of course, than the simple "on-off" one that stabilizes room temperature (Figs. 98.2 and 98.4). They incorporate features of proportional control, in which appropriate physiological responses (Fig. 98.3) respond to deviation of body heat content and deep body temperature from a control system's lower or upper dead-zone limits (Fig. 98.4). They also show features of differential control, in which body responses are proportional to the rate of change of skin and deep body temperatures, as well as those of integrational control, which provides summing operations. Most other controlled physiological, biochemical, and biological processes have these features, too.

Understanding how deep body temperature remains stable in a regulated thermal dead zone, while total body heat content may vary widely, requires insight into the body's thermal capacitance. This information is presented in the next section.

Heat Stress
Thomas Adams, Ph.D.

3 The Importance of Thermal Capacitance

Were there a change in the liquid volume of a rigid-walled container (Fig. 98.5A), its level would also change in direct proportion. If the container had flexible sides, though, like those of a rubber bag, its liquid level would no longer accurately reflect the liquid volume (Fig. 98.5B). Only when the container reached its upper limit of compliance, would its change in volume be reflected in a corresponding change in liquid level. Body heat content and temperature also change independently because there is a sizeable mass of body tissue that transiently stores, then releases heat, but does not change deep body temperature. The measurement of deep body temperature does not indicate how much heat is stored in the body until it has reached an upper limit of its thermal compliance.

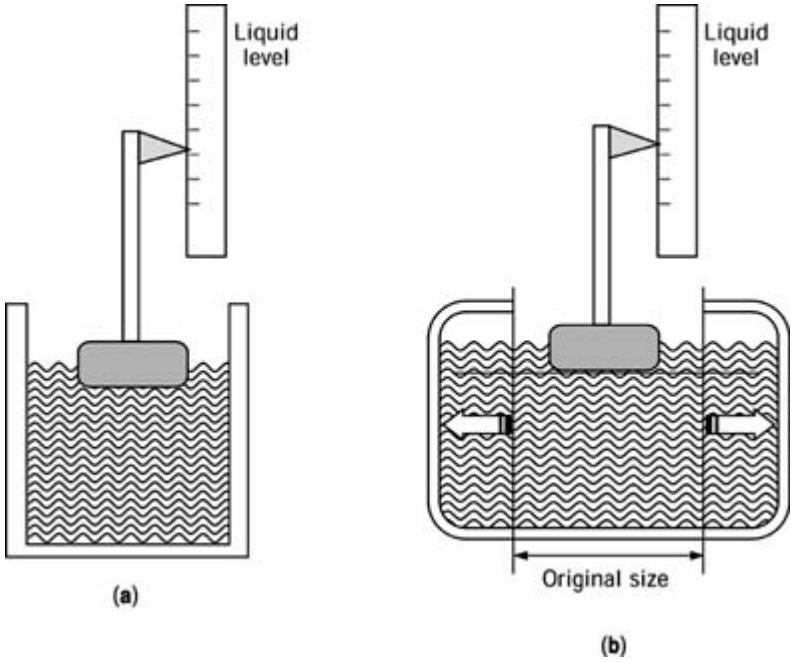

Figure 98.5. Liquid level and volume are directly related one-to-one for a rigid-walled container (A). Liquid level does not vary as a function of volume for a container that has flexible sides (B), at least within the limit of its compliance.

Humans and other animals take great advantage of the body's thermal capacitance to offset and delay the impacts of heat and cold stresses. It is necessary to keep the liver, gastrointestinal tract, heart and lungs, brain, and other internal organs at a nearly constant temperature, but skin, muscles, body fat, tendons, and other peripheral tissues can change their heat content and temperature without serious effect. The central nervous system, especially the brain, however, is particularly vulnerable to the effects of hypothermia and hyperthermia. Variations of not more than a degree Fahrenheit often produce altered reflex expression and changes in levels of consciousness. Some are reliable early warning indicators of impending heat strain. The hallucinations and convulsions that sometimes accompany a fever and the lethargy common to hypothermia testify to the need for keeping brain temperature in a range of about 96 to 101°F (35.5 to 38.3°C). The body depends, however, on allowing about 50% of its total mass to change temperature with little change in deep body temperature and no untoward effects during heat and cold stresses.

The body mass whose temperature must be kept stable is called the “thermal core.” The mass allowed to change its heat content is called the “thermal shell.” This metaphor is appropriate because the body mass of the thermal shell includes the peripheral tissues of the arms and legs. During a successful response to cold stress, a person's deep body temperature remains controlled in a thermal dead zone (Fig. 98.4), but total body heat content is low because the thermal shell is expanded. Because of a load error, however, even core temperature is predictably close to the lower limit of the thermal dead zone. During a successful response to heat stress, deep body temperature also remains

well enough regulated, although it will show a load error that holds it close to the upper limit of the thermal dead zone. The thermal shell in a heat stress, however, will no longer exist, because of heat stored in peripheral tissues. Its temperature is now close to, or even above, the level of deep body temperature.

The observant traveler recognizes well how people in different climates and at different times of year take good advantage of the buffering capacities of the body's thermal compliance. It is an informal, but common, observation that people in the summer use air conditioning to keep room temperature lower than they would when the weather turns cold. Similarly, a warmer room temperature is preferred for many homes in the winter than that adjusted in the summer. Experience has shown that heat strain is delayed if heat stress is faced with a heat depleted and expanded thermal shell. Sweating, peripheral vasodilation, and the discomfort of being hot are postponed until the thermal shell becomes heat-saturated as body heat content increases. Similarly, shivering, peripheral vasoconstriction, and the discomfort of being cold are held at bay until the heat stored in tissues of the body's thermal shell is depleted. Loading it with heat before a cold exposure has a real advantage. Entering a cold stress with a full store of body heat and beginning a heat stress with body heat stores depleted are both good strategies.

A careful analysis of heat stress and strain requires distinguishing between those exposures and exercise phenomena that affect the heat content of the thermal shell and those that threaten the stability of the thermal core. Not all heat-induced disability involves hyperthermia, an increase in deep body temperature. The majority of thermal discomfort and disabilities produced by human heat stress result from first- and second-order physiological phenomena related to body heat storage and expansion of the thermal shell. Stages of hyperthermia that lead to heatstroke, however, are exclusively related to temperature elevations of the thermal core. They occur almost without exception only when the thermal shell has become heat-saturated. Even an elementary understanding of the complexities of human thermoregulation requires knowledge of biophysical heat transfer principles. It is important, too, to see how they are linked to anatomy and physiological phenomena. The next section is a primer for this information.

Heat Stress
Thomas Adams, Ph.D.

4 How Heat is Exchanged
For good or for bad, most people know the dynamics of their savings accounts (Fig. 98.6A). Wealth, indicated by its amount of stored money, is not constant, but varies from transaction to transaction as a function of the rate at which money is deposited and earned from interest and the rate at which it is depleted by withdrawals and service charges. Wealth at any moment is their net effect. There is financial stability only when these processes are in a steady state. Mechanisms for establishing body heat content (Fig. 98.6B), as indicated by body temperature, have similar dynamics. At any moment, the system depends on the net effects at which heat is constantly gained and constantly lost. When these fluxes are balanced, the body is in a thermal steady state, as described by

$$\Delta H = q_{m} \pm q_{cd} \pm q_{cv} \pm q_{rd} \pm q_{cnd} - q_{ev} \qquad (1)$$

where

DH = change in total body heat content (kcal; kJ)
q_{m} = heat gain by metabolism (Btu/h; watts)
q_{cd} = heat exchange by thermal conduction (Btu/h; watts)

q_{cv} = heat exchange by thermal convection (Btu/h; watts)

q_{rd} = heat exchange by infrared thermal radiation (Btu/h; watts)

q_{ev} = heat loss by evaporation (Btu/h; watts)

q_{cnd} = heat gain by condensation (Btu/h; watts)

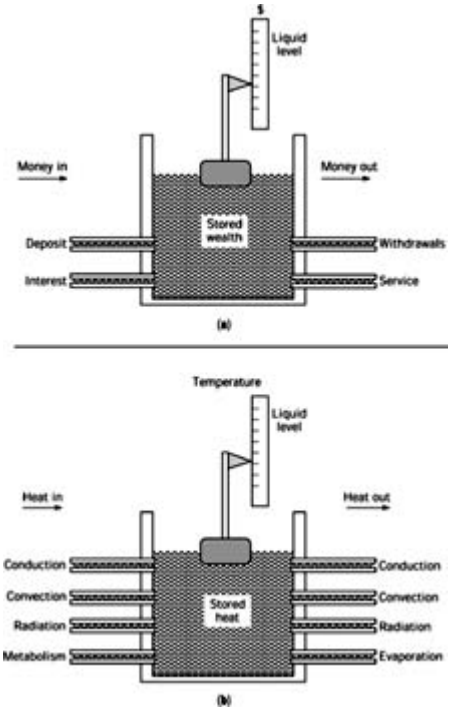

Figure 98.6. A. Savings accounts are financial steady states whose balances at any moment are a function of the dynamics of money deposited and earned as interest against that withdrawn and spent in service charges. B. Body temperature at any moment reflects the net balance of rates of heat gains and losses and the amount of stored heat. Whether heat is gained or lost by either thermal conduction, convection, or radiation depends on the direction of the associated gradients. Heat is always gained by metabolism and always lost by evaporation.

Heat Stress
Thomas Adams, Ph.D.

5 Evaluating Heat Stress

It is a complicated task to keep deep body temperature in a thermoregulatory dead zone (Fig. 98.4) during thermal stress, even with the buffering effects of the body's thermal shell. There are many factors and effects (Eq. (1)) that have to be balanced. Because the stressors wear many different faces, it is unreasonable to expect that any single environmental measure will adequately represent their net effect. The single measure of air temperature, for example, is woefully inadequate as an indicator of thermal stress, whether it is of cold or of heat. Generally, the more factors that are accurately measured in the environment and in metabolic heat production, the greater the precision in defining thermal stress. No matter how expansive and inclusive the strategies for quantifying thermal stress, however, they do not provide a reliable indicator of heat strain. But, it is still valuable to document thermal stress as completely as possible.

5.1 The Heat Index

It is common personal experience that ambient relative humidity has an effect on thermal comfort. High levels of humidity weaken the water vapor partial pressure gradient between the skin surface and the air, thereby restricting evaporative processes. Humid days also increase the heat transfer properties of the skin which affect thermal perceptions (43). It often seems hotter than the thermometer shows when ambient humidity is high. A so-called "effective temperature" for the relationship between air temperature and humidity is expressed in the evaluation of the "Heat Index" (Table 98.4).

Table 98.4. The Heat Index[a]

	Measured air temperature (°F)									
RH	**70**	**75**	**80**	**85**	**90**	**95**	**100**	**105**	**110**	**115**
0	64	69	73	78	83	87	91	95	99	103
10	65	70	75	80	85	90	95	100	105	111
20	66	72	77	82	87	93	99	105	112	120
30	67	73	78	84	90	96	104	113	123	135
40	68	74	79	86	93	101	110	123	137	151
50	69	75	81	88	96	107	120	135	150	
60	70	76	82	90	100	114	132	149		
70	70	77	85	93	106	124	144			
80	71	78	86	97	113	136				
90	71	79	88	102	122					
100	72	80	91	108						

[a] Numbers in the table indicate "effective air temperature" corresponding to the combined effects of measured air temperature (top) and ambient relative humidity (RH, left side).

An "effective temperature" is useful as a first-order indicator of the effect of humidity on how hot a particular exposure feels, but its value as an indicator of heat stress stops there. It includes no evaluation of the effect of either convective or radiative heat exchange rates, and it does not consider the rates of heat gain by physical activity (Table 98.1).

5.2 Wet-Bulb, Globe Temperature (WBGT)

Any index of heat stress is improved by measuring as many environmental factors as practicable. "Heat index" data fall short of this mark. The calculation of so-called, "wet-bulb, globe temperature" (WBGT) is an improvement (74, 75). It includes information about air temperature ("dry-bulb"), the temperature of a thermal sensor from whose surface water is freely evaporating ("wet-bulb"), and that of another thermal sensor affected by the net effect of radiant heat exchange ("globe" temperature). The algebraic sum of these assessments provides a more complete statement of heat stress than any one of them alone.

WBGT is calculated for people working outdoors when there is solar radiant heat as

$$\mathrm{WBGT} = 0.7 \cdot (\mathrm{NWB}) + 0.2 \cdot (\mathrm{GT}) + (\mathrm{DB}) \tag{9}$$

where

WBGT = wet-bulb globe temperature (°C)

NWB = natural wet-bulb temperature (°C)
GT = globe temperature (°C)
DB = dry-bulb temperature (°C)

WBGT is calculated for people working indoors or outdoors with no solar or other radiant heating as

$$\mathrm{WBGT} = 0.7 \cdot (\mathrm{NWB}) + 0.3 \cdot (\mathrm{GT}) \qquad (10)$$

WBGT has received wide acceptance as a heat stress indicator. It does not, however, reflect the effects of all heat stress factors. It includes no assessment, for example, of metabolic heat production, commonly a major contributor to the imposed heat load for those who work or exercise. Supplemental evaluation is necessary to interpret WBGT limitations in these circumstances (74). Because work and exercise are not typically sustained activities, there is value in evaluating their effects with WBGT calculations on a time-weighted basis (Table 98.5), particularly if special clothing is involved (76). Also, WBGT does not directly measure air velocity, an important factor in setting both thermal energy transfer coefficients for convective heat exchange at the skin surface and mass transfer coefficients for evaporation of water in sweat (77), although suggestions are available to compensate for their effects (Table 98.6).

Table 98.5. WBGT Criterion Values for Work Rates

Hourly Activity		Light Work		Mod. Work		Heavy Work	
%Work	%Rest	°F	°C	°F	°C	°F	°C
100	—	86.0	30.0	80.1	26.7	77.0	25.0
75	25	87.1	30.6	82.4	28.0	78.6	25.9
50	50	88.5	31.4	84.9	29.4	82.2	27.9
25	75	90.0	32.2	88.0	31.1	86.0	30.0

Table 98.6. WBGT Adjustments for Clothing

Type of Clothing	"Clo" Value[a]	Add to WBGT
Summer work uniform	0.6	0.0
Cotton overalls	1.0	–2.0
Winter work uniform	1.4	–4

[a] 1 "Clo" (insulation value of clothing) is 5.55 kcal(m^2·h) of heat exchange by radiation and convection for each degree Celsius for the temperature difference between the skin and the average of dry-bulb temperature and an average radiant temperature.

Whatever its limitations, WBGT offers a practical guideline for protecting against heat strain and hyperthermia. It has been shown, for example, that intense physical activity, even for healthy, young males should be avoided when the WBGT is greater than 77°F (25°C), if internal temperature is to be protected from rising more than about 0.6°C (78). Data from additional physiological studies (79, 80) will undoubtedly improve its predictive precision, as will the development of appropriate

mathematical models (41, 81).

5.3 The Heat Stress Index (HSI)

In the 1950s, physicists and physiologists developed the Heat Stress Index (HSI) to represent the net effects of environmental factors, metabolic heat production, and physical limitations for sweating under a thermal load (82). Its calculation uses information about dry-bulb temperature, wet-bulb temperature, globe temperature, air velocity, and a person's work rate. From this information base, HSI calculations yield many important pieces of information. It presents, for example, a dimensionless number from zero to one hundred, the "heat stress index," that reports the level of heat strain (Table 98.7). It also calculates an estimated "safe exposure time" for a person, and it presents information for partitional calorimetric analysis of the major avenues of heat exchange and heat production in the defined heat stress (Table 98.8; 83).

Table 98.7. The "Heat Stress Index" (HSI)

HSI	Level of Heat Strain
100	⇐Maximum tolerated
90	Very severe
80	
70	
60	Severe
50	
40	
30	Mild
20	
10	
0	None

Table 98.8. Sample HSI Calculations[a]

	Before[b]		After[c]	
Measurements	**English**	**SI**	**English**	**SI**
Dry-bulb temp.[d]	88.0	31.1	85.0	29.4
Wet-bulb temp.[d]	75.0	23.9	60.0	15.6
Globe temp.[d]	91.0	32.8	88.0	31.1
Air velocity[e]	50.0	0.25	400	2.0
Work rate[f]	700	205	700	205
Calculations				
HSI	107.6	109.0	19.8	19.9
	5.34	4.46	Undefined	Undefined

"Safe" exposure time[g]				
Thermal radiation[f]	–18.6	–5.1	12.0	3.8
% thermal radiation	–2.9	–2.8	2.5	2.7
Convection[f]	–47.6	–13.8	–236.7	–69.2
% convection	–7.5	–7.4	–49.8	–49.6
% metabolism	110.4	110.2	147.8	146.8
Relative humidity (%)	54.8	54.9	20.2	20.5
Required evap. heat loss[f]	633.8	186.0	475.3	139.6
Maximum evap. by sweating[f]	589.0	170.7	2400	702.9

[a] Redrawn from Ref. 83. Slight differences between corresponding values are due to rounding.
[b] *Before*: Just mild work (about 200 watts) near hot machinery on a hot day, even when relative humidity is not too high (about 55%) presents an intolerable heat stress (HSI > 100) when mass and energy transfer coefficients are low because air convection is low in still air. Even with maximum sweating, there is limited evaporative heat loss (186 watts required; 171 watts achievable).
[c] *After:* Just increasing air flow and ventilation with an exhaust fan greatly improves this work situation, even though the work rate is unchanged. The increased flow of dryer air greatly boosts the efficacy of sweating and increases convective heat loss from the skin surface.
[d] °F; °C
[e] ft/min; m/s
[f] Btu/h; watts
[g] hour and minutes

Advantages of HSI calculations are that they are based on many measurements of the environment, and they include an evaluation of a person's rate of metabolic heat production and sweating limitations. It is significant that HSI evaluates data for convective heat transfer (air velocity), infrared radiative heat exchange (globe temperature), metabolic heat production and evaporative heat loss (dry-bulb and wet-bulb temperatures). Its calculations show the effects of the rates of heat transfer by convection, radiation, and evaporation, and they also consider a person's capacity for sweating. No other heat stress index includes so many assessments or provides such a wide range of valuable information.

Despite its comparative completeness and general utility, judgments about heat strain based on a computed HSI require considerable insight and caution, as do calculations of any other indicators of heat stress. HSI calculations, for example, do not consider any of the personal characteristics of age, lean body mass, clothing, medication history and status, level of heat acclimatization, or other related factors defining the individual's ability to withstand a heat stress successfully. For this reason, the HSI's calculated "safe exposure time" must be used most carefully. HSI calculations are also quite inappropriate for heat stressed people wearing water vapor barrier clothing, encapsulated suits, or other body enclosures that restrict the free movement of dry air across the skin surface. Within these limits, however, HSI calculations have considerable value for interpreting heat stress.

Although the HSI calculations have been available for several decades, they are not in as much general use as their utility and value would predict. One reason is the substantial time and energy for making the calculations themselves. Although relationships are expressed in sets of simple, easy-to-solve, interactive algebraic equations (82, 83), it is a cumbersome, error-prone, and time-consuming process to calculate them with paper and pencil.

It is more useful to make these calculations with a small, inexpensive, portable, battery-operated, programmable calculator/computer, like the Hewlett-Packard HP48G and HP48GX models in which appropriate algorithms have been stored (83a, 84). With this easy-to-use technology, sample

problems (Table 98.8) can be solved iteratively, quickly, easily, and accurately. For example, it takes only a moment or two to determine, the consequences of changing one or more environmental or personal independent variables. There is no more straightforward, interesting, and practical way to learn about the environmental and physiological interactions of a heat stress. HSI and WBGT programs can be downloaded from a desktop computer (83b, 84a), obtained by infrared data transmission, or keyed into the HP48G or HP48GX in just a few minutes.

Listed here, are the equations by which the HSI is computed:

$$\mathrm{HSI} = 100 * (E_{\mathrm{REQ}}/E_{\mathrm{MAX}})$$

$$\mathrm{XPT} = 250 * (E_{\mathrm{REQ}} - E_{\mathrm{MAX}})$$

$$\mathrm{RD} = 15 * (\mathrm{MRT} - 95) = 15 * (T_{\mathrm{GT}} + 0.13(V^{0.5}) * (T_{\mathrm{GT}} - T_{\mathrm{DB}})) - 95$$

$$\%\mathrm{RD} = 100 * (\mathrm{RD}/E_{\mathrm{REQ}})$$

$$\mathrm{CV} = 0.65 * (V^{0.6}) * (T_{\mathrm{DB}} - 95)$$

$$\%\mathrm{CV} = 100 * (\mathrm{CV}/E_{\mathrm{REQ}})$$

$$\%\mathrm{MET} = 100 * (W/E_{\mathrm{REQ}})$$

[TEXnical Error]

$$E_{\mathrm{REQ}} = W \pm \mathrm{RD} \pm \mathrm{CV}$$

$$E_{\mathrm{REQ}} = W + 15 * (T_{\mathrm{GT}} + [0.13 * (V^{0.5})] * (T_{\mathrm{GT}} - T_{\mathrm{DB}}) - 95) + 0.65 * (V^{0.6}) * T_{\mathrm{DB}} - 95)$$

[TEXnical Error]

Definitions of Symbols:

CV = convective heat exchange (Btu/h or watts)
E_{MAX} = maximum evaporative heat loss (Btu/h or watts)
E_{REQ} = required evaporative heat loss (Btu/h or watts)
HSI = heat stress index (dimensionless)
MRT = mean radiant temperature (°F or °C)
p_{DB} = pressure of saturated water vapor at TDB (mbars)
p_{H2O} = water vapor pressure (mbars)
p_{V} = water vapor pressure (torr)
p_{WB} = pressure of saturated water vapor at TWB (mbars)
RD = radiant heat exchange rate (Btu/h or watts)
RH = relative humidity (%)
T_{DB} = dry-bulb temperature (°F or °C)
T_{GT} = globe temperature (°F or °C)
T_{WB} = wet-bulb temperature (°F or °C)
T_{WBC} = wet-bulb temperature (°F or °C)
V = air velocity (ft/min or m/s)
W = metabolic heat production rate (Btu/h or watts)
XPT = "safe" exposure time (h.min)
%RD = % E_{REQ} of infrared radiant heat transfer
%CV = % E_{REQ} for convective heat transfer
%MET = % E_{REQ} of metabolic heat production

All things considered, there is great value and interest in evaluating environmental and personal factors to define heat stress. Results give useful insight into which are primarily important for a specific exposure. Recognizing heat strain, however, requires a different kind of analysis and a different kind of insight, as described in the next section.

Heat Stress
Thomas Adams, Ph.D.

6 Evaluating Heat Strain
Disabling heat strain does not present itself precipitously, although some of its early signs and symptoms might. Its development is typically slow, but its encroachment is insidious, and the unwary can be incapacitated before they know it. There is great value in knowing how to recognize the early warning signs and symptoms of heat strain, understand what causes them, and know what

to do about them with appropriately corrective actions (11, 85, 86).

Even relatively mild thermal strain affects human performance (18–22, 87). Besides being a hazard itself, heat strain also predisposes one to other, often fatal, disorders. For example, the incidence of coronary and cerebral thrombosis was higher for a large population in the days after a heat wave (88). This greater number of vascular disorders is attributed to increases in blood viscosity, lowered platelet volume, low blood pressure, and other direct consequences of heat strain.

Although much heat strain itself is survivable, it is dangerous to tolerate it any longer than necessary. It is foolhardy to ignore its early warning signs and symptoms. Sometimes, though, the preliminary indicators of impending heat strain are hard to recognize. Signs and symptoms in early stages mimic those of many other disorders and are easily discounted as consequences of heat stress. The slow evolution of heat strain, however, has an advantage. Correctly interpreting the indicators of heat strain in its early phases and doing something appropriate to discontinue them, guarantees that they do not worsen. Few other human disorders are so well predicted (6, 89) and lend themselves as well to preventive actions (90, 91).

6.1 Personal Monitoring and Predictive Models

Because heat strain is shown in early physiological responses to heat stress, there is reason to argue for direct thermal and cardiovascular measurements of people who have to work in heat stress, particularly for those who are deemed especially vulnerable to its effects. It is hardly practical, however, to expect people to wear rectal or skin temperature probes on the job. Although they may not be as reliable as direct measurements of deep body temperature (92), periodic, infrared measurements of tympanic membrane temperature, especially when used with telemetric techniques, offer some promise for showing early stages of heat strain (93). It may also be a more reliable indicator of deep body temperature than rectal temperature for people who have heatstroke (94). In some environments, tympanic membrane temperature proved as reliable as rectal temperature measurements, although oral temperature measurements were not (93). The technique for measuring tympanic membrane temperature is painless, quick, and generally compatible with social and work settings. With experience, it could provide valuable, first-estimate information about heat strain.

In a similar way that more is known about heat stress when many different environmental measurements are made, so it is in assessing heat strain. The more information there is about a person's physiological responses, the greater the likelihood that the heat strain level will be understood. There is clearly a place for personal monitors to evaluate time-weighted measures of heart rate and skin surface measures that evaluate deep body temperature (95), those that use microprocessor technology for data acquisition (96), and those that employ radiotelemetric reporting (97) of heat stress and strain indicators. There is also a practical need to continue developing numerical models (81, 98) and computer models (99) for human thermal response.

Most cases of heat strain do not come unannounced. They send their own, sometimes loud signals. The next few sections describe how to recognize, interpret, and act on these important messages.

6.2 The First Stage: “Heat Syncope” and “Exercise-Induced Heat Exhaustion”

The least serious of the heat-induced disabilities typically occurs during the first warm days of spring, or while someone is shopping and the weather is hot and humid for the first time in the season. People who are overweight and in poor physical condition are most vulnerable. A feeling of well-being is slowly clouded by growing fatigue, dizziness, nausea, and even collapse. Body temperature is typically in a normal range (normo-thermia—Fig. 98.1C; “dead zone”—Fig. 98.4), as are levels of whole body hydration and osmolarity. It takes considerable insight, even for a trained physician, to see the contributing causes of heat strain under these circumstances. The condition is called “heat syncope.” Because it commonly occurs with the combined effects of heat stress and exercise, it is also called, “exercise-induced heat exhaustion.”

The etiology of heat syncope resides in cardiovascular, not just thermoregulatory responses. Systemic arterial blood pressure is regulated through a control system (Fig. 98.13) similar to that which controls body temperature and heat content (Fig. 98.3) and has similar dynamics (Fig. 98.4).

Keeping systemic arterial pressure within the limits of a normal dead zone is essential for adequate blood perfusion of all organs, especially the brain, to retain full consciousness. It is easier for most quadrupeds to maintain brain blood flow than for us bipedal humans. For them, the head and brain remain at about the same height as the heart during most activities. For us, however, the head and brain are considerably higher than the heart level most of the time. This makes them harder to perfuse and especially vulnerable to the effects of lowered systemic arterial pressure.

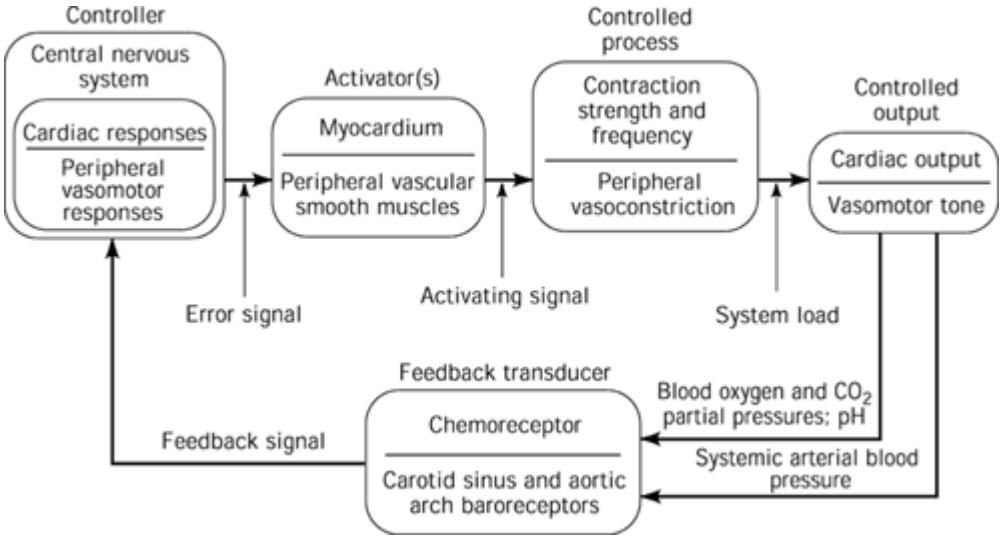

Figure 98.13. Systemic arterial blood pressure is regulated within narrow dead-zone limits by a closed-loop, negative-feedback control system that includes the myocardium and peripheral vascular smooth muscle as activators. This control system has effects coupled with that for body temperature regulation (Fig. 98.3). Reflex vasodilation produced by the simultaneous effects of exercise and heat strain causes systemic arterial pressure to fall, sometimes creating a substantial cardiovascular system load.

Unless there are compensatory control system responses (Fig. 98.13), when systemic arterial pressure falls, brain blood flow falls, and full consciousness is compromised. This happens when psychogenic stimuli cause a drop in systemic arterial pressure, for example, when someone receives astonishingly bad news or sees a particularly distressing sight. It happens also when circulating blood volume is depleted by hemorrhage. It is a common occurrence when the baroreceptor reflex is slow to respond to a change in body posture. Most people have experienced the effects of orthostatic (or "postural") hypotension. It produces a transient dizziness and lightheadedness after standing up quickly, especially if someone is recovering from the flu or has had a recent period of bed rest. Brain blood flow may also be diminished during heat strain, most commonly when there is concomitant exercise, as seen in "exercise-induced heat exhaustion."

It is a normal, control-system-activated, reflex response (Fig. 98.3) in heat strain to increase forced convective heat transfer in the body by increasing the volume of blood circulating to the skin to improve heat loss to the environment. The initiating physiological mechanism is to relax smooth muscle tone in cutaneous vascular beds, allowing their arterioles to increase in cross-sectional area, thereby decreasing peripheral vascular resistance and facilitating increased skin perfusion, with blood returning to the general circulation through deep veins (100). In normal circumstances, the consequent drop in systemic arterial blood pressure is readily countered by appropriate, controlled increases in cardiac output (Fig. 98.13).

Through similarly controlled cardiovascular responses, systemic blood pressure is well-regulated in the face of reflex vasodilation of contracting muscles during work or exercise. Their increased blood perfusion is necessary to provide needed oxygen at an increased rate and also to remove heat, as well as molecules and dissolved blood gases, that are metabolic by-products from the exercise. Reflex

cutaneous vasodilation driven by thermoregulatory reflexes, however, compromises blood supplies to exercising muscle (101). When large volumes of blood flood the skin, this also reduces circulating blood volume and inhibits venous return. It also leads to storage of water in peripheral tissues ("heat edema") (102). The effect is worsened if, at the same time, plasma volume is reduced because of water and electrolytes lost by prolonged sweating (41).

Exercise-induced heat exhaustion occurs when there are simultaneous demands on the cardiovascular control system from heat strain and exercise. Circulating blood volume may be on the low side of normal if someone is in poor physical condition, not heat acclimatized, and inadequately hydrated. Such a great fall in peripheral vascular resistance from the combined stresses of exercise and heat stress may not be adequately compensated for, so that brain blood flow is reduced. So is brain function, at least until the person collapses. Then, when the person is horizontal, the head is at the same level of the heart, its blood perfusion increases, full consciousness returns, and the person feels well, until collapse occurs again when trying to stand.

Feeling faint, light-headed, dizzy with blurred vision; experiencing tinnitus, tingling, or numbness of the face, hands and fingers, nausea, and a developing "funny taste" in the mouth are all predictable symptoms of heat syncope and exercise-induced heat exhaustion. Typical signs are low blood pressure, an elevated heart rate, redness and flushing of the face, diaphoresis, and postural instability. Both the signs and symptoms are of cardiovascular origin and are not necessarily coupled with hyperthermia.

Most people in general good health quickly and fully recover without complications from the usually short-term episodes of heat syncope and exercise-induced heat exhaustion. Feeling faint or even passing out on a particularly hot day is disconcerting, but it is not necessarily dangerous in itself. Diminished consciousness for any reason is of concern when someone is operating machinery, driving a car, or is in a compromised situation like crossing a street or working around moving machinery. Long-term exposure to heat stress, though, places many people at special risk (88).

6.3 The Second Stage: Dehydration and Loss of Body Electrolytes

Humans, other mammals, and birds depend on heat loss by evaporation for thermal balance (Eq. (1)). When ambient temperature is greater than skin temperature, this is the only way to lose heat (Eq. (2)). Most mammals do this by increasing ventilation of the respiratory dead space during panting when the thermal shell has stored heat from a bout of exercise, even when the air temperature is cool. Except for dripping saliva, panting animals retrieve molecules and electrolytes in saliva when they next swallow. They lose only water vapor and heat during panting. Humans, however, benefit from using a much larger surface area (virtually the entire skin surface) as an evaporative site but lose both water and electrolytes by sweating. Recovering these electrolytes and the lost water is essential.

For most people in general good health who do not sweat heavily on the job throughout the day, the water and electrolytes, primarily sodium chloride, lost in sweat are readily regained with a normal diet. Others need to consider electrolyte replacement fluids, in addition to drinking just plain water. Someone's physician is the most reliable consultant for determining these strategies. Failure to replace lost water leads to progressive, whole body dehydration. Water is drawn from body fluid compartments, leading to a reduced circulating blood volume. This makes it difficult to keep systemic arterial blood pressure within control system dead-zone limits and to distribute heat in the body by convection. Dehydration also increases blood viscosity and raises hematocrit, requiring greater cardiac work.

Water and electrolytes lost in sweat must be replaced so that the body eventually returns to its normal range of hydration and osmolality. Because sweat is hypotonic, prolonged sweating leads to hypovolemia and also to an increase in osmolarity. Just drinking plain water after prolonged, heavy sweating, however, can make body fluids hyposmotic. Failure to provide osmotic balance leads to muscle cramps, usually in the large muscles of the extremities and in the abdominal wall, (103), gastrointestinal disturbances, nausea, vomiting, and in extreme cases, susceptibility to toxins,

dementia, and death.

By many accounts, dehydration is an important, if not the predominant contributor to heat-induced illness in people, especially during exercise. Mild hyperthermia results from as little as a 1% body fluid loss. There is considerable impairment of work capacity when 5% has been depleted. Although humans depend solely on sweating for evaporative water loss in heat stress, we are not as good as most other animals in developing thirst and replacing lost body water in the early stages of dehydration. By the time someone senses thirst, dehydration is already established by perhaps as much as 2% of body weight (104). Even in responding to thirst, we do not replenish lost body water as effectively as many other species. We stop drinking water before we are fully hydrated again.

6.4 The Last Stage: Heatstroke

Heatstroke, also called "sun stroke," is life threatening but rare among the general population in the United States. Although only several hundred people die from heatstroke each year in this country (50), heat strain is a contributing cause of death for many thousands of others who lack normal cardiovascular and cerebrovascular reserves (105).

People who have diabetes mellitus may be predisposed to heat-induced illness and heatstroke for several reasons (40). They may be more susceptible to postural hypotension because of weakened baroreceptor reflexes. They may also have peripheral neuropathies and autonomic nervous system problems that affect peripheral vascular responses to heat and reduce sweating capacity.

6.4.1 Environmentally Induced ("Classical") Heatstroke When heatstroke develops from exposure to high ambient temperature, often with high rates of infrared radiant heating, it is called, "environmentally induced heat stroke," or "classical heatstroke." It predictably affects the elderly, the chronically ill or disabled, and those who use medication or drugs that affect thermoregulation, sudomotor, and cardiovascular functions. Typically, the affected person is sedentary or inactive, but overheated because of intolerable environmental conditions. People recovering from head injuries often have limited reserves for combating heat stress and are especially susceptible to heat strain, including heatstroke (106), as are those who have amyotrophic lateral sclerosis or cystic fibrosis (107) and those who have persistent, disabling mental illness (108).

6.4.2 Exercise-Induced Heatstroke When heatstroke results from high rates of metabolic heat production, for example, during prolonged periods of heavy exercise, it is called, "exercise-induced heat stroke," or "exertional heatstroke." It predictably affects those who are in good physical condition, often young, and who are exercising or working in the heat for extended periods. Exercise-induced heat stroke, however, can occur in virtually any set of environmental circumstances (109). It often presents itself with unique complications from strenuous muscle activity, such as rhabdomyolysis (89), intravascular coagulation (110), severe hyperkalemia (111), hypoglycemia, an increase in endogenous opioids (112), increased catecholamines (113), and major organ damage (114).

Exercise-induced heat stroke is most common among young, healthy adults. It is, in fact, the third leading cause of death among high school athletes in this country (102). It is a hazard to those in the military who are undergoing physical training (109) and is a danger to anyone involved in prolonged, high levels of exercise, especially in hot, humid environments (114).

6.4.3 Heatstroke Signs and Symptoms Even at high levels of heat strain, the skin is normally moist and cool because of sweat evaporation. In contrast, for those who have heat stroke, the skin is hot and dry, and deep body temperature is 105°F (40.6°C), or higher because the person's attempts to thermoregulate have been overwhelmed and sweating has ceased (115). As the person becomes progressively more hyperthermic, cardiac output increases to pump ever larger volumes of blood through maximally vasodilated vascular beds.

People in heat stroke may be dizzy, confused, nauseated, have a headache, be disoriented, or even delirious, in a manic state, have seizures (about 60%), or be comatose (about 85%) (40). They will

typically have polypnea, rapid and weak pulse, and will be hypotensive. Virtually all will have previously gone through earlier stages of heat strain, showing many of its early warning signs (40). Rectal temperature measurements may not be reliable indicators of deep body temperature in conditions of heatstroke and when body heat content is changing rapidly (94).

Many people who have heatstroke and sustained increases in cardiac output may develop multiple electrocardiographic anomalies (116) and abnormal heart rhythms because of hyperthermic damage to myocardial cells. Some will have demonstrable myocardial damage (117), some will die of heart failure (15), and some will experience pulmonary edema (118).

6.4.4 Heatstroke Sequelae Renal failure is common in about 30% of those who have heatstroke (15, 119). For those who have exercise-induced heatstroke, it is predictably secondary to the myoglobinuria and hyperuricemia associated with rhabdomyolysis and their high levels of muscle activity. It may also come from direct thermal damage to the kidney and its reduced perfusion when high rates of blood flow are directed to the skin. Hemorrhaging and disseminated intravascular coagulation in tissues throughout the body come from the direct thermal damage of blood vessel endothelial walls, especially in smaller vessels (120). Heatstroke endangers all tissues and organs, especially the liver (121, 122), and often causes death days after the heatstroke episode is ended (114).

Just because someone recovering from heatstroke regains consciousness and returns to a normal range of deep body temperature does not mean that the danger is ended. Possible damage to major organs may present a hazard for hours and days later. Heatstroke must be treated as a medical emergency. All who suffer its effects need prompt cooling, medical attention, and hospitalization.

The severity of injury from heatstroke and the likelihood of death clearly depend on how hot a person becomes and also on how long the hyperthermia has lasted. Some people survive damage-free after suffering heroically high body temperatures, but only for short periods. The highest recorded deep body temperature with complete recovery is a remarkable 115.7°F (46.5°C) (123). Although heat-induced hemolysis and erythrocyte damage occurs *in vitro* at temperatures as high as 118°F (48°C), there is some thermal damage at only 108°F (42°C) to blood samples held at that temperature for 24 to 48 hours (124). A good case can be made for vigorously treating people with heatstroke and lowering their deep body temperatures quickly (125). As a guideline, reducing deep body temperature to at least 102°F within an hour is a good safeguard against extending thermal damage in heatstroke (115).

There is a wide range of injuries from heatstroke, and some have no disabilities at all (126). Others have central (127) and peripheral nervous system damage (128), including that of the cerebellum, leaving them with permanent problems with balance and walking. Others may have personality changes to the point of dementia (16a).

6.5 Failure of Predictors

Considerable time and effort have been invested in establishing quantitative indices for human heat stress, and many laboratory and clinical studies provide mountains of indicators for heat strain. This is all valuable information. At first glance, it looks like we know a lot about the way people respond to this environmental stressor. We do, but we do not know everything. Limitations of our insights often come to light in reports of how well people function in the heat, despite violations of many of the rules.

Most indicators of heat strain, for example, put at high risk those people of older age, with excess body weight, histories of prior alcohol use, and who work and sweat heavily in the heat for long periods of time. But not all are at risk. Forty-three men, 18- to 59-years-old, were studied during 54 man-days of shearing sheep, pressing wool bales, and performing related heavy manual labor (129). Air temperature ranged from 66 to 105°F (19 to 41°C), WBGT indexes from 60.8 to 84°F (16 to 29°C), and just fewer than half the exposures exceeded threshold limit values for work rates of about 1365 Btu/h (400 watts). Despite problems of overweight, drinking more than 7 ounces (207 grams)

of alcohol the previous night, and sweating as much as 21.8 pounds (9.9 kg) during a 10-hour workday, none suffered disabling heat strain. Inexplicably, those who had consumed alcohol the evening before had lower rectal temperatures and were more productive than others. And surprisingly, those who were more overweight reported that they felt cooler during the workday. Age was not a factor in individual responses to the strain and heat and work. Much of the success of people in this group is attributable to their experience on the job and to their successful rehydration during the work period.

Although this carefully reported situation (129) is only one story, it is unlikely to be the only one. Its description emphasizes the need to focus on personal issues when evaluating heat strain, not relying just on formal heat stress indicators to predict who will do well in a work setting. The report also points to the important factors of personal, on the job experience and great individual variations in setting thermoregulatory competencies.

6.6 Early Warning Signs and Symptoms of Heat Strain

Heat disabilities are preventable. The best way to interrupt their predictably inevitable progression is to take appropriate actions as soon as their early warning signs and symptoms appear. Sometimes just lessening the intensity of an activity, interrupting a period of exercise, or taking a short break on the job is enough. Depleting body heat stores by resting for awhile in a cool, shaded and well-ventilated area is a good idea, too. Most people will know when they are dangerously overheated. Their disabling signs and symptoms will demand attention. It is the wiser and safer person who takes corrective actions long before that. The best time to take protective measures is when early warning signs and symptoms of heat strain first appear.

6.6.1 Visible Sweating

The rate at which atrichial sweat glands deliver their secretions to the skin surface is precisely controlled (Fig. 98.3). The process often goes without notice because the liquid water in sweat usually converts to an invisible vapor at just the rate required to supplement the other avenues of heat loss (Eqs. (1) and (3)) required for thermal balance. The neurophysiological control system that regulates sweating does so proportionally to drives from the status of deep body temperature, skin temperature, and total body heat content. As they increase, sweat glands proportionately increase their rate of secretion, sometimes bringing sweat to the skin surface at a rate faster than its water can evaporate. Then, it appears as a liquid on the skin surface. This signals danger.

Sweating does not cool. The water in sweat must evaporate at the skin surface. If sweat soaks into clothing or drips on the floor, it cools these surfaces when it evaporates, but not the body. It is a poor investment for the loss of body water and electrolytes when sweat is produced, but does not evaporate from the body surface. Liquid water on the skin surface in heat stress is a sure sign that body cooling rates are not being supported by the required rate of evaporation. It is an indisputable early warning sign of heat strain. It is as important an early warning sign as a red light on the dashboard of a car. It is not a dangerous event in itself, but it sends a clear message that trouble is on the way.

Visible sweating is the most common indicator of the first stage of heat strain. Unfortunately, it is the one that is most usually ignored. There are some who report they do nothing when they visibly sweat and claim it is just a routine consequence of their jobs or activities. They may be the same people who continue to operate their cars with red lights glowing on the dashboards. Neither practice makes sense.

6.6.2 Increased Heart Rate

Increasing the distribution of heat in the body by the forced convective flow of blood is the most effective defense against heat strain. It is reflexly triggered even in the early stages of heat loading. As heat strain increases, cardiac output and the circulation of blood increase as controlled, dependent variables (Fig. 98.3). Cardiac output is reflexly increased by a greater volume of blood ejected with each cardiac cycle (stroke volume) and also by increasing the heart rate itself. At the same time, peripheral vascular resistance is reflexly lowered to promote high flow rates in the circulation.

About 85% of this increased cardiac output may be directed to the skin alone (40). This becomes so powerful during the late stages of heat strain that the person becomes aware of a pounding and rapid pulse—a sure sign of heat strain. Supporting a high volume of blood flow throughout the body is an essential defense, especially at high levels of heat strain. Maintaining cardiac output in this circumstance by keeping cardiac filling pressure elevated is an important limiting factor in heat strain (130). Sensing a pounding pulse is a sure sign that it is time to take a break and find a place to cool off.

6.6.3 General Malaise and Deteriorated Abilities The early stages of heat strain are typically accompanied by a fall in systemic arterial blood pressure and compromised blood flow to the brain, especially for those who are not heat acclimatized and especially when the heat stress is coupled with exercise. There are several consequences. A person at this level of heat strain may find diminished psychomotor skills, periods of confusion, unexplained irritability with growing flu-like symptoms of lightheadedness, nausea, and muscle aches. Becoming clumsy with a job skill that is usually completed smoothly, efficiently, and easily sends a clear message of heat strain.
6.7 Heat Acclimatization
Most people in general good health develop some degree of heat acclimatization as a normal adjustment to working or exercising even moderately under a heat strain (131). Heat acclimatization is acquired while working in a warm environment, or even in a cool one, if someone wears thermally insulating clothing (132). With just an hour or so of activity each day, there is marked improvement in comfort in about a week. Some heat acclimatization effects begin as early as three days (133). There are many cardiovascular and thermoregulatory changes (70–72). Heat acclimatized people predictably develop an increased plasma volume at rest (72), increased circulating blood volume, and a greater cardiovascular reserve (70). This makes it easier to maintain systemic arterial pressure and avoid episodes of exercise-induced heat exhaustion (heat syncope).

Cardiovascular adjustments with heat acclimatization markedly improve the ability to distribute heat throughout the body, especially to the skin for heat loss to the environment. Blood pressure is maintained more easily in a normal dead zone because heat acclimatized people predictably develop an improved ability to reduce blood flow to viscera. This is a special bonus for adequately perfusing exercising muscle (42).

Heat acclimatization also enhances sweating responses (70), provides the ability to produce sweat at about a three times greater rate (p. 656 of Ref. 13), and decreases its electrolyte concentration (72), especially when sweating rates are low. People who are heat acclimatized also show greater precision in controlling the rate of sweating proportional to levels of hyperthermia and heat storage (134). In general, those who are heat acclimatized begin sweating sooner in heat strain and sweat at higher rates when needed (p. 181 of Ref. 1).

The major benefits of heat acclimatization are to reduce physiological strain, decrease peripheral pooling of blood, and cause a slower rate of heat storage and rise in deep body temperature under heat stress (70, 72). Because heat acclimatization also brings a greater reflexly reduced blood flow to splanchnic vascular beds, arterial blood pressure is more easily maintained. Heat acclimatization is not a permanent acquisition. Some loss of it begins even with just a few days of limited activity and discontinued heat stress (41).

Heat Stress
Thomas Adams, Ph.D.

7 Factors Affecting Heat Strain
7.1 Age

There are clear differences in responses to heat stress among age groups, but it takes some care to see the reasons. They may not be directly related to the factor of age itself. Some are traceable to differences in body geometry and its effect on heat dissipation and storage. Infants and young children, for example, have greater skin surface area to body mass ratios that increase their rates of heating, cooling, and water loss, compared to adults similarly exposed. Their smaller mass also, deprives them of tissue for heat storage. They also have smaller reservoirs for body water storage for the same reason. This means that they will experience thermal strain sooner than adults, whether the exposure is to heat or cold. Using an adult's thermal status to judge whether an infant or child is thermally safe and comfortable in thermal stress is naive and irresponsible (12). It may be a contributing factor in “sudden infant death syndrome” (9, 10, 12).

Age-related deterioration in cardiovascular function and reserve plays an important role in contributing to diminished thermoregulatory potential for the aged. This is not hard to understand considering how important this form of forced convection is in distributing body heat and storing it. Many of the aged also, have complicated medical histories that bear on thermoregulatory ability. Lowered aerobic capacity, reduced sweat gland density (135), and diminished capacity for sweating are also factors (136, 137), as are changes in body fluid distribution and thirst perception in this group (138, 139).

A general pattern is that the youngest and the oldest are at greater risk than others. Even healthy children, especially the very young, are at more risk in heat stress than adults, not because they lack intact thermoregulatory reflexes, but because of their large body surface area to mass ratio and their limited cardiovascular potential. For example, a neonate has a three times greater surface area to mass ratio (0.6 cm^{-1}), than an adult (0.2 cm^{-1}). Older people, especially those who have cardiovascular and peripheral vascular diseases, are the most susceptible to heat strain. There is great variation among older people, however, because of differences in general physical health and level of physical fitness (140). The most successful and least endangered of all in environmentally induced heat stress are young adults in good general health, who have good physical fitness, and who are heat acclimatized. Paradoxically, it is the young who most frequently succumb to exercise-induced heat exhaustion.

It is difficult to find scientifically documented differences in basic thermoregulatory reflex abilities for people of different ages, especially among the elderly (140–143). They may not have equal competencies for body temperature control, but the basic central nervous system control mechanisms (Fig. 98.3) appear to be intact. Differences among people based on age are more related to individual cardiovascular, respiratory, sudomotor, and peripheral vascular abilities and to factors of hydration and circulating blood volume. Although the basic neurophysiological control system works, its ability to force regulation differs as a function of age (138, 143).

7.1.1 The Young Based on their ability to sweat, control skin blood flow, and make appropriate changes in body position, even the youngest infants show that they have functioning, closed-loop, negative-feedback control systems (Fig. 98.3) for regulating body temperature (144). Most neonates of thirty-six or more weeks of gestation can sweat in response to a hot environment on the first day of life, although sweating was delayed a week or more for those who had a shorter gestation period (145).

Babies have a special challenge in retaining body water that makes them especially vulnerable in heat stress. Because of their thin skins, infants lose about 120 mL of water per kilogram of body weight daily (1), even without sweating. This accounts for about 290 kilojoules of heat per kilogram of body weight each day, which is more than half of their daily caloric intake. Even older children, especially those less than 5 years of age, are particularly susceptible to heat-induced disabilities. They are in special danger in severe exposure conditions, like those imposed by a sauna (146).

Some of the increased dangers children face in the heat result from their physical limitations for

storing and distributing heat. They are also at greater risk because they lack adult experiences in seeing and reacting appropriately to the early warning signs and symptoms of heat strain.

7.1.2 Older People People more than sixty-five years of age are overrepresented in heat-induced disabilities and deaths during heat waves (147, 148). Only some of the reasons are understood. In one study, for example, older men (64 to 76 years of age) had higher deep body temperatures and lower skin temperatures during controlled heat stress tests than younger men (20 to 24 years of age), and they had reduced sweating capacities (149) and reduced thirst sensitivity (139). These factors predispose heat-induced illnesses.

There is, however, another side to consider. There is no doubt that older people have more physical problems than those who are younger. Some carry the effects of injuries of long ago, and some have chronic illnesses. Cutaneous vasodilator responses are also weakened with age (150). On the face of it, there are several reasons to expect that older people are more endangered in a heat stress, and, of course, many are, but not all. There are many anecdotal reports of people in advanced age doing about as well as they ever did, and as well as anyone else, in the heat. For example, men and women, even into their seventies, showed little impairment in thermoregulatory ability or in the level of heat acclimatization in controlled tests of heat stress, as long as they were aerobically fit (140). Thermoregulatory ability for many older people is preserved whether or not they are heat acclimatized (151).

The ability to face heat stress successfully is retained even up to the age of eighty-six (141), as long as physical fitness is preserved. In addition, there are no differences between the heat responses of postmenopausal and younger women, except that the older women have a higher sodium ion concentration in forearm sweat (143). More important than age itself, the ability to counter heat stress depends on lean body mass, sweating ability, physical fitness, cardiovascular health, peripheral circulatory ability (152, 153), whole body hydration (141), and the level of heat acclimatization.

There is little doubt that both men and women benefit from being in good physical condition in heat stress (154). Some of this effect comes through changes in sweat gland function (155), and some results from increased circulating blood volume through plasma volume expansion (156). Both extend the upper limits of heat stress and exercise. Even though the circulation of blood plays a most important role in distributing body heat as an adjunct to successful thermoregulation, ischemic heart disease itself has no direct effect on a person's ability to maintain body temperature in a normal range, although it might compromise cardiopulmonary function (157).

7.2 Hydration and Osmolarity

By the same dynamics that body heat content is the net effect of a balance between heat gain and heat loss rates (Eq. (1)); Fig. 98.6B), so body water content and osmolarity are net balances of water and electrolyte influxes and effluxes (Fig. 98.14). They are regulated by their own closed-loop, negative-feedback control system (Fig. 98.15). Body water is gained by drinking it, by ingesting it in foods, and by obtaining it through metabolism. It is lost by respiration, by water diffusion through the skin (so-called, “insensible water loss”), by sweating, by bleeding, as in menstruation, and by the production of urine and feces. Each of these input and output functions brings about its own unique effect on total body water and its electrolyte density.

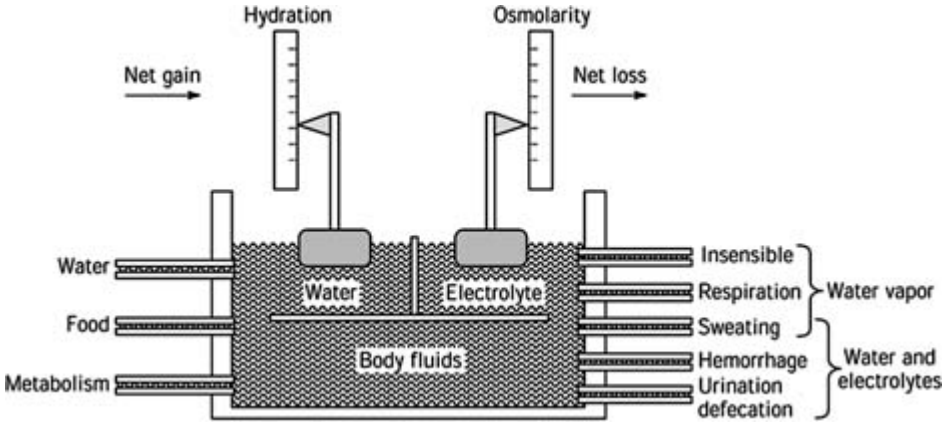

Figure 98.14. Metabolism along with beverages and food are sources of water and electrolytes that are distributed among all body fluid compartments. Water vapor is lost by diffusion across the skin ("insensible"), by every exhalation, and by sweating. Both body water and electrolytes are lost by sweating, by blood loss, and through excretions. The control system sketched regulates these fluxes to keep body fluid volumes and their electrolyte densities within dead-zone limits.

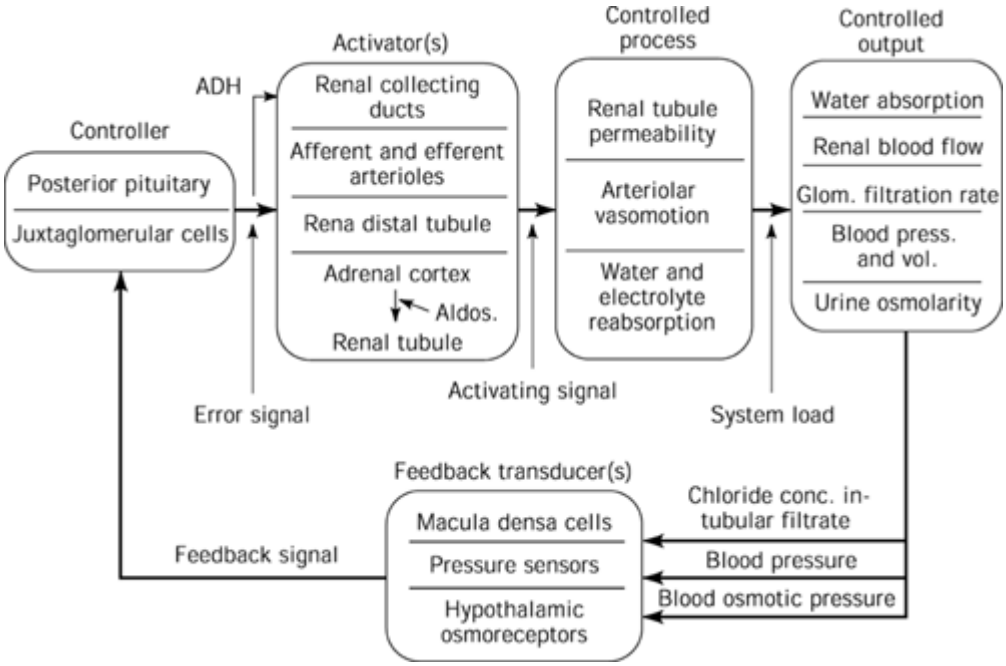

Figure 98.15. Body water and electrolytes are regulated through a negative-feedback control system that involves many organs, different regions of the kidney, and different hormones, including antidiuretic hormone (ADH) and aldosterone (Aldos.). Feedback effects are through blood volume, pressure, and electrolyte composition. An adult loses about 2.5 liters of water daily. About 500 mL is by diffusion across the skin, about 350 cc through respiration, about 1500 cc by urination, and about 150 cc by defecation (69).

Water is a unique molecule. It is chemically inert and electrically neutral, but is an essential medium and diluent for all of the body's electrochemical and biochemical processes. It is ubiquitous in all known life forms. Although the water molecule is a tightly bonded combination of elemental hydrogen and oxygen, some dissociates in body fluids to be a hydrogen ion donor. This is important for the control of body fluid compartment acid–base status (158). Water is the only molecule that freely diffuses passively along concentration gradients to penetrate all cells, tissues, and body fluid compartments, and it does so rapidly. Drinking water, for example, is just about as effective in

recovery from exercise-induced dehydration as intravenous infusion of a 0.45% saline solution (159).

Drinking plain water increases the body's hydration reservoir, but it dilutes its dissolved electrolytes, sometimes leaving a net balance of hyposmolarity (Figs. 98.14 and 98.15). Ingesting electrolytes in foods and seasonings does not affect whole body water stores directly, but it does increase osmolarity. Water is lost in a vapor phase with each exhalation, and it diffuses across intact skin to escape as an invisible vapor at the skin surface. Both processes decrease hydration and increase electrolyte concentrations. Sweating causes loss of both body water and electrolytes, especially sodium chloride, but only in diluted proportion to body fluids. Because sweat produced by atrichial glands is hyposmotic, sweating has the net effect of depleting body water, more than its electrolytes. Prolonged heavy sweating, however, challenges both.

Humans have a great, often life-sustaining, dependence on sweat gland activity for successfully confronting heat strain, but we are obliged to maintain body hydration and osmolarity. Paradoxically, we typically do not replace lost body water as well as some other animals (160). Even furred animals that do not use sweating for thermoregulation do better than we do in drinking as much water as they need after exercise and heat strain. Our failure to maintain body water and electrolyte stores isosmotically within dead zones of control (Fig. 98.4) has serious consequences in athletic performance, it threatens comfort and safety in heat stress, and it may be life-threatening.

Although both reduced body water and osmolarity contribute to thirst drives (Fig. 98.13), few people voluntarily drink enough water to reestablish a normal level of hydration after heat strain (160). Antidiuretic hormone (ADH) is not the only driving factor (Fig. 98.13) in attempts to rehydrate voluntarily (161). Osmolarity and hypovolemia have significant effects, too. Although sweating increases with mild hypohydration (about 2%), it decreases with greater loss of fluid volume (3%), and the salt concentration in sweat increases (162). Substantial hyperosmolarity with dehydration during exercise reduces sweating rates (163), but sweating does not cease until whole body dehydration is severe (26).

Dehydration is correlated with increased heat storage during heat strain, presumably because of a control system load error (Fig. 98.4) associated with decreased skin blood flow (164). This increase in heat storage occurs equally well among males and females, among those who are heat acclimatized and those who are not, and among all people independently of the level of physical fitness, assuming that they are in otherwise generally good health (165). Although there are cardiovascular and thermoregulatory compensations for mild levels of dehydration, severe levels adversely affect blood pressure and body temperature controls (166). There are dangers, however, in chronic dehydration besides those associated with heat strain. People who sweat heavily on the job and who do not adequately replace lost body fluids run a higher risk of uric acid kidney stone disease (167).

A normal amount of stored body water is important in physical performance in the heat. Dehydration diminishes athletic performance, even in the short term and even when sweating rates are low. Full hydration from periodic drinking of water, or better, using fluids with dilute carbohydrate and electrolyte concentrations, benefits long term physical activity (104), although carbohydrate concentration in ingested fluids might slow the rate of gastric emptying and slow fluid absorption (168). Gastric emptying is slowed during exercise and heat stress, compared to rest at neutral air temperature (169). It is unclear, however, how important this is in view of the speed at which water is distributed in the body (159).

Dehydration at any level is costly for thermoregulatory and cardiovascular responses to exercise in the heat, and it affects men and women equally (165). Heat strain-induced increases in heart rate and reductions in cardiac output during exercise are more related to the person's state of hypohydration than to plasma volume (170). It is unresolved whether hyperhydration improves thermoregulation for athletes (171, 172), and there is no evidence that it necessarily enhances specific physical

performance (171).

How dehydration affects thermoregulatory responses depends on its severity (173). Up to moderate levels of hypohydration reduce plasma volume, but not osmolarity, and progressively greater loss of body water increases osmolarity without further reduction in plasma volume. These differential effects have their own actions in the control of whole body water and electrolytes (Fig. 98.13). How plasma volume decreases in hydrated people during sweating in exercise is age-related, and those who are young (middle second decade) have less of a decrease than those in their late fourth and fifth decades of life (141). Hypohydration reduces the deep body temperature at which heat strain is tolerated (174).

But how does someone know when body hydration and osmolarity levels are adequately within control system dead zones? It is obviously impractical to obtain blood samples or analyze urine specimens in the field during athletic competitions or on the job. A couple of quick, subjective tests have some degree of reliability. It is a time-honored guideline to pay attention to the frequency of urination as a reflection of hydration. If someone urinates at about the same intervals and voids each time about the same volume during a hot day as during more temperate exposures, it is a reasonable, first-order indicator of adequate hydration. Urine color is also, acceptably correlated with its osmolality and specific gravity as a general, nonquantitative indicator of hydration (175). Voiding dark-colored urine signals dehydration. More precise and quantitative guidelines, however, are necessary to maintain optimum performance, effectiveness, and safety (176–178).

7.3 Medications and Alcohol

7.3.1 Medications and Recreational Drugs Several classes of pharmaceuticals reduce the ability to face heat stress successfully. Anticholinergic drugs, for example, some tricyclic antidepressants and antihistamines, may inhibit sweating (121), especially in the elderly (179). Others, like some sedatives, opioids and haloperidol, also interfere with thirst thresholds (180). Zonisamide impairs sweating and may produce a number of neurological effects that lead to hyperthermia, especially in children (181). Similarly, some appetite-depressant drugs increase metabolic heat production and induce peripheral vasoconstriction, both of which are endangering processes during heat stress, even to the point of death (182).

Antipsychotic medications, like pimozide and clomipramine, have an antidopaminergic action that increases the thermoregulatory set point. They also have anticholinergic side effects that place people who use these medications at higher risk when they are exposed to heat stress (183). Antidepressants, such as Prozac and lithium carbonate, may also induce heat intolerance, especially for those who work in the heat (184).

In contrast to weakening thermoregulatory ability by some drugs, other materials may, in fact, improve the development of heat acclimatization. Daily 250- and 500-mg doses of vitamin C (ascorbic acid), for example, improved the rate of heat acclimatization of young males (185).

Some drugs induce signs and symptoms of hyperthermia in the absence of environmental heat stress. Amphetamine-like drugs, dantrolene, for example, produce hyperthermia, and cause the breakdown of muscle tissue, inducing spontaneous intravascular coagulation and promote renal damage (186).

For adequately informed personal safety, all who use medications of any kind, prescription drugs, or over-the-counter products, need to consult frequently with their physicians to determine possible antithermoregulatory side effects of the drugs they take. These effects may come either from direct actions on the central nervous system and on cardiovascular responses or from the inhibition of sweating and induced levels of dehydration. These deleterious drug actions may appear as a direct effect of the pharmaceutical itself and also as a consequence of the way they interact with other medications taken at the same time.

7.3.2 Alcohol and Caffeine High doses of alcohol induce profound and debilitating effects, yet it is widely used in many societies and has been since prehistory. It is a well-known depressant for

central nervous system functions, it induces peripheral vasodilation, and it is a diuretic. There are many reasons to expect its use to be contraindicated for people who face thermal stress.

Despite its many actions in the body and its potency in high doses, however, low to moderate levels of alcohol intoxication have few consistent, deleterious effects on thermoregulation in the heat, for shifting the body's thermal set point or dead zone, changing skin temperature, or altering sweating responses (187–189). There is, however, an apparent effect of the level of alcohol intoxication. Whereas ingestion of a 2% alcohol beverage had no demonstrable diuretic effect on rehydration rate after mild dehydration from exercise in the heat, a 4% beverage slowed the process (189).

Alcohol use, though, presents a specific danger in the heat secondary to its direct pharmacological actions on thermoregulatory responses. It can reduce the precision of regulating systemic arterial blood pressure (Fig. 98.13), leading to orthostatic (postural) hypotension and heat-induced syncope. Because of these actions, alcohol has been implicated in twenty or so sauna-related deaths each year (190).

Similar to alcohol, caffeine is a diuretic, but in contrast to the effects of alcohol, it is a central nervous system stimulant. As such, it purportedly improves athletic performance, especially in the heat. Controlled studies, however, fail to support this claim (191).

7.4 Gender

Thermoregulatory abilities are so deeply rooted in our species that they appear to trancend variables associated with gender (192). Although there are differences between males and females at different ages in their responses to heat stress, the net effect of their responses give equal protection. Any gender differences are less important than factors of aerobic capacity, levels of heat acclimatization (193, 194), and physical fitness (192, 195). There is, however, a difference between athletic and nonathletic women in responses to controlled work in heat stress; the more physically fit people keep maintain cardiac output and peripheral blood flow better (196). There may also be gender differences in the physiological mechanisms for increasing cardiac output in exercise, but there is no net effect on cardiovascular competency (197).

Although some data indicate gender differences in preadolescent children: boys reportedly sweat at a slightly higher rate than girls, and they are more tolerant of heat stress, but these differences do not survive when factors of cardiovascular fitness, body size, and heat acclimatization are normalized (198). The effects of the menstrual cycle are also small (193, 198). If demonstrable at all (194), they are subtle and hard to demonstrate experimentally (199). There is, however, an extravascular movement of body fluid that reduces plasma volume during heat stress in women in the luteal phase of the menstrual cycle (200) and a shift in the sweating threshold (201), but it is not clear what, if any, effects these phenomena have on the level of heat strain.

Short-term heat stress is safe for women who have normal pregnancies (202) but may not be for those who have high-risk pregnancies (203). Moderate heat stress does not also induce uterine contractility in pregnant women, nor does it harm the fetus in late uncomplicated pregnancies (204). In fact, the ability to face heat stress is improved for some women in late pregnancy (205).

Heat Stress
Thomas Adams, Ph.D.

8 Summary and Conclusions

Heat stress challenges all creatures. Disabilities, dangers, and death from heat strain have dogged our species and others for as long as we have been on the planet. Heat stress is one of the all too many, unavoidable sharp edges of reality. Despite our unprecedented and unparalleled successes in developing technical defenses against heat stress, we still struggle to maintain comfort, safety, and

health when total body heat content and body temperature rise. Not all do it equally well, and some do not do it well enough. It is a good guess that unrecognized heat-induced illness, along with the diminished physical and psychological abilities it causes, contributes to injuries on the job and precipitates many ailments that are not always correctly diagnosed, treated, or identified as heat-related. People do not have to have high body temperatures to be victims of heat stress.

The weight of heat stress comes from high environmental temperature and humidity, as most would guess, and also from self-imposed elevations of metabolic heat production from heavy and prolonged work or exercise. Both disable and kill many each year. It is a surprise to some that people collapse from heat strain and die of heatstroke in winter, just as they do in the worst weather of summer. It is hard to be on guard unless people know they can be the target of heat stress and strain any time of year, in any season, and with any activity.

Building adequate defenses against the untoward consequences of heat requires careful analyses. It is not good enough, and it has never been, just to look at the thermometer, or form judgments about heat stress dangers to others based on one's own thermal comfort. Nor is it good enough to predict people's jeopardy based only on environmental measurements, no matter how precise and all-inclusive they are. Quantification of heat stress is valuable, but it does not predict an individual's peril. Heat stress is set by environmental circumstances, but heat strain, the cost to a person for remaining comfortable and safe, is what injures and kills. The only safe guideline for recognizing heat strain is that when people say they are hot, believe they are, no matter the exposure conditions or how comfortable others are. The responsibility is to examine each person's report of thermal discomfort and do whatever is necessary to protect them. No exceptions.

People vary greatly in their abilities to withstand heat stress. Infants, young children, some of the aged, and those in poor physical or mental health are particularly vulnerable. But most of us, most of the time, successfully balance personal and work circumstances to survive the heat and do whatever jobs we must in the face of it. Issues of obesity, general health, medication status, heat acclimatization, clothing, activity, and many other factors make it harder for some than for others. Many personal factors must be evaluated to understand each person's unique condition of heat strain in heat stress.

Despite wide variations in the way people cope with heat stress, there are some qualities of personal health that benefit us all. People are best prepared for the heat if they are in good health, have good physical fitness, are heat acclimatized, fully hydrated, and do not take medications, drugs or other agents that inhibit cardiovascular and sweating reflexes. They will then keep a large volume of blood circulating to distribute heat in the body, remove it quickly from exercising muscles, and deliver it to the skin for dissipation to the environment. They will also produce dilute sweat, at sweating rates precisely tuned to their need for evaporative heat loss. Benefits come from maintaining systemic arterial pressure, brain blood flow, full consciousness, and a sense of well-being, as well as from broadening safety margins when facing the heat.

Some environmental conditions are specially beneficial when we encounter heat. When we are indoors and there are no sources of high-intensity infrared radiation, exposing large areas of the skin to rapidly circulating, dry air promotes convective and evaporative heat loss. Within culturally defined limits, the less clothing, the better. It is different when thermal radiation is a major player in the heat stress game, as when we work out of doors in sunshine, or near hot machinery. Then, wearing a well-ventilated and lightweight hat and clothing that covers arms and legs, but still allows air circulation, creates effective barriers to infrared heat gain and places only limited restrictions on the body's ability to dissipate heat.

Because heat produced by muscle contraction can be a substantial contributor to overall heat stress, work and exercise in hot weather are best done when environmental heat stress is the least, most often in the morning and early evening. But it is an unobtainable luxury for most people to do the work they have to at the best times of the day. Most of us have to get on with whatever jobs we must,

no matter what extra stress it places on us. Still, it is possible to pace work periods, arrange frequent breaks, maintain hydration levels, and keep an eye out for the early warning signs and symptoms of heat strain.

Unsurvivable heat strain, like many of the other disasters that befall us, seldom comes unannounced. Few people, for example, find from the afternoon's mail that they are suddenly, without warning, bankrupt. More realistically, there is a long history of unpaid bills, an overdue mortgage, delinquent car payments, and growing credit charges. It is usually not a surprise when the end of financial solvency finally comes. Similarly with heat strain, if someone knows what to look for, there are many early signs that heat strain defenses are wearing thin, discomfort is growing, and heat-induced disabilities are on the way. Episodes of profuse, visible sweating, periods of fatigue, nausea, lightheadedness, postural instability, unexplained irritability, and many other signs and symptoms make themselves known before collapse from the heat.

Each of us has the responsibility to watch out for early indicators of heat strain in ourselves and also to look for them in others. No matter how comfortable we feel, periodic evaluations are necessary for our infants, our elderly, those who are physically or emotionally incapacitated, the socially isolated, and even for our pets. Accepting the idea that someone else might feel hot, even though we are cool ourselves, and that someone else might be cold, even though we feel hot ourselves, is a critical first step. Determining the unique basis for each person's distress and doing something about it is the important next step to minimize discomfort and prevent heat-induced illnesses and death.

Except for heat waves that seriously threaten everyone, there are few other circumstances when the able-bodied must cower in the protection of air conditioning. Given general good health and good judgment, we can usually do just about everything in the summer months that we normally enjoy or must do at other times of year. Getting out and working or exercising in the heat is, in fact, essential for acquiring heat acclimatization. Heat stress is not to be feared and avoided, but not knowing what to look for and what to do in heat strain is. As in successfully countering many other of life's challenges, heat stress is not dangerous as long as it is taken a little at a time and with adequate knowledge about ways to protect ourselves and others from its dangers.

Noise and Ultrasound
William W. Clark, Ph.D.

Introduction

Noise is America's most widespread nuisance. But excessive noise is more than just a nuisance. Day and night, at home or at work or play, excessive noise exposure annoys individuals, produces stress, impairs the ability to communicate, interferes with work and play activities, and, in high enough doses, produces permanent damage to the auditory system that can lead to significant hearing loss.

Although annoyance caused by noise affects all of us to some degree, this chapter describes the effects of excessive noise on hearing, and on the effects of ultrasonic stimulation on tissue. The chapter is organized in four sections. In the first, consideration is given to the physical characteristics of sound and the measurement of noise exposure. The second section considers the effects of excessive noise exposure within the range of human hearing, approximately 20 hertz (Hz) to 20 kilohertz (kHz). In the third section, a review of the effects of infrasonic exposure (<20 Hz) is provided. Finally, the last section reviews the effects of exposure to ultrasound (20 kHz to 20 MHz)

on humans.

Noise and Ultrasound
William W. Clark, Ph.D.

1 A World of Sound
What is sound? Acousticians define sound as “a particle disturbance in an elastic medium, which is propagated through the medium.” In order for a sound to occur, a medium must have density and elasticity. Although sound can occur in any medium with those characteristics, including most solids, liquids, and gases, we usually think about sound transmission in “our” medium, air. Air is composed of particles (air molecules) that have weight and elasticity. In fact, one cubic meter of air weighs about 1.3 kilograms (kg), and it is quite elastic, that is, it can easily be compressed into a volume much smaller than one cubic meter. This is a useful fact for scuba divers who can carry one hour's worth of breathing air (about 1500 liters) in a 20-L tank.

The information provided above allows us to answer one of the questions we all were asked in elementary school: If a tree falls in the forest and no one is there to hear it, does it make a sound? The answer, from an acoustic point of view is a resounding “Yes.” But audiologists, speech pathologists, teachers, and other professionals are concerned about the sense of hearing, that is, the perception of an acoustic event by a human listener. Adding a perceptual requirement to the definition then produces another definition: “Sound is a compression wave propagated through a medium that is capable of producing a sensation in the human ear” (1). Now, when the tree question is asked again, the answer is “No.”

The preceding discussion highlights an important distinction between two different ways of considering sound. Engineers and scientists are concerned with sound as an energy that can be measured and quantified; no consideration is usually given to whether the sound can be perceived by humans or not. However, hearing health professionals are usually concerned about the *effects* of sound on humans: what and how we hear, what sounds please us, what sounds annoy us, what sounds interfere with our ability to communicate with each other, and what sounds can be damaging to our hearing. These definitions are necessarily more complex than “simple” quantitative descriptions of acoustic energy, and often are expressed in perceptual terms, like “loudness” or “pitch.”

Noise and Ultrasound
William W. Clark, Ph.D.

2 Measurement of sound
A general description of a sound should include a description of *what* the sound is and *how much* of it is present. A *metathetic continuum* is used to describe the *what* quantity, and a *prothetic continuum* is used to describe the *how much* quantity. In acoustics and audiology, frequency of the sound is the metathetic variable, and the intensity or sound pressure level of the sound is the prothetic variable.

First, let us consider frequency. *Frequency* is defined as the number of periodic repetitions of a sound in one second, that is, the number of cycles per second of that sound. By convention, the term “hertz” (Hz) is used to label the frequency of a sound. A sound of 1000 Hz contains 1000 cycles in one second. Similarly, a sound of 20 Hz repeats 20 times per second. As the frequency of a sound changes from “low” to “high,” the perception associated with frequency (known as the *pitch*) also changes from “low” to “high.” Note that the perceptual attribute, the pitch, does not get *bigger* as the

frequency goes from low to high; it simply *changes* from one attribute, low pitch, to a different attribute, high pitch. This is what is meant by a metathetic continuum. The frequency of a sound is determined by the characteristics of the sound source. A tuba and a piccolo produce different frequency sounds because they differ in size.

The second dimension is the "how much" dimension. By this, we are referring to the amount of energy present in the sound, expressed commonly as its intensity. In acoustics, energy or *intensity* is defined as the acoustic power flowing through a unit of area, and the units of measurement are watts per meter squared (W/m^2). In practice, engineers usually measure the pressure variations produced by the acoustic power, and the units are newtons per meter squared (N/m^2), or other equivalent measures expressed in dynes or pascals. These units are metric equivalents to a unit more familiar to us: pounds per square inch. Therefore, the energy, or intensity continuum, is a prothetic continuum: As intensity increases, the perceptual attribute, the loudness of a sound also increases—it's not different, there is just more of it.

2.1 Frequency and Period

As mentioned, the frequency of a sound is the number of periodic oscillations per second, expressed in Hz. The *period* of a sound is defined as the amount of time required to complete one cycle, and is the reciprocal of the frequency:

$$F = 1/p, \quad \text{and} \quad p = 1/f$$

Therefore, the period of a 1000-Hz tone is 1 millisecond (0.001 sec), and the frequency of a tone whose period is 0.05 sec is 20 Hz.

2.2 Speed of Sound

Although the frequency of a sound is dependent upon the characteristics of the source, the *speed of sound* is dependent upon the characteristics of the medium, namely, the elasticity, density, and temperature of the medium. Sound travels faster in water than in air because water is denser and less compressible than air. The speed of sound is also faster at higher temperatures. In air, sound travels at approximately 340 m/sec (1125 ft/sec) at a temperature of 72°F (22°C). We understand from common experience that some amount of time is required for sound to reach our ears. From the outfield bleachers, the crack of the bat is heard after the batter is observed hitting the ball. And, traveling at about 1/5 mile per second, we hear the sound of distant thunder some time after seeing the flash of lightning, the number of seconds telling us how for away the lightning struck (5 sec = 1 mi). In water at a temperature of 0°C, sound travels at a speed of approximately 4700 f/sec, or about 4 times faster than in air.

2.3 Wavelength

Knowledge about the speed of sound allows us to calculate the other important variable of sound: its wavelength. Wavelength, abbreviated by the Greek symbol lambda, is the distance between two identical points on a periodic signal. It is equal to the speed divided by the frequency:

$$\lambda = c/f$$

At 340 m/sec, the wavelength of a 1000-Hz tone is:

$$\frac{340\,\text{m/sec}}{1000\,\text{Hz}} = 0.34\,\text{m/cycle} = 13.4\,\text{in./cycle}$$

Considering that a 1000-Hz tone has a wavelength of (about) 1 ft, wavelengths of other audible frequencies can easily be estimated by remembering that doubling the frequency causes the wavelength to decrease by half and halving the frequency increases the wavelength by a factor of 2. Using this rubric, the table (Table 99.1) can be constructed.

Table 99.1. Relation Between Frequency in Hertz and Wavelength

Frequency (Hz)	Wavelength (approx.)
125	8 ft
250	4 ft
500	2 ft
1000	1 ft
2000	6 in.
4000	3 in.
8000	1.5 in.

Noise and Ultrasound
William W. Clark, Ph.D.

3 Hearing sensitivity
3.1 Hearing Sensitivity: Frequency Domain
Humans cannot hear sounds of all frequencies. The range of human hearing extends from a low-frequency limit of about 20 Hz to a high-frequency limit of about 20 kilohertz (kHz) for excellent, young ears. Signals below 20 Hz are not perceived as sound, and sounds in this range are described as "infrasound." Sounds with frequencies above 20 kHz are also not perceived, and these sounds are called "ultrasound." Although ultrasonic signals are useful for cleaning jewelry, for producing fetal images, and for motion detectors, they cannot be perceived, and therefore are not sounds by Albers' definition. Descriptions of the biological effects of infrasonic and ultrasonic exposure are provided at the end of this chapter.
3.2 Intensity or Sound Pressure
The strength or power of a sound is described by its *intensity*, or the power per unit area the source imposes on the medium. A tuning fork, for example, does work as it vibrates and pushes air molecules back and forth. Each oscillation of the fork causes the air molecules next to it to be alternatively squeezed together and pulled apart. These "local pressure" disturbances are then propagated through the medium. Because it is much easier to measure pressure than intensity, sound level meters are designed to measure the atmospheric pressure variations caused by the sound, rather than the actual intensity of the sound.

The human ear is sensitive over a tremendous range of intensities. At threshold, a good, young, normal ear can detect an acoustic intensity of 10^{-12} W/m^2, a very small quantity indeed! That same young ear can be exposed to an intensity of 10^2 W/m^2 for a brief period without sustaining damage. The range from threshold to maximum tolerable level is called the dynamic range of the ear, and the ratio is 10^{14}:1, that is, 100 thousand billion to 1! The ratio of pressure variations (in air) for these intensities is 10^7 to one.

These large pressure variations can best be understood by an analogy. Imagine a very large eardrum, which moves back and forth 1 ft at threshold. How far would that eardrum move at the maximum tolerable level? When asked that question, most elementary school children respond with guesses of 100 to 500 ft; a few adventuresome souls may hazard a 1-mi estimate. However, the answer is 1894 miles! An eardrum in St. Louis that moves back and forth 1 ft at threshold, would move from St.

Louis to San Francisco to New York to St. Louis for a very loud sound.

Because these large ratios were difficult to deal with, scientists and engineers invented a shorthand method to describe the strength of sound: the *decibel scale* (dB). A complete description of the derivation of the decibel scale is beyond the scope of this chapter. However, decibels are commonly used to express the sound pressure level of a given sound, and the ratio of intensities, or pressures, of two sounds to each other. Three characteristics of the decibel scale are relevant to the discussion. These are:

1. The scale is logarithmic.
2. It requires a stated reference value.
3. "0" dB does not mean there is no sound; rather it means the measured quantity is equivalent to the reference value.

In hearing science, the decibel scale is referenced to the threshold of human hearing (10^{-12} W/m^2 for intensity and the equivalent pressure of 2×10^{-5} Pa), and the strength of sound is referred to as the "sound pressure level" (SPL) in decibels. The formulas for decibels are given below for informational purposes only.

$$\text{Intensity level}: \ \text{dB IL} = 10 \log_{10}(I_{\text{measured}}/I_{\text{reference}}), \text{where } I_{\text{reference}} = 10^{-12}\ \text{W/m}^2 \text{Sound pressure level} = \quad (1)$$

In decibels, then, the range of human hearing extends from 0 dB SPL to about 140 dB SPL.

A further complication of the decibel scale is that the measures as stated above give no consideration to whether a sound is audible to a human listener or not. An ultrasonic jewelry cleaner may produce 140 dB SPL at 30 kHz, but it would be inaudible. Therefore, a filter network was added to approximate the human response to sound at moderate intensities. This network is called the "A-weighted filter network," and sound pressure levels determined with the A-weighting network in place are noted as "sound pressure level, dBA."

Noise and Ultrasound
William W. Clark, Ph.D.

4 When is a sound a noise?
The definition of "noise" is actually rather complex. In acoustics, *noise* refers to any signal that is aperiodic. In engineering, "noise" usually means a signal that interferes with the quality or detection of another signal. In psychoacoustics, noise is usually defined as "unwanted sound." While this definition is probably the most useful for our purposes, even it can be problematic. Is rock music "noise"? The answer depends upon who is hearing it. Similarly, while a loud rattle coming from the engine of a car is most assuredly a "noise" to the owner, it may carry useful information to the mechanic whose job it is to repair the engine, and would not be considered "noise."

Noise also differs in the way it affects people. In low doses, noise can be soothing, and can be "wanted" sound. Patrons of libraries are less distracted by footsteps or page-turning when an air conditioner or ventilator produces a soft sound that masks the irregular noises. In moderate doses, noise *annoys* us. It makes communication difficult, affects task performance, increases blood pressure, and causes stress. In high doses, noise can cause permanent hearing losses.

Perhaps the most general, and most useful, definition of noise is the one proposed by Kryter (2):

Noise is an “acoustic signal which can negatively affect the physiological or psychological well-being of an individual.” This definition covers all the effects listed above. In this chapter we will limit our discussion to one aspect of annoyance caused by noise, interference with speech communication, and more generally to the risk of permanent hearing loss posed by excessive exposure to occupational or recreational noise.

Noise and Ultrasound
William W. Clark, Ph.D.

5 Speech communication in noise
Background noise affects the ability to communicate orally. A graph showing the relation between background noise level, talker to listener distance, and vocal effort required for effective speech communication is shown in Fig. 99.1.

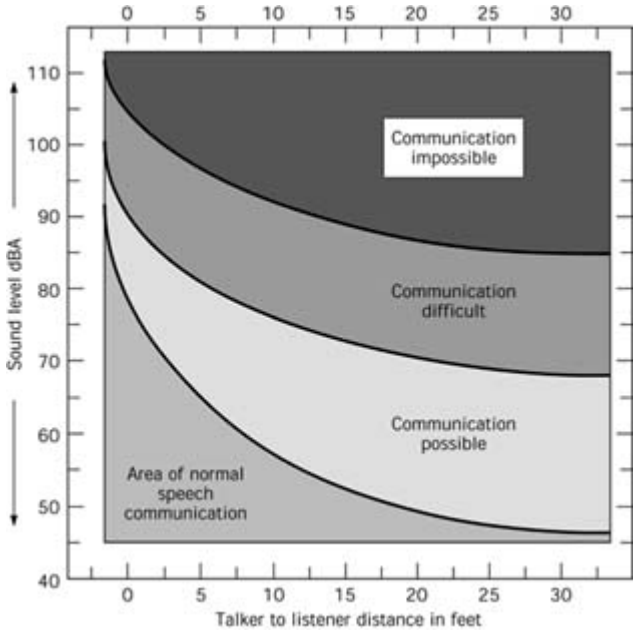

Figure 99.1. Speech communication as a function of background level and talker to listener distance in feet. Adapted from Ref. 3.

The vertical axis is the A-weighted sound level of background noise measured in decibels. The horizontal axis is the distance between the talker and listener in feet. The regions below the contours are those combinations of distance, background noise levels, and vocal outputs wherein speech communication is practical between young adults who speak similar dialects of American English. The line labeled “expected voice level” reflects the fact that the usual talker unconsciously raises his voice level when he is surrounded by noise.

Consider a situation where the background level is 50 dBA. Normal speech communication can occur at talker-to-listener distances of about 20 ft, at distances greater than 20 ft communication is still possible, but it is necessary to raise one's voice level. In a background level of 60 dBA, the normal communication range is reduced to about 8 ft; at greater distances communication is possible, but only with increased vocal effort. For higher background levels, for example, 80 dBA, it is necessary to shout at distances greater than 5 ft, and communication is difficult. In many industrial settings the background noise level is at or above 80 dBA; in these settings communication is difficult for distances greater than 5 ft without shouting, and, for levels above 90 dBA,

communication is impossible at distances greater than 10–15 ft. Clearly, speech communication is difficult or impossible for individuals who must work or choose to play in environments where the background noise levels are above 80 dBA.

Noise and Ultrasound
William W. Clark, Ph.D.

6 How does excessive noise affect hearing?
6.1 Mechanisms of Noise-Induced Hearing Loss
The ear is injured by noise in two very different ways, depending upon the level of the exposure. If the ear is exposed to a very high-level, short-duration exposure in which the peak sound pressure level exceeds 140 dB SPL, the acoustic energy in the signal can stretch the delicate inner ear tissues beyond their elastic limits, and rip or tear them apart. This type of damage is called *acoustic trauma*; it occurs instantaneously and results in an immediate hearing loss that is usually permanent. The organ of Corti becomes detached from the basilar membrane, deteriorates, and is replaced by a single layer of scar tissue that re-establishes the integrity of the fluid compartments of the inner ear. The hearing loss is often accompanied by tinnitus, a sensation of ringing in the ears, which usually (but not always) subsides within a few hours or days after the exposure.

Because the ear is damaged mechanically by impulsive sounds, it matters little what the duration of the signal is; the important variable is the peak sound pressure level. Noises in the environment capable of producing acoustic trauma usually come from explosive events: a firecracker detonating near the head (170 dB SPL), a toy cap gun fired near the ear (155 dB SPL), or the report of a pistol, high-powered rifle, or shotgun (160–170 dB SPL).

Exposures to noise between 90 and 140 dBA damage the cochlea metabolically rather than mechanically. In this case, the potential for damage and hearing loss depends on the levels and the duration of exposure. This type of injury is called *noise-induced hearing loss* (NIHL) and, in contrast to acoustic trauma, it is cumulative and insidious, growing slowly over years of exposure. Noise-induced hearing loss, commonly associated with workplace noise but in reality caused by any exposure that exceeds a daily average of 90 dBA regularly over a period of years, proceeds in three stages.

In the first stage, sensory cells are killed by excessive exposure to noise. The cells do not regenerate, but are replaced by scar tissue. The losses are cumulative and insidious, and do not elevate thresholds for pure-tone signals. In fact, up to 50% of the outer hair cells in the apical turn of the cochlea can be killed without elevating thresholds for low-frequency pure tones.

In the second stage, which starts after a few weeks, to a few years of exposure, depending upon the level, beginning hearing losses can be detected audiometrically. However, these losses occur in the frequency region around 4 kHz. Because these losses do not affect speech understanding significantly, they are seldom detected unless the hearing is tested for some other reason (i.e., annual audiometry in a hearing conservation program).

Finally, with continued exposure for decades, losses continue to accumulate at 4 kHz, although at a slower rate than in the first decade, and they spread to the lower frequencies, which are important for speech understanding. It is at this point the patient becomes aware of a problem that has been progressing for decades. If the diagnosis is noise-induced hearing loss, the recommendation made by the physician or audiologist is to avoid excessive exposure to noise and to wear hearing protection around necessary exposures. Of course, by the time this recommendation is made, much of the damage has already been done.

Photomicrographs of a normal inner ear and one permanently damaged by noise exposure are shown in Figs. 99.2 and 99.3.

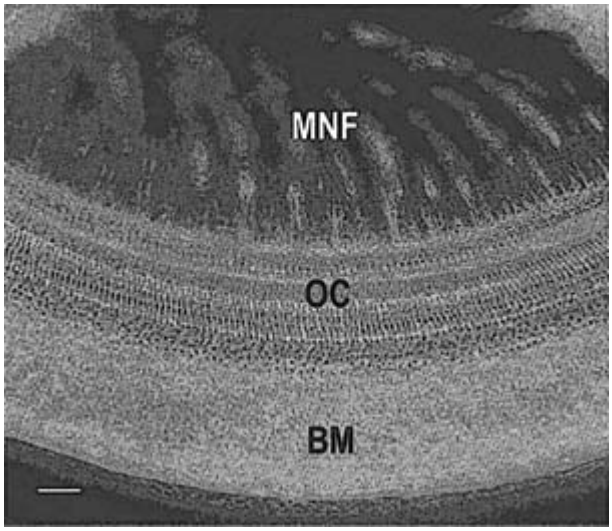

Figure 99.2. A microscopic view of the hearing portion of the inner ear, the organ of Corti (OC), which rests on a thin, elastic membrane called the basilar membrane (BM). Nerve fibers (MNF) in the inner ear are in contact with sensory cells in the organ of Corti. There are large fluid spaces in the inner ear that surround the organ of Corti and basilar membrane. The inner ear is stimulated when sound waves strike the eardrum, causing it to vibrate. Movement of the eardrum is transmitted to the fluids of the inner ear. Waves in the inner ear fluids cause the basilar membrane and organ of Corti to vibrate in a frequency-specific manner. Motion of the basilar membrane stimulates the sensory cells in the organ of Corti, which then stimulate the adjacent nerve fibers. These nerve fibers transmit electrical signals to the brain, where the auditory sounds are interpreted. (Bar equals 50 mm.) Courtesy of B.A. Bohne.

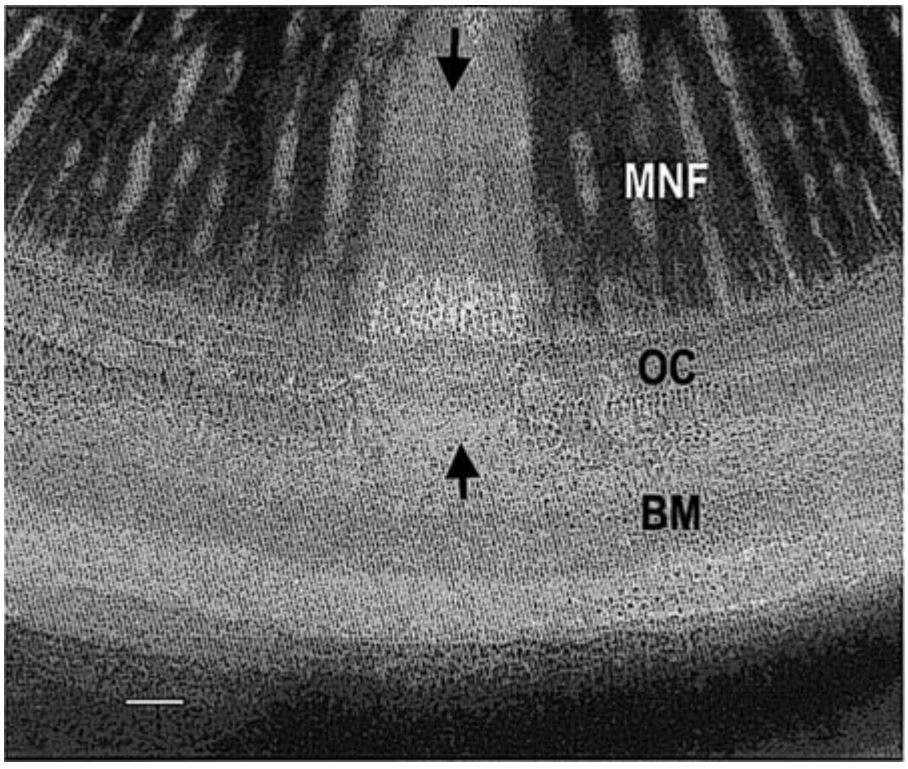

Figure 99.3. A microscopic view of an inner ear that was permanently damaged by too much noise. In the center, the up arrow points to an area of the organ of Corti (OC), which has disappeared

following the exposure. The nerve fibers (MNF) that were originally in contact with the sensory cells in the missing portion of the organ of Corti have also been permanently destroyed (down arrow). Although the basilar membrane (BM) remains intact at this location, no sensory cells are left to be stimulated, and no nerve fibers are left to carry auditory information to the brain. Thus individuals with this damage would have a mild permanent hearing loss. When this type of damage covers a broader area on the basilar membrane, the individual's hearing loss is more severe and it may affect his/her ability to communicate. (Bar equals 50 mm). Courtesy of B.A. Bohne.

Noise and Ultrasound
William W. Clark, Ph.D.

7 How much noise is too much?
If the ear of an individual is exposed to noise of sufficient strength, and/or of sufficient duration, a sensorineural hearing loss can occur. As stated, the hazard associated with a particular noise exposure depends not only upon the strength or level of the sound, but also its spectral characteristics, its temporal pattern, the number or repetitions, and the duration of the exposure. Further complicating the attempt to provide a simple descriptor for hearing hazard is the fact that individuals vary widely in their susceptibility to noise exposure; it is not possible to specify an exposure limit that is guaranteed to protect everyone. An additional complication is that because the effects of noise often go unnoticed by the patient, precise exposure histories are nearly impossible to obtain.

One way of thinking about the hazard to hearing from sound exposure is to consider the dynamic range of the human ear. This range is shown in Fig. 99.4. The bottom curve on the graph represents auditory sensitivity for young, normal human ears. Signals presented at levels below the bottom graph are inaudible, and obviously pose no risk of producing a hearing loss. At the other extreme is the threshold of pain, about 140 dB SPL. Sounds presented in excess of the pain threshold could present a risk of noise-induced hearing loss for just one short exposure; however, a precise estimate of the threshold for injury from a single brief exposure cannot be made at this time (4). Although considerable evidence suggests the ear can be injured by impulsive sounds with peak levels above 160 dB SPL (4, 5), several studies have failed to document permanent injuries for brief continuous exposures at levels of up to 140 dB SPL (6–8). The Federal noise standard, OSHA 1910.95 (9), prohibits single exposures above 140 dBA. In light of the scientific evidence, this exposure limit is reasonable.

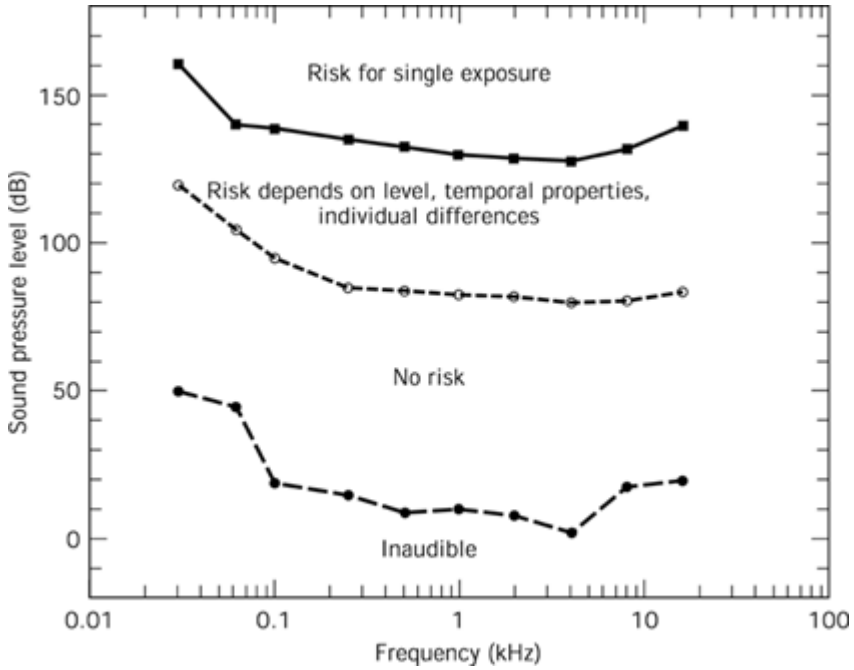

Figure 99.4. Categorization of the range of human hearing with respect to the risk of hearing loss. Closed circles = audibility; open circles, risk of TTS; closed squares, permanent injury. Adapted from Ref. 6.

Between the extremes of the threshold of pain and the threshold of audibility are two categories: risk and no risk. The “no risk” category can be called “effective quiet” or safe levels of exposure. Exposures in this range present no risk of acoustic injury, regardless of the duration of the exposure, the number of exposures, or the temporal spacing of the exposures. The “no risk” category is bounded on the upper side by levels that will not produce a measurable temporary threshold shift (TTS). These levels are also consistent with exposure limits specified by the relatively new American National Standard, ANSI S3.44 (10). At 4.0 kHz, the frequency most affected by noise, ANSI S3.44 specifies a level of 75 dB SPL as the lower limit of permanent threshold shift (PTS). That is, exposure centered at 4.0 kHz for nearly a lifetime (8 h/d) will produce no PTS in any percentile of the population. Figure 99.4 suggests a value of 74 dB SPL at 4 kHz. At 2 kHz ANSI specifies a value of 80 dB, whereas Fig. 99.4 suggests 78 dB. Thus, for noise with energy in the 2–4 kHz region, the correspondence between ANSI S 3.44 and laboratory experiments of TTS is excellent. At lower frequencies the risk estimates in Fig. 99.4 are more conservative than those promulgated by ANSI. However, it should be noted that the ANSI data predict the threshold for permanent hearing loss, and the Committee on Hearing, Bioacoustics, and Biomechanics (CHABA) data predict the threshold for temporary hearing loss.

When the ear is exposed continuously between 80 and 140 dBA for long periods, permanent hearing losses can occur. These exposures occur commonly in the workplace and in the leisure environment.

Noise and Ultrasound
William W. Clark, Ph.D.

8 Measurement of Noise exposure
Noise exposure associated with the workplace has been known to produce hearing loss for centuries. In fact, “boilermakers' deafness” was the term coined to describe the now familiar bilateral sensorineural hearing loss associated with excessive exposure to occupational noise. Largely on the

basis of knowledge gained through field studies of hearing loss in industrial workers and military personnel, the U.S. Department of Labor promulgated regulations in the 1970s and 1980s designed to protect the hearing of employees who work in noisy environments (9). The regulations specified that employees be protected against the hazardous effects of noise when daily sound levels exceed those listed in Table 99.2

Table 99.2. OSHA Maximum Daily Noise Exposure Limit[a]

Duration Per Day (h)	Sound Level (dBA)
16	85
8	90
6	92
4	95
3	97
2	100
1.5	102
1	105
1/2	110
1/4 or less	115

[a] Source: Adapted from Table G-16a of Ref. 9

The levels stated in the table represent the maximum allowable daily noise exposure, or the "permissible exposure limit" (PEL), as specified by OSHA and other federal agencies. The PEL for an 8-h exposure is referred to as the "criterion;" it reflects the sound level in dBA, which reaches the PEL after 8 h of exposure. Note that for exposure, that differ from 8 h, the allowable daily exposure level is increased or decreased by 5 dB for each halving or doubling of exposure duration. Ninety decibels is allowed for 8 h daily, 95 dB for 4 h daily, etc. Each of the exposures listed in the table represents an equivalent "time-weighted average" (TWA) exposure of 90 dBA for 8 h. By definition an 8-h TWA of 90 dB represents 100% of the allowable "dose."

When the daily noise exposure is composed of two or more periods of exposure at different levels, their effects are combined by the following rule:

$$C_1/T_1 + C_2/T_2 + \cdots + C_n/T_n$$

where C is the exposure duration at a given level; and T the allowable duration at that level.

"Percent allowable dose" is then calculated by multiplying the result by 100%. That is,

$$D = 100(C_1/T_1 + C_2/T_2 + \cdots + C_n/T_n)$$

All exposures between 80 and 130 dBA are required to be integrated into the dose calculation. Exposures below the so-called "threshold" are not counted in the calculation of daily exposure; threshold values range from 80 to 90 dBA among various regulations. For example, consider the following daily noise exposure for a sheet metal worker:

Activity	Level (dBA)	Duration (h)
Grinding	92	2.0
Buffing	85	2.5
Cutting	100	0.5
Packaging	75	2.0
Lunch, breaks	79	1.0

Calculation of Daily Dose is made as:

Activity	C/T	Dose (%)
Grinding	2/6	33
Buffing	2.5/16	16
Cutting	0.5/2	25
Packaging	2/ infinity	0
Lunch, breaks	1/ infinity	0
Total	0.74	74

Therefore, this employee's exposure would not exceed OSHA's PEL. The dose could also be expressed as a TWA level in decibels by calculating the 8-h exposure level that would result in the same dose:

$$\text{TWA} = 16.61 \log_{10}(\text{dose}/100) + 90$$

or 87.8 dBA. It is important to remember that “dose” and “TWA” really refer to the same measurement: the 8-h equivalent exposure for any measured duration or combination of levels and durations, expressed as percent or decibels.

As amended in 1983, the current U.S. occupational noise exposure standard identifies a TWA of 85 dBA, or 50% dose, as an “action level.” Workers covered by the standard who are exposed above the action level must be provided an effective hearing conservation program, including annual audiometric evaluations, personal hearing protection if desired, and education programs. With a daily noise exposure of 74%, or a TWA above 85 dBA, the sheet metal worker described should be in a company hearing conservation program.

The exposure limits set by OSHA were empirically determined from epidemiological and laboratory data concerning hearing damage from noise exposure and were designed to protect employees against sustaining a material impairment in hearing after a working lifetime. They were derived by subtracting the percent of workers sustaining a material impairment in hearing as a function of exposure level from a control population without occupational exposure. The resultant percentage is the “percent risk” or “percent additional risk” of a material impairment in hearing after, say, 40 yr of exposure, above that expected from presbycusis and sociocusis alone. Estimates of percent risk vary depending upon which criteria and databases are used; on the basis of evaluation of all the data, it can be concluded that the PEL of 90 dBA, with the 85 dBA action level, if enforced, would protect

virtually the entire working population from occupational noise-induced hearing loss.

The OSHA noise standards are useful to the physician in arriving at a diagnosis, and for the audiologist in determining whether a recommendation about hearing protection should be made. First, because workers exposed to excessive occupational noise should be in a hearing conservation program, evidence of exposure history and prior company-obtained audiograms may be available for consideration. If the worker is not in a hearing conservation program, he or she may not work in significant occupational noise. Unfortunately, because not all workers are covered by OSHA standards and because enforcement has been weak, lack of participation in a hearing conservation program by a worker does not guarantee he or she has not been exposed to excessive occupational noise. However, in evaluating a patient, if it is determined that exposure to occupational noise did not exceed a TWA of 85 dBA, or a dose of 50%, then exposure to occupational noise should be ruled out of the etiology.

The American Conference of Government Industrial Hygienists has also listed guidelines for occupational exposure to noise (11). These limits are specified as “threshold limit values” (TLVs), and they differ from the OSHA standards in several important ways. First, they specify the criterion level as a daily exposure of 85 dBA, rather than the 90-dBA TWA specified by OSHA. Second, an exchange rate of 3 dB is used rather than the 5-dB exchange rate employed by OSHA. These two differences make the ACGIH TLV more conservative than the OSHA PEL for most exposures, particularly when the exposure level fluctuates during the work shift. However, the TLV is specified by ACGIH as the minimum exposure at which one should consider implementing a hearing conservation program; it does no imply an upper limit of tolerable exposure. Viewed in this way, there is no conflict between the ACGIH TLV and the OSHA PEL.

Exposure Assessment

Two general types of exposure assessment are commonly used in industry: area noise surveys and personal noise dosimetry. Area surveys are used to identify job locations where the TWA exposure may exceed 85 dBA; they are conducted by placing a sound level meter in a specific location and sampling the noise field. Exposures are then calculated based upon the amount of time an employee works in that specific location. Area surveys are also useful in determining the sources of exposure in an industrial environment and for planning noise control engineering strategies for reducing exposure.

Occupational exposures can be measured directly by using personal noise dosimeters. These devices are small, computerized integrating sound level meters that can record the minute-by-minute sound exposure throughout the workday. They are worn on a belt or in a pocket, and the microphone is positioned on the shoulder, approximately 5 in. lateral to the ear. Technological advances in microprocessor design, incorporating low power consumption and component miniaturization, have led to sophisticated, small, lightweight dosimeters that can be worn unobtrusively. A distinct advantage to using dosimetry over other methods is that the measurement instrument travels with the worker and can therefore provide a more accurate assessment of exposure as he or she moves among different noise environments during the work day.

Exposure assessment using dosimetry does have some disadvantages. Because the instrument is mounted on the shoulder, reflection of sound off the body adds about 2 dB to the exposure assessment. In addition, it is nearly impossible to prevent bumping or touching the surface of the microphone during a normal workday. Contact with the microphone, even with a windscreen in place, will always increase the dose measure, and for short-duration, high-level impacts, the exposure can be inflated dramatically. Finally, because the dosimeter travels with the worker rather than staying under the control of the professional assessing the exposure, errors of commission and omission can occur. For example, a dosimeter attached to a jacket, which is then deposited in a locker before the workshift begins, will record the exposure of the jacket, rather than that of the worker.

9 Types of occupational noise exposure
According to a report published by the EPA in 1981, there are more then 9 million Americans exposed to daily average noise levels above 85 dBA. The breakdown is shown in Table 99.3.

Table 99.3. Workers Exposed to Average Daily Noise Levels in Excess of 85 dBA by Employment Area[a]

Agriculture	323,000
Mining	400,000
Construction	513,000
Manufacturing and utilities	5,124,000
Transportation	1,934,000
Military	976,000
Total	9,270,000

[a] From Ref. 12.

These numbers are undoubtedly outdated, but no more recent estimates are available. Although improvements in hearing conservation programs, advances in noise control engineering technology, and downsizing in major industries have undoubtedly reduced the numbers of individuals exposed to excessive noise, it is still safe to conclude that occupational noise exposure is a factor in causing hearing loss for millions of American workers.

It is impossible to specify precisely all particular job descriptions for which excessive exposure is a risk. However, as shown in Table 99.4, the textile industry, processing lumber and wood products, the food industry, and metal manufacturing industries employ large numbers of workers, a large percentage of whom work in noisy environments.

Table 99.4. Estimate of Production Workers Exposure to a TWA of 85 dB and Above[a]

Industry	Thousands of Workers Exposed to Over 85 dBA	Percentage of Workers Exposed to Over 85 dBA
Food and kindred products	820	70%
Tobacco manufacturers	48	76%
Textile mill products	855	95%
Apparel and related products	12	1%
Lumber and wood products	542	100%
Furniture and	236.6	55%

fixtures		
Paper and allied products	395	71%
Printing and publishing	132	20%
Chemicals and allied products	137	23%
Petroleum and coal products	58	50%
Rubber and plastics products	266	50%
Leather and leather products	3	1%
Stone, clay, and glass products	416	75%
Primary metals		
Primary steel	325	67%
Foundries	189	70%
Primary nonferrous	63	27%
Fabricated metal products	786	70%
Machinery, except electric	956	70%
Electrical machinery	959	70%
Transportation equipment	880	65%
Utilities	445	71%
Total	6524	59.3%

[a] From Ref. 13.

As effective as the federal regulations may be, if enforced, at protecting hearing in the workplace, they fail to consider hearing loss produced by noise exposure outside the workplace, and recent evidence suggests that these exposures are potentially hazardous for millions of Americans.

Noise and Ultrasound
William W. Clark, Ph.D.

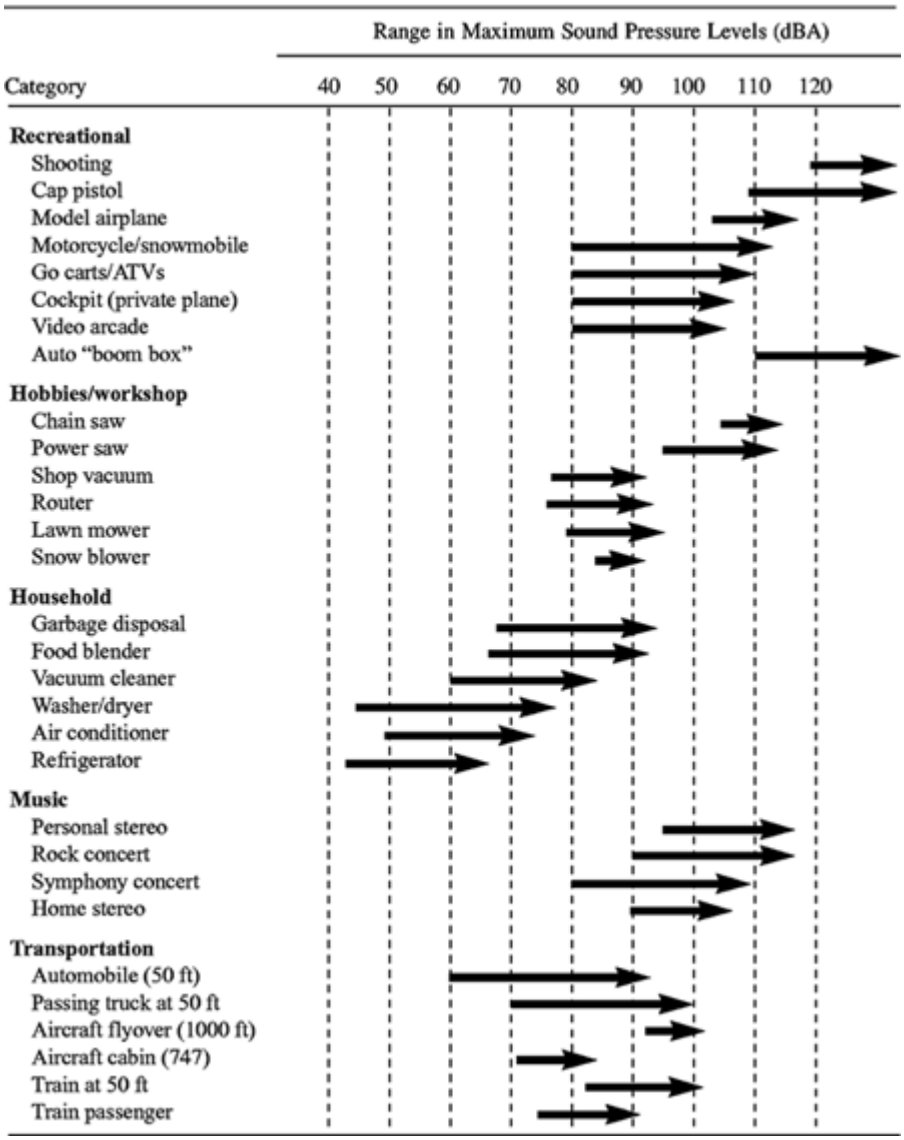
10 Types of nonoccupational exposure

There are numerous sources of noise in the environment that have the potential to produce noise-induced hearing loss. The types of exposure sources span the recreational preferences of Americans. Evidence has been mounting over the past two decades that there are sources of noise exposure outside the workplace that are potentially damaging. Precisely what the effects of these exposures are on an eventual noise-induced hearing loss has been the topic of many studies. Obviously, implicit in the assessment of the role of nonoccupational or recreational noise on NIHL is a determination not only of the level of exposure possible, but also some information about the typical exposure level

and pattern for groups of listeners.

A partial list of significant sources and maximum levels of nonoccupational noise is given in Table 99.5, which was used to demonstrate typical sound levels. If one considers a reading of >90 dBA as the borderline between "safe" and "dangerous" noise exposure, it is seen that nearly everything on the list, with the exception of household items such as refrigerators, falls in the "dangerous" category. Information about maximum levels does not, in and of itself, indicate a dangerous noise exposure (unless the continuous level exceeds 140 dB SPL); the hazards from exposure to noise from any device listed depend on the level and the duration of exposure for a typical consumer of that noise.

Table 99.5. Maximum Sound Pressure Levels for Common Sources of Nonoccupational Noises[a]



[a] Adapted from Ref. 14.

This report will be limited to an assessment of the effects of the two major sources of noise in the leisure environment: the discharge of firearms during hunting and target-shooting activities, and listening to music, either at concerts or through personal stereos.

Noise and Ultrasound
William W. Clark, Ph.D.

11 Hunting and target shooting
It is well known that individuals exposed to gunfire may sustain hearing loss associated with these exposures. Reported peak sound levels from rifles and shotguns have ranged from 132 dBA for .22 caliber rifles to more than 172 dBA for high-powered rifles and shotguns. Clinical reports documenting hearing loss after exposure to shooting can be found in the literature since the 1800s (15).

Numerous studies have attempted to assess the prevalence of hunting or target shooting in the general population. On the basis of these surveys it is estimated that more than 50% of men in the American industrial workforce fire guns at least occasionally. The National Rifle Association estimates that 70 million Americans own guns, and 20 million purchase hunting licenses each year (16). The severity of injury produced by impulsive noise exposure and the prevalence of shooting by Americans make gun noise America's most serious nonoccupational noise hazard.

Because of the logarithmic nature of the decibel scale, it is difficult to grasp how much acoustic energy is in a single gunshot. Consider the following example. An individual is exposed to a single report of a high-powered rifle at 165 dB SPL and a duration of 0.003 sec. How long would that individual have to work in an occupational noise environment in which the sound level was 90 dBA until the acoustic energy received was equal to the gunshot? The answer is almost a full work week of 8-h work days. In other words, one bullet equals 1 wk of hazardous occupational noise exposure. Because shells are often packaged in boxes of 50, shooting one box of shells is equivalent to working in a 90 dBA environment for a full year! An avid target shooter can produce an entire year's worth of hazardous occupational exposure in just a few minutes on the target range.

One method of determining the role of shooting on hearing loss is to compare audiometric data in groups of individuals who engage in shooting with a matched group who do not. Variations of such an approach have been reported in a number of studies. Virtually all of them show significant effects on hearing produced by gunfire noise, with the ear contralateral to the firearm exhibiting thresholds worse than the ipsilateral ear by about 15 dB for high-frequency (3–8-kHz) stimuli, and up to 30 dB for avid shooters.

Because shooting is so prevalent in our culture, it is the most important source of excessive noise outside the workplace. However, there are other significant nonoccupational sources of excessive noise exposure.

Noise and Ultrasound
William W. Clark, Ph.D.

12 Listening to amplified music
Rock Concerts
There is a large body of research published within the past two decades that detail exposures to individuals attending rock concerts and noisy discotheques. An analysis of all the data indicated the geometric mean of all published sound levels from rock concerts was 103.4 dBA (5). In general, it is reasonable to conclude that attendees at rock concerts or noisy discotheques are routinely exposed to sound levels above 100 dBA. Studies of temporary threshold shift (TTS) after exposure to rock

music have most often considered only the hearing levels of performers; a few studies have shown TTSs in listeners attending rock concerts. Generally, these studies show that most listeners sustain moderate TTSs (up to 30 dB at 4 kHz), which recover within a few hours to a few days after the exposure. The risk of sustaining a permanent hearing loss from attending rock concerts is small, and is limited to those who frequently attend such events. However, attendance at rock concerts remains an important contributor to cumulative noise dose for many Americans.

Personal Stereos

Increased use and availability of personal listening devices, such as the Sony Walkman, has led to general concern about potentially hazardous exposures, particularly for younger listeners. The question of whether listening to music through headphones may cause hearing loss depends on, among other things, the volume level selected by the listener, the amount of time spent listening, the pattern of listening behavior, the susceptibility of the individual's ear to noise damage, and other noisy activities that will contribute to the individual's lifetime dose of noise.

Although several studies have suggested that personal stereos are capable of producing exposures above 120 dBA, analysis of listening habits suggests that most users of personal stereos listen at volume levels that do not pose a risk of hearing loss. Fewer than 5% of users select volume levels and listen frequently enough to risk any hearing loss whatsoever.

Noise and Ultrasound
William W. Clark, Ph.D.

13 The keys to prevention and management

With so many diverse sources of excessive noise exposure in our work and play environments, identifying strategies to prevent hazardous exposures, to protect the hearing of individuals who must or choose to be exposed, and to offer methods of rehabilitation for those who must communicate in a noisy environment or who must cope with a noise-induced hearing loss, is a daunting task. However, it should be remembered that, unlike other diseases or injuries, noise-induced hearing loss is preventable. It can be avoided by reducing excessive exposure, or by protecting our ears during exposure.

If it is that easy, then why do so many people have noise-induced hearing loss? The answer lies in the insidious way in which noise-induced hearing loss creeps up on its victims. By the time enough damage has accumulated to produce a functional impairment, it is far too late to prevent the loss. Add to that the fact that protecting hearing is not generally considered a “macho” thing to do and that exposure to some loud noises can be exciting, and one has all the ingredients for a noise-induced hearing loss. It has been stated that prevention of excessive noise exposure would be more easily accomplished if the ear would bleed after a rock concert or an afternoon of shooting. What is needed is an approach that informs the patient about the potential for noise to cause a hearing loss before it is too late.

Key 1 Education

Whether in the workplace or at home, the key to prevention is education. Several national professional associations have been working to provide educational curricula about hazardous noise for elementary and secondary school children. These curricula are designed for use by science or health teachers to train “healthy hearing habits” for young ears, before the damage begins to accrue. Axelsson and Clark (17) have suggested schools invite “hearing professionals” to augment the curriculum with real-life experiences to help get the message across to children. Of course, professionals involved in aural rehabilitation would be ideal candidates for such a position.

Federal law requires regular education programs for employees exposed to potentially hazardous noise. However, these programs are only required to consider workplace noise, and they are often only given to employees in high-noise environments. However, since the ear does not know the

difference between an occupational and a recreational exposure to hazardous noise, education programs should be provided to all employees, and the emphasis should be placed on global hearing health and not restricted to job-related exposures.

Key 2 Prevention of Exposure

The second key is to prevent excessive exposure to noise. In the workplace, emphasis on engineering control of noise emission has reduced occupational exposures for many kinds of jobs. For example, lightweight fiber materials have replaced sheet metal in several manufacturing operations, and glues are now used to bond airplane wings, rather than the noisy rivets used in prior decades.

Administrative controls can also reduce employee exposure. An example of an administrative control is to assign workers to noisy jobs only part of the workday, and to quiet areas for the rest. By careful placing of individuals, exposures can be reduced, even though the noise in the plant is not.

Administrative and engineering controls can also be employed in the home. One can avoid excessive exposure to unwanted noise, and become a judicious consumer of wanted noise. Are rock concerts your fancy? By all means, enjoy them, but limit attendance to the special concerts you really like. And don't participate in other noisy activities on the day you attend the concert (mow the lawn another day).

Key 3 Wear Hearing Protection

In situations where the noise cannot be eliminated, hearing protectors should be worn. The two most commonly used protectors are earplugs or muffs. Earplugs come in a variety of styles and sizes. Recommended are the foam-type plugs, which are squeezed gently between the thumb and forefinger, and inserted into the external ear canal. The foam then expands and forms a seal. Other types of earplugs are made of plastic or silicone, and some are custom-fit for the user. The advantages of earplugs are their small size, comfort, and the fact that they are disposable. However, some individuals find the plug and the resulting occlusion of the ear canal uncomfortable.

The other type of hearing protector is a muff that fits over the ear. The advantage of this type of protection is that it is heavier and often provides a little better attenuation than the smaller earplug. Muffs are also reusable, and when kept in good condition can be considerably cheaper than disposable earplugs. In occupational environments it is easier to see that a worker is wearing a muff than a plug. A disadvantage of the muff-type protector is that a seal must be made between the earmuff cushion and the side of the head; any break in the seal renders the muff useless. Individuals who wear eyeglasses have a difficult time wearing the muffs because the temple piece of the eyeglass interferes with the seal.

In home environments, it is recommended that individuals wear hearing protection anytime they are exposed to loud, unnecessary sound. The type of plug or muff selected is of secondary importance. There is an adage in hearing conservation that says: “The most effective hearing protective device is one that is worn.” Comfort is of utmost importance. Most individuals will find the foam plugs the protector of choice. They are cheap, comfortable, disposable, and readily available at hardware and drug stores.

All hearing protectors are sold with a listing of the “noise reduction rating” (NRR). This rating refers to the decibel attenuation of the muff observed under laboratory test conditions, and varies from about 15 to 35 among various plugs or muffs. Although the NRR is useful for comparing among hearing protectors, it does not describe the actual attenuation one would expect in practice. In fact, studies have shown that muffs or plugs with NRRs of 25–30 actually only provide about 10 dB of protection when fit by the workers in actual working environments. But, as a matter of fact, most industrial and many environmental noise sources are in the 85–95 dBA range. In these environments, it is only necessary to reduce the level to below 85 dBA to make the environment safe, even for a working lifetime. Therefore, hearing protectors with attenuations of greater than 10 dB are not needed, and if they are used, they present additional problems for the user.

An individual working or playing in a 90-dB environment and wearing a hearing protector that

provides 25 dB of attenuation will have difficulty understanding speech while he is wearing the protectors. Many workers fear they will not hear warning shouts from co-workers if they wear hearing protection, and for the worker using a protector with more than the necessary attenuation, this is a valid concern. In this scenario, it is far better to recommend a hearing protector with more modest attenuation rating, and speech understanding will be preserved.

Special types of hearing protectors have been developed for special situations. One type, the "musician's" earplug, is specially developed to provide a flat attenuation. Unlike the traditional plug, which makes speech or music sound muffled, the "musician's" plug provide a much more realistic sound to the user, and, although they are expensive, are preferred by musicians and others who desire a more realistic quality to their auditory perception.

Another type of earmuff incorporated a microphone and amplifier into its design. Sometimes called the "hunter's earmuff," these protectors attenuate high-level sounds, like the report of a shotgun, but amplify low-level sounds, like the snapping of a twig by prey. They are particularly useful in environments characterized by high-level, impulsive sounds.

Finally, the field of active noise cancellation (ANC) technology has reached the hearing protector market, and several protectors are now commercially available that incorporate ANC. First developed by the military for use in tanks, ANC utilizes a very fast computer that samples the noise and generates a "mirror image" of it, which is then played along with the source noise, thus cancelling it. Although the field is still in its infancy, ANC is an effective means to cancel low-frequency noise, and hearing protectors using it generate an extra 5–10 dB of attenuation in the low frequencies, reducing the masking of speech considerably. Hearing protectors incorporating ANC are expensive (about $300), but look for the price to drop rapidly as the technology advances.

Noise and Ultrasound

14 Biological Effects of Infrasound

Infrasound is usually considered to include the acoustic frequency range from 0.1 to 20 Hz (18). This range is below the range of human auditory sensitivity, although individuals can perceive high-level signals lower than 20 Hz as pressure fluctuations. Although there are studies showing hazardous effects of intense infrasonic exposure in animal subjects, only one study appears to document permanent hearing loss in humans. In that study, Tonndorf (19) described scarring in the tympanic membranes of German submariners assigned to snorkel submarines.

Hazardous exposures to infrasound appear to be limited to exposures that produce levels of greater than 130 dB SPL at the ear. In humans, these exposures are usually transient or of short duration. A partial list of exposures from natural or manmade activities is included in Table 99.6.

Table 99.6. Sources of Infrasound Found in Nature and in Man-Made Activities[a]

Source	Predominant Frequency (Hz)	Est. Max. SPL (dB)
Natural		
Thunder		
Earthquake		

Ocean waves	<1	
Wind (100 km/h)	<1	135
Manmade		
Sonic booms	1–20	120–160
Jet engines	1–20	135
Helicopters	1–20	115
Large rockets	1–20	150
Diesel engines	10–20	110
Air bags	10–20	170
Door slams	1–20	150
Manmade activities		
Running	<2	90
Swimming	<2	140
Ear cleaning	3–5	185
Vibrating finger	1–5	170
Diving	0.1–5	180
Snorkel submarines	5–20	140
Blowing in one's ear		170

[a] Adapted from Ref. 20.

It is interesting to note that the only source listed in Table 99.6 causing lengthy exposures, the snorkel submarines, is the one exposure documented to cause permanent damage to the human auditory system. Nixon and Johnson (21) reviewed studies of temporary threshold shift (TTS) in volunteer subjects after exposure to infrasound. Although the data are meager, they concluded that infrasound does not cause TTS for exposures below 140 dB and continuing for less than 30 min. Higher-level, short-duration exposures (up to 142 dB for 5 min) also did not generally cause TTS. The few subjects who did experience TTSs had them in the high frequencies (2–6 kHz), even though the exposures were to very low-frequency stimuli.

Only a few studies have addressed the hazardous effects of infrasound in animals. A comprehensive report of anatomical effects observed in chinchillas exposed to infrasonic stimuli (1, 10, 20 Hz) at levels of 150, 160, and 170 dB SPL detailed extensive pathology (22). Subjects exposed to the highest-level, lowest-frequency stimuli sustained tympanic membrane perforations, stapes subluxations, bleeding in the middle ear, strial pathology, Reissner's membrane rupture, endolymphatic hydrops, and saccular wall rupture. Only the animals exposed at 20 Hz sustained significant damage to the sensory receptor cells. It should be remembered that the chinchilla is much more susceptible to damage from noise exposure than humans (by about 20 dB); so the effects noted in the report would be limited to continuous exposures that exceed 170 dB SPL.

But what about impulse noise? Unlike continuous exposure, impulsive sounds produce rapid changes in atmospheric pressure. The two most common sources of impulsive infrasonic exposures come from sonic booms and from the detonation of automobile air bags. Sonic booms from low-flying (<1000 ft) aircraft are relatively rare, and usually are limited to military personnel. Personnel exposed to 30 sonic booms daily for two 30-d periods at levels up to 157 dB SPL showed no evidence of hearing loss (23). Although these booms can startle listeners, shake dishes in cabinets, rattle windows, and cause cracks in building foundations, they do not cause hearing loss.

Sonic booms from high-flying (>10,000 ft) aircraft lose most of the higher-frequency energy by the time the boom strikes the ground, and thus become infrasonic in nature. Typically, a community

might experience booms in the range of 121–140 dB peak sound pressure level. Because a 10,000-ft minimum is used in the United States in those few areas where sonic booms are allowed, sonic booms should not be expected to constitute a hazard to human hearing.

More common are exposures from airbag deployment. Recently, publication of case studies of hearing loss from airbag deployment (24, 25), have suggested that airbags are capable of causing noise-induced permanent hearing loss. Studies of exposures in cats (26) have documented permanent damage to the auditory system from airbag deployments of approximately 170 dB peak sound pressure level. The addition of side airbags to passenger vehicles, which must inflate much faster than dashboard-mounted units because the distance between the collision and the passenger is much shorter than for front-end collisions, may increase the risk. Rapid inflation of an airbag causes an impulsive sound that has its maximum energy in the infrasonic frequency range. The expanding gas inside the airbag, generated from burning powder, also generates a noise burst of lesser energy, but with much higher frequency content. Of the two components, the noise burst causes more TTS than the infrasonic impulse. In fact, the infrasonic signal may "load" the middle ear, and actually attenuate high-frequency sound from reaching the inner ear (26).

The data reviewed suggest that the biological effects infrasound do not pose a significant threat to human hearing. However, there may be some physiological or psychological effects from prolonged exposure to infrasound. Verzini et al. (27) described laboratory and field studies of the physiological and psychological effects of infrasound in volunteer subjects. Subjects were exposed in the field and inside a specially constructed pressure chamber to pure tones (10 Hz at 110 dB SPL), and to a 1/3-octave band of filtered boiler noise (10 Hz at 105+–2 dB SPL). They measured changes in heart rate, galvanic skin response, peripheral temperature, body resonances, and subjective assessment of the anxiety produced by the exposures. No differences in the physiological variable were observed. However, subjects felt more anxiety inside the pressure chamber, and they rated all sounds as more stressful under laboratory rather than field conditions. Although body resonances were felt, particularly in the chest and in the ears, they did not contribute significantly to the anxiety felt by the subjects. Low-frequency noise exposures similar to those experienced by Verzini's subjects probably occur for those exposed to high-amplitude music from "boom boxes." Although extremely annoying, these exposures probably do not cause hearing loss or any other physiological pathology.

Noise and Ultrasound
William W. Clark, Ph.D.

15 Biological Effects of Ultrasound
Although the human auditory system does not respond to acoustic signals above approximately 20 kHz, intense acoustic signals at very high frequencies (750 kHz to 8 MHz) are used diagnostically to provide images of human tissue. Ultrasonographic imaging has been used as an effective diagnostic tool for more than 30 yr. During that period, there has been no documented epidemiological evidence of adverse effects in patients caused by exposure to ultrasound (28). However, technological advances that have greatly increased the sensitivity of the imaging techniques have been accompanied by large increases in the acoustic output levels of ultrasonographic equipment. These advances have led to increasing use of the techniques clinically, and they may increase the risk of injury to patients or health care providers.

Laboratory studies have shown that ultrasound is capable of producing serious biological damage if the intensity is sufficiently high. Damage is produced from thermal as well as nonthermal effects. Both mechanisms are important, and the mode of damage depends upon the exposure parameters used. Excellent reviews of the biological effects of ultrasound are available (29, 30). The following information is adapted largely from those reviews.

Noise and Ultrasound
William W. Clark, Ph.D.

16 Temperature
Much of the information about the effects of temperature on adult and fetal tissue relates to the effects of hypothermia in the absence of ultrasound. Ultrasonic stimulation causes an increase in temperature of tissue during stimulation. Resulting hyperthermia from the stimulation may cause damaging effects, either due to the absolute temperature elevation or due to rapid changes in temperature. There may be synergistic effects between external stimuli and the internal core temperature of the patient; for example, a febrile patient may be more susceptible to ultrasound tissue damage than an afebrile patient.

Temperature increases within the human body may be due to fever or to hypothermia. There is a difference between these two factors in that fever results in an elevation of the body's "set point" for thermoregulation, whereas hypothermia does not, even though much higher temperatures may be encountered. Fever is considered to be an adaptive mechanism that destroys invading viral or bacterial agents that cannot tolerate high temperatures. Fever is accompanied by the production of an endogenous pyrogen released by leucocytes and shifts the body's thermostat to a higher level. On the other hand, hyperthermia does not induce pyrogen release, but, when a certain temperature is reached, it may induce the release of heat shock proteins. In the environment, hyperthermia may result from exposure to hot water, hot air, or sunshine. In contrast to environmentally induced hyperthermia, ultrasound exposures use microwave or radio frequency energy transmitted along a narrow beam. The absorption of ultrasonic energy results in rapid increase in temperature along the area of the beam. The time constant for ultrasonic absorption of heat is much too fast (on the order of seconds) for any protection to be afforded by the release of heat shock proteins, which require many minutes of exposure before their protective mechanisms are activated.

Homeothermia refers to the capacity of most mammals to maintain a constant internal body temperature. For humans, a "normal" core temperature is considered to be 37°C, although skin temperatures are considerably below that (31–34°C), and organs with very high metabolic activity, such as the liver, can have temperatures as high as 39°C. Core temperatures of other mammals commonly used as experimental subjects, such as dogs, mice, rats, sheep, and goats have higher core temperatures (39–40°C). When evaluating the safety of temperature effects from data obtained in animal subjects, the difference in core temperatures needs to be taken into account. A temperature of 41°C in a guinea pig represents a 1.5°C elevation above normal core temperature; the same temperature in a human would be 4°C above core.

In humans the physiological effects of temperature elevations up to 40.5°C are reversible. They include circulatory collapse, muscular cramps, and exhaustion. Sustained temperatures above 41.5°C are barely compatible with life, and a temperature above 43°C is an ominous warning of death by heat stroke. Although biological tissue can withstand larger variations in temperature, it is known that temperature elevations exceeding 6°C can cause cell death. Smaller elevations can cause significant biological effects, including increased heart rate, leakage of proteins through capillary membranes, edema, and production of heat shock proteins.

Embryos, fetuses, and fetal tissue present additional challenges. In mammals, fetal temperature is usually 0.5–1°C higher than the maternal core temperature. The embryos and fetuses of all species, including humans, are susceptible to increases in temperature. Early effects are usually lethal. At later stages, developmental effects are observed. These include anencephaly/exencephaly, encephalocele, microphthalmia, micrencephaly, and disorders of locomotion, among others. The type and extent of damage depends upon the species studied, the developmental stage during exposure, and the dose of heat delivered to the embryo. These effects are all severe, and represent a

serious hazard from heating of embryonic tissue. In many cases, developing neuroepithelial cells are damaged by heat, and the death of these cells results in defects in neural tube closure.

Local hypothermia can also produce lesions in humans. In the skin, a temperature above 47°C induces erythema and pain; above 55°C, a blistering, and above 60°C for 1 min necrosis. The threshold level for irreversible damage in fatty tissue, muscle, cartilage, and gut is 43°C. Local hyperthermia is used clinically to destroy more active (and warmer) cancer cells while sparing neighboring normal cells. This is accomplished by heating the desired tissue to just above 42°C.

Therefore, the greatest concerns for safety for ultrasound use in clinical diagnosis are for stimuli that raise temperature above 42°C, or change tissue temperature by more than 4°C, and additional precautions to prevent fetal anomalies.

Interrogation of tissue by an ultrasonic beam produces narrow, localized regions of tissue heating. In addition, the extent of heating depends upon both acoustic and biological properties of the tissue. Dense materials, such as bone teeth, and optic lenses have high acoustic absorption coefficients, and are differentially heated more than soft tissue. Bone has an absorption coefficient at least 30 times that of the adjacent soft tissue; the tissue is also heated by the bone. As mentioned, the most sensitive target for ultrasound biological effects is the developing fetus. During the early stages of development (approximately 60 d gestation), the fetus has low mass and a low acoustic absorption coefficient. As bone develops, the potential risk for damage to the developing neuroepithelial tissue increases.

Based in part upon the evidence reviewed, the World Federation of Ultrasound in Medicine and Biology (WFUMB) issued consensus statements on thermal issues, which were published in 1998 (29). It concluded that diagnostic ultrasound applications which use the so-called B-mode imaging do not operate at levels capable of producing harmful temperature elevations. Its use in medicine is therefore not contraindicated on thermal grounds. Systems that used Doppler diagnostic equipment can produce biologically significant temperature rises, specifically at bone/soft tissue interfaces. It recommended that elevated temperature effects be minimized by keeping the time for which the beam passes through any one point to a minimum. The WFUMB also recommended that the lowest output power consistent with obtaining the desired diagnostic information be used. Finally, it labeled all procedures which prevent tissue heating above 38.5°C as safe, even for obstetric applications.

Noise and Ultrasound
William W. Clark, Ph.D.

17 Acoustic Cavitation
Acoustic cavitation is defined as sound-induced activation of gas-filled cavities. It is a physical phenomenon, present in all forms of liquids and gases. There are two types of cavitation effects: inertial and noninertial. *Inertial cavitation* occurs when a gas-filled cavity in a liquid expands in response to being driven during a part of an acoustic cycle, then “collapses” or relaxes to a small fraction of its original volume. While the cavity, or bubble, is collapsing, liquid is drawn inward, thus the “inertial” effect.

At the end of the collapse, shock waves can propagate through the gas, and be emitted into the liquid. These shock waves can produce acoustic pressures of several hundreds of megapascals and generate temperatures of several thousands of degrees Kelvin. The collapse of the bubble can also produce free radicals that can yield reactive elements. In some cases the collapse causes emission of a flash of light, which has been termed *sonoluminescence*. With periodic stimulation, bubbles sometimes oscillate, collapsing, regrouping, expanding, and collapsing again. Occasionally they disintegrate into smaller bubbles, which sometimes are dissolved. Cavity collapse can also cause jets

of liquid to be ejected away from the collapse area; the momentum of these jets can damage tissue structures.

Noninertial cavitation refers to acoustic effects not caused by inertial actions of the fluids. These effects include formation of jets, surface distortion, and heat generation. In general, noinertial cavitation effects are observed at acoustic pressures lower than those required to produce inertial cavitation effects. Whether a bubble responds with inertial or noninertial cavitation depends, upon other things, upon the pressure, the acoustic frequency, and the initial bubble size. Noninertial cavitation is also called *stable cavitation*. It refers to the continuous oscillation of bubbles in response to alternating positive and negative pressures in the acoustic field, and it exists for a number of cycles with continuing stimulation.

Biophysical Considerations

A wide variety of physical, chemical, and biophysical effects can be produced by ultrasonic stimulation through the action of inertial and noninertial cavitation. Although the physical behavior is very complex, considerable insight has been gained through the study of simplified models. Studies of cavitation activity by physicists and acousticians have been spurred not only by health considerations for ultrasound, but also on practical grounds. Initial fascination with sonoluminescense has led to understanding of the large amounts of energy released during bubble collapse, and ultimately to proposals for devices, such as pumps, motors, and loudspeakers that are driven acoustically.

The major biophysical effects of cavitation activity are summarized as:

1. Linear resonance. As long as the driving force is not too high, spherical bubbles respond to sinusoidal stimulation linearly; that is, both the pressure in the liquid and the radius of the bubble varies sinusoidally with the driving force. Therefore, the bubble responds as a harmonic oscillator with a resonance frequency that is inversely related to the bubble volume, or, alternatively, the resting or average bubble radius. For a bubble with a radius of 10 mm, the resonance frequency is 0.33 MHz (29).
2. Scattering. When an ultrasonic signal impinges upon any object that has a different acoustic impedance than the medium it is traveling in, such as a gas bubble in a fluid, much of the energy is scattered or reradiated into the medium. It is just this reason that gas-containing particles are particularly effective as contrast agents for diagnostic ultrasound (30).
3. Heat production. The part of the energy that is not scattered when an ultrasonic wave strikes a bubble is converted into heat. When cavitation occurs in tissue, acoustic absorption coefficients can increase by as much as twofold. That is, for a given intensity of ultrasound beam, the rate of heat production would double.
4. Diffusion and rectified diffusion. As a bubble contracts and expands sinusoidally in the presence of a continuous ultrasonic wave, gas diffuses sinusoidally from the fluid into and out of the bubble. Even in a sound field where the acoustic pressure varies sinusoidally, the inward flow of gas exceeds the outward flow. Consequently, the net effect is an increase in volume of the bubble. This process is called *rectified diffusion*, and it results in bubble growth. Increase is bubble size through rectified diffusion has been observed in mammalian tissue (31), and it also plays a major role in bubble dynamics associated with lithotripsy fields.
5. Radiation forces on bubbles. Cavitation activity is affected strongly by net forces, called *acoustic radiation forces*, which act on bubbles. These forces cause bubbles to move around, to change their radii, and to combine with each other. For example, in an acoustic standing wave, smaller bubbles accumulate at pressure nodes, and bubbles larger than resonance size accumulate at pressure antinodes, as would be expected. In a plane progressive wave, bubbles move away from the source, sometimes at high speed. Bubbles smaller than resonance size may attract each other and coalesce, contributing to bubble growth.
6. Attraction of cells to a vibrating bubble. In a liquid medium, oscillating bubbles will attract particles with densities higher than the surrounding medium, such as red blood cells. Aggregation

of red blood cells can affect cavitation damage.

7. Acoustic microstreaming. As bubbles oscillate, the fluid surrounding the bubble is moved, sometimes with great velocity, around the bubble. Microstreaming effects have been related to the following types of damage: hemolysis, release of protein, degradation of DNA in solution, release of ATP from erythrocytes, and mechanical damage to plant cells. The mechanism of damage is thought to be related to the large shear forces generated by microstreaming effects, particularly near the walls of cells.
8. Inertial effects. These include sonoluminescence, production of free radicals, and destructive pressure pulses, as described.

The biological effects of cavitation depend upon the mechanism of stimulation (continuous or pulsed), and the amount of stimulation, and the substrate, cells in suspension, plants or insects, or mammals. In mammals, effects of cavitation include lesions of lung tissue and focal lesions of the brain, and irreversible hind limb paralysis. Some therapeutic findings have also been reported, including blood vessel repair. It is interesting to note that many of the destructive effects of ultrasound have been reported at clinically therapeutic levels. A summary of the major bioeffects of cavitation is given in Table 99.7.

Table 99.7. Summary of Relevant Cavitation-Related Bioeffects[a]

Effect	Frequency (MHz)	Pulse Duration or Continuous Wave	Exposure Parameters	Exposure Time	Duty Factor	Remarks	I
Bubble growth in guinea pig hind limb	0.75	CW	Temp. avg. effective Int = 110 mW/cm^2	7–70 min		Bubbles observed ultrasonically after 30 min	3
		Physiotherapy 2-ms pulses	Temp. max. effective Int. = 240 mW/cm^2		50%		
Bubble growth in gels	0.75	CW	P_r = 65 kPa	1–5 min		Bubble growth threshold for CW; pulsed exposure is below threshold	3
	0.75	100 ms	P_r = 1 MPa	5 min	50%		
Tissue regeneration	3.50	2 ms	I_{SPTA} = 0.1 W/cm^2 Temp. max. effective Int = 0.5 W/cm^2	5 min 3 per week	20%	Physical therapy; beneficial effect due to stable cavitation	
Kidney damage	shock wave	1-ms pulse	P_c = 100 MPa P_r = 10 MPa	1500 shocks in 15 min		*In vivo*, in dogs, robust effect	3
Drosophila larvae killed	2.50	1 ms	I_{SPTA} = 3 mW/cm^2	2.5 min	0.06%	Indicates *in vivo* conditions	3

			I_{SPPA} = 50 W/cm^2			under which diagnostic ultrasound intensities may cause cavitation effects	
Lung damage in mice	1.2	10 ms	P_c = 0.7 MPa I_{SPTA} = 1 mW/cm^2	3.0 min	0.1–0.01%		3
Mutagenicity	1.0	CW	I_{SPTA} = 35 W/cm^2	10–180 s		Rotating test tube; effect due to enhanced cavitation	3 4
	1.0	CW	I_{SPTA} = 35 W/cm^2	120 s	—		
Chromosome single-strand breaks	1.61	CW	I_{SPTA} = 8 W/cm^2	10 or 30 min	—	Cavitation-induced toxic sonochemicals responsible for effect	4
Free radicals detected in aqueous sols	1.0	6.5 ms	I_{SPTA} = 2.5 W/cm^2 I_{SPTA} = 90 W/cm^2 P_r = 2 MPa	10 min	2.6%	Detected in aqueous solutions *in vitro*, not observed *in vivo*	4
Hind limb paralysis in mouse neonate	1.0	CW	I_{SPTA} = 289 W/cm^2	500 ms	—	Threshold for paralysis in mouse	4
Necrosis in cat brains	1.0–8.0	CW	I_{SPTA} = 500 W/cm^2 *in situ*	0.5 s	—	*In vivo* focal lesions; robust effect; I_2t intensity/time constant for theshold	4
Cavitation in blood	0.5–1.6	CW	I_{SPTA} = 16 W/cm^2		—	Bubbles not detected in canine flowing blood, although produced *in vitro* in water	4

Noise and Ultrasound

William W. Clark, Ph.D.

18 Summary

Ultrasonic stimulation, although not audible, can cause adverse biological responses in humans, plants, and other animals. Thresholds for damage are time dependent for thermal effects and time independent for cavitation effects. The magnitude of the effect, however, depends upon the total duration for any exposure once the threshold has been exceeded. Thermal effects, and the risk of damage or death, is greatest during embryonic development; the presence of a fever may exacerbate the risk of ultrasound damage from thermal effects.

Cavitation effects are considered to be responsible for most of the adverse biological effects produced by ultrasonic stimulation. Significant biological effects, such as cell death and irreversible damage to lung tissue, have been observed experimentally in mammals including nonhuman primates. Effects were noted at pressure/duration combination similar to levels currently available in diagnostic ultrasound equipment.

Based upon its review of extant scientific data, the World Federation of Ultrasound in Medicine and Biology (WFUMB) published a list of recommendations for the safe use of ultrasound (30). These recommendations are listed in the following.

Noise and Ultrasound
William W. Clark, Ph.D.

19 Recommendations: Thermal Effects

- A diagnostic exposure that produces a maximum *in situ* temperature rise of no more than 1.5°C above normal physiological levels (37°C) may be used clinically without reservation on thermal grounds.
- A diagnostic exposure that elevates embryonic and fetal *in situ* temperature above 41°C (4°C above normal temperature) for 5 min or more should be considered potentially hazardous.
- For diagnostic ultrasound systems that are capable of producing a tissue temperature increase >1.5°C above normal, users should be provided with worst-case estimates of temperature increase for all pertinent operating models.
- The risk of adverse effects of heating is increased with the duration of exposure. Thus safety guidelines should include an appropriate duration factor.
- Care should be taken to avoid unnecessary additional embryonic and fetal risk from ultrasound examinations in febrile patients.
- If temperatures above 41°C may occur at the surface of an intracavitary transducer when in use, such equipment should provide temperature information to the user during equipment operation.

Noise and Ultrasound
William W. Clark, Ph.D.

20 Recommendations: Nonthermal effects

- The possible occurrence of cavitation, either inertial or noninertial, should be considered in assessing the safety of diagnostic ultrasound and of other forms of medical ultrasound.
- Caution is required in applying results of *in vitro* ultrasound biological effect studies to medical ultrasound exposures *in vivo*.
- It has been shown experimentally that acoustic cavitation can alter mammalian tissues. It is therefore important to consider its significance in medical applications of ultrasound.
- Currently available animal data indicate that it is prudent to reduce ultrasound exposure of human postnatal lung to the minimum necessary to obtain the required diagnostic information.
- Estimates of tissue field parameters at the point of interest should be based of derated values calculated according to an appropriate specified model and be extrapolated linearly from small signal characterization of source–field relationships.
- The acoustic *pressure amplitude* at the point of interest for a given frequency should be used as a *primary* index of the potential for adverse, nonthermal biological effects of an ultrasound exposure.
- A risk–benefit analysis should be performed if anticipated acoustic pressure amplitude at the surface of postnatal lung tissue exceeds 1 MPa.
- Safety evaluations should consider the characteristics of the site of ultrasound exposure. Thresholds for nonthermal biological effects are lowest in:

  1. tissues that naturally contain gas bodies, e.g., postnatal lung and intestine, and
  2. all tissues in the presence of introduced gas bodies, e.g., ultrasonic contrast agents

- *In vitro* studies: Because the probability of cavitation is much greater for *in vitro* conditions, one must be cautious in applying *in vitro* experimental results to the clinical situation.
- Contrast agents: Gas bodies introduced by a contrast agent increase the probability of cavitation. A physician should take this into account when considering the benefit–risk ratio of an examination.
- Pulmonary capillary bleeding: In considering the significance of ultrasound-induced pulmonary red blood cell extravasation and capillary bleeding, one must realize that these effects also can occur as a result of coughing and can occur spontaneously in neonates. For the most part, unless there is extensive hemorrhage, the clinical significance is negligible, and its occurrence would be difficult to detect. Nevertheless, it is prudent to reduce ultrasound exposure to the postnatal lungs to the minimum necessary to obtain the required diagnostic information.
- B-mode imaging: When tissue–gas interfaces or contrast agents are not present, the use of B-mode imaging need not be withheld because of concern for ultrasound safety. This statement also applies to endoscopic, transvaginal, and transcutaneous applications. When tissue–gas interfaces or contrast agents are present, ultrasound exposure levels and durations should be reduced to the minimum necessary to obtain the required diagnostic information.
- Doppler: When tissue–gas interfaces or contrast agents are not present, and where there is no risk of significant temperature elevation, the use of diagnostic Doppler equipment need not be withheld because of concern for ultrasound safety. When any of the above conditions might be present, ultrasound exposure levels and durations should be reduced to the minimum necessary to obtain the required diagnostic information.
- Information about clinically relevant quantities describing, for example, the anticipated temperature elevation or the potential for cavitation should made available to health care professionals. Methods for making this information available include, for example, the continuously updated display of a thermal index and mechanical index, and the classification of ultrasound fields.
- Education: Diagnostic ultrasound has potential for both false-positive and false-negative results. Misdiagnosis is far more dangerous than any effect that might result from the ultrasound exposure. Therefore, diagnostic ultrasound should be performed only by persons with sufficient training and

education.

Electric and Magnetic Fields and Occupational Health
Leeka I. Kheifets, Ph.D.

1 Introduction

Electric and magnetic fields (EMF) are ubiquitous. The earth has static electric fields, which produce lightning during thunderstorms, and geomagnetic fields created by electric currents within its core. Electric and magnetic fields are also produced during electric power generation, transmission, and use.

Electric power has generally been considered safe during the more than 100 years of its use, although shocks and burns from direct contact with electrical conductors are a recognized health

hazard. Of the approximately 1100 deaths from electric shock that occur each year in the United States, about three-fourths result from unsafe operation of household appliances; accidents in the workplace account for the rest (1). The possible health consequences of electric and magnetic field exposure are a much more recent concern.

Power-frequency EMF exposure—unavoidable since the use of electricity has spread throughout the world—has been under investigation since the early 1970s. Investigations have included epidemiologic as well as *in vitro* and *in vivo* laboratory studies encompassing a wide range of diseases. The literature on EMF and health is vast, comprising over 1000 published studies, and has been reviewed in depth by several authoritative committees. Of note are reviews by the National Research Council of the National Academy of Sciences (NAS) (2), the National Institute of Environmental Health Sciences (NIEHS) (3), and the U.K. National Radiological Protection Board (NRPB) (4).

Electric and Magnetic Fields and Occupational Health
Leeka I. Kheifets, Ph.D.

2 The Nature of Electric and Magnetic Fields
Electric power systems in the United States, Canada, and Mexico generate and transmit electricity as alternating current (ac), which oscillates at a frequency of 60 cycles per second, or 60 hertz (Hz). Most of the rest of the world generates power at 50Hz. Power-frequency 50- and 60-Hz fields occupy the extremely low-frequency (ELF), nonionizing range of the electromagnetic spectrum (Fig. 100.1). The ELF range includes frequencies from 3 to 3000Hz. Above 3000Hz are, in order of increasing frequency or decreasing wavelength, radio waves, microwaves, infrared radiation, visible light, ultraviolet radiation, x-rays, and gamma rays. Microwaves have enough photon energy to heat tissue; ionizing radiation like x-rays and gamma rays can damage biological systems by breaking chemical bonds. Extremely low-frequency electric and magnetic fields can neither break bonds nor heat tissue, and the electric currents they induce in the body are very weak.

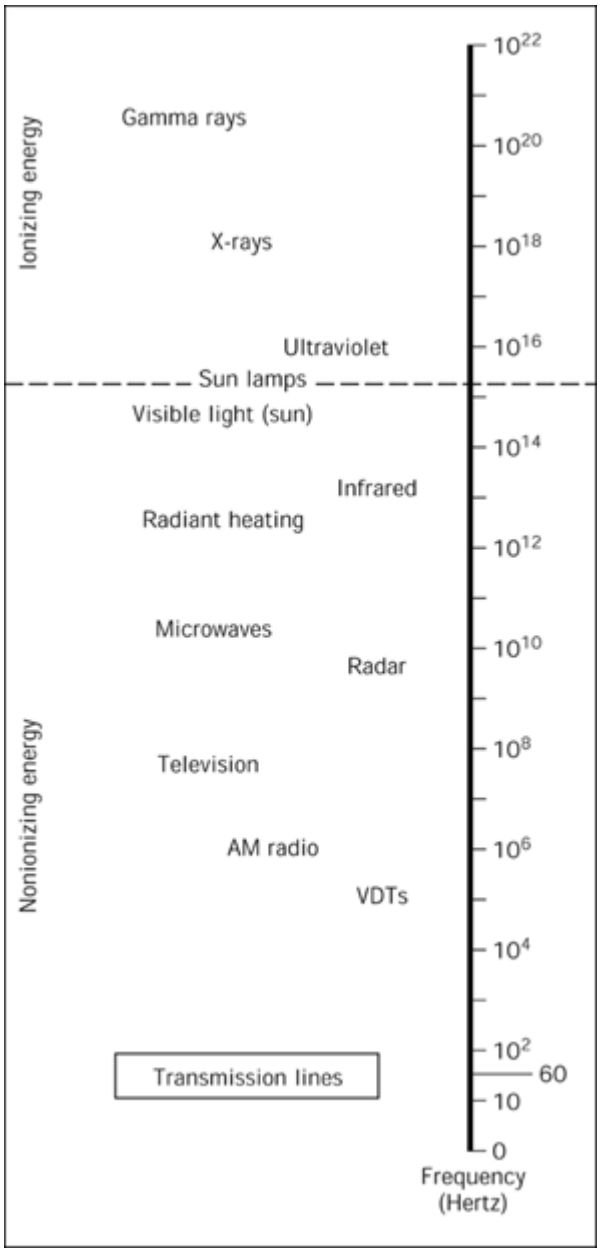

Figure 100.1. The electromagnetic spectrum.

Power-frequency fields have very long wavelengths of about 5000km. Exposure distances are much shorter than this wavelength; under these circumstances, electric and magnetic fields are independent. Electric fields, measured in volts per meter (V/m) or kilovolts per meter (1kV/m = 1000V/m), are produced by electric charges. Magnetic fields are created by moving electric charges, or current, measured in amperes (A). Electric fields are present when an electrical device is connected to an outlet even when turned off, and both electric and magnetic fields are present when the device is turned on. Magnetic fields are measured in tesla (T), millitesla (mT), or microtesla (mT); 1T = 1000mT, and 1mT = 1000mT. Magnetic field measurements may also be expressed in gauss (G) or milligauss (mG), where 1mT = 10mG.

Electric field strength increases with increasing voltage, or electric potential; magnetic field strength increases with increasing current. Both electric and magnetic fields decline rapidly with distance from their source, with a faster decline of fields from point sources such as machinery and a slower decline of fields from power lines. Electric fields are further reduced when shielded by conducting objects like buildings and have little penetrative ability; magnetic fields, on the other hand, are capable of penetrating tissue and are not easily shielded.

Occupational exposure to electric and magnetic fields occurs from proximity to large motors as well as from wiring in buildings and the use of computers, office machines, and heating and air conditioning systems. Power transmission and distribution facilities are other sources.

Electric and Magnetic Fields and Occupational Health
Leeka I. Kheifets, Ph.D.

3 Exposure Assessment
Accurate assessment of EMF exposure has presented many difficulties in epidemiologic studies and continues to be a considerable challenge. EMF have several unique characteristics that make them more difficult to measure than most other types of exposures. EMF are not readily detectable, are variable in time and space, and are to some extent present in all environments (5). Additionally, electric fields are both perturbed and intensified by conducting objects like the human body, so that fields measured at various points on the body's surface have different values. Because of the complexity of exposure circumstances, exposure reports from workers are not reliable.
3.1 Exposure Surrogates
Because for most studies of EMF health effects, the relevant exposures are those that occurred in the past, the use of surrogate indexes is necessary. The use of surrogates likely leads to misclassification and/or bias. Surrogates for occupational EMF measurements used in epidemiologic studies include job titles, work histories, and present-day area and personal measurements.

Early occupational studies used job titles as an exposure surrogate (6, 7). Job titles alone, however, do not yield accurate exposure estimates. Of equal or greater importance are specific industry, work environments, and specific tasks performed. Magnetic field exposure in the electric utility industry, for example, is substantially lower among electricians using de-energized equipment in new facility construction than in those doing repair or maintenance work with energized equipment in existing facilities. Electricians working outside the utility industry are likely to experience different exposure patterns than those working in the utility industry. EMF exposures in nonelectrical occupations could also be higher than job title alone would predict; administrative assistants or managers working in power plants, for example, may experience higher exposures than their counterparts working in an office environment. Exposure assessments using only job title or occupational group are thus likely to misclassify exposures in individual workers.

Recent research has estimated historical exposures using measurements collected for specific job titles among the present-day workforce, particularly in the electric utility industry (8–11). Exposure assessment strategies in a number of studies have made use of measurements for both job title and usual work environment (12, 13). Measurements for specific tasks were used in one study of EMF health effects (14, 15) and in several exposure characterization studies (16, 17). More recent studies have employed quantitative job–exposure matrices based on personal monitoring and/or area magnetic field measurements. This approach, however, is still fundamentally tied to job title, since average exposure levels for a job title are assigned to individual workers. A recent analysis by Kelsh et al. (18) shows the contribution of various parameters to overall exposure within and between worker variability, work environment, company and job variability.
3.2 Exposure Measurement
Exposure meters that can be held in the hand (Fig. 100.2) or worn on a belt are used to measure electric and magnetic fields. Selection of the appropriate meter, as well as regular calibration, is essential for maximal quality, quantity, and relevance of exposure data. Instruments vary in sophistication and function. Some can survey field strengths; others can capture waveforms and count transient fields. The most sophisticated instruments are capable of a number of complex functions, such as calculating the resultant from field strengths measured along three orthogonal axes, recording data over time, and generating pass bands for estimating fundamental and harmonic

fields. For further detail, see guidelines (19, 20) that recommend appropriate instrumentation.

Figure 100.2. EMDEX II (Electric and Magnetic Field Digital Exposure) exposure meter.

As instrumentation facilitates the gathering and storage of large amounts of information, data collection, analysis, and management assume special importance. Appropriate and well-documented procedures for handling data are necessary to ensure their quality and integrity. Freshly collected data should be regularly examined for consistency, completeness, and accuracy.

Another important part of exposure assessment is measurement protocol. Which protocol is most suitable is determined by assessment objectives. For example, spot measurements in specific locations or measurements along a specific path to allow plotting of contours or profiles of field strengths may be adequate to characterize sources and spatial variability. Twenty-four-hour stationary measurements or personal measurements may be more useful in situations where temporal variability is likely to be large (Fig. 100.3).

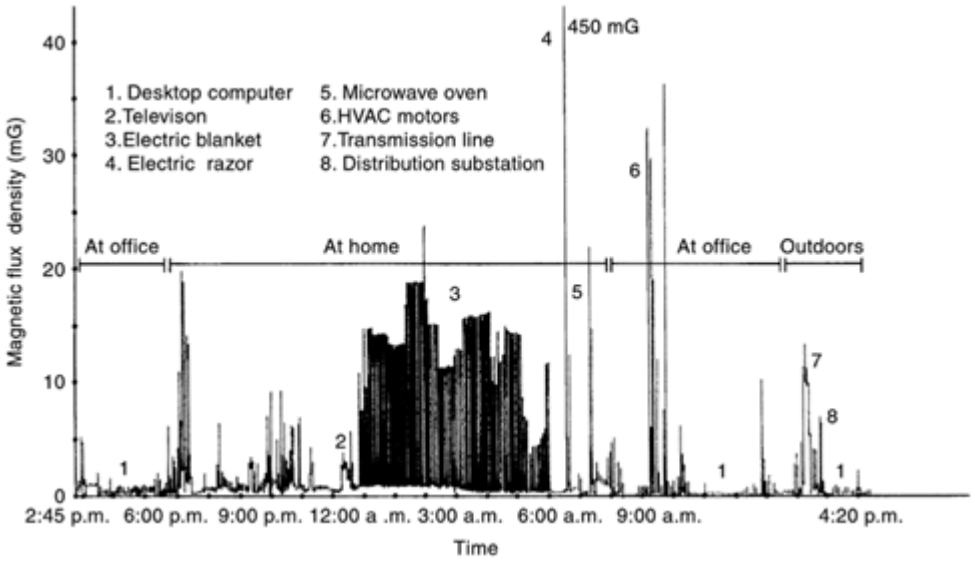

Figure 100.3. Personal magnetic field exposure. Fields from different sources encountered throughout the day vary widely. HVAC, heating ventilation, and air conditioning.

Because error in measurements of EMF can be large, evaluation of factors that may contribute to uncertainty is advisable. In addition, estimating observed overall uncertainty for protocol development, as well as uncertainty introduced by various factors, can help in analysis and interpretation of results.

3.3 Sampling Strategy and Protocol Development

Exposure assessment is complicated by the high temporal and spatial variability of EMF, as previously noted, and by limited understanding of the contributions of different sources to total exposure. Thus an important component of an effective assessment program is selection of a sampling scheme. The sampling scheme must maximize the precision of the quantities being measured. To do so, the number of measurements, the diversity of locations, and the need for repeated measurements must be taken into account. Lack of knowledge about the biological relevance of different characteristics of exposure, or exposure metrics, makes a decision on what to measure difficult. Researchers have developed guidelines for determining which exposure metrics to use in measurement studies (19, 20). At least a time-weighted average magnetic field exposure measurement is suggested, though alternative metrics may be of interest. These guidelines for protocol development also discuss sampling strategies, sample size, sampling parameters, and resource limitations. Additionally, questionnaires and other time–activity record-keeping protocols are covered, along with documentation of methods and results and handling of data.

Most studies of magnetic field exposure are based on nonrandom samples of volunteers. (21). Nonrandom, or purposeful, sampling could give rise to bias if volunteers are not representative of a whole group of workers. If, on the other hand, participants do represent their job classification and perform tasks that are typical of their jobs, nonrandom samples may provide representative exposure estimates. Another potential source of bias in studies using either random or nonrandom sampling is the measurement process. To avoid bias, obtainment of exposure measurements should strive not to alter normal behavior and performance at work.

Since exposure assessment is likely to be complex, pilot studies are recommended. These preliminary studies should test sampling, instrumentation, time–activity record-keeping, subject participation, and quality assurance procedures.

Electric and Magnetic Fields and Occupational Health
Leeka I. Kheifets, Ph.D.

4 Occupational Exposures

Occupational EMF exposures are considerably higher than nonoccupational ones, which are usually in the 0.01–0.3mT range. Occupational exposures have been studied most extensively in the electric utility industry. Average exposures have been found to be higher in “electrical occupations” than in other occupations such as office work, ranging from 0.4–0.6mT for electricians and electrical engineers to approximately 1.0mT for power line workers. Welders have the highest average exposures at 3.7mT. Average measurements, or arithmetic means, however, can be strongly influenced by a few high measurements. Geometric means, which are not thus influenced, are much lower for some occupations. Geometric means are 0.2–0.3mT for electricians and electrical engineers, 0.4mT for power line workers, and 0.6mT for welders.

Much less is known about exposures in nonelectrical occupations; few data, if any, are available for many jobs and industrial environments. Of note in the few surveys conducted are high exposures among railway engine drivers (about 4mT) and seamstresses (about 3mT). The best information on

work exposures among the general population is available in a survey conducted by Zaffanella and Kalton (22). The survey included 525 workers employed in a variety of occupations (Table 100.1). The largest geometric mean (0.16mT) during work occurred in electrical and service occupations. Technical, sales, and administrative support positions had a geometric mean of 0.11mT; managerial and professional specialty occupations, 0.10mT; and precision production, craft and repair work, operation, fabrication, and labor, 0.09mT. At 0.05mT, farming, forestry, and fishing occupations had the lowest geometric mean. Work exposures were often significantly higher and more variable than other exposures; people spent significantly more time, for example, in fields exceeding 1.6mT at work than at home (Fig. 100.4). Nevertheless, average work exposures for the general population are low, with about 4% exposed to magnetic fields above 0.5mT (22).

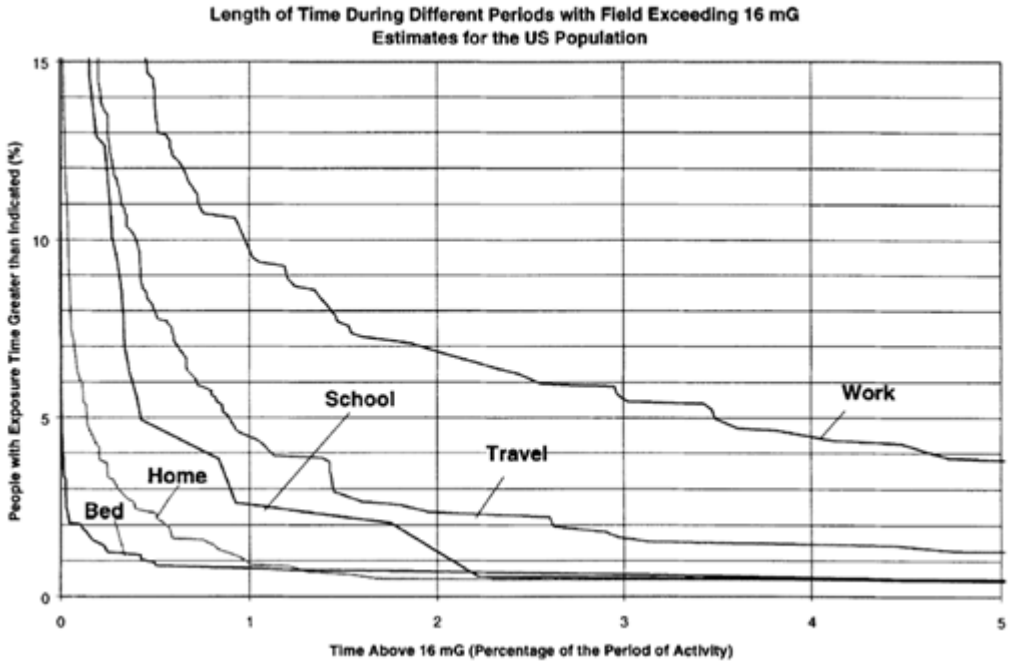

Figure 100.4. Estimated U.S. population distributions of times above 16mG for different activity periods. From Ref. 22.

Table 100.1. Parameters of the Distributions of Average Magnetic Field During Work for Different Types of Occupations[a]

Description	Number of People Surveyed	Mean (mT)	Standard Deviation (mT)	Geometric Mean (mT)	Geometric Standard Deviation
Managerial and professional specialty occupations	204	0.164	0.282	0.099	2.47
Technical, sales, and administrative supports occupation	166	0.158	0.167	0.109	2.30

Precision production, craft, and repair occupations, and operators, fabricators, and laborers	128	0.173	0.415	0.089	2.80
Electrical occupations[b]	16	0.215	0.162	0.161	2.25

[a] *Source*: From Ref. 22.

[b] Electrical occupations are those classified as such by Dr. Samuel Milham in his study of leukemia mortality in men occupationally exposed to electric and magnetic fields (EMF) (3). The electrical occupations include: electronic technicians, radio and telegraph operators, electricians, linemen (power and telephone), television and radio repairmen, power station operators, aluminum workers, welderse and flame cutters, motion picture projectionists, electrical engineers, streetcar and subway motormen.

5 Acute Effects of Emf Exposure

5.1 Perception

Humans can detect electric fields of 5 to 10kV/m. At this field strength, a slight vibration of the hair, felt as a tingling sensation, occurs. Electrical workers may experience contact currents known as microshocks. It has been suggested that microshocks can affect cells and tissues, even causing chromosomal abnormalities (23). Evidence, however, is unsubstantial.

Power-frequency magnetic fields are detectable as transient flashes of light (24) at very high field strengths of 3–5mT. These flashes, known as magnetophosphenes, are perceived as flickering visual phenomena. Similar phenomena are caused by nonphotic stimulation, such as optical pressure and mechanical shock, and by direct application of weak electric currents to the head. Magnetophosphenes are produced in the retina, rather than the optic nerve or visual cortex (25). The threshold current density for induction of magnetophosphenes in the retina is approximately 10 milliamperes per square meter (mA/m^2) at 20Hz, an order of magnitude less than the threshold for 60-Hz currents.

Magnetophosphenes are one of the few universally recognized physiological effects of magnetic field exposure in humans. They do not, however, appear to cause retinal lesions or any other permanent damage (26).

5.2 Induced Currents

Time-varying, ac electric and magnetic fields—including power-frequency fields—as well as movement through static fields induce electric currents in the body. Currents induced by EMF can be measured according to current density, the amount of current flowing through a unit cross-sectional

area of the body. Induced current density depends upon the frequency and magnitude of electric and magnetic fields. Adverse biological effects, such as neural and cardiac stimulation, are produced by induced current densities of above 1000 mA/m^2 (see Exposure Guidelines section). This level, however, is much greater than levels experienced in normally encountered fields. At 60Hz, current density in grounded humans in a 100-V/m vertical electric field measures about $25mA/m^2$ in the torso; in a 1mT 60-Hz magnetic field, average current density is $1–2mA/m^2$ (2).

Current densities for electric and magnetic fields vary between humans and different species of animals according to body size, shape, and orientation to a field (Fig. 100.5). In laboratory animal experiments, both electric and magnetic field levels must be increased 5–15 times to model current densities in human beings.

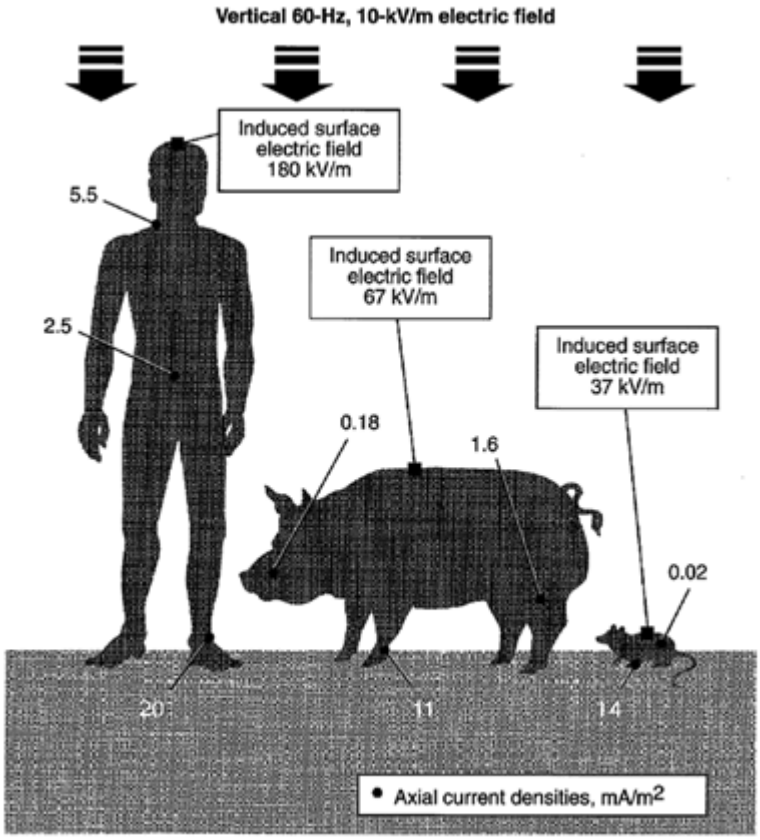

Figure 100.5. Electric and magnetic field interactions with different species. Current densities vary according to body size, shape, and orientation to a field. From Ref. 27.

5.3 Central Nervous System

Concern about the potential effects of exposure to EMF on the central nervous system was first generated in the 1960s by studies of utility workers in the Soviet Union (28). These studies reported symptoms such as headache, fatigue, and insomnia among workers in extra-high-voltage switchyards. Subsequent studies in several western countries, however, failed to confirm any adverse effects on the general health of utility workers (29, 30). Laboratory studies of volunteers have included electroencephalogram (EEG) activity, sleep disturbances, and cognition and performance under various exposure conditions. Exposures tested included intermittent combinations, found in some occupational environments, of 6kV/m and 10mT; 9kV/m and 20mT; and 12kV/m and 30mT. These exposures were found in some studies to affect cerebral potentials and sleep patterns (31, 32). The magnitude of alteration of observed effects, is generally of the order of 10% or less, and results are well within normal ranges for the parameters assessed. There are a number of potential sources of error in many of the studies, and there is not a consistent dose–response relationship. Though results are inconsistent and effects subtle, they provide some evidence of a biological response to

EMF in humans. Current evidence is insufficient to indicate that daytime exposure to extremely low-frequency EMF at occupational levels presents a health risk.

5.4 Cardiovascular System

Study of occupational EMF exposure found that exposure to 50-Hz fields directly under transmission lines produces no change in mean heart rate (33). A more recent investigation suggests that certain electric and magnetic field combinations may produce cardiovascular effects. Slowing of the heart rate in male volunteers has been reported in some laboratory-based studies (31). The magnitude of the observed effects, is small (<10% change from the mean), and the underlying biological mechanism is unknown.

Heart-rate reactivity is a response to consciously perceived stimuli, such as anxiety or exercise. Heart-rate variability (HRV) is an unconscious slowing or stimulation of heart rate governed by the autonomic nervous system. HRV is caused by neuronal and cardiovascular reflexes involved in such processes as control of blood pressure, body temperature, and respiration. Studies conducted by Sastre et al. (34) found that 20-mT intermittent magnetic fields altered heart-rate variability. No effect was found with exposure to 1-mT intermittent or 20-mT continuous fields. In a more recent study, volunteers were exposed overnight to both intermittent and continuous 20-mT fields; no effects on HRV were observed (35). A follow-up study of identical design using 90-mT fields also reported no field-related differences in HRV (36). Although there appear to be no residual effects in the exposed volunteers and despite apparently conflicting data among studies, these results provided the basis for the biological hypothesis linking magnetic field exposure, heart-rate variability, and acute cardiovascular disease (see Cardiovascular Disease section). A new analysis of data to develop a better understanding of reasons for differences in results has recently been published (37). This multistudy analysis suggests that reduction in Heart Rate Variability (HRV) is apparent only in studies with concomitant sleep interruption (37).

5.5 Melatonin

Melatonin, a hormone produced by the pineal gland, is involved in regulation of biological rhythms. Production of melatonin has a definite circadian rhythm; circulating levels are high at night and low during the day. The possibility of long-term disruption of this rhythm in humans has been little studied, although it has been suggested that the use of artificial light at night, shift work, alcohol consumption, and exposure to electric and magnetic fields can chronically interrupt melatonin synthesis. In animals, manipulation of melatonin levels seems to affect the development of several types of cancer, most notably mammary tumors. Recent reviews indicate that melatonin, acting through a number of antiproliferative, antioxidative, and immunostimulatory mechanisms, has oncostatic capabilities (38, 39).

Most laboratory studies of sheep, baboons, and humans exposed to EMF have found no effect on either circulating melatonin or its major urinary metabolite. In contrast, most small animal studies report that EMF suppress different elements of melatonin synthesis, secretion, or metabolism. Despite the abundance of data associating EMF exposure with melatonin suppression in these studies, results have been difficult to reproduce even within the same laboratory (39).

Several recent field studies with electric utility, railway, and garment workers, as well as video display terminal (VDT) operators, suggest that EMF exposure suppresses melatonin (40–42). Also relevant is a study by Kaune et al. (43), which provides evidence that residential exposure to both power-frequency magnetic fields and light at night reduces nocturnal urinary concentrations of the primary metabolite of melatonin. Effects, which were relatively small, were observed mostly in women using certain medications.

5.6 Electromagnetic Hypersensitivity

Reports of sensitivity to electric and magnetic fields first appeared in the late 1970s when VDTs became part of the modern office. Adverse reactions have been reported among thousands of VDT operators, primarily in Sweden (for recent reviews, see Ref. 44). Symptoms reported have included eyestrain, fatigue, headache, difficulty in concentrating, dizziness, and disturbances in sleep patterns. Dermatological problems such as itching, burning, stinging, dry skin, rosacea, and seborrhetic eczema on the face have also been reported. Symptoms are experienced intermittently when they

first appear, worsen with time and finally interfere with ability to work or to tolerate the work environment (45).

Double-blind, controlled laboratory studies (e.g., Refs. 45, 46) have not found consistent associations between actual exposures and either subjective symptoms or biochemical measures. Moreover, study subjects have reported an increase in symptoms when they thought that they were being exposed, regardless of actual exposure conditions (47). To date, no convincing, double-blind challenge studies have conclusively established the existence of hypersensitivity to EMF or proposed a mechanism for this hypersensitivity.

Electric and Magnetic Fields and Occupational Health

6 Chronic Effects
Investigation of long-term EMF health effects has focused on cancer, reproductive disorders, and neurobehavioral and neurodegenerative effects. Recently, cardiovascular disease has been added to the list.
6.1 Cancer
6.1.1 Experimental Studies *In vitro* studies of the possible carcinogenicity of electric and magnetic fields have investigated a variety of processes in a number of cell lines and tissue cultures, under a wide range of exposure conditions. Among exposures used in these experiments were sinusoidal, pulsed, and sawtooth-shaped magnetic fields; electric fields; and combined electric and magnetic fields. Investigators have examined static magnetic fields, static electric fields, and combined static and time-varying fields as well. Studies have also included co-exposure of fields with other carcinogens, such as ionizing radiation, ultraviolet light, and chemical mutagens.

An extensive review of studies of the genotoxic effects of EMF by McCann et al. (48, 49) concludes that electric and magnetic fields are not likely to damage genetic material. Although a number of the studies reviewed reported positive genotoxic effects, they need independent replication. A preponderance of high-quality studies have been negative.

Studies of gene expression—the process by which genes direct protein synthesis—have reported conflicting results. Several studies have suggested that exposure to weak magnetic fields may alter this process at the transcription, translation, and protein synthesis stages (50–52). However, effects were small, with less than a twofold enhancement. Other studies with better experimental control reported that magnetic field exposure has no significant effect (53, 54).

A simplified model of carcinogenesis, a multistep process, proposes three discrete stages. The first stage, damage to genetic material, is known as initiation. The second, promotion, entails stimulation of initiated cells to grow into a tumor. Third is progression, stimulation of tumor cells to invade surrounding tissues and metastasize to distal sites. Various agents may act as cancer initiators, promoters, or progressors, or be involved in more than one stage of carcinogenesis. In multiple studies, exposure to EMF has failed to induce mutations (55), chromosome breakage, or other cellular changes that usually occur when normal cells are transformed into tumor cells (56). Since exposure to EMF does not appear to initiate cancer, researchers have hypothesized that EMF may act as a cancer promoter or progressor.

Investigations studying the potential role of EMF on signal transduction—important in regulating intracellular processes—have emphasized calcium flux, cell proliferation, receptor-mediated signaling pathways, enzyme synthesis and activity, and apoptosis. Some evidence suggests that relatively strong magnetic fields of more than 100mT can influence cell growth and signal transduction (2).

Recently, some researchers (57–59) have reported complete blocking of antiproliferative action of melatonin and tamoxifen by a 1.2-mT field. The use of extremely low fields, as well as several other aspects of experimental design, raises questions about this finding; nevertheless, it is unique in that it appears to have been replicated in several laboratories. An effort to replicate and extend this work is underway. Other important new work is focusing on cell differentiation and cell–cell communication.

7 Exposure Guidelines
Several national and international organizations have formulated guidelines establishing limits for occupational electric and magnetic field exposure. These organizations include the International Radiation Protection Association/International Non-Ionizing Radiation Committee (IRPA/INIRC) (206), the Comit Europeen de Normalization Electrotechnique (CENELEC) (207), the National Radiological Protection Board (NRPB) in the United Kingdom (208), the Deutsches Institut für Normung-Verband Deutscher Elektrotechniker (DIN/VDE) (209), the American Conference of Governmental Industrial Hygienists (ACGIH) (204), and the International Commission on Non-Ionizing Radiation Protection (ICNIRP) (205). The basis of the guidelines is prevention of stimulation of nerves and muscle by induced currents and avoidance of such known effects as magnetophosphenes and cardiac fibrillation. Guidelines focus on acute EMF effects and do not cover potential long-term effects, such as cancer, because they are not considered to be sufficiently well-established for guideline setting.

Definite hazards are posed by exposures above 1000mA/m^2. At these exposures, rhythmic cardiac function, such as extrasystole and ventricular fibrillation, are disturbed. Induced current densities of 100–1000mA/m^2 appear unlikely to produce adverse health effects. A maximum tissue dose of 10mA/m^2 induced current density is specified by all the occupational guidelines and incorporates a safety factor of about 10. This dose also represents an upper limit for endogenous currents that occur naturally in the body; estimates for these currents are based on electroencephalograms and electrocardiograms (ECGs), electrophysiological recordings of the brain and heart. In addition to the 10-mA/m^2 limit for workers, ICNIRP specifies a maximum tissue dose of 2mA/m^2 for the general public.

Though specifying the same limit of induced current density, different guidelines are based on biophysical models that estimate the relationship between external magnetic fields and induced currents using different assumptions. These models, in conjunction with different safety factors, thus yield different values for exposure limits, shown in Table 100.5. Table 100.5 gives whole-body exposures; several guidelines permit limits 5–20 times higher for exposure to limbs (19). Previous guidelines specified lower limits for the “whole working day” but permitted considerably higher exposures for short periods of time (hours). Later guidelines (ACGIH and ICNIRP) (204, 205, 210) specify momentary, or ceiling, limits. The elimination of relaxed limits for shorter exposures, as well as the introduction of ceiling values, makes a key difference. Overall magnetic field guidelines have become progressively more stringent, culminating with the latest ICNIRP guidelines (205, 211) (Fig. 100.6).

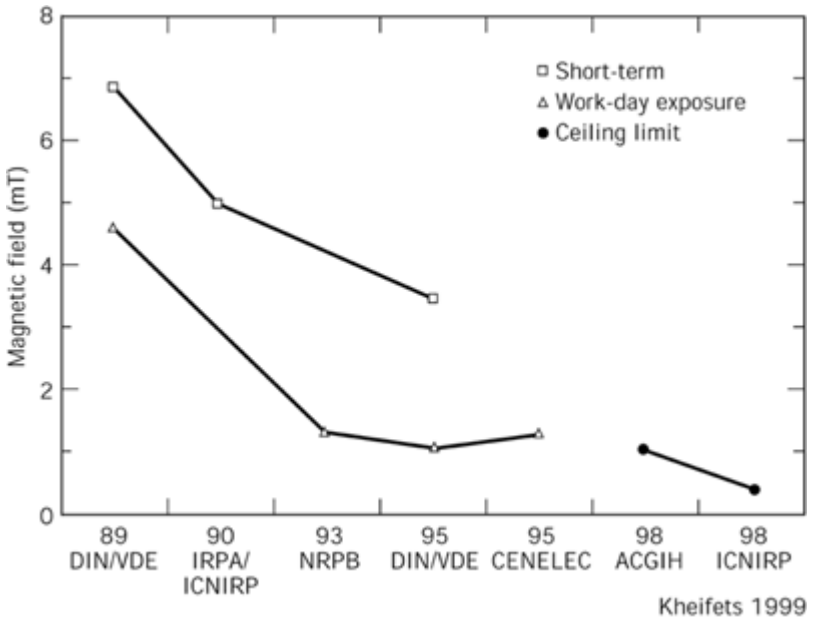

Figure 100.6. Changes in occupational magnetic field exposure limits. Table 100.5. Occupational Exposure Guidelines for Power Frequency Fields

			Exposure Limit	
Organization[a]	**Year**	**Exposure Duration**	**Magnetic Field (mT)**	**Electric Field (kV/m)**
DIN/VDE (209)	1989	Work-day	4.6	19
		Short-term (5min/h)	6.9	29
IRPA/INIRC (206)	1990	Work-day	0.5	10
		Short-term (2h/d)	5.0	30
NRPB (208)	1993	Work-day	1.3	10
DIN/VDE (209)	1995	Work-day	1.1	18
		Short-term (2h/d)	2.1	30
		Short-term (1h/d)	3.5	30
CENELEC (207)	1995	Work-day	1.3	25

ACGIH (204)	1998 Ceiling value	1	25
ICNIRP (205)	1998 Ceiling value	0.4	8

[a] DIN/VDE, Deutsches Institut für Normung-Verband Deutscher Elektrotechniker; IRPA/INIRC, International Radiation Protection Association/International Non-Ionizing Radiation Committee; NRPB, National Radiological Protection Board (U.K.); CENELEC, Comite European de Normalization Electrotechnique; ACGIH, American Conference of Governmental Industrial Hygienists; ICNIRP, International Commission on Non-Ionizing Radiation Protection.

The new ICNIRP guidelines cover both occupational and nonoccupational exposure to time-varying electric and magnetic fields with frequencies up to 300gigahertz (GHz), and to contact currents with frequencies up to 110GHz. Only ACGIH has specifically stated permissible levels for workers with pacemakers.

The ICNIRP guidelines specify a "basic restriction" and a "reference level." The basic restriction is an internal body dose that cannot be exceeded; the reference level is the corresponding external field exposure. The new ICNIRP reference levels are frequency-dependent within the power-frequency range, and do not permit relaxation of exposure limits for short time periods or for exposures to limbs.

The guidelines state that "reference levels are intended to be spatially averaged over the entire body of the individual." Higher exposures are permitted to portions of the body if the reference level for the whole body and the basic restriction are not exceeded. ICNIRP guidelines are based on dosimetric modeling that considers the human body an isotropic homogeneous mass of spherical shape. New induced current models that incorporate anatomically correct body shape and pinpoint tissue-specific conductivity are not used.

The guidelines permit electric field exposures at twice the reference levels for occupational exposures, if "adverse indirect effects from contact with electrically charged conductors can be excluded." Magnetic field reference levels limit induced currents due to direct field coupling; electric field reference levels restrict induced currents from both direct field coupling and indirect effects.

Because higher frequencies induce higher current density, ICNIRP's occupational electric and magnetic field reference levels for 25–820-Hz fields are frequency dependent. Reference levels are $500/f$ kV/m for electric fields and $25/f$mT for magnetic fields, where f is frequency in Hz. Reference levels are thus 8.3kV/m and 0.42mT, or 4.2G, for 60-Hz fields and 10kV/m and 0.5mT (5G) for 50-Hz fields. Reference levels for the general public are 4.2kV/m and 0.083mT (0.83G) for 60-Hz and 5kV/m and 0.1mT (1G) for 50-Hz fields. For contact currents, the occupational reference level is 1.0mA at frequencies up to 2.5kHz. The purpose of this limit is apparently to "avoid shock," but since only about 40% of men can perceive 60-Hz contact currents of 1mA (212), limiting even perception of contact current is implied.

ICNIRP guidelines include formulas for combined exposures of different frequencies. They also advise that coincident electric and magnetic fields "should be considered separately and not additively." Finally, ICNIRP urges that, in the event that the basic restriction is exceeded, protective measures be used. These measures include engineering and administrative controls, as well as personal protection programs and medical surveillance. Compliance procedures, however, are not specified in the guidelines.

8 Exposure Management

Exposure to electric and magnetic fields in the workplace can be reduced in a number of ways. The engineering reference *Electric and Magnetic Field Management Reference* (213) describes various options for reducing fields from electrical facilities and transmission and distribution lines. In addition to field-reduction techniques illustrated by engineering case studies, this reference covers basic theory and calculations and includes terminology, unit conversions, and a reference list.

The first step in exposure management is EMF measurement and assessment (see Exposure Assessment section). Assessment strategies may combine measurements of field levels with patterns of time spent in different activities and locations to estimate personal exposure.

8.1 Low-EMF Design

Power system components, such as circuit currents, conductors, equipment, and facilities, can be designed or modified to minimize EMF without compromising cost or performance. Low-EMF computer monitors are a good example of design improvement that has neither increased cost nor decreased functionality.

Improving design before installation is an easier task than modifying existing equipment and facilities. Whether field reductions are global or local (applied to an entire facility or system or to part of it) affects the nature and impact of modifications. The addition of cancellation loop wires (in which current induced by a power line's magnetic field creates another field that partially cancels the original one) to only a portion of a transmission line, for example, results in little system loss or line impedance, whereas modification to the entire line may have enough impact to warrant serious consideration.

The term *net current* refers to current in a conductor that is not balanced by an equal and opposite current in a nearby conductor. Net currents often occur in building wiring in neutral conductors that are close together. These currents produce high magnetic fields that decrease less with distance than balanced currents. Since shielding is not practical, often wiring must be modified so that incoming current balances return currents in neutral wires.

8.2 Shielding Electric and Magnetic Fields

Shielding sources of electric and magnetic fields can effectively reduce exposure. Electric fields are easily shielded by conducting objects—including screens, walls, trees, and shrubs. Magnetic fields are not shielded by most materials. Shields have been developed, however, based on induced currents in conductive materials, magnetic flux patterns in high-permeability materials, or both.

Magnetic field shielding technology derives from technologies developed to shield radio waves and microwaves. High-permeability alloys were initially used to shield static or direct current (dc) fields; application to power-frequency, ac fields was only moderately successful. More recently, composite shields combining conducting materials with sheet steel have been found to effectively reduce magnetic fields.

Wires conducting current can cancel magnetic fields through passive or active shielding. Active shielding makes use of currents or voltages derived from independent power sources to cancel magnetic fields. Passive shielding, on the other hand, employs materials or circuits without using additional power sources.

Electric field exposures can be reduced by shielding people rather than field sources. Work areas or Faraday cages can provide highly effective shielding. For high-voltage line workers, wearing conductive suits and working in insulated buckets virtually eliminates power-frequency electric field exposure.

Magnetic fields in work areas can be shielded either passively or actively. Shielding may be based, like shielding of sources, on conductive or high-permeability patterns, alone or in combination.

8.3 Reducing EMF Exposure by Selective Use of Space and Time

Altering activity patterns or time spent in the presence of electric and magnetic fields is another

approach to reducing exposure. Exposure reduction measures may include establishment of regulations limiting time spent in high-exposure areas. In extra-high-voltage substations in Russia, for example, time spent in areas with electric fields over 5kV/m is limited to 1h/d. Access to areas with high EMF, such as those where energized equipment is in use, may also be restricted. Finally, facilities and equipment may be arranged such that fields are lowered in frequently occupied areas. High-EMF areas in office buildings, for instance, could be designated storage or filing areas, and electrical panels could be installed in janitors' closets rather than work areas. Similarly, VDTs in schools can be arranged back-to-back, so that students are seated away from the back panels of computers.

8.4 Evaluating Field Management Options

Evaluation of field management programs includes, in addition to field reduction, issues of safety and reliability. Safety codes covering power system design and modification have been established. Design and modifications must comply with The National Electrical Safety Code (NESC) (214), the National Electrical Code (NEC) (215), and other safety codes, such as state codes and building and structural codes. Minimum design standards for utility-owned wiring and equipment in the United States can be found in the NESC; the NEC contains standards for consumer-owned wiring and equipment.

Compliance with the NEC code, which is incorporated into local ordinances, is required by the Occupational Safety and Health Administration (OSHA). State utility commissions use NESC standards. Additionally, city, county, and state governments have installation codes. These codes have been tested over many years and have been proven adequate to ensure safety. Any design or modification that would violate any code requires review and approval and every EMF management option should be tested against established standards.

9 Summary

The widespread introduction of electrical power, electric light, and electrical and electronic devices during the past 100 years has clearly improved the standard of living and benefited modern societies. Power-frequency EMF exposure—unavoidable since the use of electricity has spread throughout the world—has been under investigation since the early 1970s. Investigations have included epidemiologic as well as *in vitro* and *in vivo* laboratory studies encompassing a wide range of diseases. The literature on EMF and health is vast, comprising over 1000 published studies, and has been reviewed in depth by several authoritative committees; of note are reviews by the U.K. National Radiological Protection Board (4), the National Academy of Sciences (2), which focuses on residential exposures, and the National Institute of Environmental Health Sciences (3). The focus of this chapter is on occupational exposures to electric and magnetic fields. In addition to a review of both cellular and animal data, the chapter details numerous occupational epidemiologic studies and includes a description of exposure guidelines and exposure assessment and management techniques.

Electric field strength increases with increasing voltage, or electric potential; magnetic field strength increases with increasing current. Both electric and magnetic fields decline rapidly with distance from their source, with a faster decline of fields from point sources such as machinery and a slower decline of fields from power lines. Electric fields are further reduced when shielded by conducting objects like buildings; magnetic fields, on the other hand, are not easily shielded. Occupational exposure to electric and magnetic fields occurs from proximity to large motors as well as from wiring in buildings and the use of computers, office machines, and heating and air conditioning systems. Power transmission and distribution facilities are other sources.

Accurate assessment of EMF exposure represents a considerable challenge. Electric and magnetic

fields have several unique characteristics that make them more difficult to study than most other types of exposures. They are not readily detectable, are variable in time and space, and are to some extent present in all environments. Exposure assessment is further complicated by limited understanding of the contributions of different sources to total exposure and by lack of understanding of what the relevant exposure metric might be. Portable exposure meters that can be held in the hand or worn on a belt can be used to measure electric and magnetic fields. More sophisticated stationary instruments can capture waveforms and transient fields. Detailed guidelines that recommend appropriate instrumentation, sampling strategies, sampling parameters, and time–activity-keeping protocols have been developed. At least a time-weighted average magnetic field exposure measurement is suggested, though alternative metrics may be of interest.

The best information on work exposures among the general population is available from a "1000-person survey" (22). Occupational EMF exposures are considerably higher than nonoccupational ones. Nevertheless, average work exposures for the general population are low, with only 4% exposed to magnetic fields above 0.5mT. Occupational exposures have been studied most extensively in the electric utility industry. Average exposures have been found to be higher in "electrical occupations" than in other occupations such as office work. Much less is known about exposures in nonelectrical occupations; few data, if any, are available for many jobs and industrial environments.

Investigation of long-term EMF health effects has focused on cancer, reproductive disorders, and neurobehavioral and neurodegenerative effects. Recently, cardiovascular disease has been added to the list.

In vitro studies of the possible carcinogenicity of electric and magnetic fields have investigated a variety of processes in a number of cell lines and tissue cultures, under a wide range of exposure conditions. Since exposure to EMF does not appear to initiate cancer, researchers have hypothesized a role in cancer promotion or progression. *In vitro* research on the carcinogenicity of EMF has been plagued by a lack of consistency and reproducibility. Recent reviews (3, 2) have concluded that cellular effects have been observed for exposures above 100–500mT, although mechanisms for these effects are not known. Overall, a coherent picture is lacking. Although sporadic EMF effects have been reported in some animal studies, most have been negative. Of the approaches to evaluating EMF as a potential health hazard, toxicologic experiments provide the most consistently negative data. In particular, data on leukemia in experimental animals are negative.

About 100 epidemiologic studies have investigated the possible association between magnetic fields in occupational settings and numerous types of cancer. Several of these studies also examined electric fields as a risk factor. Studies have varied widely in design and quality and have used a number of different methods to assess exposures in a wide range of occupations. Despite considerable heterogeneity in results, an increase in risk of leukemia and brain tumors in electrical workers has been noted in many studies.

Study limitations and the possibility that chance alone could be responsible for positive findings are important considerations in evaluating results. Many of the occupational studies were secondary analyses of existing data collected for other purposes than testing the EMF hypothesis. The magnitude and direction of biases and confounding, often present in epidemiologic studies, are not well understood in studies of EMF. Also, sources of potential bias vary from study to study. Although some have been eliminated as study design has improved, others remain. Inconsistencies, lack of a clear dose–response relationship, the small magnitude of reported elevations in risk, and large misclassification and measurement error are among the main difficulties in the interpretation of results. Additionally, several endpoints have not been rigorously examined in a sufficient number of studies.

Improved methodology in occupational studies has not resulted in higher estimates of risk. It is unlikely that a large overall risk has been overlooked. However, since many studies have reported

some elevation in cancer risk, chance alone as an explanation seems unlikely. The potential role of EMF exposure in cancer etiology thus remains uncertain. Because of the ubiquity of EMF exposure, however, even a small risk could have substantial public health consequences. Future studies based on exposure matrices that incorporate both jobs and locations might reduce misclassification. Nevertheless, only development of relevant exposure metrics and improvements in methodology that will reduce between-worker and day-to-day variability are likely to reduce measurement error sufficiently to provide conclusive results.

Clinical studies conducted by Sastre et al. (34) have suggested that exposure to magnetic fields can alter heart-rate variability. Although this work has not been reproduced in subsequent studies, it prompted an analysis of electric utility worker studies that found an increase in risk for arrhythmia-related disease and myocardial infarction. Although these findings raise an important possibility, they need to be interpreted with caution, as they are first to raise this possibility.

There is little support for an association between EMF exposure and adverse pregnancy outcomes. Methodological problems such as the difficulty of studying EMF exposure levels that are very close to background, possible omission of early miscarriages, and information and recall bias may weaken this conclusion.

Investigation of potential EMF effects on neurodegenerative diseases is in its infancy. Currently, the most interesting suggestion is that electric shock may play a role in the development of amytrophic lateral sclerosis. Studies incorporating better exposure assessment methods, including assessment of contact currents, more accurate diagnosis of diseases, and adjustments for potential confounding from occupational exposures to substances such as solvents might clarify the issue.

Reports of sensitivity to electric and magnetic fields have been connected most often with VDT use. To date, however, no double-blind challenge studies have conclusively established the existence of hypersensitivity to EMF or proposed a mechanism for it.

Several national and international organizations have formulated guidelines establishing limits for occupational electric and magnetic field exposure. The basis of the guidelines is prevention of stimulation of nerves and muscle by induced currents and avoidance of such known effects as magnetophosphenes and cardiac fibrillation. Guidelines focus on acute EMF effects and do not cover potential long-term effects, such as cancer, which are not considered to be sufficiently well established for guideline formulation. Overall magnetic field guidelines have become progressively more stringent, culminating with the latest ICNIRP guidelines. The ICNIRP guidelines define a "basic restriction" as an internal body dose that cannot be exceeded and a "reference level" as the corresponding external field exposure. The reference levels for 60-Hz fields are 8.3kV/m for electric fields and 0.42mT for magnetic fields. ICNIRP urges that, in the event that the basic restriction is exceeded, protective measures be used. These measures include engineering and administrative controls, as well as personal protection programs and medical surveillance.

Pacemakers and implantable cardioverter defibrillators (ICDs) have enabled many cardiac patients to return to work. Very high electric and magnetic fields in the workplace can interfere with the functioning of pacemakers and ICDs. The threshold for magnetic field interference appears to be in the range of 0.2–1.2mT; for electric field interference, above 1.5–2kV/m (203).

Various options for reducing exposure to electric and magnetic fields produced by power generation, transmission, and use in the workplace are available. Power system components, such as circuit currents, conductors, equipment, and facilities, can be designed or modified to minimize EMF without compromising cost or performance. Shielding sources of electric and magnetic fields can effectively reduce exposure. Electric fields are easily shielded by conducting objects—including screens, walls, trees, and shrubs. Magnetic fields are not shielded by most materials. Composite shields have been developed, however, using conducting materials combined with sheet steel. Magnetic fields can also be reduced through passive or active cancellation by wires conducting

current. Altering activity patterns or time spent in the presence of electric and magnetic fields is another approach to reducing exposure. Finally, facilities and equipment may be arranged such that fields are lowered in frequently occupied areas. Evaluation of field management programs should include, in addition to field reduction, consideration of safety and reliability.

Radio-Frequency and Microwave Radiation

R. Timothy Hitchcock, MSPH, CIH

1 Introduction

Radio-frequency radiation (RFR) is a type of nonionizing electromagnetic energy. Electromagnetic energy is the propagation of energy by time-varying electric and magnetic fields. The fields are described by three vector quantities: electric-field strength, magnetic-field strength, and propagation vector, as shown in Figure 101.1

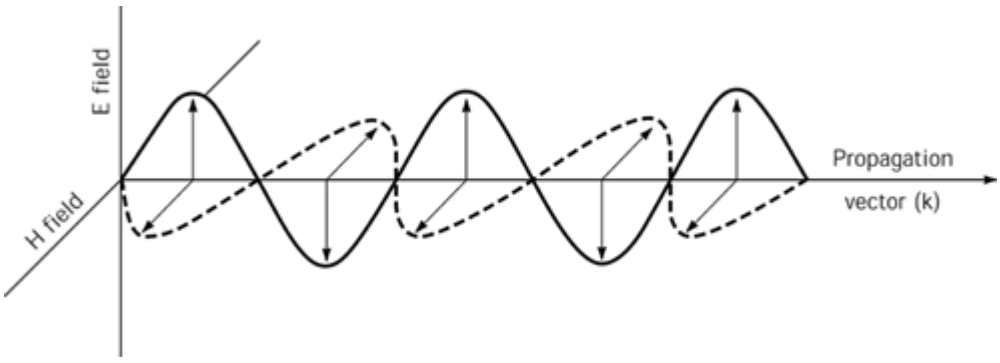

Figure 101.1. Propagation Vector: Time-varying electric and magnetic fields.

Radiation may be described by frequency, wavelength, and photon energy. RFR is described by frequency. Frequency is the number of wave cycles that pass a point in space in a second, and the unit is the hertz (Hz). Sometimes, the interaction of RFR with matter is described by the wavelength, which is the length of one complete wave cycle (see Table 101.1).

Table 101.1. Physical Characteristics of Radio-Frequency Fields

Region	Frequency	Wavelength
Microwave	300 GHz[a] to 300 MHz[b]	1 mm[c] to 1 m[d]
Radiowave	300 MHz to 3 kHz[e]	1 m to 100 km[f]

[a] Gigahertz.
[b] Megahertz.
[c] Millimeter.
[d] Meter.
[e] Kilohertz.
[f] Kilometer.

For the purposes of this chapter, the boundaries of the RF spectral region are 3 kilohertz (kHz) to 300 gigahertz (GHz). Usually, microwave radiation is considered a subset of RFR; however, an alternate convention treats radiowave and microwave radiation as two spectral regions, as shown in Table 101.1.

1.1 Characteristics

RF emissions may be pulsed or continuous wave (CW). A CW device emits RF energy continuously when in operation, whereas pulsed sources emit RFR in a noncontinuous, cyclic manner, characterized by switching emissions on and off. Hence, the duty cycle of pulsed sources, which is equal to the "on time" is equal to the "on time + off time," is less than unity.

RFR output may be modulated. A modulated emission has two components, carrier wave and the modulating signal. The carrier wave is higher in frequency, and carries the information, and the signal is lower in frequency. Modulation is accomplished when some characteristic (e.g., amplitude, frequency, or phase) of the carrier wave is varied by the modulating signal. For example, if the amplitude of the carrier wave is modulated at the frequency of the signal, the waveform is frequency modulated (FM). Other forms of modulation include amplitude modulation (AM), phase modulation (PM), pulse modulation, frequency-division multiple access (FDMA), time-division multiple access (TDMA) and code-division multiple-access (CDMA). Polarization describes the time-varying direction and amplitude of the E-field vector. A field may be linearly, circularly, or elliptically polarized. A field lacking polarization would show no spatial preference in the vibrations of the electric field.

1.2 Quantities and Units

Exposure to RFR may be characterized by the seven quantities listed in Table 101.2. The SAR is the dosimetric quantity that describes RF power deposition or the rate of RF energy absorption as,

$$\mathrm{SAR} = \frac{\sigma E_i^2}{\rho} \qquad (1)$$

where s is the tissue conductivity in siemens per meter (S/m) E_i is the internal electric field in volts per meter (V/m), and r is the tissue density in kilograms per cubic meter (kg/m^3). The SAR is the fundamental quantity of the exposure criteria because it has been found to be the most reliable single predictor of the potential for biological effects in test animals. The whole-body average (WBA) SAR used in the exposure criteria is 0.4 W/kg.

Table 101.2. Important Quantities and Units

Quantity	Abbreviation	Units	Description

Specific absorption rate	SAR	Watts per kilogram (W/kg)	RF dose rate
Specific absorption	SA	Joules per kilogram (J/kg)	RF dose
Electric-field strength	E	Volts per meter (V/m)	Intensity of E field
Magnetic-field strength	H	Amperes per meter (A/m)	Intensity of H field
Power density	W, S	Milliwatts per centimeter square (mW/cm^2)	Power incident on a surface÷surface area
Contact current	I_c	Milliamperes	Current flow into body
Induced current	I_i	Milliamperes	Current flow induced within the body

The SA is the time integral of the SAR and, as such, is the RF dose in J/kg. For much of the RF spectral region, the averaging time is 6 minutes, which results in an acceptable whole-body SA of (0.4 W/kg×360 seconds) 144 J/kg.

SAR and SA are difficult to determine outside of the laboratory, so *E*, *H* and *W* are usually evaluated to determine exposure to RF fields. Exposure guidelines are written in terms of the field strength or power density that will maintain the SAR at a safe level. In general, *E* and *H* may be used throughout the RF spectral region, whereas *W* is most applicable to microwaves.

I_c and I_i are associated with relatively low frequency RF fields, less than 100 MHz. I_c may occur when one contacts a conductive object that is illuminated by the RF field and RF current flows into the body. I_i occurs when exposure to RF fields induces currents within the body which may flow to ground or circulate as eddy currents.

1.3 Generation

RFR is generated by the acceleration of electric charges in oscillatory circuits. Significant generators at the lower RF frequencies are power grid tubes (RF vacuum tubes). Higher frequency (microwave) generators include microwave vacuum tubes (e.g., klystrons, magnetrons, and traveling wave tubes) and solid-state devices (e.g., Gunn diode and tunnel diodes).

Sources of RFR are both natural and man-made. Natural sources include terrestrial and extraterrestrial sources, and even the human body. Major man-made sources are shown in Table 101.3 and reviews are available (1–3). The source that has most consistently demonstrated the potential for overexposure during normal use is the unshielded dielectric heater (also called plastic sealers) (4–7). Induction heaters have demonstrated the potential for overexposures to the magnetic field (8). Certain maintenance activities associated with broadcasting (9) and radar (10) have the potential for overexposure.

Table 101.3. Major Sources of Exposure to RF Radiation

Sources	Uses	Comments
Dielectric heaters	Heat, form, seal, or emboss	Operational band 1–

	dielectric materials like plastics	100 MHz primary is 27.12 MHz
Induction heaters	Heat, harden, forge, weld, anneal, or temper conductive materials (metals)	250 to 500 kHz
Microwave heaters	Dry, cure, heat, or bake materials such as foods, wood, paper, or films	915 and 2450 MHz
Welding	RF-stabilized welding used for pipe, tubing, beam, and plate welding	0.4 to 100 MHz with harmonics
Radar	Acquisition, tracking, and traffic control	Primarily 1–15 GHz
Communications	Fixed systems (satellite communications, microwave, high-frequency, tropospheric scatter)	0.8 to 15 GHz
	Mobile systems (two-way transceivers, wireless devices, two-way pagers)	27 MHz to 3 GHz
Broadcasting	AM radio	535–1605 kHz
	FM radio	88–108 MHz
	VHF-TV	54–72, 76–88, 174–216 MHz
	UHF-TV	470–890 MHz
Diathermy	Shortwave or microwave diathermy in physiotherapy	13, 27, 915, or 2450 MHz

Radio-Frequency and Microwave Radiation
R. Timothy Hitchcock, MSPH, CIH

2 Exposure Assessment
Exposure assessment involves modeling and/or measurement to estimate the intensity of RF fields in space or to estimate the SAR within tissues. SAR determination is usually restricted to laboratory measurement or to computer modeling in support of dosimetry. Workplace evaluation typically involve measurement or modeling E, H, or W.
2.1 Modeling
Numerical modeling may be used to estimate W or E in the area surrounding certain antennas. For example, the far-field hazard distance for a circular aperture antenna may be estimated from

$$r = \sqrt{\frac{PG}{4\pi \mathrm{EL}}} \qquad (2)$$

where r is distance in centimeters (cm), *P* is power in watts (W), *G* is absolute gain (dimensionless), and EL is the exposure limit (W/cm^2). If, it is assumed that there is 100% ground reflection, this

becomes $r = \sqrt{(PG/\pi EL)}$.

Dosimetric studies utilize dielectric characteristics of various human tissues at the wavelength of interest to estimate the SAR. Numerous computational methods have been used, but the finite-difference time-domain (FDTD) method is used most often. This method models the body as a large number of rectangular cells which are assigned frequency-dependent dielectric properties of permittivity, conductivity, and permeability. In the simplest case, the cells may all be assigned the same dielectric properties to produce a homogeneous model. More complex models include dielectric properties of a large number of tissue types.

2.2 Measurement

Currently, there are no RFR dosimeters or personal exposure monitors so field measurements are made with broadband instruments that are calibrated for a broad frequency range. In the calibrated band, the instrumental response is largely independent of frequency, so that the instrument exhibits a relatively constant sensitivity versus frequency. The major components of a broadband instrument are the probe (antenna elements and detectors) and the metering instrumentation that are typically separate assemblies that are connected with a cable or lead. Instruments may be dedicated to the *E* or *H* field, or both, depending upon the type of antenna used. Linear antennas (monopoles or dipoles) are used for *E* fields, and loop antennas (coils) are used for *H* fields. Most modern broadband instrument utilize three mutually orthogonal antennas in an array so that the antenna reception pattern is as nearly isotropic. Thermocouples and diodes are the most frequently used detectors.

2.3 Evaluation

Workplace evaluations involve determining the spatial average exposure. The spatial average is an arithmetic average determined along the vertical dimension of a worker, but with the worker absent. This is necessary because the human body is so conductive that it will perturb or modify the RF field, and the exposure guidelines are in terms of non-perturbed fields, the operator must be absent during evaluation. A nonconductive (dielectric) stickman, typically made from polyvinyl chloride (PVC) tubing, is substituted for the worker. The average is determined along the tubing at a minimum of 10 locations, from 0 to 200 cm (1, 2).

Radio-Frequency and Microwave Radiation

3 Interactions with Matter and Dosimetry

Studies of interactions with matter and dosimetry include both experimental and numerical evaluations. The general findings from these studies are summarized in the paragraphs below.

3.1 Energy Transfer

When the human body is exposed to RFR, the radiation may be reflected, refracted, transmitted, absorbed, or scattered. When RFR is incident on or transmitted into tissues, there are complex interactions because the human body is composed of layers of tissues that have different dielectric characteristics. The penetration depth into tissues is greatest for relatively long wavelengths, and decreases with decreasing wavelength until, at frequencies above about 30 GHz, the energies are absorbed topically, similar to infrared radiation.

RFR interacts with tissues at the cellular, molecular and atomic levels. There are three modes of tissue interaction at the molecular level: polar molecule alignment, molecular rotation and vibration, and the transfer of kinetic energy to free electrons and ions (10a). Alignment of polar molecules with the *E* field is an ubiquitous mechanism. The major polar molecule in the body is the water molecule. Subsequently, the absorption of RF energy is higher in tissues of high water content (muscle) than in tissues with low water content (fat). Vibrational and rotational modes of absorption are important in intramolecular interactions. The oscillation of free electrons and ions associated with biological macromolecules might have functional consequences for those molecules.

Factors important in the absorption of RF energy include wavelength, polarization, body size and dielectric properties, and the presence of conductive (reflective) objects in the local environment. Some studies have suggested that absorption by the body is greater when the electromagnetic energy is in the form of plane waves (RFR having a planar front) than when the body is exposed in the near field (RF fields very near a source) of a source (11, 12), although this has not been observed by other researchers (13).

Absorption results in the conversion of RF electromagnetic energy to some other form of energy. Typically, the absorbed energy increases molecular motion, thereby increasing the total energy of the system which is realized as heat. This produces thermal effects to the exposed tissues.

3.2 Whole-Body Exposure and Absorption

The distribution of the RF field lines in the space surrounding the human body is disturbed, or perturbed, by the body. Standing waves may form on the exposed side of the body whereas, on the side of the body opposite the radiator, an RF shadow may form. This may be either a whole-body (14, 15) or partial-body shadow (16), depending upon the type of exposure.

The body demonstrates a frequency dependency in its ability to absorb RFR, a phenomenon called geometrical resonance. The maximum SAR is observed when body length (height) is around 40% of the incident wavelength and the direction of the E-field vector is parallel with the body. For an ungrounded man of standard height, this would occur at a frequency around 70 MHz. Because geometrical resonance is directly related to wavelength and inversely related to frequency, the resonance frequency would be less than 70 MHz for taller individuals because they couple well with longer wavelengths. Conversely, the resonance frequency would be greater than 70 MHz for shorter individuals, because they couple better with shorter wavelengths.

When an individual is exposed at a frequency beneath the resonance frequency, the ability of the body to absorb RF energy decreases rapidly. In fact, studies have shown that below-resonance absorption decreases with an f^n dependence, where n = 1.7 to 3 (17, 18). Exposure at a frequency above the resonant frequency results in gradually diminished absorption, becoming asymptotic as the frequency increases (17).

For a given body height, there are two exposure conditions, free space and grounded, that produce different values of resonance frequency. Free-space absorption occurs when an individual is not in conductive contact with earth. For standard man, this is around 70 MHz, as mentioned earlier. Resonance is shifted to a lower frequency if exposure occurs when the body is in conductive contact with earth (grounded condition). In general, the grounded resonance frequency is about one-half the free-space resonance frequency (17).

3.3 Partial-Body Resonance and Hot Spots

Geometrical resonance has also been demonstrated for body parts. For example, the resonance of the head has been reported to be around 350 to 450 MHz (19, 20).

Typically, whole-body exposure produces inhomogeneous absorption of RF energy. This may produce spatial-peak or localized values of absorption on the order of around twenty times higher than the whole-body average. These areas of relatively high local SARs are often called hot spots.

Inhomogeneous absorption has been well illustrated in studies of local RF fields from portable cellular telephones, where SARs were highest near the surface of the tissues nearest the radiator. Peak values were observed in various anatomical locations including the eye (21, 22), ear (23), skin above the ear (24), skin behind the ear (24, 25), and skin of the face (23, 26).

4 Biological and Health Effects
This section will survey long-term studies, ocular effects, behavioral effects, reproductive and developmental effects, and cancer. For the interested reader, some worthwhile reviews of biological effects are available (2, 27–33).
4.1 Experimental Studies
Both *in vitro* and *in vivo* studies include have been performed. These have evaluated the responses of most major organs and systems, including special senses, central nervous, reproductive and developmental, hematopoietic, immunological, and neuroendocrine.

4.1.1 Long-term Studies Prausnitz and Susskind (34) found no differences in body weights of mice exposed to 10-GHz, pulsed microwaves (estimated WBA-SAR≅50 W/kg) but the controls had a higher death rate than the exposed animals. The authors attributed this to RF-induced thermal stress, essentially a fever, which may have helped the exposed animals combat a pneumonia outbreak that occurred during the experiment. Spalding, Freyman, and Holland (35) exposed mice (800 MHz, WBA-SAR≅1.3 W/kg) and found that voluntary activity and bloodborne parameters were not significantly different. The exposed mice lived longer than the control mice, although this was not statistically significant. No significant differences were observed in bloodborne end points, tumor incidence and type, and macro- and microscopic evaluations during necropsy for rats exposed to electromagnetic pulses (peak E = 447,000 V/m, 250 million pulses delivered over 94 weeks (36).

In an evaluation (50-MHz, 2.5-GHz) using rats and rabbits, researchers found that blood cholesterol and sulfhydryl levels decreased throughout the experiment, while urinary 17-ketosteroid increased (36a). However, these findings were not replicated by D'Andrea et al. (37) who exposed rats (2.45 GHz, WBA-SARs of 0.11 to 0.18 W/kg). They observed a difference in the levels of 17-ketosteroid between exposed and control groups during the adaptation period that may be due to stress induced by handling and housing conditions. No significant differences were found in body mass, food and water consumption, blood levels of cholinesterase, and poststudy evaluations for electrolyte levels, ion gaps, and CO_2. Significant differences were observed in two of four behavioral tests, but these may be of "little biologic significance." In another report, they found statistically significant differences in three behavioral tests, where rats were intermittently exposed (2.45 GHz, 0.7 W/kg) (38).

White rabbits (2450 MHz, WBA-SAR≅1.7 W/kg) had a significant reduction in red blood cell counts (RBC) and food intake, but not in water consumption, white blood cell count (WBC), ocular changes, and coat condition (39). Other researchers used the same species and frequency (WBA-SAR≅1.5 W/kg) and determined statistically significant reductions in albumin, calcium, and eosinophils. No significant changes were found in postexposure bloodborne end points, albumin levels in the exposed animals had decreased, and globulin levels had increased. Pathologic findings showed a significant difference in the myeloid/erythroid ratio in bone marrow samples from the sternum. "The biologic importance of this finding is questionable since the hematologic (erythrocyte and leukocyte counts) parameters did not differ between treated and control rabbits." No significant differences were noted in the other 38 parameters evaluated (40, 41).

5 Exposure Guidelines and Standards
In the United States the exposure guidelines most often used are IEEE C95.1-1991 (227) and the

American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit values (TLVs) (228). C95.1 recommends RFR exposure limits between 3 kHz and 300 GHz, by way of two sets of exposure criteria called the controlled environment (CE) and the uncontrolled environment (UE). A simple definition of the two environments is as follows: Individuals who work in the CE know that they are being exposed to RFR, and those in the UE have no knowledge or control of their exposure. For the human whole-body resonance spectral region, from about 3 MHz to 6 GHz, exposure criteria for the CE are five times higher than corresponding values in the UE. Outside the resonance range, the exposure limits are identical. The TLVs address 30 kHz to 300 GHz and are identical to the exposure limits in the CE within this band.

The exposure limits in C95.1, in terms of power density or field strength, are called maximum permissible exposures (MPEs). Field strength and power density are surrogate measures of exposure because the fundamental quantity of the exposure criteria is the SAR, as mentioned earlier. The MPEs are exposure limits that are derived to maintain the WBA-SAR below given values, 0.4 W/kg in the CE and 0.08 W/kg in the UE. The WBA-SAR for the CE is derived from studies with test animals where reversible behavior disruption occurred at WBA-SARs around 4 W/kg. A tenfold safety (uncertainty) factor was applied to this number to arrive at the exposure criterion, 0.4 W/kg. The WBA-SAR for the UE is based on the same body of biological effects, except that it incorporates a safety factor of 50 times, so it is five times lower than the CE value.

C95.1 also has recommendations for spatial-peak SARs, where the local SAR is a small mass (1 gram) of tissue. Spatial-peak SARs are based upon the finding that SARs within models of man may be on the order of 20 times greater than the WBA-SAR. The combination of this factor and the WBA-SAR (20×0.4 W/kg) led to the derivation of the spatial-peak SAR for the CE, 8 W/kg in 1 g of tissue. The spatial-peak SAR for the UE was derived by the inclusion of an additional fivefold safety factor to the CE value, to yield 1.6 W/kg per g (see Table 101.6).

Table 101.6. Specific Absorption Rate (SAR) Recommendations in IEEE C95.1 (W/kg)[a]

Target Population	Whole body average	Spatial-peak[b] (partial body)	Extremities[c]
Occupational environment / controlled exposure	0.4	8.0	20.0
General population / uncontrolled exposure	0.08	1.6	4.0

[a] Applicable to the spectral region between 100 kHz and 6 GHz.

[b] Averaged in 1 g of tissue in the shape of a cube.

[c] Applicable to hands, wrists, feet, and ankles, averaged in 10 g of tissue in the shape of a cube.

Hence, the spatial-peak criterion for the CE is based on experimental observations and uncertainty factors. No biological effects have been directly linked to spatial-peak SARs, although it is possible that auditory perception of pulsed RFR may be associated with the spatial-peak dose rate delivered to the head. Hence, the biological significance of these values is not clear.

The U.S. Federal Communications Commission (FCC) has requirements for the broadcast and communications industries in 47 CFR 1.1307(b), 1.1310, 2.1019, and 2.1093. These are a combination of IEEE C95.1-1991 and recommendations made by the National Council on Radiation Protection and Measurements (NCRP) (229). The Occupational Safety and Health Administration (OSHA) addresses microwave radiation in the general industry standard in 29 CFR 1910.97 and 1910.268(p)(2) and (3) and in the construction industry standard in 29 CRF 1026.54(l). In general,

the 10-mW/cm^2 limit in 1910.97 is not enforceable, but OSHA inspectors may use consensus standards in enforcement activities based on the General Duty Clause, Section 5(a)(1) of the Occupational Safety and Health Act of 1970 (2).

Infrared, Visible and Ultraviolet Radiation
Maurice Bitran, Ph.D., William Murray, MS

1 Introduction

Sir William Herschel's discovery of "obscure rays," extending beyond the red end of the visible spectrum, launched the exploration of the electromagnetic spectrum outside the visible range in the year 1800. The following year Johann Ritter demonstrated that invisible rays beyond the violet end of the spectrum are capable of chemical action. These three adjacent portions of the electromagnetic spectrum: infrared (IR), visible (vis), and ultraviolet (UV) are collectively known as optical radiation. Although infrared and ultraviolet radiations are invisible to the human eye, they are considered to be "optical" because they share some propagation and interaction characteristics with visible. As does the rest of the electromagnetic spectrum, optical radiation obeys the laws of electrodynamics and can be described both as electromagnetic waves and as energy corpuscles.

A wave is characterized by the distance between two successive peaks—its wavelength—or by the number of peaks passing a given point in space per unit time—its frequency. The wavelength l is measured in meters (m) or its multiples such as the kilometer (km) or nanometer (nm). The frequency n is measured in hertz (Hz) or its multiples such as kilohertz (kHz) or megahertz (MHz). One hertz is simply one cycle per second (s^{-1}). The propagating speed V of a wave of wavelength l (m) and frequency n (Hz) is measured in meters per second (m/s) and is given by the expression:

$$V = \lambda\nu \qquad (1)$$

Unlike waves on a pond or sound waves in air, electromagnetic waves do not need a physical medium to propagate. Electromagnetic waves are composed of mutually perpendicular electric and magnetic fields oscillating in phase and propagating at the speed of light in a direction perpendicular to both fields. The speed of light is a physical constant that depends only on the dielectric characteristics of the medium. In vacuum and in air, the speed of light, c, is approximately 3×10^8 m/s. Since the propagation speed of electromagnetic radiation is a constant, either the frequency or the wavelength can be used to describe any given radiation. The frequency is the physically invariant quantity, and the wavelength changes depending on the propagation medium. However, it has become customary to designate bands in the optical radiation range in terms of wavelength, usually in nanometers (1 nm = 1×10^{-9} m), micrometers (1 mm = 1×10^{-6} m), or angstroms (1 Å = 1×10^{-10} m) (Å is obsolete).

Electromagnetic radiation can also be described as energy corpuscles called *photons*. The energy of a photon is proportional to the wave's frequency, and thus, inversely proportional to the wavelength. The photon energy of electromagnetic radiation of frequency n and wavelength l is given by the equation:

$$E = h\nu = hc/\lambda \qquad (2)$$

where the energy E is expressed in joules (J) and h is Planck's constant (h = 6.63×10^{-34} joule second (J·s). In atomic physics and chemistry, it is customary to use an energy unit in the atomic-particle scale: the electron volt (eV). The electron volt is much smaller than the joule; the conversion factor is 1 eV = 1.6×10^{-19} J.

Infrared, Visible and Ultraviolet Radiation

2 Optical radiation and the electromagnetic spectrum
All known electromagnetic radiations are customarily arranged monotonically according to their energy in a continuum called the *electromagnetic spectrum*. The electromagnetic spectrum spans many orders of magnitude in energy and, correspondingly, in frequency and wavelength. As is

shown in the schematic representation of the electromagnetic spectrum in Figure 102.1, the optical radiation range is located between microwave radiation and X-rays. The optical radiation range is composed, in order of increasing energy, of infrared, visible, and ultraviolet radiation.

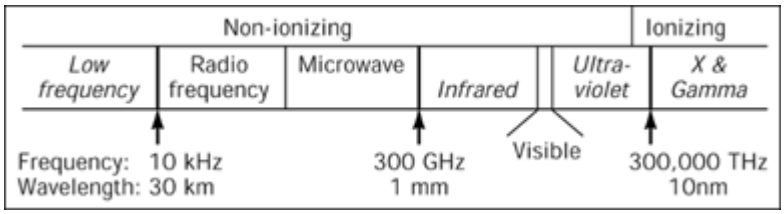

Figure 102.1. The electromagnetic spectrum. The frequency of electromagnetic fields is measured in *Hz* (hertz), or cycles per second. 1 kHz = 1000 cycles/second. 1 GHz (gigahertz) = 1000 million cycles/second. 1 THz (terahertz) = 1 million million cycles/second.

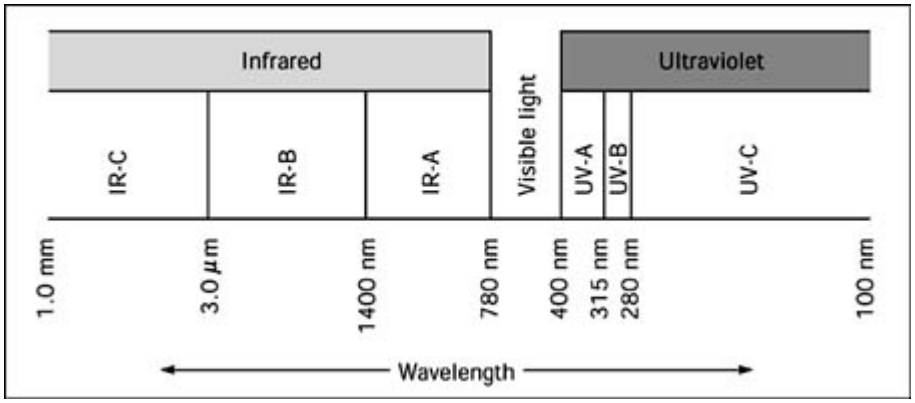

Figure 102.2. The optical spectrum. The wavelength of light, both visible and nonvisible, is typically measured in nanometers (nm) 1 nm = 0.001 mm = 0.000 001 mm = 0.000 000 001 m.

Although there are no sharp, well-defined boundaries in the electromagnetic spectrum, the optical radiation range is conventionally defined as extending from 1 mm at the bottom end of the infrared to 100 nm at the upper end of the ultraviolet. The optical range is divided as follows:

Ultraviolet: 100–400 nm
Light: 380–400 to 760–780 nm
Infrared: 760–780 nm to 1 mm

The reason for the "fuzzy" boundaries for the visible range is that they are defined by the physiological process of vision, which has some intrinsic variability.

The important boundary between ionizing and nonionizing radiation, marked in the electromagnetic spectrum in Figure 102.1, falls in the optical radiation range. When the energy of radiation incident on an atom or molecule exceeds the binding energy of the target's outer electrons (the ionization potential of the substance), the target is ionized (i.e., the outer electrons are separated from the rest of the atom or molecule). The chemical changes produced by ionization account for the serious health effects of ionizing radiation. When the energy of the incident radiation is below the ionization potential of the target, energy is transferred to the substance's electronic levels, leading to photochemical effects, or to its rotational, vibrational, or translational states, leading to increases in thermal energy of the molecules. Although there is no well-defined boundary between ionizing and nonionizing radiation (it depends on the ionization potential of the substance to be ionized), it is conventionally set at 100 nm, which corresponds to a frequency of 3 PHz (3×10^{15} Hz), and a

quantum energy of 12.4 eV. This value is very close to the ionization potential of atomic hydrogen, the most abundant element in the universe.

Infrared, Visible and Ultraviolet Radiation

3 The generation of optical radiation
The main mechanisms that produce optical radiation are incandescence, electrical discharge, and lasing. Incandescence is the emission of radiation by hot bodies. Large numbers of energy transitions in the material's molecules, excited by the increase in kinetic energy, emit radiation over a wide frequency range. All substances at temperatures above absolute zero (–273°C) emit radiation. At low temperatures most of the emitted radiation is in the infrared range. At temperatures greater than 500° C, many substances start to emit in the visible range. As the temperature increases, the wavelength of the most intense radiation shifts in color from the red toward the blue. This phenomenon is known as Wien's displacement law: "The wavelength of maximum intensity, l_{max}, is inversely proportional to the absolute temperature, *T*, of the emitting body."

$$\lambda_{\max} = 0.29(\text{cm K})/T(\text{K}) \qquad (3)$$

The total energy flux, integrated over all wavelengths, emitted per unit area by a body at absolute temperature *T* is given by the Stefan–Boltzmann law:

$$W(\text{W/m}^2) = \sigma T^4 \qquad (4)$$

where s = 5.67×10^{-8} (w/m^2) and the temperature, *T*, in kelvin.

In order to study the emission of incandescent bodies, the simplifying assumption of an idealized nonreflecting object, or "blackbody," is often made. The distribution of the intensity of the emitted radiation as a function of wavelength for a blackbody is given by Planck's radiation law. Both Wien's and Stefan–Boltzmann's laws can be deduced mathematically from Planck's law. Dense incandescent bodies approximate the behavior of the ideal blackbody. Examples of incandescent sources of optical radiation are filament lamps, molten metals, and the sun. The sun is the main source of optical radiation in the environment. Radiation from the sun fits closely the spectral emission of a blackbody at 5900°C (6173 K).

Unlike incandescence, which produces an emission continuum, electrical discharge in a gas results in the emission of optical radiation at discrete, characteristic wavelengths (emission lines). An electric current passing through a low-pressure gas ionizes the gas and excites the electrons. The radiative de-excitation of the electrons taking place between energy levels produces photons of specific wavelengths. Increasing the pressure of the gas broadens the emission lines. At high pressures, neighboring lines start to merge, emulating a continuum. Examples of electrical-discharge sources of optical radiation are fluorescent tubes and high- and low-pressure gas lamps. Electric arcs, such as welding arcs, are powerful sources of optical radiation. Electric arcs take place when the electric potential difference between two electrodes is high enough for the electrons to breach the dielectric separating them.

Laser (light amplification by stimulated emission of radiation) radiation is generated by when the radiative de-excitation of electrons is brought about by photons of the same energy. This process is called "stimulated emission" and requires that more electrons stay in an exited atomic state than in the ground state (population inversion) for a relatively long time (metastable levels). The photons produced by stimulated emission have the same frequency (and therefore the same wavelength) and

are in phase (the radiation is said to be coherent). By using a resonant cavity, the lasing is amplified and the photons are collimated in a very narrow beam that can propagate for a long distance with minimum divergence or spread. It is the low divergence and the coherence of the monochromatic laser light that creates the unique capabilities, and hazards, of laser radiation. Different lasers can produce radiation at many wavelengths over the optical range. A comprehensive treatment of laser radiation can be found in the Chapter 103.

Infrared, Visible and Ultraviolet Radiation
Maurice Bitran, Ph.D., William Murray, MS

4 The interaction of optical radiation with matter
Electromagnetic radiation must be absorbed by a medium in order to take effect on it. Not all electromagnetic radiation incident on a surface is absorbed; a fraction of the radiation may be reflected, and some may be transmitted through the medium. The biologically relevant energy fraction absorbed by the target, E_a, is given by:

$$E_a = E_i - E_r - E_t \quad (5)$$

where E_i is incident energy; E_r, reflected energy; and E_t, transmitted energy. In addition to reflection, transmission, and absorption, electromagnetic energy interacting with matter can undergo refraction, diffraction, and scattering. The reflection of optical radiation at the interface between two media can be specular or diffuse. In specular reflection the interface acts like a mirror, and the reflected rays follow the familiar law of reflection (the angle of reflection is equal to the angle of incidence). Specular reflection requires that the reflecting surface be smooth compared to the size of the wavelength of the incident radiation. When the surface irregularities are greater in size than the wavelength, and are oriented randomly, the reflection is diffuse. A surface that reflects radiation equally in all directions is called a *Lambertian surface*. Refraction is the change in direction that light rays, and by extension other optical radiations, undergo when traveling from one medium to another with a different index of refraction. This process is frequency dependent (that is why a prism can be used to separate the colors in white light) and follows Snell's law, which states that the ratio of the sine of the angle of incidence to that of the angle of refraction is inversely proportional to the ratio of the indexes of refraction of the media.

Scattering takes place when energy from a radiation beam is removed and redirected by particles along its path. The intensity, direction, and spectral content of scattered radiation depend on the size, orientation, and dielectric properties of the particles and on the intensity and spectral content of the incident radiation. Rayleigh scattering of sunlight by air molecules is inversely proportional to the fourth power of the wavelength and thus removes preferentially blue light. This phenomenon accounts for the blue color of the sky and the red color of sunsets.

Infrared, Visible and Ultraviolet Radiation
Maurice Bitran, Ph.D., William Murray, MS

5 Quantities and units of optical radiation
The measurement of optical radiation requires knowledge of the amount, rate, and spectral distribution of energy emitted by sources and impinging on surfaces. Two systems are used to measure optical radiation: the radiometric and the photometric systems. The radiometric system, used throughout the optical range, is based on absolute measurements that are independent of the

characteristics of any detector. In the visible range, however, the spectral response of the human eye is all-important, and a special system of photometric quantities, relative to the spectral response of the human eye, has been developed. The main radiometric and photometric quantities and units are listed in Table 102.1

Table 102.1. Radiometric and Photometric Quantities and Units

Radiometric System		Photometric System	
Quantity	**Unit**	**Quantity**	**Unit**
Radiant energy	J	Quantity of light	lm s
Radiant flux	W	Luminous flux	lm
Irradiance	W m^{-2}	Illuminance	lm m^{-2}
Radiant intensity	W sr^{-1}	Luminous intensity	lm sr^{-1}
Radiance	W m^{-2} sr^{-1}	Luminance	lm sr^{-1} m^{-2}
Radiant exposure	J m^{-2}	Light exposure	lx s

J, joule; W, watt; sr, steradian; lm, lumen; lx = lux = lm m^{-2}; cd = candela.

The prefix “spectral” indicates that the quantity refers to a unit wavelength. The spectral irradiance at the target (W m^{-2} nm^{-1}) and the source's spectral radiance (W m^{-2} sr^{-1} nm^{-1}) are the most useful quantities in UV hazard evaluations.

The relative luminous efficiency of the eye for photopic (day) vision peaks at about 555 nm. The efficiency falls off rapidly to less than 10% of the maximum in the blue and orange wavelengths and has decreased by about four orders of magnitude at 400 and 750 nm (1). Because of this variation in the luminous efficiency as a function of wavelength, the correspondence between the radiometric and photometric output of a visible radiation source is complex.

All the quantities and units shown in Table 102.1 conform to the International System of Units [Système International (SI) d'Unitès] (2). Irradiance and radiant exposure are specified frequently in units of mW/cm^2 and mJ/cm^2, respectively (1 W/m^2 = 0.1 mW/cm^2; 1 J/m^2 = 0.1 mJ/cm^2).

The term luminance *L* describes the brightness, or luminous intensity of an object per unit area. There are several different measures of luminance; the basic unit is the candela per square meter (cd/m^2). In the English system, the unit is the footlambert (ftL). The conversion is 1 ftL = 3.426 cd/m^2. Illuminance *E* is the luminous flux per unit area impinging upon a surface. The common unit is the lumen per square meter (lm/m^2) or lux (lx). The English unit is the footcandle (ftcd), which is 10.76 lx. The candela is the unit of luminous intensity *I*. The candela is equal to one lumen per unit solid angle [steradian (sr)]. One lumen is 0.00147 W at 555 nm. The relationship between the SI and English units is summarized as:

$$\begin{aligned} \text{illuminance} \quad &- \quad \text{lm/m}^2;\ \text{lm/cm}^2;\ \text{lux (lx)};\ \text{footcandle (ftcd)} \\ &\quad 1\,\text{lm/m}^2 = 10^{-4}\,\text{lm/cm}^2 = 1\,\text{lx} = 0.0929\,\text{ftcd} \\ \text{luminance} \quad &- \quad \text{cd/m}^2;\ \text{cd/cm}^2;\ \text{footlambert (ftL)} \\ &\quad 1\,\text{cd/m}^2 = 10^{-4}\,\text{cd/cm}^2 = 0.2919\,\text{ftL} \end{aligned}$$

Infrared, Visible and Ultraviolet Radiation
Maurice Bitran, Ph.D., William Murray, MS

6 Characteristics of Optical Radiation Sources
Radiation sources are often classified as point or extended sources. Theoretically, no source is a point source because it has a finite size. Distant stars are treated as "point" sources, although the sun is certainly an extended source. The laser is the only man-made device that is treated as a point source. All other sources are extended sources.

The intensity of the radiation emitted by a point source varies with the distance from the source according to the inverse square law. The ratio of the irradiance (E_1) at distance r_1 to that (E_2) at distance r_2 is calculated as follows:

$$\frac{E_1}{E_2} = \frac{r_2^2}{r_1^2} \qquad (6)$$

This equation is a good approximation for extended sources at distances of >10 times the maximum dimension of the source. For lasers or other collimated sources, this law can be used only at very large distances from the source. The region in which the inverse square relationship applies is called the "far" field. It does not hold in the "near" field region at distances close to the source.

Infrared, Visible and Ultraviolet Radiation
Maurice Bitran, Ph.D., William Murray, MS

7 The Biological effects of optical radiation
The wavelengths in the optical radiation range have limited penetration into the human body. Therefore, the main organs affected by optical radiation are the skin and the eyes, although systemic effects have also been identified. Evolving in an environment where the sun is the main source of optical radiation, humans have developed adaptive characteristics, such as skin pigmentation, a hairy scalp, receded eyes, and aversion responses to bright lights and to excessive heat. These characteristics, however, provide only partial protection against optical radiation.

Optical radiation can act on biological tissue through thermal and photochemical processes. The extent of damage depends on the intensity of the radiation, the wavelength, the exposure time, and the optical and physiological characteristics of the tissue exposed. The variability in biological effectiveness of different wavelengths (three orders of magnitude within the ultraviolet range) is particularly striking. This has led to the definition of "biologically effective" quantities, which are obtained by using a biological spectral effectiveness function. Both the eye and the skin are at risk of acute and chronic injury from optical radiation. The ocular media transmit visible and near-infrared radiation to the retina, but most ultraviolet and far-infrared radiation are absorbed in the cornea and the lens. The response of the skin depends strongly on its albedo and pigmentation.
7.0 Optical Radiation
Optical radiation extends between X-rays and microwave radiation in the electromagnetic spectrum and includes ultraviolet radiation (UVR), visible radiation or light, and infrared radiation (IR). These regions are further subdivided and receive various names.
7.1 Synonyms

Ultraviolet radiation, ultraviolet light (incorrect)
Visible radiation, light
Infrared radiation, radiant heat

7.2 Physical Properties
7.2.1 General Several schemes are used to divide the optical wavelengths into spectral bands, but that of greatest importance to the photobiologist and health professionals is that adopted by the Committee on Photobiology of the International Commission on Illumination (Commission International de l'Eclairage, CIE) (3, 4). Although sharp demarcation points have been given to the regions, there is no physical basis for these transition points. Rather they serve only as a convenient framework for discussing the biological effects and exposure hazards.

In the CIE classification, ultraviolet radiation extends between 100 and 400 nm and is subdivided into 3 bands: UV-A, UV-B, and UV-C:

Lasers

David H. Sliney, Ph.D.

1.1 Properties of Lasers

Laser light is produced from transitions between atomic or molecular energy levels. Generation of light requires two energy levels, E_1 and E_2, separated by the photon energy E_p of the light that is to be produced.

$$E_p = h\nu = hc/\lambda = E_2 - E_1 = \Delta E \qquad (1)$$

where h is Planck's constant, c is the velocity of light, and E_1 and E_2 are, respectively, the lower and higher energy levels. The relevant energy levels may be those of atoms or molecules in a gas, as in the case of the helium–neon laser, or of ions embedded in a solid host material, as in a ruby laser, or they may be energy levels that belong to a crystalline lattice as a whole, as in the aluminum gallium arsenide AlGaAs, semiconductor laser.

The light emitted by a laser has a number of unusual properties that distinguish it from light emitted by conventional light sources. Unusual properties include a high degree of collimation, a narrow spectral linewidth, good coherence, and the ability to focus to an extremely small spot. Because of these properties, there are many possible applications for which lasers are better suited than conventional light sources. For example, alignment applications utilize the collimation of laser light. Spectroscopic and photochemical applications depend on the narrow spectral linewidth of tunable laser sources. Interferometric and holographic applications require a high degree of coherence.

1.1.1 Collimation

One of the most important characteristics of laser radiation is its highly directional collimated beam. Although the beam divergence angle is very small, it is not zero.

1.1.2 Spectral Linewidth

Laser light is highly monochromatic; that is, it has a very narrow spectral linewidth. This linewidth is not zero, but is typically much less than that of conventional light sources. The discussion of linewidth is complicated by the presence of the resonant longitudinal cavity modes. The spacing between the longitudinal modes is given by $c/2D$, where c is the velocity of light and D is the length of the laser. Several longitudinal modes may be present simultaneously in the laser output.

1.1.3 Coherence

Coherence implies a regular, orderly progression of the vibrations of the electromagnetic radiation. Coherence can be understood only by reference to a considerable body of mathematical development, a detailed discussion of which can be found in the literature (9). Conventional light sources do not share the property of coherence; rather these sources have a certain amount of randomness or irregularity in the oscillations of the light waves. Radio waves exhibit coherence, or orderliness, and because of coherence properties information can be impressed on radio waves for communications applications. The advent of lasers made available coherent light sources of reasonably high intensity in the visible portion of the spectrum. Coherence is important in any application in which the laser beam is to be split into parts, such as interferometry and holography. Such applications rely on the high coherence of the laser beam.

The time period Dt in which the light wave undergoes random changes is called the *coherence time*. It is related to the linewidth Dn of the laser by the equation

$$\Delta t \simeq \frac{1}{\Delta \nu} \qquad (2)$$

1.1.4 Focusing Laser Light

One of the most important properties of laser radiation is the ability to collect all the radiation using a simple lens and to focus it to a spot. It is not possible to focus the laser beam down to a mathematical point; there is always a minimum spot size, set by the physical phenomenon of diffraction. A convenient equation is

$$D_m = F\theta \quad (3)$$

where D_m is the smallest focal diameter that can be obtained, F is the focal length of the lens, and q is the beam divergence angle of the laser beam.

1.1.5 Spatial Profiles

The cross sections of laser beams have certain well-defined spatial profiles called *transverse modes*. The word *mode* in this sense should not be confused with the same word as used to discuss the spectral linewidth of lasers. Transverse modes represent configurations of the electromagnetic field determined by the boundary conditions in the laser cavity.

1.1.6 Temporal Characteristics

Laser operation may be characterized as either pulsed or continuous. There are a number of distinctive types of pulsed laser operation having widely different pulse durations.

The earliest solid-state lasers, such as ruby lasers, were simply pulsed by discharging a capacitor through a flashlamp, without any attempt to control the duration of the laser output. Such lasers typically had durations around 1 ms. The pulses were called normal or free-running laser pulses.

Lasers
David H. Sliney, Ph.D.

1.2 Production

The widespread interest in lasers is based on practical applications. Lasers are used to perform many useful functions in science, engineering, industry, and education. Additionally, many other applications are under development. An application such as welding depends on the collimation and focusing ability of the beam, which leads to high power density. A conventional light source, even one having higher total radiant power than a welding laser, cannot be focused well and thus is not useful for welding.

Most applications for which lasers are used were originally demonstrated using conventional light sources. In many cases, the application was only marginally successful using conventional sources and required the development of laser light sources to be practical.

1.2.1 Material Processing

Laser radiation can be used for a variety of material processing functions such as welding, cutting, shaping, marking, and drilling (10–12). Even a fairly modest pulsed laser can be focused to produce a power density greater than 10^9 W/cm^2; lasers can melt and vaporize materials. Spot welding using pulsed lasers was demonstrated in the 1960s (13). Seam welding is possible by overlapping pulses, or using continuous lasers. However, the penetration depth for such welding is limited. The energy is deposited at the surface of the workpiece. For complete penetration of the weld through the workpiece, thermal conduction has to carry heat energy through the entire thickness of the specimen. In practice, this factor limited maximum weld depths to perhaps 0.1 cm, depending on the thermal conductivity of the sample.

The advent of multikilowatt carbon dioxide lasers in the early 1970s eased the 0.1-cm restriction (14, 15). The beam can drill a hole into the workpiece, then, as the beam is translated, the hole moves through the material. Molten material flows into the region behind the moving hole and resolidifies. Thus a continuous seam is produced. Because the energy is deposited at the bottom of the hole, limitations because of slowness of thermal conduction do not apply. Welds having much greater depth can be produced by this technique, called deep-penetration laser welding. Welds as deep as 5 cm have been produced in stainless steel (16). Laser welding has become widely used in practical industrial processing (17–19).

High-power laser beams can vaporize material, leading to applications such as hole drilling and cutting. Higher power densities are used for these applications than for hardening and welding. Hole drilling in ceramic materials has become common. There is a need for small (less than 0.5-mm) holes in the alumina substrates used in many electronic applications. Holes drilled before the ceramic is fired tend to change dimension during firing. After firing, the material is very hard, brittle, and difficult to drill by conventional techniques. Laser drilling offers an improved technique for producing holes in the fired ceramic, and has become an important application for lasers in the electronics industry.

High-power lasers have impressive capabilities for cutting both metallic and nonmetallic materials. The cutting rates can be increased by the presence of gases. Typically oxygen is used but other gases have sometimes been employed. A jet of oxygen or air is blown on the workpiece at the position where the beam strikes it. The exothermic chemical reaction with the oxygen can greatly increase the cutting rate for reactive materials. Laser cutting is widely used in many practical applications, such as cutting titanium in the aerospace industry, cutting steel plates in the automotive industry, and cutting fabric in the garment industry.

Another important application involving material processing is trimming of resistors. Thick-film resistors used in many electronic circuits must be trimmed to the final desired value. This can be done by fabricating the resistor using a low value of resistance and then cutting part way through it with a laser. The resistance can be monitored as cutting proceeds. Trimming is terminated when the desired value is reached. Repetitively Q-switched Nd:YAG lasers are commonly used for resistor trimming. Laser trimming has become a standard procedure in the electronics industry.

Lasers
David H. Sliney, Ph.D.

1.3 Use
1.3.1 Measurement Applications
Lasers have been used for measurement of many physical parameters. These include length and distance, velocity of fluid flow and of solid surfaces, dimensions of manufactured goods, and the quality of surfaces, including flaw detection and determination of surface finish.

Lasers are used in measurement of lengths in a variety of ways (20, 21). A very short pulse of high-power laser light may be directed toward a target the distance of which is desired. A photodetector viewing the target collects a signal resulting from light reflected by the target. The time t between the outgoing pulse and the detection of the reflected signal, that is, the time for the light to make a round trip from the laser to the target and back, is measured. Because the velocity of light is known, the range R to the target is

$$R = ct/2n \tag{4}$$

where n is the index of refraction of the air through which the pulse travels. Because the index of refraction depends on air temperature, pressure, altitude, and other factors, this method is subject to some uncertainties. It has been used for accurate measurement of the distance from the earth to the moon. Table 103.2 lists methods using lasers for measuring distances.

Table 103.2. Distance Measurement Using Lasers

Method	Laser type	Range	Typical application

Round-trip time-of-flight	Q-switched solid state	many km	Military ranging, satellite ranging
Phase comparison of amplitude-modulated beam	He–Ne, AlGaAs	km	Surveying
Interferometry	Frequency-stabilized He–Ne	few meters	Machine-tool control
Laser Doppler displacement	He–Ne	to 120 m	Machine-tool control

1.3.2 Holography

Holography, a photographic process that yields three-dimensional images, was invented in the prelaser era in 1948 (22). Light sources available at that time were not adequate for making good holograms and holography became practical only after the invention of the laser (23). The properties of coherence and monochromaticity offered by lasers are important for holography.

1.3.3 Medical Applications

Lasers have been used for a variety of medical applications. Perhaps the repair of tears and holes in the retina may be the best-known example.

Laser photocoagulation also has been widely used to treat diabetic retinopathy, one of the leading causes of blindness in the United States.

Laser removal of tattoos and of colored birthmarks has been widely studied. A high-power pulsed laser at a wavelength absorbed by the pigment is used to vaporize the pigment and to bleach the colored area. Ruby, Nd:YAG, and dye lasers are favored for this purpose.

High-power carbon dioxide lasers have been used for surgery. Absorption by tissue is very high at the 10-mm wavelength of the carbon dioxide laser. Laser surgery provides a possibility for simultaneous cutting and cauterization. Use of carbon dioxide lasers for bloodless surgery has been widely studied, especially for blood-rich organs such as the liver. Laser surgery has also been widely used for ear, nose, and throat procedures.

Laser angioplasty, a procedure in which laser energy is delivered through an optical fiber inserted into a blood vessel to a location of a blockage in the vessel and used to burn through the blockage, was studied extensively during the 1980s. Early enthusiasm for the procedure as a treatment for coronary disease seems to have waned because blockages can recur at the same locations.

The development of so-called photodynamic therapy uses lasers for treatment of cancer. The patient is injected with a substance called hematoporphyrin derivative, which is preferentially localized in cancerous tissues. The patient is later irradiated with laser light, often with a dye laser at a wavelength around 630 nm. The light energy catalytically photooxidizes the hematoporphyrin derivative, releasing materials that kill the nearby cancerous tissue. Normal tissue that did not retain the chemical is not harmed. Photodynamic therapy offers promise as a new form of cancer treatment.

1.3.4 Communications

The advent of the laser improved prospects for optical communications enormously. The coherence of the laser meant that techniques developed in the radio portion of the electromagnetic spectrum could be extended to the optical portion of the spectrum. Because lasers operate at frequencies near 10^{15} Hz, they offer a potentially wide bandwidth, equal to about 10^{7} television channels of width (ca. 10^{8} Hz). It has not proved possible to take advantage of this full bandwidth because devices such as modulators capable of operating at 10^{15} Hz are not available.

Laser communication systems based on free-space propagation through the atmosphere suffer drawbacks because of factors like atmospheric turbulence and attenuation by rain, snow, haze, or fog. Nevertheless, free-space laser communication systems were developed for many applications (24–26). They employ separate components, such as lasers, modulators, collimators and detectors. Some of the most promising applications are for space communications, because the problems of turbulence and opacity in the atmosphere are absent.

The most important application of fiber-optic laser-based communication is in long-distance telecommunications (27, 28). Fiber-optic systems offer very high capacity, low cost-per-channel, light weight, small size, and immunity to crosstalk and electrical interference.

Laser-based fiber-optic telecommunications has had a revolutionary impact on long-distance telephone communication and is now expanding into many new applications areas.

1.3.5 Consumer Products

Laser-based products have emerged from the laboratories and become familiar products used by many millions of people in everyday circumstances. Examples include the supermarket scanner, the laser printer, and the compact disk.

1.3.6 Spectroscopic Applications

Laser technology has led to a revolution in spectroscopic techniques. Absorption spectroscopy can be carried out at much higher resolution than is available from conventional spectrometers.

1.3.7 Laser Photochemistry

Photochemical applications of lasers generally employ tunable lasers that can be tuned to a specific absorption resonance of an atom or molecule. Examples include the tunable dye laser in the ultraviolet, visible, and near-infrared portions of the spectrum; the titanium-doped sapphire, Ti:sapphire, laser in the visible and near infrared; optical parametric oscillators in the visible and infrared; and line-tunable carbon dioxide lasers, which can be tuned with a wavelength-selective element to any of a large number of closely spaced lines in the infrared near 10 mm.

Other uses include purification of materials, deposition of thin films, isotope separation, and laser-assisted thermonuclear fusion.

1.4 Toxic Effects

Laser radiation can pose significant risks to vision when the eye is located within the beam (intrabeam viewing), and occupational Exposure Limits (ELs) have been developed for these conditions (1–10). Lasers pose a more significant optical radiation hazard than conventional light sources because lasers have a far greater brightness (radiance) and because a typical laser has a collimated beam, which can present a hazard to the eye at a significant distance. The potential hazards vary with wavelength, and this is particularly true for the eye, which is the more vulnerable organ because of its special optical properties. The eye is particularly vulnerable to injury in the retinal hazard region from 400 nm at the short-wavelength end of the visible spectrum to 1400 nm in the near-infrared part of the spectrum (29, 30). Within this spectral band, a collimated beam can be focused to a 15–20-mm-diameter retinal spot (i.e., much smaller than the diameter of a human hair). The gain in beam irradiance from cornea to retina is approximately 100,000 times in the visible spectrum. Hence, a corneal beam irradiance of 1 W/cm^2 becomes 100 kW/cm^2 at the retina. Vision loss can vary from temporary after-images to a permanent blind spot (scotoma) or even total loss of vision in an eye (29). Figure 103.1. illustrates that because of the great brightness of a laser, its radiant energy can be greatly concentrated when focused (e.g., upon the retina) as compared to the rays from conventional light sources, which are much less bright. This very high radiance can be

expressed as MW and TW cm^{-2} sr^{-1}, and this radiance is responsible for the laser's great value in material processing and laser surgery. When compared to a xenon arc or the sun, even a small He–Ne alignment laser or diode laser pointer is typically ten times brighter.

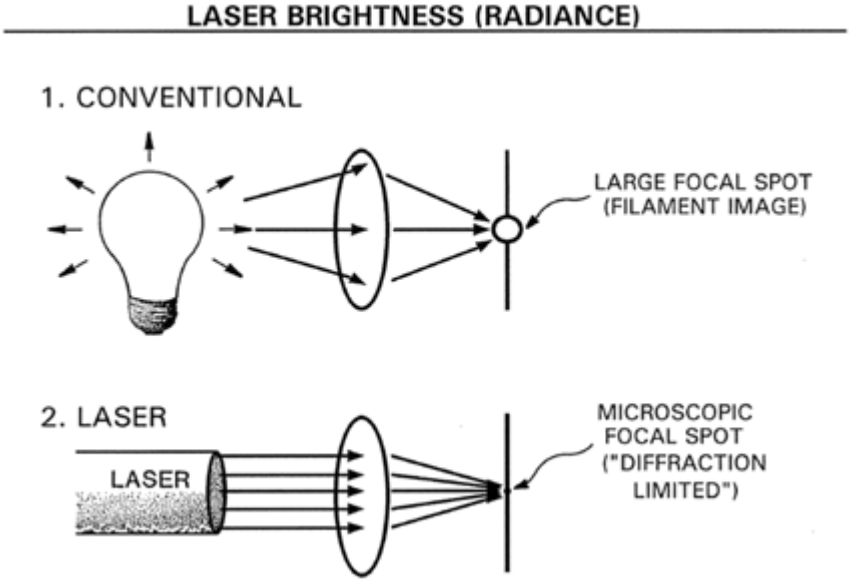

Figure 103.1. The great brightness (radiance) of a laser permits its beam to be greatly concentrated when focused as compared to the rays from conventional light sources, which are much less bright.

Although the laser focal image on the retina may cover only 20–30 cone cells, the retinal injury is always larger because of heat flow and acoustic transients (29). Even a small disturbance of the retina can be significant. This is particularly important in the region of central vision referred to by eye specialists as the *macula lutea* (Latin for "yellow spot"), or simply the "macula." The central region of the macula, the fovea centralis, is responsible for detailed "20/20" vision. Damage to this extremely small (about 150-mm-diameter) central region can result in severe vision loss even though 99% of the retina remains unscathed. The surrounding (peripheral) retina is useful for movement detection and other tasks but possesses little acuity. The eye moves across a line of print to read, because an individual's detailed vision covers only a very small angular subtense centered in the fovea. Outside the 400–1400-nm retinal hazard region the cornea—and even the lens—can be damaged by laser beam exposure (29, 30).

Diffuse reflections of laser beams are normally safe to view, since the energy is dissipated upon reflection into all directions and the resulting image on the retina is normally that of an extended source. However, under special conditions, it is a realistic possibility to produce a hazardous diffuse reflection. This can result from a diffuse reflection of a Q-switched (1–100-ns) laser in the retinal hazard region (29). This retinal injury hazard from diffuse reflections was one of the criteria for placing some pulsed lasers in the high-risk category known as Class 4 (29, 30).

The adverse effects associated with viewing lasers or other bright light sources such as the sun, arc lamps, and welding arcs have been studied for decades (31–35). Injury thresholds for acute injury in experimental animals for corneal, lenticular and retinal effects have been corroborated for the human eye from accident data.

1.4.1 Injury Mechanisms

For most exposure durations (t>1 s), laser-induced injury is dominated by either photochemically or thermally initiated events taking place during or immediately following the absorption of radiant energy. At nanosecond (1 ns = 10^{-9} s) or shorter durations, nonlinear mechanisms may play a role (29, 31, 36). Following the initial insult, biological repair responses may play a significant role in determining the final consequences of the event (38, 39). While inflammatory, repair responses are

intended to reduce the sequellae, in some instances, this response could result in events such as scarring, which could have an adverse impact upon biological function (40). Within the first several weeks, the inflammatory reaction itself (e.g., edema) may interfere with function (40, 41).

Laser damage thresholds vary with wavelength, duration, and spot size. However, photochemical and thermal effects vary differently depending on the wavelength, the exposure duration, and the size of the irradiated area. Indeed, experimental biological studies in humans and animals make use of these different relationships to distinguish between which of several competing mechanisms is playing a dominant role in observed injury (39). Photochemical injury is highly wavelength dependent, while thermal injury depends upon exposure duration. Each of these factors will be examined in the following.

1.4.1.1 Exposure Duration The Bunsen–Roscoe Law of photochemistry describes the *reciprocity* of exposure rate and duration of exposure. This law applies to any photochemical event. The product of the irradiance or dose rate (in watts per square centimeter) and the exposure duration (in seconds) equals the exposure dose (in joules per square centimeter at the site of absorption) to produce a threshold injury. Radiometrically this is expressed as: The irradiance E in W/cm^2 multiplied by the exposure duration t is the radiant exposure H in J/cm^2.

$$H = Et \tag{5}$$

Repair mechanisms and other biochemical changes over long periods (hours) and photon saturation for extremely short (submicrosecond) periods will lead to reciprocity failure. This reciprocity helps to distinguish photochemical injury mechanisms from thermal injury (burns). Because of heat conduction, thermal injury generally requires a very intense exposure within seconds to cause photocoagulation; otherwise, surrounding tissue conducts the heat away from the absorption site (e.g., a retinal image).

Thermal injury is a *rate process* dependent upon the volumic absorption of energy across the spectrum. The thermochemical reactions that produce coagulation of proteins and cell death require critical temperatures for detectable biological injury. The critical temperature for an injury gradually decreases with the lengthening of exposure duration. This approximate decrease in temperature varies over many orders of magnitude in time and deceases approximately as the exposure duration t raised to the – 0.25 power [i.e., $f(t^{-0.25})$].

1.4.1.2 Wavelength Action Spectrum As with any photochemical reaction, the *action spectrum* should be known (42). The action spectrum describes the relative effectiveness of different wavelengths in causing a photobiological effect. For most photobiological effects (whether beneficial or adverse), the full width at half-maximum of the action spectrum is less than 100 nm, and a long-wavelength “cutoff” exists where photon energy is insufficient to produce the effect. This is not at all characteristic of thermal effects, where the effect occurs over a wide range of wavelengths where optical penetration and tissue absorption occur. For example, significant radiant energy can penetrate the ocular media and be absorbed in the retina in the spectral region between 400 and nearly 1400 nm, and the absorbed energy can produce retinal thermal injury (29, 30).

Although the action spectra for acute photochemical effects upon the skin, cornea, lens, and retina have been published (43), the action spectra of some other effects appear to be quite imprecise or even unknown (35, 41, 43, 44).

1.4.1.3 Eye Movements Several physiological factors must be considered for CW exposures (generally thought of as greater than 0.25 s), where the person's visual task will limit the exposure duration and the retinal area illuminated. Physiological factors, such as pupillary activity, eye movements, breathing, heartbeat, blood flow, other bodily movements, and visual task behavior become important. In addition, at short visible wavelengths, another injury mechanism

(photochemical) plays an important role. All these factors were considered in setting the ELs for exposure durations greater than 10 s.

Eye-movement studies of Ness et al. (53) showed that the retinal image can remain remarkably still for a few seconds, but that within 30 s, the central retina (the fovea) must move to other points in space for cognition. Two viewing conditions were studied: with a stabilized head (as could occur with ophthalmic instrument applications of lasers), and without head restraint (normal conditions) while volunteers attempted to fixate on a small "point" light source. Results are evaluated in a variety of ways. The fixation history of the small retinal image diameter d_r (< 30 mm) can be plotted as a function of time to determine the integration of retinal exposure dose. The accumulated radiant exposure in the retinal image area directly predicts the extent and position of photochemical retinal injury, since retinal radiant exposure determines the risk of photoretinitis for a given wavelength. While these data permitted the determination of the photoretinitis ("blue-light hazard") EL value, the determination of the thermal hazard ELs was more complex, since thermal retinal injury thresholds decrease for increasing retinal spot size.

The determination of the potential for retinal thermal injury for long fixation times requires an examination of three factors:

1. The time-averaged retinal irradiance
2. The thermal effects that result from the way eye movements transform a fixed retinal image into the equivalent of a repetitive-pulse exposure
3. The manner in which image size affects the retinal thermal injury threshold due to radial heat flow during and after the exposure

The time-averaged retinal irradiance must not exceed the CW irradiance permitted for a fixed image. The thermal repetitive-pulse exposure obeys what is referred to as the $N^{-0.25}$ additivity rule, where the net effect is modified as the number of pulses N raised to the –0.25 power ($N^{-0.25}$).

Correction factors for eye movements are only important for viewing durations exceeding 10 s. Only the thermal mechanism is important at durations less than 1 s for small images. Although the physiological eye movements known as saccades do spread the absorbed energy in minimal retinal images (of the order of 25 mm or less) within the 0.1 to 10 s time regime, the limits recommended in these guidelines provide an added safety factor for this viewing condition. At 0.25 s with unrestrained head viewing, the mean retinal spot illuminated is spread out to approximately 50 mm. By 10 s, the illuminated retinal zone becomes approximately 75 mm, and the added safety factor for the minimal image condition becomes 1.7 over a stabilized eye, with the spot-size dependence taken into account. By 100 s, it is rare to achieve an illuminated zone (measured at 50% points) as small as 135 mm, and this means that there is, in effect, an additional safety factor of 2.3 or more above the minimal image condition. The data from eye-movement studies and retinal thermal injury studies were combined to derive a break-point in viewing time T_2 at which eye movements compensated for the increased theoretical risk of thermal injury for increased retinal exposure durations if the eye were immobilized.

The impact of eye movements is dramatic for minimal retinal spot sizes and permits a leveling of the thermal EL for a > 1.5 mrad to a constant irradiance of 1 mW/cm^2 in the visible spectrum (400–700 nm) for t > 10 s. However, as would be expected, there is only a small impact for a source size of 100 mrad, and the plateau of no further risk of retinal injury due to eye movements does not occur until 100 s. For photochemical injury, eye movements had already been incorporated into the visible laser limits for exposure durations between 10 and 100 s. Beyond 100 s, it is probably unreasonable to assume that fixation could realistically take place, and it was concluded that the limits for all but very large sources (greater than 100 mrad) should end there.

1.4.2 Acute Effects upon Vision

Accidental exposure of the eye to intense laser radiation can result in a range of visual effects. Three general effects upon vision are of particular importance. These three effects are: scotoma, visual disturbances, and acute injury to the cornea. Within the retinal hazard region, a scotoma, or blind spot can appear in the injured person's visual field. The scotoma will appear instantaneously if the injury from thermocoagulation and acoustic disruption of the retina is caused by a pulsed laser beam (approximately 420–1300 nm) focused on the retina. The result of this injury can be permanent functional loss depending upon the severity of the initial injury and whether scarring takes place in the retina which can produce a larger lesion than if biological repair is optimal. At levels below the MPE, temporary visual disturbances may occur. There are two sources of such a transient vision disturbance: (*1*) Veiling glare and (*2*) afterimages, or "flashblindness." Veiling glare from a CW laser is comparable to viewing oncoming automobile headlights while driving. While this glare can make it difficult to see (disability glare) or can be very uncomfortable (discomfort glare), it exists only as long as the laser illuminates the eyes. An afterimage (flashblindness) is most pronounced for low ambient illuminations. The duration of the afterimage is greatest for low ambient illumination (i.e., at night) and for the brightest sources. Although these transient effects are difficult to quantify, they may result in a transient, partial scotoma. The third category of visual effect results from acute injury to the cornea or lens. The effect may be immediate from thermal coagulation or thermal ablation, or it may be delayed for 9–24 h following UV photochemical injury. These injuries can cause the entire visual field to become cloudy due to light scatter.

1.4.3 Types of Injury

The human eye is actually quite well adapted to protect itself against the potential hazards from ambient environmental optical radiation (ultraviolet, visible, and infrared radiant energy) from sunlight unless ground reflections are unusually high, as when snow is on the ground, and reflected UV radiation can produce "snow blindness." Another exception to the general rule occurs during a solar eclipse, when some individuals stare directly at the solar disc for more than a couple of minutes without eye protection and incur an "eclipse burn" of the retina (photoretinitis) (29, 34). Lasers may injure the eye when the normal defense mechanisms of squinting, blinking, and aversion to bright light are overcome, as can occur when viewing pulsed lasers or when the eye is exposed to an invisible infrared or ultraviolet beam.

There are at least six separate types of injuries to the eye from lasers and other intense optical sources (listed with the approximate spectral region noted in parentheses):3

1. Ultraviolet photochemical injury to the cornea (photokeratitis)—also known as "welder's flash" or "snow blindness (180–400 nm) (41, 44) and erythema ("sunburn") of the skin (29, 43).
2. Ultraviolet photochemical injury to the crystalline lens (cataract) of the eye (295–325 nm, and perhaps to 400 nm) (29, 30, 44).
3. Blue-light photochemical injury to the retina of the eye (principally 400–550 nm; unless aphakic, 310–550 nm) (34, 35).
4. Thermal injury (photocoagulation) to the retina of the eye (400 to nearly 1400 nm), and thermoacoustic injury at very short laser exposure durations.
5. Near-infrared thermal hazards to the lens (approximately 800–3000 nm) (45, 46).
6. Thermal injury (burns) of the cornea of the eye (approximately 1400 nm to 1 mm) or to the skin (approx 320 nm to 1 mm) (29, 30).

The range of the aforementioned potential hazards to the eye and skin are illustrated in Figure 103.2, which shows how specific effects are generally dominant in certain CIE photobiological spectral bands, UV-A, -B and -C and infrared A, B, and C (47). Although these photobiological bands are useful shorthand notations, they do not define fine lines between no effect and an effect in accordance with changing wavelengths.

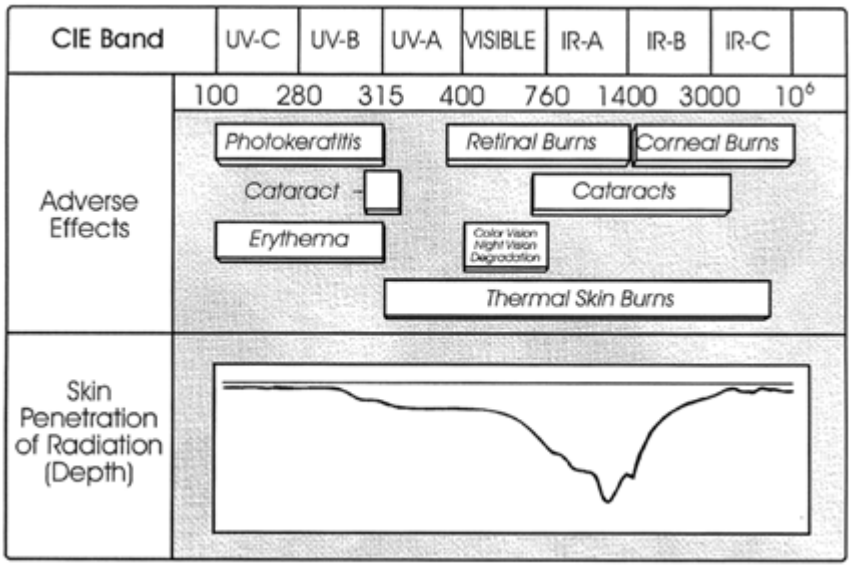

Figure 103.2. The potential hazards to the eye and skin as a function of wavelength. Certain effects are generally dominant in each CIE photobiological spectral band.

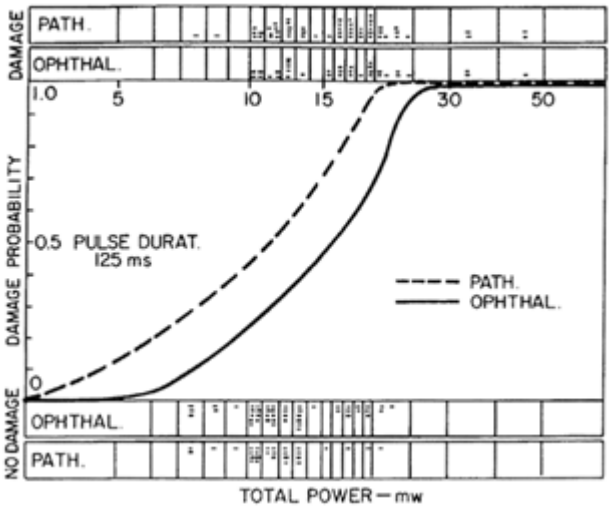

Figure 103.3. A typical probit presentation of experimental laser retinal threshold injury data where the ED_{50} has a probit value of 5.0. Strictly speaking, the probit value of 5.0 occurs at a 50% probability value.

1.4.3.1 Photokeratitis The relative position of the laser source and the degree of lid closure can greatly affect the proper calculation of this ultraviolet exposure dose low-level; scattered UV from excimer lasers has produced photokeratitis in workers. For assessing risk of photochemical injury, the laser wavelength is of great importance. Wavelengths between 260 and 280 nm are at the peak of the action spectrum and are the most dangerous (44).

1.4.3.2 Cataract Ultraviolet cataracts can be produced from exposure to UVR of wavelengths between 295 and 325 nm (and perhaps to 400 nm). Action spectra can only be obtained from animal studies, which have shown that cortical and anterior subcapsular cataract can be produced by intense exposure delivered over a period of days. Human cortical cataract has been linked to chronic, lifelong UV-B radiation exposure. Although the animal studies and some epidemiological studies suggest that it is primarily UV-B radiation in sunlight (44), and not UV-A, that is most injurious to the lens, biochemical studies suggest that UV-A radiation may also contribute to accelerated aging of

the lens. Since there is an earlier age of onset of cataract in equatorial zones, UVR exposure has frequently been one of the most appealing of a number of theories to explain this latitudinal dependence (35, 48). Laser exposure from the xenon–chloride laser at 308 nm is of particular concern, since this wavelength is in the narrow action spectrum for acute cataract. The ACGIH TLV and ICNIRP laser and noncoherent UVR guidelines are also intended to protect against cataracts (31, 36, 49, 50).

Since the only direct pathway of UVR to the inferior germinative area of the lens is from the extreme temporal direction, it has been speculated that side exposure is particularly hazardous. In the case of the lens, the germinative layer where lens fiber cell nuclei are located is of great importance. The DNA in these cells is normally well shielded by the parasol effect of the irises. However, Coroneo et al. have shown that the focusing of very a peripheral 308-nm beam by the temporal edge of the cornea can enter the pupil and focus in the equatorial region (48, 51). The Coroneo effect argues for assuring well-fitting side shields on UV laser eye protectors.

1.4.3.3 Photoretinitis The principal retinal hazard resulting from lengthy staring at bright CW light sources is photoretinitis. The best example is *solar retinitis* with an accompanying scotoma ("blind spot"), which results from staring at the sun. Solar retinitis was once referred to as "eclipse blindness" and associated "retinal burn." At one time, solar retinitis was thought to be a thermal injury, but it has been since shown conclusively to result from a photochemical injury related to exposure of the retina to shorter wavelengths in the visible spectrum, that is, violet and blue light (52). For this reason, it has frequently been referred to as the "blue-light" hazard. The action spectrum for photoretinitis peaks at about 445 nm in the normal phakic eye (34, 52). Laser exposure limits were revised to better characterize and quantify the risk from these blue laser wavelengths in 1999.

As a consequence of the Bunsen–Roscoe Law of photochemistry, blue-light retinal injury (photoretinitis) can result from viewing either an extremely bright blue laser reflection for a short time, or a less bright source for longer periods. The approximate retinal threshold for a helium–cadmium laser at 441.6 nm is approximately 22 J/cm^2; hence a retinal irradiance of 2.2 W/cm^2 delivered in 10 s, or 0.022 W/cm^2 delivered in 1000 s, will result in the same threshold retinal lesion (34). Eye movements will reduce the hazard, and this is particularly important for sources subtending an angle less than 11 mrad. Saccadic motion even during fixation is of the order of 11 mrad. In 1999 laser exposure limits were adjusted to provide for dual limits (photochemical or thermal) for retinal exposure and for the effect durations greater than 1–10 s (53).

1.4.3.4 Infrared Cataract Infrared cataract in industrial workers appears only after a lifetime of exposure to radiances of the order of 80–150 mW/cm^2 (29, 45). Although thermal cataracts were observed in glassblowers, steel workers, and others in metal industries at the turn of the century, they are rarely seen today (45). These irradiances are almost never exceeded in modern industry, where workers will be limited in exposure duration to brief periods above 10 mW/cm^2 or they will be wearing eye protectors. Good compliance in wearing eye protection occurs at higher irradiances if only because the worker desires comfort of the face. This is not a realistic exposure condition from infrared laser radiation. Laser heat treating of metal surfaces can produce reasonably high reflected irradiances, but levels of concern would be felt and considered quite uncomfortable. Thus a lengthy exposure of today's worker to such levels is unrealistic.

1.4.4 Experimental Studies

ELs for laser radiation are based largely upon experimental ocular injury studies. Most threshold data have been obtained from animal studies (primates and rabbits), although some limited human data exist for confirmation of the animal model.

W. T. Ham, Jr., and others studied (54) the effect of cumulative long-term exposure to pulsed laser on retinal injury in rhesus monkeys and cynomolgus monkeys. The main optical source was a continuous-wave argon/krypton laser (ArKrL) with emission lines at 647, 514.5, and 488 nm. The

pulses were produced at pulse repetition frequencies (PRFs) of 100, 200, 400, and 1600 Hz by chopping with a rotating disk. A helium/neon laser (HeNeL) was used to compare the ocular effects of 632.8-nm light width with the 647-nm line emitted by the ArKrL. The appearance of a visible minimal lesion in the paramacular area of the retina at 48 h postexposure was the biological threshold. The mean exposure damage level was determined by interpolation. A comparison of thresholds between wavelengths 632.8 and 647-nm for 500-mm-diameter retinal images at exposure times of 1, 16, 100, 1000, 3000, and 10,000 s showed that up to exposure times of 1000 s there was no significant difference between the thresholds for retinal damage from the krypton 647-nm and from the HeNeL 632.8-nm exposures. Beyond the 1000-s exposures the 632.8-nm wavelenght had a significantly lower threshold than the 647-nm line. The threshold for minimal retinal injury was always lower for the blue than for the red pluse trains. For 1000-s exposures at PRF of 1600 Hz the threshold was lower than for continuous-wave red light. The authors concluded that no ocular hazards exist in conventional application of nominal 1 mW HeNeL, such as those used in supermarket scanners.

W. T. Ham, Jr., and others also (55) exposed seven rhesus monkeys (14 eyes) to 1064-nm radiation in single pulses of 25 to 35 ps from a mode-locked Nd:YAG laser. Threshold injury resulted from single pluse with a mean energy of 13 mJ. Electron microscopy of the retina revealed that damage was highly localized in the photoreceptor and pigmented epithelial cells at the outer retina. Membrane disruption, distorted outer segments, and abnormal melanin granules resembling fetal premelanosomes were observed.

D. N. Farrer and others (56) conducted studies to evaluate retinal threshold burns and subthreshold exposures of the mammalian macula in terms of visual acuity. Rhesus monkeys (*Macaca mulatta*) were trained by a reward system to respond to the automated presentation of Landolt rings. After appropriate training, these animals were exposed to threshold and subthreshold levels of retinal energy density ranging from 3.2 to 10.7 J/cm^2, exposure time approximately 135 ms, spectral quality approximately that of color, a temperature of 6000 K with wavelength above 900 nm removed, and image sizes on the retina of about 1 nm in diameter, covering a major portion of the monkey macular area. Results, in terms of visual acuity decrement (monocular), indicated that energy densities on the retina below 5 J/cm^2 were not statistically significant, whereas energy densities greater than 5 J/cm^2 produced losses in visual acuity (monocular) that were significant. These results indicate that, at levels of energy density on the retina 80–50% below the threshold burn level, no loss in visual acuity can be detected in the rhesus monkey by the Landolt-ring testing system adopted for this investigation.

The ELs must be based upon an understanding of the mechanisms of laser/tissue interaction as well. A major point of discussion in the EL derivation process relates to the level of uncertainty of the threshold of injury. An indication of the level of uncertainty relates to the slope of the transformed dose-response curve, or the "probit plot" of the data. The most important point on the probit plot is the exposure which represents a 50% probability of injury: the ED_{50}. It is this value that is frequently referred to as the "threshold," even though some experimental damage points exist below this "threshold."

An analysis of any number of example data sets reveals that the slope in most experiments could not be explained by biological variation alone. This type of critical analysis is essential in deriving ELs. For example, if the slope is not very steep, as with some retinal injury studies, the probit curve may suggest that at one-tenth the ED_{50} energy value, there might be a 0.1% risk of injury—a risk generally

not acceptable in the laser safety community. Yet, from fundamental biophysical principles, this result could be shown clearly to be flawed. If the ED_{50} energy corresponds to a retinal temperature elevation of 150, an energy of 10% of the ED_{50} must correspond to 1.50 (10% of the ED_{50}

temperature elevation), which could not produce photocoagulation. This aptly illustrates that any derivation of human exposure limits for laser-induced injury requires one to estimate the true biological variation and separate this from the added experimental errors which reduces the probit slope.

Analysis of reported experimental data indicates that the thermal and thermoacoustic damage mechanisms apparently have an intrinsic slope of approximately 1.15 to 1.2. However, experimental threshold data from retinal studies give slopes that are often much greater (e.g., 1.5–1.7), which is really not surprising. The enormous difficulty of seeing a minimally visible lesion and focussing the laser beam to produce the nearly diffraction-limited image leads to this greater spread of data and shallower slopes. A probit curve applied to the derivation of exposure limits should have a slope of 1.2 or less with the ED_{50} point shifted to a lower value. The steepness of the probit curve is therefore not only related to the type of damage mechanism and variation among individual animals, but also indicates problems in conducting the experiment. Traditionally, all of these factors are assessed collectively in order to derive an appropriate "safety factor" for deriving the EL from the ED_{50}. The safety factor is not a true ratio between a true "threshold of injury" and the EL, but represents a committee judgement of uncertainties. Greater safety factors have been applied when uncertainties are greatest, and considerations of extrapolation from animal to human are also part of the process.

In an ideal experiment where the experimental errors introduced by the beam propagation through the ocular media were not present, the true spread of retinal threshold data would be much smaller than that obtained by current experimental methods aimed at determining the minimum visible lesion (MVL). The type of damage mechanism will affect the absolute spread of threshold data. Based upon the current understanding of the retinal injury mechanisms by short-pulsed lasers, thermal photocoagulation dominates for pulse durations of 10 ns to many milliseconds. Injury thresholds appear to vary little from 10 ns to about 18–50 ms. At longer durations, the thresholds increase because heat flow occurs during the exposure. At subnanosecond exposure durations, other nonlinear damage mechanisms come into play, such as self-focusing and laser-induced breakdown. The thermal and thermomechanical mechanisms have sharply defined thresholds in experiments where tissue is directly exposed without confounding factors, as in CO_2 laser-induced corneal injury. More stochastic effects appear in the subnanosecond regime (37, 40).

In the determination of thresholds of laser-induced injury, direct observation by ophthalmic instrument is most frequently used. For retinal studies, the ophthalmoscope or slit-lamp microscope is used by the experimentalist to observe the retinal location where the laser exposure takes place. In some cases the visibility of the laser-induced lesion can be improved by a technique known as *fluorescein angiography*, and some workers have even used light and electron microscopy to examine the exposed tissue. These measures claim to have greater sensitivity, but are more costly and less practical. Although fluorescein angiography is frequently used, the detailed histological studies with microscopic examination of thin slices of exposed tissue have only been carried out for specified laser wavelengths and exposure durations to quantify the reduction in the ophthalmoscopically determined ED_{50} by the more elaborate techniques.

The quantitative value of ED_{50} and the spread of data points can change by varying the experimental techniques. One of the most critical elements of the experimental protocol is the delay between laser exposure and time of examination, because biological changes undergo a time course following injury. Typical delays for examination range from 5 min to 48 h, with 1 and 24 h being the most frequently used. Depending upon damage mechanism (i.e., thermal, thermomechanical, photochemical, etc.), the optimum period to determine the ED_{50} changes as the time course varies for the biological response and amplification of the initial biophysical tissue insult.

Another factor that affects the ED_{50} value is the choice of experimental animal. One of the most

frequently used animals in ophthalmic research is the rabbit; it is used most often for corneal injury studies and in many early retinal studies. However, the optical quality of the rabbit eye is poor, leading to distorted retinal images and inaccurate threshold determinations (1–2). There have been studies employing ophthalmic contact lenses and careful optical alignment of the anesthetized rabbit to eliminate most corneal aberrations in the eye. These conditions produce nearly diffraction-limited retinal images and low threshold values; however, the required extrapolation to the human eye with its reduced optical performance leads to some level of uncertainty. Hence the currently most favored animal model has become the rhesus monkey for retinal studies by most investigators, and this has greatly increased the cost of the experiment, leading to fewer threshold determinations.

Still another factor, the retinal pigmentation, will determine the fraction of incident energy absorbed at each wavelength and thereby affect the resulting ED_{50}. Pigmentation in the retinal pigment epithelium (RPE) and choroid varies with the individual subject, the species, and the retinal location. Although the color of the rabbit retina appears to more closely resemble the human retina, it has been argued that the pigment density in the rhesus monkey is more similar to that of humans. In any case, these variables are accounted for in the derivation of MPEs and are considered in this report.

Another factor of concern is the refractive state of the experimental subject. As this refractive state determines whether the minimal retinal image size of a collimated laser beam is achieved, this is critical. A one-diopter error in the refractive state can result in an increase in the achieved retinal blur circle from approximately 25 mm to about 120 mm—a change in image area of 22 times. Investigators therefore normally attempt to correct the animal's state of refraction in the visible, but even this does not take into account the chromatic aberrations—also of the order of one diopter across the visible spectrum. Investigators are able to correct the refraction to within 0.25 D, which leads to an uncertainty in actually achieved minimal retinal image diameter of approximately 20–50 mm. Furthermore, during an investigative session, the animal's refractive state will vary slightly from exposure to exposure, the degree depending upon the level of anesthesia.

Eye movements during the experimental exposure will also affect the outcome. These eye movements will only be of concern for exposures lasting more than 10 ms. In the derivation of ELs, the impact of anesthetized animal exposures on the retinal injury threshold is measured (50, 53). This showed that laser energy was concentrated in a much smaller retinal area for exposures of several seconds, with the effect of eye movements considered in the derivation.

The actual site of retinal exposure will influence the ED_{50}. This occurs for two reasons. The optical quality of the eye for off-axis beams is somewhat less than for axial exposures to the fovea. Furthermore, the pigmentation and thickness of the neural retina vary from the center of the fovea, through the macula to the para-macular regions. As a general rule, the ED_{50} values will be less in the fovea than parafoveal or paramacular. This variation is of the order of twofold.

The state of the ocular media (cornea, aqueous, lens, and vitreous) influences the distribution of radiant energy at the retina. Intraocular scatter diffuses the beam, and depending upon the nature and size of the scattering centers in the ocular media, small-angle forward scatter and diffuse scatter will vary. The age of the eye, the care taken by the experimentalist to preserve corneal clarity by frequent irrigation of the cornea (or use of contact lens), and the potential for subtle lenticular opacities (early stages of cataractogenesis) all play a role in producing scatter.

The ability of the experimental investigator observing the retina to detect a just-perceptible minimum visible lesion (MVL) also influences the ED_{50} value. As investigators have more experience, the reported ED_{50} traditionally decreases. The visual contrast of the threshold injury is usually low, making the task of correct lesion detection difficult. Furthermore, the chance of scoring the presence of a very small lesion when an injury is actually not present (i.e., false positive) will increase if the retina appears mottled or otherwise exhibits abnormalities that could be mistaken for a laser-induced

lesion. It may also be difficult to discern the edges of some very large lesions, making positive identification difficult. Nevertheless, our review of the published threshold studies that provide dose-response slopes show a general trend for a steeper slope for larger images, suggesting the greater difficulty of executing the small-lesion experiments.

The optical quality of the incident laser beam influences the minimal retinal image size. In earlier studies, multimode lasers were frequently used, leading to a larger retinal image area and increased values of the ED_{50}. Today, most lasers used in these experiments have been carefully aligned to achieve a single transverse mode. The presence of apertures in the beam path can also alter the quality of the retinal image.

It is evident that aside from false positive identification of a lesion, all the other aforementioned sources of error will tend to increase the ED_{50} values and the spread of the data from which they are derived.

Lasers

1.5 Standards, Regulations, or Guidelines of Exposure
A number of national and international groups have recommended occupational or public exposure limits (ELs) for laser radiation for wavelengths extending from 180 nm in the ultraviolet (UV) region, to 1000 mm (1 mm) in the far infrared (IR). These ELs apply for pulse durations from 100 fs (10^{-13} s) to 30 ks (8 h). In the United States, both the American Conference of Governmental Industrial Hygienists (ACGIH) and the American National Standards Institute (ANSI) have produced comprehensive sets of exposure limits (31, 49, 57). These ELs are virtually identical, although ELs are termed threshold limit values (TLVs) by ACGIH and maximum permissible exposure limits (MPEs) in the ANSI Standard Z-136.1. On the international scene, the International Commission on Non-Ionizing Radiation Protection (ICNIRP) publishes Guidelines on Limits of Exposure to Laser Radiation (36, 50). ICNIRP guidelines are developed through collaboration with the World Health Organization (WHO) by jointly publishing criteria documents that provide a scientific database for the exposure limits (30). The International Electrotechnical Commission (IEC) uses the ICNIRP guidelines (10). The ICNIRP ELs are essentially identical to the ACGIH, and ANSI limits (31, 32, 36, 40, 49, 50, 57). The ELs based in large part on ocular injury data from animal studies and from data from human retinal injuries resulting from viewing lasers, the sun, and welding arcs. All the guidelines have an underlying assumption that outdoor environmental exposures to visible radiant energy is normally not hazardous to the eye except in very unusual environments such as snow fields and deserts (29, 30).

The ACGIH ELs and ICNIRP ELs are generally applied to derive accessible emission limits (AELs) used in product safety standards of the International Electrotechnical Commission, the American National Standards Institute, and other technical standards groups. The U.S. Food and Drug Administration also uses these AELs in the Federal Laser Performance Standard (21 *CFR* 1040). These product safety standards must have carefully defined measurement conditions to simulate "worst-case" ocular exposure conditions (Tables 103.3–103.6).

Table 103.3. Intrabeam Laser Ocular Threshold Limit Values

Wave length l	Expos. *t* (s)	Threshold Limit Value EL (J/cm^2 or

(nm)	Duration t	W/cm^2)	Restrictions
		Ultraviolet	
180–302	1 ns–30 ks	3 mJ/cm^5	
303	1 ns–30 ks	4 mJ/cm^5	All ELs for l less than 315 nm must be $0.56t^{3/4}$ J/cm^5
304	1 ns–30 ks	6 mJ/cm^5	
305	1 ns–30 ks	10 mJ/cm^5	
306	1 ns–30 ks	16 mJ/cm^5	
307	1 ns–30 ks	25 mJ/cm^5	
308	1 ns–30 ks	40 mJ/cm^5	
309	1 ns–30 ks	63 mJ/cm^5	
310	1 ns–30 ks	0.1 J/cm^5	
311	1 ns–30 ks	0.16 J/cm^5	
312	1 ns–30 ks	0.25 J/cm^5	
313	1 ns–30 ks	0.40 J/cm^5	
314	1 ns–30 ks	0.63 J/cm^5	
315–400	1 ns–10 s	$0.56t^{3/4}$ J/cm^5	
315–400	10 s–30 ks	1.0 J/cm^5	
		Visible and IR-A	
400–700	1 ns–18 ms	0.5 mJ/cm^5	
400–700	18 ms–10 s	$1.8t^{3/4}$ mJ/cm^5	
400–550	10 s–10 ks	10 mJ/cm^5	
550–700	10–T_1 s	$1.8t^{3/4}$ mJ/cm^5	
550–700	T_1 s–10 ks	10 C_B mJ/cm^5	7 mm limiting aperture
400–700	10–30 ks	C_B mW/cm^5	
700–1050	1 ns–18 ms	0.5 C_AmJ/cm^5	
700–1050	18 ms–1 ks	1.8 $C_A t^{3/4}$ mJ/cm^5	
1051–1400	1 ns–50 ms	5 C_C mJ/cm^5	
1051–1400	50 ms–1 ks	9.0 $C_C t^{3/4}$ mJ/cm^5	
700–1400	1–30 ks	320 $C_A C_C$ m/cm^5	
		Far Infrared	
1400–1500 nm	1 ns–1.0 ms	0.1 J/cm^5	
1400–1500 nm	1.0 ms–10 s	$0.56t^{1/4}$ J/cm^5	
1500–1800 nm	1 ns–10 s	1.0 J/cm^5	
1801–2600 nm	1 ns–1.0 ms	0.1 J/cm^5	
1801–2600 nm	1.0 ms–10 s	$0.56t^{1/4}$ J/cm^5	
2601 nm–1 mm	1–100 ns	10 mJ/cm^5	3.5 mm limit. aperture

2601 nm–1 mm	100 ns–10 s	$0.56t^{1/4}$ J/cm^5
1400 nm–1 mm	1.0 s–30 ks	100 mW/cm^5

NOTES:

Time: All values of t in s; 1 ks = 1000 s, and 30 ks = 8 h. **spectral correction factors**: $C_A = 1$ for l = 400–700 nm; $C_A = 10^{[0.02(l-700)]}$ if l = 700–1050 nm

$C_B = 1$ for l = 550 nm; $C_B = 10^{[0.015(l-550)]}$ for l = 550–700 nm

$C_C = 1$ for l = 1150; $C_c = 10^{[0.0181(l-1150)]}$ for 1150 < l < 1200

$C_C = 8$ for 1200 ≤ l < 1400

$T_I = 10 \times 10^{[0.02(l-550)]}$ for l = 550–700 nm

Extended-source TLVs: For extended-source laser radiation (e.g., diffuse reflection) viewing at wavelengths between 400 and 1400 nm, the intrabeam viewing TLVs can be increased by the following correction factor C_E provided that the angular subtense of the source (measured at the viewer's eye) is greater than l_{min}, where l_{min} is: $l_{min} = 1.5$ mrad for $t < 0.7$ s

$l_{min} = 2\ t^{3/4}$ mrad for 0.7 ≤ t < 10 s

$l_{min} = 11$ mrad for t ≥ 10 s.

$C_E = l/l_{min}$ for $l_{min} < l < 100$ mrad

$C_E = l^2/(l_{min}l_{max})$ for l ≥ 100 mrad

$C_E = 10l^2/l_{min}$ for l ≥ 100 mrad for l expressed in rad

The angle of 100 mrad may also be referred to as l_{max}, at which point the extended source limits can be expressed as a constant radiance using the last equation written in terms of l_{max}.

$L_{TLV} = (8.5 \times 10^3)(TLV_{pt\ source})$ J/(cm^2 sr) for $t < 0.7$ s

$L_{TLV} = (6.4 \times 10^3\ t^{-3/4})(TLV_{pt\ source})$ J/(cm^2 sr) for 0.7 ≤ t < 10 s

$L_{TLV} = (1.2 \times 10^3)TLV_{pt\ source})$ J/(cm^2 sr)[a] for t ≥ 10 s

[a]or W/(cm^2@sr) for point-source limits expressed in W/cm^2

Terminology: The term *exposure limit* (EL) is used by IRPA. The same values are termed MPEs (maximum permissible exposure limits) by ANSI and TLVs (threshold limit values) by ACGIH. Essentially all groups have the same limit values.

Table 103.4. Laser Threshold Limit Values for Skin Exposure

Wave length l (nm)	Expos. t (s) Duration t	Threshold Limit Value EL (J/cm^2 or W/cm^2)	Restrictions
		Ultraviolet	
200–400	1 ns–30 ks	Same as eye EL[a]	
		Visible and IR-A	
400 nm–1 mm	1–100 ns	20 C_A mJ/cm^5	
400 nm–1 mm	100 ns–10 s	1.1 $C_A t^{1/4}$ J/cm^5	3.5 mm limit. aperture
400 nm–1 mm	10 s–30 ks	0.2 C_A W/cm^5	
		Far Infrared	
1400 nm–1 mm	1 ns–30 ks for 2601 nm–1 mm	Same as eye EL	

Note: See Notes, Table 103.3.

[a] Or W/(cm^2@sr) for point-source limits expressed in W/cm^2.

Table 103.5. Limiting Apertures Applicable to Laser TLVs (mm)

Spectral Region	Duration	Eye (mm)	Skin (mm)
180–400 nm	1 ns–0.25 s	1	3.5
180–400 nm	0.25 s–30 ks	3.5	3.5
400–1400 nm	1 ns–0.25 s	7	3.5
400–1400 nm	0.25 s–30 ks	7	3.5
1400 nm–0.1 mm	1 ns–0.25 s	1	3.5
1400 nm–0.1 mm	0.25 s–30 ks	3.5	3.5
0.1–1.0 mm	1 ns–30 ks	11	11

Table 103.6. Selected Occupational Threshold Limit Values (TLVs) for Some Common Lasers

Type of Laser	Wavelength	Threshold Limit Value
Argon–fluoride	193 nm	3.0 mJ/cm^2 over 8 h
Xenon–chloride	308 nm	40 mJ/cm^2 over 8 h
Argon ion	488,514.5 nm	3.2 mW/cm^2 for 0.1 s
		2.5 mW/cm^2 for 0.25 s
Helium–neon	632.8 nm	1.8 mW/cm^2 for 1.0 s
		1.0 mW/cm^2 for 10 s
Krypton ion	568,647 nm	
Helium–neon	632.8 nm	17 mW/cm^2 for 8 h
Neodymium–YAG	1064 nm	5.0 mJ/cm^2 for 1 ns to 100 ms
		5 mW/cm^2 for 10 s
Erbium glass	1540 nm	1.0 J/cm^2 for 1 ns–10 s
Erbium:YAG	2940 nm	10 mJ/cm^2 for 1–100 ns
Hydrogen fluoride	2.7–3.1 mm	10 mJ/cm^2 for 1–100 ns
Carbon dioxide	10.6 mm	100 mW/cm^2 for 10 s to 8 h, limited area
		10 mW/cm^2 for >10 s

Source: ACGIH TLVs.

Note: To convert TLVs in mW/cm^2, multiply by exposure time *t* in s; e.g., the He-Ne or argon TLV at 0.1 s is 0.32 mJ/cm^2.

1.5.1 Examples

Several representative exposure limits are shown in Table 103.4 for the most commonly available lasers. One should also remember that the way most of the laser safety standards are organized, one

makes use of a laser's hazard classification (initially based upon ELs) to perform a hazard evaluation, rather than to perform measurements of beam exposure for comparison with ELs. The ELs are actually used only in special instances where human exposure is intended and the laser beam irradiance or radiant exposure may actually be measured or calculated to determine if the EL will be exceeded.

1.5.2 Discussion

1.5.2.1 Exceeding the Exposure Limits In deriving the ELs for all optical radiations, the ACGIH and ICNIRP generally applied a factor of 10 to reduce the 50% probability of retinal injury by a factor of 10. This is not a true "safety factor" because there is a statistical distribution of damage and this factor was based upon several considerations. These included the difficulties in performing accurate measurements of source radiance or corneal irradiance; measurement of the source angular subtense; as well as histological studies showing retinal changes at the microscopic level at levels of approximately 2 below the ED_{50} value.3 In actual practice, this means that an exposure at 2–3 times the EL would not be expected to actually cause a physical retinal injury. At five times the EL, one would expect to find some injuries in a population of exposed subjects. As with other TLVs, the laser ELs are guidelines for controlling human exposure and should not be considered as fine lines between safe and hazardous exposure. With benefit versus risk considerations, it should therefore be considered appropriate to have some relaxed guidelines; however, to date, no standards group has seen the need to do this. This may apply to the development of safety standards for ophthalmic medical instruments.

1.5.2.2 Application of Limits in Laser Safety Standards Laser safety standards exist in the United States and worldwide. All the standards group manufactured laser products into four general hazard classes and provide safe measures for each hazard class (1 through 4) (36, 44). U.S. Federal regulations (21 *CFR* 1040) require all commercial laser products to have a label indicating the hazard class. The safety measures recommended in workplace safety standards are quite obvious (e.g., beam blocks, shields, baffles, eye protectors), once one understands and recognizes the hazards. The ocular hazards are generally of primary concern. Figure 103.4 illustrates the relative retinal hazard from intrabeam viewing of a laser in comparison with the hazard of viewing conventional light sources.

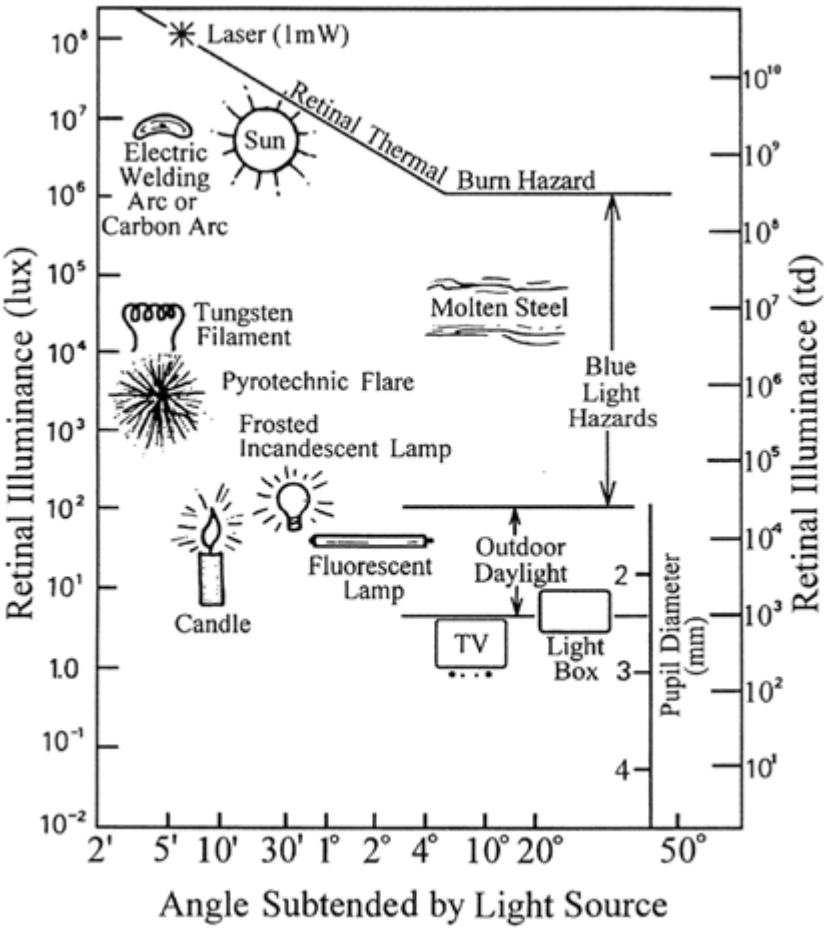

Figure 103.4. Relative retinal irradiances for staring directly at various light sources. Two retinal exposure risks are depicted: retinal thermal injury, which is image-size dependent, and photochemical injury, which depends on the degree of blue light in the source's spectrum. The horizontal scale indicates typical image sizes. Most intense sources are so small that eye movements and heat flow will spread the incident energy over a larger retinal area. The range of photoretinitis (the “blue-light hazard”) is shown to be extending from the normal outdoor light levels and above. The xenon arc lamp is clearly the most dangerous of nonlaser hazards.

The primary workplace safety standard in the United States is the American National Standard, ANSI Z136.1-2000, *The Safe Use of Lasers*. It is a national consensus standard for laser safety in the user environment. It has evolved through several editions since 1973. Although the ELs are termed maximum permissible exposure (MPE) limits by ANSI, they are all the same values. MPEs are provided for all wavelengths from 180 nm to 1 mm, and for exposure durations of 100 fs to 30 ks (8-h workday) the MPEs appear at the end of the safety standard. Since almost all control measures are based upon the laser's hazard class (1 through 4), the MPEs are seldom actually used. The MPEs did form the basis for deriving the hazard classifications. For example, the accessible emission limits (AELs) for class 1 are derived to prevent human access to levels above the MPE under reasonably foreseeable worst-case laser operating conditions. The Class 1 AELS are derived by multiplying the MPE for the longest foreseeable exposure duration by the area of the limiting aperture specified for that MPE. For example, the limiting aperture for visible lasers is 7 mm based upon a dark-adapted pupil. The resulting AEL has units of energy or power.

Nevertheless, health and safety specialists want the simplest expression of the limits, but some more mathematically inclined scientists and engineers on standards committees argue for sophisticated formulas to express the limits (which belie the real level of biological uncertainty) and the health and safety specialists at the same time demand greater simplification. These exposure limits (and the

identical ELs of ACGIH) formed the basis for the U.S. Federal Product Performance Standard (21 *CFR* 1040). The latter standard regulates only laser manufacturers. On the international scene, IEC standard 825-1 (1993) grew out of an amalgam of the ANSI standard for user control measures, the WHO-endorsed exposure limits of ICNIRP, ACGIH, and ANSI, and the CDRH product classification regulation. The International Commission on Nonionizing Radiation Protection (ICNIRP) has a special relationship with the World Health Organization in developing criteria documents on laser radiation and recommending exposure limits for laser radiation (ICNIRP, 1996). These standards are all basically in agreement.

1.5.2.3 Acute Exposure In realistic workplace settings, accidental and therefore exposures to a hazardous laser beam represent a low probability, but exposures can have severe consequences. This is illustrated by a typical accident in which a young investigator in a physical chemistry laboratory is aligning a short-pulse (10-ns) laser beam to direct it into a gas cell to study photodissociation parameters for a particular molecule. Leaning over a beam director, he glances down over an upward, secondary beam and approximately 80 mJ enters his left eye. The impact produces a microscopic hole in his retina, a small hemorrhage is produced over his central vision, and he sees only red in his left eye. Within an hour he is rushed to an eye clinic where an opthalmologist tells him he has only 20/400 vision (41). In a university laboratory, a physics graduate student attempts to realign the internal optics in a Q-switched Nd:YAG laser system—a procedure normally performed by a service representative that the student had witnessed several times before. A “weak” secondary beam reflected from a beam splitter enters the student's eye, producing a similar hemorrhagic retinal lesion with a severe loss of visual acuity (Fig. 103.5). Similar accidents occur each year, and frequently do not receive publicity because of litigation or for administrative reasons. Scientists and engineers working with open-beam lasers really need to realize that almost all such lasers pose a very severe hazard to the eye if eye protection is not worn or other safety measures are not observed.

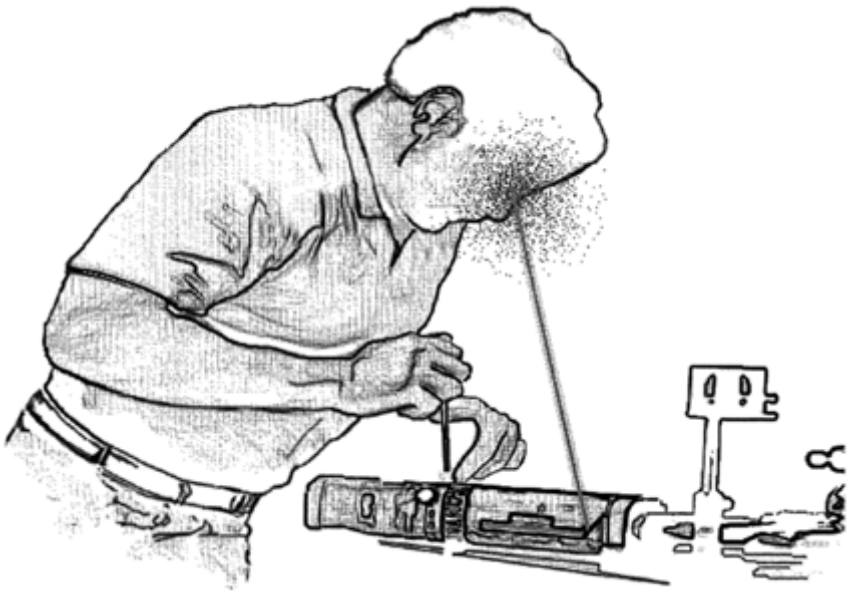

Figure 103.5. A “weak” secondary beam reflected from a beam splitter can enter the unprotected eye, as during laser alignment. An beam energy of only 0.1 mJ can produce a hemorrhagic retinal lesion with a severe loss of visual acuity.

In virtually all accidents, eye protectors were available but not worn. The probability that a small beam will intersect a 3–5-mm pupil of a person's eye is small to begin with, so injuries do not always happen when eye protectors are not worn.

1.6 Guidelines
The one area of TLV guidelines being considered for possible revision relates to further refinements of correction factors in the IR-B, that is, in C_D. Recently ELs for visible and near-infrared laser radiation in the subnanosecond pulse regime have been developed and have been published (37). Exposure limits for lengthy viewing have also just been modified. These changes would still not affect most applications. As in the past, the understanding of the basic interaction mechanisms is critical to setting limits.

Occupational Ergonomics: Principles and Applications
Amit Bhattacharya, Ph.D., Nancy Talbott, MS, PT, Laurel Kincl, MS

1 Introduction

This chapter provides the basic principles that underlie the field of ergonomics and their application to some of the current issues of importance in the workplace. Sections 2 to 4 deal with the physiology of muscles; biomechanics; cellular responses to tissue, nerve, and joint injuries as they relate to cumulative trauma disorders; and common types of overuse syndromes. The remaining sections deal with applications of the principles to workplace ergonomic issues and proposed ergonomic regulations.

Occupational Ergonomics: Principles and Applications
Amit Bhattacharya, Ph.D., Nancy Talbott, MS, PT, Laurel Kincl, MS

2 Principles of Ergonomics

The word “ergonomics” is made up of two Greek words, “ergo” meaning work and “nomas” meaning laws. The field of ergonomics is highly interdisciplinary. It applies principles from engineering, physiology, medicine, and psychology to the understanding of the interaction of humans with their workplace. The interaction of humans with their workplace may consist of identifying the relationship between job physical risk factors and physiological responses. For example, a specific ergonomic problem of paramount importance in the occupational health and safety is the issue of work-related musculoskeletal disorders (WMD). Some of these issues are discussed further in this chapter. The specific areas of application relevant for the field of ergonomics are defined and briefly explained in the following.

2.1 Physiology of Muscle Contraction and Movements

2.1.1 Structure of Muscles and Contraction Characteristics The generation of forces and movements in living cells such as muscles requires special protein molecules and contractile proteins. These

types of proteins are available in great abundance in the muscle cell. These proteins can convert chemical energy such as adenosine triphosphate (ATP) into mechanical energy (1).

There are three major types of muscles in the human body: skeletal, smooth, and cardiac. Skeletal and cardiac muscles are striated muscles. Skeletal muscles such as muscles of the arms, legs, and back perform most of the voluntary actions, and smooth muscles such as muscles in the internal organs perform involuntary actions. The cardiac muscles also act autonomically (2). The major focus of this section is the skeletal muscle.

The skeletal muscle, the largest of the tissues in the human body, constitutes about 45% of the total body weight. The skeletal muscle is made up primarily of 75% water and the remaining 25% is protein, inorganic salts and high energy phosphates, urea, lactic acid, enzymes, minerals, etc (3). There are about 600 muscles in the human body. Each muscle is made up of many thousands of muscle fibers. Small muscles have only a few hundred fibers whereas larger muscles may contain several hundred thousand fibers. Each end of the whole muscle is attached to a bone by bundles of collagen fibers called tendons that can transmit forces from the muscles to the bones. Tendons have great strength, but unlike the muscle fibers, they cannot contract. Each muscle fiber is composed of thousands of myofibrils, the contractile element of the skeletal muscle. These myofibrils are about 1 micron (=1/1000 mm) in diameter. Each of these myofibrils has millions of filaments made up of two proteins, actin and myosin. Actin is known as the thin filament and myosin is called the thick filament. During electrical stimulation via nerve, attractive forces between the actin and myosin filaments cause muscle to contract. Table 104.1 gives a list of the major sequence of events between nerve action potential and contraction and relaxation of muscle fiber (2).

Table 104.1. Sequence of Events for Muscle Contraction

1	An action potential is generated in a motor axon.
2	Release of acetylcholine from the axon terminal at the neuromuscular junction known as muscle end plate.
3	A motor end plate potential is produced at the muscle end plate.
4	The motor end plate potential depolarizes the muscle membrane (to about–15 mV) causing it to generate a muscle action potential that travels along the surface of the muscle membrane. Acetylcholine-esterase (enzyme) immediately destroys acetylcholine so that the depolarized membrane returns to its resting potential of about–90 mV.
5	Depolarization of transverse tubules by the muscle action potential causes release of calcium ions from the sarcoplasmic reticulum around the myofibrils.
6	Calcium ions cause the actin-myosin filaments to slide, thereby producing contraction of the muscle fiber.
7	As the concentration of calcium ions falls, the actin-myosin sliding action reduces and the muscle relaxes.

2.1.2 Motor Neurons and Motor Units A neuron consists of the soma (main body), the dendrites, and the axon. The axon carries signals away from the neuron cell body, and dendrites bring signals from other neurons. However, one exception is the sensory nerve fiber, which is a single dendrite that transmits sensory signals from a peripheral receptor. Each neuron has many dendrites but only one axon. In the center of axon is a gel-like substance called axoplasm. Some nerve fibers have an additional layer surrounding their membranes called a myelin sheath. The myelin sheath is broken at

the nodes of Ranvier. The myelin sheath has insulating properties and is instrumental in propagating an electric signal along the axon by allowing it to jump from one node of Ranvier to the next. This process of impulse "jumping" decreases the amount of energy required for signal transmission.

A motor unit consists of a single motor neuron and all the muscle fibers controlled by it. Generally, large muscle fibers that perform strong body motions have more motor units than those for the smaller muscles. When excited, these motor units respond to activate all of the muscle fibers connected to them (4).

2.1.3 Energy Transform and Use The human body gets its energy from foodstuff (carbohydrates, fats, and proteins) it consumes. However, the foodstuffs have to be converted to a certain chemical form before the cells in the human body can use it as a supply of energy. This chemical compound is called adenosine triphosphate (ATP). This compound contains high-energy phosphate bonds. Each mole of ATP releases 8000 calories of energy each time a phosphate radical is broken away from ATP at the high-energy bond. This released energy is used as an immediate supply of energy for a variety of functions such as transport of glucose through the membrane, synthesis of chemical compounds inside the cell, muscle contraction, and neuronal activity. Once this ATP is used it becomes like a discharged battery known as adenosine diphosphate (ADP) which needs to be recharged with foodstuff via much slower chemical reactions with oxygen (5).

The formation of ATP within the cell uses carbohydrates, fats, and proteins. The absorption of carbohydrates forms glucose that is then used as an energy source by the cells. Two processes release energy from glucose; (*1*) glycolysis which does not require oxygen and (*2*) oxidation. The oxidative process releases much more energy than that released by glycolysis. For each molecule of glucose metabolized, the oxidative process produces thirty-four molecules of ATP whereas glycolysis produces only two molecules. The overall efficiency of energy transfer from glucose to ATP is about 39%; the remaining energy is lost as heat (of 686,000 calories of available energy in a mole of glucose, only 266,000 calories are stored in ATP). The 20% of total energy used by the cells is from the oxidation of glucose, and the remainder comes from fats and proteins (3).

In addition to ATP as an immediate source of energy, the cells have another source of energy, known as phosphocreatine, that contains high-energy phosphate bonds. Cells contain phosphocreatine in amounts much larger than that of ATP. The ATP and phosphocreatine help in each other's resynthesis to build up their presence in the cells. These reactions to resynthesize ATP and phosphocreatine are much more rapid than the oxidative process. Therefore, ATP and phosphocreatine serve as the rapid and immediate sources of energy in tasks such as the 100-yard dash and weight lifting.

2.1.4 Metabolism During Physical Exertion The source of energy varies depending upon the intensity and duration of physical exertion. For intense physical exertions that last less than one minute, the body relies primarily on the existing energy supplies of ATP and phosphocreatine in the muscles. The anaerobic glycolytic processes are used to provide energy for tasks of intense levels that last about 1–2 minutes. Once the physical exertion continues for several minutes, the primary source of energy becomes dependent on the aerobic process. In general, daily energy expenditure varies from 2700 to 3000 kcal for men and 2000 to 2100 kcal for women. Several factors such as age, level of physical activity, health status, and genetics can modify the daily expenditure. During physical exercise, skeletal muscle blood flow, mean arterial pressure, systolic arterial pressure, cardiac output, and heart rate may increase as much as 175%, 15%, 50%, 120% and 100%, respectively (2).

2.2 Skeletal System

The skeletal framework in the human body is needed to support its structure, muscles, nerves, organs, and blood vessels. This framework consists of "living girders," bones that can sustain the stresses and strains produced by the body's weight and the daily tasks of living. The performance of any task requires movement of body segments relative to each other. The skeletal joints that connect two adjacent bones allow articulating motion. Therefore, joints provide mobility to the

musculoskeletal system. There are three types of joints in the human skeletal system: (*1*) synarthrodial joints that do not allow any relative motion (skull bones), (*2*) amphiarthrodial joints that allow slight motion (vertebrae), and (*3*) diathrodial joints (knee, elbow, hip and shoulder) that allow much more relative motion than the other two. In general, joints that have a higher degree of mobility or relative motion suffer from reduced stability that makes them more prone to injuries.

2.3 Biomechanics

Biomechanics is the science of applying the laws of mechanics to understand the biology of work. The field of biomechanics relies on applying static and dynamic equilibrium conditions for calculating the forces experienced at the articulating bone surfaces (joints) during human body movements. When these forces appear repeatedly, they may cause trauma to the joint surfaces that gives rise to the development of musculoskeletal disorders.

2.3.1 Basic Concepts and Relevant Terminology (6)

2.3.1.1 Terms

- Center of mass: A point in an object about which the mass is equally distributed. Gravity acts upon it as though all mass was concentrated at that point.
- Moment of inertia ($kg \cdot m^2$ or $N \cdot msec^2$): The resistance to change in angular velocity depends upon the mass of the body and its distribution about the center of rotation. This resistance to change in angular velocity is called the moment of inertia (*I*).

$$M = I\alpha$$

  In angular motion, the moment of force (*M*) is proportional to the angular acceleration (a).
- Radius of gyration (r): In angular motion, the mass is not considered concentrated at the center of mass (or center of gravity). Therefore, the radius of gyration is defined as the radial distance from the axis of rotation at which the mass of the body could be concentrated without altering the moment of inertia of the body about that axis.
- Ground reaction force (Newton): Forces imposed upon the body due to direct contact with the ground.
- Center of pressure: The point at which the resultant force is applied.
- Impulse ($N \cdot sec$): The area under the force–time curve (or the integral of the force–time curve).
- Linear momentum ($kg \cdot m/sec$): Mass × linear velocity.
- Angular momentum ($kg \cdot m^2/sec$): Moment of inertia × angular velocity.
- Kinematics: The science of motion.
- Kinetics: The science of forces (and vectors) and torques associated with the motion of the body.

2.3.1.2 Types of Motion

The types of motion in joints include the following:

- Rotatory or angular: Few joints have pure rotational movement. The superior radioulnar joint moves in a spin-like movement, and the hip also makes an almost pure arc during flexion and extension.
- Translatory or linear (gliding): Compression, distraction, and gliding are most common. The lever arm moves towards the articulating surface, away from the surface, or in an anterior/posterior or medial/lateral direction.
- Curvilinear: This is the most common type of motion; the majority of joints move by a combination of rotation and compression. As rotation occurs, the lever arm also glides in one or more directions.

2.3.1.3 Laws Relevant to Biomechanics

- Law of inertia: Newton's first law of motion states that a body remains at rest or in uniform motion until acted upon by an unbalanced or outside set of forces. If the body is in equilibrium, then the

sum of all forces (F_{XYZ}) is zero.

For a body to be in static equilibrium, the following condition must be met:

$$\Sigma F_{x,y,z} = 0$$

- Law of acceleration: Newton's second law of motion states that the acceleration of a body is proportional to the unbalanced force acting upon it and inversely proportional to the mass of the body.

For a body to be in dynamic equilibrium, the following condition must be met:

$$\Sigma F_{x,y,z} = \text{mass} \times \text{acceleration}_{x,y,x} \rightarrow \text{Newton's second law of motion}$$

- Law of reaction: Newton's third law states that for every action there is an equal and opposite reaction. Forces come in pairs, and gravity exerts a force on all objects. Two objects in contact exert a force on each other.

2.3.1.4 Friction Friction is the resistance offered to the relative motion of two bodies in contact. As one body slides over another, the force that opposes the motion is called the force of friction. The magnitude depends on the kind of materials in contact with each other and how tightly the two surfaces are pressed together. Friction is a potential force that occurs only if movement is attempted.

- Static friction: The force that opposes a body at rest from being put into motion

$$f(s) = [(s)F(N)]$$

where $F(N)$ = the perpendicular force holding the two bodies in contact(s) = the coefficient of static friction of the material

- Kinetic friction: The force that opposes a body in motion from continuing that motion. Kinetic friction is always less than static friction.

$$f(k) = [(k)F(N)]$$

(k) = the coefficient of kinetic friction of the material

2.3.1.5 Torque Torque or moment is the ability of any force to cause rotation of a lever arm. The use of pulleys changes the direction of muscle force. Its use can also improve the ability of the muscle to generate torque by increasing the line of action of the muscle away from the axis of the joint. In the human anatomy, the patella serves as a pulley to transfer muscle force from the quadriceps to the ligament connecting to the tibia. The patella also increases the lever arm of the tibio-femoral muscle ligament providing an increased torque to flex and extend the knee joint.

2.3.1.6 Joint Reaction Forces Joint reaction forces are the forces applied by one segment on its

adjacent segment during joint compression. Joint reaction forces come in pairs. Forces between two joint surfaces in contact with each other can be resolved into components, contact or normal force and shear force. The contact or normal force is the component of the force that lies perpendicular to the contacting surfaces, and the shear force is the component of force that lies parallel to the contacting surfaces. Force applied perpendicular to a bony lever and parallel to the contacting joint surfaces will create a torque around the joint axis and a shear between the joint surfaces. A force applied parallel to a bony lever but not intersecting the joint axis will create compression or distraction and a small amount of rotation.

2.3.1.7 Stress and Strain

- Stress: Stress for a body that can be either stretched or compressed is the ratio of the applied force acting on the body to the cross-sectional area of the body.
- Strain: The ratio of the change in length to the original length of a body that can be either stretched or compressed, is called the strain.

The change in length (the strain) is directly proportional to the magnitude of the applied force, inversely proportional to the cross-sectional area of the body, and directly proportional to the original length:

$$L = \frac{1}{Y} \frac{F \cdot L_o}{\mathrm{A}}$$

Y Young's modulus of elasticity (material dependent)

F magnitude of the applied force

A cross-sectional area

L_o original length

L change in length

- Limits: The elastic limit is the point where the stress on a body becomes so great that the atoms of the body are pulled permanently away from their equilibrium position in the lattice structure. When stress exceeds the elastic limit, the material will not return to its original size or shape when the stress is removed.
- Shear: The elastic ability of a body to deform by changing shape when a stress is applied.

2.3.2 Application of Mechanical Lever System to Human Body Mechanical lever system laws are applicable to the human body. The bone, muscle, and joint are analogous to the mechanical lever system components, fulcrum, load, and effort.

2.3.2.1 Application of Lever Systems in Biomechanics

- Muscle moment or lever arm: The perpendicular distance from the action line of the muscle or tendon to the axis of rotation of the joint (fulcrum).
- Load moment or lever arm: The perpendicular distance between the center of gravity of the external load and the axis of rotation of the joint (fulcrum).

Load, force, lever arm, and fulcrum relationships:

$$\text{Force} \times \text{distance} = \text{load} \times \text{distance}$$

The three types of joints include the

- Hinge joint, such as the elbow
- Ball and socket joint, such as the hip
- Plate joint, such as the atlas joint in the neck

The mechanical laws of levers apply to each of these bone–muscle–joint systems. Each joint involves two bones that are in contact. A knowledge of the location, function, and limitations of anatomical levers involved in specific occupational movements is essential for ergonomic analysis and evaluation of operator-task systems.

The three bone–joint–muscle lever systems include the:

- First class lever: Fulcrum between load and force. Best suited for precision work.
- Second class lever: Load between fulcrum and force. Best suited for ballistic motion.
- Third class lever: Force between load and fulcrum. Best suite for heavy work.

Figure 104.1 gives examples of bone–joint–muscle lever systems from human anatomy.

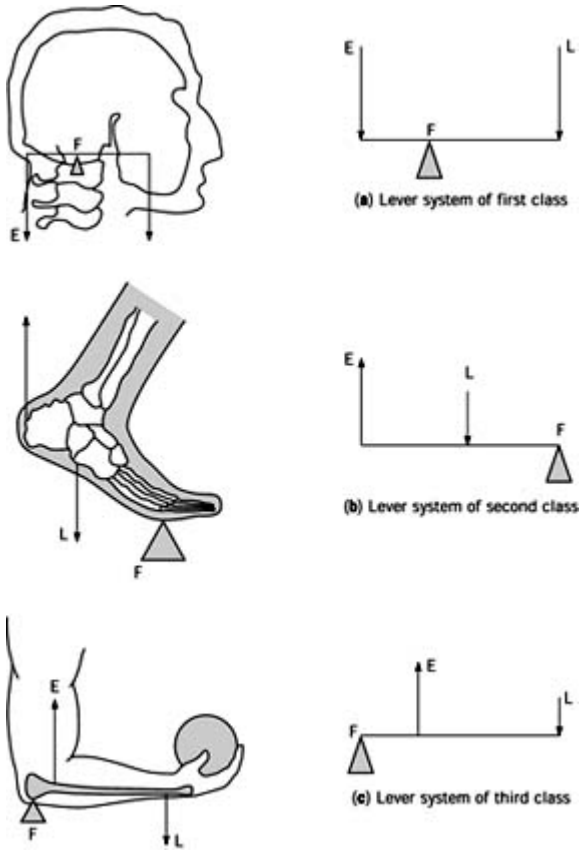

Figure 104.1. Three classes of lever systems. Examples from human anatomy (taken from Ref. 6).

Each class of levers is specifically suited to perform certain types of movements and postural adjustments efficiently without undue strain and risk of accidents. There is a potential of failure in a operator-task system if the

1. Degree of movement required exceeds that of the lever system employed.

2. Lever system performs at a mechanical disadvantage.
3. Muscles used are too small.
4. Blood supply to the muscles is impaired.
5. Sensory feedback is defective.

Example: Biomechanical Analysis of Holding an Object in Hand

[see Figure 104.2]

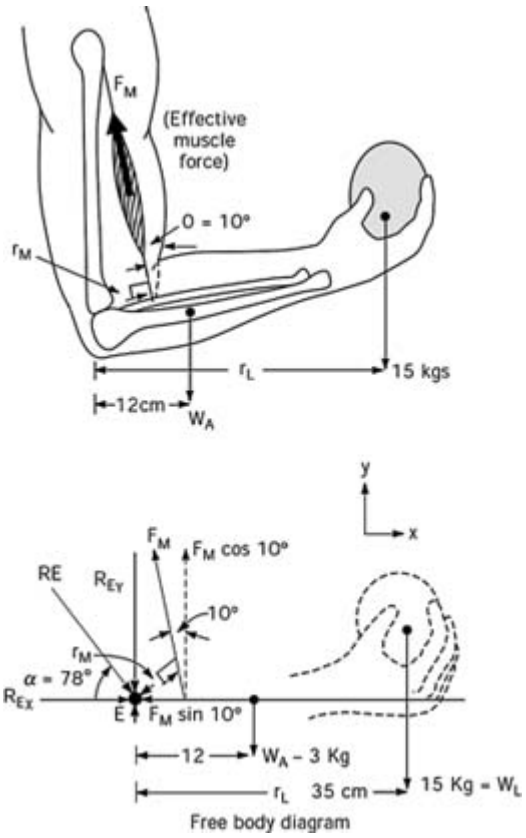

Figure 104.2. Biomechanical analysis of holding a weight in the hand.

Calculate the muscle force and the reaction force at the elbow joint (humerus against ulna).

$$Nomenclature: {}^{y}\uparrow is + ve \;\; and \;\; \rightarrow_{x} \;\; is \; + \; ve \; and \; (\; is - ve \; moment$$

Given:

$$\mathrm{WA} = \text{forearm weight} = 3\,\mathrm{kg} \text{ acting at } 12\,\mathrm{cm} \text{ from the elbow joint } \; W = \text{weight in hand} = 15\,\mathrm{kg}\text{Muscle mor} \tag{1}$$

Find:

$$F_{\mathrm{M}} = \text{Biceps muscle force} R_{\mathrm{E_{X,Y}}} = \text{Reaction force at the elbow joint} \Sigma F_{\mathrm{y}} = 0, \Sigma F_{\mathrm{x}} = 0, \text{ and } \Sigma M = 0 \text{ around} \tag{1}$$

Solution:

$$\text{For } \Sigma M = 0 - 15{\cdot}35 - 3{\cdot}12 + (F_M){\cdot}5 + R_E{\cdot}0 = 0 - 525 - 36 + F_M{\cdot}5 = 0 \text{ or } F_M = 112.2 \text{ kg For } \Sigma F_Y = 0 F_M \cos 10° - \quad (1)$$

Resultant reaction forces at the elbow joint:

$$R_E = \sqrt{R_{E_X}^2 + R_{E_Y}^2} = \sqrt{363.8 + 8456.6} \text{or } R_E = 93.9\, kg \qquad (1)$$

$$\text{Direction of } R_E = \tan\alpha = R_{E_Y}/R_{E_X} = 4.82 \text{ or } \alpha = 78.3° \text{ with respect to the horizontal}$$

Conclusion: It takes muscle force levels more than seven times the weight being held by the worker because the human lever system works at a mechanical disadvantage. For this reason, even holding small weights for a prolonged period or repetitively can cause muscle sprain and strain in a worker.

2.3.2.2 Biomechanical Loading of the Wrist Previous studies have shown that cumulative trauma disorders such as tenosynovitis, bursitis, and carpal tunnel syndrome are associated with repeated deviations (or extensions) and excessive use of force by the hand. Biomechanical studies (7, 8) have shown that tasks that require excessive and repeated use of force in nonneutral (deviation and flexion) wrist/hand postures produce stress concentrations on the tendons and tendon sheaths. The buildup of excessive strain might weaken the tendon and/or create inflammatory reactions. The following example illustrates the use of biomechanical models of wrist to estimate tendon force while holding a tool.

Example: Biomechanical Loading of the Wrist. Figure 104.3 shows the forces that act on the hand of a person who operates a screwdriver. Calculate the tendon force F_T and the reaction (or radial supporting) force F_R. For the purpose of this example, the grip force P acting at the finger may be assumed to be 1.5 newton. Assume a small hand in operation on a small grip size. Also assume that the subtended angle (wrist deviation or contact angle =) is 40°.

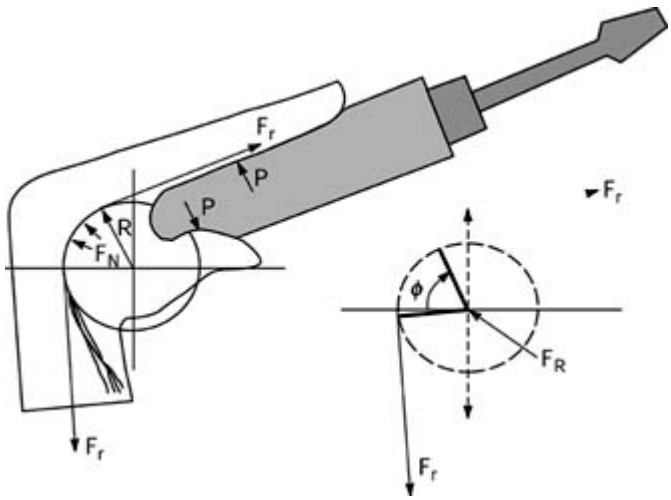

Figure 104.3. Internal forces acting on the wrist during flexion (taken from Ref. 6).

Solution: Using the equation for small object grasp (with a small hand) developed by Armstrong (9),

$$F_T = 2.8\, P = 2.8 \times 1.5 = 4.2 \text{ N} \quad (\text{Note : Foralargehanduse } F_T = 3.1\, P) \quad (1)$$

Using the simple pulley model of the wrist developed by Armstrong (10), the equation for F_R is

$$F_R = 2\,F_T \sin\phi/2 = 2 \times 4.2 \times \sin 40^\circ/2 \text{or } F_R = 2.87\text{N} \qquad (1)$$

2.3.3 Anthropometry Anthropometry is the science of measuring human body dimensions. Because people come in different sizes and shapes, it is critical to quantitate the characteristics of their body dimensions so that this information can be used to design workplaces. The major goal of anthropometry is to match the dimensions of workers' workstations with the appropriate body dimensions so that body postures used are neutral and exert minimal strain on the musculoskeletal systems. For example, people who have fifth percentile reach or short will be forced to extend their forearms excessively to reach for objects in workstations which are designed for a ninetieth percentile population or a population that has a longer reach. Therefore, it is critical to base workstation design on an anthropometric database that represents the user population well. The principles and practices of anthropometrics accommodate the diversity of human body size in designing equipment and workplace environments. In general, the anthropometric goal is to design a workplace so that 90% of the working population is accommodated.

The anthropometric parameters to be measured depend on the application. For example, workstation designs generally require measuring linear dimensions of body segments such as height, length, depth, and breadth. However, clothing design requires measures of body segment circumferences and contours. In biomechanical modeling, anthropometric measures of interest are the location of body joint centers of rotation, body segment centers of mass, interjoint link lengths, and radii of gyration. A detailed discussion of these issues can be found in the literature (11, 12).

2.3.4 Work Physiology The job or work demand should be matched or be comparable to the individual's work capacity, otherwise the potential for injury increases. The field of work physiology gives us tools to quantify the physiological work demand of a task. The individual work capacity or capability depends on a variety of factors such as genetics, training/adaptation, gender, age, body size, environmental (temperature, altitude, and air pollution), and attitude/motivation. The science of work physiology is essential for performing ergonomic evaluation of a task at the workplace. All physical work requires the use of muscles. Therefore, the foundation of work physiology is based on the principles of classical exercise physiology (1, 5). The ergonomic evaluation of work uses appropriate physiological measures that can directly or indirectly assess the workers' cardiopulmonary performance. It is a common practice in the classical exercise physiology literature, to measure whole body oxygen consumption as a direct indicator of physiological work done, but this measure may not be practical to obtain at a workplace. Therefore, ergonomists have used heart rate as a practical (yet scientifically acceptable) surrogate of whole body oxygen consumption during task performance at workplace. For example, it is a common practice to calculate “work pulse” to indicate the physiological workload of a task performed by a worker. “Work pulse” is defined as the average heart rate during task performance minus the workers' resting heart rate. The use of resting heart rate in the calculation of work pulse incorporates the fitness level effect (a fitter person generally has a lower resting heart rate) of the worker. Based on research studies where both oxygen consumption and heart rate were measured, ergonomic criteria for “acceptable” work pulses for men and women are 35 beats per min and 30 beats per minutes, respectively (13). Based on research studies by work physiologists in academia and NIOSH, physiological workload guidelines have been developed for task performance for various time periods without causing whole body fatigue (14, 15). NIOSH determined that any manual task, performed for an 8-hour period at a workload of more than 33% of the worker's maximum oxygen consumption capacity will produce unacceptable fatigue (13, 15). For occasional lifting tasks that last 1 hour or less, metabolic energy costs should not exceed 9 kcal/min for physically fit males and 6.6 kcal/min for physically fit females. Primary tasks variable that affect metabolic demand during a lifting task are the load lifted, the vertical location at the beginning of the lift, the vertical distance, and the frequency of the lift. Based on these metabolic cost criteria, one can then determine the need for appropriate rest periods during task performance.

2.3.5 Psychophysics The field of ergonomics relates workplace factors to human response, so it is reasonable to apply established principles of psychology to capture the subjective perception of the workers who perform a task. One such principle is Fechner's law (16), that relates physical stimulus intensity (*I*) to strength of sensation (*S*) logarithmically:

$$S = K \log I$$

where *k* is a constant. Stevens (17) further modified this as a power law in 1960 to accommodate a wider range of physical stimuli:

$$S = k I^n$$

where *k* is a constant of a particular unit of measurement and the exponent *n* depends on the type of physical intensity being tested. The values of *n* for muscular force, handgrip force, and light brightness are 1.6, 1.7, and 0.33, respectively.

Psychophysical methods are ideally suited for simultaneously assessing workers' subjective perceptions of exposure to a physical stimulus. For example, during a lifting task, the body is exposed to a physiological demand and a biomechanical stress in the low back area. The human brain does not evaluate this lifting task demand separately as physiological and biomechanical; rather it assesses the total demand simultaneously. The CNS performs the simultaneous evaluation, but modern day technology lacks methods for a directly and objectively measuring this simultaneous evaluation. Therefore, in the lifting task example, we have to rely on workers' perceptions of their CNS's assessment of the total (physiological and biomechanical) workload of the lifting task.

The ergonomic literature provides examples of psychophysical scales developed to capture whole body cardiopulmonary exertion (BORG's scale) (18), localized muscle fatigue, body part discomfort, perceived sense of slipperiness (19), and perceived sense of fall (20). These scales have been tested and validated by objective measures. Because these measures use only a paper and pencil questionnaire (usually one-page long) type of scale, they are ideally suited for epidemiological studies that generally use large cohorts.

3 Physiological Effects
Injuries of any source are attributable to trauma. Whether the trauma is chemical, mechanical, thermal or due to some other agent, otherwise normal tissue must respond to a load that is either too large (macrotrauma) or repeated too often for recovery to occur (microtrauma). Macrotrauma usually involves insults that are sudden and direct and produce immediate symptoms. Microtrauma, the focus of the problem in most overuse syndromes, is the result of repeated loads in a physiological range. It is unlikely that one incident of exposure to the smaller loads involved in microtrauma will result in dysfunction. Instead, it is the longstanding and recurrent nature of the trauma that is responsible for tissue changes. It is also important to recognize that the extent of the repetitive microtrauma is likely to continue to affect the tissue that undergoes the load and also will result in abnormal effects on structures at secondary sites that are attempting to compensate for the impaired function. This propagation of the original insult can lead to microtrauma at the secondary site and further compensation at a more distal or proximal segment. An example of such a chain of events occurs with shoulder bursitis. Inflammation of the bursa due to repetitive stress from painting leads to pain and limited movement in the glenohumeral joint. The scapulothoracic joint substitutes for the

limited movement and increases the tension in the upward rotators of the scapula (upper and lower trapezius). Due to overuse during the substitution, the lower trapezius, fatigues and cannot maintain the depression of the scapula. The scapula elevates as it upwardly rotates and results in abnormal force, pain, and dysfunction of the trapezius. Cervical spine disorders may result.

As shown in Table 104.2, the sources of trauma are varied. The table summarizes some of the more common types of insults that can result in injury. The effects of these injuries can include decreased vascular supply, disruption of cells via direct force, damage by microorganism, or immunological responses that cause further harm to a wide range of tissues. If the initial insult is repeated, as in the case of overuse syndromes, further tissue reactions can perpetuate inflammation and result in changes in tissue size, cell size, cell function, and cell number. Most areas of the body consist of connective tissue along neurovascular bundles and muscle, and therefore a complex series of reactions occurs during the injury and repair process. Further complicating this scenario is the recognition that the effect of an insult on a group of cells is not always uniform. Cell injury is usually mild at the periphery of the application of a force. The damage to the cell can be reversible if it is limited in magnitude and short-lived. In such cases, the nucleus is preserved and continues to function. Cytoplasmic changes, however, occur. The injury produces an environment of decreased oxygen and energy and, under these conditions, the sodium pump cannot maintain the appropriate levels of ions. As Na^+ and Cl^- enter the cell, water follows and swelling occurs in the cytoplasm and in the mitochondria. Anaerobic glycolysis becomes the major source of energy production that results in higher levels of lactic acid. The lactic acid decreases pH slowing metabolism in the energy-deprived state. Protein synthesis decreases, and organelles may be damaged if lysosomal enzymes leak. Because the nucleus and the cell membrane are still intact, energy will slowly be restored. In time, the cell will return to the normal state. Changes, though, have occurred during the period of recovery, and cell function is altered. It follows that the ability of the cell to resist another insult is decreased and it is more susceptible to a lethal injury during this period.

4 Common Upper Extremity Overuse Syndromes
Space does not permit a detailed description of all impingements or entrapments, but common upper extremity conditions are described following. Summaries include common signs, symptoms, methods of diagnosis, and treatment.
4.1 Thoracic Outlet Syndrome
Thoracic outlet syndrome (TOS) is a compressive neurovascular disorder of the upper extremity (78). Potential causes of this disorder include congenital abnormalities (cervical ribs), anatomic abnormalities of the anterior and middle scalene muscle, trauma, posture, tightness in the pectoralis minor muscle, and repetitive motion that involves continued abduction of the arms. Signs and symptoms are related to the compression of the nerves, arteries, and veins as they exit the cervical area and begin to transverse to the axilla (Fig. 104.10).

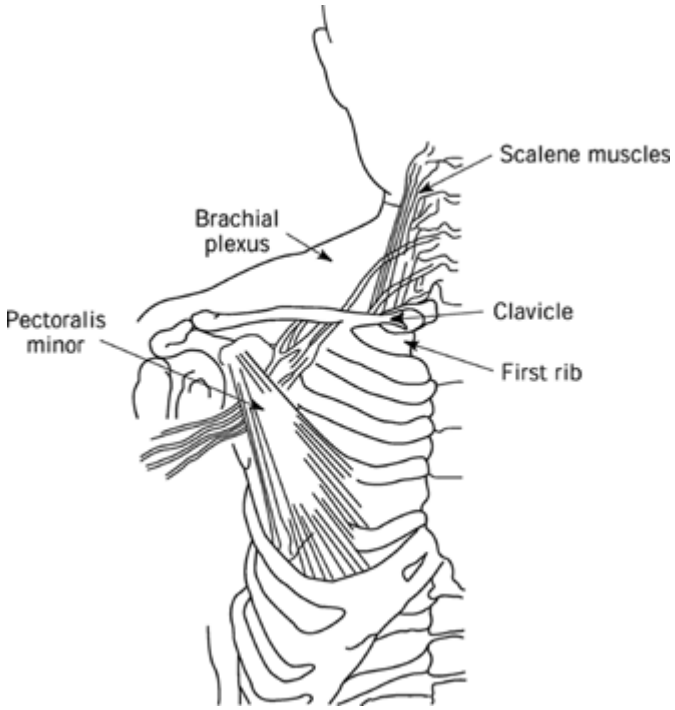

Figure 104.10. Thoracic outlet syndrome. The brachial plexus and related vascular structures can be compressed by the scalene muscles, the first rib, or the pectoralis minor muscle.

Signs and symptoms include pain or paresthesia in the upper limb, especially in the medial arm, forearm, and fifth digit. Pain is nocturnal but, unlike carpal tunnel syndrome, radial digits are not affected in TOS. Elevation above the shoulder increases symptoms as do provocative tests that include hyperabduction of the shoulder. Diagnosis can be made through X ray (cervical ribs), vascular tests (venous and arterial obstructions), provocative tests, and ruling out peripheral entrapments. Treatment depends on cause. Conservatively, physical therapy may be initiated to normalize posture and muscle lengths. Work situations may be modified to lower work positions of arms. Surgery may be indicated for cervical ribs or other entrapments of the neurovascular bundle (104).

4.2 High Median Nerve Entrapment

As the median nerve passes down the arm to the elbow, it travels anterior to the brachialis muscle and between the superficial and deep heads of the pronator teres muscle. It then traverses through the arch formed by the two heads of the flexor digitorum superficialis. Compression can occur as the nerve passes through the pronator teres or through the flexor digitorum superficialis. Signs and symptoms include pain in the proximal volar forearm and disturbances that may radiate proximally. Pain is increased with use of the upper extremity, especially forceful pronation and repeated pronation/supination. Unlike carpal tunnel syndrome, there is little nocturnal pain. Conservative treatment includes avoidance of aggravating activities, drugs, physical therapy, and splinting. Surgery may be indicated if motor and sensory symptoms persist (105).

4.3 Subacromial Impingement

Subacromial impingement is a painful condition that results from contact between the rotator cuff, the subacromial bursa, and the undersurface of the anterior acromion.

The supraspinatus tendon travels from the supraspinous fossa of the scapula underneath the coracoacromial arch to its attachment on the greater tuberosity of the humerus. In normal overhead elevation of the arm, the humerus must remain stable in a moving glenoid fossa. Kinematics involves complex dynamic stability of the rotators of the scapula, including a force couple that consists of the upper trapezius, the lower trapezius, and portions of the serratus anterior. These muscles contract throughout overhead movement of the humerus and cause upward rotation of the scapula without scapular elevation or depression. Stability is also needed to prevent superior movement of the

humeral head in the glenoid fossa. In a normal shoulder, the superior translatory force of the deltoid is opposed by the strong inferior and medial pull of the rotator cuff. The result is minimal superior movement of the humeral head as the arm flexes.

In a patient who has impingement syndrome, there is likely to be an increase superior movement of the humeral head during elevation of the arm (Fig. 104.11). As the humeral head moves up, the supraspinatus is compressed against the acromion. Individuals who have this problem usually have a history of overhead activity in which the arm is repetitively abducted or flexed above the shoulder level.

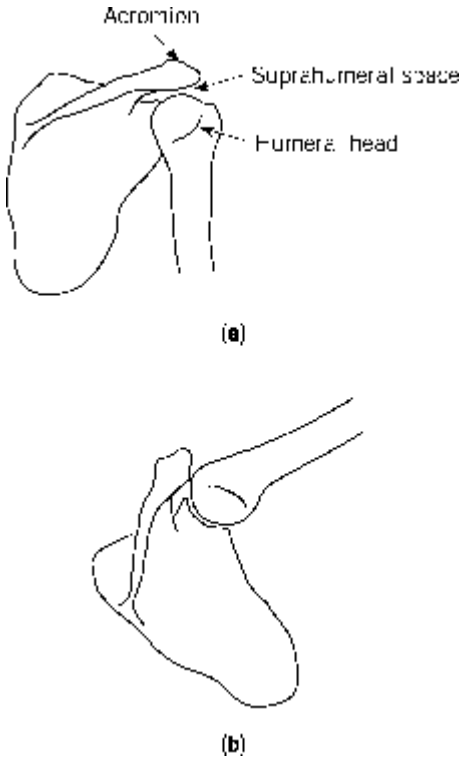

Figure 104.11. A. At rest, a space exists between the humeral head and the acromion. The suprasinatus tendon occupies this space. B. With humeral elevation, the scapula upwardly rotates and the humerus externally rotates. If the upward rotation is accompanied by elevation, the suprahumeral space can decrease. Impingement of the supraspinatus tendon can result.

Certain anatomical factors can also contribute to impingement. The presence of anterior acromial spurs, greater tuberosity spurs, inferior acromioclavicular osteophytes, or posteroglenoid rim spurs can narrow the outlet through which the supraspinatus tendon travels. It is expected that weakness in the rotator cuff that results in superior translation of the humeral head will be symptomatic earlier under these conditions.

The clinical picture of impingement begins with a history of overhead movement and pain. Initially, pain is present only with elevation. Without relief of the stress, pain develops with activities of daily living and progresses to pain at rest and then pain at night. Adhesive capsulitis and rotator cuff muscle weakness may occur secondary to pain. Examination shows a loss of internal rotation and localized weakness of rotator cuff muscles. Scapular muscles may also be weak. Impingement signs such as forced shoulder flexion and cross-body adduction can be positive. Magnetic resonance is the most objective test for accurately assessing the status of the supraspinatus tendon.

Conservative treatment of impingement includes modifying activities, physical therapy to restore rotator cuff and scapular strength, drugs, modifying the work position, and normalizing movement. If these are not successful, a range of surgical interventions can be considered.

4.4 Medial and Lateral Epicondylitis

Repetitive tension overload of the wrist extensors, lateral epicondylitis, or the wrist flexors, medial epicondylitis, results in a degenerative condition rather than a typical inflammatory tendinitis. Unorganized fibrotic tissue found in the tendons of individuals who have these syndromes indicates a failed healing response to low-grade reinjury. Inflammatory cells are absent which supports the belief that the process is not acute and repair is not being attempted. Tendon arrangement is disorganized as illustrated by abnormal collagen orientation and abnormal maturation of collagen. Cellular affects include alteration in the size and shape of mitochondria, decreases in mitochondrial enzymes, differences in RNA transcription, and changes in calcium release and uptake. Intracytoplasmic calcifications, longitudinal collagen fiber splitting, and abnormal fiber cross-links have also been documented. Evidence suggests that mechanical, tensile, and vascular hypoxic injuries have occurred. As changes progress in the tendons, muscles become weak and inflexible and can no longer resist normal loads. As stresses persist, effects are cumulative, and degeneration continues (106).

In lateral epicondylitis, the extensor carpi radialis brevis is involved in 100% of cases, the extensor digitorum in 30% (107). Medial epicondylitis usually involves the pronator teres and the flexor carpi radialis. Both result in aching pain in the tendon and muscle region and radiation of pain into the forearm. Symptoms increase with activity, with stretch, or with contraction of the involved muscles and decrease with rest. Lateral epicondylitis is accompanied by weak elbow extensors and posterior shoulder muscles. Medial epicondylitis is accompanied by weak elbow flexors and pronators.

Treatment for epicondylitis aims to reduce load on the muscles by avoiding identified activities that stress the muscles. Physical therapy, drugs, splinting, work modification, and cortisone injections may be used. Surgical intervention is not frequent and depends on the cause determined.

4.5 High Radial Nerve Compression

Compression of the radial nerve may occur proximal to the elbow as the nerve transverses the posterior aspect of the humerus. Trauma or pressure from crutches or support surfaces may be responsible. Strenuous muscular activity of elbow extensors may also contribute as the lateral head of the triceps constricts the radial nerve. Diagnosis is through EMG and nerve conduction studies. Therapy is conservative, although fractures may require surgical exploration.

4.6 Radial Tunnel Syndrome

Compression of the posterior interosseous nerve, the deep branch of the radial nerve, can occur 6 to 8 cm distal to the lateral epicondyle. Etiology can include overuse of extensor carpi radialis brevis or the possible calcification of the origin of the extensor muscles. More often, compression occurs after unreduced anterior dislocation or after excision of the radial head. Symptoms include motor weakness of the extensors of the wrist and fingers and sparing of the extensor carpi radialis longus and brevis. Diagnosis is confirmed via EMG, and denervation changes are seen in the muscles supplied by the posterior interosseous nerve. Treatment is usually surgical to remove compressive bands or structures (78).

4.7 Ulnar Nerve Entrapment

Ulnar nerve entrapment at the elbow is the second most frequently seen compression neuropathy. The ulnar nerve passes through the ulnar groove at the medial epicondyle and continues through the cubital tunnel. Compression can occur from hypertrophy of the origin of the flexor carpi ulnaris or from repeatedly resting the elbow on a flat surface. Fracture damage at the elbow and resultant scarring can also cause pressure on the ulnar nerve. Throwing can result in recurrent subluxation of the ulnar nerve over the medial epidoncyle and can also result in this type of neuropathy. Synovial cysts at the elbow and, more rarely, an abnormal insertion of the triceps brachii muscle may also cause symptoms in this part of the ulnar nerve. The cubital tunnel is 4 cm distal to medial epicondyle, and if the flexor-pronator aponeurosis tightens, symptoms may result. Common complaints that involve ulnar entrapment include symptoms of pain, numbness or tingling from elbow flexion, and weakness in finger abduction, thumb abduction, thumb and finger pinch, and power grip (78, 108).

Diagnosis is based on motor and sensory nerve conduction studies. Conservative treatment should be

considered for patients who have intermittent symptoms, mild neuropathy, or mild neuropathy that is from an occupational cause. Avoiding repetitive elbow extension and flexion, resting the elbow, splinting the elbow in extension, job modification, and patient education are included. Surgical techniques have mixed results.

4.8 Carpal Tunnel

Carpal tunnel syndrome (CTS) is the most common entrapment neuropathy in the United States. In 1988, the National Center for Health Statistics estimated that 1.89 million workers were affected with CTS. By 1995, that figure had increased to more than 5 million. Incidence was highest in women between the ages 35 and 55. More than 450,000 surgeries, it is estimated, are performed annually, usually in women in the 45–55 age group and in men over 65. It is estimated that up to 15% of workers in the high-risk industries are affected annually (109). In 1994, the Bureau of Labor and Statistics attributed 8.5% of the carpal tunnel cases to repetitive typing or key entry, 5.5% to repetitive use of tools, and 12% to repetitively grasping or moving objects (not tools) (110). Costs, including those for surgery, compensation, and expenses, can exceed $15,000 per worker (109).

4.8.1 Normal Anatomy of the Carpal Tunnel The carpal tunnel is an anatomic space in the anterior wrist that contains the median nerve and nine flexor tendons that pass from the forearm to the palm (Fig. 104.12). The floor is made up of the concave arch formed from the carpal bones and covered by intercarpal ligaments. The roof consists of the transverse carpal ligament as it extends from the scaphoid and trapezium bones to the pisiform and the hook of the hamate. The median nerve and its thirty to thirty-five fascicles are in line with the longitudinal axis of the third digit and contain sensory and motor fibers. The median nerve relays sensation from the thumb, index, middle, and the radial half of the fourth digit. Its motor fibers innervate the superficial head of the flexor pollicis brevis, the abductor pollicis brevis, the opponens pollicis, and the lumbricals of fingers one and two. The diameter of the carpal tunnel varies in the normal population, and changes with normal wrist movements. Wrist flexion decreases the cross-sectional area of the tunnel in the pisiform and hamate areas. Wrist extension also decreases tunnel size and alteration is noted only in the pisiform area. Normal pressures in the tunnel are approximately 2.5 mmHg at rest, 31 mmHg for wrist flexion, and 30 mmHg for wrist extension (111).

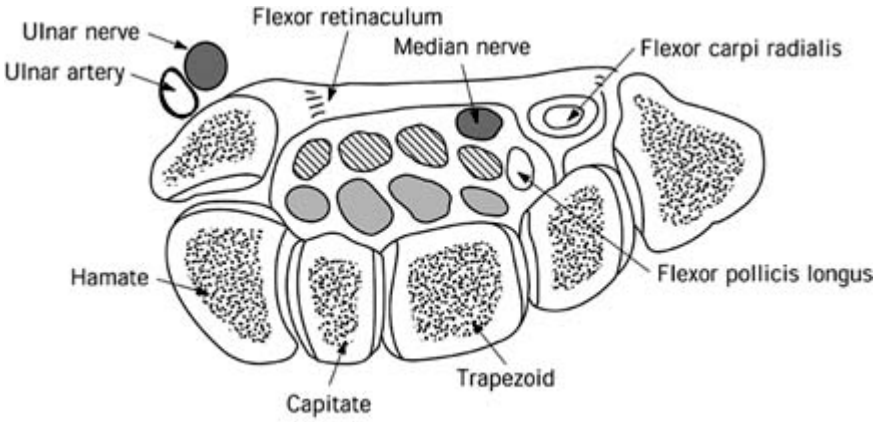

Figure 104.12. Carpal tunnel. A transverse view of the carpal tunnel. Flexor tendons and the median nerve travel under the flexor retinaculum.

4.8.2 Etiology of Carpal Tunnel Syndrome The major signs and symptoms of carpal tunnel syndrome are pain, tingling, numbness, paresthesia, and later, muscle weakness in the distribution of median nerve. Typically, symptoms are worse at night. All of these findings are considered the result of compression on the median nerve.

Theoretically, impingement on the median nerve could be due to any disorder that increases the volume of the contents of the carpal tunnel or that decreases the volume of the carpal tunnel. Rarely,

enlargement of the median nerve may result in compression. In addition, the prevalence of a decrease in the volume of the carpal tunnel due to rheumatic disease or bony deformities is unusual. The majority of symptoms are linked to increased content in the carpal tunnel that leads to tendonitis and/or tenosynovitis (89).

4.8.3 Risk Factors of Carpal Tunnel Syndrome Work factors are the most strongly associated risk factors of carpal tunnel syndrome. People who perform jobs with high repetition and high load have an increased risk of developing carpal tunnel (112). Risk is even higher if these high-repetition and high-load jobs also involve extreme wrist flexion, wrist extension, pinching, or ulnar deviation. Occupations that use high force and highly repetitive manual movements include meat packers, grocery store and assembly line workers, jackhammer operators, computer operators, and grinders. Vibration and awkward postures are additional stressors that increase the risk of carpal tunnel syndrome. Normal lumbrical muscle incursion into the tunnel may also contribute to work-related CTS (113, 114). Because the size of the tunnel may decrease, rheumatoid tenosynovitis, edema, pregnancy, and hypothyroidism have been identified as conditions that may contribute to the development of CTS.

4.8.4 Pathogenesis of Carpal Tunnel Syndrome The contents of the carpal tunnel, including the transverse ligament and the carpal bones are displaced against the walls of the carpal tunnel by flexion and extension. MRIs in normal persons have demonstrated changes in the size of the carpal tunnel, the shape of the tunnel, and the alignment of the contents with wrist flexion and extension (115, 116). The median nerve migrates during these movements, and the tendons slide over a curved surface. Friction occurs resulting in tendon edema and inflammation. As the tendon increases in size, it occupies a greater space in the carpal tunnel and increases the volume of the contents. The greater volume in the enclosed compartment results in more pressure on the median nerve. Signs and symptoms develop (90).

Studies confirm the differences in the pressure in the carpal tunnel between patients who have median nerve symptomatology and that in normal subjects. Pressures are lowest for both groups in the neutral position, increase significantly with wrist flexion, and increase even more with extension. Symptomatic patients exhibit significantly increased pressures in all positions. They also experience a prolonged recovery of pressures to baseline (117–120). Normal resting pressure in individuals without carpal tunnel syndrome is 2.5 mmHg; it is 32 mmHg in those who have carpal tunnel syndrome. Values for flexion and extension in the individual who have CTS range from 94–110 mmHg, significantly higher than normal range of 30–31 mmHg (111). This elevation of pressure leads to an ischemic compromise of the median nerve. The epineural venous blood flow is impaired and results in venous congestion, hyperemia, and circulatory slowing. Continued epineural edema leads to endoneural edema and alteration of the local ionic environment. Axonal transport is interrupted, and pathological changes occur. Ischemia and the presence of exudate promote fibroblastic activity and proliferation of fibroblasts. The epineurium and endoneurium are destroyed and replaced with dense, fibrous scar tissue that shows abnormal impulse generation and transmission, conduction delay, nerve block, and sheath enlargement (111). If repetitive flexion and extension continue, the coefficient of friction will increase and lead to further increases in the tenosynovitis. The volume of the content in the tunnel will become larger and lead to progressive entrapment. The unrelieved compression creates an initial neurapraxia and segmental demyelination of axons. Without relief, the pressure creates an axonotmesis in which axon continuity is lost and wallerian degeneration takes place.

4.8.5 Carpal Tunnel Syndrome, Clinical Manifestations Signs and symptoms reflect the median nerve distribution. Pain and paresthesia, especially nocturnal pain and numbness, are the hallmarks of carpal tunnel syndrome. Complaints usually involve the distal forearm and wrist and radiate into the thumb, index, and middle fingers. Symptomatic individuals are often awakened at night by painful numbness. Sensory complaints usually precede motor symptoms. Thenar weakness and atrophy can be seen in advanced cases. Half of the individuals who have carpal tunnel syndrome have bilateral symptoms. If untreated, pain will persist, the thenar musculature will atrophy, grip and

pinch strength will be lost, and further sensory impairment will lead to clumsiness.

4.8.6 Carpal Tunnel Syndrome, Diagnosis Provocation tests for carpal tunnel include the tethered median-nerve stress test, Phalen's test, Tinel's sign, and carpal compression. The tethered median-nerve stress test positions the forearm in supination with hyperextension of the index finger. As the median nerve becomes ischemic, pain will increase. Phalen's test involves bilateral wrist flexion to 90° for one minute. Pain will increase within that period if the test is positive. Percussion over the carpal tunnel (Tinel's) or pressure applied over the flexor retinaculum (carpal compression) are also positive if pain increases during application.

Diagnosis is confirmed by nerve conduction velocity studies of the median nerve. Changes in sensory conduction across the wrist are the most sensitive and most predictive (121). Magnetic resonance may be an aid, especially to rule out cervical radiculopathy.

4.8.7 Treatment of Carpal Tunnel Syndrome Early diagnosis and treatment are important because delay can result in irreversible median nerve damage, persistent symptoms, and permanent disability (78). Nonsurgical treatment is advised for patients who have mild symptoms, intermittent symptoms, or an acute flare-up from a specific condition. Conservative treatment includes steroid injection, oral steroids or nonsteroidal anti-inflammatory drugs, ergonomic measures, modification of occupation to avoid activities that precipitate the condition, wearing a splint that holds the wrist in the neutral position, patient education, and possible diuretics.

Surgical treatment is indicated if there has been no relief after 2–3 months of conservative treatment, if the symptoms have been present for more than one year with motor and sensory NCV involvement, or if denervation as evidenced by fibrillation potentials on EMG is documented. The most common surgical technique is the release of the transverse carpal ligament. Approaches to the release may vary. Newer techniques are performed through limited incisions and involve less exposure and less manipulation of the nerve (122). Seventy-six percent of surgical patients experience return of normal two-point discrimination, and up to 70% have normal muscle strength return (123). Prognosis depends on the severity of the nerve entrapment, the cause, and the mode of treatment. Recovery of impaired sensation and motor function may take several months; full recovery is not always the end result.

Occupational Ergonomics: Principles and Applications

5 Ergonomic Analysis of Low Back Loads and Pain
5.1 Specific Work-Related Injuries in the Low Back Region
5.1.1 Scope of Problem Low back pain and injuries among workers are major concerns of occupational safety and health personnel. Work-related back injuries continue to account for significant suffering, both physically and economically in the United States (124). Workers' compensation data support this. In the United States, approximately one-fourth of workers' compensation claims are filed for back injuries, and one-third of the costs are paid for back injury claims (125–127). The cost, however, is not only in the workers' compensation costs but in the loss of personal productivity, training of other workers to do the job, and medcal and supervisory time spent deciding the appropriateness of the injured worker's return to work and work restrictions (128).

The Occupational Health Supplement to the 1988 National Health Interview Survey (129) provides data on back injuries in the United States. Guo analyzed some of these data and reported that back pain is a major cause of morbidity and lost production for U.S. workers. This article also identified the risk of back injury as the highest among construction workers for males and among nursing aides

for females. Some previously unidentified high-risk occupations include carpenters, automobile mechanics, maids, janitors, and hairdressers (130). The National Safety Council released a report in 1990 (131) identifying overexertion as the most common cause of occupational injury and the back as the body part most frequently injured and most costly to workers' compensation systems.

Tables 104.3 and 104.4 show the incidence rates of nonfatal occupational injuries and illnesses according to industry and the number and percent distribution of days away from work for injuries to the neck, back, and shoulder (132). The transportation and public utilities industries have the highest incidence rates for neck, back, and shoulder injury. For the neck and back, 3–5 days away from work due to injury had the highest percentage distribution, and the shoulder had 31 days or more as the highest.

Table 104.3. The Incidence Rates for Nonfatal Occupational Injuries and Illnesses Involving Days Away from Work per 10,000 Full-Time Workers by Industry and Body Part Affected by Injury or Illness[a]

Industry	Neck	Back	Shoulder
Agriculture, forestry, and fishing	3.8	71.9	14.8
Construction	5.0	89.7	15.7
Manufacturing	3.7	56.8	13.6
Mining	5.9	56.5	10.3
Transportation and public utilities	10.1	108.2	25.3
Wholesale and retail trade	3.7	78.6	9.4
Finance, insurance, and real estate	1.4	14.8	2.8
Services	3.8	55.1	9.7

median days away	5	6	8

5.1.2 Biomechanics of Spinal (Vertebral) Column and Low Back Region The spinal unit is a complex structure that allows humans to perform a range of physiological motions such as flexion, extension, lateral bending, and rotation around its long axis. The spinal unit supports the attachments of internal organs, the head, and the extremities. It also provides mobility via a series of motion segments that consist of vertebral bodies (bony structure), intervertebral discs (soft tissue structures) sandwiched between each vertebra, and the surrounding ligaments (Fig. 104.13). This series of motion segments constitutes the entire spinal unit. The movement of the motion segment is controlled by active contraction of muscles and passive support provided by ligaments. This anatomical structure consists of thirty-three vertebrae. The major muscle groups that support the lower back are erector spinae muscles, hip flexor and extensor muscles, and abdominal muscles. Because of the short lever arm (2.5 cm) of the erectores spinae muscles, it has to generate a very high force to keep the body from falling forward during lifting or holding weight in the sagittal plane. The hip flexors and extensors are instrumental during forward, backward, and lateral bending. The abdominal muscles are instrumental in providing stabilizing force to the spine and because they are located anterior to the spinal unit, they provide an assistive torque that reduces the force needed by the erectores spinae muscle. The action of the trunk muscles converts the thoracic and abdominal cavities (chambers) into nearly rigid-walled cylinders of (1) air (thoracic cavity) and (2) liquid and semisolid material (abdominal cavity). Both of these cylinders can resist part of the force generated in loading the trunk and, thereby, relieve the load on the spine itself.

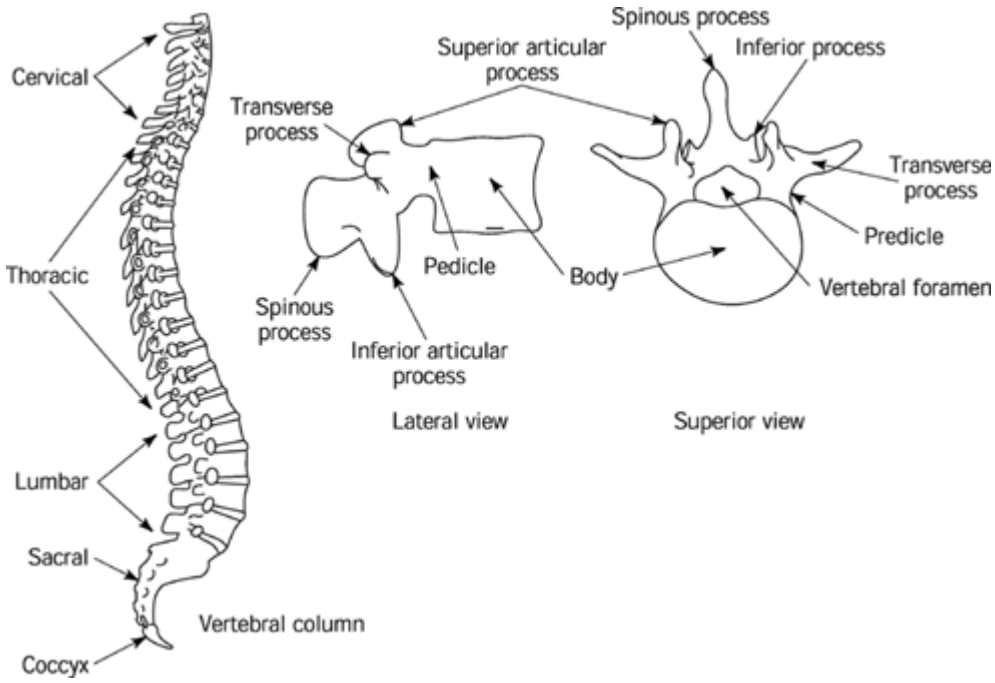

Figure 104.13. Spinal column.

The spinal unit also houses and protects the spinal cord and nerves along its entire length. The range of motion of the motion segments varies depending on their location in the spinal column and the mode of motion. The range of motion in the lumbosacral region is the largest for flexion/extension and the least for axial rotation. The range of motion in the lower thoracic region (T-10 to T-12) is the largest for flexion/extension and the least in axial rotation. Axial rotation in the cervical region is much larger than that available in the lumbar region (133, 134).

The literature provides data about the compressive strength of vertebrae at various levels of the spinal unit ranging from the cervical to the lumbar region (135, 136). In general, compressive strength is the smallest at the cervical level, and values increase for the thoracic and lumbar regions. Vertebral strength also decreases with age especially beyond 40 years. The rib cage provides strength and overall stability to the spinal column (137).

5.1.3 Intervertebral Disc About 20–30% of the entire height of the spinal column is made up of intervertebral discs. The disc has three components called nucleus pulposus, annulus fibrosus, and cartilaginous end plates. The intervertebral discs do not have a direct blood supply and do not carry any nerve endings. Upon the application of a load due to body segment weight associated with postures assumed, the fluid pressure within the nucleus pulposus (in a young healthy person, the inside of the disc is moist) pushes the surrounding annulus fibrosus and the end plates (Fig. 104.14). The orientations of the annulus fibers and the nucleus pulposus play a significant role in load transmission from one vertebra to the next.

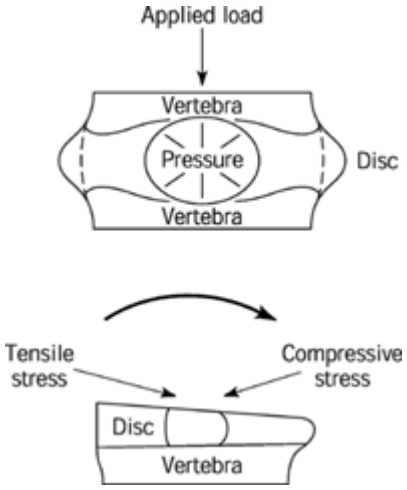

Figure 104.14. Spinal disc loading (Adapted from Ref. 133).

During normal physiological upright posture, the intervertebral disc along with facet joints is exposed primarily to compressive forces. However, during dynamic motions such as jumping and jogging, the disc loading may be severalfold higher than that observed in the static case. The types of stresses produced within the disc depend on the nature of physiological motion performed. For example, during bending (flexion, extension, and lateral bending), one side of the disc is subjected to compression and the opposite side experiences tensile load (Fig. 104.14). The compressive loading causes bulging of disc material which in the pathological case may impinge on the spinal nerve to cause back pain. Figures 104.15 and 104.16 show relative intradiscal pressure during various postures and the effect of various lumbar support on intradiscal pressure, respectively (138) (Fig. 106.17).

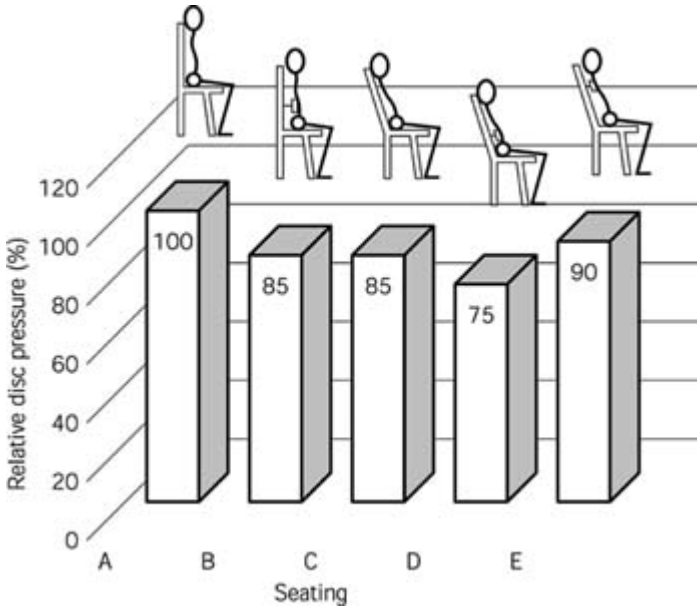

Figure 104.15. Effect of seat back inclinations on relative spinal disc pressure taken from Ref. 6.

Figure 104.16. Effect of body postures on relative spinal disc pressure taken from Ref. 6.

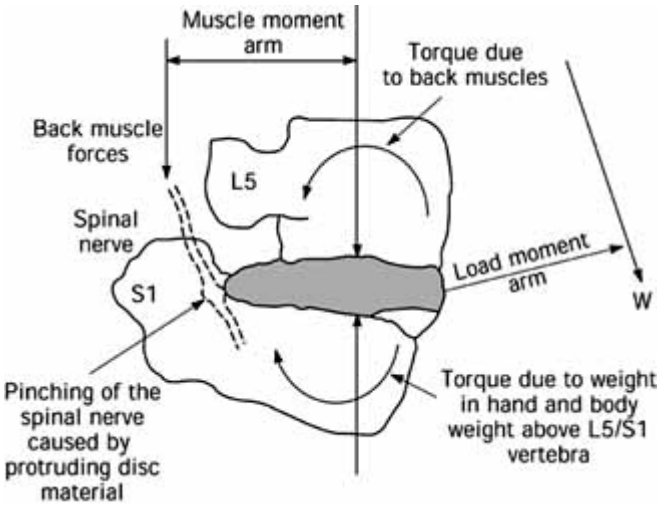

Figure 104.17. Potential pinching of spinal nerve during lifting weight taken from Ref. 6.

Axial rotation of the torso with respect to the pelvis causes *torsional* loads that result in *shear* stresses in the discs. Research studies have shown that bending and torsional loadings are more dangerous than compressive loads. Intervertebral discs have time-dependent properties such as fatigue and viscoelasticity characterized by hysteresis, creep, and relaxation. These properties determine disc failure due either to short-duration (high-amplitude load, i.e., jerk lifting) or long-duration (low-amplitude load) application of forces (11).

5.1.4 Biomechanical Aspects of Low Back Pain Low back pain symptoms can result from one of the following: disc degeneration, injuries and tumors of the spine, disc inflammation due to arthritis, and referred pain from abdominal or pelvic organs. A majority of low back pain cases (68%) fall into the category of disc degeneration (5).

A variety of factors such as physical, psychosomatic, biochemical, and anatomical can cause back pain. The biomechanical reason for back pain is explained in the following: Because disc materials do not have any nerve endings, simple compression forces do not create pain. Rather, during compression, the disc material can protrude outside and impinge upon the spinal nerves that surround the disc and the vertebral units. In the static spine, an increase in the lumbosacral angle can cause an increase in lumbar lordosis. This is called "swayback." About 75% of all postural low back pain is due to excessive lordosis. Pain caused is possibly due to facet impingement and irritation. See Fig. 104.17 (16, 139).

Kinetic low back pain is caused by abnormal body movement such as sudden movement or nonsymmetrical bending. Standing in a forward-flexed posture of 10–15° causes high loading of lumbar discs. This type of loading can also occur in a seated forward position.

These are common postures used in many industrial occupations that are responsible for occupational low back pain (5) (Table 104.5).

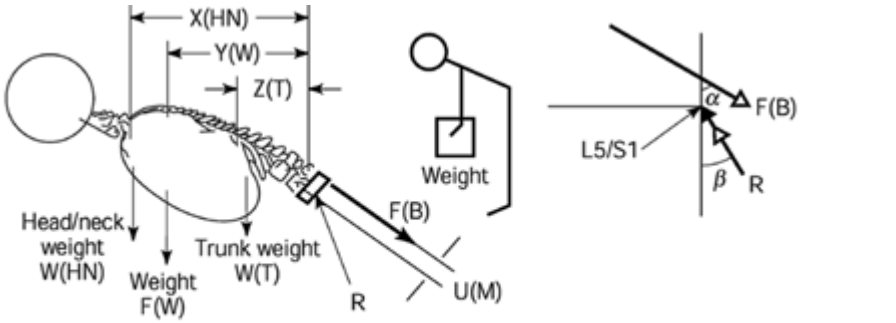
Table 104.5. List of Aggravators of Low Back Pain[a]

Descriptions of Tasks/Postures That Aggravate Low Back Pain
Constant standing and sitting
Low working height that makes worker bend
Extended reach to perform a task continuously for more than one minute
Turning and twisting of the trunk, such as lifting weights from the front to the side
Crouching posture for more than 1 minute
Repeated sustained work above the shoulder
Seats with improper low back support
Handling of loads with shifting weights of > 25 lb, such as liquids
Fixed work place height; frequent (one or more per minute) lifting or lowering of objects that weigh > 25 pounds
Handling of bulky loads whose physical dimensions are > 20 inches on any side of the box
Sustained (> 30-second period) pushing or pulling of loads in excess of 40 lb
Bending trunk below the waist for > 1 minute

[a] Ref. 5.

5.1.5 Analysis of Holding Weight in Hand and Its Effect on the Low Back Lumber-Sacral Joint The most common forces that determine the effect on the lower back during lifting in the sagittal plane are (1) gravity (BW, weight carried by the body) [external], (2) tension in the deep muscles of the back and in the muscles of the abdominal wall [internal], (3) pressure in the internal cavities of the trunk (intra-abdominal and intrathoracic) [internal], and (4) force transmitted by the spinal column [internal]. To determine the forces on the spine at a given level, say the L5/S1 point, it is necessary to consider the *external* (gravity) forces on the body above the L5/S1 level and the *internal* forces that resist or support the external forces. The stability of the spine depends largely on the action of the extrinsic support provided by the trunk muscles. The portion of the trunk above the L5/S1 is about 30% of body weight. The force of a weight lifted by the arms is transmitted to the spinal column by the shoulder-girdle muscles, principally the trapezius, and then to the abdominal cylinder and to the pelvis, partly through the spinal column but also through the rigid rib cage.

Example: The following data (Fig. 104.18) are given for a sagittal lifting activity (140). Calculate the back muscle force F(B) and the magnitude and direction of reaction force R at the L5/S1 joint. The person weighs 170 lb. Assume that F(B) is at an angle a = 40° to the vertical. Assume the right horizontal as the positive x-axis and vertical down as the positive y-axis (adapted from Ref. 18).



W(HN) = 17.7% of body weight; W(T) = 30% of body weight; F(W) = Lift weight = 200 lbs;
X(HN) =18 inches; Y(W) = 14 inches; Z(T) = 7 inches; U(M) = Back muscle moment arm = 2 inches.

Figure 104.18. Example of a biomechanical analysis of a lifting weight problem.

Solution:

$$\Sigma M = 0 \text{ around the L5/S1 joint } 30{\cdot}18{+}200{\cdot}14{+}51{\cdot}7 = F(\mathrm{B}){\cdot}2F(\mathrm{B}) = \frac{540+2800+357}{2} = \frac{3697}{2} = 1848.5\,\mathrm{l}$$
(1)

$$\Sigma F_{\mathrm{Y}} = 0 = F(\mathrm{W}){+}W(\mathrm{HN}){+}W(\mathrm{T}){+}F(\mathrm{B}){\cdot}\cos\alpha - R\cos\beta = R\cos\beta = 200{+}30{+}51{+}1848.5\cos 40^\circ = 281{+}18$$
(1)

$$\Sigma F_{\mathrm{x}} = 0 R\sin\beta = F(\mathrm{B})\sin\alpha = 1848.5 \cdot 0.642 = 1188.19\,\mathrm{lbs} \qquad (1) \qquad (2)$$

From Equations (1) and (2),

$$\tan\beta = \frac{1188.19}{1697} = 0.7 \therefore \beta = 35^\circ \therefore R\sin 35^\circ = 1188.19 \therefore R = \frac{1188.19}{0.573} = 2073.62\,\mathrm{lbs}$$
(1)

Conclusion: The back muscle force F(B) needed to sustain the posture and the 200-lb weight in the hand is about nine times that of the weight held because the body's lever system works at a

mechanical disadvantage.

6 Job Analysis
Ergonomic job analysis is used to identify and measure potential hazards. From such an analysis, solutions for reducing or eliminating ergonomic risk factors can be developed. Potential ergonomic hazards include work conditions that cause fatigue, overexertion, injuries, and chronic musculoskeletal disorders (141). Physical, mental, and perceptual demands due to these hazards can be measured during a job analysis (142). The type of job analysis can vary according to the purpose and scope of the investigation but generally involves the following elements: (*1*) identifying the potential hazards, (*2*) preparing to conduct a job analysis, (*3*) conducting the job analysis, (*4*) interpreting the results, (*5*) developing solutions, and (*6*) documentation (143).
6.1 Identifying Potential Hazards
First a review of injury data should be completed. Statistics on injury, absenteeism, or a high turnover rate on specific jobs can be obtained from plant records and/or employee surveys. These jobs can then be ranked according to their severity. After this has been completed, jobs of the highest severity should be investigated further. Walk-through surveys can then be conducted for the selected jobs. Background information about the job, employee and supervisor interviews, checklists, and surveys can be used to collect information (143). Various checklists (144) that have been developed can be modified to analyze specific jobs as needed.
6.2 Preparing to Conduct a Job Analysis
Observation and direct measurements can be used to evaluate the ergonomic hazards identified. The equipment required will depend on the type of hazard and the specific type of job analysis to be evaluated. Table 104.6 displays some examples of measurements that may be quantified for physical, physiological, and mental work. Some items that are generally useful for job analysis are video cameras, tape measures, force gauges, and stopwatches. More sophisticated, equipment and techniques such as electromyography, accelerometers, finger force sensors, and electrogoniometers are available and have been applied in the field (143).

Table 104.6. Measurements for a Job Analysis[a]

Type of Measurement	Example of Measurement
Biomechanical	Reach height and distance
	Weight and dimension of material handled
	Forces and torques
Motions	Frequency
	Degree of rotation
	Duration
	Dexterity/coordination requirements
Timed activity analysis	Pattern of activities during shift
	Time to perform a task
	Frequency of more demanding tasks
Environmental	Temperature, humidity, air movement

	Noise
	Illumination
	Shift schedule
	Other physical or chemical factors (odors, work surface)
	Use of protective clothing or equipment
Mental and perceptual	Visual and auditory requirements
	Complexity
	Information handling/decision making requirements
	External pacing
	Productivity during shift (units/hour, interruptions, etc.)
	Quality of output (defects, incomplete work, etc)
Physiological	Heart rate
	Blood pressure
	Oxygen consumption
	Surface electromyography
	Psychophysical scaling (perceived exertion, comfort, stress)
	Minute ventilation
	Body temperature

[a] Ref. 142.

Methods and tools have been developed for analyzing a specific risk factor for some job tasks. For example, Waters et al. recently studied some methods for assessing manual materials handling (MMH) tasks (145). The review article provides information for selecting appropriate methods for a particular job/task and included the following:

1. The revised National of Institute for Occupational Safety and Health (NIOSH) lifting equation (146)
2. The University of Michigan 3D Static Strength Prediction Program (147)
3. The Oxylog portable consumption meter (148)
4. The Polar portable heart rate monitor
5. The University of Michigan Energy Expenditure Program (149)
6. The Chattanooga Corporation Lumbar Motion Monitor
7. The Ohio State University risk assessment model (150)
8. The Snook and Ciriello psychophysical approach for assessing manual lifting demands (151)

After equipment and/or an analysis tool are selected, a sampling strategy must be developed. A typical work period should be observed under normal conditions. At least three workers who perform the job and the entire work cycle should be observed at least three times. If the job does not have repetitive cycles or is an irregular task, the workers may need to be observed randomly during an extended period to capture all tasks.

6.3 Conducting the Job Analysis

For accuracy, the job should be disrupted as little as possible. A large part of the job analysis will be direct observation of the work tasks. Discussion with workers to obtain information on specific elements of the job and supervisors to obtain information on the broader view of the operations and the feasibility of future proposed changes can also be conducted. Finally, preliminary measurements of the worksite should be recorded, including a dimensioned sketch of the layout of the workstation

and tools. The specific measurements would depend on the type of analysis performed and the equipment used.

6.4 Interpreting the Results

To analyze the results, the job must be broken down in tasks or subtasks. Then, each task can be evaluated for such factors as force required, posture assumed, repetitiveness, duration of work and recovery periods, and other physical exposures such as vibration or cold temperatures. Factors such as these increase the risk of cumulative trauma disorders. However currently, there are no known limits for force and repetition that are safe for the working population. Estimates can be made from strength data, anthropometry, physiological data, psychosocial data, and integrated models.

6.5 Developing Solutions

The results from the ergonomic job analysis should include methods to eliminate, reduce, or control the ergonomic hazards identified. This can involve modifying equipment, workstation layout, work practices, and raw material packaging and administrative changes such as employee rotation, longer rest breaks, and reduced production rates. A follow-up job analysis should be conducted after the interventions are in place to ensure the feasibility and effectiveness of any changes made to the job.

6.6 Documentation

Finally, a report of the entire job analysis process should be written. It can include the reason that the analysis was done, what risk factors were identified, how they were evaluated, and recommendations for correcting the problem (143).

7 Regulations and Recommendations

The Occupational Safety and Health Administration (OSHA) has issued guidelines for controlling ergonomic hazards in the meatpacking industry (152). OSHA is also developing a general ergonomic standard and will soon issue a draft of the proposed standard (153). California has a standard that regulates repetitive motion injuries (154). In addition, the American National Standards Institute's (ANSI) Z-365 (155) is another proposed general ergonomic standard for cumulative trauma disorders.

7.1 Occupational Safety and Health Administration's Meatpacking and Proposed Ergonomics Standards

The Occupational Safety and Health Act of 1970 states that it is the general duty of all employers to provide a workplace free of serious hazards. These hazards include ergonomic hazards. The management of worker safety and health protection includes all hazards even if they are not specified by a U.S. federal regulation. In 1990, OSHA issued general guidelines (OSHA 3123) for ergonomic management programs, specifically for the meatpacking industry. OSHA's proposed ergonomics standard, if passed, will be an enforceable regulation in the United States. A draft of the national standard is expected to become public in the near future.

7.1.1 Ergonomic Program Management Guidelines for Meatpacking Plants These guidelines are neither a standard nor a regulation but provide information on the approach that employers should take to determine if ergonomically-related problems exist in their workplaces, to identify the nature and location of these problems, and to implement measures to reduce or eliminate these problems. The guidelines are divided into three sections (1) management commitment and employee involvement, (2) program elements, and (3) detailed guidance and examples.

The *management commitment and employee involvement* section stresses the importance of management's commitment and a team approach to a successful program. It states that a written program should be developed and communicated to all employees. The importance of employee involvement in the program and in decision making is also stressed in this section. Finally, regular review and evaluation of the program by managers, supervisors, and employees is recommended.

The section on *program elements* includes four major elements: *worksite analysis, hazard prevention and control, medical management, and training and education*. The *worksite analysis* objectives described are to recognize, identify, and correct ergonomic hazards. The *hazard prevention and control* element includes guidelines for using engineering controls, work practice controls, personal protective equipment, and administrative controls. The third major element involves guidelines for implementing a *medical management* system that identifies, evaluates, treats signs and symptoms, and aids in preventing ergonomically related injuries and illnesses. Finally, the element that involves *training and education* presents information to inform employees about the ergonomic hazards to which they are exposed and their role in the ergonomics program.

The last section on *detailed guidance and examples* gives more specific information on an ergonomics program related to the meatpacking industry. A recommended worksite analysis for ergonomics is described in detail. It provides information on gathering information from available resources, conducting baseline screening surveys, performing ergonomic job hazard analyses both before and after controls are in place, and conducting periodic surveys and follow-ups to evaluate changes. This section also includes specific examples of engineering controls for hazard prevention and control and medical management programs to prevent and cumulative trauma disorders in the meatpacking industry (152).

7.1.2 OSHA's Ergonomics Standard The proposed standard includes the following sections: introduction, purpose, scope and application, identification of problem jobs, control of workplace risk factor exposures, ergonomic design and controls for new or changed jobs, training, medical management, recordkeeping, effective date and definitions. The standard can be found in 29 CFR 1910.500 or the OSHA homepage (http://www.OSHA.gov) on the internet. This standard is scheduled to go into effect, January 2001.

The *purpose* of this standard is to prevent and reduce the severity of musculoskeletal disorders by controlling the exposure to risk factors, medical management, information dissemination, technology, and management and employee participation in ergonomic programs. The *scope* covers employees who are exposed to risk factors that are measured in hours and employees who have recorded work-related musculoskeletal disorders. The *application* of this standard depends on the extent of workplace risk factors and work-related musculoskeletal disorders.

The *identification of problem jobs* includes sections on employee information, a workplace risk factor checklist, and start-up dates. An OSHA workplace risk factor checklist would be provided in an appendix. The *control of workplace risk factor exposures* describes the requirements for determining and implementing an appropriate strategy to control problem jobs by reducing or preventing employee exposure to workplace ergonomic risk factors. The *ergonomic design and controls for new or changed jobs* section includes ways to prevent or control problem jobs when changes are made in the workplace in the future. This includes information on eliminating workplace risk factors in job design and the employer's responsibilities when job changes introduce signal risk factors. The *training* section describes the training requirements for the employee. The *medical management* section describes the requirements for plans to assess and manage musculoskeletal disorders among employees. Such plans are proposed to provide for early assessment and treatment of work-related musculoskeletal disorders and to reduce their severity and prevent progression. The *recordkeeping* section details the maintenance of records according to the requirements of 29 *CFR* 1910.20. Finally, the effective date and definitions for the standard will be provided (153).
7.2 California's Repetitive Motion Injury Standard
This standard, Title 8, General Industry Safety Orders, Article 106, Ergonomics, Section 5110, Repetitive Motion Injuries, went into effect on July 3, 1997 in California. This standard is comprised of three sections, including scope and application, a repetitive motion injury program, and satisfaction of an employer's obligation.

The *Scope and Application* states that the standard applies to a job, process, or operation where at

least one employee has a repetitive motion injury (RMI) diagnosed by a licensed physician. This RMI must be work-related and must be reported by the employee within 12 months. Employers are exempt from this standard if they have fewer than nine employees.

The employer is required to develop an *RMI program*. This program is required to include a worksite evaluation, control of exposures that have caused RMIs and training of employees. The worksite evaluation involves evaluating jobs, processes, or operation for exposures that may cause RMIs. Control of exposures may include engineering controls and administrative controls and must eliminate the exposure or at least minimize it. The training must include an explanation of the employer's program, potential exposures, symptoms and consequences of injuries caused by repetitive motion, the importance of reporting RMIs and finally, the methods that are being implemented to minimize exposures.

Finally, the section on *satisfaction of an employer's obligation* states that the employer is obligated to take measures that would greatly reduce RMIs as long as they do not impose excessive costs (154).

7.3 ANSI Z-365

The ANSI Z-365 draft consensus standard for cumulative trauma disorders (CTDs) is a proposed voluntary standard, which means that it is not regulated and not enforceable. It is comprised of four sections, including purpose and scope, definitions, conformance, and the process.

The *Purpose and Scope* of the standard is divided into three sections. *The Purpose and Intended Audience* states the standard and describes the processes and principles for controlling work-related CTDs. A definition of CTDs is given, including their causes and their characteristics. The *Scope* states that the aim of the standard is to control work-related CTDs that arise from manual lifting, assembly, manipulation of tools, machinery and other devices, and other stresses on muscles, nerves, tendons, and associated soft tissues of the body. The *Scope* also describes the ergonomic considerations such as work postures, work layout, force requirements, vibration, work rates, tool design, and flexibility of workstations to accommodate individual variations. Finally, the *Standard Content* describes that the scope will be addressed through surveillance, job analysis and design, management of CTD cases, and training sections.

The *definition* section contains words relevant to understanding the standard. The section on *conformance* explains that the standards/guidelines in this document would be voluntary and, would be established by consensus. This section also discusses the wording used in the document. A section on the *process* includes background to explain how and why the standard came about. The *CTD Control Process* proposes a CTD control program that includes management responsibilities, training, employee involvement, surveillance, evaluation and management of CTD cases, job analysis and job design, and intervention. Finally the Program Implementation states that priorities will have to be established by individual employers to determine which component should be addressed first. This section also states that regular evaluations are required to determine if the evaluation and reduction of CTD risk factors is beneficial.

Occupational Vibration
Donald E. Wasserman, MSEE, MBA

1 Vibration Defined
1.1 Vibratory Motion
Vibration (2), by definition, is a vector quantity, consisting of both a magnitude (or intensity) and direction. Vibration motion measured at any one point is defined by a total of six vectors: three mutually perpendicular "linear vectors" and three corresponding "rotational vectors" called "pitch," "yaw," and "roll." Most occupational vibration measurements use only the three mutually linear vectors, ignoring the rotational vectors. Hand–arm vibration measurements use a special vector coordinate system, as shown in Figure 105.1. Whole-body vibration measurements use another special vector coordinate system, as shown in Figure 105.2.

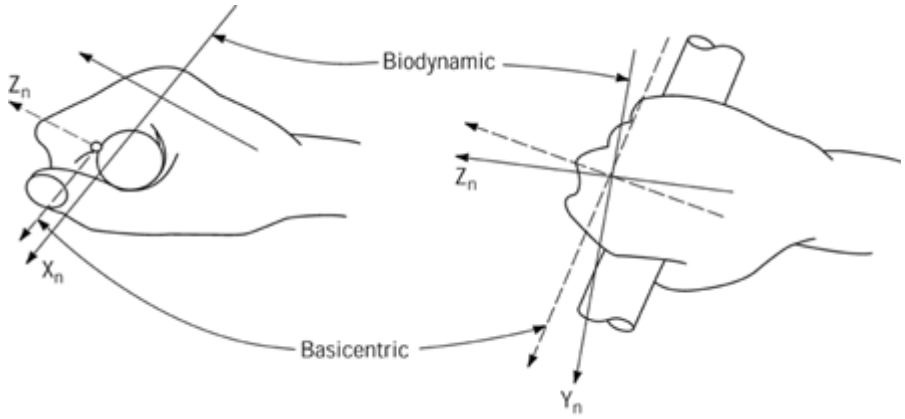

Figure 105.1. Coordinate system directions used to measure hand–arm vibration acceleration for use with ANSI S3.34 and ACGIH standards.

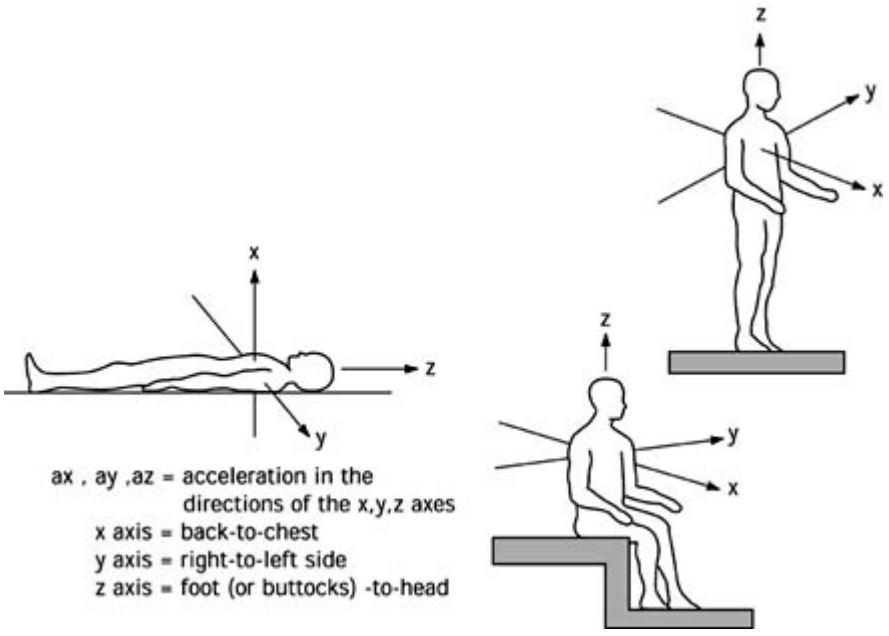

Figure 105.2. Coordinate system directions used to measure whole-body vibration acceleration for use with ANSI S3.18 and ACGIH standards.

1.1.1 Types of Vibratory Motion Vibratory motion can be: periodic or nonperiodic; continuous, impact, or random. The motion can be purely single sinusoidal (or pure tone, if it were audible) or a complex mixture containing many sinusoids. If sinusoidal motion is completed in one second, then the vibration frequency is one cycle/second or 1 hertz (Hz). If five complete cycles of sinusoidal motion occur in one second, then 5 Hz is the frequency; 1000 complete cycles in one second is 1 kHz (kilohertz), and so on.

1.2 Measures of Intensity

There are three interrelated descriptors of motion, which can be used as measures of intensity: displacement, velocity, or acceleration.

Displacement is motion measured away from some reference point. The units of displacement can be meters, feet, centimeters, inches, and so on.

Velocity is the time rate of change of displacement, or the speed of a moving object. The units of velocity are distance divided by time; feet per second, meters per second, and so forth.

Acceleration is the time rate of change of velocity. The units of acceleration are usually either in meters per second per second or in gravity *g* units, where 1 *g* = 9.81 meters per second per second. Acceleration is usually the measurement quantity of choice as the "intensity" descriptor for human vibration measurements.

Since displacement, velocity, and acceleration are all related mathematically, it is necessary to measure only one of these parameters, and the remaining two parameters can be mathematically obtained; for example, if acceleration is measured, mathematically integrating the acceleration function will yield velocity. Repeating the integration process on the velocity function will yield displacement.

1.3 Vibration Acceleration Intensity

Characterizing *vibration acceleration intensity*, as measured in the workplace, necessitates that the following issues be addressed:

- What is needed is a typical measure of the vibration acceleration intensity or "dose" impinging on the worker's body without collecting data over the entire workday.
- Workplace vibration is usually complex and time-varying and thus contains a mixture of vibration frequencies.

What parameter of acceleration intensity represents *vibration dose*? If we choose to measure only the "peak," or the largest value of acceleration occuring in a specific direction over a specific measurement time period, does this represent the vibration dose impinging on the worker? Probably not, since there is no guarantee that this motion will be repeated. The answer to these questions is to use a type of average vibration acceleration intensity measurement called *root-mean-squared* (rms) acceleration, which is more desirable than using peak measurements. If varying peak acceleration values do occur during measurements, then the rms mathematical process can account for these values. The Following equation defines RMS acceleration:

$$a_{\text{rms}} \sqrt{\frac{1}{T} \int_0^T a^2(t)\, dt} \qquad (1)$$

where: a = measured acceleration (m/s^2 or g value) t = time (s)T = measurement time period, (s)

In equation (1), acceleration values are first squared; thus negative values become positive. All such

values are summed or integrated over the measurement period; the sum is then divided by the total measurement time *T*; the square root of the resulting value yields the rms value. For pure sinusoidal motion the rms acceleration value is

$$a_{\text{rms}} = (0.707)\, A_{\text{peak}} \tag{2}$$

where *A* = peak acceleration, (m/s^2 or *g* values).

1.4 Using Fourier Spectrum Analysis to Calculate Workplace Vibration

Workplace vibration is rarely a single sinusoid, but is usually complex motion containing several vibration frequencies. A frequency separation method for data analysis known as *Fourier spectrum analysis* is needed and is used to

- Convert time-domain data to corresponding frequency domain data, thus forming a spectrum
- Determine the acceleration intensity contribution to the overall vibration spectrum for each frequency in the spectrum

Fourier spectrum analysis is analogus to chemical spectrophotometry, where the concentration of each element forming a compound is separated into its elements and graphically displayed as a *line spectrum*, in which position of each vertical spectral line denotes an element's wavelength in the spectrum and the corresponding height of each line represents the concentration that element contributes to the compound. In the 1800s a French mathematician, Jean-Baptiste Fourier (1768–1830), showed that a linear, complex waveform was composed of a mathematical series of sines and cosines of differing frequencies and amplitudes as given by equation 3:

$$\begin{aligned} F(t) = a_0 + a_1 \sin\omega t + a_2 \sin 2\omega t + a_3 \sin 3\omega t + \cdots + a_n \sin(n)\omega t + b_1 \cos\omega t \\ + b_2 \cos 2\omega t + b_3 \cos 3\omega t + \cdots + b_n \cos(n)\omega t \end{aligned} \tag{3}$$

where the *a* and *b* terms are intensity values for each sinusoid frequency that constitutes the spectrum. The a_0 term is the zero hertz [or DC] component and is seldom used.

The Fourier spectrum computer's output is a graphical line spectrum; the graph's abscissa is vibration frequency in hertz; the graph's ordinate is intensity in rms acceleration in m/s^2 or *g* units. Spectrum analysis is a very powerful analytical method for identifying the frequency/intensity characteristics of different vibration sources.

1.5 Vibration Transmissibility

Often many times it is necessary to determine how vibration entering and then exiting a structure is modified. An often used descriptive term is called *vibration transmissibility*, which is defined as the ratio of output acceleration exiting the structure divided by input acceleration entering the structure, as a function of vibration frequency, with both input and output vibration moving in the same direction. Transmissibility is a “transfer function” and is a dimensionless number; a transmissibility ratio equaling unity (one) means that there is no change between input and output; a ratio less than one (< 1) means that the structure internally reduces the input vibration; a ratio greater than one (> 1) means that the structure is internally amplifying the original vibration and may be “resonating,” which is an undesirable phenomenon, discussed next.

1.6 Resonance

Virtually all physical structures vibrate when mechanically excited, this is also true of the human body. There are certain preferred vibration frequencies (known as “natural” or *resonance frequencies*) where a structure will naturally vibrate with very little externally applied input excitation. Simply stated, resonance is the tendency of a mechanical system (or the human body) to act in concert with externally generated vibration and to internally amplify the input vibration and exacerbate its effects. Maximum vibration energy is transmitted from the source to the receiver at resonance. Resonance is undesirable, is uncontrollable, and can be very destructive (This is one reason why soldiers never march across a bridge); in rare instances, resonance can be managed and

controlled, and can even be desirable, such as in the construction of certain musical instruments (3). Undeniably, in the workplace situation, resonance is totally undesirable, because if a vibrating source such as a vehicle or powered handtool should emit frequencies corresponding to human resonances, and a worker's body comes in physical contact with that source, most likely the emitted vibration would be internally amplified by the worker's body. Resonance is the Achilles heal of human vulnerability to vibration and must be avoided.

1.7 Damping and Isolation

Finally, there are two main engineering methods for minimizing vibration: damping and isolation. Vibration *damping* is the conversion of mechanical vibratory motion into a corresponding small amount of heat, due to the deformation of the damping material as in a glove containing viscoelastic materials. Vibration *isolation* is the intentional design mismatch or alteration of the pathway(s) between the vibration source and the receiver; as, for example, in an automotive shock absorber.

Occupational Vibration
Donald E. Wasserman, MSEE, MBA

2 Hand-Arm Vibration

2.1 Health Effects and Epidemiology

There are some 2 million workers (1) in the United States alone exposed to hand–arm vibration (HAV). These include workers using vibrating pneumatic, electric, and gasoline-powered handtools such as chippers, grinders, impact hammers, rachet hammers, jack-leg-type drills, demolition tools, jackhammers, chain saws, and brush removers. The negative health effects (4, 5) of this HAV exposure have been recognized since the very early 1900s. In 1911, Loriga in Italy reported white fingers in workers using pneumatic tools in mining (6). During 1918, in a study of cutters and carvers using vibrating pneumatic tools in the Oolitic limestone mines of Bedford, Indiana, the famous occupational physician, Dr. Alice Hamilton, first reported some 80% prevalence of a disease of their hands called white finger or *Raynaud's phenomenon* (7). Since those early times there have been numerous studies causally linking HAV exposure with disease of the fingers and hands (4, 5). Typically this condition's initial symptoms are attacks of tingling and/or numbness (paresthesia) in the fingers, followed by an initial attack of finger whitening (or blanching), usually of one finger, lasting a few minutes. As the vibration exposure continues, blanching attacks increase in number and severity, and include multiple fingers; cold temperatures often trigger these blanching attacks (4, 5), and smoking exacerbates this condition (8). Often the thumbs are the very last of the fingers to be affected. A small percentage of the population (mostly women) have naturally occurring *Raynaud's disease*, which is not an occupationally induced condition, but the symptoms of which are similar to the condition described above. Through the years occupationally induced Raynaud's has undergone several name changes from “dead fingers” to “white fingers,” to *Raynaud's phenomenon*, to “vibration white fingers” (VWF), and currently hand–arm vibration *syndrome* (HAVS). For the most part HAVS is an irreversible condition of the fingers and hands after the blanching process is well under way. *Calcium channel blockers* are the current medications used to relieve some signs and symptoms of HAVS; however, these agents are palliative and *not* a cure. The timespan from when a worker begins using a vibrating handtool to the appearance of the first white fingertip is called the *latent period* and has been used as the HAVS peripheral vascular time marker for many years. Depending on the type of tool used, worker exposure time and conditions, and attendent tool acceleration levels, the latent period can vary from as little as a few months to several years. Generally, higher tool acceleration levels result in shorter latent periods (4, 5, 9–11).

Patient diagnosis of HAVS consists of a vibrating toolwork and hobby history and a specialized battery of medical tests (4, 5), which include finger plethysmography and Doppler blood flow tests, finger systolic blood pressure, two-point discrimination, finger depth sense, vibrometry/frequency threshold measurements, and thermal hot/cold perception of the fingers.

In 1968 the Taylor–Pelmear medical classification system for scaling HAVS (11) was introduced and used successfully until 1986. Table 105.1 describes the Taylor–Pelmear system. The initial stages of tingling and/or whitening are noted as OT, ON, TN, followed by the initial blanching Stage 1, whose timespan is defined as the aforementioned latent period. With increased vibration exposure, overall finger blanching progresses, more fingers become involved, and the person's ability to perform work and overall quality of life steadily deteriorate in Stage 2, 3, and 4. If vibration exposure is allowed to continue beyond Stage 4, finger gangrene (tissue necrosis) can occur. In reality, in most cases the pain and suffering from HAVS is so extensive in these latter Stages that the worker is essentially forced to change jobs, thus avoiding any finger gangrene. Sadly, the white finger condition will persist despite removal of the vibration source. In 1986 the Taylor–Pelmear system was modified by the *Stockholm scale*, which separately grades each hand for peripheral vascular loss (Table 105.2) and sensorineural loss (Table 105.3). This modified system was requested by the international medical community because it was found that some HAVS patients never advanced to the finger blanching stages and only the early neurological stages occured with vibration exposure (12).

Table 105.1. Taylor–Pelmear Medical Classification System for HAV Syndrome[a]

Stage	Condition of Digits	Work and Social Interference
0	No blanching of digits	No complaints
OT, ON or TN	Intermittent tingling, numbness, or both	No interference with activities
1	Blanching of one or more fingertips with or without tingling and numbness	No interference with activities
2	Blanching of one or more fingers with numbness; usually confined to winter	Slight interference with home and social activities; no interference at work
3	Extensive blanching; frequent episodes, summer as well as winter	Definite interference at work, at home, and with social activities; restriction of hobbies
4	Extensive blanching; most fingers; frequent episodes, summer and winter	Occupation changed to avoid further vibration exposure because of severity of symptoms and signs

[a] Adapted from Ref. 9.

Table 105.2. Stockholm (Modified Taylor–Pelmear) Peripheral Vascular Classification System for HAV Syndrome[a]

Stage	Grade	Description
0		No attacks
1	Mild	Occasional attacks affecting only the tips of one or more fingers
2	Moderate	Occasional attacks affecting distal and middle (rarely also proximal) phalanges of one or more fingers

3	Severe	Frequent attacks affecting all phalanges of most fingers
4	Very severe	As in stage 3, with trophic skin changes in the fingertips

[a] Adapted from Ref. 4.

Table 105.3. Stockholm (Modified Taylor–Pelmear) Sensorineural Classification System for HAV Syndrome[a]

Stages[a]	Symptoms
0SN	Exposed to vibration but no symptoms
1SN	Intermittent numbness, with or without tingling
2SN	Intermittent or persistent numbness, reduced sensory perception
3SN	Intermittent or persistent numbness, reduced tactile discrimination and/or manipulative dexterity

[a] Adapted from Ref. 4.

Although the major components of HAVS are neurological and peripheral vascular, there are other conditions related to HAV exposure which are suspect but less documentated; these include some prevalence of elbow and wrist osteoarthritis and some damage to the articular cartilage due to impact tool vibration exposure (13) and a tonic vibration reflex that reduces tactile sensibility because the hand muscles are involuntarily contracting (14). The occurence of HAV-induced *carpal tunnel syndrome* (CTS), a compression syndrome, with or without HAVS (4, 5) can also occur. A combined medical treatment is needed for both CTS and HAVS.

Worldwide there have been numerous epidemiology studies of vibration-induced HAVS over the years. It is common to discover about a 50% prevalence of HAVS with relatively short latent periods of 1–2.5 years in foundry workers, for example, using vibrating pneumatic handtools (4, 5, 9–11, 15).

2.2 Hand–Arm Vibration Measurements (2, 4, 5)

Only the salient aspects of measuring both HAV and WBV in the workplace are discussed here. It is beyond the scope of this chapter to present the numerous details of this process, which are available elsewhere (2).

2.2.1 Premeasurement First, it is not advisable to attempt vibration measurements without careful planning; it is advisable to initially perform a “walk through” visit before conducting any vibration measurements, preferably with a portable videocamcorder, recording those vibration processes that are to be measured together with personal taped narration. Try to observe both new and experienced workers performing the same or similar vibration tasks. Later replay the video at normal speed and then in slow motion to observe how the worker(s) interact with the vibration process. Recognize that many work processes can be divided into a series of work, rest, vibration, and nonvibration steps; these steps and the vibration work cycle form the basis of the required measurements. Finally, plan how, when, and where the vibration measurements will be made for minimal disruption of production lines, and so on. When possible, test adjacent to, but not directly in, the actual production line area using experienced workers performing their regular tasks in a normal manner. Sometimes off-hour testing can be done, using experienced workers to avoid work disruptions. During testing it is advisable to maintain both written test logs and a videotape of the actual vibration measurements.

2.2.2 Workplace Vibration Testing Occupational vibration testing consists of the basic elements

shown in Figure 105.3. For a single HAV measurement, three axes (*viz.*, triaxial), mutually perpendicular, linear, rms acceleration measurements are required to quantify, record, and analyze the vibration impinging on a worker's hand. When both hands operate a tool, two triaxial simultaneous measurements are needed.

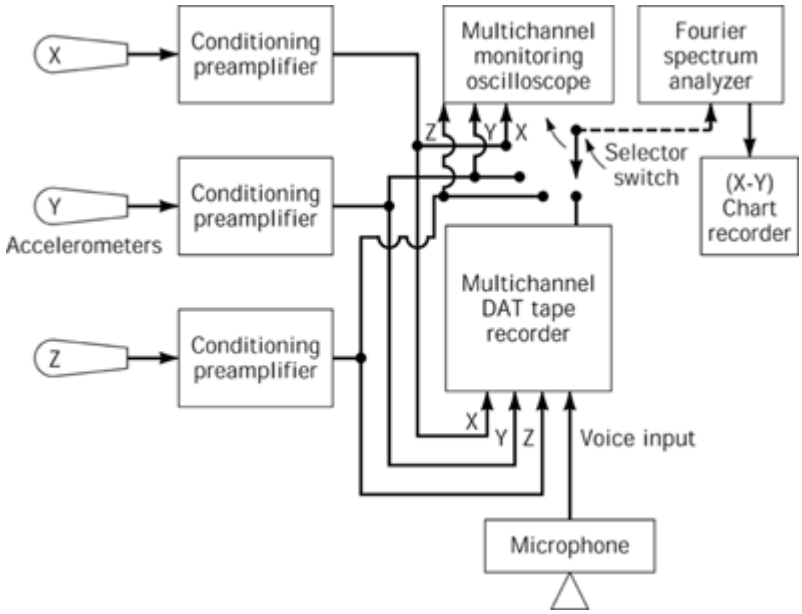

Figure 105.3. Typical equipment setup used to measure occupational hand–arm or whole-body vibration (adapted from Ref. 2).

All accelerometers used should be identical, very lightweight (<15 g each), piezoelectric/quartz crystal devices. Quartz crystal is a force transducer normally found in nature and is strongly *piezoelectric*, becoming electrically polarized with a negative charge on one end and a positive charge on its opposite end when subjected to mechanical force or pressure. The bonding of a small, light, mass to a quartz crystal transforms this natural force transducer into an accelerometer. An acceleration signal results when an external vibration force is applied to the accelerometer, and this small mass presses or accelerates against the crystal, resulting in a corresponding electrical charge; the effect is to simulate Newton's law, $F = ma$.

Finally, since the electrical impedance of an accelerometer is very high, it is difficult to directly extract and use this charge signal from the device; thus a *charge amplifier* is used with the accelerometer to both amplify and convert its charge into a corresponding useable electrical voltage.

Using this instrumentation, HAV testing basically consists of

- First, calibrating and recording each accelerometer to be used for testing, using a calibrator traceable to the National Bureau of Standards.
- For each hand position on the tool, mounting and orientating each triaxial accelerometer using the "basicentric coordinate system" shown in Fig. 105.1.
- The selection and mounting of each triaxial accelerometer and fixturing needs be done with care and must be tightly clamped to the tool to avoid internal resonances in the measurement system, which can result in incorrect results.
- A minimum collection time of one minute of continuous vibration data at each tool/hand position is needed. All three (or six) charge amplifier acceleration outputs are simultaneously recorded on a multitrack tape recorder called a *digital audio tape* or (DAT) for later analysis.
- Each recorded vibration data channel requires a separate spectrum analysis to be performed and each result separately compared to the HAV standards currently used in the United States.

- Most human standards contain *weighting functions* that must be taken into account when using these standards.
- There are a few commercially available portable, handheld, numerical readout, triaxial, vibration meters that contain HAV and/or WBV weighting functions in their software. They are primarily used as survey meters to assess whether a vibration problem may in fact exist. They are not Fourier spectrum analyzers and thus have limited use in clarifying and quantifying the problem once found.

2.2.3 Human Vibration Weighting Functions (2, 4, 5) Human response to vibration is not necessarily *linear*, which simply means that one unit of vibration impinging on the human body for a given time does not necessarily produce a corresponding one unit of biological damage. An example of nonlinearity is at resonant frequencies where the human body responds to a very small vibration excitation input, by internally amplifying and exacerbating the input vibration as much as twice, 3 times or more. Nonlinearity is not unusual for the human body; for example, it is well known that the human ear responds to sounds nonlinearly. Other body sensors most likely respond nonlinearly.

In human vibration, this nonlinearity has led to the development of *weighted human response functions*, which represent attempts to generate exposure-time-dependent dose–response relationships for HAV (and WBV). Thus weighting functions try to simulate how humans respond to impinging vibration; it is an evolving process as the scientific database improves with new knowledge. Most human vibration standards use weighting functions to help evaluate whether a given standard has been exceeded. The weighting function used for HAV is not the same as those used for WBV. Thus each weighting function is presented separately as the respective HAV and WBV standards are described individually.

2.3 Hand–Arm Vibration Standards and Guides Used in the United States

Currently three HAV standards and guides are used in the United States for occupational safety and health purposes:

- American Conference of Governmental Industrial Hygienists (ACGIH) standard for HAV (16), first issued in 1984.
- American National Standards Institute (ANSI) HAV standard (17), #S3.34, first issued in 1986.
- National Institute for Occupational Safety & Health (NIOSH) *Criteria for a Recommended Hand–Arm Vibration Standard* (18), #89–106, first issued in 1989.

At this writing the Occupational Safety and Health Administration (OSHA) has not issued any standard for HAV. The above ACGIH and ANSI documents listed above are *consensus standards*. There are two international HAV standards *not* used for safety and health purposes in the United States, issued by the International Standards Organization, ISO 5349 and ISO 8662. ISO 5349 provides some limited guidance for health and safety but provides no daily exposure limits for hand–arm vibration syndrome; rather, it defers to each country to determine such guidance. ISO 8662 is a multipart-tool-specific-limited measurement document used mainly by various tool manufacturers. This document clearly states that it is *not* intended for safety and health purposes. The European Community (EC) of nations has issued exposure limits for HAV and affects U.S. and other products sold in EC countries.

2.3.1 Hand–Arm Vibration Standards and Guides and the Weighting Function (*Caution*: It is imperative that a complete up-to-date copy of the applicable HAV standard be obtained, read, and understood by the user *before* attempting measurements or data evaluation, since descriptions given herein are for information only and are not exhaustive.)

Figure 105.4).X shows the graphical version of HAV weighting function used for both the ACGIH and ANSI standards; the shape of this function is defined by the family of parallel “elbow”-shaped HAV exposure-time-dependent curves and exposure zones ranging from 0.5 to 8 h/day. This same graph is used three separate times with the aforementioned results of the Fourier Spectrum analysis;

once with the tool spectrum for the *x*-axis acceleration, again with the spectrum for the *y*-axis acceleration, and finally again with the spectrum for the *z*-axis acceleration. The graph's abscissa shows the broad frequency range in $\frac{1}{3}$-octave bands extending from 5.6 to 1250 Hz, to accommodate the large number of different power tools that can be tested using these standards. Similarly, the graph's ordinate extends very high in rms acceleration intensity to 1000 m/s^2; corresponding to approximately 102 *g*.

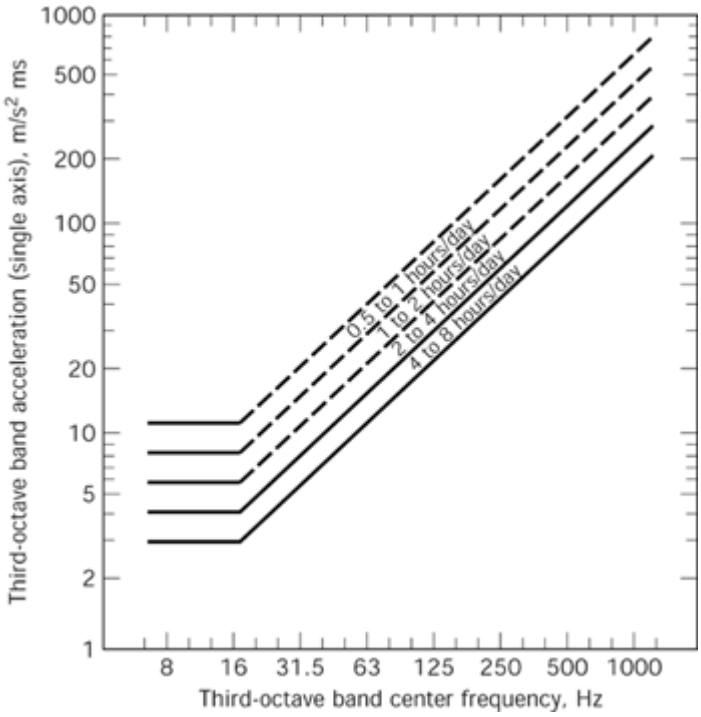

Figure 105.4. Hand–arm vibration weighted daily exposure zones used in the ANSI S3.34 standard.

In practice, for each measurement axis, a programmed Fourier computer automatically:

1. The computer calculates the entire unweighted vibration spectrum.
2. The computer compares and "overlays" this spectrum across the weighting graph (see example in Fig. 105.4
3. The computer numerically calculates the *overall weighted acceleration intensity* across this spectrum.
4. The interpretation of the *weighted* results are mainly based on the given HAV standard used as follows:

*ANSI S3.34*uses graphical evaluation criteria such that when no peak in the spectra either touches or pierces through any daily exposure zone in the family of weighted curves, that axis acceleration has passed the standard. Should one or more spectral peaks touch and/or pierce any of the exposure curves at any place(s) on these curves, the standard has been exceeded for that axis. The higher the peak(s) touching/piercing these curves, the higher the acceleration intensity and thus the shorter the allowable daily exposure time the worker is permitted to use the tool. Each of the three axes spectra is processed in the same manner. Usually the axis with the highest (acceleration intensity) peak(s) "dominates" over the other two axes. This dominant axis then determines the maximum permissible daily HAV exposure a worker can be subjected to when using the tested tool.

The *ACGIH standard* uses only the aforementioned weighted numerical *values* and separately assesses each of the computer's overall weighted rms values for each tested axis against those in

Table 105.4. Once again the largest overall weighted acceleration value dominates over the other two axes values. The dominant weighted value determines the daily permissible exposure levels for the tested tool. Both ANSI S3.34 and the ACGIH standards correlate well with each other, yielding similar, but not necessarily indentical, daily HAV exposure recommendations. It is important to note that these two standards try to minimize the potential of HAVS blanching in most workers, not necessarily the initial stages of finger tingling and/or numbness. Finally, a *time-weighted average* can be calculated for daily intermittent tool use and applied accordingly to the above two standards.

Table 105.4. ACGIH Threshold Limit Values®–Standard for Daily Exposure to HAV for Each Linear Vibration Axis[a]

Total Daily Exposure Duration (h)[b]	Values of the Dominant,[c] Frequency-Weighted, RMS, Component Acceleration, Which Shall Not be Exceeded[d] $a_{K'}$ (aK_{eg})	
	m/s^2	*g*
4–8	4	0.40
2–4	6	0.61
1–2	8	0.81
< 1	12	1.22

[a] Courtesy of ACGIH.
[c] Usually one axis of vibration is dominant over the remaining two axis. If one or more vibration axis exceeds the total daily exposure, then TLV has been exceeded.
[d] 1*g*=9.81 m/s^2.
[b] The total time vibration enters the hand per day; whether continously or intermittently.

The *European Community's* evaluation is also weighted numerically as a *vector sum*. This requires that *each* of the three axes overall weighted rms values be individually squared and then summed; the square root of this summed value is obtained, resulting in a vector sum value that is numerically compared to, and should not exceed, the EC "action level" of 2.5 m/s^2 (rms) acceleration for 8 h/day HAV exposure (19).

The *NIOSH HAV standard #89-106* does not contain permissible daily values for HAV workplace exposure (18). Administratively, NIOSH has chosen to issue an interim HAV document citing the need for a better dose–response relationship for HAVS, while agreeing that HAVS is a serious occupational health problem. The NIOSH document cites various administrative measures that can be taken in order to help minimize HAVS. This document also recommends collecting and analyzing both weighted and unweighted triaxial vibration data that have been extended in the upper frequency range to 5000 Hz. This extended frequency range, says NIOSH, is needed because of the recent introduction of some very high speed tools in selected industries. At this writing this NIOSH interim document appears to have limited value for HAVS and it has not been adopted by OSHA.

2.4 Hand–Arm Vibration Control in the Workplace

The control of hand–arm vibration (2, 4, 5) includes the following:

- Use power tools that are *both* anti vibration (A/V) *and* ergonomically designed. If a tool is only ergonomically designed without a corresponding reduction in its vibration levels, then most likely the potential of HAVS will be increased because of the better match between the hand and the tool handle. If a tool's acceleration levels have been reduced and the body and handle design are not ergonomically correct, then other cumulative trauma disorders, such as CTS, can be expected.
- Avoid the use of so-called vibration protective tool handle "wraps;" although inexpensive, many

are minimally effective at reducing vibration exposure, especially at low frequencies. These wraps also increase tool handle diameter and can lead to other cumulative trauma disorders.

- For personal protection, use only good-fitting *full-finger-protected* gloves. Since HAVS begins at the fingertips and then moves down toward the palm, gloves where only the palm is protected and the "fingers remain exposed" *do not* protect the worker from HAVS and are *not* recommended.
- In places where fixed workstations exist, use tool balancers and, where possible, antitorque devices. The former effectively removes the tool weight from the operator, the latter reduces some of the "twisting" or rotational tool motion.
- Comply with the aforementioned HAV standards.
- Workers should let the tool do the work using as light a grip strength as necessary to maintain safe tool operation; maintain the tools properly and replace as needed—operate tools at reduced speeds if possible; keep their hands and bodies dry and warm; avoid smoking, since cold, vibration, and nicotine all constrict blood vessels; see a physican immediately if signs and symptoms of HAVS occur, and adhere to manufacturer's vibration warnings on the tools and/or instruction books.

Occupational Vibration
Donald E. Wasserman, MSEE, MBA

3 Whole-Body Vibration
3.1 Epidemiology and Health Effects
Some 7 million workers (1) in the United States alone are exposed to head-to-toe whole-body vibration (WBV). These workers include truck, bus, forklift, heavy-equipment, farm vehicle, overhead crane, subway, locomotive, ship, fixed-wing aircraft, and helicopter drivers and operators. There are potential safety consequences and documented health effects of chronic occupational WBV exposure (2, 20–22). Historically, in the 1960s and 1970s, much of the initial and basic WBV research was conducted by U.S. Air Force, Navy, and Army laboratories in an effort to determine the ability of military personnel such as aircraft pilots, tank operators, and naval personnel to successfully execute their mission requirements. This experimental testing was conducted mostly under (acute) simulated or actual WBV military conditions. These studies were concerned primarily with human performance measures and not necessarily chronic health issues. The overall results of this military effort led to the following:

- The determination of WBV human resonances (23).
- The mathematical modeling of human mechanical response to WBV (23–25).
- The determination of the overall WBV human response weighting functions used in many standards today (26).
- The determination that under certain WBV conditions, human performance decrements can and do occur (26, 27).
- The issue of *chronic* WBV exposure effects was not addessed by these military studies; rather, it remained for other nonmilitary researchers to later investigate.

Relevant history shows that with the passage of the U.S. Occupational Safety & Health Act of 1970 and the subsequent creation of U.S. National Institute for Occupational Safety & Health, NIOSH chose to establish its first occupational vibration program (28). As part of this early NIOSH program, an extensive series of WBV epidemiological medical records studies, with control groups, were conducted of heavy-equipment operators (29, 30), and over-the-road truck (31) and bus drivers (32), all in an effort to help determine the *chronic effects* of occupational WBV exposure. The

summarized results of these early epidemiological medical records studies follows:

- The bus driver study showed a significant excess of venous, bowel, respiratory, muscular, and back disorders in a group of 1448 interstate bus drivers as compared to two control groups: office workers and the general population. This study concluded that the combined effects of body posture, postural fatigue, dietary habits, and WBV appear to contribute to the occurrence of these disorders.
- The truck driver study looked at 3205 long-haul truck drivers and a control group of air-traffic controllers. The results showed the truck drivers significantly suffered from the combined effects of forced body posture, handling cargo, WBV, and poor eating habits contributed to their vertebral pain, spinal deformities, sprains and strains, and hemorrhoids.
- There were two heavy equipment operators studies; the first study examined several hundred health claims of operators and showed they had elevated risks of certain musculoskeletal diseases, male genital diseases, ischemic heart disease, and obesity. The second study was a follow-up to determine whether these workers left their jobs due to WBV; the study results were equivocal.

These early epidemiology studies served to point the NIOSH vibration program in the direction of musculoskeletal and spinal disorders associated with WBV exposure. Some study results were confounded with similar spinal disorders in workers who both lifted cargo and were exposed to WBV (*i.e.*, while operating vehicles for long time periods in over-the-road bus and truck driving).

Subsequent WBV studies by other investigators, confirmed the thesis that chronic WBV exposure was and is associated with lumbar spine herniated disks and low-back pain (33, 34) and related degenerative spinal disks diseases (20–22). Laboratory studies of Wilder and Pope in the United States (35–37) and Dupuis, in Germany (22), and others began and continue to elucidate the biomechanical mechanisms of the human spine's response to WBV exposure. The summarized salient relationships of WBV exposure and the human spine are as follows:

- The (lumbar) spine has its own resonance at 4.5–5.5 Hz; located at L3–downward; in the vertical WBV direction; when the spinal dis pressure is at its maximum.
- When persons are seated, their lumbar spine vertebral facets normally disengage, leading to prestressing of the lumbar discs and limited rotation. When WBV occurs, for example, during the driving of a vehicle, this causes alternate stretching and rotation of these discs with maximum response occuring at the spinal resonance.
- During WBV exposure, lumbar discs can slide (prolapse); disks can tear; disk distortion, flattening, or increased height can occur; or herniation or a break in the disk can occur with a leaking out of its rubbery pulposus. Disk thinning can occur because of moisture reduction caused by WBV exposure.
- Vertically applied WBV creates an overload of the motion segments leading to disk buckling and instability; pelvic rocking can also result.

Thus, undeniably, the spine is a major target organ for WBV exposure.

3.1.1 Whole-Body Vibration and Work-Hardening (38) Inappropriately, medical rehabilitation specialists have begun to use WBV as part of “work hardening” simulation regimes used for the rehabilitation of vehicle drivers, many of whom have undergone back surgery and other medical procedures. WBV is *not* therapeutic and is definitely *not advised* in the work-hardening situations, since it could do serious harm to these patients! The reasons should be in part obvious:

1. As stated, WBV has been identified as one major cause of severe spinal problems.
2. The ability of the human spine, the autonomic nervous system, and the spinal musculature to respond to impinging (sudden-load) WBV is very limited, since it both lags and is out of phase with the input by as much as 120 ms; also, visual, proprioceptive, and vestibular responses

triggered by changes in posture take some 150 ms; and voluntary reaction time with latency take another 180 ms. Thus the human body cannot respond and adjust quickly enough to impinging WBV without potential damage.

3. Because the spine has its own resonant frequency of 4.5–5.5 Hz, should the source's impinging vibration contain these frequencies, the spine will amplify and exacerbate the effects of the input vibration.

In conclusion, because of the foregoing, WBV should *not* be used in work-hardening simulation regimes.

3.1.2 Other Medical Effects of Whole-Body Vibration Virtually all WBV epidemiology studies conducted to date have been of exposed male workers and not females (39–44). A major reason has been that until recently most of these WBV-exposed jobs were male dominated and suitable female study populations did not exist. Of growing concern, however, have been a number of reports of pregnant female vehicle drivers spontaneously aborting their fetuses as well as cases of other gynecological disorders in female drivers. These reports have prompted new and ongoing animal research studies in this area to determine the effects of WBV exposure on both the pregnant mother and the fetus.

3.2 Safety Aspects of Whole-Body Vibration

Many of the early studies of human subjects exposed to WBV were concerned with either "performance effects and/or comfort effects." The former was of primary concern to the military to ensure safe mission success; the latter was of concern to automobile and other vehicle manufacturers to design and sell comfortable products (21, 25, 45). Some of these first studies focused on the perception of magnitude (acceleration intensity), vibration frequency dependence, exposure time, and the effects of using seatbelt and other body restraint systems. These study results led in part to the early conclusions that a person's perceived endurance to WBV was both frequency-and magnitude-dependent, with the lowest tolerance occurring in the 4–8-Hz resonance band for seated subjects exposed to vertical WBV. This is a potential safety issue. Some early study designs consisted of various progressive multidimensional tracking tasks, memory and simple mathematical tasks, and pattern and visual monitoring (both of which appear to be minimally affected by WBV). Another related performance issue is of great safety concern: the "direct mechanical effects on performance." For those exposed to WBV while driving a vehicle, it is not always possible for a driver's hand(s) to safely control and grasp a steering wheel when a resonant frequency situation occurs, because of the involuntary "mechanical decoupling" between the hand and the steering wheel. Resonant vibration can potentially pose great difficulty in maintaining a safe grip on the steering wheel. Thus it is possible to envisage a situation where a truck driver, for example, encounters a resonant vibration condition through either the driver's seat and/or the steering wheel, which is triggered by driving off-road or over a series of potholes. The driver next loses control of the steering wheel, resulting in an accident or worse ... . a definite safety issue.

3.2.1 Whole-Body Vibration and the "Root Mean Quad" Discomfort Factor (21) Although discomfort is not in the forte of occupational health and safety, it is important that the reader appreciate the difficulty involved in assessing, in a simple measure, the numerous types of WBV motion encountered in various real-world situations. For example, in 1990, Griffin in Britain empirically determined that a reasonable measure of subjective discomfort due to WBV was related to the exposure time multiplied by the impinging acceleration raised to the Fourth power, using his *root-mean quad* (rmq) method, rather than the customary method of time multiplied by the acceleration square, or

$$a^4 t = \text{constant} \tag{4}$$

By introducing the Fourth-power concept, Griffin hoped that a wide variety of WBV motions "from individual bumps and repeated impacts to intermittent vibration and long-duration continuous vibration" (21) could all be simply taken into account by these rmq averaging proceedures. Although

his concept is now well known, it is not universally accepted; it appears to be of significant value when distinguishing between the comfort of various seating used in vehicles. Unfortunately, there have been attempts to use rmq methods to expand into the health aspects of WBV exposure. At this writing, there are *no* hard medical or epidemiological studies to justify the use of the rmq method to be used with medical assessments of WBV exposures. Work continues in this area.

3.3 Whole-Body Vibration Measurements

The basic elements shown in Figure 105.3 for HAV also apply to WBV measurements (2), but with differences in the actual hardware and software used for WBV measurements and data analysis.

3.3.1 The Piezoresistive Accelerometer WBV measurements usually require another different type of triaxial device known as a *piezoresistive accelerometer* rather than a *piezoelectric* accelerometer. The former accelerometer is suitable for very low frequency (WBV) use; the latter, for higher frequency (HAV) use. Refer to Figure 105.5, noting that

- Piezoresistive accelerometers are composed of four separate and identical pieces of the same type of semiconductor material, either P or N type (positive or negative).
- Each semiconductor element forms one “arm” of a classic four-arm Wheatstone electric bridge.
- Each bridge arm is physically arranged as side-by pair: one upper pair and one lower pair.
- One end of a small metal beam is next sandwiched and pinned between these two sets of semiconductor pairs, thus constraining the beam's movement at this pinned end. The opposite end of this metal beam protrudes outward beyond the constraining sandwich and is free to flex up and down when vibration is applied, similar to a flexible diving board pinned at one end.
- Vibration force applied to the free end of this beam moving in one direction causes it to bend, compressing one pair of the semiconductor devices, thus creating an “electrical unbalance” and a corresponding electrical signal voltage. A vibration force applied to this beam in the opposite direction compresses the opposite pair of semiconductor devices, creating another corresponding electrical voltage of the opposite polarity. A constant bending force (0 Hz) applied to the free end of the beam causes a constant output voltage to appear and remain until the force is removed. Thereupon the beam returns to its original neutral position, rebalancing the electrical bridge with zero output voltage.
- This device thus far is a classic force gauge, *not* an accelerometer. Placing and fixing a small mass at the free end of the beam transforms this force gauge into an accelerometer, using Newton's law, $F = ma$. When vibration is applied to the mass, it accelerates against the free end of the metal beam, causing it to bend and thus creating an output “acceleration” voltage.
- This accelerometer works well at low vibration frequencies down to 0 Hz. Since semiconductor materials are used as the bridge elements, the device is ambient-temperature-sensitive and must be purchased with a small external temperature-compensation module.
- Since this device is configured as a Wheatstone bridge, a single external DC voltage source is needed to power the bridge, usually a small stable battery. The bridge output voltage is measured “differentially” between two bridge arms using a differential voltage amplifier; *not* a charge amplifier as was used with HAV piezoelectric devices.

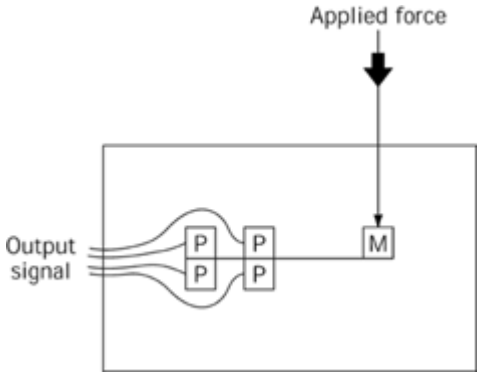

Figure 105.5. Operating principle and construction of piezoresistive accelerometers used for whole-body vibration measurements (adapted from Ref. 2).

3.3.2 WBV Mounting and Positioning The WBV measuring system usually consists of three piezoresistive accelerometers, each mounted mutually perpendicular (triaxially) to a metal cube. This cube and triaxial accelerometers are placed in the hollow center of a hard-rubber pie-plate-type disk (see Fig. 105.6). This instrumentated disk, in turn, can be used in many ways; frequently it is placed on a driver's seat cushion top with the driver actually sitting on the disk. The vibration so measured is the triaxial acceleration entering the lower spine. When a second instrumentated triaxial disk is mounted under the driver's seat, vibration transmissibility can be determined and the effectiveness of the seat as a vibration damper can be determined. If a worker is standing in a WBV situation, then the instrumentated disk can be appropriately placed near the feet. The axes orientation of the triaxial accelerometers and the disk is as shown in Figure 105.2.

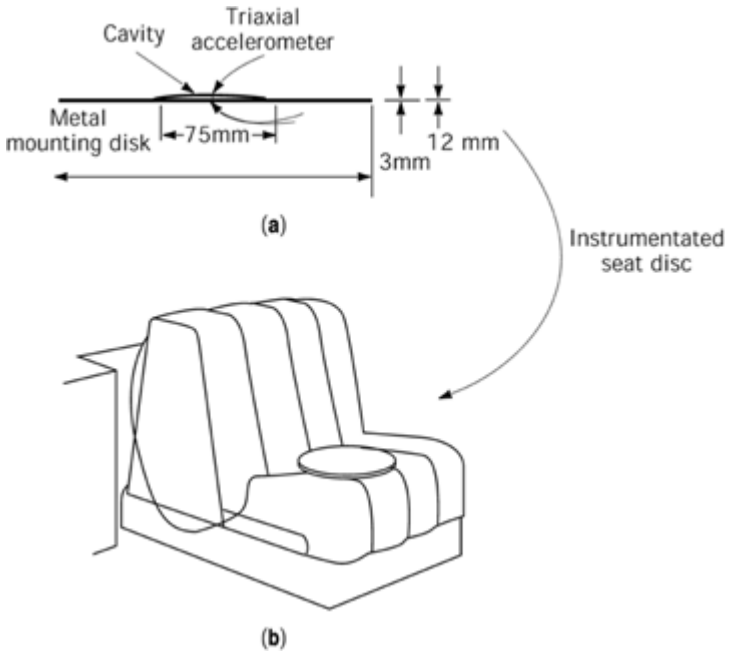

Figure 105.6. (**a**) Instrumentated triaxial accelerometer hard-rubber seat disk used for (**b**) whole-body vibration measurements (adapted from Ref. 2).

3.3.3 WBV Data Analysis WBV measurements first require triaxial calibrations to be performed and recorded; triaxial measurements are next all simultaneously recorded on separate data tracks using a DAT recorder for later Fourier spectrum analysis. The actual WBV measurement time depends to a great extent on the WBV task cycle time involved, since driving buses, trucks, trains, and other vehicles can easily extend from several minutes to hours. Measurements of as many complete work

cycles as feasible is desired. WBV data reduction analysis can therefore be a large task and must include calculations of *different* weighting functions for each vibration axis, as compared to HAV data analysis, which uses the *same* weighting function for each of the three measurement axes. Once data analysis is completed, the results need to be compared to the appropriate WBV standards.

3.4 Whole-Body Vibration Standards and Guides used in the United States

Currently there are two WBV standards/guides used in the United States for occupational safety and health:

- American National Standards Institute (ANSI) WBV standard (46), S3.18, first issued in 1979
- American Conference of Governmental Industrial Hygienists (ACGIH) standard for WBV (47), first issued in 1996

Note: At this writing neither OSHA nor NIOSH have issued any WBV standard. These ANSI and ACGIH documents are both "consensus standard." Salient parts of both the ANSI and ACGIH standards have been derived from international WBV standard (48), ISO 2631, which was first issued in 1972. Major changes to ISO 2631 were adopted in 1998 and are not reflected in either of the WBV standards listed above. There is a special ANSI standard for WBV exposure in buildings (49), ANSI S3.29, which in great part was derived from both ISO 2631 and ANSI S3.18. Also, The European Community (EC) has issued exposure limits for WBV and HAV (19); the former will be briefly discussed, the latter has already been discussed.

3.4.1 WBV Standards and Weighting Functions It is imperative that a complete up-to-date copy of the applicable WBV standard be obtained, read, and understood by the user *before* attempting measurements or data evaluation, since descriptions given herein are for information only and are not exhaustive.)

Figures 105.7Fig. 105.7 and 105.8 show the graphical versions of the two different WBV weighting functions shared by used in both the ANSI and ACGIH standards. Figure 105.7 is used only for the "vertical, or *z*-axis" vibration. Figure 105.8 is used twice: once for the "side-to-side or *y*-axis" vibration, then separately again for the "front-to-back or *x*-axis" vibration. In particular, the shape of the weighting functions shown in Figures 105.7 and 105.8 are each defined by their respective families of parallel WBV exposure-time-dependent curves ranging from 1 min per day up to 2 h/day exposures. In, for the vertical *z*-axis, the U-shaped family of curves acknowledge that WBV vertical resonance occurs at 4–8 Hz and that permitted time-dependent daily exposures are minimized at resonance more than at other non resonant frequencies. The same is true for Figure 105.8, where resonance occurs at 1–2 Hz for either the *x* or *y* axes. Beware that these "elbow"-shaped family of curves are based on WBV resonance data in the *x* and *y* axes; these curves should *not* be confused with similar shaped HAV weighting curves (Fig. 105.4) described previously. Refer to both Figures 105.7 and 105.8 and note that the graph's abscissa show a frequency range of 1–80 Hz divided into $\frac{1}{3}$-octave bands to accommodate the large number of vehicles, trains, buses, aircraft, and so on that can be tested using these standards. Similarly, the graph's ordinate extends in rms acceleration intensity to 20 m/s^2 or about 2*g*. Although ANSI S3.18 and the ACGIH WBV standard both use the same graphical evaluation criteria, each uses the criteria differently.

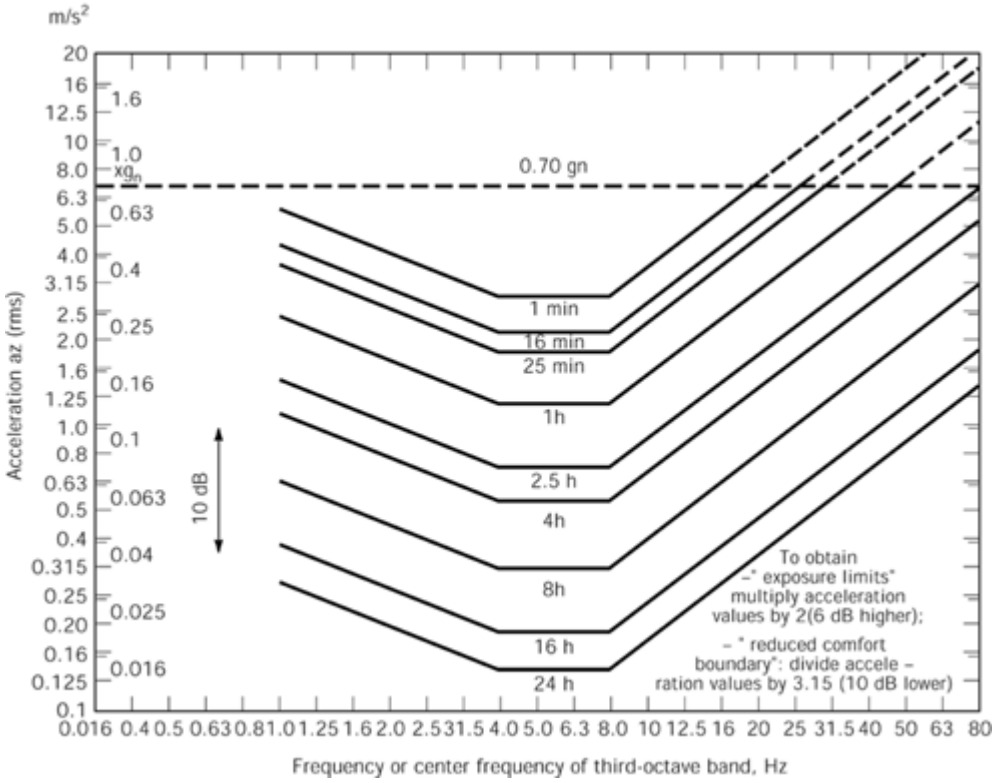

Figure 105.7. Whole-body vibration weighted *z* (vertical axis) daily exposure curves used by the ANSI S3.18 standard.

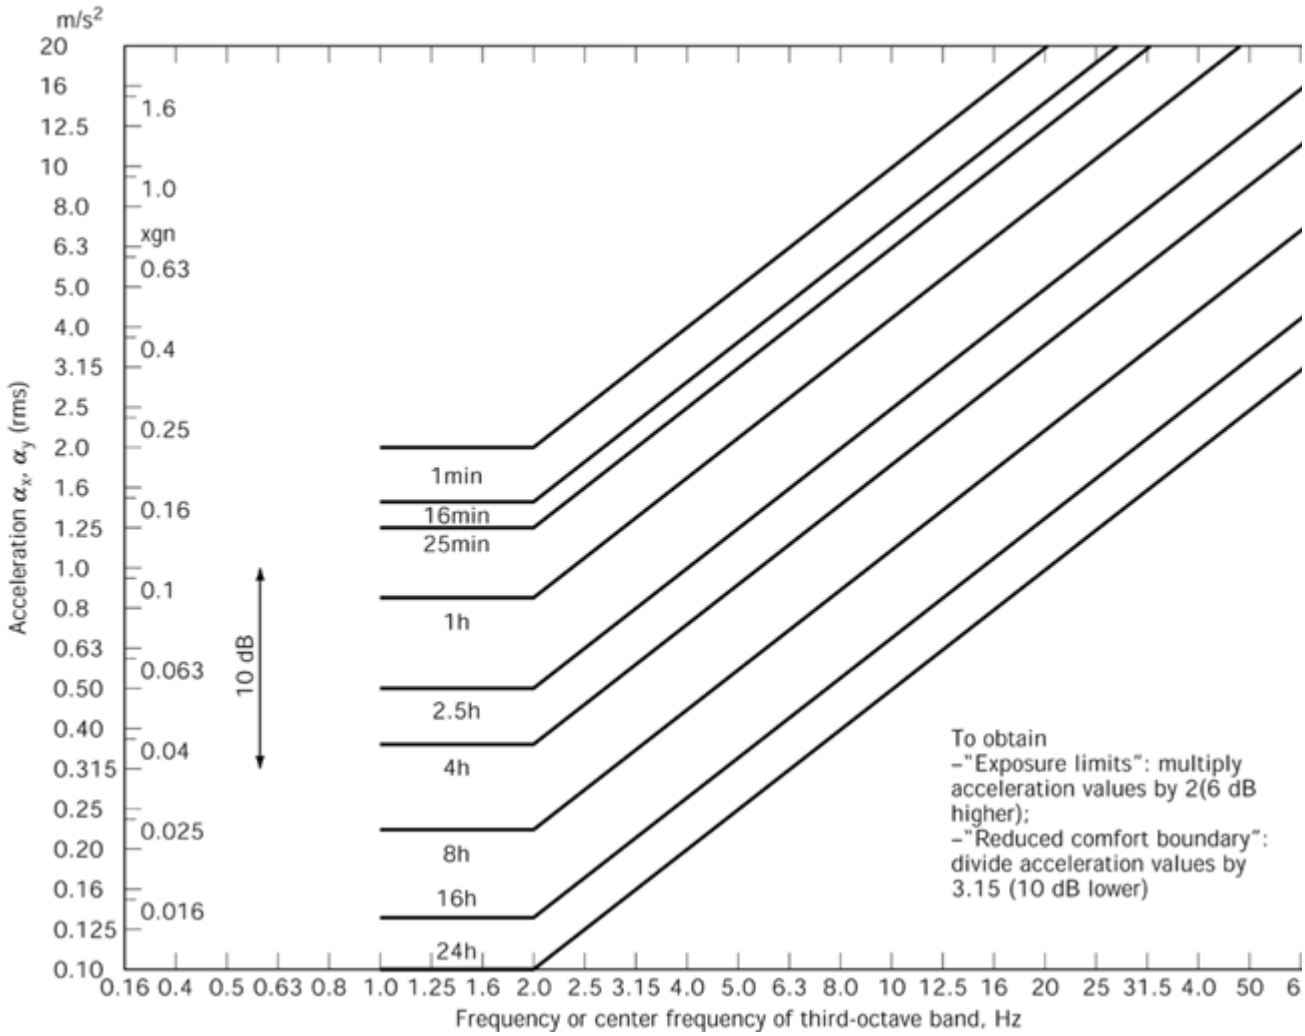

Figure 105.8. Whole-body vibration weighted *x* and *y* (transverse axes) daily exposure curves used in the ANSI S3.18 standard.

As adopted and used *only* in ANSI S3.18, in Figures 105.7 and 105.8 there are three distinct acceleration intensity criteria which can be evaluated depending on the study needs: fatigue-decreased proficiency (FDP); reduced comfort (RC), and exposure limits (EL). FDP curves are essentially concerned with performance effects of WBV. The RC curves are concerned with comfort. The EL curves are concerned with health effects of WBV. First, the FDP curves are directly shown in Figures 105.7 and 105.8. To determine the RC exposure boundaries, divide the FDP acceleration values by 3.15 (10 dB lower). The EL limits are obtained by multiplying the FDP acceleration by 2 (6 dB higher). In using this standard, it is important to inform you the reader that since the FDP, RC, and EL curves were developed in the early 1970s, experience has shown that the EL family of curves as used in ANSI S3.18 (and ISO 2631, before 1998) have been shown to be too permissive and *not* sufficiently worker-health-protective and thus the EL curves use is *not* advised by this author and others (2, 20). However, both the FDP and RC families of curves have been found effective and are recommended.

The *ACGIH standard* disregards all reference to the EL criteria, in all axes, and uses only the depicted FDP criteria shown in Figures 105.7 and 105.8 for both health and safety, without so naming these curves as FDP. Although useful, the RC curves are also unused in the ACGIH standard since it only addresses occupational health and safety issues and not comfort criteria.

3.4.2 Computer Analysis of WBV Data In practice, for each measurement axis, WBV triaxial data are simultaneosly collected and separately stored on a DAT recorder; a Fourier computer is then

used to analyze each data axis separately and automatically:

1. Calculates unweighted vibration spectra. For WBV, the spectral plots should first be determined by and subdivided into portions of the observed work cycle. Then all such spectral plots (for the same axis) are averaged into a single overall spectrum representing the entire work cycle in that axis. This process repeated separately for all three (*x,y,z*) axes. Using this method allows one to not only observe the overall spectrum over the entire work cycle by axis, but also to compare spectral plots by axis, over parts of the work cycle and thus determining the relative acceleration intensity in each part of the work cycle.
2. The computer next compares and "overlays" each spectrum across the appropriate (FDP) weighting graph; Figure 105.7 is used only for the vertical *z* axis; Figure 105.8 is used separately twice, once for the *x* axis and again for the *y* axis.
3. The computer numerically calculates the "overall weighted acceleration intensity" for each spectral plot.
4. The interpretation of the "weighted" results are based mainly on the given WBV standard used as described in the following paragraph.

ANSI S3.18 and ACGIH standards both use the same FDP graphical evaluation criteria shown in Figures 105.7 and 105.8 such that when no peak in the spectra either touches or pierces through any daily exposure curve in any family of weighted curves, that axis acceleration has passed the standard. Should one or more spectral peaks touch and/or pierce any of the exposure curves at any place(s) on these curves, the standard has been exceeded for that axis. The higher the peak(s) touching or piercing these curves, the higher the acceleration intensity and thus the shorter the allowable daily exposure time the worker can be exposed to WBV. Each of the three axes spectra is processed as described using the appropriate weighting functions given in Figures 105.7 and 105.8. Usually the axis with the highest (acceleration intensity) peak(s) "dominates" over the remaining two axes. This dominant axis then determines the maximum permissible daily WBV exposure a worker can be subjected to when using the tested WBV product.

Finally, it is important to know the validity for the above mentioned WBV standards as a function of the data collected in the time domain and as analyzed in the frequency domain for each vibration axis. This question is best answered by first recalling the term "crest factor," which is equal to the ratio of peak acceleration divided by rms acceleration, obtained over a one-minute period of WBV exposure time-domain data. By definition crest factor is a dimensionless number. The data collected and analyzed using the above WBV standards are valid for crest factors less or equal to the number 6. Crest factors exceeding the number 6 in the collected (time-domain) data, will result in an *underestimation* of the true results of the analyzed weighted WBV data. The higher the crest factor above 6, the less accurate the predictive are the standards presented above.

The *European Community's* WBV evaluation (19) is weighted numerically as a "modified vector sum" per the following equation:

$$a_{sum} = \sqrt{(1.4\,a_x)^2 + (1.4\,a_y)^2 + a_z^2} \qquad (5)$$

Equation (5) requires that first the numerical values for each axis' total weighted rms acceleration intensity value be determined. Next, only the *x* and *y* values are each multiplied by a constant value of 1.4, which represents the ratio of the values of the longitudinal and transverse curves of equal response in the most sensitive human response regions. The *z* axis has no multiplier. Next each of these axis values is squared and summed. Finally, the square root of this resultant value is obtained. This result is the "overall weighted total rms acceleration" and is compared to the EC 8-h "action level" of 0.5 m/s^2. In meeting this EC standard there are certain EC obligations and rules that must be followed should a product exceed the 0.5 m/s^2, 8-h WBV action level and be allowed to be used

in an EC country.

3.5 Control of WBV in the Workplace

Definitions of both vibration damping and isolation have been given previously. WBV control measures used in the workplace (2, 20, 21, 50) usually consist of protectively isolating the vibration source from the worker. For example, in common use are “air ride” isolated seats in many buses, trucks, heavy-equipment farm, and similar vehicles. These seats require a source of compressed air and operate effeciently to reduce 4–8 Hz WBV resonance vibration attempting to reach the spine. Air-ride seats with lumbar support, arm rests, and adjustable seat backs are highly recommended. In addition, many truck cabs use isolators and are suspended in addition to their use of air-ride seats. A properly tuned vehicle suspension and proper tire pressures will help reduce WBV.

Within plants, machines can be isolated from the floor and their vibration reduced; remote controls of machinery and processes using small videocameras can also be used to protect workers from WBV exposure. Using baloon tires in place of solid tires on forklift trucks can also help reduce WBV exposure. Contact the manufacturer first before doing so.

Finally, pregnant female operators should be especially careful to minimize WBV exposure (39, 51) and for all workers it is advisable to avoid lifting and bending immediately following WBV exposure (52, 53).

Occupational Vibration

4 Crossover and Combined Exposure to Hand–Arm and Whole-Body Vibration

As initially stated in this chapter, in most cases HAV exposure and WBV exposure are distinct and produce differing health consequences and require different control measures, but there are a few exceptions, such as using jackhammer-type tools, stand grinders, buffers, motorcycles, and water-powered skis.

It is important to appreciate that mechanical vibration must come into physical contact with the human body in order to produce the effects previously described in this chapter. Many times it is the *pathway into the body* that determines to a great extent the resulting health and safety effects workers experience from this stressor. When, for example, an operator uses a road ripper or jackhammer tool with arms extended away from the upper torso, one can expect potential HAVS; however, when the operator operates this same tool with the tool pressed against the abdomen and with arms close to the torso, nontraditionally vibration-induced medical problems can occur, such as a highly inflamed omentum (the veil-like sheath that covers the intestines) (54, 55). In a similar example using another powered tool, a male maintenance worker routinely operated a large vibrating floor-polishing-buffer machine “by holding it firmly against his lower abdomen. Ordinarily, hours of mechanical shaking of his abdomen caused no discomfort; however, on the night of his admission to the hospital, he had acute severe pain,” which was promptly diagnosed as a ruptured sigmoid colon and required surgery for correction (56). In both of these instances is the operators attempted to damp the power tool vibration using their abdomens and thus substituted HAV exposure for WBV exposure, causing *pathway changing* in the major vibration from entering the body via the hands to entering the body via the lower abdomen. The results were nontraditionally vibration-induced medical conditions because of the exposure “crossover” from HAV to WBV. Recall that these were normally hand-operated power tools. Another example, where many workers use floor-mounted “stand grinders” to remove outer metal flash from small castings (4, 5), one might expect WBV-related medical problems to develop because of the close whole-body coupling of this large machine to the worker's torso. Not so; instead, many of these workers routinely develop HAVS because the floor acts as a large reaction mass and damps the WBV but not HAV in contact with the hands. The vibration *pathway* into the worker's body is via the hands, which must firmly hold and press small castings

against the large grinder wheel to remove the excess metal flash.

Finally, a great pastime of many is to operate motor cycles, dirt bikes, water-powered skis, and similar, all of which represent significant exposures to *both* HAV and WBV (57).

In conclusion, observing the pathway vibration impinges on and then enters the human body is one key element to determining the potential destructive track vibration can leave in its wake, especially at resonance frequencies, which is the Achilles heal of human vulnerability to this insidious stressor.

Occupational Vibration
Donald E. Wasserman, MSEE, MBA

5 Summary
The salient aspects of recognition, measurement, evaluation, and control of both occupational hand–arm vibration and whole-body vibration have been presented. The physics of vibration is also given as the basis for and the interpretation of workplace vibration measurements, which are also described. Descriptions, interaction, and interpretation of the major occupational HAV and WBV standards and guides currently used in North America are presented. Comprehensive vibration control measures used to minimize worker exposure to both hand–arm and whole-body vibration are also discussed.

1 The Universal Nature of Pressure

1.1 The Pressure Continuum—From Deep Sea to Space

This chapter deals with the interrelated physiological effects of the continuum of altered ambient pressure. These pressures may be both higher and lower than the sea level pressure to which we are accustomed and in which we have evolved.

The chapter first discusses what pressure is, and where and why alternative pressures are encountered by humans. It reviews the occupational, medical, and recreational incentives for forays into both environments, high and low. It points out the role of time in evaluating pressure exposures and the importance of transitions to and from higher and lower pressures. Then, it covers first the effects of elevated pressures, then the effects of lack of pressure, emphasizing the importance of breathing gases in most alternative pressures. Last, it pays particular attention to the main pressure-related disorder, decompression sickness, and its treatment.

This is a book on industrial hygiene and toxicology, so the chapter deals primarily with healthy individuals fit for the workplace, but does mention the special concerns about pressure needed for people who have various diseases.

1.2 Where Is Pressure Found, and What Is It All About

A physics book defines pressure as force per unit area. The important thing for our purposes here is how pressure is exerted on the human body. Normally this is as gas pressure, such as that of the atmosphere. Pressure may also be exerted by a column of liquid, such as the water pressure encountered in diving. Pressure, as a force, is due to the weight of the atmosphere above or of a column of liquid, or more usually, a combination of both. Gas pressure is due to the kinetic energy of the molecules of gas; increasing pressure is due to an increasing number of molecular collisions. The pressure of a column of gas or liquid is exerted in all directions.

Humans encounter elevated pressure when they are under water or in chambers used to simulated water pressure. Pressure chambers are also used in medicine and in various industrial situations. Low pressures are encountered on ascent to altitude. This may be by ascending mountains, in aviation or space activities, or in chambers used for simulating altitude or for other purposes.

High pressure is given before low, because the concept of pressure as such is more cogent in that direction. The chapter initially tells where these pressure environments are encountered, then later shows the effects.

1.2.1 Pressure: Atmospheric, Absolute, and Differential

Although pressure may vary substantially due to location and weather conditions, the average or typical barometric pressure (P_B) at sea level is considered “atmospheric pressure” or a pressure of 1 atmosphere. This is the weight of the atmospheric air above mean sea level; it is called the standard atmosphere. A universally recognized value is defined for atmospheric pressure, and it is expressed in various units. Many pressures such as those in pressure vessels (“gauge pressure”) or those due to water pressure in the sea (“depth”) may be referenced to atmospheric pressure. The barometric pressure at depth is a gauge pressure (pressure in excess of sea level pressure, the total of sea level atmospheric pressure plus the water pressure).

Abnormal Pressures: Hyperbaric and Hypobaric

2 Effects of Pressure
2.1 Effects of Pressure Changes on Body Cavities That Contain Gas
This section discusses the effects of high pressures and of low pressures. It deals with a set of problems common to both environments, that of gas-filled spaces in the body. Because this is almost always the first thing to come to our attention when the ambient pressure changes, this section is first among the effects.

2.1.1 Expansion and Compression of Gas Spaces The body contains a number of gas-filled cavities that communicate in various degrees with the outside of the body. During changes in the ambient pressure, these spaces must equilibrate, or the individual will suffer adverse effects. The lungs, paranasal sinuses, and middle ears are semiclosed spaces, and the interior of the gut, as well as occasional spaces in teeth, are functionally closed (49). When pressure is reduced as a diver or aviator ascends, the volume of gas increases, and when pressure is increased or during descent, the reverse takes place. This is an effect of Boyle's law. Divers call an imbalance of pressure during descent a “squeeze.” Because these spaces are semiclosed and communicate with the ambient environment at various rates, the rate of change of pressure has a big impact on whether it causes problems.

2.1.1.1 Ears and Sinuses The middle-ear space is separated from the canal of the outer ear by the ear drum or tympanic membrane. The middle ears communicate with the nasopharynx by small tubes, the Eustachian tubes. The middle-ear portion of the Eustachian tube is lined with soft tissue so that the tube is not normally open. The outer pharyngeal end tends to form a one-way valve that allows gas to escape from the middle-ear when pressure is raised there, but prevents it from easily entering from the nasopharynx when pressure is lower in the middle ear (Figure 106.3).

Biological Rhythms, Shiftwork, and Occupational Health
Allene J. Scott MD, MPH,, Joseph LaDou, MD

A. Introduction

" ... and God divided the light from the darkness, and God called the light *day*, and the darkness He called *night*. And the evening and the morning were the first day" (Genesis 1:4–5, King James Version). Thus, as has been recognized for millennia, *Homo sapiens*, as well as all other living creatures on earth, are destined to live in a regular cycle of light and darkness, that is, the 24-h solar day. For diurnal species, such as human beings, the sunlight portion of the day is the time of activity and the dark, nighttime portion the time for sleeping. Periodicity is an integral part of life.

Although we are under the influence of environmental rhythms, such as the daylight–night cycle, we are also under the physiological influence of our own internal biological clock. Normally the synchronization of our biological rhythms with each other and with environmental rhythms (external time cues) maximizes our waking and sleeping performance and promotes overall well-being. Night work is opposed to the innate drive to sleep at night and work during the daytime. This unnatural mismatch of environmental and internal temporal influences is of concern for shiftworkers due to the often disruptive effect of schedule-related time shifts on the normal synchronization of individual biological rhythms with each other as well as with the external time cues.

This chapter reviews basic chronobiological principles as they relate to shiftworker safety and health. Studies dealing with the effects of time shifts on sleep and alertness are discussed as well as performance rhythms. Research exploring the consequences of shiftwork on physical and mental health is reviewed. Countermeasures for minimizing adverse health and safety effects of sleep deprivation and biological rhythm disruption are presented, including work scheduling considerations and medical surveillance. Industrial hygiene considerations related to control of worker exposure to potential toxins during extended and rotating shifts are presented. Finally, international and U.S. regulatory policy regarding shiftwork scheduling and special provisions for shiftworkers are reviewed.

Biological Rhythms, Shiftwork, and Occupational Health

1.0 Circadian Rhythms
1.0.1 Definitions
There is considerable terminology peculiar to the study of biological rhythms. The necessity of developing a consistent definition of terms for researchers in this field was recognized in the 1970s, leading to the publication of the *Glossary of Chronobiology* in 1977 (1). The most commonly used terms are briefly defined here to assist the reader unfamiliar with the field. Readers who plan to review the primary chronobiology literature may benefit from first studying the referenced glossary, which contains extensive examples and in depth discussion of the terms.

Biorhythm, in the true scientific meaning of the term, refers to a repeating pattern of a quantifiable biological parameter, which persists as a fundamental property of a living cell or organism under varied conditions of constancy in environmental factors. The term should be reserved for cyclical biological phenomenon meeting testable criteria. However, the term biorhythm has been misused by nonscientific interests promoting the somewhat mystical "biorhythm theory" of forecasting times of optimal physical and cognitive functioning. The science of chronobiology does not support the biorhythm theory, and discussions of biological rhythms in this chapter have no relevance to that nonscientific school of thought (2). Due to the frequent misuse of the term biorhythm by proponents of the biorhythm theory, which became a fad in the 1970s, the term *biological rhythm* is used in this chapter, and in general in the chronobiological literature.

Chronobiology is that discipline which studies biological rhythms. It is the science of objectively studying and quantifying mechanisms of biologic time structure. Subspecialities of chronobiology include chronophysiology, chronopathology, and chronopharmacology, which includes chronotoxicology and chronotherapy.

Circadian rhythm: The primary category of biological rhythms of interest for shiftworkers and frequent transmeridian jet travelers are circadian rhythms. The term *circadian* (Latin: *circa*, about; *dies*, a day) was first used by Halberg and associates (3) to denote a periodicity of *about* 24h, specifically 20–28h. Thus a circadian rhythm is a biological rhythm with a frequency of 1 cycle in 24±4h. (Rhythms with periods less than 20h are referred to as *ultradian* and periods greater than 28 as *infradian*).

Desynchronization refers to the condition when two or more rhythms, which had previously been synchronized (having the same frequency) with each other, have different frequencies and no longer have the same phase relationship. When desynchronization has occurred between a biological rhythm and an environmental cycle, the term *external desynchronization* applies. *Internal desynchronization* occurs when two or more biological rhythms within the same organism become desynchronized from each other. *Forced desynchronization* of biological rhythms refers to a research

condition in which subjects are isolated from normal 24-h time information, and abnormally long or short days are artificially imposed by scheduling the sleep–wake cycle to a period length outside the bounds of the circadian entrainment of the temperature rhythm.

Diurnal refers to events or activity occurring during the daylight portion of the 24-h day. The opposite of diurnal is nocturnal, meaning the period of activity occurs between sunset and sunrise. Human beings are diurnal creatures with their natural awake, activity hours occurring primarily between sunrise and sunset.

Entrainment refers to the coupling of an endogenous biological rhythm with a synchronizing trigger such that they share the same frequency. Biological rhythms can be entrained with an external cycle, such as the 24-h day (external entrainment) in response to an environmental time cue. Entrainment with other biological rhythms (internal entrainment) is effected by response to an internal pacemaker.

Free-running refers to rhythms that are self-sustaining biological rhythms, desynchronized from the environmental time schedule, but continuing to exhibit a regular cycle that has a systematic, changing phase relationship to the external time period.

Nychthermal refers to occurring under the normal conditions of daytime activity and sleep during the night. Chronobiological observations made under nychthermal conditions, such as the timing of the peak and trough of a biological rhythm and the rhythm amplitude, cannot be assumed to be the same when the activity and sleep times are inverted.

Phase relation refers to the time relation between two rhythms.

Zeitgeber (German: *Zeit*, time; *Geber*, giver) refers to an external synchronizing trigger or time cue capable of entraining a biological rhythm. A zeitgeber is thus an entraining agent.

1.0.2 Overview of Biological Rhythms

The most obvious environmental periodicity is day and night. Although the earth's rotation on its axis takes 23h, 56min, and 4s (the sideral day), the solar day, which is the time interval between noon of successive days, takes about 24h and 4min. Since the earth's orbit is slightly elliptical, the time of the solar day varies, but not by more than 16min from its mean of 24h 3'57". Thus 24h is an approximation of the day–night cycle, but a reasonable one when studying its effects on living organisms (4).

Numerous psychological and physiological variables have been found to have a demonstrable 24-h rhythm, such as body temperature, the sleep–wake cycle, cardiovascular parameters, alertness and cognitive performance, endocrine and metabolic factors, therapeutic responsiveness to certain medications as well as sensitivity to toxic agents, and psychological variables of mood and anxiety. It should be noted that often there is not a simple two-state description of a parameter's rhythm with a maximum level and a minimum, but instead there is a continuous variation during the 24-h period, with a “peak” and “trough” usually coinciding with the natural light and darkness cycle (5). Some variables have rhythms that, when recorded with frequent measurements, are seen not to be smooth curves. For example, plasma cortisol normally has an episodic pattern with periods of large amounts of secretion.

Quantitative data for a physiological parameter can be most simply plotted on the vertical axis in reference to a horizontal time axis. Such a plot is properly referred to as a chronogram. However, in analyzing rhythms to demonstrate a 24-h pattern and to allow for quantitative descriptions, the wave form of the rhythm is often submitted to cosinor analysis to determine the best fitting cosine curve. In so doing, deviations in the data with respect to the curve are minimized in a fashion similar to linear regression analysis (6, 7). Descriptive terms may then be used to describe a rhythm presented by cosinor-analyzed data, including: the *acrophase* or crest of the curve; the *mesor* or overall 24-h mean value; the *amplitude*, which is the extent of variation between the trough and peak; and the

period of the oscillation (7–9). An example of a chronogram and cosinor analysis of the same data is presented in Figure 107.1.

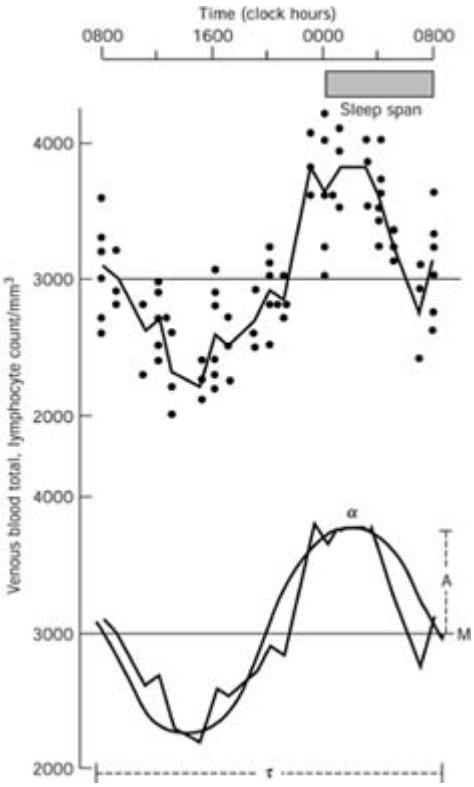

Figure 107.1. The circadian rhythm of the total lymphocyte count of venous blood is shown from samples from 12 subjects who were synchronized with respect to diurnal activity. The bottom panel is the best-fitting cosine curve approximating the raw data, by single cosinor analysis. Adapted with permission from Ref. 9a.

1.0.3 Endogenous Rhythms and the Biological Clock
The simple observation of a 24-h rhythm occurring under normal nychthermal conditions does not provide evidence for an endogenous biological rhythm. A rhythm such as this could be just a direct manifestation of an external 24-h influence. If biological rhythms merely reflected responses to external time cues, they would be of little consequence for the shiftworker. However, it has been well documented that most of the 24-h biological rhythms have an endogenous component. It is the desynchronization of endogenous biological rhythms with the external time cues and the associated disruption of the circadian system that are of great concern, when looking at the effects of work schedule-related time shifts on the workers.

1.0.3.1 Plant and Animal Studies One of the earliest demonstrated endogenous rhythms was that of the daily rhythm of a plant's leaf movements by de Mairan in 1729 (10). The opening and closing of the leaves, observed during daylight and darkness, respectively, had been assumed to represent a direct effect of sunlight and its absence during night hours. De Mairan, however, demonstrated that the rhythm of the opening and closing of the leaves continued when the plant was kept in total darkness for 24h. This finding indicated that the rhythm was not simply a response to the rhythmic presence and absence of sunlight.

Over two centuries later, Richter (11) did an elegant series of studies on over 900 rats which clearly demonstrated the existence of a “biological clock” in rodents. After characterizing the activity–rest cycles of the animals under conditions of 12-h periods of light and darkness, the rats were blinded. Almost immediately after blinding, the beginning and ending of the activity period began later each day, on a regular schedule. For example, in one of the rats, the activity period began 20min later each day, with the rhythm persisting for 7mo with great accuracy. The same phenomenon was observed in

60 other rats, with the same degree of regularity. However, the rhythm of an individual rat was not identical to the others. Some of the rats showed delays (up to 28min), and some advanced the period (up to 41min). Thus an independent "clock" was demonstrated, and because the different rats did not have exactly the same periodicities, a cosmic influence could not have been operating to produce the rhythm. The "clock" was also demonstrated to be inborn, by studying newborn rats blinded before their eyes had begun to function. Biological rhythms similar to those for rats blinded as adults were documented.

1.0.3.2 Human Studies The existence of a biological clock in humans was first demonstrated in temporal isolation studies in an underground cellar beneath a hospital in Munich (12). Three men and three women were isolated from all environmental and social time cues for 8–19d. All the subjects maintained a regular activity–rest cycle, free-running with a period slightly longer than 24h. The subjects consistently went to bed about an hour later each day and awoke an hour later than the previous day. This precise, regular delay in bedtime and spontaneous awakening has been demonstrated in numerous, subsequent temporal isolation studies, suggesting that the biological clock runs slow with respect to the 24-h solar day. For example, Wever (13, 14) compiled data from 156 subjects studied in temporal isolation which consistently demonstrated a slow biological clock with free-running periods of 25±0.5h for the body temperature and the sleep–wake cycle.

In order to determine if the sleep–wake cycle was maintaining the observed 24-h biological rhythms of physiological parameters, sleep deprivation studies were conducted (15, 16). In these studies, subjects were sleep deprived for 72h in temporal isolation (i.e., without 24-h cues). Again, persistent circadian rhythms were documented for several variables. Examination of the alertness rhythm revealed that subjects were found to be more alert after 58h of sleep deprivation than after 40h, providing further evidence for endogenous biological rhythms. These and several other classic studies demonstrating the endogenous nature of circadian rhythms in humans are summarized in Table 107.1.

Table 107.1. Studies Demonstrating Endogenous Circadian Rhythms in Humans

Type of Study	Findings	Reference
Temporal isolation, 3 male and 3 female subjects	All subjects maintained free-running rest/activity cycle	12
N=29, 72h sleep deprivation in temporal isolation; subjects aware of 3-h intervals between urine collections	Persistent diurnal rhythm in several parameters, e.g., fatigue, urinary adrenalin	15
Several temporal isolation studies (*N*=156)	Free-running period of 25.00±0.5h for temperature and sleep–wake cycle	13, 14
Temporal isolation, 72h sleep deprivation; 16 female subjects unaware of timing of collection intervals	Circadian rhythms in temperature, alertness, performance variables	16
Temporal isolation, polygraphic sleep recordings, blood cortisol and growth hormone sampled every 20 minutes,	During free-running conditions, timing and duration of sleep occurred at specific phase of temperature rhythm; 2 components of cortisol curve relative to phase of temperature curve; growth	145

continuous temperature readings, N=10	hormone related to first 2 hrs of sleep onset	
23 year old male subject, 2 weeks temporal isolation, choosing own sleep and meal times	Circadian rhythm of sleep/wake cycle free-ran at 24.7hrs	145a
Reviewed results of previous studies on same individuals at 1 to 5yr intervals	Rhythm patterns could be used as individual markers; Intra individual differences smaller than interindividual	14a
Temporal isolation, subjects' estimation of 1-hr time intervals recorded, N=14	Bimodal circadian rhythms	12a

Very recent studies continue to confirm the existence of the biological clock, but have presented evidence that the average length of the intrinsic circadian period may be closer to 24h than to 25h (17–19). In the recent widely publicized study by Czeisler et al. (19) the average intrinsic period of the temperature rhythm was determined to be 24.18±0.04h. In this study 24 subjects were placed into 20- and 28-h forced-desynchrony protocols (see Section 1.1.5) lasting 3½wk. The study protocols were carried out in conjunction with maintaining constant low light levels (15 lux, which is much lower than ordinary room lighting) during the scheduled wake time. In addition, sleeping was allowed only during the scheduled sleep time. Core body temperature was measured continuously, and plasma melatonin and cortisol were frequently sampled during the protocol. Several subjects were, in addition, tested during a standard temporal isolation, free-running protocol. During the free-running protocol these subjects, who had been shown to have temperature rhythms with periods just slightly longer than 24h under the forced-desynchrony protocol, had temperature rhythms with periods averaging slightly longer than 25h. The results of this study are consistent with several animal studies demonstrating a circadian pacemaker running very close to 24h with little intersubject variability (20–22).

Czeisler and his associates19 have suggested that the longer and more variable pacemaker period reported in the earlier classical free-running protocols reflected the subjects preferentially choosing exposure to room light prior to the circadian temperature nadir and to darkness following the minimum temperature. They have hypothesized that this behavior elicits light-induced phase delays and an overestimation of the circadian period. On the other hand, the Czeisler et al. (19) strict, forced-desynchrony protocol has been criticized as being too artificial, and may therefore somewhat underestimate the length of the intrinsic period.

1.0.3.3 Neuroanatomical Studies The first evidence of a neuroanatomic site of an endogenous pacemaker was uncovered by Richter (11) in a series of experiments conducted on over 900 rats. After demonstrating the existence of a biological clock by the persistence of a regular free-running endogenous activity rhythm after blinding the rats, the effect of the removal of various glands including the gonads, pancreas, adrenals, pituitary, thyroid, and pineal was determined. The circadian pacemaker was not disrupted by the removal of any of these tissues. Neither was it disturbed by a variety of insults including electric shock, anaesthesia, alcohol, or induced convulsions. However, lesions of the hypothalamus, specifically the ventral hypothalamus, did lead to a loss of circadian organization of activity, feeding, and drinking.

Later, as reviewed by Moore-Ede et al. (23) the suprachiasmatic nuclei (SCN) was identified as the specific pacemaker cite in the hypothalamus. This was accomplished by tracing tritiated amino acids injected into the vitreous humor of the eyes, reaching retinal ganglion cells, and subsequently

reaching the suprachiasmatic nuclei (24). Recently neural transplantation of the SCN in rodents has also demonstrated the pacemaker role of this group of neural cells. SCN grafts from mutant hamsters exhibiting an abnormally short circadian timing system were transplanted into normal hamsters that had undergone SCN ablation. The graft recipients had circadian rhythmicity restored, but with a period matching the mutant donors' (25). Additional evidence for the pacemaker function of the SCN are laboratory studies of rats, which have demonstrated circadian rhythms in electrical discharges from isolated SCN tissue *in vitro* (26, 27).

The complexity of the pacemaker role of the SCN precludes a complete discussion of the large amount of recent research addressing this topic. An entire journal supplement has very recently been devoted to a review of the nature of the SCN and its critical role in the maintaining of the circadian system (28). This supplement addresses entrainment mechanisms, including not only the principal photic mechanisms, but also the more recent research exploring nonphotic entrainment mechanisms. The multioscillator organization of the SCN is also scrutinized, as well as findings dealing with the communication pathways between the SCN and the circadian effector systems.

1.0.3.4 Molecular Genetic Studies The requirement for protein synthesis for circadian timing systems to function implies that gene expression directing circadian protein transcription/translation underlies the molecular control of the circadian system. It has been demonstrated that the existence of circadian rhythms in the fruit fly (*Drosophila melanogaster*) requires the interaction of certain proteins, involving gene transcription feedback loops. In *Drosophila*, several clock genes, including the *dbt* (double-time) gene, have been found to regulate molecular cycles underlying circadian rhythms. The *dbt* gene has been identified as the regulator of synthesis of two “clock” proteins (PER and TIM). In addition, two other clock proteins, CLOCK and BMAL1, have been demonstrated to interact with PER and TIM, producing periodicity in the fly and in mammals. Specifically, a negative feedback loop has been found with CLOCK and BMAL1, driving expression of PER and TIM until the latter two proteins accumulate sufficiently and inhibit the CLOCK and BMAL1 proteins. Evidence also exists for the conservation of PER gene homologs in the suprachiasmatic nucleus of mammals. Cloning of genes involved in abnormal circadian activity has also identified other clock genes in the fruit fly, including one named *dClock*. Isolation of a mouse mutation that changed the intrinsic period length and the persistence of rhythmicity has recently provided evidence for an analogous mammalian gene, named *Clock*, and its role in controlling the circadian timing system at the molecular level (20, 29–34).

A detailed discussion of research on the molecular basis of circadian regulation is beyond the scope of this chapter. However, the reader is alerted to this topic because research findings in this area will likely have implications for predicting genetic vulnerability to circadian rhythm dysfunction and shiftwork tolerance. In addition, doors are being opened for the development of molecular-level therapeutic interventions. In depth reviews of this area of research have recently been provided by Dunlap (35, 36) Herzog and Block (37), and Edery (38).

1.0.3.5 The Temperature Rhythm The body temperature rhythm is the most studied human rhythm. It is the rhythm most commonly used as the marker of the circadian pacemaker's phase and amplitude. For over a century it has been known to be, under nychthermal conditions, highest near evening and lowest in the early morning hours (39). Under these conditions the relationship of the temperature rhythm to the sleep–wake cycle is very predictable. The temperature peaks during the second half of the wake episode. More specifically, there is a pronounced rise upon awakening with a more gradual rise to the early evening peak. The temperature rhythm trough occurs during the last part of sleep in the early morning around 0500. The amplitude of the temperature rhythm averages 0.5°C (40, 41).

The relationship between the body temperature rhythm and other variables has been extensively studied. Examples of other rhythms that parallel the temperature rhythm with their nadir being during the night include adrenaline, alertness, cortisol, and blood pressure (15, 16, 42, 43). The normal relationship of the temperature rhythms to several other physiological parameters as well as to the sleep–wake cycle is demonstrated in Figure 107.2.

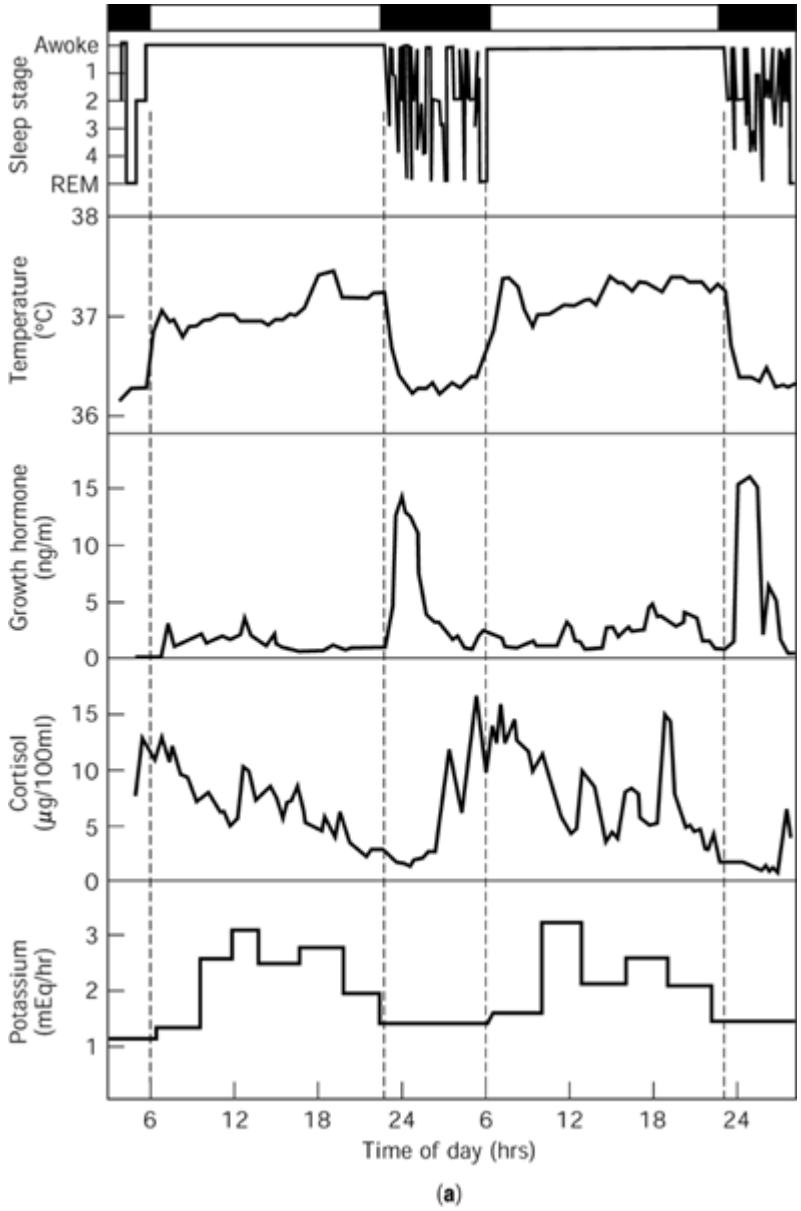

Figure 107.2. The circadian rhythms of five physiological parameters are plotted for a 48-h period. The rhythms for sleep stages, body temperature, plasma concentrations of growth hormone and cortisol, and urinary potassium concentration are shown in relation to each other and to the phase of the sleep–wake cycle. Adapted with permission from Ref. 42.

1.1 Adjustment to Time Shifts

1.1.1 Zeitgebers Although it has been shown that there is an endogenous circadian time-keeper active in humans, the fact that under normal nychthermal conditions the biological rhythms are synchronized with the 24-h day points to the presence of external triggers to which the biological clock is responsive. These time cues, which are capable of entraining the biological rhythms to an external periodicity, have been termed *zeitgebers*. Zeitgebers allow the biological clock to be reset and entrained to the 24-h day (39).

Various agents have been shown to act as zeitgebers including light, natural noises, social factors, awareness of the time of day, and behavioral patterns such as eating schedules, and sleep–wake schedules (44–47). Even electromagnetic fields appear to be able to act as zeitgebers (48).

1.1.2 Light as a Zeitgeber In the 1970s social cues and the sleep–wake schedule were generally considered the most important zeitgebers for humans, and light, a strong synchronizer in other

species, was considered to played a minor role (47, 49, 50). However, as the relationship of the hormone melatonin to sleep and light became recognized (51–53), the question of the importance of sunlight in entraining biological rhythms was again raised. Melatonin was shown to be a strong sleep inducer, and light was shown to affect the activity of the pineal gland where melatonin was known to be produced (53). A circadian rhythm was demonstrated in urinary melatonin excretion (52). Czeisler (54) demonstrated that an absolute light–dark cycle could entrain human circadian rhythms. Moore-Ede and Richardson (55) suggested that earlier experimental conditions did not allow dismissal of the light–dark cycle as an important zeitgeber for humans, because in those previous studies subjects were allowed to use auxiliary lighting such as desk lamps during the "dark" phase of the experiment.

Lewy et al. (56) demonstrated a dose–response effect of light on melatonin secretion. Bright light of about 2500 lux suppressed human melatonin secretion, while levels of 500 lux had no such effect, and light around 1500 lux had an intermediate effect. Successful clinical treatment of depressed patients was accomplished with bright-light exposure in the morning with an associated phase advance of night-time melatonin production (57). Broadway and Arendt (58) observed a subject living in the Antarctic during the 24-h darkness of winter (light level never over 500 lux) and during the spring time. A more rapid recovery from night-watch-induced sleep disturbance occurred during the spring (1wk for recovery) versus the winter (3-wk recovery time). A concurrent shift in the 6-hydroxymelatonin sulfate rhythm was also observed.

Based on animal experiments demonstrating a phase response to timed bright-light exposure, Daan and Lewy (59) successfully used sunlight exposure to hasten entrainment after transmeridian flights. Other researchers reported bright light exposure could expand the normal (approximately 22–27h) range of entrainment of the human circadian system. Wever and colleagues (60) found bright light (4000 lux) could synchronize the human circadian rhythm to over 29h. Lewy (61) observed that under the near-constant conditions of sunlight during the Arctic summer, humans could entrain to a 21-h period, which is normally below the entrainment range. Other studies demonstrated that bright light is a synchronizer of the human circadian clock (62). Recent studies have demonstrated that social cues, the sleep–wake schedule, and the rest–activity cycle are weak zeitgebers in comparison to the light–dark cycle (63), and sunlight and bright electrical lighting (7,000–13,000 lux) are now recognized to be a strong zeitgeber for humans. Recently, even low light exposure (typical indoor lighting of 50–300 lux) has been shown to effect phase shifts of the human biological clock (64).

1.1.3 Entrainment and Time Shifts There are two important limitations on the circadian timing system with respect to internal and external entrainment. Because of these limitations, time shifts experienced by shiftworkers can result in internal desynchronization between endogenous biological rhythms and in external desynchronization with the 24-h day.

One of the limitations is the range of entrainment of the circadian pacemaker. Wever (65) used the technique of "fractional desynchronization" to determine this range. Gradual lengthening or shortening (by 5–10min) of a zeitgeber-determined period was carried out and the limits of different overt rhythms observed. When the limit was reached, the variables began to free-run. The phenomenon of internal desynchronization was seen as different rhythms reached their limits of entrainment at different times. The range of entrainment for body temperature was found to have an upper limit of approximately 27h and a lower limit of about 22h.

Internal desynchronization had been observed prior to this study, and should be discussed a bit further because its occurrence is important when considering the body's response to time changes. Spontaneous desynchronization has been observed in some individuals, most often at the end of studies of regular free-running periods. Aschoff (39) studied human subjects isolated from temporal cues in underground bunkers for up to 4wk, allowing them to choose their own times for sleeping and eating. Continuous measurements of rectal temperature and activity (and analysis of urine volume, calcium, and potassium from specimens collected at self-chosen times) were carried out. Free-running periods of about 25h were noted for all variables. However, one subject was noted to

develop an extremely slow sleep rhythm of 32.6h while the body temperature and urine variables ran at 24.7h. The activity rhythm regained its original phase with respect to the other variables every third to fourth day. (When all rhythms were in phase, the subject noted in his diary that he felt especially good.)

Wever (48), in reviewing his many isolation studies, has noted internal desynchronization in almost 30% of subjects during the first month of free-running experiments and in almost all his subjects participating in longer experiments. Internal desynchronization was also seen in a sleep study where 6 out of 12 subjects in free-running conditions demonstrated an extremely long duration of sleep–wake cycles (up to 50h) with the circadian body temperature rhythm persisting (66).

It should be noted here that internal desynchronization can be induced in any person by imposing artificial zeitgebers such as a sleep–wake schedule or light–dark cycle outside the range of entrainment range of the body temperature rhythm, that is, less than 22 or greater than 27h (13, 19). Such study designs are referred to as forced-desynchronization protocols.

The second limitation of entrainment is the rate at which the circadian clock can be phase-shifted to match an imposed time-shift such as occurs with working night shifts, or with transmeridian jet travel. In addition, different individual biological rhythms have been shown to re-entrain to time shifts at different rates, reflecting different relative strengths of endogenous and exogenous rhythm components. For example, sodium and potassium excretion are closely linked in a stable rhythmic environment, but have significant differences in their re-entrainment to phase shifts (67). Adjustment of rhythms of urinary volume and potassium excretion in full-time night nurses required 4d for temporal phasing after returning to work after their days off (68). Urinary 17-hydroxycorticosteroid excretory rhythm did not fully reverse itself until the second week after sleep–wake reversal in a study of 5 healthy males (69).

Another study demonstrating desynchrony of rhythms due to different rates of adjustment after time shifts was done by Wever (70). Rhythms of rectal temperature and computation speed were seen to need more time than the 2d required for the sleep–wakefulness rhythm to adjust in this isolation experiment. Weitzman (71) has shown in several studies that the body temperature curve takes 2–3wk to adjust completely to sleep–wake reversal.

In phase-shift studies designed to simulate transmeridian flights (6-h time shift), Wever (70) also found that rhythms of different variables adapt at different rates to shifted zeitgebers, and that the sleep–wake rhythm adjusts faster than the body temperature rhythm. For both advance and delay time shifts, the activity rhythm adjusted in about 2d. More time was needed for adjustment of the temperature and performance speed.

When subjects entrained to an artificial day have been studied, it has been observed that when the phase of the artificial day is shifted, different rhythms entrain at different rates, with activity always adjusting faster than physiologic functions (72). Differences in the rate of phase adjustment of performance rhythms for various tasks to shiftwork and transmeridian flights have also been documented (73).

Mechanisms of reentrainment have also been studied. Mills et al. (74), observed subjects in isolation units under 24h of constant routine (continuous light and sedentary activity) and after time shifts of 8–12h. The direction of reentrainment of the circadian rhythms of temperature and urinary constituents was by phase delay. Again it was found that, under these controlled conditions, different variables reentrained at different rates. “Reentrainment by partition” was been observed in some subjects who were observed to have their circadian system split into the components of activity and temperature rhythms. After a 6-h advance in artificial zeitgebers, the temperature reentrained by an 18-h phase delay, while the activity rhythm shifted in the same direction as the zeitgeber shift. This phenomenon has also been observed in studies of eastbound transmeridian flights summarized by Ashcoff (75).

1.1.4 Light, Melatonin, and Photoreceptors For almost two decades, timed light exposure and administration of oral melatonin have been a focus of research directed towards helping jet travelers and shiftworkers adjust to time shifts. Therefore, some detailed discussion of the mechanism of action of these zeitgebers is necessary.

The phase-shifting effect of light on the circadian timing system is secondary to its suppressing action on the secretion of melatonin by the pineal gland. Melatonin is an internal signal to the circadian system that it is night time. This hormone, which is normally produced only during darkness, induces sleep and depresses the core body temperature. The normal relationship of the melatonin rhythm to the temperature rhythm and the time of day is shown in Figure 107.3 (76–78).

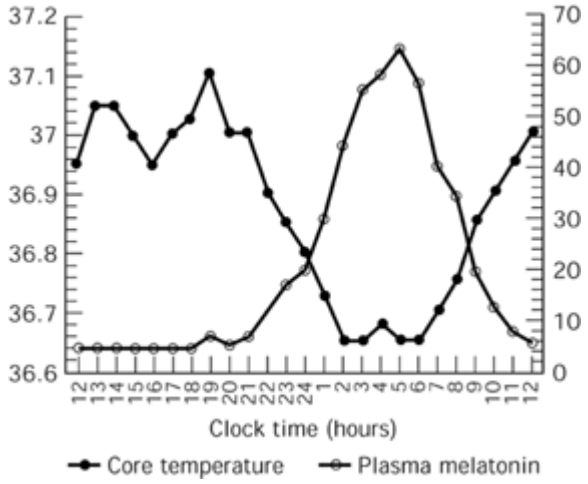

Figure 107.3. Graph of human plasma melatonin (pg/mL) and rectal temperature (°C) plotting real data from a 24-h constant routine condition. Under these entrained conditions the peak of the melatonin secretion is shown to correspond to the radir in core body temperature. Used with permission from Ref. 78a.

The mechanism of the chronobiological action of light has long been believed to require stimulation of retinal photoreceptors (79). Transmission of this information received by the retina is via the retinohypothalamic neuronal tract to the suprachiasmatic nucleus (SCN), which in turn suppresses the pineal gland secretion of melatonin. Melatonin in turn activates melatonin receptors in the SCN, which inhibit SCN metabolic activity (80, 81). This traditional pathway is diagrammatically illustrated in Figure 107.4.

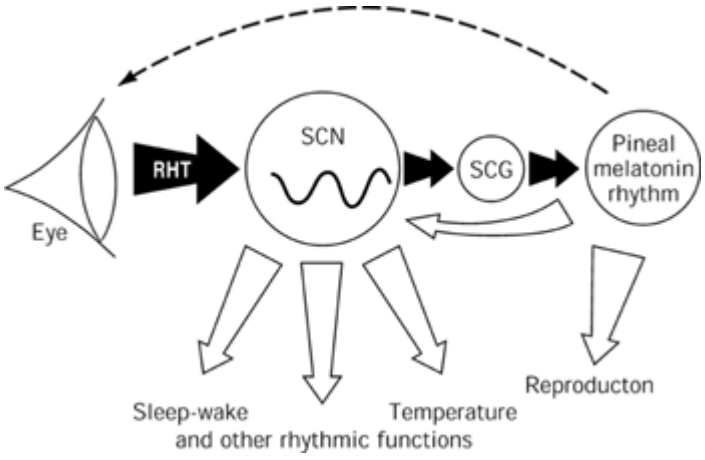

Figure 107.4. Generalized diagram of the circadian system central rhythm-generating system in the suprachiasmatic nucleus (SCN). Melatonin is shown to feed back at the level of the SCN to shift

circadian phase and also to influence rhythmicity at the retinal level. RHT, retinohypothaolamic tract; SCG, superior cervical ganglion. Used with permission from Ref. 78a.

In mammals, the retina of the eyes has long been considered the exclusive site for the chronobiological effects of light exposure. Evidence for the role of the eye as the receptor for the zeitgeber action of light includes studies of the effect of preventing light from reaching the retina. Shielding sighted individuals from the normal 24-h light–dark cycle in temporal isolation results in free-running endogenous circadian rhythms, including melatonin and the body temperature rhythm. It has also been observed that many blind persons have free-running circadian rhythms despite maintaining a regular 24-h sleep–wake schedule, and that these individuals often have cyclic disturbances of sleep quality due to phase changes in the circadian pacemaker (82–85). In addition, timed ocular light exposure had been successfully used to treat sleep–wake disorders and symptoms of seasonal affective disorder (winter depression), but exposure to light while the skin and eyes were shielded had been reported to be ineffective (86). Also several studies of rodents had failed to demonstrate entrainment to light after total enucleation of the eyes (87).

There is now an accumulation of findings from several studies providing evidence for a nonretinal circadian photoreceptor. First of all, some nonsighted persons do sustain a 24-h sleep–wake cycle without difficulty and maintain synchrony of biological rhythms including melatonin and core body temperature (83, 88, 89). The observation that some completely blind persons with no pupillary light reflex do have a positive melatonin suppression test (suppression of melatonin by ocular exposure to light) suggests that the photoreceptors that are involved with the entrainment of the biological clock by light are not the same as the visual light receptors. That is, the retinal projections that send information about light exposure to the visual and the circadian centers of the brain may not be the same, as had long been assumed to be the case (83, 90, 91). Rodent studies have demonstrated that genetic loss of the known mammalian retinal photoreceptors (i.e., the rods and cones) does not interfere with the normal light-induced suppression of melatonin secretion nor with normal light-induced phase shifting of behavioral responses (92, 93). Perhaps the most convincing evidence is from a recent study by Campbell and Murphy (94). These researchers showed a response to light in human subjects using extraocular light exposure. At varying times with respect to the baseline circadian phase, 3-h light exposures were directed over the popliteal area (posterior area of the leg at the knee joint) of 15 healthy subjects. Body temperature and salivary melatonin were monitored and used to determine the subjects' pre-light exposure circadian phase. Significant phase shifts were documented following the light exposures. Depending on the time of the light exposure, a phase-delay or a phase-advance response occurred.

Oren (95) has proposed a mechanism for this nonocular response, suggesting that there is a blood-borne circadian photoreceptor, such as hemoglobin, able to receive light stimulation through superficial vasculature. Hemoglobin is a likely candidate for the photoreceptor function as the tetrapyrrole-based heme pigment portions of its molecular structure are very similar to the plant photoreceptor pigment chlorophyll. This theory of “humoral phototransduction” is supported by other studies demonstrating light-induced release of the neuroactive gases carbon monoxide and nitric oxide from heme moieties (96). Two other classes of pigments, in addition to heme pigments, are potential candidates for having circadian photoreceptor properties. These additional pigments are opsin/retinal-based photopigments and pterin/flavin-containing crytochrome blue-light photoreceptors (97, 98).

1.1.5 Shiftwork Applications The studies reviewed in the preceding sections demonstrate that a major function of the circadian system is the internal sequencing of physiologic events and metabolism. Biological processes are thus coordinated for optional functioning of the organism. Under normal nychthermal conditions, rhythms may show a peak just before an expected environmental event such as the rise of body temperature and the peak of plasma cortisol occurring just before awakening. Restorative functions of sleep are maximized by the normal phase of biological rhythms during the night-time hours.

For a shiftworker, however, activity at night will be out of phase with the circadian body temperature and other coupled rhythms. In addition, each time the work schedule rotates, or there is a return to night work after off-work days, for some duration of time after the time shift, the circadian system will be in a desynchronized state.

In humans, circadian rhythms are more easily shifted if all the important zeitgebers, including the light–dark cycle, are synchronously shifted, such as occurs with transmeridian flights. For shiftworkers, zeitgebers shift in a nonsynchronized manner (99). A week's time is necessary after a transmeridian jet flight for the circadian system to adjust to a 6-h time change, a situation where all social time cues, meals, sleep–wake schedule, and light–dark schedule remain in normal phase relationship to each other (100). Laboratory studies of subjects experiencing an inversion of the sleep–wake schedule, with no intervention with a timed light exposure, demonstrated no significant re-entrainment of the temperature rhythm after 10d. Knauth and Rutenfranz (101) failed to find complete inversion of the body temperature rhythm in shiftworkers even after 21 consecutively worked night shifts, and concluded that the circadian system never fully adapts to night work. Other field studies of shiftworkers have also found adaptation to night work to be incomplete (102–105). The slow rate of adaptation by workers to new shift-work schedules is apparently due to competing influences of different zeitgebers (106).

2.0 Performance and Safety
2.0.1 Characteristics of Performance Rhythms Researchers have been analyzing 24-h variation in human performance for over a century. The circadian nature of human performance rhythms is well documented and was recognized even before the term circadian was coined (107, 108). Initial investigators of time-of-day performance variation were more interested in mental performance and adjusting school schedules to coincide with peak academic ability than they were in industrial safety or productivity. Research efforts therefore focused on learning and memory. The observation that complex cognitive tasks were different from simple ones with respect to diurnal variation was made before the beginning of the twentieth century (108). In the early 1900s, Gates reported differences between the circadian rhythms of different types of cognitive tasks (109).

Despite these early findings, Kleitman (110) concluded there was a general performance rhythm, having a causally related parallelism with the body temperature rhythm. His opinion was based on his observations that performance speed and accuracy for several tasks followed consistent rhythms, with poorest scores in the early AM and late PM and maximum scores at mid-day. However, the six tests Kleitman used (dealing and sorting cards) were immediate-processing, simple repetitive tasks, with low cognitive load.

Colquhoun and associates (111–113) did a series of laboratory shiftwork studies using variations of naval watch schedules. The type of tasks used resembled sonar operations and were low-cognitive-load, maintenance and vigilance, immediate- processing-type tasks. Like Kleitman, this group also reported a positive correlation between the performance rhythm of these simple repetitive tasks and the body temperature rhythm. However, rather than suggest that this was a direct causal relationship, he proposed a unidimensional arousal theory to explain his observations. In this theory, sleepiness is compared to a lack in arousal, and as arousal rises (or the level of sleepiness falls), reaching a maximum in the evening (or minimum for sleepiness), performance also peaks. The theory involves an “inverted U” relationship with increasing levels of arousal allowing improving performance up to a certain arousal level at which time a decline in performance begins. The arousal theory provided an explanation for deviations from parallel relationships with the temperature rhythm demonstrated for

certain tasks, particularly the digit-span memory task, due to there being different levels of optimal arousal for these tasks (114). A detailed discussion of the arousal model, its limitations, and advances in the model are provided in a recent review by Monk (115). Briefly, simple repetitive and vigilance tasks are considered to have a high optimal arousal level and therefore to parallel the arousal rhythm (and also the temperature rhythm) (111–113). Complex, high-memory-load performance has a low optimal arousal and decline over the waking day with a phase inverse to the temperature rhythm (116). In other words, the arousal theory proposes that there is a circadian rhythm for arousal that rises over the waking period, peaking in early evening and generally paralleling the temperature rhythm. The optimum arousal level is low for high-memory-load tasks, and high for low-memory-load tasks.

The arousal theory has been supported by several studies. Research by Folkard (117) and Englund (118) indicates that performance is task dependent and that speed and accuracy may represent different diurnal components of performance with different relationships to arousal. Monk and Folkard (119) tested immediate recall (memory tested within a few minutes after presentation of the material to be learned) and long-term memory of hospital training films in 26 part-time nurses, all having normal day-oriented circadian rhythms.

Biological Rhythms, Shiftwork, and Occupational Health
Allene J. Scott MD, MPH,, Joseph LaDou, MD

3.0 Shiftwork and Health
3.1 General Well-being
3.1.1 Desynchronosis (A Time Shift Is a Time Shift) As has been discussesd in the preceding sections, when individuals experience sudden time shifts, the phase alignment of their previously synchronized biological rhythms is disrupted. Both external and internal desynchronization result. The term *desynchronosis* refers to the presence of rhythm desynchronization with associated signs and/or symptoms of physical and/or mental dysfunction. Probably the most well-recognized examples of desynchronosis are “Monday morning malaise” and “jet lag” (or in proper chronobiological terminology, *transmeridian flight desynchronosis)*. Symptoms of jet lag are universally recognized and include (in order of typical frequency as reported by frequent jet travelers): daytime sleepiness and fatigue, difficulty sleeping at night, poor concentration, slow physical reflexes, irritability, digestive system complaints (e.g., abdominal discomfort, diarrhea, appetite changes), and feelings of depression. Not surprisingly, studies of the general well-being of shiftworkers have demonstrated that shiftworkers experience very similar symptoms (197, 198). That is, symptoms of “shift lag” (199) are essentially the same as those of jet lag. However, the complaints of shiftworkers may not be as readily recognized as being related to time shifts by the non-shift-working community. A side-by-side comparison (Table 107.3) of typical complaints of jet travelers and shiftworkers clearly demonstrates the similarity.

Table 107.3. Symptoms of Jet Lag and Shift Lag

Jet-Lag Symptoms	Shift-Lag Symtoms
Daytime sleepiness/fatigue	Fatigue/falling asleep at work
Inability to sleep at night	Sleep disruption
Poor concentration	Decreased vigilance
Slowed physical reflexes	Impaired performance
Irritability	Irritability

Digestive upset and hunger at unusual times	Gastrointestinal disturbance
Depression	Depression and apathy

Despite the similarity in symptoms of desynchronosis reported by both jet travelers and shiftworkers, there is an important difference between these two groups. For jet travelers, the new time for sleep and activity will be in concert with the 24-h solar day and the social/work schedule of society. These two factors will assist the jet traveler in re-entrainment of biological rhythms. For the night shiftworker experiencing a time shift, the sleep–wake cycle will be opposed to the 24-h solar day and night, and the work schedule will be in conflict with the work/leisure activity of most of the rest of society and often with other family members. Therefore, while jet-lag symptoms are typically limited to a few days, symptoms of shiftwork related desynchronosis are often continually present to some degree when night shift work is a regular part of the work schedule. This is usually true even for those assigned permanently to the night shift, since most of these workers will revert to regular diurnal schedules on their days off. Airline personnel may be subject to the most severe desynchronosis due to combined effects of repeated transmeridian time crossings and shiftwork (200).

Biological Rhythms, Shiftwork, and Occupational Health

4.0 Shiftwork Scheduling Issues
4.1 Types of Shift Schedules
Shiftwork, broadly defined, refers to work regularly performed outside the normal day shift period from 0700–0800 to 1600–1700. There are many variations of shiftwork schedules (419–422). Work shift systems fall into two general categories, *Continuous* (work coverage is provided continually over the 7-d week) or *discontinuous* (there is a break in work operations at some time during the week, usually during on the weekend period). The general types of shift schedule arrangements include:

1. *Fixed*. Only the day, afternoon/evening, or night shift is worked by an individual employee.
2. *Rotating*. An individual employee rotates between more than one shift. The rotation may be in either a *forward, clockwise* (phase-delay) direction or a *backward, counterclockwise* (phase-advance) direction. A forward rotation progresses from the morning shift to the evening to the night. The backward rotation, of which the "Southern swing" is a common example in the United States, progresses from the day to the night to the evening shift.

   The type of rotation is also classified by how many days on one shift are worked before moving on to another shift (i.e., by the speed of the rotation). The rotation speed may be: (*1*) *slow*—greater than weekly, usually 21d or greater on the same shift; (*2*) *weekly*—5–7d in a row of each shift; or (*3*) *rapid*—1–4d in a row on any one shift. Examples of rapid rotations include:

   1. *Continental*. This is a rapidly rotating system, frequently referred to in European work studies, in which two consecutive, identical shifts are followed by two of another shift, and then three of the third (2–2–3).
   2. *Metropolitan*. This is also a rapidly rotating system of European origin, in which two identical, consecutive shifts follow one another until all three are worked (2–2–2).
3. *Alternativea*.

1. The “compressed” 4-d work week, with either 10- (“4/40”) or 12-h work periods. This may be used in a single, two-shift, or three-shift, continuous or noncontinuous operation.
2. The 8-d week with four, 10-h days followed by 4d off. This is used primarily in firms operating 10h/d, 7d/wk or working 20h/d in two shifts.
3. Flexitime, originated in Europe, gives the employee considerable choice in designing one's own daily work hours to meet weekly requirements.
4. Staggered refers to working hours in which employees are assigned to, or allowed to choose, their starting time, which will determine their quitting time.
5. Split shifts have a hiatus of a few hours separating the work hours performed on the same day. For example, this may be done in service businesses such as restaurants or transportation, where there are major peaks in business.
6. Relief shifts are ones in which the worker may follow any of the above patterns, but the time of work is determined by someone else's absence.

Biological Rhythms, Shiftwork, and Occupational Health
Allene J. Scott MD, MPH,, Joseph LaDou, MD

5.0 Countermeasures
5.1 Employer/Workplace Actions
Chronobiologically sound scheduling strategies and the provision of appropriate occupational health programs for employees are central countermeasures for minimizing deleterious effects of shiftwork. These are discussed in detail in Sections 4.0 and 3.6.3.

Equivalent human resources support including educational programs for workers and their families on shiftwork-related health, safety, and coping topics are also important measures. Monk and Folkard (502) have recommended employers develop a “Shift Work Awareness Programme” for coordinating educational and social support programs. Some proactive companies, having recognized the difficulty night workers with families face in obtaining child care, have established 24-h childcare facilities for their workers (503).

Workplace facilities and environmental conditions can impact tolerance to shiftwork and shiftworker performance. In order to assist employees in dietary countermeasures (see Section 5.1), equivalent canteen/eating facilities should be provided for night workers as for day workers. At a minimum, a microwave, refrigerator, and vending machines with low fat, nutritious foods should be available including dairy products and fruit juices.

Other environmental factors should be assessed, which can be adjusted toward increasing alertness on the job and preventing nodding off when working. For instance, sufficiently intense and uniform lighting will enhance alertness. Nonvariable background noise, which can promote boredom, should be replaced with judiciously used music and, if appropriate, social interactions between workers. Keeping room temperatures below 70°F and maximizing opportunities for physical activity have also been recommended (502, 504).
5.2 Coping Strategies for Shiftworkers and their Families
As the heading of this section implies, in order for individual coping strategies to be effective, families must be involved. In addition, the shiftworker must remember the toll that the shiftwork schedules may take on the family as well. The provision of educational programs for both the worker and family is essential for employees to cope successfully with shiftwork schedules. Educational materials addressing shiftwork issues, including countermeasures published in laymen's terms, are available to assist employers and employees in this endeavor (474, 502, 505, 506). Strategies for

coping with jet lag will not be addressed in this chapter but are reviewed in depth by Comperatore and Krueger (200) and Lamberg (507).

5.2.1 Maximizing Sleep The sleep problems of shiftworkers, both night workers and early morning starters, have been discussed in detail in Section 2.0. A large part of this problem relates to work scheduling issues beyond the control of the worker. However, there are some coping strategies that can be used to maximize sleep within the scheduling constraints.

One often significant interfering factor for night workers in particular is daytime noise, as discussed in Section 2.1.1. Even if the worker is not aware of actually being awakened by noise, sleep quality may be compromised (508). Actions should be taken to soundproof the bedroom as much as possible. In addition to using sound damping items such as ceiling tile and perhaps carpeting, white noise from a fan or air conditioner may be helpful. Family and even neighbor cooperation should be sought to help control noisy activities near the night worker's sleeping quarters. The phone and doorbell should not be audible in the bedroom. Earplugs can also be used to attenuate noise as long as the fit is comfortable.

Light exposure should be minimized to as close to night time conditions as possible. Lined drapery and window blinds or dark room shades may be helpful in this effort. Eye shades are another option for decreasing light exposure.

Applying “sleep hygiene” techniques, initially developed to help patients with insomnia, is also a recommended coping strategy for shiftworkers. Sleep hygiene is a program applying regular procedures and following behavioral rules that enhance the ability to fall asleep and stay asleep. Sleep hygiene recommendations have been recently summarized (509) and include: (*1*) maintaining a regular wake time, (*2*) avoiding excessive time in bed, (*3*) avoiding naps, except if a shiftworker, (*4*) using the bed only for sleeping and conjugal relations, (*5*) avoiding nicotine, caffeine, and alcohol, (*6*) engaging in regular exercise, (*7*) doing a relaxing activity before bedtime, (*8*) not watching the clock, and (*9*) eating a light snack before bed if hungry. Although shiftworkers will not be able to comply with the first recommendation, the others can be followed and may help to promote sleep.

Although the regular use of sleeping pills is not advised, short-acting hypnotics such as triazolam have been shown to improve quality and duration of daytime sleep (510). Occasional use for a day or two, under a physician's care, may be useful when beginning a run of night shifts or following a transmeridian flight. However, caution must be exercised, as impaired cognition has been demonstrated to linger 8h after administration of a 0.5-mg dose (511).

5.2.2 Caffeine and Other Alertness-Enhancing Drugs Caffeine belongs to the xanthene class of drugs. This class of substances has been shown to cause phase shifts of the temperature rhythm in animals (512). The alteration of the circadian pacemaker seen with xanthines may explain the general use of caffeine by many to “get going” in the morning (23). However, its role in shiftwork coping relates to its stimulant effect counteracting sleepiness, and to its ability to delay sleep onset at night (513, 514). Its effect in increasing alertness is most apparent after a time of abstinence, and with repeated doses the effect may diminish (515). Simulated night-shift studies have reported caffeine use to have beneficial effects on alertness and performance, and to decrease sleep tendency as measured by multiple sleep latency tests (516, 517).

It takes about 5h for the effects of caffeine to disappear. Therefore, if caffeine is consumed, it should not be ingested closer than around 5h before bedtime (518). Excessive amounts of caffeine are not recommended for a variety of reasons. Shiftworkers are advised to limit the dose to around 300mg of caffeine per day, and to use during the first half of night or evening shifts. It is important to avoid caffeine during the last half of the evening shift or night shift, since the worker's bedtime will come soon after getting home. Fruit juice is a good alternative drink for the second half of the shift.

Illicit drugs such as amphetamines should never be used for obvious reasons. Due to deleterious side effects, stimulant diet pills should not be used to counteract shiftwork sleepiness. Research is being conducted on some new alertness-enhancing drugs, namely pemoline and modafinil, which may, in the future, have some usefulness for occasional alertness promotion. Findings to date have recently been reviewed by Åkerstedt and Ficca (518). Even if these prove to be effective for counteracting sleepiness, as pointed out by these authors, their use on any regular basis to make work at nonphysiological times tolerable raises ethical questions.

5.2.3 Bright Light and Melatonin Bright light pulses and the administration of melatonin show promise as chronobiotics, that is, for inducing phase shifts of the circadian system allowing for rapid reentrainment to new work–sleep times. The role of light as a zeitgeber is discussed in Section 1.1.2, and the physiological aspects of melatonin and its relationship to light have been reviewed in Section 1.1.4.

In addition to its sleep-inducing property, animal and human laboratory studies suggest that melatonin may effect phase shifts when administered with appropriate timing (519, 520).

Several field studies have demonstrated melatonin to be useful for ameliorating jet-lag symptoms. These have recently been reviewed in detail (200, 521). Five milligrams daily, orally administered, is the pharmacological dose frequently used in research protocols, although lower doses may also be effective (522). Specific instructions (and side-effect warnings) for taking the hormone for east- and westbound flights, as given to subjects participating in jet-lag studies, are included in the review by Arendt and Deacon (521). However, routine use of the product by travelers is not recommended.

There is limited research available on the use of melatonin in shiftwork situations. Beneficial effects on sleep and alertness have been reported associated with bedtime administration, but some performance measures may be adversely affected (523). Although the melatonin may be approved for use by shiftworkers at some time in the future, and it is recognized that there are some shiftworkers reporting benefits from using over-the-counter (OTC) preparations for shift-lag symptoms (524), its use cannot be recommended at this time (474, 521). Because it is a naturally available dietary supplement, melatonin is available OTC; however, licensed controlled preparations are only available as an investigational drug. Purity and strength are not regulated by the FDA in the United States for the OTC preparations (525), which are unfortunately widely available due to the inappropriate marketing of the hormone as a “cure-all” miracle drug. Effects of long-term usage are not known, and inappropriately timed administration may be dangerous due to its sedative effect.

Exposure to bright light has been demonstrated to result in phase shifts of the circadian timing system. The timing of the exposure determines the direction of the shifts, that is, either a phase-advance or phase-delay response (526–528). Figure 107.14 graphically demonstrates the results of a simulated shiftwork study (528) in which enhanced circadian readjustment to night work was achieved using timed, bright light exposure (7,000–12,000 lux, comparable to natural sunlight at dawn). The methodology of this study included provision of sleeping quarters with complete darkness, and strict timing of the sleep period.

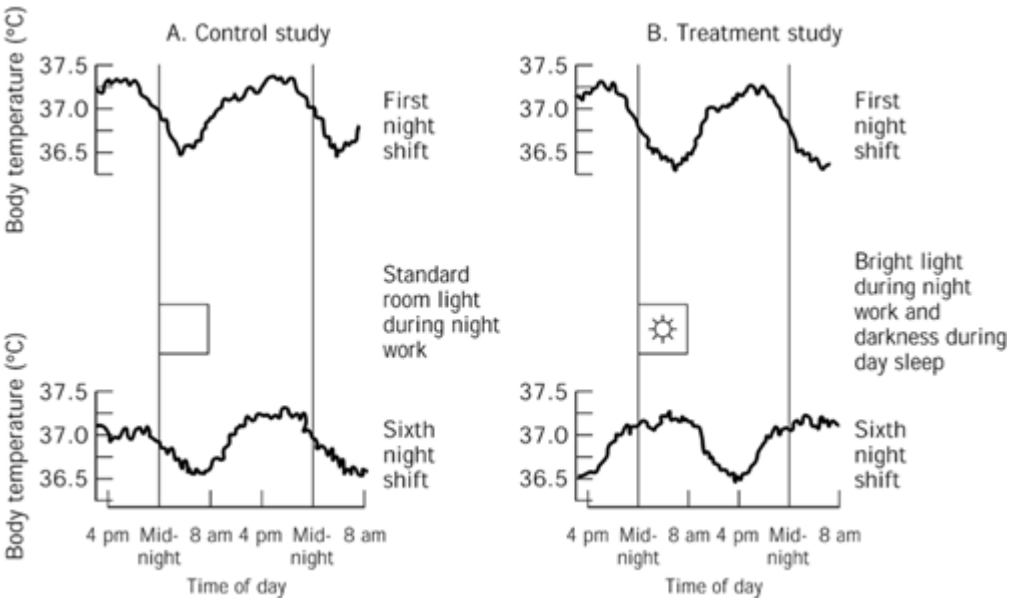

Figure 107.14. Effects of bright light on the adjustment of a worker to shiftwork. Body temperature phase shifts are shown on the first night and on the sixth night of work (A) with normal light levels and (B) with exposure to bright light on the second through fifth night of work. Phase shift of the body temperature rhythm to the night shift is demonstrated with the timed bright light exposure treatments. Adapted with permission from Ref. 528.

Although it is clear that appropriately timed, bright light exposure can enhance adjustment to night shifts, practical application for shiftworkers is a different matter. Not only is the timing of the light exposure critical, prevention of outdoor sunlight exposure at other times is necessary (requiring workers to wear dark goggles for a commute home after dawn), and night time darkness must be maintained in the bedroom/bathroom. In addition, there is considerable individual variation in the degree of phase-shift response.

Recently combined use of melatonin and light have received attention as potentially the most effective way to encourage reentrainment after time shifts (529). Again, practical application for shiftworkers may not be realistic, even when detailed recommendations for exposure/medication timing are available.

5.2.4 Diet and Exercise Good dietary habits and regular exercise are recommended in general for preventive health reasons to prevent/reduce obesity and decrease risks of diseases such as coronary heart disease and diabetes. These recommendations, of course, apply to shiftworkers as well as regular day workers. As pointed out in Section 3.2.2, it may be even more important for shiftworkers to follow preventive health recommendations for reducing the risk of coronary heart disease than for workers in general. However, there is no consistent evidence to date that dietary manipulations, such as the “jet-lag diet” (530), can speed up adjustment to time shifts. Nevertheless, it may be prudent, when trying to stay awake, to avoid foods high in carbohydrates, which may promote sleepiness by stimulating serotonin synthesis and choose protein items instead, which may increase alertness by stimulating release of catecholamines. It is also reasonable to recommend avoidance of heavy, greasy, or otherwise difficult-to-digest meals before bedtime or during the night shift, when the gastrointestinal system is not geared up for the digestion process (200, 531).

Physical fitness training has been demonstrated in shiftworkers to reduce general fatigue and sleepiness at work, increase sleep duration somewhat, and decrease musculoskeletal symptoms. Recommendations for exercise for shiftworkers include: (1) Moderate physical exercise is preferred over intensive training; (2) exercise should be done a few hours before the main sleep period; and (3) for morning or day shifts, the best exercise time is after the shift. After night shifts, the exercise

should be done before an evening nap (386, 532).

Smoke and Combustion Products

Barbara C. Levin, Ph.D.

1 Introduction

Seventy-six percent of the people that died in structural fires in 1990 died from the inhalation of toxic combustion products, not from burns (1). This percentage has been rising by about one percentage point per year since 1979. Although total deaths in fires are declining, the percentage attributed to smoke inhalation has increased. An area of research called *combustion toxicity* has evolved to study the adverse health effects caused by smoke or fire atmospheres. According to the American Society for Testing and Materials (ASTM), smoke consists of "the airborne solid and liquid particulates and gases evolved when a material undergoes pyrolysis or combustion" (2) and therefore, includes combustion products. In this chapter, a fire atmosphere is defined as all the effluents generated by the thermal decomposition of materials or products regardless of whether that effluent is produced under smoldering, nonflaming, or flaming conditions. The objectives of combustion toxicity research are to identify potentially harmful products from the thermal degradation of materials, to determine the best measurement methods for the identification of the toxicants as well as the degree of toxicity, to determine the effect of different fire exposures on the composition of the toxic combustion products, to predict the toxicity of the combustion atmospheres based on the concentrations and the interaction of the toxic products, and to establish the physiological effects of such products on living organisms. The ultimate goals of this field of research are to reduce human fire fatalities due to smoke inhalation, to determine effective treatments for survivors, and to prevent unnecessary suffering of fire casualties caused by smoke inhalation. Other reviews of various aspects of this subject can be found in Refs. 3–8.

2 Fire Death Statistics In the United States

According to the U.S. Fire Administration, fire kills more people in the United States than the combination of floods, hurricanes, tornadoes, and earthquakes. Although the reasons are not clear, the number of fire deaths per capita in the United States and Canada is about double the international average of the other countries in the industrialized world (9). Fire statistics collected by the National Fire Protection Association (NFPA) indicated that approximately 1,795,000 fires occurred in the United States in 1997, the latest year for which complete statistics are available (10). Calculated another way, these statistics translate into a fire occurring in the United States every 18 sec, in property located outside every 37 sec, in a structure every 57 sec, in a residence every 78 sec, and in a motor vehicle every 79 sec. These fires caused 4,050 deaths and 23,750 reported injuries in 1997. This number for injuries is believed to be less than the actual number, since many injuries are not reported. The property loss for 1997 is estimated at 8.525 billion dollars.

In 1997, residential fires accounted for only 22.6% of the total fires, but were responsible for 83% of all fire deaths and 75% of the reported injuries. Of 552,000 fires reported in structures, 17,000 or 3% were in a category designated as Industry, Utility, and Defense by the NFPA. These numbers only include those fires handled by public fire departments and reported to the NFPA and do not include fires handled by private companies or fire suppression systems. Although in the years 1977–1997 the number of civilian fire fatalities in homes dropped from 6000 to 3390, fires in homes still cause the greatest concern to the fire community. In 1997, only 120 deaths occurred in the category of nonresidential structures, which includes public assembly, educational, institutional, store and office, industry, utility, storage, and special structures (10). Statistics show that children under five and adults over 65 years of age are the most frequent casualties of residential fires (9). This is attributed to their inherent difficulties in trying to escape. Statistics also show that males are more likely to die in fires than females, especially males between the ages of 25 to 34 (9, 11, 12). In 1997 as in past years, the South had the highest fire incident rate (7.8 per thousand inhabitants) when compared with other geographical areas of the U.S. However, for the first time, the Northeast tied with the South to claim the highest death rates (17.5 per million people) (10).

One must distinguish between the causes of fires and the causes of fire deaths. The primary causes of residential fires have been shown to be heating and cooking (9, 11). Lack of central heat and the incorrect use of portable space heaters are two of the reasons given for the high fire and death rate in the South. Heating fires result in the highest property losses, primarily because cooking fires are usually noticed and extinguished before getting out of control. Fire deaths, however, usually result from fires ignited by cigarettes (11). The most common fire scenario leading to fire deaths is one in which a person (usually intoxicated) falls asleep in an upholstered chair while smoking (9). The cigarette falls into a crevice and starts the upholstered chair smoldering. The individual awakes and goes to bed unaware of the danger. The chair can smolder for an extended period of time [an hour was not unusual in laboratory tests at the National Institute of Standards and Technology (NIST)] before bursting into flames. Once the flaming starts, the smoke will fill the room and escape to the other rooms. It is common to find people who have died from smoke inhalation (not burns) in or near their beds, indicating that their little or no effort to escape was probably due to no warning and incapacitation from the asphyxiants in the smoke. Smoke detectors in this scenario would save many lives. Statistics have shown that working smoke detectors double one's probability of escaping alive. Recently, the problem has arisen that many homes have smoke detectors that are nonfunctioning because the batteries were removed following a false alarm (usually from smoke produced by a kitchen or wood stove) or because old batteries were never replaced.

3 Generation of Toxic Gases in Fires; Adverse Effects of Particulates
The adverse effects from smoke inhalation are believed due mainly to toxic gas exposures, although the role of the particulates alone and in combination with fire gases needs further investigation. The importance, therefore, of determining the identities and concentrations of toxic gases produced from materials thermally decomposed under various fire conditions is evident. In addition, the increased variety of plastics in buildings and homes has raised the issue of whether synthetic materials may produce unusually or extremely toxic combustion products. In this chapter, the phrase "extremely toxic" is a relative term indicating that the effluent from the thermal decomposition of very small quantities of a material has been noted to cause death of experimental animals (usually rats or mice) under controlled laboratory conditions. "Unusually toxic" indicates that the toxic effect cannot be totally attributable to the combustion gases (either singly or in combination) that are normally considered the main toxicants. In 1975, the journal *Science* documented a case in which an experimental rigid polyurethane foam containing a fire retardant produced a very unusual toxic combustion product identified as 4-ethyl-1-phospha-2,6,7-trioxabicyclo[2.2.2]octane-1-oxide (commonly referred to as a bicyclic phosphate ester) (13). Bicyclic phosphate compounds have been shown to cause seizures at very low concentrations. Based on these test results, this fire-retarded rigid polyurethane foam never became commercially available. To a large extent, however, it was this case that generated the burgeoning interest in the field of combustion toxicology and the widespread concern about the potential formation of "supertoxicants." Although research since the 1970s has shown that this concern is largely unfounded, the bicyclophosphate ester case and at least one other product that generated extremely toxic combustion products have indicated the need to test new formulations or materials containing new combinations of compounds to ensure that extremely or unusually toxic products are not generated.

The gas composition of smoke depends on the chemical composition, the molecular structure and polymer formulation of the burning material, which may include a variety of additives, plasticizers, stabilizers, flame retardants, cross-linking agents, fillers, and blowing agents. In addition, the conditions of thermal degradation, such as temperature, oxygen availability, and ventilation, will affect the nature of the combustion atmosphere. In a series of literature reviews by NIST on the generation of combustion products and the combustion product toxicity from seven plastics [acrylonitrile-butadiene-styrenes (ABS), nylons, polyesters, polyethylenes, polystyrenes, poly(vinyl chlorides) (PVC), and rigid polyurethane foams] commonly found in materials and products, and decomposed under various thermal and atmospheric conditions, over 400 different decomposition products were noted (14–21). At about the same time, the Consumer Product Safety Commission reviewed the combustion products and the toxicity of those combustion products generated from acrylics, phenolics, polypropylene, and flexible polyurethane foam (22–25), and the National Academy of Sciences did the same type of literature review on an additional 10 plastics, namely, acetal, aramid, cellulose acetate butyrate, epoxy resins, melamine–formaldehyde, polybutylene, polycarbonate, polyphenylene oxide, polytetrafluoroethylene, and urea–formaldehyde (26). Many of the combustion products were common to more than one plastic. In addition, there are probably many other combustion products that were not detected. At this time, the toxicity of most of these individual compounds is not known, and little has been done to tackle the enormous problem of determining the toxicity of combinations of these compounds. It is important to note that lack of detection of a specific combustion product from a material may only mean that the particular analytical techniques used were not suitable to detect that compound or that the investigator did not specifically analyze for that combustion product. Animal testing becomes important to ensure that an unsuspected and, therefore, undetected toxic byproduct has not formed.

Since the number of compounds one can reasonably analyze in any one test is limited, knowledge of

the chemical composition, molecular structure, and formulation of the polymer can be used to provide some indication of the main gaseous products, which may or may not be generated under specified experimental conditions. However, one needs to be cautious when predicting the combustion products from generic materials of unknown formulations. For example, one would expect nitrogen-containing materials (e.g., ABS, nylons, rigid and flexible polyurethanes) to produce hydrogen cyanide (HCN) and not expect HCN from a material like PVC. However, PVC containing zinc ferrocyanide, an additive being tested as a smoke suppressant, [this material was never made commercially available after toxicity testing indicated that its combustion products produced very rapid deaths of experimental animals (rats)] and a vinyl chloride–vinylidene chloride copolymer were found to generate HCN. In a similar fashion, based on the chemical composition, PVC is the only one of the seven plastics reviewed by NIST that would be expected to generate chlorinated combustion products. However, widespread usage of halogenated fire retardants in plastic formulations makes predicting which materials will produce halogenated products extremely difficult. In addition, many of the fire extinguishing agents contain halogens and can interact with the other combustion products in unpredictable ways when they are used to extinguish fires, making the problem of assessing health risks of workplace exposure during and after suppression difficult.

Temperature also plays an important role in influencing the production of decomposition products. In general, as the temperature and thus the rate of decomposition increases, the quantity of the more complex compounds and heavier hydrocarbons decreases and the concentrations of carbon monoxide (CO), carbon dioxide (CO_2), and nitrogen dioxide (NO_2) increase. The generation of HCN has also been shown to increase as a function of temperature. Another example is hydrogen chloride (HCl), the detection of which begins when stabilized PVC is heated to approximately 200°C; rapid dehydrochlorination then occurs at about 300°C (16). On the other hand, more acrolein was generated from polyethylene under lower temperature, nonflaming conditions than under higher-temperature flaming conditions (18).

As mentioned earlier, more work is needed to examine the adverse effects of the particulate matter that is also produced when materials are thermally decomposed. Examination of the smoke particulate and condensible matter are important for a number of reasons. First, many of the thermal degradation products may condense or be adsorbed by the soot particles and be transported along with the smoke into the body. Hydrogen chloride is one example of a compound that may be transported in such a fashion or can form a corrosive acid mist in moist air, such as that found in a person's lung. One study of the particulate matter that formed during the smoldering decomposition of rigid polyurethane foam showed that many of the compounds detected in the soot fraction were not found in the volatile fraction (19, 27). Free radicals, which form in fires and are of toxicological concern due to their high reactivity (28–30), are usually considered to have very short life spans; however, if adsorbed onto soot particles, their lifetimes can be considerably longer, and if the soot particle is the correct size, they can be inhaled deep into the individual's respiratory system. In addition, the particulate matter may interfere with the escape and rescue of individuals by causing the obscuration of vision, eye irritation (the eyes clamp shut and the victim is unable to see), and upper respiratory distress. An extreme case indicating the adverse effect of particulates was noted in experiments conducted at NIST. Rats exposed for 30 min to the smoke from flaming polystyrene died during the exposures and the concentration of CO in the blood, even in combination with CO_2, was too low to account for the deaths (31). Pathological examination of these rats showed that their respiratory passages were completely blocked by soot and that suffocation was the likely cause of death (B. C. Levin, NIST, unpublished data).

Particulates have also been implicated in the toxicity of polytetrafluoroethylene (PTFE). Using the National Bureau of Standards (NBS) cup furnace test method, the combustion products of PTFE were found to be 300 times more toxic than other materials decomposed in a similar fashion (32, 33). Further studies showed that inhalation of the combustion products of PTFE decomposed in the NBS cup furnace caused focal hemorrhages, edema, and fibrin deposition in the lungs of rats (34). These same studies showed that with time, focal interstitial thickenings developed due to hypertrophy and

hyperplasia of alveolar cells and macrophages accumulated in the alveoli. Thrombosis of pulmonary capillaries and disseminated intravascular coagulation also occurred. Renal infarcts were common. The exact reason of the unusual toxicity of PTFE's combustion products is unknown and has generated a great deal of interest (35–37). The specific heating conditions of the NBS cup furnace (38, 39) and the particulate fraction from PTFE have been cited (40–42). However, thermal decomposition in the U. Pitt I test method also produced a toxicity classification of "much more toxic than wood" (35, 43) and decomposition in the German Din System produced a toxicity at least 10 times more toxic than wood (44). Full-scale fire tests seem to implicate hydrogen fluoride or carbonyl fluoride as the toxic agent (45).

An extensive review on the toxicology of soot which concentrated on the induction of respiratory diseases and the potential long term carcinogenic effects was published in 1983 (46).

Smoke and Combustion Products
Barbara C. Levin, Ph.D.

4 Toxic Potency versus Fire Hazard Versus Fire Risk
Death in a fire may be caused by:

1. Carbon monoxide (CO)
2. Toxic gases in addition to CO
3. Oxygen (O_2) at levels too low to sustain life
4. Incapacitation—either physical (inability to escape) or mental (incorrect decision making)
5. Bodily burns from flame contact
6. Very high air temperatures
7. Smoke density or irritants in smoke that affect vision and interfere with ability to escape
8. Psychological effects (e.g., fear, shock, and panic)
9. Physical insults (e.g., building or ceiling collapses, broken bones from jumping from upper floors).

Research in the field of combustion toxicology is primarily concerned with items 1–4, all of which are related to the toxic potency of the fire gas effluent. Toxic potency is defined by ASTM as "A quantitative expression relating concentration (of smoke or combustion gases) and exposure time to a particular degree of adverse physiological response, for example, death on exposure of humans or animals" (2). This definition is followed by a discussion, which states, "The toxic potency of smoke from any material or product or assembly is related to the composition of that smoke which, in turn, is dependent upon the conditions under which the smoke is generated." One should add that the LC_{50} is a common endpoint used in laboratories to assess toxic potency. (The LC_{50} value is the result of a statistical calculation based on multiple experiments, each with multiple animals, and indicates the concentration at which 50% of the experimental animals exposed for a specific length of time would be expected to die either during the exposure time or the post-exposure observation period.) In the comparison of the toxic potencies of different compounds or materials, the lower the LC_{50} (i.e., the smaller the amount of material necessary to reach the toxic endpoint), the more toxic the material is.

It is important to note that a toxicity assessment based on lethality due to toxic gases is only part of the total fire hazard that needs to be evaluated especially when one is making choices as to the best material for a specific end use. ASTM defines "fire hazard" as the potential for harm associated with fire (2). The discussion that follows this definition states, "A fire may pose one or more types of

hazard to people, animals or property. These hazards are associated with the environment and with a number of fire-test-response characteristics of materials, products or assemblies including but not limited to ease of ignition, flame spread, rate of heat release, smoke generation and obscuration, toxicity of combustion products and ease of extinguishment." Other factors that need to be evaluated when considering a material for use in a given situation include the quantity of material needed, its configuration, the proximity of other combustibles, the volume of the compartments to which the combustion products may spread, the ventilation conditions, the ignition and combustion properties of the material and other materials present, the presence of ignition sources, the presence of fire protection systems, the number and type of occupants, and the time necessary to escape.

"Fire risk" is defined as "An estimation of expected fire loss that combines the potential for harm in various fire scenarios that can occur with the probabilities of occurrence of those scenarios" (2). The discussion following the definition of fire risk states, "Risk may be defined as the probability of having a certain type of fire, where the type of fire may be defined in whole or in part by the degree of potential harm associated with it, or as potential for harm weighted by associated probabilities. Risk scales do not imply a single value of acceptable risk. Different individuals presented with the same risk situation may have different opinions on its acceptability." A simple way to explain the difference between fire hazard and fire risk is to compare the fire to sky diving, a very hazardous sport; however, if one never goes sky diving, no risk is incurred.

Smoke and Combustion Products
Barbara C. Levin, Ph.D.

5 Toxicity Assessment: Animal Exposures
In most combustion toxicology experiments, the biological endpoint has been lethality or incapacitation of experimental animals, usually rats or mice. Incapacitation (sublethal effects) in a fire can be as perilous as lethality if an individual becomes incapable of correct decision making or physically unable to move. Under these circumstances, the ability to escape will be lost, and death will occur unless the individual is rescued. Therefore, many fire scientists are concerned with the levels of combustion products or amounts of materials that when combusted will cause incapacitation. However, an incapacitation model for use in laboratory testing has been especially difficult to develop. Most of the tests for incapacitation that have been designed are based on the physical-motor capability of an experimental animal to perform some task (e.g., running in a motorized wheel, jumping onto a pole or lifting a paw to escape a shock, running in a maze, or pushing the correct lever to open a door to escape an irritating atmosphere) (47–49). The concentration of toxic combustion products that cause the loss of these types of physical-motor capabilities is usually close to the concentration that is lethal and does not usually add much additional information. More recently, however, there have been attempts at examining neurological endpoints such as measuring the increased number of errors by humans doing mathematical problems while exposed to low levels of CO (Arthur Callahan, Naval Submarine Medical Research Laboratory, Groton, CT, private communication) or exposing rats and pigeons to a complete neurobehavioral battery of 25 tests (50).

Whether one needs to examine incapacitation or lethality depends upon the problem one is trying to solve. To determine the best material for a particular end-use application, the lethality endpoint has proven to be more definitive and will flag the materials that produce extremely toxic combustion products better than an incapacitation endpoint. There are at least two reasons for this: (*1*) Incapacitation is only measured during the exposure, which is usually 30 min or less, but lethality can also occur during the post-exposure observation period, which can be two weeks or longer. A material that only causes delayed effects during the post-exposure period (e.g., a material that generates HCl) can thus have an LC_{50} value that is lower (more toxic) than the incapacitation EC_{50}

value (i.e., the amount of thermally decomposed material necessary to cause post-exposure deaths is less than the amount needed to cause incapacitation during the exposure). (The definition of the EC_{50} is essentially the same as that of the LC_{50}, except incapacitation rather than lethality is the endpoint, and incapacitation is monitored only during the exposure and not during the post-exposure period.) (*2*) In many cases in which the combustion products contain high concentrations of irritant gases, the animals would only appear to be incapacitated (i.e., they would stop responding to the incapacitation test indicator due to the high irritant quality of the smoke), but when removed from the combustion atmosphere, would immediately start responding normally.

Smoke and Combustion Products
Barbara C. Levin, Ph.D.

6 Toxicity Assessment: Predictive Models
In the 1970s, there were essentially two experimental strategies to examine the issues raised by the field of combustion toxicology: (*1*) the analytical chemical method and (*2*) the animal exposure approach. In the analytical chemical method, investigators thermally decomposed materials under different experimental conditions and tried to determine every combustion product that was generated (14, 51). This approach generated long lists of compounds. The toxicity of most of these individual compounds was unknown, and the concept of examining the toxicity of all the various combinations of compounds was and still is considered an impossible task. An additional problem with the analytical method was that, as mentioned earlier, one could not be certain that every toxic product was detected and identified. This approach enabled one to identify many of the multiple products that were generated, but not know the toxic potency of all the identified compounds, especially when combined.

In the animal exposure approach, the animals (usually rats or mice) serve as indicators of the degree of toxicity of the combustion atmospheres (32, 52–54). The materials of concern are thermally decomposed under different combustion conditions, and the animals are exposed to the combined particulate and gaseous effluent. Multiple animal experiments (each with multiple animals) with different concentrations of material are conducted to determine an EC_{50} (incapacitation) or an LC_{50} (lethality) for a specific set of combustion conditions. Each material would then have a particular EC_{50} or an LC_{50} value that can be used to compare the toxicities of different materials decomposed under the same conditions. The lower the EC_{50} or LC_{50}, the more toxic the combustion products from that material. In this approach, one knows the relative toxicity of a material as compared to another material, but does not know which of the toxic gases is responsible for the adverse effects.

In the 1980s, investigators began examining the possibility of combining the analytical chemical method with the animal exposure approach to develop empirical mathematical models to predict the toxicity (8, 31, 55, 56). These predictions were based on actual experiments with animals and their response to each of the main toxic combustion gases, CO, CO_2, low O_2, HCN, NO_2, HCl, and hydrogen bromide (HBr) and various combinations of these gases. The advantages of these predictive approaches are (*1*) The number of test animals is minimized by predicting the toxic potency from a limited chemical analysis of the smoke; (*2*) smoke may be produced under conditions that simulate any fire scenario of concern; (*3*) fewer tests are needed, thereby reducing the overall cost of the testing; and (*4*) information is obtained on both the toxic potency of the smoke (based on the mass of material burned) and the responsible gases (based on the primary toxic gases in the mixture). The prediction is checked with one or two animal tests to assure that an unexpected gas or toxic combination has not formed. The results of using these empirical mathematical models indicated that, in most cases, one could predict the toxic potency of a combustion atmosphere based on the main toxic gases and did not need to worry about the effects of minor or more obscure gases.

A. Primary Toxic Combustion Gases

Complete combustion of a polymer containing carbon, hydrogen, and oxygen in an atmosphere with sufficient O_2 yields CO_2 and H_2O. It is during incomplete combustion under various atmospheric conditions in either flaming or nonflaming modes that compounds of greater toxicological concern are generated. When O_2 is limited, as in nonflaming or ventilation-limited fires, the primary gases formed during the combustion of most materials are CO, CO_2, and H_2O. If the materials contain nitrogen, HCN and NO_2, two principal thermo-oxidative products of toxicological concern, are also likely to be generated. Halogenated or flame-retarded materials generally produce HCl or HBr. Other commonly found fire gases include nitrogen oxides (NO_x), ammonia (NH_3), hydrogen sulfide (H_2S), sulfur dioxide (SO_2), and fluorine compounds. One also needs to consider that in fire situations, O_2 levels drop and exposure to low O_2 atmospheres will have additional adverse physiological effects. Some of these toxic combustion gases (e.g., CO, HCN, low O_2) produce immediate asphyxiant symptoms, while others (e.g., HCl, HBr, NO_2) fall into an irritant category and produce symptoms following the exposures.

B. The **N**-Gas Models

The *N*-gas models for predicting smoke toxicity were founded on the hypothesis that a small number (*N*) of gases in the smoke account for a large percentage of the observed toxic potency. These predictive models were based on an extensive series of experiments conducted at NIST on the toxicological interactions of the primary gases found in fires (8, 31, 55–60). Both the individual gases and complex mixtures of these gases were examined. To use these models, materials are thermally decomposed using a bench-scale method that simulates realistic fire conditions, the concentrations of the primary fire gases—CO, CO_2, low O_2, HCN, HCl, HBr, and NO_2—are measured, and the toxicity of the smoke using the appropriate *N*-gas model is predicted. The predicted toxic potency is checked with a small number of animal (Fischer 344 male rats) tests to assure that an unanticipated toxic gas was not generated or an unexpected toxicological effect (e.g., synergism or antagonism) did not occur. The results indicate whether the smoke from a material or product is extremely toxic (based on mass consumed at the predicted toxic level) or unusually toxic (the toxicity cannot be explained by the combined measured gases). These models have been shown to predict correctly the toxicity in both bench-scale laboratory tests and full-scale room burns of a variety of materials of widely differing characteristics chosen to challenge the system (31, 61). The six-gas model (without NO_2) is now included in two national toxicity test method standards—ASTM E1678, approved by the American Society for Testing and Materials (ASTM) (62), and NFPA 269, approved by the National Fire Protection Association (63). It is also included in an international standard (ISO 13344:1996) that was approved by 16 member countries of the International Standards Organization (ISO), Technical Committee 92 (TC92) (64).

The objectives of developing the *N*-gas models were:

- To establish the extent to which the toxicity of a material's combustion products could be explained and predicted by the interaction of the major toxic gases generated from that material in the laboratory or whether minor and more obscure combustion gases needed to be considered
- To develop a bioanalytical screening test and a mathematical model that would predict whether a material would produce extremely toxic or unusually toxic combustion products
- To predict the occupant response from the concentrations of primary toxic gases present in the environment and the time of exposure
- To provide data for use in computer models designed to predict the hazard that people will experience under various fire scenarios

1 The Six-Gas Model The six-gas model (see Eq. 1) was based on studies at NIST on the toxicological interactions of six gases, CO, CO_2, HCN, low O_2 concentrations, HCl, and HBr. First,

individual gases in air were tested to determine the concentrations necessary to cause 50% of the laboratory test animals (Fischer 344 male rats) to die either during the exposure (within exposure LC_{50}) or during the exposure plus a 14-d post-exposure observation period (within plus post-exposure LC_{50}). The studies on HCl and HBr were conducted at Southwest Research Institute (SwRI) under a grant from NIST (65). Similar measurements for various combinations of these gases indicated whether the toxicity of the mixtures of gases was additive, synergistic, or antagonistic.

Based on these empirical results, the following six-gas model was developed, where the numbers in brackets indicate the time-integrated average atmospheric concentrations:

$$\frac{m[\mathrm{CO}]}{[\mathrm{CO_2}]-b}+\frac{[\mathrm{HCN}]}{\mathrm{LC_{50}\,HCN}}+\frac{21-[\mathrm{O_2}]}{21-\mathrm{LC_{50}\,O_2}}+\frac{[\mathrm{HCl}]}{\mathrm{LC_{50}\,HCl}}+\frac{[\mathrm{HBr}]}{\mathrm{LC_{50}\,HBr}}=N\text{-gas value} \qquad (1)$$

during a 30-min exposure period [(ppm × min)/min or for O_2 (% × min)/min] (3, 8, 53, 60, 62–64). The other terms are defined in the following paragraphs.

Under the experimental conditions used at NIST and with Fischer 344 male rats, the 30-min LC_{50} value of CO_2 is 47% (470,000 ppm) with 95% confidence limits of 43–51% (56, 57, 59). (*Caution:* The values given for use in Eqs. 1 and 3 are dependent on the test protocol, on the source of test animals, and on the rat strain. It is important to verify the above values whenever different conditions prevail and if necessary, to determine the values that would be applicable under the new conditions.) No deaths occurred in rats exposed to 26% CO_2 for 30 min. In a real fire, the highest theoretically possible concentration of CO_2 is 21%, a concentration that could only occur if all the atmospheric O_2 were converted to CO_2, an event highly improbable. Therefore, CO_2 concentrations generated in fires are not lethal. However, CO_2 is a respiratory stimulant causing an increase in both respiratory rate and tidal volume. It also increases the acidosis of the blood. When combined with any of the other tested gases, CO_2 has a synergistic toxicological effect; that is, the toxicities of the other gases are increased in the presence of CO_2 (Table 108.1). Empirically, however, we found that the effect of the CO_2 can only be added into the *N*-gas equations once. Therefore, we included the CO_2 effect with the CO factor since we had more data on the effect of different concentrations of CO_2 on the toxicity of CO and CO is the toxicant most likely to be present in all fires. The results on the synergistic effect of CO_2 on CO indicated that as the concentration of CO_2 increases (up to 5%), the toxicity of CO increases. Above 5% CO_2, the toxicity of CO starts to revert back towards the toxicity of the CO by itself. The terms *m* and *b* in Eq. 1 define this synergistic interaction and equal –18 and 122,000, respectively, if the CO_2 concentrations are 5% or less. For studies in which the CO_2 concentrations are above 5%, *m* and *b* equal 23 and –38,600, respectively.

Table 108.1. Synergistic Effects of CO_2

	LC_{50} Values[b]	
Gas[a]	Single Gas	With 5% CO_2
CO_2	470,000 ppm	—

CO	6,600 ppm	3,900 ppm
NO_2	200 ppm	90 ppm
O_2	5.4%	6.4%

[a] All gases were mixed in air.

[b] 30-min exposures of Fischer 344 rats; deaths occurred during and following the exposures.

In rats, the 30-min LC_{50} for CO is 6,600 ppm, and with 5% CO_2, this value drops to 3,900 ppm. Exposure to CO in air only produced deaths during the actual exposures and not in the post-exposure observation period; however, exposures to CO plus CO_2 also caused deaths in the post-exposure period. Carbon monoxide is a colorless, odorless, tasteless, and nonirritating poisonous gas. The toxicity of CO comes from its binding to the hemoglobin in red blood cells and the formation of carboxyhemoglobin (COHb). The presence of CO on the hemoglobin molecule prevents the binding of O_2 to hemoglobin (O_2Hb) and results in hypoxia in the exposed individual. Since the binding affinity of hemoglobin for CO is 210 times greater than its affinity for O_2, only 0.1% CO (1000 ppm) is needed to compete equally with O_2, which is normally present at 20.9% in air (20.9%/210 ≈ 0.1%). Thus only 1000 ppm of CO in the atmosphere is enough to generate 50% COHb, a value commonly quoted (but not necessarily proven) as the concentration that is lethal to humans. The time to get to 50% COHb at 1000 ppm CO would be longer than 30 min.

The LC_{50} value of HCN is 200 ppm for 30-min exposures or 150 ppm for 30-min exposures plus the post-exposure observation period. HCN caused deaths both during and following the exposures.

The 30-min LC_{50} of O_2 is 5.4%, which is included in the model by subtracting the combustion atmospheric O_2 concentration from the normal concentration of O_2 in air, that is, 21%. The LC_{50} values of HCl or HBr for 30-min exposures plus post-exposure times are 3,700 and 3,000 ppm, respectively. HCl and HBr at levels found in fires only cause post-exposure effects.

The pure- and mixed-gas studies showed that if the value of Eq. 1 is 1.1 ± 0.2, then some fraction of the test animals would die. Below 0.9, no deaths would be expected, and above 1.3, all the animals would be expected to die. Since the concentration–response curves for animal lethalities from smoke are very steep, it is assumed that if some percentage (not 0 or 100%) of the animals die, the experimental loading is close to the predicted LC_{50} value. Results using this method show good agreement (deaths of some of the animals when the *N*-gas values were above 0.9) and the good predictability of this approach.

This model can be used to predict deaths that will occur only during the fire exposure or deaths during and following the fire. To predict the deaths that would occur both during and following the exposures, Eq. 1 is used as presented. To predict deaths only during the exposures, HCl and HBr, which only have post-exposure effects, should not be included in Eq. 1. In small-scale laboratory tests and full-scale room burns, Eq. 1 was used successfully to predict the deaths during and following exposures to numerous materials (61, 66). In the case of PVC, the model correctly predicted the results as long as the HCl was greater than 1000 ppm; therefore, it is possible that HCl concentrations under 1000 ppm may not have any observable effect on the model even in the post-exposure period. More experiments are necessary to show whether a true toxic threshold for HCl does exist.

Although most of the work at NIST concentrated on deaths during or following 30-min exposures, the LC_{50}s of many of these gases both singly and mixed were determined at times ranging from 1 to 60 min and in all the cases examined, the predictive capability of Eq. 1 holds if the LC_{50}s for the

other times are substituted into the equation.

2 The Seven-Gas Model; Addition of NO_2 to the **N**-Gas Model Nitrogen dioxide is an irritant gas that will cause lachrymation, coughing, respiratory distress, increases in methemoglobin levels, and lung edema (67). Single brief exposures to less than lethal concentrations can cause lung damage, emphysema, or interstitial fibrosis. Low levels have been alleged to increase one's susceptibility to respiratory infections, and aggravate one's reactions to allergens. Impairment of dark adaptation has also been noted. Delayed serious effects can be observed as late as two to three weeks following exposures. In the lungs, NO_2 forms both nitric (HNO_3) and nitrous (HNO_2) acids, which are probably responsible for the damage to the lung cells and connective tissue.

In fires, NO_2 may arise from atmospheric nitrogen fixation, a reaction that is material independent, or from the oxidation of nitrogen from nitrogen-containing materials. To examine the generation of NO_2 from nitrogen fixation, a small study was undertaken at NIST. In two full-scale fires of rooms in which the main source of fuel was polystyrene- covered walls, only low levels of NO_x (10 and 25 ppm, respectively) were found, indicating little nitrogen fixation under these conditions (59). A real example of burning nitrogen-containing materials was the 1929 Cleveland Clinic fire, in which 50,000 nitrocellulose x-ray films were consumed (68). The deaths of 97 people in this fire were attributed mainly to NO_x. An additional 26 people died between 2 h and 1 mo following the fire, and 92 people were treated for nonfatal injuries. In laboratory tests of nitrogen-containing materials under controlled conditions, 1–1000 ppm of NO_x was measured (61, 69–71). In military tests of armored vehicles penetrated by high-temperature ammunition, NO_2 levels above 2000 ppm were found (72).

a Individual and Binary Mixtures In small-scale laboratory tests of NO_2 in air, deaths of Fischer 344 male rats occur only in the post-exposure period, and the LC_{50} value following a 30-min exposure is 200 ppm (59). Carbon dioxide plus NO_2 show synergistic toxicological effects (59). The LC_{50} for NO_2 following a 30-min exposure to NO_2 plus 5% CO_2 is 90 ppm (post-exposure deaths) i.e., the toxicity of NO_2 doubled.

The details of the following research are provided in Ref. 60. As mentioned, CO produces only within-exposure deaths, and its 30-min LC_{50} is 6600 ppm. In the presence of 200 ppm of NO_2, the within-exposure toxicity of CO doubled (i.e., its 30-min LC_{50} became 3300 ppm). An exposure of approximately 3400 ppm CO plus various concentrations of NO_2 showed that the presence of CO would also increase the post-exposure toxicity of NO_2. The 30-min LC_{50} value of NO_2 went from 200 to 150 ppm in the presence of 3400 ppm of CO. A concentration of 3400 ppm of CO was used as that concentration would not be lethal during the exposure, and any post-exposure effects of CO on NO_2 would become evident; the LC_{50} of CO (6600 ppm) would have caused deaths of the animals during the 30-min exposure.

The 30-min LC_{50} of O_2 is 5.4% and the deaths occur primarily during the exposures. In the presence of 200 ppm of NO_2, the within-exposure LC_{50} of O_2 and its toxicity increased to 6.7%. In the case of O_2, increased toxicity is indicated by an increase in the value of the LC_{50}, since it is more toxic to be adversely affected by a concentration of O_2 ordinarily capable of sustaining life. Exposure of the animals to 6.7% O_2 plus various concentrations of NO_2 showed that the NO_2 toxicity doubled (i.e., its LC_{50} value decreased from 200 to 90 ppm).

One of the most interesting findings was the antagonistic toxicological effect noted during the experiments on combinations of HCN and NO_2. As mentioned, the 30-min LC_{50} for NO_2 alone is 200 ppm (post-exposure) and the 30-min within-exposure LC_{50} for HCN alone is also 200 ppm. These concentrations of either gas alone are sufficient to cause death of the animals (i.e., 200 ppm HCN or 200 ppm NO_2 would cause 50% of the animals to die either during the 30-min exposure or following the 30-min exposure, respectively). However, in the presence of 200 ppm of NO_2, the within-exposure HCN LC_{50} concentration increases to 480 ppm, or, stated in other words, the toxicity of HCN decreases by 2.4 times.

The mechanism for this antagonistic effect is believed to be as follows: In the presence of H_2O, NO_2 forms nitric acid (HNO_3) and nitrous acid (HNO_2) (73). These two acids are the most likely suspects responsible for the lung damage leading to the massive pulmonary edema and subsequent deaths noted following exposure to high concentrations of NO_2. Nitrite ion (NO_2^-) formation occurs in the blood when the nitrous acid dissociates. The nitrite ion oxidizes the ferrous ion in oxyhemoglobin to ferric ion to produce methemoglobin (MetHb) (Eq. 2) (74). MetHb is a well-known antidote for CN^- poisoning (75). MetHb binds cyanide-forming cyanmethemoglobin, which keeps the cyanide in the blood and prevents it from entering the cells. In the absence of MetHb, free cyanide will enter the cells, react with cytochrome oxidase, prevent the utilization of O_2, and cause cytotoxic hypoxia. If, on the other hand, cyanide is bound to MetHb in the blood, it will not be exerting its cytotoxic effect. Therefore, the mechanism of the antagonistic effect of NO_2 on the toxicity of cyanide is believed to be due to the conversion of oxyhemoglobin [$O_2Hb(Fe^{2+})$] to methemoglobin [$MetHb(Fe^{3+})$] in the presence of nitrite:

$$2\,H^+ + 3\,NO_2^- + 2\,O_2\,Hb(Fe^{2+}) \Rightarrow 2\,MetHb\,(Fe^{3+}) + 3\,NO_3^- + H_2O \qquad (2)$$

b Tertiary Mixtures of NO_2, CO_2, and HCN Earlier work indicated that the presence of 5% CO_2 with either HCN or NO_2 produced a more toxic environment than would occur with either gas alone (31, 59). The antagonistic effects of NO_2 on HCN indicate that the presence of one LC_{50} concentration of NO_2 (~ 200 ppm) will protect the animals from the toxic effects of HCN during the 30-min exposures, but not from the post-exposure effects of the combined HCN and NO_2. Thus it was of interest to examine combinations of NO_2, CO_2, and HCN (60). In this series of experiments, the concentrations of HCN were varied from almost 2 to 2.7 times its LC_{50} value (200 ppm). The concentrations of NO_2 were approximately equal to one LC_{50} value (200 ppm) if the animals were exposed to NO_2 alone and approximately ½ the LC_{50} (90 ppm) if the animals were exposed to NO_2 plus CO_2; the concentrations of CO_2 were maintained at approximately 5%; and the O_2 levels were kept above 18.9%. The results indicated that CO_2 does not make the situation worse, but rather provided additional protection even during the post-exposure period. In each of six experiments, some or all of the animals lived through the test even though they were exposed to greater than lethal levels of HCN plus lethal levels of NO_2, and in four tests, some of the animals lived through the post-exposure period even though the animals were exposed to combined levels of HCN, NO_2 and CO_2 that would be equivalent to 4.7–5.5 times the lethal concentrations of these gases. One possible reason that CO_2 seems to provide an additional degree of protection is that NO_2 in the presence of 5% CO_2 produces 4 times more MetHb than does NO_2 alone (59).

c Mixtures of CO, CO_2, NO_2, O_2, and HCN The initial design of these experiments was to look for

additivity of the CO/CO_2, HCN, and NO_2 factors keeping each at about $\frac{1}{3}$ of its toxic level, while keeping the O_2 concentration above 19% (60). When these initial experiments produced no deaths, we started to increase the concentrations of CO up to $\frac{1}{3}$ of the LC_{50} of CO alone (6600 ppm), HCN was increased to 1.3 or 1.75 times its LC_{50} depending on whether the within-exposure LC_{50} (200 ppm) or the within- and post-exposure LC_{50} (150 ppm) is being considered, and NO_2 was increased up to a full LC_{50} value (200 ppm). The results indicated that just adding an NO_2 factor (e.g., $[NO_2]/LC_{50}\ NO_2$) to Eq. 1 would not predict the effect on the animals. A new mathematical model was developed and is shown as Eq. 3. In this model, the differences between the within-exposure predictability and the within-exposure and post-exposure predictability is: (1) the LC_{50} value used for HCN is 200 ppm for within-exposure or 150 ppm for within-exposure and post-exposure and (2) the HCl and HBr factors are not used to predict the within-exposure lethality, only the within-exposure and post-exposure lethality. According to Eq. 3, animal deaths will start to occur when the *N*-gas value is above 0.8 and 100% of the animals will die when the value is above 1.3. Results indicated that in those few cases where the values were above 0.8 and no deaths occurred, the animals were severely incapacitated (close to death), as demonstrated by no righting reflex or eye reflex.

The *N*-Gas Model Including NO_2

$$N\text{-gas value} = \frac{m[CO]}{[CO_2]-b} + \frac{21-[O_2]}{21-LC_{50}O_2} + \left(\frac{[HCN]}{LC_{50}\ HCN}\ \frac{0.4[NO_2]}{LC_{50}NO_2}\right) + 0.4\left(\frac{[NO_2]}{LC_{50}NO_2}\right) + \frac{[HCl]}{LC_{50}HCl} + \frac{[HBr}{LC_{50}H} \quad (1)$$

For an explanation of these terms, see the paragraphs following Eq. 1. Eq. 3 should be used to predict the within-exposure plus post-exposure lethal toxicity of mixtures of CO, CO_2, HCN, reduced O_2, NO_2, HCl, and HBr. The LC_{50} values will be the same as those given for Eq. 1 using 150 ppm for HCN and 200 ppm for NO_2. If one wishes to predict the deaths that will occur only during the exposure, the LC_{50} value used for HCN should be 200 ppm, and the HCl and HBr factors should not be included. To predict the lethal toxicity of atmospheres that do not include NO_2, Eq. 1 should be used.

Smoke and Combustion Products
Barbara C. Levin, Ph.D.

7 Combustion Toxicity Test Methods
The toxicity of the combustion products from any new material formulation or product containing additives or new combinations of additives needs to be examined. Material and polymer chemists are currently trying to develop new “fire-safe” materials (5). The terms “fire-safe” or “fire resistant” are not the same as noncombustible. Unless these new materials are truly noncombustible, some thermal decomposition will occur when the materials are exposed to fire conditions. Both the toxic gases and the irritants that are present in all smoke need to be considered potential dangers. The toxic products can cause both acute and delayed toxicological effects. It is the acute and extremely short-term effects that prevent escape from burning buildings by causing faulty judgement, incapacitation, and death. The irritants in the smoke can also interfere with one's ability to escape by causing severe coughing and choking and by preventing one from keeping one's eyes open long enough to find the exits. In addition, the delayed effects, such as tissue or organ injury, mutagenicity, carcinogenicity, and teratogenicity need to be studied, since they may ultimately lead to permanent disability and

post-exposure deaths. Some of the issues involved in delayed effects are addressed in a paper by Lewtas (76) and a review by Barfknecht (46). The current advances in the field of genetics provide investigators with new opportunities to examine the effects of combustion products at the molecular level. One objective could be to determine whether these toxic products cause DNA damage and/or mutations. Specific problems of interest include: does the damage occur in nuclear DNA and/or mitochondrial DNA; are certain areas of the DNA more prone to these mutations (i.e., are there hot spots?); can we categorize the types of mutations (e.g., transitions, transversions, deletions, insertions); and how efficient are the repair mechanisms? Are these mutagens also known to be carcinogens?

Toxicity screening tests for both the acute and delayed effects are, therefore, needed to evaluate the combustion products, including any irritants that may be present in newly proposed materials and products. It is imperative that the materials and products be tested under experimental conditions that simulate realistic fire scenarios of concern (e.g., flash-over conditions emanating from, first, smoldering and then, flaming of upholstered furniture in homes or smoldering fires in concealed spaces in aircraft). The ideal tests should be simple, rapid, inexpensive, use the least amount of sample possible (since, in many cases, only small amounts of a new experimental material may be available), use a minimum number of test animals, and have a definitive toxicological endpoint for comparison of the multiple candidates.

While faulty judgement and incapacitation are significant causes of worry since they can prevent escape and cause death, they are extremely difficult and complex endpoints to define and measure in nonhuman test subjects. Death of experimental animals (e.g., rats), on the other hand, is a more definitive and easily determined endpoint and can be used to compare the relative toxicities of alternate materials deemed suitable for the same purpose. The assumption made here is that if the combustion products of material *X* are significantly more lethal than those of material *Y*, the combustion products of *X* would probably cause more incapacitation and more impairment of judgment than *Y* as well. The number of experimental animals can be significantly reduced by utilizing one of the predictive mathematical models developed for combustion toxicology such as the *N*-gas models previously discussed in this chapter.

Many test methods for the determination of the acute toxicity of combustion products from materials and products have been developed over the past two decades and continue to be developed and/or improved (52). In 1983, thirteen of the methods published up to that time were evaluated by Arthur D. Little, Inc., to assess the feasibility of incorporating combustion toxicity requirements for building materials and finishes into the building codes of New York State (77). On the basis of seven different criteria, only two methods were found acceptable. These two methods were the flowthrough smoke toxicity method developed at the University of Pittsburgh (43, 54, 78) and the closed-system cup furnace smoke toxicity method developed at NIST [known at that time as the National Bureau of Standards (NBS)] (32, 53). In 1991 and 1992, Standard Reference Materials were developed at NIST and made available to the users of these methods to provide assurance that they are performing the methods correctly (53, 54). Based on the results of the Arthur D. Little report, the state of New York under Article 15, Part 1120 of the New York State Fire Prevention and Building Code decided to require that building materials and finishes be examined by the method developed at the University of Pittsburgh and that the results be filed with the state (79). It is important to note, however, that although the results are filed, the state of New York does not regulate any materials or products based on the results of this or any other toxicity test at this time.

Since 1983, a number of new approaches to assess acute combustion toxicity have been examined. These approaches include a radiant furnace smoke toxicity protocol developed by NIST and SwRI (61, 80–82), the University of Pittsburgh II radiant furnace method (83–85), and the National Institute of Building Sciences (NIBS) toxic hazard test method (86, 87). All three use radiant heat to decompose materials.

The NIST radiant test and the NIBS toxic hazard test use the same apparatus, consisting of three

components: a radiant furnace, a chemical analysis system, and an animal exposure chamber. The chemical analysis system, and animal exposure system are identical to that developed for the NBS cup furnace smoke toxicity method. Although the apparatus of both methods are essentially the same, they have different toxicological endpoints. In the NIST method, an approximate LC_{50}, based on the *mass* of material needed to cause lethality in 50% of the test animals during a 30-min exposure and/or a 14-day post-exposure period, is the determinant of toxicity. The number of animals needed to run the test is substantially reduced by first estimating the LC_{50} by the *N*-gas model and analytical tests without animals. This estimate is then verified with one or two animal tests to assure that no unforeseen gas was generated. The toxicological endpoint of the NIBS toxic hazard test is the IT_{50}, the irradiation *time* (the time that the material is exposed to the radiant heat) that is required to kill 50% of the animals during a 30-min exposure or 14-d post-exposure time. The actual results of the NIBS test with 20 materials indicated that the test animals died in very short periods of time (personal communication) and the test was unable to discriminate very well between materials. These results substantiate the thesis that mass (the smaller the mass necessary for an LC_{50}, the more toxic the material) is a better indicator of acute toxicity than time.

Both the NIST and NIBS test procedures are designed to simulate a post-flashover scenario. The premise for simulating a post-flashover fire is that most people that die from inhalation of toxic gases in *residential* fires are affected in areas away from the room of fire origin. Smoke and toxic gases are more likely to reach these distant areas following flashover. This scenario may not be relevant in certain circumstances (e.g., aircraft interior fires, where a smoldering fire in a concealed space may cause significant problems if the plane is over a large body of water and unable to land for a considerable period of time).

The NIST radiant test has been accepted by the American Society for Testing and Materials (ASTM) as a national standard designated ASTM E1678 and entitled “Standard Test Method for Measuring Smoke Toxicity for Use in Fire Hazard Analysis” (62). The National Fire Protection Association (NFPA) has also adopted the NIST Radiant Test Method as a national standard called “Standard Test Method for Developing Toxic Potency Data for Use in Fire Hazard Modeling,” NFPA 269 (63). In 1995, the International Standards Organization, Technical Committee 92, Subcommittee 3 (ISO/TC92/SC3) on Toxic Hazards in Fire published an international standard for combustion toxicity after approval by 16 countries (64). This standard—ISO/IS 13344, entitled “Determination of the Lethal Toxic Potency of Fire Effluents”—describes the mathematical models (including the *N*-gas model) available for predicting the toxic potency of fire atmospheres based on the toxicological interactions of the main combustion gases present. In the international standard, investigators have the flexibility of designing or choosing a system that will simulate conditions relevant to their fire scenario, rather than having to accept a designated combustion system.

Smoke and Combustion Products
Barbara C. Levin, Ph.D.

8 Toxicant Suppressants

Fire scientists are very familiar with fire-retardant chemicals, which are defined by ASTM as “Chemicals, which when added to a combustible material, delay ignition and combustion of the resulting material when exposed to fire” (2). The discussion adds “A fire-retardant chemical can be a part of the molecular structure, an admixture or an impregnant.” The term *toxicant suppressant*, however, is a new expression arising from research at NIST that demonstrated that the addition of copper compounds to flexible polyurethane foam (FPU) significantly reduced the generation of hydrogen cyanide (HCN) as well as the toxicity of the combustion products when the foam was thermally decomposed (88–92). These experiments were designed to simulate the nonflaming and

then flaming stages of a chair ignited by a cigarette (a two-phase heating system which simulates the fire scenario that results in the most fire deaths in the U.S.) (93). The term toxicant suppressant may be defined as a chemical that when added to a combustible material significantly reduces or prevents one or more toxic gases from being generated when that material undergoes thermal decomposition. The resultant gas effluent should be less toxic than that from the untreated material; that is, the toxic gas whose concentration is being reduced should not be converted to an equally or more toxic product.

The results of these studies at NIST indicated that:

1. Hydrogen cyanide concentrations in the thermal decomposition products from a flexible polyurethane foam were reduced approximately 85% when the foam was treated with 0.1% or 1.0% Cu_2O and thermally decomposed via a two-phase heating system in the cup furnace smoke toxicity apparatus.
2. The copper or copper compounds could be added to the foams during or after the foams were formulated and still be operative in reducing the toxicity and HCN yield. (The BASF Corporation prepared the foams that had the Cu powder and Cu_2O added during formulation.) The addition of the copper or copper compounds during formulation did not affect the foaming process or the physical appearance on the foams except for a slight change of color.
3. Low levels of the copper compounds were effective. In particular, when cupric oxide (CuO) was used, the concentration of copper needed was only 0.08% by weight and when cuprous oxide (Cu_2O) was used, only 0.07% by weight was needed to significantly reduce the generation of HCN.
4. Full-scale room burns indicated that the presence of Cu_2O in the FPU reduced the HCN generation by approximately 50–70% when the experimental plan was designed to simulate a realistic scenario (the foams contained 1.0% Cu_2O, were covered with a cotton upholstery fabric and arranged to simulate a chair; smoldering was initiated with cigarettes, and flaming occurred spontaneously).
5. Under small-scale conditions, less than 3 ppm of NO_x was generated from the un-treated foams, whereas a range of 3–33 ppm of NO_x was measured from the 0.1–1.0% Cu_2O-treated foams. About 6% of the HCN appeared to be converted to NO_x. In the full-scale room tests, approximately 23% of the HCN appeared to be converted to NO_x. Since we have shown in our laboratory that NO_2 acts as an antagonist to HCN, this amount of NO_x may also act to counteract the immediate toxic effects of any residual HCN.
6. Since the atmospheric oxygen (O_2) concentrations can reach very low levels in real fires, it was important to know if the reduction of HCN by copper would occur under low O_2 conditions. Small-scale tests with the ambient O_2 concentrations as low as 6% indicated that the HCN levels were reduced by as much as 82% when the FPU was treated with 0.1% Cu_2O.
7. The toxicity of the gas effluent was also reduced (an indication that the HCN was not being converted into some compound that was even more toxic). Fewer animal (Fischer 344 rats) deaths occurred during the 30-min exposures to the FPU treated with the copper and copper compounds compared to the untreated FPU. Toxicity based on LC_{50} values was reduced 40–70% in the small-scale tests with 0.1% Cu_2O-treated foams. The blood cyanide levels in the animals exposed to combustion products from the CuO-treated foams for 30 min were ½ to ¼ those measured in the animals exposed to the smoke from the same amount of untreated foam.
8. Post-exposure deaths were also reduced in the animals exposed to the combustion products from the Cu and Cu_2O-treated FPU foams in the small-scale tests. These delayed post-exposure deaths have not been observed in animals exposed to combustion products from flexible

polyurethane foams decomposed in large-scale room fire tests. The specific cause of these post-exposure deaths is not known.

9. No differences in flammability characteristics between the 0.1% Cu_2O-treated and untreated FPU foam were observed. These characteristics were examined to assure that the positive effect on toxicity was not contradicted by negative effects on the flammability properties. The flammability characteristics examined were: (a) ignitability in three systems [the cup furnace smoke toxicity method, the cone calorimeter, and lateral ignition and flame spread test (LIFT)], (b) heat release rates under small-scale (cone calorimeter) and medium-scale (furniture calorimeter) conditions, (c) heats of combustion under small-scale (cone calorimeter) and medium-scale (furniture calorimeter) conditions, (d) CO/CO_2 ratios under small-scale (cone calorimeter) and medium-scale (furniture calorimeter) conditions, (e) smoke obscuration (cone calorimeter), and (f) rate of flame spread (LIFT).
10. Research conducted at the BASF Corporation indicated that the physical properties of the 1.0% Cu_2O-treated FPU were not significantly different from the comparable untreated FPU. The physical properties examined were tensile strength, elongation, tear strength, resilience, indentation force deflection, support factor, compression sets, and air flow.
11. The use of melamine-treated FPU is becoming more common (94, 95); it is one of two FPU foams currently allowed in Great Britain. Small-scale tests indicated that a melamine-treated FPU generated 6 times more HCN than an equal amount of a non-melamine-treated foam. The presence of Cu_2O reduced the HCN from the melamine foam by 90%.

Jellinek and co-workers in the late 1970s also showed that the concentrations of HCN generated from the thermal decomposition of a polyurethane at 300 and 400°C decreased when flowed through copper compounds (96, 97). In their studies, the polyurethane films were very thin (15 mm thick and 50 mg in weight). In some experiments, the metal powder was mixed with the polymer and, in others, copper metal films of 400 to 1000 Å were deposited on top of the polymer films. In most cases, the percent of copper was 10% or greater. The lowest concentration that they tested was a 2.6% copper film, which inhibited the evolution of HCN by 66%. Their experiments indicated that the copper is probably acting as an oxidative catalyst, which would decompose gaseous HCN into N_2, CO_2, H_2O, and small amounts of nitrogen oxides. Further research is needed to determine if this is the actual molecular mechanism that allows copper to act as an HCN toxicant suppressant.

Levin and her co-workers' research differed from that of Jellinek in that much larger samples of FPU (including full-scale room burns of cushions and simulated chairs), much smaller concentrations of copper were used, and the toxicity of the combustion products from the copper-treated FPU was also examined.

Unpublished data of Levin also indicated that a wool fabric treated with copper would generate 50% less HCN than the untreated fabric. These results demonstrate a potentially more universal effect, namely, that treating nitrogen-containing materials with copper compounds will probably reduce the HCN generated when that material is exposed to fire conditions. Taking these results one step further, one could develop other toxicant suppressants that when added to materials and products would now prevent or significantly reduce the toxic effluents that are generated when they are thermally decomposed.

Smoke and Combustion Products
Barbara C. Levin, Ph.D.

9 Conclusions

The field of toxicology of combustion products has come a long way since the early 1970s, when the National Commission on Fire Prevention and Control submitted their report entitled "America Burning" to President Nixon (98). That report, which included the statement that "Appallingly, the richest and most technologically advanced nation in the world leads all the major industrialized countries in per capita deaths and property loss from fire," provided the impetus to determine the cause of and to try to solve this major problem being experienced by the United States. It was shortly thereafter that Petajan et al. published their paper in *Science* entitled "Extreme Toxicity from Combustion Products of a Fire-Retarded Polyurethane Foam" (13) and raised the specter of "supertoxicants" emanating from combustion atmospheres. In the following years, the field of combustion toxicology expanded greatly, and many materials and products were tested by various test methods. With the exception of the material described in the Petajan et al. paper and one other product described in Section 3, the concern about "Supertoxicants" has proven to be largely unfounded. However, the potential that the combustion products from new formulations or combinations of compounds may prove to be extremely or unusually toxic has encouraged manufacturers to test their new products. The state requirements of New York has also been a motivating force for manufacturers to test the building products they wish to sell in New York (79). This testing may have prevented dangerous products from reaching the marketplace.

After reaching a peak in the 1980s, the amount of research in the area of combustion toxicology has declined significantly. With the exception of some military laboratories, very few laboratories are still doing this type of research. The Building and Fire Research Laboratory at the National Institute of Standards and Technology, where much of the research quoted in this chapter was conducted, abolished its combustion toxicology research program in 1992. Some of the areas that remain to be examined include: the effects of the addition of more gases and heat to the *N*-gas model; the effects of particulates alone and in combination with the *N*-gases; the effects of chronic exposures to fire atmospheres (e.g., those experienced by fire fighters); sublethal effects on the neurological and other organ systems; mutagenic, teratogenic, and carcinogenic effects of acute and chronic exposures; the development of improved therapeutic methods for the treatment of smoke (including particulates) inhalation victims; and additional research on toxicant suppressants with the ultimate aim of developing fire-safe materials (i.e., materials that do not produce toxic gases even when they are thermally decomposed). Since 80% of fire deaths are the result of smoke inhalation, a less toxic smoke could significantly increase the time available for escape and reduce the number of injuries and deaths from fire.

Smoke and Combustion Products
Barbara C. Levin, Ph.D.

Notes
Certain commercial equipment, instruments, materials, or companies are identified in this chapter to specify adequately the experimental procedure. Such identification does not imply recommendation or endorsement by the author, nor does it imply that the materials or equipment identified are the best available for the purpose.

Chemical and Physical Agent Interaction

Per Nylén, Ph.D., Ann-Christin Johnson, Anders Englund, MD

1 Introduction

This chapter, concerning interactions at simultaneous or successive exposure to both physical and chemical factors, focuses on the industrial environment. Examples of this kind of interaction can probably be found in a large variety of totally different and unrelated areas, and the present text is not intended to be a complete review but to present illustrative examples of studies and occupational areas in which such interactions are included. Reported findings are of both physicochemical and biological nature, most often descriptive observations, and referred papers rarely include mechanistic information or hypotheses. Exposure levels are often higher than those found at today's work sites, and the possibility of using data for making reasonable, adequate extrapolations often remains unknown. Despite these limitations, it is the main intentions of the present text to inform and alert occupational health practitioners and other interested readers about what attempts have been made so far to gain knowledge about the situation in the vast majority of work sites, specifically, combined exposure to both at least one physical agent and one chemical agent.

The presentation is ordered using the respective physical factors as subtitles under which published data concerning the particular factor's interaction with different chemicals are presented. Physical factors presented are mechanical factors such as sound waves (most often referred to as “noise”) and vibrations; the thermal factors heat and cold, electrostatic fields; and electromagnetic radiation from low frequency fields, radio frequencies, visible light, ultraviolet light, to ionizing radiation. Since many of these physical factors most naturally interacts with sensory functions, the text often focuses on interactions seen as sensory and nervous system alterations in both animals and humans.

Exposures to physical factors and chemicals that are not primarily related to occupational exposure, for example, the multitude of drugs that can interact with sunlight, are considered as being a general toxicological problem rather than a specific occupational toxicological issue. Readers interested in such interactions are therefore referred to the pharmacological literature.

1.1 Frequency of Mixed Exposure to Physical and Chemical Factors

It has been estimated that the number of chemical agents frequently used occupationally is of the magnitude of 10^4 (1). If the number of physical factors of significant occupational importance is ~10, the number of possible combined exposures to both a physical and a chemical agent is approximately 10^5. Furthermore, occupational exposure to industrial chemicals is in itself most often multiple (2–4); that is, workers are exposed to two or more chemicals simultaneously, or with a short delay between the individual exposures. In one study (5) it was found that many car and industrial painters were exposed daily to 10 different solvents, and weekly to about 20 solvents. Adding known exposure to physical factors in this occupation such as light, noise, vibrations, and heat makes the

number of possible interactions between chemical and physical agents huge in this group, and most certainly in many other groups of workers.

Almost by definition, all occupational exposures to chemicals also include exposure to at least one physical agent, such as visible light, noise, vibration, and heat. It may be argued that studying specific combinations is of limited use for risk assessment since the number of physical and chemical agents present and used occupationally is so large. Some combinations of physical and chemical agents occur more frequently than others, because of the use of commercial products containing fixed chemical mixtures. The number of agents is nevertheless so large that toxicological testing of all combinations individually seems unrealistic. This fact has contributed to an interest in models for general risk approximation at combined exposure.

1.2 Frequency of Nonadditive Interactions

Within the area of developmental toxicology, interactive effects have been studied after concurrent exposures to a variety of chemical and physical agents, including therapeutic drugs, industrial agents, and some biological organisms or their toxins. Of approximately 160 reports of concurrent exposures reviewed (6), about one-third report no interactive effects (including additive effects, usually referring to response as opposed to dose additivity); another third report antagonistic effects, and the final third report potentiating or synergistic effects. It was, however, pointed out that the quality of the studies and the used terminology were highly variable.

In a review of approximately 600 studies concerning combined exposure to different chemicals, synergistic interactions were also reported in about 30% of the studies (7). Antagonistic effects were also reported in about 30%, which made nonadditive interactions in total more common than additive ones.

The terminology used to describe additive or nonadditive outcomes in the information presented is not consistent. The lack of unified terminology is general within the research area, but promising initiatives have been taken (8). In referred papers, the statistical procedures are sometimes undefined as well as the use of interaction descriptors such as *synergistic, hyperadditivity*, and *enhancement of risk*. These missing pieces of information do not, however, motivate a total rejection of the reported findings. Even if the degree of synergism, for instance, were not exactly and reliably quantified, the fact that a more-or-less pronounced synergistic interaction probably was observed would be of great interest to both practitioners and researchers who deal with combined exposure interactions.

1.3 Methods for Risk Assessment of Combined Exposures in Risk Management

1.3.1 Mixtures Including Chemical Agents Only In the United Kingdom (9), the United States (10), and Sweden, for instance, proposed procedures for occupational risk assessment of exposure to mixtures of chemicals include calculation of a hazard index (HI).

$$HI = \frac{E_1}{L_1} + \frac{E_2}{L_2} + \cdots + \frac{E_i}{L_i} \qquad (1)$$

where E_i = exposure level to the toxicant L_i = occupational exposure limit value level for the toxicant.

If HI is below 1.0, the combined exposure is considered acceptable, thus a person exposed to the contaminants is regarded as protected against ill health. Use of this model includes an assumption that the chemicals act on the same organ system. If the included chemicals have different toxic endpoints, and there is no evidence of toxic interaction, it has been suggested that the guidelines for a single exposure may provide acceptable protection also at mixed exposure (2, 11). If it is not known whether the substances in the combination have different modes of action, it has been suggested that the combined effect should be assumed to be additive, since the allowed level of the combined exposure will then be lower than if independence is assumed (1).

Equation (1) should be used with some limitations kept in mind. It does not predict nonadditive

interactions, even if the possibility of such interactions is sometimes commented upon in regulatory texts. Further, the dose–response functions of the individual agents or the mixtures may not be linear.

Mixed exposure is, in addition, also more difficult to define qualitatively and quantitatively than individual exposures, which increases the uncertaninty of its effects. Finally, only substances given an occupational exposure limit value can be included in the HI calculation. The applicability of the HI equation is thus limited, which leaves a number of common combined exposures without guidelines.

1.3.2 Mixtures Containing both Physical and Chemical Agents No consensus exists concerning risk assessment of occupational exposures that include both chemicals and physical agents, such as noise or light. An attempt including similarities with equation (1) concerning exposure to toluene and noise has been presented by the Danish Institute of Occupational Health. To calculate the contribution of noise using equation (2), using the logarithmic unit dB, the measured sound pressure should be normalized, that is, a doubled sound pressure should have the same impact as a doubled concentration:

$$L_h = C_0/C_{lv} + \frac{10^{n_0/10}}{10^{n_{lv}/10}} \qquad (2)$$

where C_0 = actual concentration of solvent C_{lv} = occupational exposure limit value of solvent n_0 = actual level (dB) of noise n_{lv} = occupational exposure limit value of noise (often 85 dB)

A consideration of the complexity of the different variables that can influence possible interactions at combined exposure has led the “commission for the investigation of health hazards of chemical compounds in the work area” in Germany to conclude that occupational exposure limit values for mixtures cannot be satisfactorily ascertained by simple calculations, but can be assigned only as an estimate after specific toxicological considerations or examination of the mixture in question (12).
1.4 A Gap in Knowledge
The number of physical–chemical agent combinations on which interaction data are available is minute, compared to the total number of occupationally relevant combined exposures. No method with reliable precision for general risk assessment is available, despite the fact that such combined exposures probably represent the large majority of occupational exposures. Mechanistic models are rare. In a review on interaction between low level radiation and other environmental agents (13), several proposed mechanisms are presented. Multistep mechanisms are pointed out as theoretically the most critical interactions. Here, two or more agents can promote different necessary steps, needed for the toxic effect(s), that at single exposure have low probability of simultaneous occurrence.

Chemical and Physical Agent Interaction
Per Nylén, Ph.D., Ann-Christin Johnson, Anders Englund, MD

2 Noise
2.1 Interactions between Noise and Chemical Agents: Effects on Hearing
2.1.1 Noise-Induced Hearing Loss The most prominent effect of noise exposure is hearing loss in humans and experimental animals, but several factors such as age, heredity, and exposure to ototoxic substances may influence the degree of hearing loss. The hearing loss caused by noise can thus be potentiated or summated to the effects caused by exposure to chemical agents. Much interest has focused on the combined exposure to noise and various ototoxic agents.

The degree of damage from noise exposure depends on the characteristics of the noise, such as the intensity, duration, and frequency of the exposure. In experimental animals, species differences are found. Several different temporary or permanent impairments to the auditory system have been demonstrated after excessive exposure to noise. Direct mechanical destruction, metabolic exhaustion followed by oxidative stress in the cochlear hair cells, and changes in the cochlear vascular system have been postulated as important etiological factors for noise-induced damage (14, 15). Permanent hearing loss after noise exposure is associated with damage to the hair-cell stereocilia, as shown on fusion and fracture of inner hair cell (IHC) stereocilia in rabbits (16). The outer hair cells (OHCs) may also be damaged or lost (16, 17). The degree of damage after noise exposure is often correlated to noise level and exposure time. However, influence of internal as well as external factors can modulate the degree of damage caused by a certain noise exposure. New knowledge has shown that the efferent system in the brainstem modulates the mechanical response of the organ of Corti in the inner ear. The inner ear can by this mechanism be protected from noise induced hearing loss (18, 19). Thus also blocking of efferent control may cause an indirect potentiation of noise-induced hearing loss since the modulation can be disturbed, as has been shown in guinea pigs given strychnine, which inhibits the efferent control (20).

2.1.2 Combined Exposure to Noise and Ototoxic Drugs Many commonly used drugs are known to be ototoxic, some causing reversible, but most causing irreversible, hearing loss. The ototoxic drugs are found among many different categories of drugs. The interaction between noise and drugs might be of interest for the mechanistic understanding of effects after occupational exposure to noise and chemicals even if some, but not all, drugs are mainly used in hospitals.

2.1.2.1 Acetyl Salicylic Acid and Other Nonsteroidal Anti-inflammatory Drugs Acetyl salicylic acid (ASA) is one of the most commonly used nonprescription drugs; therefore, this is the drug that should have the highest interest concerning interaction with occupational noise exposure since it is often used by the working population at work. ASA and other salicylates cause a reversible hearing loss of 20–40 dB often associated with tinnitus after acute intoxication and long-term administration. The hearing returns to normal within 24–72 h after cessation of the drug intake. The mechanism for the ototoxicity may be related to biochemical and subsequent electrophysiological changes in the inner ear. Localized drug accumulation and vasoconstriction in the inner ear have been suggested to be mediated by the antiprostaglandin activity of these drugs (21).

The issue as to whether combined exposure to ASA and noise can cause a more severe hearing loss than the single exposures is, however, a subject of discussion. The results from several investigations are not consistent. In humans, increased temporary threshold shifts (TTSs) were shown after combined exposure (22, 23), whereas another study failed to produce a higher TTS (24). Different doses were used in these studies, and the temporary interaction possibly occurs only after high doses of ASA (> 1–2 g/day). An additive effect of noise and ASA on the TTS is supported by the results of a study in chinchillas (25). Permanent threshold shift was not found in other similar experiments (26, 27). In guinea pigs an existing noise-induced damage attenuated the additional ototoxicity of salicylate, whereas attenuation did not occur when salicylate administration preceded noise exposure (28). In rats, a more extensive hair-cell loss was found after combined exposure to high doses of both agents than after the noise exposure alone (29). When taking all these studies into account, it is not possible to conclude whether a permanent synergistic interaction between noise and ASA exists. If it does, it is probably not pronounced.

2.1.2.2 Aminoglycoside Antibiotics These antibiotics are among the most well known and thoroughly investigated ototoxic substances. They should be used only in case of life-threatening infections mainly because of their toxicity. Aminoglycosides cause a high frequency hearing loss followed by loss of outer hair cells starting with the inner row in the basal turn of the cochlea, continuing with the second and third rows and spreading up through the cochlea, also involving lower frequencies. The hair-cell loss causes a loss of auditory sensitivity of ~40 dB (30). The hair cells of the cochlea accumulate aminoglycosides, and noise exposure has been shown to increase the uptake of the drug into the cells (31).

Interactions between noise and aminoglycoside antibiotics, resulting in enhanced auditory thresholds as well as increased hair-cell loss, have been demonstrated in several animal experiments as well as in humans (27, 32–34).

2.1.2.3 Anti cancer Drugs Another drug that causes irreversible hearing loss in humans and experimental animals is the cytostatic agent *cis*-platinum. This drug is used as a chemotherapuetic agent in treatment of cancer, in the lungs, testis, and ovaries. A loss of outer hair cells starting at the basal turn of the cochlea has been shown. Both additive and synergistic effect on the threshold shift have been reported in chinchillas simultaneously exposed to cisplatin and noise (27, 34, 35). Other chemotherapeutic agents, such as carboplatinum, have also been shown to be ototoxic, and suggestions of interactions with noise have been proposed (27, 34, 36, 37). The mechanism for *cis*-platinum ototoxicity has been suggested to result from oxidative stress in the inner ear (12).

Interactive effects on hearing have also been shown between *cis*-platinum and another physical factor—irradiation treatment in cancer patients (38, 39).

2.1.2.4 Other Drugs Interactions after combined exposure to loop diuretics and noise have not demonstrated a clear difference between the effect caused by noise alone and that induced by the combined exposure (33, 34). The mechanism for the ototoxic effect of diuretics is mainly through alterations in the stria vascularis in the cochlea. Also, antimalarial drugs and other antibiotics than the aminoglycosides have shown some ototoxicity (27, 34, 36) that might interact with noise exposure.

2.1.3 Combined Exposure to Noise and Other Chemicals 2.1.3.1 Solvents and Noise 2.1.3.1.1 Ototoxicity of Solvents The ototoxicity of solvents was first discovered by Pryor et al. (40–42), who conducted neurobehavioural studies in rats and found a frequency-specific hearing loss after exposure to toluene. Several other animal studies have further investigated the otoxicity of solvents. Currently certain solvents such as toluene, xylene, styrene, trichloroethylene, ethylbenzene, and *n*-heptane have been shown to be ototoxic in rats. The ototoxicity consists of a midfrequency loss of OHCs. The loss starts in the mid to basal cochlea at the third row of OHCs and progresses along the frequencies subsequently affecting all rows of outer hair cells (43–48). The mechanism of toluene ototoxicity has been investigated by using isolated outer hair cells *in vitro*. A dose-response relationship was observed in the extent of OHC shortening induced by toluene, and toluene also enhanced free intracellular calcium levels of both OHCs and spiral ganglion cells within 5 min of exposure (49, 50).

After the initial animal studies, reports from occupational exposure of solvents causing hearing loss began to appear in the literature. Studies of occupational exposure to solvent mixtures have reported different kinds of alterations in the auditory system. In some studies on workers exposed to aliphatic and aromatic solvents, abnormalities in interrupted speech discrimination and cortical response audiometry tests that assess more central portions of the auditory pathways, were observed. Indications of a dose response relationship were also found, as well as affected vestibular function (51–53).

Trichloroethylene exposure can cause hearing deficiency in humans as shown by audiometric measurements in workers exposed 1–23 years (54). In these workers the vestibular system was also affected as shown by nystagmography.

Rotogravure printers chronically exposed to toluene, without any hearing loss as shown by audiometry, have shown alterations in the latencies in auditory brainstem recordings measured as effects of repetition rate (55).

Styrene exposure often occurs as a single solvent exposure in the plastics industry, and these workers have been investigated in several studies. Effects on cortical responses from the auditory system

were found together with vestibular disturbances in workers exposed to styrene in a boat-building shop in Sweden (56). Muijser et al. (57), used high frequency tone audiometry (≤ 20 kHz) to determine the frequency-specific effect of styrene-exposed workers, and a difference in hearing threshold was demonstrated between directly and indirectly exposed workers at 8 kHz, but not at higher frequencies. This finding is interesting in view of the above mentioned reports of midfrequency loss in animal experiments (43, 44, 46, 47).

2.1.3.1.2 Combined Exposure to Solvents and Noise 2.1.3.1.2.1 Animal Experiments In animal experiments, the interaction between solvents and noise was first reported by Johnson et al. (58, 59) who exposed rats sequentially to toluene and noise. This combination caused a more severe loss of auditory sensitivity than did toluene alone or noise alone. At some frequencies, a potentiation was found when the toluene exposure preceded the noise exposure, while the reversed exposure order resulted in only an additive effect. In more recent experiments, Lataye and Campo (44, 45) exposed adult rats to toluene and noise and to styrene and noise simultaneously. These studies confirm the interaction between toluene and noise on auditory brainstem response thresholds as well as showing a similar or worse synergistic interaction between styrene and noise. The studies also add new morphological data. The rats mono-exposed to toluene or styrene showed loss of OHCs (predominantly in the third row). In contrast, the noise-exposed rats showed damaged stereocilia of OHCs but no cell loss. The combined exposure group the OHC loss was further enhanced, implicating an interacting effect. No interaction between styrene and noise was found in guinea pigs after acute exposure to styrene (7 h) and noise (60), a negative finding that could be due to the short solvent exposure or a species difference.

2.1.3.1.2.2 Human Studies In work environments where solvent exposure occurs, a high level of noise exposure is also common. A critical aspect of solvent ototoxicity, therefore, is the possible interaction with noise. The combined effects of solvents and noise have thus been investigated also in work environments. In shipyard painters a higher degree of hearing loss than could be expected from the noise exposure alone was found (61). In a paper mill factory the most severe cases of hearing loss were seen among solvent-exposed workers from the chemical department, in which the noise exposure was lower than in other studied parts of the factory (62).

In 1990, Bielski (63) found an increased prevalence of hearing disorders in workers exposed to noise and a mixture of solvents that included toluene, benzene, styrene, xylene, and butyl acetate.

Audiometric measurements were conducted on workers exposed to carbon disulfide and noise in a viscose rayon factory (64). A high proportion of hearing losses that could be related to the work environment was determined in all age groups (60% of the workers). There was also a correlation between exposure time and degree of hearing loss.

In a cross-sectional occupational study of exposure to solvents and noise, four groups of workers in a printing plant were tested audiometrically. Workers exposed to noise [88–98 dB(A)] and toluene (100–365 ppm) were compared to groups of workers exposed solely to noise 88–97 dB(A), or workers exposed to a mixture of solvents in which toluene was the major component. A fourth group served as controls. The adjusted relative risk estimates for hearing loss were 4 times higher [95% confidence interval (95% CI) 1.4–12.2] for the noise group, 5 times higher (95% CI 1.4–17.5) for the solvent-mixture group, and 11 times higher (95% CI 4.1–28.9) for the noise and toluene group. These findings strongly suggest that an interaction between noise and toluene took place. The results from the acoustic reflex findings suggest a non-cochlear site of the lesion. A peripheral component of the observed hearing loss was, however, not excluded (65).

In a later study, Morata et al. investigated the hearing in petroleum workers exposed to noise and solvent mixtures. The exposures for both noise and solvents where within the exposure limits. The prevalence of hearing loss in exposed workers exceeded the prevalence in unexposed controls. The adjusted odds ratios (ORs) varied between 1.8 and 3.0 in the different departments compared to unexposed controls (66). In another study among rotogravure printing workers, a significant

association was found between the biological marker of toluene in urine and the degree of hearing loss (67). In this study no interaction with noise was found; only toluene exposure showed the association with hearing loss.

Jacobsen et al. (68) studied the relationship between occupational exposure to solvents and self-assessed hearing problems in a cross-sectional study of 3284 Danish men aged 53–74 years. The adjusted relative risk for hearing impairment after exposure to mixed solvents for ≥ 5 years was 1.4 (95% CI 1.1–1.9) in men without occupational exposure to noise. In men exposed to both solvents and noise, the effect of the noise effect dominated and no synergistic or additive effect could be demonstrated.

Combined exposure to styrene and noise was investigated in workers exposed to a mixture of polystyrene resin, methanol, and methyl acetate at levels below threshold limit values (69). Findings were analyzed as the percentage of subjects falling outside the 90th percentile of the upper limit of hearing. The percentages were 8.7 for the control group, 12.1 for the noise-exposed group, and 33.3 for the solvents and noise-exposed group. In the combined exposure group, styrene was the only solvent likely to be ototoxic. However, the combination of any of the solvents, or noise and solvents, could have played an important role in causing this effect. A more recent study explored the relationship between hearing loss, age, and exposures to noise and styrene (70). The exposures were assessed for 299 workers in the glass-reinforced plastics industry in Canada. No consistent relationship was found between cumulative noise or styrene exposure and audiometric thresholds. Age, however, showed a strong association even after an exclusion of individuals over 50, and a positive correlation with age and both cumulative exposures was noted. Age as a possible confounder may be a problem in studies of occupational hearing loss, and treatment of the age factor in the analysis of the outcome of these studies may be handled in different ways (71).

In summary, most of these reports and studies strongly indicate that chemicals, in different ways, can interact with noise to cause hearing loss.

2.1.3.2 Carbon Monoxide and Noise Carbon monoxide (CO) in high concentrations has ototoxic effects in humans and experimental animals (72). The mechanism is postulated to be an impairment of the normal oxidative metabolism in the inner ear. Later findings suggest involvement of free radical generation since the effect of CO is blocked by free-radical blockers (73). Combined exposure of rats to CO and noise showed a synergistic effect on auditory thresholds that was also confirmed by exaggerated loss of outer hair cells in rats exposed to the combination (74). Short-term exposure to a combination of impulse noise and CO (3 h) in guinea pigs showed no interaction between the exposures. This can be interpreted as a counteracting effect in the cochlear blood flow, which was reduced by impulse noise and increased by CO (75). In a big hearing conservation program in Germany, a subgroup of workers exposed to ototoxic factors such as carbon monoxide, lead, and carbon disulfide suffered from a slightly higher risk of hearing loss (odds ratio 1.5) (76). In a human experimental study, the amount of noise needed to produce a temporary threshold shift (TTS) was not altered at simultaneous exposure to 200 ppm CO (77).

2.1.3.2.1 Smoking and Noise The interaction between noise and CO is of interest when studying noise-induced hearing loss and smoking. Several studies have reported that heavy smoking interacts synergistically with noise, thus causing a more severe hearing loss in humans (78–80).

2.1.3.3 Metals and Noise 2.1.3.3.1 Lead Lead has been proposed to cause hearing loss especially in children with high blood levels of lead (81–83). However, in later studies of children in remote areas with really high blood levels of lead no effect on hearing thresholds or auditory brainstem responses were found (84, 85). No interaction with noise has been reported in these studies. Forst et al. (86) found a relationship between blood lead levels and the hearing threshold at 4 kHz in workers. Even if no excessive noise exposure were present, the effect at 4 kHz might implicate an interaction since this frequency is the one most commonly associated with noise-induced hearing loss.

2.1.3.3.2 Manganese Effects on hearing and the vestibular system have been seen after occupational exposure to manganese. Hearing thresholds are elevated at all frequencies. Simultaneous or subsequent noise exposure has also been shown to interact with the hearing loss caused by manganese (36).

2.1.3.3.3 Other Metals In humans, early signs of mercury poisoning have been associated with cochlear damage. In contrast, the hearing loss after progressive or heavy exposure is due to the neurotoxic effects of mercury. In animal experiments a loss of outer hair cells has been shown in the middle region of the cochlea (36). Trimethyltin and triethyltin have been shown to cause a rapid hearing loss affecting the cochlear inner hair cells (87).

A protection from noise-induced hearing loss has been shown in humans treated with magnesium (88). Rats kept on a magnesium-deficient diet and exposed to noise stress showed elevated systolic and diastolic blood pressure and increased vascular calcium levels, which were more pronounced after the combined "exposure" to magnesium deficiency and noise (89).

2.2 Interactions between Chemical Agents and Noise: Nonauditory effects

Noise exposure in the work environment can cause effects other than hearing loss. Best known is perhaps the disturbing effect caused by low frequency noise from equipment such as ventilation systems, engines, or computers that can cause mainly stress reactions. These effects caused by noise are not discussed in detail here, but disturbing noise may cause many types of physiological reactions in humans. Nonauditory effects of noise are different from noise-induced hearing loss since they are not specific for noise exposure but may be caused by other stress situations. Also, the ability to compensate for these effects is more pronounced. Effects seen are peripheral vasoconstriction, changes in catecholamine levels and metabolism, as well as different cardiovascular signs such as blood pressure elevations or pulse rate changes (90, 91). Some of these effects have been found also after exposure to noise in combination with chemical factors.

2.2.1.1 Solvents and Noise When rats were exposed to various solvents (acetone, carbon disulfide, and trichloroethylene) in combination with noise, effects were found in the nervous, cardiovascular, endocrine, and immune systems. The interaction noted was, however, of an antagonistic type meaning that noise exposure minimized the effects of the solvents in these biological parameters (92). In rats exposed to noise and/or 1,1,1-trichloroethane, no specific effects were found except for some changes in liver weight/body weight relationship after the combined exposure (91). Exposure to alcohol in drinking water and/or noise modified the a-adrenergic effects of noradrenaline in rats (93). In rats, disturbances of the metabolism in the myocardium have also been found after exposure to noise in combination with dimethylformamide or xylene (94). Effects on mutagenicity in rats were investigated after exposure to several solvents (acetone, carbon disulfide, and trichloroethylene) in combination with noise, and it was found that noise exposure does not aggravate the mutagenicity of these chemicals (95).

2.2.1.2 Other Chemicals and Noise Ozone is an environmental pollutant that causes airway toxicity especially affecting the lower respiratory tract. Effects include appearance of plasmamarkers, edema, and inflammation (90). In a study on rats exposed to noise and/or ozone, the effect parameters shown after exposure to ozone alone were modulated in both directions by the noise exposure. The overall toxicity was not increased but the modulation may be important after repeated ozone exposure (96).

The teratogenicity of combined exposure to noise and cadmium was studied in mice. The combined exposure resulted in an increase of total percentages of malformed fetuses compared to the same dose of cadmium alone, but the interactions between cadmium and noise showed no synergistic effect on teratogenicity. Also in the groups exposed to noise alone, the total percentages of malformed fetuses were significantly higher than those in the control group (97).

Different effects of smoking and nicotine on the nervous system, including EEG, mood, b-endorphine, cortisol, and ACTH, where investigated also in combination with noise exposure. Even if several effects were found after smoking alone, no sign of interaction between noise and nicotine

could be demonstrated (98, 99).

Chemical and Physical Agent Interaction
Per Nylén, Ph.D., Ann-Christin Johnson, Anders Englund, MD

3 Vibrations
Both whole-body and hand–arm vibrations affect a vast number of workers. A common deleterious effect from vibration exposure is the white-finger syndrome, which includes disturbances in both nerve and blood vessels. Since drugs and chemicals can also alter the function of these structures, it is of interest to what degree vibrations and chemicals interact at simultaneous or subsequent exposure.
3.1 Smoking and Vibrations
Heavy smoking can induce white-finger symptoms (100). After investigation of single and combined exposure to hand–arm vibrations and duration of heavy smoking in 2705 workers, a hyperadditive effect was seen on white-finger symptoms (101). It was pointed out that vibrations and smoking have effects in common, such as disturbances in sympathetic nervous system and obstructive lesions in vessels; but the agents also have different degenerating effects such as increased risk of thrombosis (smoking) and functional changes in arteries (vibrations).
3.2 Arsenic and Vibrations
Exposure to inorganic arsenic can cause Raynaud's phenomenon, acrocyanosis, and gangrene of the lower legs (“black foot” disease). Smelters and miners are workers who might be exposed to arsenic dust, the latter group also to considerable vibration. A lower finger systolic pressure has been observed in arsenic-exposed workers at skin temperatures of 10 and/or 15°C expressed as a percentage of the pressure at 30°C (102). There was also a covariation between the duration of exposure to arsenic and the decrease in finger systolic pressure between the measurements at 30 and 10°C. The increased vasospastic reactivity in the fingers and Raynaud's phenomenon in smelter workers seems to be due to functional alterations in the vessels caused by inhalation of arsenic. In a later study the authors showed that the peripheral vascular disturbances caused by arsenic were dependent on long-term arsenic exposures and seemed to be independent of short-term fluctuations in arsenic exposure (103).

In a hygienic evaluation on gold miners (104), some workers were exposed to high levels of both vibration and arsenic, the latter seen as extensive arsenic accumulation in the hair and excretion with the urine. The vibration disease and sensory polyneuropathy in subjects exposed to both vibrations and arsenic were reported to be of a more severe course and were interpreted by the authors as results from synergistic-action between vibration and arsenic.

Chemical and Physical Agent Interaction
Per Nylén, Ph.D., Ann-Christin Johnson, Anders Englund, MD

4 Temperature
No occupational studies on thermal interaction with chemicals in workers have been found. Such temperature dependence has, however, been studied in human volunteers and in mice.

It is well known that body temperature of workers can vary by >1°C, depending on environmental temperature and physical intensity of the task. Thus, the impact of temperature on metabolic enzymatic velocity of chemical compounds and its impact on general health can be considered of interest (105).

Temperature changes in the environment may also alter physiological functions, which may, in turn, influence the chemical's toxicokinetics. Peripheral vasodilatation and sweating, which enhances skin hydration (see paragraph about humidity below), are responses that have been shown to increase percutaneous absorption (106). Temperature also affects respiratory rate, changes in volume and composition of blood and urine flow, and changes that may affect uptake, distribution, and elimination of chemical vapors (107). The percutaneous absorption of chlorinated solvents is accelerated by higher ambient temperature (108).

4.1 2-Butoxyethanol and Temperature

In volunteers dermally exposed to 2-butoxyethanol vapors, elevated ambient-air temperature and humidity resulted in higher blood solvent levels, which suggests an increased dermal uptake rate under these conditions (109). Skin heating, by hot showers or sauna baths taken after toluene exposure, did not, however, affect the solvent kinetics in blood (110).

Chemical exposure within a cold environment also can cause secondary responses in physiological functions such as shivering, peripheral vasoconstriction, elevated blood pressure, increases in respiratory rate and cardiac output, and a progressive fall in blood pH. Below a rectal temperature of ~35°C, the metabolic rate begins to decline. Subjects exposed to a cold environment (16°C, 2 h) had decreased plasma volume and increased urine flow (107).

4.2 Arsenic and Temperature

Arsenate-exposed hamsters produced synergistically greater percentages of malformed offspring when short-term hypertermia was added to the arsenate exposure (111). In another study on hamster, elevated arsenic concentrations were seen several hours after the cessation of heat exposure (112).

4.3 Ethanol and Temperature

Both maternal hypertermia and alcohol have been associated with birth defects in humans as well as mice. After combined exposure to both agents to doses at which teratogenicity could not be observed on day 8 of gestation, synergistic increase in resorption and frequency of externally malformed fetuses, skeletal malformations, and visceral variations were found (113).

4.4 Mercury, Ionizing Radiation, and Temperature

The effect of temperature on chemical toxicity has been studied on preimplantated mouse embryos exposed to mercuric chloride (3 mM, 10 mM), or to X-rays (1 Gy) or to a combination of the two agents (114). The embryos were cultured *in vitro* at 34–39°C with an increment of 1°C. A combined risk greater than expected from the sum of the individual effects was observed only (for a combination of 1 Gy+3 mM) in the range of the optimum temperature, that is, between 36 and 38°C (for a combination of 1 Gy+10 mM). Temperature and mercury tended to interact slightly, seen as a reduced number of cells per embryo at a 10 mM mercury chloride concentration. At binary exposure to X-rays and heat, a synergistic lowering in the latter parameter was indicated.

Combined postnatal effects were studied (115) after prenatal exposure to heat (42°C, 10 min a day) and methyl mercury (5 mg/kg, day 12). Heat alone affected postnatal open-field activity, response to diazepam, and spatial learning. The mercury exposure affected body temperature. No distinct interactions at combined exposure were recognized.

4.5 Formaldehyde and Temperature

Odors are a high priority problem in many industries. Odor intensity and sensory irritation was studied in 20 volunteers exposed to formaldehyde and radiant heat (116). The subjects estimated the odor intensity as higher when jointly being exposed to radiant heat on the face. Most volunteers also reported a change in the odor perception toward a more intense or pungent one at the strongest radiant-heat condition, a finding that indicates a possible combined effect according to the authors. It should be pointed out that the level of radiant heat used is rarely found in nonindustrial conditions, and thus less likely to contribute to sensations reported in connection with sick buildings.

5 Humidity
As mentioned in Section 4.2, humidity can indirectly interact with chemicals within the human body. The percutaneous absorption can be altered by humidity-induced changes in the hydration state of the skin and thereby alter the total uptake of a chemical. Volunteers exposed to 2-butoxyethanol vapor had blood concentrations, and hence presumably an uptake rate, that was 3–4 times higher during skin-only exposure than during mouth-only exposure (109).

Chemical and Physical Agent Interaction
Per Nylén, Ph.D., Ann-Christin Johnson, Anders Englund, MD

6 Dust and Particles
Toxic ions, molecules, and microscopic particles can be adsorbed on the surface of inhaled dust and particles, which increases the exposure of the respiratory tract. An increased forming of toxic reactive oxygen species on cobalt metal particles have been observed when these particles are associated with tungsten particles (117). An electrostatic field–mediated transport of dust and particles has also been suggested to deposit, and thus transport, chemicals to the skin of cathode ray tube (CRT) based videodisplay terminals (see Section 7).
6.1 Radon and Particles
The excess of lung cancer seen in miners has been assumed (118) to originate at least partly in an increased lung concentration of radon progeny adsorbed on inhaled particles although unattached progeny is believed to play the greater role.
6.2 Polyaromatic Hydrocarbons and Particles
Adsorption of polyaromatic hydrocarbons (PAHs) on dust similar to that of radon progeny described above has also been proposed (119). The activation of PAHs into reactive metabolites has also been reported to increase on the surface of asbestos fibers (120).
6.3 Smoking and Asbestos
The interaction between asbestos and tobacco smoking is perhaps the most commonly used example of occupationally relevant synergistic interactions. Asbestos includes several fibrous minerals, many being reported to be human carcinogens. At phagocytosis, the inflammatory processes alters growth and differentiation of target lung cells. As is also the case for tobacco smoke, asbestos is a complex carcinogen that can induce alterations at different levels of carcinogenesis (121). In one study, the death rate due to lung cancer was about fourfold higher than in smokers not exposed to asbestos and 12 times higher than in asbestos exposed nonsmokers (122). Most occupational studies on this combined exposure do in fact support a synergistic interaction between the two agents (123–125), but additive outcomes have also been indicated (126). A possible reason for observed differences in the degree of synergistic interaction might be the type of asbestos fibers the workers in question have been exposed to. Simultaneous smoking in the presence of asbestos does not increase the incidence of mesothelioma as compared to exposure to asbestos alone.
6.4 Smoking and Arsenic Dust
An overall comparison between studies on combined occupational exposure to arsenic dust and smoking has suggested a synergistic increase in the rate of lung cancer due to such exposure (127). The mechanism for the synergism was, however, unclear at the time.

Chemical and Physical Agent Interaction

7 Electrostatic Fields
It has been proposed by several authors that electrostatic fields, originating from the CRT-based computer screen and induced by movements of the human subject (e.g. by friction against synthetic

cloths), can increase deposition of particles and chemical substances. Such hypothesis are discussed in relation to hypersensitivity to electricity as well as skin symptoms perceived at CRT computer screens. Chemical substances discussed are chlorinated substances, PCB (polychlorinated biphenyls), various flame retardants, contact allergens, radon progeny, and dust particles. A finding opposing that hypothesis is that a connection between the CRT screen and the operator to electric earth, which reduces the field considerably, does not seem to decrease the frequency of skin problems (128, 129). It is believed that a high static charge on the surface of the operator's body might increase the deposition on the skin of the operator; a process that thus could be unrelated to the potential charge from a computer screen.

Chemical and Physical Agent Interaction

8 Electromagnetic Radiation and Fields
8.1 Low Frequency Fields and Thorium
In the search for treatment at accidental inhalation of thorium isotopes, both low frequency electromagnetic fields (EMFs) and the chelating agent CaDTPA have been found to decrease the retention of intravenously injected thorium. After ^{234}Th nitrate exposure, the effect of EMF alone (50 Hz, 10 mT) has been reported (130) to cause a substantial decrease in deposition in different parts of the body (23–59% remaining as compared to controls). Rather surprisingly, the combined exposure to the EMF and CaDTPA resulted in a considerably less effective decrease.
8.2 Radiofrequency Radiation and Fields
Workers within the plastic sealing and electrosurgical units of the microelectronics industry are often exposed to concurrent exposures to chemical and physical agents. Hyperthermia induced by radio-frequency (RF; 10 MHz) radiation can potentiate the toxicity and teratogenicity of some chemicals. 2-Methoxyethanol (2ME), an industrial solvent, produces enhanced teratogenicity in rats when combined with exposure to RF.

In a preliminary study (131), RF radiation exposure of rats for 30 min, which was sufficient to elevate rectal temperature to 42.0°C (4°C above normal for rats), and 2ME (150 mg/kg) were administered on gestation day 13. Pregnant rats were sacrificed on gestation day 20. Combined exposures enhanced the adverse effects produced by the experimental agent alone (no malformations were detected in a double-sham group). Mean fetal malformations per litter increased from 14% after 2ME and sham RF (15/26 litters affected, with an average of 2 fetuses/litter malformed) and 30% after RF radiation and water gavage (10/18 litters affected, with an average of 4 fetuses/litter malformed), to 76% after the combined treatment (18/18 litters affected, with an average of 12 fetuses/litter malformed). In addition to a significant increase in the frequency of malformations, the severity of malformations also was enhanced by the combination treatment (on a relative severity ranking scale, the 2ME-only severity score was <1, at RF only the score was 3, and at the combined exposure the score was 6).

In a later study (132), the authors investigated the interactive dose-related teratogenicity of RF radiation (sham exposure or maintaining colonic temperatures at 42.0°C for 0, 10, 20, or 30 min) and 2ME (0, 75, 100, 125, or 150 mg/kg) by administering various combinations of RF radiation and 2ME to groups of rats on gestation day 9 or 13. On gestation-day 20 fetuses were examined for external, skeletal, and visceral malformations. Exposure to 2ME, either by itself or in combination with RF radiation at gestation day 13, resulted in highly significant effects from both 2ME and RF radiation. The structures showing strong evidence of effects were the forepaw digits, forepaw phalanges, hindpaw digits, hindpaw phalanges, hind limbs, metacarpals, and metatarsals. Day 9 exposures generally evidenced little effect. Synergism was observed between RF radiation and 2ME for some, but not all, treatment combinations. In a subsequent study (133), it was shown that

concurrent RF radiation exposure can also change the shape of the dose–effect curve of 2ME.

In a third study (134), the same research group studied the effects of varying the degree and duration of hyperthermia induced by RF radiation (sufficient to maintain colonic temperatures at control, 38.5, 39.0, 40.0, or 41.0°C for ≤ 6 h) and 2ME (100 mg/kg) administered on gestation day 13 to rats. On day 20, fetuses were examined for external and skeletal malformations. Significant interactions were observed between 2ME and RF radiation sufficient to maintain colonic temperatures at 41°C for 1 h, but no consistent interactions were seen at lower temperatures even with longer exposure durations.

So far these studies have not demonstrated whether the found effects are induced primarily by the hyperthermia or by the non-temperature-related influences of the RF. In a more recent study (135), however, the authors attempted to determine whether altered environmental temperatures would affect the interactive developmental toxicity of RF and 2ME. RF radiation sufficient to maintain colonic temperatures at the control value (38°C), 39.0, or 40.0°C for 2 or 4 h combined with either 0 or 100 mg/kg 2ME at environmental temperatures of 18, 24, and 30°C were given on gestation day 13 to Sprague–Dawley rats. Dams were killed on gestation day 20. The environmental temperature did affect the specific absorption rate (SAR) necessary to maintain a specific colonic temperature, but it did not affect the interactive developmental toxicity of RF radiation and 2ME in rats. The findings support earlier evidence that the developmental toxicity of RF radiation (combined or alone) is associated with colonic temperature, and not with SAR.

8.3 Visible light

Several drugs have been shown to be phototoxic to the eye. These symptoms are, however, most pronounced in sunlight and thus not a specific occupational problem and therefore not discussed further here.

8.3.1 Solvents and Light Occupational exposures to chemicals have been associated with different kinds of visual disorders. The number of reports concerning reduced color discrimination ability has increased and the findings have been made after exposures that are around respective occupational exposure limit values levels in Canada, Finland, and Italy; above these levels in Russia, and of unknown levels in Taiwan (136–148). The main findings are reduced color discrimination ability, which is found in as much as 80% of the exposed workers, compared to 30% in unexposed workers.

More recent studies made on workers exposed to different classes of chemicals confirm earlier findings. A dose-related subclinical color vision impairment has been observed in two studies (149, 150) on mercury-exposed workers compared to referents matched for sex, age, tobacco smoking, and alcohol habits. A subclinical colour vision loss, mainly in the blue-yellow axis, was present in perchloroethylene exposed dry cleaners compared to controls matched for sex, age, alcohol consumption, and cigarette smoking (151). In a study on styrene-exposed workers (136) visual color impairment was reported from 4 ppm.

The impact of simultaneous exposure to ambient light was not included in these studies. Data on the light exposure would have been of considerable interest, since recent studies presented below show that combined exposure to fluorescent light and a *n*-hexane metabolite has a pronounced synergistic effect on the retinal function in the rat.

The conditions that usually produce light-induced damage to the retina are photochemical rather than thermal. The shorter the wavelength is, the greater the effectivity of damaging tissue. Therefore, violet and blue lights cause most retinal injury. In experimental studies it has been shown that blue light may damage the retina of rats in a dose-dependent manner. After exposure to light from fluorescent tubes, a decrease in the activity of cytochrome oxidases, a family of mitochondrial enzymes, has been observed in the rat retina (152). It is known that cytochrome oxidase activity is decreased after exposure to 2,5-hexanedion (2,5-HD). Cytochrome oxidase might therefore be site of interaction between light and 2,5-HD.

In rats exposed to 2,5-hexanediol (2,5-HDol) in both light and total darkness, the presence of light caused damage to the exposed rat retina, and the reduction in the number of photoreceptors progressed after termination of the exposure (153, 154). In darkness there was no loss of photoreceptor cells in the retina of the albino rats. After exposure to *n*-hexane metabolites in light or in total darkness, 2,5-HDol potentiated light-induced damage. In addition, the retinal damage caused by 2,5-HDol together with light exceeded a simple summation of the action of these two agents alone after the recovery periods. The 2,5-HDol-exposed group of albino rats in darkness showed no or minor loss of photoreceptor cells compared to the control group, strongly indicating that 2,5-HDol had no, or only a minor, toxic effect of its own on the retina.

8.4 Ultraviolet Radiation

8.4.1 Halogenated Hydrocarbons and UV Trichloroethylene, perchloroethylene, and methyl chloroform are examples of halogenated hydrocarbons often used as degreasing agents in the metal industry. The ultraviolet radiation emitted from welding arcs decomposes these hydrocarbons to phosgene and dichloroacetyl chloride, when welding is performed in such atmospheres (155–158). Phosgene, earlier used as a war gas, is a colorless gas or fuming liquid (boiling point 8°C). The substance yields an acidic solution when it decomposes in water and gives rise to pulmonary edema, which can be fatal at exposures of ~25–50 ppm for 0.5–2 h. The odor is said to be like new-mown hay, and the odor threshold is ~0.5 ppm (159). The highest amount of phosgene is produced by perchloroethylene, followed by trichloroethylene, whereas 1,1,1,-trichloroethane yields comparably small amounts. The amount of phosgene produced also depends on the amount of UV emitted by the welding method used. MIG welding on aluminum generates considerably more phosgene than, for example, the use of coated electrodes on mild steel (160).

8.4.2 Cuteaneous Phototoxic Substances and UV 8.4.2.1 Ultraviolet-Cured Ink and UV External exposure of skin to cuteaneous phototoxic chemicals and subsequent exposure to ultraviolet irradiation cause adverse dermal alterations such as intense burning sensations, blisters, dermatitis, and erythema. Occupational exposure to ultraviolet-cured ink (161) caused complaints from several workers concerning sensitivity to sunlight, including burning and later swelling of exposed areas within 5–10 min of sun exposure. Amyl dimethylaminobenzoate, a substance included in the ink, was found to produce diphasic phototoxic reaction *in vivo* after topical application on symptomatic workers, asymptomatic workers, and previously unexposed subjects.

8.4.2.2 Coal Tar Compounds and UV Wheal-and-flare formations, mediated by histamine released from dermal mast cells, are common symptoms of cutaneous phototoxicity from coal-tar compounds. Rat serosal mast cells were used as an *in vitro* model system to study the direct effect of phototoxic compounds on mast-cell degranulation. The coal-tar compounds studied included acridine and pyrene. Combined exposure of cells to acridine and UV-A (320–400 nm) radiation caused mast cells to degranulate (162).

Phototoxicity has also been associated with direct coal distillation (EDS liquids). Such liquid coal–based fuels with a boiling point above 200°C, which may be chemically similar to coal-tar products, were found to be phototoxic in guinea pigs (163).

Cuteaneous photosensitivity reactions were seen in 28 workers after exposure to bitumen, an impure mixture of hydrocarbons including known potent photosensitizers as anthracene and phenanthrene. The bitumen was included in a “hot-black” paint that was removed at a shipyard (164). Signs on sunlight- and dust-exposed skin varied from erythema, through marked erythema, to vesiculation and exudation in three cases. Symptoms resolved normally over 7–10 days.

8.4.2.3 Vegetables and UV Potent photosensitizers can also be found in raw common vegetables (165). Two cases exposed to raw parsnip juices while peeling, and subsequent UV-A irradiation a few hours later suffered from blisters at the site of substantial parsnip contact. Celery has also been reported to have phototoxic properties (166).

8.5 Ionizing Radiation

High level exposures to ionizing radiation due to accidents or serious human mistakes and

mishandling have occurred but are rare. Low level exposures are, however, fairly common in occupations such as mining, nuclear therapy, dental care, research, and nuclear plants. In this respect, it is of occupational health interest that interactions between ionizing radiation and chemicals have been reported.

8.5.1 Smoking and Radon Data concerning combined exposure to radon and smoking covers a wide span of both qualitatively and quantitatively different interaction outcomes ranging from strong synergism to a kind of relative protection (167, 168). Most of the studies on miners have indicated a strong synergistic interaction between the two agents (169), thus providing results often used to illustrate synergistic exposure interactions in occupational health. There are some divergent observations from the past, however, that have also led to a suggestion that high concentrations of dust and particles in older mines together with active smoking may increase mucus secretion and thereby somewhat reduce the short-ranging a-radiation to the epithelium and consequently also the absorbed dose. An increase of just 10 mm, of a mucous sheath can be calculated to reduce deposited energy from the poorly penetrating a-particles to the bronchia by as much as ~ 50%. This shielding mechanism, possibly together with increased coughing, was considered to contribute a somewhat protective effect from smoking at radon exposure in an early study on miners (170). A corresponding protective phenomenon also has been noted experimentally in smoke-exposed dogs with exposure to uranium ore dust and radon progeny (171). However, in reports on lung cancer in miners from modern and low dust mines, as well as regarding indoor exposure to radon progeny, a generally multiplicative interaction between smoking and radon progeny has been explained by the mutagenic action of the smoke chemicals and the irradiation.

Radon progeny, much of which is normally deposited on physical surfaces such as walls and furniture in the room, can attach to the surface of tobacco smoke particles. This phenomenon has been proposed to increase the amount of radon progeny available in the air for respiration (172). However, this particleborne “attached” fraction is usually given less emphasis than the unattached radon progeny in calculations of the dose delivered to the epithelium. Furthermore, an increased air turbulence in a room tends to lower the radon progeny levels through enhancing attachment of radon progeny to surfaces, but this plating out of radon progeny is reduced in the presence of smoke by providing the most nearby surfaces for attachment. Findings obtained in an office study corroborate this view (173), as a smoke-free environment and prolonged daily air conditioning were found to lower the annual effective lung exposure dose. As a consequence of these findings, smoking in a room has also been proposed to potentially bias retrospective glass-based radon assessment through a reduction of the plating out of radon progeny on glass (and other) surfaces (174).

A study with some bearing on the interaction between radon progeny exposure and other agents was based on an ongoing lung cancer screening program among 8346 radon- and arsenic-exposed tin miners. A total of 243 new lung cancer cases were identified in this study and radon and arsenic exposures were determined to be the predominant risk factors (175). Increased lung cancer risk was also associated with chronic bronchitis and silicosis, as well as with exposure to tobacco smoke, including smoking from an early age, duration, and cumulative exposure.

8.5.2 Caffeine and Ionizing Radiation Studies have shown combined effect of radiation (0.5–2.5 Gy) and caffeine (100 and 250 mg/kg maternal body wt) on day 11 of gestation in mouse embryos (176). The intrauterine mortality and frequencies of cleft palate and defects of forelegs and hindlegs were higher than the sum of the single exposures.

8.5.3 Mercury Chloride and Ionizing Radiation In a number of studies (177–179) on early mouse embryos *in vitro*, the risk from combined exposure to ionizing radiation and mercuric chloride was observed to be higher than that expected from either of these agents individually. To achieve an enhanced risk, the mercury exposure had to start as soon as possible after irradiation and then maintained as long as possible. The authors conclude that if inhibition of DNA repair is involved in the mechanism of interaction at all, an additional late process induced by mercury must also be involved.

8.5.4 Arsenic, Cadmium, Caffeine, Lead or Mercury, and Ionizing Radiation The influence of arsenic, cadmium, lead, or mercury at combined exposure to ionizing radiation in terms of risk to preimplantation mouse embryos *in vitro* was studied under various conditions (180). Morphological development, cell proliferation, and formation of micronuclei were used as endpoints. Arsenic did not alter the radiation risk. After cadmium and radiation exposure, only a few results indicated that the morphological development might have been impaired more strongly after exposure to two or more of these substances combined. Lead enhanced the radiation risk only with regard to micronucleus formation. Mercury had the greatest potential for enhancement of radiation risk, when morphological development and cell proliferation were studied. The observed combination effects exceeded even those effects that were calculated by taking factoring in the shape of the dose–effect curves (isobologram analysis, envelope of additivity). Mercury neither induced micronuclei nor enhanced their formation in combination experiments.

The effects of various doses of X-rays (0.25–2 Gy, given immediately before the chemicals) and to different concentrations of two chemicals—caffeine (0.5–2 mM) and mercury (0.5–5 mM)—on preimplanted mouse embryos *in vitro* have been studied (181). Morphological, proliferative, and cytogenetic endpoints were used. No synergistic enhancement in risk was observed after exposure to the three agents as compared to the interactions already detected at the level of a combined exposure to only two agents. Binary exposure to X-rays and caffeine, or to X-rays and mercury (but not to caffeine and mercury), caused synergistic increases in the percentage of alterations in various morphological stages of early mouse embryonic development.

8.5.5 Paraquat and Ionizing Radiation Lung changes have been observed in rats (n = 160) after combined exposure to the common herbicide paraquat (0.46 mg/kg bw, 5 times per week for 4 months) and ionizing radiation (4 Gy; directly on termination of paraquat intake) (182). The combined exposure induced more marked and more prolonged depression of the three parameters (superoxide dismutase, catalase, and nonprotein sulfhydrylgroups) of lung antioxidant defense and synergistic increase in bronchoalveolar lavage fluid content of thiobarbituric acid reactants and lactate dehydrogenase activity than did the single-factor exposures.

8.5.6 1,2-Dibromoethane and Ionizing Radiation Somatic mutations in the stamen hair cells of Tradescantia KU 9 (183) can be induced by combined exposure to 1,2-dibromoethane (DBE) and X rays. Synergistic interaction at low radiation doses has been found between the two agents for both DBE exposure followed by acute X-rays and chronic simultaneous exposures (184). An interaction of single strand lesions in the DNA as a cause of the synergism was discussed by the authors.

8.5.7 Caffeine, Mercaptoethylamine, and Ionizing Radiation After low doses of g-radiation (dose range 5–50 cGy), supersensitivity of Chinese hamster cells was revealed as studied by the cytokinesis block micronucleus test. Treatment with caffeine (repair inhibitor) and mercaptoethylamine (radioprotector) and the exposure to secondary radiation emitted by protons with an energy of 70 GeV revealed that the supersensitivity was associated with the absence of cytogenetic repair (185).

8.5.8 N-Nitroso-N-methylurea and Ionizing Radiation In a study on cultured Chinese hamster V79 cells (186), the toxicity and mutagenicity of formaldehyde with or without previous exposure to ionizing radiation was investigated. Both agents caused a dose-dependent decrease in colony-forming efficiency and a parallel increase in 6-thioguanine-resistant colonies. Mutant frequencies were induced by 0.3–1 mM formaldehyde, and by 2 and 4 Gy of radiation. As compared with the corresponding separate effects caused by single exposures, ionizing radiation followed by submutagenic concentrations of formaldehyde potentiated both the cytotoxicity and the mutagenicity.

8.5.9 Acrylamide and Ionizing Radiation Mutations induced by combined treatment with acrylamide and X-rays have been studied using the dominant lethal mutation test in male mice (187). Both doses

at which mutagenicity was found and was not found of both agents (1.00 Gy, 125 mg/kg bw and 0.25 Gy, 25 mg/kg bw, respectively) were used. After combined exposure at nonmutagenic doses, enhanced risk was observed in late spermatids, whereas exposure to mutagenic doses induced an enhanced risk in spermatozoa, spermatids, and late spermatocytes.

8.5.10 Biochemical Modulation of Ionizing Radiation Treatment The development of biochemical radiobiology includes a growing number of studies concerning biochemical modulation of ionizing radiation treatment (188). Even though substantial exposure to the chemical agents studied (e.g. non-nitro- compounds, pyrimidine analogs, misonidazole) are rarely found within industrial plants, such modulations are interesting regarding mechanistic aspects of occupationally found interaction between ionizing radiation and chemical factors.

Populations at Risk
David H. Pedersen, Ph.D., Randy O. Young, and Vernon E. Rose, Dr.P.H., CIH

Introduction
The practice of industrial hygiene and toxicology both involve recognition, as well as anticipation of the potential for occupational health problems (1). In the anticipation and/or recognition phase, an assessment of the risk to health or well-being resulting from exposure to an agent (chemical, physical, or biological) is made. This phase usually involves identifying the agents to which workers are or might be exposed; assessing the agents' properties, including toxicity; and understanding the conditions surrounding the use of, or interaction with, the agents. This information allows occupational health and safety professionals to make a preliminary assessment of occupational health risk based on the inherent properties of chemical, physical, or biological agents combined with the potential for contact or exposure under actual use conditions, including environmental level and in-use exposure control measures. The two basic applications of the anticipation/recognition process can be classified as either individual or aggregate.

The individual process is used by occupational health and safety practitioners who apply anticipation and recognition techniques to the exposure and conditions of exposure prevalent in a single facility or group of facilities under his or her professional jurisdiction. In that process, the individual professional needs an understanding of the toxic properties of those agents associated with these specific workplaces or processes and an understanding of the conditions of exposure existing in those situations. The data necessary for the individual process have been available to the practitioner for quite some time, either through the scientific literature or through investigation in the workplaces under his or her jurisdiction, with the possible historical exception of accurate information regarding the formulation of trade-named products.

The broader aggregate process of anticipation and recognition is applicable to definable industrial or occupational populations, and is an assessment of the potential risk of these populations for adverse health effects due to occupational exposure to chemical, physical, or biological agents in the workplace. The aggregate approach is common to occupational health and safety researchers, regulatory bodies, and others interested in the extent of exposure to a specific agent or list of agents with known adverse health effects. For example, in the initial stages of an epidemiologic study, researchers might wish to identify populations of workers who are exposed to a specific agent or group of agents. Government agencies need a measure of the potential impact of research or regulatory efforts based on the number of industries and workers impacted when they decide on the priorities to assign to research or regulatory efforts or the development of occupational health standards. This type of data was not available until after the implementation of the Occupational Safety and Health Act of 1970, and required several efforts by the federal government.

This aggregate approach to the identification of worker populations at risk due to their occupational exposures to specific individual or grouped chemical agents also serves the general occupational health community by profiling the industries in which exposure may occur, thereby permitting an assessment of the relative potential for specific adverse health effects in selected industries. This type of broad overview is not normally available to the individual occupational health practitioner, and has the potential for improving the practitioner's initial assessment of occupational risk in his or her area of responsibility. This was recognized, prior to his untimely death, by Dr. Charles H. Powell (2), whose original suggestion prompted this effort to provide aggregate analyses of the industrial distribution of chemical exposure for consideration by the professional community.

Populations at Risk

Background
In the early 1960s, the Occupational Health Program of the U.S. Public Health Service (the forerunner to the National Institute for Occupational Safety and Health) constantly received requests for assistance from state and local health departments interested in establishing or expanding their occupational health programs (3). A typical question asked might have been “What is the extent of exposures in the workplaces for which we have responsibility?” The data needed to answer this question include: (*1*) the prevalence of exposure to specific agents in the nation; (*2*) the types of workplaces (industries) in which exposure to these agents occurs; (*3*) the number of workplaces in which such exposure takes place; (*4*) the number of workers exposed to specific agents; and (*5*) the extent to which these exposures are controlled. Unfortunately, the Public Health Service could not provide answers to these questions because such data did not exist.

This lack of knowledge was strongly addressed in a 1966 report to the Surgeon General of the United States (commonly known as the Frye Report), which stated, “It is almost inconceivable that this nation, with its vast resources and technical skills, has never developed a comprehensive picture of the work environment to determine the relationship with the health status of its productive work

force” (4). The Frye Report went on to identify three major steps necessary for assessment of the national occupational health situation, which included the establishment of continual surveillance of: (*1*) the incidence and prevalence of occupational disease; (*2*) aspects of the work environment responsible for, or contributing to, occupational disease; and (*3*) the relationship between disease and the work environment to enhance the “preventive” aspects of occupational health (5). These concepts, as described later, were addressed in the federal surveillance efforts that eventually provided most of the data needed for the aggregate process of anticipation and recognition of occupational hazards.

Despite a lack of available data, the Occupational Health Program did address the questions from states and municipalities through a program that involved limited study of the extent of hazards in defined working populations in city or metropolitan areas (6). The program identified industries of interest, usually in the manufacturing sector, plus other identified workplaces, and selected a sample of workplaces to be visited for purposes of cataloging predetermined information of interest. The data collected included basic background information about specific plants, including availability of occupational health and safety services and specific information on the hazardous agents observed, the number of workers exposed, and estimates of the degree to which these hazards were controlled. The results obtained from the sample of workplaces visited were extrapolated to a larger population base and used to determine the need for occupational health specialists, and identifying industry-specific priorities for inspection and consulting programs.

Another federal effort by the Bureau of Occupational Safety and Health of the U.S. Public Health Service, reported in 1970, developed the “environmental” segment of the National Surveillance Network (NSN), which was also directed at survey activity in limited geographical areas. This network was intended to collect environmental and medical control data on specific plants, their workers, and the working environment. There were three intended uses for these data, addressing the need to: (*1*) provide information to participating agencies by projecting local data to the geographical areas of concern; (*2*) supplement projected data as necessary with data from participating agencies; and (*3*) estimate the scope of national health problems to “give input and direction to federal projects, such as the development of criteria and standards” (5).

Building upon the principles of the NSN, the National Institute for Occupational Safety and Health (NIOSH) conducted the National Occupational Hazard Survey (NOHS) from 1972 to 1974. This study involved the administration of a standardized questionnaire to facility management and a traditional industrial hygiene walkthrough in 4636 randomly selected workplaces in the United States. This statistical sample of the U.S. workplace was designed to be representative of all nonagricultural businesses covered under the Occupational Safety and Health Act of 1970 and employing eight or more workers. A team of 20 extensively trained surveyors visited the selected workplaces, recording potential exposure agents, duration of exposure, and controls in place (7–9). One of the major surprises of the survey was documentation of the extent of use of trade-name products in the workplaces and the lack of information about the ingredients of these products. An amazing 70% of the observed and recorded exposures in the NOHS involved trade-name products. It required several years for NIOSH to contact manufacturers to identify the ingredients or components of their products so that actual chemical names could be entered into the database in place of the unresolved trade names. When completed, the NOHS provided the first comprehensive national view of the chemical, physical, and biological agents to which American workers were potentially exposed, and the degree to which these exposures were controlled.

A second national survey, the National Occupational Exposure Survey (NOES), was initiated in 1981. A team of 15 trained surveyors conducted standardized management interviews and walkthrough surveys in 4490 workplaces from 1981 to 1983. The NOES was similar in design to the earlier NOHS survey, but specifically excluded most Agricultural, Mining, Wholesale, Retail, and Finance/Real Estate facilities. These deliberate exclusions were made either because other surveys were planned (Mining) or to focus survey resources on those industrial sectors believed to present the greatest potential hazard to the workforce (e.g., Construction, Manufacturing, and Services). The

data collected were quite similar to that in the NOHS, with the notable addition of gender-specific information on workers potentially exposed to chemical, physical, or biological agents, and data on the exposure of workers to ergonomic stress (10–12). Again, approximately 70% of the observed occupational exposures involved trade-name products, and extensive efforts were required to replace more than 100,000 observed trade names with their actual chemical constituents in the NOES database.

The information from the two surveys has been combined into one database with six interactive data files for ease of retrieval (13). These files include:

1. *The Industrial Classification File* This file, contains the 1972 Standard Industrial Classification (SIC) system codes and titles used to code the establishments visited during the surveys.
2. *The Occupational Codes File*. This file contains the Bureau of the Census occupation codes and titles used to code the job titles of workers observed in the walkthrough surveys.
3. *The Chemical Master File*. This file contains a listing of all the agents (hazards) in the survey databases. Each hazard observed was assigned a unique code by NIOSH, and these codes were cross-referenced to Chemical Abstracts Service (CAS) (14) numbers and identification codes from the Registry of Toxic Effects of Chemical Substances (RTECS) (15).
4. *The Facilities File*. This file contains all information collected for each facility surveyed except for exposure data and facility name and address. This information includes the type of industrial hygiene, safety, and medical services at the facility.
5. *The Exposure File*. This file contains all observations made by the surveyors during the walkthrough survey. Included is information on the use of personal protective equipment, engineering controls present, number of workers exposed, gender (for the NOES), and the occupations of observed worker groups.
6. *The "Trade Named" Ingredients File*. This file contains the ingredients for the trade-name products observed during each survey.

The data from the NOHS and NOES surveys are obviously useful in the broad aggregate process of anticipation and recognition, and represent a major step toward the national occupational health surveillance goals established in the 1966 Report to the Surgeon General (4). Evidence of the usefulness of these data in planning and prioritizing occupational health and safety research, regulation, and standards setting is demonstrated in extensive use by federal agencies. A partial list of these agencies includes the National Institute for Occupational Safety and Health, the Occupational Safety and Health Administration, the National Institute for Environmental Health, the Environmental Protection Administration, the Centers for Disease Control and Prevention, the National Cancer Institute, the National Toxicology Program, and the National Institutes of Health. In addition, labor organizations, academic researchers, state and local governments, industrial associations, and citizen's groups have made extensive use of the survey data in their efforts to identify occupational health problems and propose possible solutions.

The utility of the NOHS/NOES data is also demonstrated in its use as the basis for related research work that illustrates occupational health trends and identifies specific possible problem areas. Examples from NIOSH publications and the peer-reviewed literature include: computer modeling of relative health risk due to occupational exposures (16), mapping of the distribution of occupational chemical exposures (17), industrial compliance with OSHA record-keeping requirements (18), analyses of worker access to medical care (19, 20), identification and location of possible occupational asthma cohorts (21), and estimation of the number of workers potentially exposed to carcinogens (22, 23).

Perhaps the best evidence of the continuing need for this type of data is the effort by NIOSH to develop and conduct a successor to the NOES survey. This project (the National Occupational Exposure Survey for the 21st Century) is the current responsibility of a NIOSH team whose charge

includes working collaboratively with other federal agencies and nongovernmental partners to plan for and conduct a new national survey. This survey is to be complementary to both the NOHS and NOES, address the known data needs of NIOSH and its partners, allow for known changes in the American industrial universe since 1983, and permit a detailed examination of occupational health and safety problem areas that have emerged since the NOES was conducted (24).

Populations at Risk

Data Source Considerations

The NOES data files were used to develop the tables in this chapter that identify populations at potential risk of exposure to many of the chemical hazards reviewed in this publication. However, readers should be aware that there are definite limitations to the survey data that are related to its statistical design or to survey protocols, and should take these into account when reviewing the data displays.

These limitations include a lack (except for observed noise) of environmental level information, the accuracy of the estimates of the number of workers potentially exposed to specific agents, the age of the survey data, a bias towards larger (by employment size) facilities, the use of trade-name ingredient data in the estimation process, and the "provisional" nature of the data. Finally, readers should be aware that if they combine the estimates for individual agents to derive an estimate of the number of workers exposed to a list of agents, the estimate will be inflated, since at least some workers would be counted multiple times. This practice is discouraged. A brief explanation of the NOES limitations follows.

The NOES survey protocol did not allow for the measurement of environmental agent exposure levels for a variety of practical reasons, including the lack of available tests for the environmental concentration of the approximately 12,000 chemical, physical, or biological agents in the NOES database. In essence, simple logistical difficulties and constrained resources would not permit the standardized sampling of environmental concentrations of all observed exposures. For this reason, all NOES estimates of the number of workers exposed to specific agents are regarded as "potential exposures."

One of the fundamental factors considered in the design of the NOES survey was the relative accuracy of the estimates associated with facility totals and potentially exposed worker totals. Since survey design and sampling considerations made it impossible to achieve equal accuracy for both, it was decided that the accuracy of the estimates of the number of workers was the more important of the two estimates. Therefore, given that the majority of the U.S. workforce is employed in larger facilities (measured by employment totals), the survey data are biased towards larger plant workforces, and may under-represent workers in smaller plant workforces. In addition, NOES estimates may be associated with large standard errors, and should not be regarded as absolutes. Complete documentation of the sources of error in the NOES estimates is found in the NIOSH NOES Sampling Methodology publication (11).

The age of the NOES data is an obvious drawback, and means that the data may not accurately reflect current conditions or industrial worker and occupational exposure distribution in the national workplace. The long delay in updating this survey is a problem that the current NIOSH working committee is attempting to address through the establishment of external partnerships with other agencies with an interest in this type of data (24).

The NOES estimates are based upon the observed number of workers at the facility level exposed to specific agents projected to the national universe (11). In the NOES, such observations consisted of

"actual" and "trade-name" exposures, with "actual" exposures being those that were immediately recognizable on site (e.g., a drum labeled benzene), and a "trade name" exposure being an observed use and occupational contact with a trade-name product (12). However, as noted, approximately 70% of all occupational exposures are to trade-name compounds, and the exact nature of the resultant chemical exposures is not always clear at the actual user level. Therefore, as the composition of individual trade-name compounds became known, their component list was substituted for that trade name in the electronic database, and the NOES estimates of workers potentially exposed were generally based on both sources of exposure identification. This was because estimates based only on "actual" observation would have grossly underestimated the number of workers exposed. The practice of using both "actual" and "trade-name" sources of data in deriving the NOES estimates was followed in generating the tabular estimates presented in this chapter.

Finally, the NOES data presented in this chapter should be regarded as "provisional." This is because the NOES trade-name ingredient clarification effort was never completed. Of the approximately 100,00 trade names observed during the NOES survey, a 5-year communications effort ultimately resulted in the resolution of approximately 80,000 trade names. Since the addition of the missing data would change the NOES chemical inventory and the estimates of the number of workers potentially exposed, the data must be technically regarded as "provisional."

Data Display Considerations

Chemicals were selected for tabular display in this chapter in a two-stage process. First, the list of agents in the threshold limit values for Chemical Substances and Physical Agents (25) was searched, and the cited Chemical Abstracts Service (CAS) (14) numbers for specific chemicals were used to search the CAS file in the NOES database for a match. Three situations were immediately evident. In most cases, the cited CAS number was used to represent a single, specific chemical agent. But, in some cases, such as nickel, a number of different agents were represented by a single CAS number. In these cases, a special aggregated estimate of the number of workers potentially exposed was derived from the NOES data, and the tabular display was entitled in similar fashion to the display in threshold limit values for Chemical Substances and Physical Agents. For both of these cases, a single CAS number is cited in the table title. In the third case, a grouping of chemicals with different CAS numbers had been established under a common name for the threshold limit values publication. In this case, a special aggregated estimate of the number of workers potentially exposed was derived from the NOES data, the tabular display was entitled in similar fashion to the display in the TLV book, and multiple CAS numbers are cited in the table title.

Second, if a match (by CAS number) between the threshold limit values booklet (TLV) and the NOES database was observed, the NOES file was queried for the overall estimate (without regard to industry) of the number of workers potentially exposed. As previously mentioned, NOES estimates of the number of workers potentially exposed to an agent are subject to a degree of standard error, and estimates of less than 8000 may have unacceptable standard error. Accordingly, NOES data presented in tabular form in this chapter are restricted to those chemical agents for which the overall NOES estimate of workers potentially exposed exceeds 8000.

Considerable thought was given to the generation of estimates from the NOES database for this publication, given the wide variety of information and the space available. It was decided that the interests of the general audience could best be served by producing estimates of the workers potentially exposed to the agents identified in the TLV book/NOES search, and stratifying these estimates by the 1972 Standard Industrial Classification (SIC) (26) used in the NOES and by facility employment size. Readers interested in other analysis from the NOES database should contact

coauthor Randy Young at NIOSH.

The NOES database contains information on total employment in the surveyed facilities, and on the total number of workers who were observed to be potentially exposed to some agent by NOES survey protocol. This latter group can be referred to as "production workers," since their employment involved occupational exposure to at least one agent. There is a considerable difference between these groups. NOES estimates show that approximately 33 million workers were employed in the industrial universe surveyed during the NOES in 1981–1983 (12). Of these, approximately 19 million were observed (by NOES protocol) to be potentially exposed to some chemical, physical, or biological agent. Since, from an industrial hygiene viewpoint, the group of workers potentially exposed to at least some agent is of greater professional immediacy, it was decided that all NOES estimates provided here should profile these "production workers" rather than the total employed workforce.

Table 1 of this chapter provides the NOES estimates of the number of "production workers" for 38 two-digit SIC groups, stratified by facility employment size. The reader should note that there are "cells" (e.g., facilities employing 500 or more in SIC 07 [Agricultural Services]) in this table labeled with a "···" notation rather than containing estimates. This is because the statistical nature of the survey sampling procedure (11) resulted in failure to identify a number of facility employment strata within SIC for survey due to their sparsity in the national universe, and there are no NOES data for these cells. This "···" identification of an empty cell (no NOES data) has been carried over into the tabulations presented here, to distinguish between *no data* and data that indicate *no potential exposures* (zeros).

Table 110.1. Estimated Production Employees by SIC and Facility Employment Size (1981–1983 National Occupational Exposure Survey)

Another function of Table 1 is to display the 38 SIC groups, by code number and industry title, (26) to be profiled in the NOES estimates provided here. It should be noted that the actual survey design of the NOES called for survey activity in 43 two-digit SICs (11, 12). However, as documented in the third NOES publication, (12) five of these SICs contained so little survey data that estimates of the number of potentially exposed workers in them was felt to be associated with unacceptably high standard error. Therefore, they are not represented in Table 1, or in any of the agent specific tabulations presented here.

Calculation and Display of Estimates

The estimates of potentially exposed workers displayed in this chapter were generated using the inverse inclusion probability of the facilities surveyed in the NOES. These weights were used to project facility-specific numbers of observed workers potentially exposed to *any* NOES agent ("production workers") to the national NOES universe, as documented in the second of the NIOSH publications on the NOES (11). As previously mentioned, these data are shown in Table 1.

Estimates of the number of production workers potentially exposed to *specific* agents by SIC and facility employment size strata *and* for all industries without regard to facility employment size were generated in a similar fashion and are displayed in the Appendix to this Chapter. Note that only those industries for which there were observations of exposure to the specified agent are listed in each table. In other words, the number of two-digit SIC industries cited in a specific table will not exceed 38, but may well be less, depending on the distribution of observed potential exposure.

In addition to these estimates of the number of workers potentially exposed, the tables in this chapter provide estimated proportion data, expressed as percent values for each facility employment size strata (small, medium, and large) within each SIC profiled. These values were generated by dividing the estimated number of workers potentially exposed to *specific NOES agents* by the estimated number potentially exposed to *any NOES agent* for that particular industry—facility employment size or industry "cell" in the tables (see Table 1). These percent values are used to convey three types of information:

1. *Industry-Specific Exposure Concentration by Facility Employment Size*. Percent values in the industry–facility employment size "cells" indicate the proportion of *all* potentially exposed workers in that cell who are potentially exposed to a specific agent. For example, in a table profiling potential exposure to agent *X*, a value of 4.1% in the SIC 28 small (employing fewer than 100 workers) facilities cell would indicate that 4.1% of all workers potentially exposed to *any* NOES agent in small facilities in SIC 28 are potentially exposed to agent *X*. Therefore, these data provide a proportional estimate of the relative concentration of worker exposure to a specified agent by employment size strata within specified industries.
2. *Industry-Specific Exposure Concentration*. Percent values in the industry–total "cells" indicate the proportion of all workers potentially exposed to a specific agent who are employed in that industry. For example, in a table profiling potential exposure to agent *X*, a value of 4.1% in the SIC 28 total cell would indicate that 4.1% of all workers potentially exposed to agent *X* are employed in SIC 28. Therefore, these data provide a proportional estimate of all worker exposure to a specified agent by listed industry.
3. *All Industries Exposure Concentration by Facility Employment Size*. Percent values displayed by facility employment size strata in the all industries facility employment strata "cell" displays indicate the proportion of all workers potentially exposed to any NOES agent who are potentially exposed to a specific agent in small, medium, and large facilities, without regard to industry. For example, in a table profiling potential exposure to agent *X*, a value of 4.1% in the all industries–small facilities cell would indicate that 4.1% of all small facilities workers exposed to any NOES agent are potentially exposed to agent *X*. Therefore, these data provide a proportional estimate of the relative concentration of worker exposure to a specific agent by facility employment size without regard to industry.
4. *Summary Estimate*. The value in the all industry total "cells" in the summary estimate of all workers potentially exposed to the agent specified in the table title without regard to facility employment size or industry of employment. Note that the percent data will always equal 100%.

These data points are further illustrated in Figure 1.

SIC Code	Industry	Workers by Facility Employment Size			
		Small (8–99)	Medium (100–499)	Large (500+)	Total
XX	Xxxxxxx	Est. %	Est. %	Est. %[c]	Est.[b–d] Col %[f]
•					
•					
All Industries		Est. T%	Est. T%	Est. T%[h]	Est.[g] All %[i]

[a]All specific chemical names are in NOES format, which generally follows the nomenclature used in the Registry of Toxic Effects of Chemical Substances (RTECS).[15]

[b]NOES estimates of the number of workers potentially exposed are presented by two-digit 1972 Standard Industrial Classification (SIC) and for all (all industries) NOES industries. Note that only those SICs for which there are survey data will be displayed, and that there are a maximum of 38 SIC groups in any table.

[c]NOES estimates of the number of workers potentially exposed (est. values) are presented by facility employment size and for all facilities within an SIC. A lack of NOES survey observations in an individual cell of the table is denoted with "…", and no estimates are provided.

[d]The first row of data (est. values) in each SIC cluster in the table presents the NOES estimates of the number of workers potentially exposed to the specified agent in small, medium, large, and all facilities in that SIC.

[e]The first three elements in the second row of data in each SIC cluster (% values) in the table presents the number of workers potentially exposed to the specified agent as the percent of all workers potentially exposed to any NOES agent in small, medium, and large facilities in that SIC. All percent values are expressed to the nearest tenth of a percent.

[f]The fourth element in the second row of data in each SIC cluster (Col % values) presents the number of all potentially exposed workers in that SIC as the proportion (as a percent) of all workers (regardless of industry of employment) potentially exposed to the specified agent. This datum displays the proportion of all workers potentially exposed to the specified agent within the cited industry.

[g]The first line (est. values) of the all industries data presents the NOES estimates of all workers potentially exposed to the specified agent, in small, medium, large, and total facilities regardless of industry of employment.

[h]The second line of the all industries data (T% values) presents the number of workers potentially exposed to the specified agent as the percent of all workers potentially exposed to any agent in small, medium, and large facilities without regard to industry.

[i]The all industries data (all % values) in the second data line represent the summary percentage value for all industry-specific observations. This number will always equal 100%.

Appendix
This appendix displays the tabular information on the industrial distribution of potential occupational exposures to 289 selected chemical agents or groups of agents in Tables 2 through 291. These tables are essentially in alphabetical order by RTECS (15) naming convention, and the page number in the appendix for specific chemical agents are referenced by Chemical Abstract Service (14) (CAS) number in the overall Patty's index and in the CAS numbers cited in the various chapters of Patty's.

Carbon Black

Robert J. McCunney, MD, MPH, Henry J. Muranko, MPH, CIH, Peter A. Valberg, Ph.D.

1 Introduction

Carbon black is a powdered form of elemental carbon in the form of near-spherical colloidal

particles and coalesced particle aggregates of colloidal size, obtained by partial combustion or thermal decomposition of hydrocarbons (1). It is distinguishable from other commercial carbons, such as charcoal, by its fine particulate nature and the shape, structure, and degree of fusion of the particles observed with the electron microscope. The fundamental unit of a carbon black particle is the aggregate (2). Although carbon black is often equated with soot, it differs markedly from the unwanted, uncontrolled by-products of combustion found in chimneys and the ambient air. The contrast between carbon blacks, soots, and diesel particulate is discussed in more detail in the following.

Carbon black is the earliest known synthetic pigment, having been produced by the Chinese more than 1500 years ago. They made the ink pigment lampblack by burning purified animal or vegetable oils in small lamps with the flames impinging on cool porcelain surfaces on which the carbon black collected.

Carbon black has been commercially produced in the United States for more than 100 years. Although it is still used as a pigment in printing inks, paints, and lacquers, its major use over the past 50 years has been as a reinforcing agent in rubber, particularly in tires. It is also used in plastics, to which it imparts weathering resistance, antistatic, and electrically conductive properties.
1.0 Carbon Black
1.0.1 CAS Number: [*1333-86-4*]

1.0.2 Synonyms: Carbon Lampblack; Acetylene black; Lampblack; Thermal black; Channel black

1.0.3 Trade Names: NA

1.0.4 Molecular Weight: 12.0

1.0.5 Molecular Formula: C
1.1 Production and Use
From the primitive Chinese process mentioned, the production of carbon black has evolved into a high-volume, continuous process in which carefully controlled conditions determine the final characteristics of the product. Channel black manufacture started in the United States in the 1870s with plants located close to sources of the feedstock, natural gas. The introduction of the higher-yielding oil furnace process in the 1940s, the high level of smoke pollution, and the increasing cost of natural gas caused a steady decline in channel black production. The last channel black plant in the United States closed in 1976. Now over 95% of carbon black worldwide is produced by the oil furnace process. The unique association between the physicochemical characteristics of carbon blacks and their performance in various applications has, however, ensured the continued production of small quantities of blacks by the thermal, lampblack, channel, and acetylene black processes.
