Preface

Financial econometrics and statistics have become very important tools for empirical research in both finance and accounting. Econometric methods are important tools for doing asset pricing, corporate finance, options and futures, and conducting financial accounting research. Important econometric methods used in this research include: single equation multiple regression, simultaneous regression, panel data analysis, time series analysis, spectral analysis, non-parametric analysis, semi-parametric analysis, GMM analysis, and other methods.

Portfolio theory and management research have used different statistical distributions, such as normal distribution, stable distribution, and log normal distribution. Options and futures research have used binomial distribution, log normal distribution, non-central chi square distribution, Poission distribution, and others. Auditing research has used sampling survey techniques to determine the sampling error and non-sampling error for auditing.

Based upon our years of experience working in the industry, teaching classes, conducting research, writing textbooks, and editing journals on the subject of financial econometrics and statistics, this handbook will review, discuss, and integrate theoretical, methodological, and practical issues of financial econometrics and statistics. There are 99 chapters in this handbook. Chapter 1 presents an introduction of financial econometrics and statistics and shows how readers can use this handbook. The following chapters, which have been contributed by accredited authors, can be classified by the following 14 topics.

i. Financial Accounting (Chapters 2, 9, 10, 61, 97)
ii. Mutual Funds (Chapters 3, 24, 25, 68, 88)
iii. Microstructure (Chapters 4, 44, 96, 99)
iv. Corporate Finance (Chapters 5, 21, 30, 38, 42, 46, 60, 63, 75, 79, 95)
v. Asset Pricing (Chapters 6, 15, 22, 28, 34, 36, 39, 45, 47, 50, 81, 85, 87, 93)
vi. Options (Chapters 7, 32, 37, 55, 65, 84, 86, 90, 98)
vii. Portfolio Analysis (Chapters 8, 26, 35, 53, 67, 73, 80, 83)
viii. Risk Management (Chapters 11, 13, 16, 17, 23, 27, 41, 51, 54, 72, 91, 92)
ix. International Finance (Chapters 12, 40, 43, 59, 69)
x. Event Study (Chapters 14)
xi. Methodology (Chapters 18, 19, 20, 29, 31, 33, 49, 52, 56, 57, 58, 62, 74, 76, 77, 78, 82, 89)

xii. Banking Management (Chapters 64)
xiii. Pension Funds (Chapters 66)
xiv. Futures and Index Futures (Chapters 48, 70, 71, 94)

In addition to this classification, based upon the keywords of chapter 2-99, we classify the information into a) finance and accounting topics and b) methodology topics. This information can be found in chapter 1 of this handbook.

In the preparation of this handbook, first, we would like to thank the member of advisory board and contributors of this handbook. In addition, we would like to make note that we appreciate the extensive help from the Editor Mr. Brian Foster, our research assistants Tzu Tai, Lianne Ng, and our secretary Ms. Miranda Mei-Lan Luo. Finally, we would like to thank the financial support from the Wintek Corporation and APEX International Financial Engineering Res. & Tech. Co. Ltd. that allowed us to write the edition of this book.

There are undoubtedly some errors in the finished product, both typo-graphical and conceptual. I would like to invite readers to send suggestions, comments, criticisms, and corrections to the author Professor Cheng F. Lee at the Department of Finance and Economics, Rutgers University at the email address lee@business.rutgers.edu.

Advisory Board

About the Editors

Cheng-Few Lee is a Distinguished Professor of Finance at Rutgers Business School, Rutgers University and was chairperson of the Department of Finance from 1988–1995. He has also served on the faculty of the University of Illinois (IBE Professor of Finance) and the University of Georgia. He has maintained academic and consulting ties in Taiwan, Hong Kong, China and the United States for the past four decades. He has been a consultant to many prominent groups including, the American Insurance Group, the World Bank, the United Nations, The Marmon Group Inc., Wintek Corporation, and Polaris Financial Group.

Professor Lee founded the *Review of Quantitative Finance and Accounting* (RQFA) in 1990 and the *Review of Pacific Basin Financial Markets and Policies* (RPBFMP) in 1998, and serves as managing editor for both journals. He was also a co-editor of the *Financial Review* (1985–1991) and the *Quarterly Review of Economics and Finance* (1987–1989). In the past 39 years, Dr. Lee has written numerous textbooks ranging in subject matters from financial management to corporate finance, security analysis and portfolio management to financial analysis, planning and forecasting, and business statistics. In addition, he edited two popular books, *Encyclopedia of Finance* (with Alice C. Lee) and *Handbook of Quantitative Finance and Risk Management* (with Alice C. Lee and John Lee). Dr. Lee has also published more than 200 articles in more than 20 different journals in finance, accounting, economics, statistics, and management. Professor Lee was ranked the most published finance professor worldwide during the period 1953–2008.

Professor Lee was the intellectual force behind the creation of the new Masters of Quantitative Finance program at Rutgers University. This program began in 2001 and has been ranked as one of the top ten quantitative finance programs in the United States. These top ten programs are located at Carnegie Mellon University, Columbia University, Cornell University, New York University, Princeton University, Rutgers University, Stanford University, University of California at Berkley, University of Chicago, and University of Michigan.

John C. Lee is a Microsoft Certified Professional in Microsoft Visual Basic and Microsoft Excel VBA. He has a Bachelor and Masters degree in accounting from the University of Illinois at Urbana-Champaign.

John has worked over 20 years in both the business and technical fields as an accountant, auditor, systems analyst and as a business software developer. He is the author of the book on how to use MINITAB and Microsoft Excel to do statistical analysis which is a companion text to *Statistics of Business and Financial Economics*, 2nd and 3rd, of which he is one of the co-authors. In addition, he has also coauthored the textbooks *Financial Analysis*, *Planning and Forecasting*, 2ed (with Cheng F. Lee and Alice C. Lee), and *Security Analysis*, *Portfolio Management*, *and Financial Derivatives* (with Cheng F. Lee, Joseph Finnerty, Alice C. Lee, and Donald Wort). John has been a Senior Technology Officer at the Chase Manhattan Bank and Assistant Vice President at Merrill Lynch. Currently, he is the Director of the Center for PBBEF Research.

C.-F. Lee, J. Lee (eds.), *Handbook of Financial Econometrics and Statistics*,
DOI 10.1007/978-1-4614-7750-1_1,

Abstract

The main purposes of this introduction chapter are (i) to discuss important financial econometrics and statistics which have been used in finance and accounting research and (ii) to present an overview of 98 chapters which have been included in this handbook. Sections 1.2 and 1.3 briefly review and discuss financial econometrics and statistics. Sections 1.4 and 1.5 discuss application of financial econometrics and statistics. Section 1.6 first classifies 98 chapters into 14 groups in accordance with subjects and topics. Then this section has classified the keywords from each chapter into two groups: finance and accounting topics and methodology topics. Overall, this chapter gives readers of this handbook guideline of how to apply this handbook to their research.

1.1 Introduction

Financial econometrics and statistics have become very important tools for empirical research in both finance and accounting. Econometric methods are important tools for asset-pricing, corporate finance, options, and futures, and conducting financial accounting research. Important econometric methods used in this research include: single equation multiple regression, simultaneous regression, panel data analysis, time-series analysis, spectral analysis, nonparametric analysis, semi-parametric analysis, GMM analysis, and other methods.

Portfolio theory and management research have used different statistics distributions, such as normal distribution, stable distribution, and log-normal distribution. Options and futures research have used binomial distribution, log-normal distribution, non-central Chi-square distribution, Poisson distribution, and others. Auditing research has used sampling survey techniques to determine the sampling error and non-sampling error for auditing. Risk management research has used Copula distribution and other distributions.

Section 1.1 is the introduction. Section 1.2 discusses financial econometrics. In this section, we have six subsections. These subsections include single equation regression methods, simultaneous equation models, panel data analysis, as well as alternative methods to deal with measurement error, time-series analysis, and spectral analysis. In the next section, Sect. 1.3, we discuss financial statistics. Within financial statistics, we discuss six subtopics, including statistical distributions; principle components and factor analysis; nonparametric, semi-parametric, and GMM analyses; and cluster analysis. After exploring these topics, we discuss the applications of financial econometrics and financial statistics in Sects. 1.4 and 1.5. In Sect. 1.6, we discuss the overview of all papers included in this handbook in accordance with the subject and methodologies used in the papers. Finally in Sect. 1.7, we summarize all the chapters in this handbook and add our concluding remarks.

As mentioned previously, Sect. 1.2 covers the topic of financial econometrics. We divide this section into six subsections. Within Sect. 1.2.1, we talk about single equation regression methods. We discuss some important issues related to single equation regression methods, including Heteroskedasticity, Specification Error, Measurement Error, Skewness and the Kurtosis Effect, Nonlinear Regression and Box-Cox transformation, Structural Change, the Chow Test and Moving Chow Test, Threshold Regression, Generalize Fluctuation Test, Probit and Logit Regression for Credit Risk Analysis, Poisson Regression, and Fuzzy Regression. The next subsection, Sect. 1.2.2, analyzes simultaneous equation models. Within the realm of simultaneous equation models, we discuss two-stage least squares estimation (2SLS) method, seemly unrelated regression (SUR) method, three-stage least squares estimation (3SLS) method, and disequilibrium estimation method. In Sect. 1.2.3, we study panel data analysis, in which we go over fixed effect model, random effect model, and clustering effect. The next subsection, Sect. 1.2.3, explores alternative methods to deal with measurement error. The alternative methods we look over in this section includes LISREL model, multifactor and multi-indicator (MIMIC) model, partial least square method, and grouping method. After we discuss alternative methods to deal with measurement error, we examine in Sect. 1.2.4 time-series analysis. We include in our section about time-series analysis some important models, including ARIMA, ARCH, GARCH, fractional GARCH, and combined forecasting. In Sect. 1.2.5, we look into spectral analysis.

In the following section, Sect. 1.3, we discuss financial statistics, along with four subsequent subtopics. In our first subsection, Sect. 1.3.1, we discuss some important statistical distributions. This subsection will look into the different types of distributions that are in statistics, including Binomial and Poisson distribution, normal distribution, log-normal distribution, Chi-square distribution, and non-central Chi-square distribution, Wishart distribution, symmetric and non-symmetric stable distributions, and other known distributions. Then, we talk about principal components and factor analysis in Sect. 1.3.2. In the following subsection, Sect. 1.3.3, we examine nonparametric, semi-parametric, and GMM analyses. The last subsection, Sect. 1.3.4, explores cluster analysis.

After discussing financial econometrics, we explore the applications of this topic in different types of financial and accounting field research. In Sect. 1.4, we describe these applications, including asset-pricing research, corporate finance research, financial institution research, investment and portfolio research, option pricing research, future and hedging research, mutual fund research, hedge fund research, microstructure, earnings announcements, real option research, financial accounting, managerial accounting, auditing, term structure modeling, credit risk modeling, and trading cost/transaction cost modeling.

We also discuss applications of financial statistics into different types of financial and accounting field research. Section 1.5 will include these applications in asset-pricing research, investment and portfolio research, credit risk management research, market risk research, operational risk research, option pricing research, mutual fund research, hedge fund research, value-at-risk research, and auditing.

1.2 Financial Econometrics

1.2.1 Single Equation Regression Methods

There are important issues related to single equation regression estimation method. They are (a) Heteroskedasticity, (b) Specification error, (c) Measurement error, (d) Skewness and kurtosis effect, (e) Nonlinear regression and Box-Cox transformation, (f) Structural change, (g) Chow test and moving Chow test, (h) Threshold regression, (i) Generalized fluctuation, (j) Probit and Logit regression for credit risk analysis, (k) Poisson regression, and (l) Fuzzy regression. These issues are briefly discussed as follows:

(a) Heteroskedasticity
  - White (1980) and Newvey and West (1987) are two important papers discussing how the heteroskedasticity test can be performed. The latter paper discusses heteroskedasticity when there are serial correlations.

(b) Specification error
  - Specification error occurs when there is missing variable in a regression analysis. To test the existence of specification error, we can refer to the papers by Thursby (1985), Fok et al. (1996), Cheng and Lee (1986), and Maddala et al. (1996).

(c) Measurement error
  - Management error problem is when there exists imprecise independent variable in a regression analysis. Papers by Lee and Jen (1978), Kim (1995, 1997, 2010), Miller and Modigliani (1966), and Lee and Chen (2012) have explored how measurement error methods can be applied to finance research. Lee and Chen have discussed alternative errors in variable estimation methods and their application in finance research.

(d) Skewness and kurtosis effect
  - Both skewness and kurtosis are two important measurement variables to prepare stock variation analysis. Papers by Lee (1976a), Sears and Wei (1988), and Lee and Wu (1985) discuss the skewness and kurtosis issue in asset pricing.

(e) Nonlinear regression and Box-Cox transformation
  - Nonlinear regression and Box-Cox transformation are important tools for finance, accounting, and urban economic researches. Papers by Lee (1976, 1977), Lee et al. (1990), Frecka and Lee (1983), and Liu (2006) have discussed how nonlinear regression and Box-Cox transformation techniques can be used to improve the specification of finance and accounting research. Kau and Lee (1976), and Kau et al. (1986) have explored how Box-Cox transformation can be used to conduct the empirical study of urban structure.

(f) Structural change
  - Papers by Yang (1989), Lee et al. (2011b, 2013) have discussed how the structural change model can be used to improve the empirical study of dividend policy and the issuance of new equity.

(g) Chow test and Moving Chow test
  - Chow (1960) has proposed a dummy variable approach to examine the existence of structure change for regression analysis. Zeileis et al. (2002)

have developed software programs to perform the Chow test and other structural change models which has been frequently used in finance and economic research.

(h) Threshold regression
   – Hansen (1996, 1997, 1999, 2000a, and 2000b) have explored the issue of threshold regressions and their applications in detecting structure change for regression.

(i) Generalize fluctuation test
   – Kuan and Hornik (1995) have discussed how the generalized fluctuation test can be used to perform structural change to regression.

(j) Probit and Logit regression for credit risk analysis
   – Probit and Logit regressions are frequently used in credit risk analysis. Ohlson (1980) used the accounting ratio and macroeconomic data to do credit risk analysis. Shumway (2001) has used accounting ratios and stock rate returns for credit risk analysis in terms of Probit and Logit regression techniques. Most recently, Hwang et al. (2008, 2009) and Cheng et al. (2010) have discussed Probit and Logit regression for credit risk analysis by introducing nonparametric and semi-parametric techniques into this kind of regression analysis.

(k) Poisson regression
   – Lee and Lee (2012) have discussed how the Poisson Regression can be performed, regardless of the relationship between multiple directorships, corporate ownership, and firm performance.

(l) Fuzzy regression
   – Shapiro (2005), Angrist and Lavy (1999), and Van Der Klaauw (2002) have discussed how Fuzzy Regression can be performed. This method has the potential to be used in finance accounting and research.

1.2.2 Simultaneous Equation Models

In this section, we will discuss alternative methods to deal with simultaneous equation models. There are (a) two-stage least squares estimation (2SLS) method, (b) seemly unrelated regression (SUR) method, (c) three-stage least squares estimation (3SLS) method, (d) disequilibrium estimation method, and (e) generalized method of moments.

(a) Two-stage least squares estimation (2SLS) method
   – Lee (1976a) has applied this to started market model; Miller and Modigliani (1966) have used 2SLS to study cost of capital for utility industry; Chen et al. (2007) have discuss the two-stage least squares estimation (2SLS) method for investigating corporate governance.

(b) Seemly unrelated regression (SUR) method
   – Seemly unrelated regression has frequently used in economic and financial research. Lee and Zumwalt (1981) have discussed how the seemly unrelated regression method can be applied in asset-pricing determination.

(c) Three-stage least squares estimation (3SLS) method
  – Chen et al. (2007) have discussed how the three-stage least squares estimation (3SLS) method can be applied in corporate governance research.
(d) Disequilibrium estimation method
  – Mayer (1989), Martin (1990), Quandt (1988), Amemiya (1974), and Fair and Jaffee, (1972) have discussed how alternative disequilibrium estimation method can be performed. Tsai (2005), Sealey (1979), and Lee et al. (2011a) have discussed how the disequilibrium estimation method can be applied in asset-pricing test and banking management analysis.
(e) Generalized method of moments
  – Hansen (1982) and Hamilton (1994, ▶ Chap. 14) have discussed how GMM method can be performed. Chen et al. (2007) have used the two-stage least squares estimation (2SLS), three-stage squares method, and GMM method to investigate corporate governance.

1.2.3 Panel Data Analysis

In this section, we will discuss important issues related to panel data analysis. They are (a) fixed effect model, (b) random effect model, and (c) clustering effect model.

Three well-known textbooks by Wooldridge (2010), Baltagi (2008) and Hsiao (2003) have discussed the applications of panel data in finance, economics, and accounting research. Now, we will discuss the fixed effect, random effect, and clustering effect in panel data analysis.

(a) Fixed effect model
  – Chang and Lee (1977) and Lee et al. (2011a) have discussed the role of the fixed effect model in panel data analysis of dividend research.
(b) Random effect model
  – Arellano and Bover (1995) have explored the random effect model and its role in panel data analysis. Chang and Lee (1977) have applied both fix effect and random effect model to investigating the relationshipbetween price per share, dividend per share, and retained earnings per share.
(c) Clustering effect model
  – Papers by Thompson (2011), Cameron et al. (2006), and Petersen (2009) review the clustering effect model and its impact on panel data analysis.

1.2.4 Alternative Methods to Deal with Measurement Error

In this section, we will discuss alternative methods of dealing with measurement error problems. They are (a) LISREL model, (b) multifactor and multi-indicator (MIMIC) model, and (c) partial least square method, and (d) grouping method.

(a) LISREL model
  – Papers by Titman and Wessal (1988), Chang (1999), Chang et al. (2009), Yang et al. (2010) have described the LISREL model and its way to resolve the measurement error problems of finance research.

(b) Multifactor and multi-indicator (MIMIC) model
  – Chang et al. (2009) and Wei (1984) have applied in the multifactor and multi-indicator (MIMIC) model in capital structure and asset-pricing research.

(c) Partial least square method
  – Papers by Core (2000), Ittner et al. (1997), and Lambert and Lacker (1987) have applied the partial least square method to deal with measurement error problems in accounting research.

(d) Grouping method
  – Papers by Lee (1973), Chen (2011), Lee and Chen (2013), Lee (1977b), Black et al. (1972), Blume and Friend (1973), and Fama and MacBeth (1973) analyze grouping method and its way to deal with measurement error problem in capital asset-pricing tests.

There are other errors in variable method, such as (i) Classical method, (ii) instrumental variable method, (iii) mathematical programming method, (iv) maximum likelihood method, (v) GMM method, and (vi) Bayesian Statistic Method. Lee and Chen (2012) have discussed all above-mentioned methods in details.

1.2.5 Time Series Analysis

In this section, we will discuss important models in time-series analysis. They are (a) ARIMA, (b) ARCH, (c) GARCH, (d) fractional GARCH, and (e) combined forecasting.

- Two well-known textbooks by Anderson (1994) and Hamilton (1994) have discussed the issues related to time-series analysis. We will discuss some important topics in time-series analysis in the following subsections.
- Myers (1991) discloses ARIMA's role in time-series analysis: Lien and Shrestha (2007) discuss ARCH and its impact on time-series analysis: Lien (2010) discusses GARCH and its role in time-series analysis: Leon and Vaello-Sebastia (2009) further research into GARCH and its role in time series in a model called Fractional GARCH.
- Granger and Newbold (1973), Granger and Newbold (1974), Granger and Ramanathan (1984) have theoretically developed combined forecasting methods. Lee et al. (1986) have applied combined forecasting methods to forecast market beta and accounting beta. Lee and Cummins (1998) have shown how to use the combined forecasting methods to perform cost of capital estimates.

1.2.6 Spectral Analysis

Anderson (1994), Chacko and Viceira (2003), and Heston (1993) have discussed how spectral analysis can be performed. Heston (1993) and Bakshi et al. (1997) have applied spectral analysis in the evaluation of option pricing.

1.3 Financial Statistics

1.3.1 Important Statistical Distributions

In this section, we will discuss different statistical distributions. They are: (a) Poisson distribution, (c) normal distribution, (d) log-normal distribution, (e) Chi-square distribution, (f) non-central Chi-square distribution.

Two well-known textbooks by Cox et al. (1979) and Rendleman and Barter (1979) have used binomial, normal, and lognormal distributions to develop an option pricing model. The following subsections note some famous authors that provide studies on these different statistical distributions. Black and Sholes (1973) have used lognormal distributions to derive the option pricing model. Finally, Aitchison and Brown (1973) is a well-known book to investigate lognormal distribution. Schroder (1989) has derived the option pricing model in terms of non-central Chi-square distribution.

Fama (1971) has used stable distributions to investigate the distribution of stock rate of returns. Chen and Lee (1981) have derived statistics distribution of Sharpe performance measure and found that Sharpe performance measure can be described by Wishart distribution.

1.3.2 Principle Components and Factor Analysis

Anderson's (2003) book entitled "*An Introduction to Multivariate Statistical Analysis*" has discussed principal components and factor analysis in detail. Chen and Shimerda (1981), Pinches and Mingo (1973), and Kao and Lee (2012) discuss how principal components and factor analyses can be used to do finance Lee et al. (1989) and accounting research.

1.3.3 Nonparametric and Semi-parametric Analyses

Ait-Sahalia and Lo (2000), and Hutchison et al. (1994) have discussed how nonparametric can be used in risk management and derivative securities evaluation. Hwang et al. (2010), and Hwang et al. (2007) have used semi-parametric to conduct credit risk analysis.

1.3.4 Cluster Analysis

The detailed procedures to discuss how cluster analysis can be used to find groups in data can be found in the textbook by Kaufman and Rousseeuw (1990). Brown and Goetzmann (1997) have applied cluster analysis in mutual fund research.

1.4 Applications of Financial Econometrics

In this section, we will briefly discuss how different methodologies of financial econometrics will be applied to the topics of finance and accounting.

(a) Asset-pricing Research
   – Methodologies used in asset-pricing research include (1) Heteroskedasticity, (2) Specification error, (3) Measurement error, (4) Skewness and kurtosis effect, (5) Nonlinear regression and Box-Cox transformation, (6) Structural change, (7) Two-stage least squares estimation (2SLS) method, (8) Seemly unrelated regression (SUR) method, (9) Three-stage least squares estimation (3SLS) method, (10) Disequilibrium estimation method, (11) Fixed effect model, (12) Random effect model, (13) Clustering effect model of panel data analysis, (14) Grouping method, (15) ARIMA, (16) ARCH, (17) GARCH, (18) Fractional GARCH, and (19) Wishart distribution.

(b) Corporate Finance Research:
   – Methodologies used in Corporate finance research include (1) Heteroskedasticity, (2) Specification error, (3) Measurement error, (4) Skewness and kurtosis effect, (5) Nonlinear regression and Box-Cox transformation, (6) Structural change, (7) Probit and Logit regression for credit risk analysis, (8) Poisson regression, (9) Fuzzy regression, (10) Two-stage least squares estimation (2SLS) method, (11) Seemly unrelated regression (SUR) method, (12) Three-stage least squares estimation (3SLS) method, (13) Fixed effect model, (14) Random effect model, (15) Clustering effect model of panel data analysis, and (16) GMM Analysis.

(c) Financial Institution Research
   – Methodologies used in Financial Institution research include (1) Heteroskedasticity, (2) Specification error, (3) Measurement error, (4) Skewness and kurtosis effect, (5) Nonlinear regression and Box-Cox transformation, (6) Structural change, (7) Probit and Logit regression for credit risk analysis, (8) Poisson regression, (9) Fuzzy regression, (10) Two-stage least squares estimation (2SLS) method, (11) Seemly unrelated regression (SUR) method, (12) Three-stage least squares estimation (3SLS) method, (13) Disequilibrium estimation method, (14) Fixed effect model, (15) Random effect model, (16) Clustering effect model of panel data analysis, (17) Semiparametric analysis.

(d) Investment and Portfolio Research
   – Methodologies used in investment and portfolio research include (1) Heteroskedasticity, (2) Specification error, (3) Measurement error, (4) Skewness and kurtosis effect, (5) Nonlinear regression and Box-Cox transformation, (6) Structural change, (7) Probit and Logit regression for credit risk analysis, (8) Poisson regression, and (9) Fuzzy regression.

(e) Option Pricing Research
   – Methodologies used in option pricing research include (1) ARIMA, (2) ARCH, (3) GARCH, (4) Fractional GARCH, (5) Spectral analysis, (6) Binomial distribution, (7) Poisson distribution, (8) normal distribution,

(9) log-normal distribution, (10) Chi-square distribution, (11) non-central Chi-square distribution, and (12) Nonparametric analysis.

(f) Future and Hedging Research
   – Methodologies used in future and hedging research include (1) Heteroskedasticity, (2) Specification error, (3) Measurement error, (4) Skewness and kurtosis effect, (5) Nonlinear regression and Box-Cox transformation, (6) Structural change, (7) Probit and Logit regression for credit risk analysis, (8) Poisson regression, and (9) Fuzzy regression.

(g) Mutual Fund Research
   – Methodologies used in mutual fund research include (1) Heteroskedasticity, (2) Specification error, (3) Measurement error, (4) Skewness and kurtosis effect, (5) Nonlinear regression and Box-Cox transformation, (6) Structural change, (7) Probit and Logit regression for credit risk analysis, (8) Poisson regression, (9) Fuzzy regression, and (10) Cluster analysis.

(h) Credit Risk Modeling
   – Methodologies used in credit risk modeling include (1) Heteroskedasticity, (2) Specification error, (3) Measurement error, (4) Skewness and kurtosis effect, (5) Nonlinear regression and Box-Cox transformation, (6) Structural change, (7) Two-stage least squares estimation (2SLS) method, (8) Seemly unrelated regression (SUR) method, (9) Three-stage least squares estimation (3SLS) method, (10) Disequilibrium estimation method, (11) Fixed effect model, (12) Random effect model, (13) Clustering effect model of panel data analysis, (14) ARIMA, (15) ARCH, (16) GARCH, and (17) Semiparametric analysis.

(i) Other Application
   – Financial econometrics is also important tools to conduct research in (1) Trading cost/transaction cost modeling, (2) Hedge fund research, (3) Microstructure, (4) Earnings announcement, (5) Real option research, (6) Financial accounting, (7) Managerial accounting, (8) Auditing, and (9) Term structure modeling.

1.5 Applications of Financial Statistics

Financial statistics is an important tool for research in (1) Asset-pricing research, (2) Investment and portfolio research, (3) Credit risk management research, (4) Market risk research, (5) Operational risk research, (6) Option pricing research, (7) Mutual fund research, (8) Hedge fund research, (9) Value-at-risk research, and (10) Auditing research.

1.6 Overall Discussion of Papers in this Handbook

In this section, we classify 98 papers (chapters 2–99) which have been presented in Appendix 1 in accordance with (A) Chapter titles and (B) Keywords.

(A) Chapter title classification in terms of Chapter Titles

Based on chapter titles, we classify 98 chapters into the following 14 topics:

(i) Financial Accounting (▶ Chaps. 2, 9, 10, 61, 97)
(ii) Mutual Funds (▶ Chaps. 3, 24, 25, 68, 88)
(iii) Microstructure (▶ Chaps. 4, 44, 47, 96)
(iv) Corporate Finance (▶ Chaps. 5, 21, 30, 38, 42, 46, 60, 63, 75, 79, 95)
(v) Asset Pricing (▶ Chaps. 6, 15, 22, 28, 34, 36, 39, 45, 50, 81, 85, 87, 93, 99)
(vi) Options (▶ Chaps. 7, 32, 37, 55, 65, 84, 86, 90, 98)
(vii) Portfolio Analysis (▶ Chaps. 8, 26, 35, 53, 67, 73, 80, 81, 83)
(viii) Risk Management (▶ Chaps. 11, 13, 16, 17, 23, 27, 41, 51, 54, 72, 91, 92)
(ix) International Finance (▶ Chaps. 12, 40, 43, 59, 69)
(x) Event Study (▶ Chap. 14)
(xi) Methodology (▶ Chaps. 18, 19, 20, 29, 31, 33, 46, 49, 52, 56, 57, 58, 62, 74, 76, 77, 78, 82, 89)
(xii) Banking Management (▶ Chap. 64)
(xiii) Pension Funds (▶ Chap. 66)
(xiv) Futures and Index Futures (▶ Chaps. 48, 70, 71, 94)

(B) Keywords classification

Based on the keywords in Appendix 1, we classify these keywords into two groups: (i) finance and accounting topics and (ii) methodology topics. The number behind each keyword is the chapter it is associated with.

(i) Finance and Accounting Topics

Abnormal earnings (87), Accounting earnings (87), Activity-based costing system (27), Agency costs (5, 97), Aggregation bias (43), Analyst experience (2), Analyst forecast accuracy (63), Analysts' forecast accuracy (97), Analysts' forecast bias (63, 97), Arbitrage pricing theory (APT) (6, 7, 36, 81), Asset (93), Asset allocation (45), Asset allocation fund (88), Asset pricing (34, 81), Asset return predictability (76), Asset returns (52), Asset-pricing returns (96), Asymmetric information (5), Asymmetric mean reversion (15), Asymmetric stochastic volatility (62), Asymmetric volatility response (15), Balanced scorecard (29), Bank capital (13), Bank holding companies (13), Bank risks (13), Bank stock return (6), Banks (12), Barrier option (65), Basket credit derivatives (23), Behavioral finance (55, 66, 73), Bias (57), Bias reduction (92), Bid-ask spreads (96, 99), Binomial option pricing model (37), Black-Scholes model (7, 90), Black-Sholes option pricing model (37), Board structure (42), Bond ratings (89), Bottom-up capital budgeting (75), Bounded complexity (85), Bounds (71), Brier score (72), Brokerage reputation (63), Business cycle (67), Business models (75), Business performance evaluation (29), Business value of firm, Buy-and-hold return (50), Calendar-time (50), Calendar-time portfolio approach (14), Call option (37), Capital asset-pricing model (CAPM) (6, 25, 28, 36, 81, 93), Capital budgeting (75, 29), Capital markets (25), Capital structure (5, 60), Carry trade (69), Case-Shiller home price indices (19), CEO compensation (97), CEO stock options (97), Change of measure (30), Cheapest-to-deliver bond (71), Chicago board of trade, (71), Cholesky decomposition (23), Closed-end Funds (25), Comparative financial systems (12), Composite trapezoid rule (51), Comprehensive earnings (87), Compromised solution (89), Compustat database (38), Compound sum method (46), Conditioning information (35), Constant/dynamic hedging (44), Contagious effect (11), Corner portfolio (45), Corporate earnings (9), Corporate finance (5), Corporate merger (21), Corporate ownership structure (42), Corporate policies (38), Corporation regulation (9), Correlated defaults (11), Cost of capital (93), Country funds (25), Credit rating (21), Credit rating (27), Credit risk (27, 65, 91), Credit risk index (27), Credit risk rating (16), Credit VaR (91), Creditworthiness (16), Cumulative abnormal return (50), Cumulative probability distribution (45), Currency market (58), Cyberinfrastructure (49), Daily realized volatility (40), Daily stock price (82), Debt maturity (64), Delivery options (71), Delta (45), Demand (33), Demonstration effect (17), Deterioration of bank asset quality (64), Determinants of capital structure (60), Discount cash flow model (46), Discretionary accruals (61), Discriminant power (89), Disposition effect (22), Dividends (38, 65, 79), Domestic investment companies (17), Double exponential smoothing (88), Duality (83), Dynamics (67), Earning management (61), Earnings change (10), Earnings level (10), Earnings quality (42), Earnings surprises (81), Economies of scale (21), Ederington hedging effectiveness (70), Effort allocation (97), Effort aversion (55), EGB2 distribution (80), Electricity (33), Empirical Bayes (85), Empirical corporate finance (95), Employee stock option (30), Endogeneity (38, 95), Endogeneity of variables (13), Endogenous supply (93), Equity valuation models (87), Equity value (75), European option (7), European put (5), Evaluation (34), Evaluation of funds (3), Exactly identified (93), Exceedance correlation (52), Exchange rate (43, 59), Executive compensation schemes (55), Exercise boundary (30), Expected market risk premium (15), Expected stock return (80), Expected utility (83), Experimental control (4), Experimental economics (4), Extreme events (67), Fallen angel (72), Finance panel data (24), Financial analysts (2), Financial crisis (64), Financial institutions (12), Financial leverage (75), Financial markets (12), Financial modeling (3), Financial planning and forecasting (87), Financial ratios (21), Financial returns (62), Financial service (49), Financial simulation (49), Financial statement analysis (87), Financial strength (16), Firm and time effects (24), Firm Size (9), Firm's performance score (21), Fixed operating cost (75), Flexibility hypothesis (79), Foreign exchange market (40), Foreign investment (17), Fourier inversion (84), Fourier transform (19), Free cash flow hypothesis (79), Frequentist segmentation (85), Fund management (53), Fundamental analysis (87), Fundamental asset values (73), Fundamental transform (84), Futures hedging (70), Gamma (45), Generalized (35), Generalized autoregressive conditional heteroskedasticity (51), Global investments (3), Gold (58), Green function (84), Grid and cloud computing (49), Gross return on investment (GRI) (75), Group decision making (29), Growth option (75), Growth rate (46), Hawkes process (11), Heavy-tailed data (20), Hedge ratios (98), Hedging (98), Hedging effectiveness (94), Hedging performance (98), Herding (66), Herding towards book-to-market factor (66), Herding towards momentum factor (66), Herding towards size factor (66), Herding towards the market (66), High end computing (49), High-dimensional data (77), Higher moments (80), High-frequency data (40), High-order moments (57),

Price on earnings model (10), Pricing (78), Pricing performance (98), Probability of informed trading (PIN) (96), Property (78), Property rights (12), Put option (37), Put-call parity (37), Quadratic cost (93), Quality options (71), Random number generation (49), Range (74), Rank dependent utility (83), Rating migration (72), Rational bias (2), Rational expectations (43), Real estate (78), Real sphere (59), Realized volatility (74), Recurrent event (72), Recursive (85), Reflection principle (65), Regime-switching hedging strategy (70), Registered trading firms (17), Relative value of equity (75), Research and development expense (61), Restrictions (59), Retention option (75), Return attribution (75), Return models (10), Reverse-engineering (16), Risk (83), Risk adjusted performance (3), Risk aversion (55), Risk management (41, 49, 67, 74, 80), Risk measurement (26), Risk premium (80), Risk-neutral pricing (32), Robust estimation (41), S&P 500 index (7), Sarbanes-Oxley act (63), SCAD penalty (77), Scale-by-scale decomposition (19), Seasonality (33), Semi-log (78), Sentiment (30), Shape parameter (82), Share prices (59), Share repurchases (38), Sharpe ratios (35, 53), Short run (59), Short selling (26), Short-term financing (64), Signaling hypothesis (79), Sigma (37), Smile shapes (32), Smooth transition (74), Special items (61), Speculative bubbles (73), Spot price (33), Stationarity (10), Statistical learning (77), Stochastic discount factors (25, 35), Stochastic interest rates (98), Stochastic order (83), Stochastic volatility (44, 84, 85, 92, 98), Stock market overreaction (15), Stock markets (67), Stock option (65), Stock option pricing (98), Stock price indexes (62), Stock/futures (44), Strike price (55), Structural break (31), Subjective value (30), Substantial price fluctuations (82), Sustainable growth rate, synergy (21), Synthetic utility value (68), Systematic risk (3, 79), TAIEX (45), Tail risk (67), Timberland investments (34), Time-varying risk (25), Time-varying risk aversion (40), Time-varying volatility (15), Timing options (71), Tobin's model (99), Top-down capital budgeting (75), Total risk (79), Tournament (73), Trade direction (96), Trade turnover industry (9), Transaction costs (99), Transfer pricing (29), Treasury bond futures (71), Trend extraction (18), Trust (12), Turkish economy (59), U.S. stocks (52), Ultrahigh-dimensional data (77), Unbiasedness (43), Uncertainty avoidance (12), Uncovered interest parity (69), Unexpected volatility shocks (15), Unsystematic risk (3), Utility-based hedging strategy (70), VaR-efficient frontier (45), Variability percentage adjustment (21), Visual Basic for applications (37), Volatility index (VIX) (92), Volatility (37, 80), Volatility co-persistence (44), Volatility daily effect (92), Volatility dependencies (62), Volatility feedback effect (15), Weak efficiency (43), Weak instruments (95), Wealth transfer (75), Write-downs (61), Yaari's dual utility (83), Yield curve (39), Zero-investment portfolio (50).

(ii) Methodology Topics

A mixture of Poisson distribution (98), Analyst estimation (ANOVA) (2, 28), Analytic hierarchy process (29), Analysis of variance (19), Anderson-Darling statistic (20), Anderson-Rubin statistic (95), ANST-GARCH model (asymmetric nonlinear smooth transition- GARCH model) (15), Approximately normal distribution (28), ARCH (41, 44), ARCH models (32), ARX-GARCH (autoregressive (AR) mean process with exogenous (X) variables- GARCH model) (85), Asset-pricing tests (35), Asset-pricing regression (24) Asymmetric dependence (52), Asymptotic distribution (44), Autocovariance (99), Autoregression (62), Autoregressive conditional jump intensity (82), Autoregressive model (88), Autoregressive moving average with exogenous variables (10), Autoregressive parameters (44), Bankruptcy prediction (27), Bayesian updating (2), Binomial distribution (28), Block bootstrap (56), Block granger causality (17), Bootstrap (8, 50), Bootstrap test (14), Bootstrapped critical values (24), Boundary function (31), Box-Cox (78), Bubble test (31), Change-point models (85), Clayton copula (8, 11), Cluster standard errors (24), Custering effect (79), Co-integration (76), Co-integration breakdown test (31), Combination of forecasts (88), Combinatorial optimization (16), Combined forecasting (87), Combining forecast (27), Complex logarithm (84), Conditional distribution (56), Conditional market model (50), Conditional skewness (80), Conditional value-at-risk (26, 83), Conditional variance (70), Conditional variance estimates (44), Contemporaneous jumps (85), Contingency tables (28), Contingent claim model (75), Continuous wavelet transform (19), Cook's distance (63), Copula (8, 41, 67, 74, 91), Correction method (92), Correlation (67, 73), Correlation analysis (99), CoVar (54), Covariance decomposition (72), Cox-Ingersoll-Ross (CIR) model (22, 71), Cross-sectional and time-series dependence (42), CUSUM squared test (31), Data-mining (16), Decision trees (37), Default correlation (23, 91), Dickey-Fuller test (10), Dimension reduction (77), Discrete wavelet transform (19), Discriminant analysis (89), Distribution of underlying asset (7), Double clustering (24), Downside risk model (26), Dynamic conditional correlation (52, 58, 74), Dynamic factor model (11), Dynamic random-effects models (38), Econometric methodology (38), Econometric modeling (33), Econometrics (12), Error component two-stage least squares (EC2SLS) (12), Error in variable problem (60, 96), Estimated cross-sectional standard deviations of betas (66), Event study methodology (5, 50), Ex ante probability (82), Excess kurtosis (44), Exogeneity test (95), Expectation–maximization (EM) algorithm (96), Expected return distribution (45), Explanatory power (89), Exponential trend model (88), Extended Kalman filtering (86), Factor analysis (68, 89), Factor copula (23, 91), Factor model (39, 50), Fama-French three-factor model (14), Feltham and Ohlson model (87), Filtering methods (19), Fixed effects (57, 63, 79), Forecast accuracy (2, 9), Forecast bias (2), Forecasting complexity (97), Forecasting models (27), Fourier transform method (92), Frank copula (11), GARCH (8, 40, 41, 96), GARCH hedging strategy (70), GARCH models (48, 52), GARCH-in-mean (40), GARCH-jump model (82), GARJI model (82), Gaussian copula (8), Generalized correlations (77), Generalized hyperbolic distribution (94), 1.7 Summary and Conclusion Remarks

This chapter has discussed important financial econometrics and statistics which have been used in finance and accounting research. In addition, this chapter has presented an overview of 98 chapters which have been included in this handbook. In Sect. 1.2 "Financial Econometrics," we have six subsections which are: a single equation regression methods, Simultaneous equation models, Panel data analysis, Alternative methods to deal with measurement error, Time-series analysis, and

Spectral Analysis. Section 1.3 "Financial Statistics" has four subsections: Important Statistical Distributions, Principle components and factor analysis, Nonparametric and Semi-parametric analyses, Cluster analysis review and discuss financial econometrics and statistics. In Sect. 1.4 "Applications of financial econometrics," we briefly discuss how different methodologies of financial econometrics will be applied to the topics of finance and accounting. These methods include: Asset-pricing Research, Corporate Finance Research, Financial Institution Research, Investment and Portfolio Research, Option Pricing Research, Future and Hedging Research, Mutual Fund Research, and Credit Risk Modeling. Section 1.5, "Applications of Financial Statistics," states that financial statistics is an important tool to conduct research in the areas of (1) Asset-pricing Research, (2) Investment and Portfolio Research, (3) Credit Risk Management Research, (4) Market Risk Research, (5) Operational Risk Research, (6) Option Pricing Research, (7) Mutual Fund Research, (8) Hedge Fund Research, (9) Value-at-risk Research, and (10) Auditing. Section 1.6 is an "Overall Discussion of Papers in this Handbook." It classifies 98 chapters into 14 groups in accordance to Chapter title and keywords.

Appendix 1: Brief Abstracts and Keywords for Chapters 2 to 99

Chapter 2: Experience, Information Asymmetry, and Rational Forecast Bias

This chapter uses a Bayesian model of updating forecasts in which the bias in forecast endogenously determines how the forecaster's own estimates weigh into the posterior beliefs. The model used in this chapter predicts a concave relationship between accuracy in forecast and posterior weight that is put on the forecaster's self-assessment. This chapter then uses a panel regression to test the analytical findings and find that an analyst's experience is indeed concavely related to the forecast error.

Keywords: Financial analysts, Forecast accuracy, Information asymmetry, Forecast bias, Bayesian updating, Panel regressions, Rational bias, Optional bias, Analyst estimation, Analyst experience

Chapter 3: An Overview of Modeling Dimensions for Performance Appraisal of Global Mutual Funds (Mutual Funds)

This paper examines various performance models derived by financial experts across the globe. A number of studies have been conducted to examine investment performance of mutual funds of the developed capital markets. The measure of performance of financial instruments is basically dependent on three important models derived independently by Sharpe, Jensen, and Treynor. All three models are based on the assumptions that (1) all investors are averse to risk, and are single period expected utility of terminal wealth maximizers, (2) all investors have identical decision horizons and homogeneous expectations regarding investment opportunities, (3) all investors are able to choose among portfolios solely on the basis of expected returns and variance of returns, (4) all trans-actions costs and taxes are zero, and (5) all assets are infinitely divisible. Overall, this paper has examined nine alternative mutual funds measure. The method used in this kind of research is regression analysis.

Keywords: Financial modeling, Mutual funds, Performance appraisal, Global investments, Evaluation of funds, Portfolio management, Systematic risk, Unsystematic risk, Risk adjusted performance, Prediction of price movements

Chapter 4: Simulation as a Research Tool for Market Architects

This chapter uses simulation to gain insights into trading and market structure topic by two statistical methods. The statistical methods we use include experimental design, and careful controls over experimental parameters such as the instructions given to participants. The first is discrete event simulation and the model of computer-generated trade order flow that we describe in Sect. 3. To create a realistic, but not ad hoc, market background, we use draws from a log-normal returns distribution to simulate changes in a stock's fundamental value, or P*. The model uses price-dependent Poisson distributions to generate a realistic flow of computer-generated buy and sell orders whose intensity and supply-demand balance vary over time. The order flow fluctuations depend on the difference between the current market price and the P* value. In Sect. 4, we illustrate the second method, which is experimental control to create groupings of participants in our simulations that have the same trading "assignment." The result is the ability to make valid comparisons of trader's performance in the simulations.

Keywords: Trading simulations, Market microstructure, Order flow models, Random walk models, Experimental economics, Experimental control

Chapter 5: Motivations for Issuing Putable Debt: An Empirical Analysis

This paper is the first to examine the motivations for issuing putable bonds in which the embedded put option is not contingent upon a company-related event. We find that the market favorably views the issue announcement of these bonds that we refer to as bonds with European put options or European putable bonds. This response is in contrast to the response documented by the literature to other bond issues (straight, convertible, and most studies examining poison puts), and to the response documented in the current paper to the issue announcements of poison-put bonds. Our results suggest that the market views issuing European putable bonds as helping mitigate security mispricing. Our study is an application of important statistical methods in corporate finance, namely, Event Studies and the use of General Method of Moments for cross-sectional regressions.

Keywords: Agency costs, Asymmetric information, Corporate finance, Capital structure, Event study methodology, European put, General method of moments, Management myopia, Management entrenchment, Poison put

Chapter 6: Multi Risk-Premia Model of U.S. Bank Returns: An Integration of CAPM and APT

Interest rate sensitivity of bank stock returns has been studied using an augmented CAPM: a multiple regression model with market returns and interest rate as independent variables. In this chapter, we test an asset-pricing model in which the CAPM is augmented by three orthogonal factors which are proxies for the innovations in inflation, maturity risk, and default risk. The methodologies used in this chapter are multiple regression and factor analysis.

Keywords: CAPM, APT, Bank stock return, Interest rate risk, Orthogonal factors, Multiple regression

Chapter 7: Non-parametric Bounds for European Option Prices

This chapter derives a new nonparametric lower bound and provides an alternative interpretation of Ritchken's (1985) upper bound to the price of the European option. In a series of numerical examples, our new lower bound is substantially tighter than previous lower bounds. This is prevalent especially for out-of-the-money (OTM) options where the previous lower bounds perform badly. Moreover, we present that our bounds can be derived from histograms which are completely nonparametric in an empirical study. We first construct histograms from realizations of S&P 500 index returns following Chen et al. (2006), calculate the dollar beta of the option and expected payoffs of the index and the option, and eventually obtain our bounds. We discover violations in our lower bound and show that those violations present arbitrage profits. In particular, our empirical results show that out-of-the-money calls are substantially overpriced (violate the lower bound). The methodologies used in this chapter are nonparametric, option pricing model, and histograms methods.

Keywords: Option bounds, Nonparametric, Black-Scholes model, European option, S&P 500 index, Arbitrage, Distribution of underlying asset, Lower bound, Out-of-the-money, Kernel pricing

Chapter 8: Can Time-Varying Copulas Improve Mean-Variance Portfolio?

This chapter evaluates whether constructing a portfolio using time-varying copulas yields superior returns under various weight updating strategies. Specifically, minimum-risk portfolios are constructed based on various copulas and the Pearson correlation, and a 250-day rolling window technique is adopted to derive a sequence of time-varied dependences for each dependence model. Using daily data of the G-7 countries, our empirical findings suggest that portfolios using time-varying copulas, particularly the Clayton-dependence, outperform those constructed using Pearson correlations. The above results still hold under different weight updating strategies and portfolio rebalancing frequencies. The methodologies used in this chapter are Copulas, GARCH, Student's *t*-Copula, Gumbel Copula, Clayton Copula, Time-Varying Dependence, Portfolio Optimization, and Bootstrap.

Keywords: Copulas, Time-varying dependence, Portfolio optimization, Bootstrap, Out-of-sample return, Performance evaluation, GARCH, Gaussian copula, Student's *t*-copula, Gumbel copula, Clayton copula

Chapter 9: Determinations of Corporate Earnings Forecast Accuracy: Taiwan Market Experience

This chapter examines the accuracy of the earnings forecasts by the following test methodologies. Multiple Regression Models are used to examine the effect of six factors: firm size, market volatility, trading volume turnover, corporate earnings variances, type of industry, and experience. If the two-sample groups are related, Wilcoxon Two-Sample Test will be used to determine the relative earnings forecast accuracy. Readers are well advised and referred to the chapter appendix for methodological issues such as sample selection, variable definition, regression model, and Wilcoxon tow-sample test.

Keywords: Multiple regression, Wilcoxon two-sample test, Corporate earnings, Forecast accuracy, Management earnings, Firm size, Corporation regulation, Volatility, Trade turnover, Industry

Chapter 10: Market-Based Accounting Research (MBAR) Models: A Test of ARIMAX Modeling

This study uses standard models such as earnings level and earnings changes, among others. Models that fit better to the data drawn from companies listed on the Athens Stock Exchange have been selected employing autoregressive integrated moving average with exogenous variables (ARIMAX) models. Models I (price on earnings model) "II (returns on change in earnings divided by beginning-of-period price and prior period)" V (returns on change in earnings over opening market value), VII (returns deflated by lag of 2 years on earnings over opening market value), and IX (differenced-price model) have statistically significant coefficients of explanatory variables. These models take place with backward looking information instead of forward looking information that recent literature is assessed. The methodologies used in this chapter are price on earnings model, return models, autoregressive moving average with exogenous variables (ARIMAX), minimum value of squared residuals (MSE loss function), and Dickey-Fuller test.

Keywords: Market-based accounting research (MBAR), Price on earnings model, Earnings level, Earnings change, Return models, Autoregressive moving average with exogenous variables (ARIMAX), Minimum value of squared residuals (MSE loss function), Unit root tests stationarity, Dickey-Fuller test

Chapter 11: An Assessment of Copula Functions Approach in Conjunction with Factor Model in Portfolio Credit Risk Management

This study uses a mixture of the dynamic factor model of Duffee (1999) and a contagious effect in the specification of a Hawkes process, a class of counting processes which allows intensities to depend on the timing of previous events (Hawkes 1971). Using the mixture factor- contagious-effect model, Monte Carlo simulation is performed to generate default times of two hypothesized firms. The goodness-of-fit of the joint distributions based on the most often used copula functions in literature, including the Normal, t-, Clayton, Frank, and Gumbel copula, respectively, is assessed against the simulated default times. It is demonstrated that as the contagious effect increases, the goodness-of-fit of the joint distribution functions based on copula functions decreases, which highlights the deficiency of the copula function approach.

Keywords: Static factor model, Dynamic factor model, Correlated defaults, Contagious effect, Hawkes process, Monte Carlo simulation, Normal copula, *t*-copula, Clayton copula, Frank copula, Gumbel copula

Chapter 12: Assessing Importance of Time-Series Versus Cross-Sectional Changes in Panel Data: A Study of International Variations in Ex-Ante Equity Premia and Financial Architecture

This chapter uses simultaneous equation modeling and uses Hausman test to determine whether to report fixed or random-effects estimates. We first report random-effects estimates based on the estimation procedure of Baltagi (Baltagi 1981; Baltagi and Li 1995; Baltagi and Li 1994). We consider that the error component two-stage least squares (EC2SLS) estimator of Baltagi and Li (1995) is more efficient than the generalized two-stage least squares (G2SLS) estimator of Balestra and Varadharajan-Krishnakumar (1987). For our second estimation procedure, for comparative purposes, we use the dynamic panel modeling estimates recommended by Blundell and Bond (1998). We employ the model of Blundell and Bond (1998), as these authors argue that their estimator is more appropriate than the Arellano and Bond (1991) model for smaller time periods relative to the size of the panels. We also use this two-step procedure, use as an independent variable the first lag of the dependent variable, reporting robust standard errors of Windmeijer (2005). Thus, our two different panel estimation techniques place differing emphasis on cross-sectional and time-series effects, with the Baltagi-Li estimator emphasizing cross-sectional effects and the Blundell-Bond estimator emphasizing time-series effects.

Keywords: Panel data estimates, Time-series and cross-sectional effects, Econometrics, Financial institutions, Banks, Financial markets, Comparative financial systems, Legal traditions, Uncertainty avoidance, Trust, Property rights, Error component two-stage least squares (EC2SLS), The generalized two-stage least squares (G2SLS)

Chapter 13: Does Banking Capital Reduce Risk?: An Application of Stochastic Frontier Analysis and GMM Approach

This chapter employs stochastic frontier analysis to create a new type of instrumental variable. The unrestricted frontier model determines the highest possible profitability based solely on the book value of assets employed. We develop a second frontier based on the level of bank holding company capital as well as the amount of assets. The implication of using the unrestricted model is that we are measuring the unconditional inefficiency of the banking organization. This chapter applies generalized method of moments (GMM) regression to avoid the problem caused by departure from normality. To control for the impact of size on a bank's risk-taking behavior, the book value of assets is considered in the model. The relationship between the variables specifying bank behavior and the use of equity is analyzed by GMM regression.

Keywords: Bank capital, Generalized method of moments, Stochastic frontier analysis, Bank risks, Bank holding companies, Endogeneity of variables

Chapter 14: Evaluating Long-Horizon Event Study Methodology

This chapter examines the performance of more than 20 different testing procedures that fall into two categories. First, the buy-and-hold benchmark approach uses a benchmark to measure the abnormal buy-and-hold return for every event firm, and tests the null hypothesis that the average abnormal return is zero. Second, the calendar-time portfolio approach forms a portfolio in each calendar month consisting of firms that have had an event within a certain time period prior to the month, and tests the null hypothesis that the intercept is zero in the regression of monthly portfolio returns against the factors in an asset-pricing model. This chapter also evaluates the performance of bootstrapped Johnson's skewness-adjusted t-test. This computation-intensive procedure is considered because the distribution of long-horizon abnormal returns tends to be highly skewed to the right. The bootstrapping method uses repeated random sampling to measure the significance of relevant test statistics. Due to the nature of random sampling, the resultant measurement of significance varies each time such a procedure is used. We also evaluate simple nonparametric tests, such as the Wilcoxon signed-rank test or the Fisher's sign test, which are free from random sampling variation.

Keywords: Long-horizon event study, Johnson's Skewness-adjusted *t*-test, Weighted least-squares regression, Bootstrap test, Calendar-time portfolio approach, Fama-French three-factor model, Johnson's skewness-adjusted t-statistic, Large-scale simulations

Chapter 15: Effect of Unexpected Volatility Shocks on Intertemporal Risk-Return Relation

This chapter employs the ANST-GARCH model that is capable of capturing the asymmetric volatility effect of a positive and negative return shock. The key feature of the model is the regime-shift mechanism that allows a smooth, flexible transition of the conditional volatility between different states of volatility persistence. The regime-switching mechanism is governed by a logistic transition function that changes values depending on the level of the previous return shock. With a negative (positive) return shock, the conditional variance process is described as a high (low)-persistence-in-volatility regime. The ANST-GARCH model describes the heteroskedastic return dynamics more accurately and generates better volatility forecasts.

Keywords: Intertemporal risk-return relation, Unexpected volatility shocks, Time-varying rational expectation hypothesis, Stock market overreaction, Expected market risk premium, Volatility feedback effect, Asymmetric mean reversion, Asymmetric volatility response, Time-varying volatility, Volatility regime switching, ANST-GARCH model

Chapter 16: Combinatorial Methods for Constructing Credit Risk Ratings

This chapter uses a novel method, the Logical Analysis of Data (LAD), to reverse-engineer and construct credit risk ratings which represent the creditworthiness of financial institutions and countries. LAD is a data-mining method based on combinatorics, optimization, and Boolean logic that utilizes combinatorial search techniques to discover various combinations of attribute values that are characteristic of the positive or negative character of observations. The proposed methodology is applicable in the general case of inferring an objective rating system from archival data, given that the rated objects are characterized by vectors of attributes taking numerical or ordinal values. The proposed approaches are shown to generate transparent, consistent, self-contained, and predictive credit risk rating models, closely approximating the risk ratings provided by some of the major rating agencies. The scope of applicability of the proposed method extends beyond the rating problems discussed in this study, and can be used in many other contexts where ratings are relevant. This study also uses multiple linear regression to derive the logical rating scores.

Keywords: Credit risk rating, Reverse-engineering, Logical analysis of data, Combinatorial optimization, Data-mining, Creditworthiness, Financial strength, Internal rating, Preorder, Logical rating score

Chapter 17: Dynamic Interactions in the Taiwan Stock Exchange: A Threshold VAR Models

This chapter constructs a six-variable VAR model (including NASDAQ returns, TSE returns, NT/USD returns, net foreign purchases, net domestic investment companies (dic) purchases, and net registered trading firms (rtf) purchases) to examine: (i) the interaction among three types of institutional investors, particularly to test whether net foreign purchases lead net domestic purchases by dic and rtf (the so-called demonstration effect); (ii) whether net institutional purchases lead market returns or vice versa, and (iii) whether the corresponding lead-lag relationship is positive or negative? Readers are well advised to refer to chapter appendix for detailed discussion of the unrestricted VAR model, the structural VAR model, and the threshold VAR analysis. The methodologies used in this chapter are multivariate threshold autoregression model, structural VAR, and Block Granger Causality.

Keywords: Demonstration effect, Multivariate threshold autoregression model, Foreign investment, Lead-lag relationship, Structural VAR, Block Granger causality, Institutional investors, Domestic investment companies, Registered trading firms, Qualified foreign institutional investors

Chapter 18: Methods of Denoising Financial Data

This chapter uses denoising analysis which imposes new challenges for financial data mining due to the irregularities and roughness observed in financial data, particularly, for instantaneously collected massive amounts of tick-by-tick data from financial markets for information analysis and knowledge extraction. Inefficient decomposition of the systematic pattern (the trend) and noises of financial data will lead to erroneous conclusions since irregularities and roughness of the financial data make the application of traditional methods difficult. The methodologies used in this chapter are linear filters, nonlinear filters, time-series analysis, trend extraction, and wavelet.

Keywords: Jump detection, Linear filters, Nonlinear filters, Time-series analysis, Trend extraction, Wavelet

Chapter 19: Analysis of Financial Time: Series Using Wavelet Methods

This chapter presents a set of tools, which allow gathering information about the frequency components of a time-series. In the first step, we discuss spectral analysis and filtering methods. Spectral analysis can be used to identify and to quantify the different frequency components of a data series. Filters permit to capture specific components (e.g. trends, cycles, seasonalities) of the original time-series. In the second step, we introduce wavelets, which are relatively new tools in economics and finance. They take their roots from filtering methods and Fourier analysis, but overcome most of the limitations of these two methods. Their principal advantages derive from: (i) combined information from both time-domain and frequency-domain and (ii) their flexibility as they do not make strong assumptions concerning the data generating process for the series under investigation.

Keywords: Filtering methods, Spectral analysis, Fourier transform, Wavelet filter, Continuous wavelet transform, Discrete wavelet transform, Multi-resolution analysis, Scale-by-scale decomposition, Analysis of variance, Case-Shiller home price indices

Chapter 20: Composite Goodness-of-Fit Tests for Left Truncated Loss Sample

This chapter derives the exact formulae for several goodness-of-fit statistics that should be applied to loss models with left-truncated data where the fit of a distribution in the right tail of the distribution is of central importance. We apply the proposed tests to real financial losses, using a variety of distributions fitted to operational loss and the natural catastrophe insurance claims data. The methodologies discussed in this chapter are goodness-of-fit tests, loss distribution, ruin probability, value-at-risk, Anderson-Darling statistic, Kolmogorov-Smirnov statistic.

Keywords: Goodness-of-fit tests, Left-truncated data, Minimum recording threshold, Loss distribution, Heavy-tailed data, Operational risk, Insurance, Ruin probability, Value-at-risk, Anderson-Darling statistic, Kolmogorov-Smirnov statistic

Chapter 21: Effect of Merger on the Credit Rating and Performance of Taiwan Security Firms

This chapter identifies and defines variables for merger synergy analysis followed by principal component factor analysis, variability percentage adjustment, and performance score calculation. Finally, Wilcoxon sign rank test is used for hypothesis testing. We extract principle component factors from a set of financial ratios. Percentage of variability explained and factor loadings are adjusted to get a modified average weight for each financial ratio. This weight is multiplied by the standardized Z value of the variable, and summed a set of variables get a firm's performance score. Performance scores are used to rank the firm. Statistical significance of difference in pre- and post-merger rank is tested using the Wilcoxon sign rank.

Keywords: Corporate merger, Financial ratios, Synergy, Economies of scale, Credit rating, Variability percentage adjustment, Principle component factors, Firm's performance score, Standardized Z, Wilcoxon rank test

Chapter 22: On-/Off-the-Run Yield Spread Puzzle: Evidence from Chinese Treasury Markets

This chapter uses on-/off-the-run yield spread to describe "on-/off-the-run yield spread puzzle" in Chinese treasury markets. To explain this puzzle, we introduce a latent factor in the pricing of Chinese off-the-run government bonds and use this factor to model the yield difference between Chinese on-the-run and off-the-run issues. We use the nonlinear Kalman filter approach to estimate the model. The methodologies used in this chapter are CIR model, nonlinear Kalman filter and Quasi-maximum likelihood model.

Keywords: On-/off-the-run yield spread, Liquidity, Disposition effect, CIR model, Nonlinear Kalman filter, Quasi-maximum likelihood

Chapter 23: Factor Copula for Defaultable Basket Credit Derivatives

This chapter uses a factor copula approach to evaluate basket credit derivatives with issuer default risk and demonstrate its application in a basket credit linked note (BCLN). We generate the correlated Gaussian random numbers by using the Cholesky decomposition, and then, the correlated default times can be decided by these random numbers and the reduced-form model. Finally, the fair BCLN coupon rate is obtained by the Monte Carlo simulation. We also discuss the effect of issuer default risk on BCLN. We show that the effect of issuer default risk cannot be accounted for thoroughly by considering the issuer as a new reference entity in the widely used one factor copula model, in which constant default correlation is often assumed. A different default correlation between the issuer and the reference entities affects the coupon rate greatly and must be taken into account in the pricing model.

Keywords: Factor copula, Issuer default, Default correlation, Reduced-form model, Basket credit derivatives, Cholesky decomposition, Monte Carlo simulation

Chapter 24: Panel Data Analysis and Bootstrapping: Application to China Mutual Funds

This chapter estimates double- and single-clustered standard errors by wild-cluster bootstrap procedure. To obtain the wild bootstrap samples in each cluster, we reuse the regressors (X), but modify the residuals by transforming the OLS residuals with weights which follow the popular two-point distribution suggested by Mammen (1993) and others. We then compare them with other estimates in a set of asset-pricing regressions. The comparison indicates that bootstrapped standard errors from double clustering outperform those from single clustering. They also suggest that bootstrapped critical values are preferred to standard asymptotic *t*-test critical values to avoid misleading test results.

Keywords: Asset-pricing regression, Bootstrapped critical values, Cluster standard errors, Double clustering, Firm and time effects, Finance panel data, Single clustering, Wild-cluster bootstrap

Chapter 25: Market Segmentation and Pricing of Closed-End Country Funds: An Empirical Analysis

This chapter finds that for closed-end country funds, the international CAPM can be rejected for the underlying securities (NAVs) but not for the share prices. This finding indicates that country fund share prices are determined globally, whereas the NAVs reflect both global and local prices of risk. Cross-sectional variations in the discounts or premiums for country funds are explained by the differences in the risk exposures of the share prices and the NAVs. Finally, this chapter shows that the share price and NAV returns exhibit predictable variation, and country fund premiums vary over time due to time-varying risk premiums. The chapter employs Generalized Method of Moments (GMM) to estimate stochastic discount factors and examines if the price of risk of closed-end country fund shares and NAVs is identical.

Keywords: Capital markets, Country funds, CAPM, Closed-end funds, Market segmentation, GMM, Net asset value, Stochastic discount factors, Time-varying risk, International asset pricing

Chapter 26: A Comparison of Portfolios Using Different Risk Measurements

This study uses three different risk measurements: the Mean-variance model, the Mean Absolute Deviation model, and the Downside Risk model. Meanwhile short selling is also taken into account since it is an important strategy that can bring a portfolio much closer to the efficient frontier by improving a portfolio's risk-return trade-off. Therefore, six portfolio rebalancing models, including the MV model, MAD model and the Downside Risk model, with/without short selling, are compared to determine which is the most efficient. All models simultaneously consider the criteria of return and risk measurement. Meanwhile, when short selling is allowed, models also consider minimizing the proportion of short selling. Therefore, multiple objective programming is employed to transform multiple objectives into a single objective in order to obtain a compromising solution. An example is used to perform simulation, and the results indicate that the MAD model, incorporated with a short selling model, has the highest market value and lowest risk.

Keywords: Portfolio selection, Risk measurement, Short selling, MV model, MAD model, Downside risk model, Multiple objective programming, Rebalancing model, Value-at-risk, Conditional value-at-risk

Chapter 27: Using Alternative Models and a Combining Technique in Credit Rating Forecasting: An Empirical Study

This chapter first utilizes the ordered logit and the ordered probit models. Then, we use ordered logit combining method to weight different techniques' probability measures, as described in Kamstra and Kennedy (1998) to form the combining model. The samples consist of firms in the TSE and the OTC market, and are divided into three industries for analysis. We consider financial variables, market variables as well as macroeconomic variables and estimate their parameters for out-of-sample tests. By means of Cumulative Accuracy Profile, the Receiver Operating Characteristics, and McFadden, we measure the goodness-of-fit and the accuracy of each prediction model. The performance evaluations are conducted to compare the forecasting results, and we find that combing technique does improve the predictive power.

Keywords: Bankruptcy prediction, Combining forecast, Credit rating, Credit risk, Credit risk index, Forecasting models, Logit regression, Ordered logit, Ordered probit, Probability density function

Chapter 28: Can We Use the CAPM as an Investment Strategy?: An Intuitive CAPM and Efficiency Test

The aim of this chapter is to check whether certain playing rules, based on the undervaluation concept arising from the CAPM, could be useful as investment strategies, and can therefore be used to beat the Market. If such strategies work, we will be provided with a useful tool for investors, and, otherwise, we will obtain a test whose results will be connected with the efficient Market hypothesis (EMH) and with the CAPM. The methodology used is both intuitive and rigorous: analyzing how many times we beat the Market with different strategies, in order to check whether when we beat the Market, this happens by chance.

Keywords: ANOVA, Approximately normal distribution, Binomial distribution, CAPM, Contingency tables, Market efficiency, Nonparametric tests, Performance measures

Chapter 29: Group Decision Making Tools for Managerial Accounting and Finance Applications

This chapter adopts an Analytic Hierarchy Process (AHP) approach to solve various accounting or finance problems such as developing a business performance evaluation system and developing a banking performance evaluation system. AHP uses hierarchical schema to incorporate nonfinancial and external performance measures. Our model has a broader set of measures that can examine external and nonfinancial performance as well as internal and financial performance. While AHP is one of the most popular multiple goals decision-making tools, Multiple Criteria and Multiple Constraint (MC^2) Linear Programming approach also can be used to solve group decision-making problems such as transfer pricing and capital budgeting problems. The methodologies used in this chapter are Analytic Hierarchy Process, multiple criteria and multiple constraint linear programming, and balanced scorecard and business performance evaluation.

Keywords: Analytic hierarchy process, Multiple criteria and multiple constraint linear programming, Business performance evaluation, Activity-based costing system, Group decision making, Optimal trade-offs, Balanced scorecard, Transfer pricing, Capital budgeting

Chapter 30: Statistics Methods Applied in Employee Stock Options

This study provides model-based and compensation-based approaches to price subjective value of employee stock options (ESOs). In model-based approach, we consider a utility-maximizing model that the employee allocates his wealth among the company stock, market portfolio, and risk-free bond, and then derive the ESO formulae which take into account illiquidity and sentiment effects. By using the method of change of measure, the derived formulae are simply like that of the market values with altered parameters. To calculate compensation-based subjective value, we group employees by hierarchical clustering with K-Means approach and back out the option value in an equilibrium competitive employment market. Further, we test illiquidity and sentiment effects on ESO values by running the regressions which consider the problem of standard errors in finance panel data.

Keywords: Employee stock option, Sentiment, Subjective value, Illiquidity, Change of measure, Hierarchical clustering with K-Means approach, Standard errors in finance panel data, Exercise boundary, Jump diffusion model

Chapter 31: Structural Change and Monitoring Tests

This chapter focuses on various structural change and monitoring tests for a class of widely used time-series models in economics and finance, including $I(0)$, $I(1)$, $I(d)$ processes and the co-integration relationship. In general, structural change tests can be categorized into two types: One is the classical approach to testing for structural change, which employs retrospective tests using a historical data set of a given length; the other one is the fluctuation-type test in a monitoring scheme, which means for given a history period for which a regression relationship is known to be stable, we then test whether incoming data are consistent with the previously established relationship. Several structural changes such as CUSUM squared tests, the QLR test, the prediction test, the multiple break test, bubble tests, co-integration breakdown tests, and the monitoring fluctuation test are discussed in this chapter, and we further illustrate all details and usefulness of these tests.

Keywords: Co-integration breakdown test, Structural break, Long memory process, Monitoring fluctuation test, Boundary function, CUSUM squared test, Prediction test, Bubble test, Unit root time series, Persistent change

Chapter 32: Consequences of Option Pricing of a Long Memory in Volatility

This chapter use conditionally heteroskedastic time-series models to describe the volatility of stock index returns. Volatility has a long memory property in the most general models and then the autocorrelations of volatility decay at a hyperbolic rate; contrasts are made with popular, short memory specifications whose autocorrelations decay more rapidly at a geometric rate. Options are valued for ARCH volatility models by calculating the discounted expectations of option payoffs for an appropriate risk-neutral measure. Monte Carlo methods provide the expectations. The speed and accuracy of the calculations is enhanced by two variance reduction methods, which use antithetic and control variables. The economic consequences of a long memory assumption about volatility are documented, by comparing implied volatilities for option prices obtained from short and long memory volatility processes.

Keywords: ARCH models, Implied volatility, Index options, Likelihood maximization, Long memory, Monte Carlo, Option prices, Risk-neutral pricing, Smile shapes, Term structure, Variance reduction methods

Chapter 33: Seasonal Aspects of Australian Electricity Market

This chapter develops econometric models for seasonal patterns in both price returns and proportional changes in demand for Australian electricity. Australian Electricity spot prices differ considerably from equity spot prices in that they contain an extremely rapid mean reversion process. The electricity spot price could increase to a market cap price of AU$12,500 per Megawatt Hour (MWh) and revert back to a mean level (AUD$30) within a half hour interval. This has implications for derivative pricing and risk management. We also model extreme spikes in the data. Our study identifies both seasonality effects and dramatic price reversals in the Australian electricity market. The pricing seasonality effects include time-of-day, day-of-week, monthly, and yearly effects. There is also evidence of seasonality in demand for electricity.

Keywords: Electricity, Spot price, Seasonality, Outlier, Demand, Econometric modeling

Chapter 34: Pricing Commercial Timberland Returns in the United States

This chapter uses both parametric and nonparametric approaches to evaluate private- and public-equity timberland investments in the United States. Private-equity timberland returns are proxied by the NCREIF Timberland Index, whereas public-equity timberland returns are proxied by the value-weighted returns on a dynamic portfolio of the US publicly traded forestry firms that had or have been managing timberlands. Static estimations of the capital asset-pricing model and Fama-French three-factor model are obtained by ordinary least squares, whereas dynamic estimations are obtained by state-space specifications with the Kalman filter. In estimating the stochastic discount factors, linear programming is used.

Keywords: Alternative asset class, Asset pricing, Evaluation, Fama-French three-factor model, Nonparametric analysis, State-space model, Stochastic discount factor, Timberland investments, Time series, Time-varying parameter

Chapter 35: Optimal Orthogonal Portfolios with Conditioning Information

This chapter derives and characterizes optimal orthogonal portfolios in the presence of conditioning information in the form of a set of lagged instruments. In this setting, studied by Hansen and Richard (1987), the conditioning information is used to optimize with respect to the unconditional moments. We present an empirical illustration of the properties of the optimal orthogonal portfolios. The methodology in this chapter includes regression and maximum likelihood parameter estimation, as well as method of moments estimation. We form maximum likelihood estimates of nonlinear functions as the functions evaluated at the maximum likelihood parameter estimates.

Keywords: Asset-pricing tests, Conditioning information, Minimum variance efficiency, Optimal portfolios, Predicting returns, Portfolio management, Stochastic discount factors, Generalized, Method of moments, Maximum likelihood, Parametric bootstrap, Sharpe ratios

Chapter 36: Multi-factor, Multi-indicator Approach to Asset Pricing: Method and Empirical Evidence

This chapter uses a multifactor, multi-indicator approach to test the capital asset-pricing model (CAPM) and the arbitrage pricing theory (APT). This approach is able to solve the measuring problem in the market portfolio in testing CAPM, and it is also able to directly test APT by linking the common factors to the macroeconomic indicators. We propose a MIMIC approach to test CAPM and APT. The beta estimated from the MIMIC model by allowing measurement error on the market portfolio does not significantly improve the OLS beta, while the MLE estimator does a better job than the OLS and GLS estimators in the cross-sectional regressions because the MLE estimator takes care of the measurement error in beta. Therefore, the measurement error problem on beta is more serious than that on the market portfolio.

Keywords: Capital asset-pricing model, CAPM, Arbitrage pricing theory, Multifactor multi-indicator approach, MIMIC, Measurement error, LISREL approach, Ordinary least square, OLS, General least square, GLS, Maximum likelihood estimation, MLE

Chapter 37: Binomial OPM, Black-Scholes OPM and Their Relationship: Decision Tree and Microsoft Excel Approach

This chapter will first demonstrate how Microsoft Excel can be use to create the Decision Trees for the Binomial Option Pricing Model. At the same time, this chapter will discuss the Binomial Option Pricing Model in a less mathematical fashion. All the mathematical calculations will be taken care by the Microsoft Excel program that is presented in this chapter. Finally, this chapter also uses the Decision Tree approach to demonstrate the relationship between the Binomial Option Pricing Model and the Black-Scholes Option Pricing Model.

Keywords: Binomial option pricing model, Decision trees, Black-Sholes option pricing model, Call option, Put option, Microsoft Excel, Visual Basic for applications, VBA, Put-call parity, Sigma, Volatility, Recursive programming

Chapter 38: Dividend Payments and Share Repurchases of U.S. Firms: An Econometric Approach

This chapter uses the econometric methodology to deal with the dynamic interrelationships between dividend payments and share repurchases and investigate endogeneity of certain explanatory variables. Identification of the model parameters is achieved in such models by exploiting the cross-equations restrictions on the coefficients in different time periods. Moreover, the estimation entails using nonlinear optimization methods to compute the maximum likelihood estimates of the dynamic random-effects models and for testing statistical hypotheses using likelihood ratio tests. This study also highlights the importance of developing comprehensive econometric models for these interrelationships. It is common in finance research to spell out "specific hypotheses" and conduct empirical research to investigate validity of the hypotheses.

Keywords: Compustat database, Corporate policies, Dividends, Dynamic random-effects models, Econometric methodology, Endogeneity, Maximum likelihood, Intangible assets, Model formulation, Nonlinear optimization, Panel data, Share repurchases

Chapter 39: Term Structure Modeling and Forecasting Using the Nelson-Siegel Model

In this chapter, we illustrate some recent developments in the yield curve modeling by introducing a latent factor model called the dynamic Nelson-Siegel model. This model not only provides good in-sample fit, but also produces superior out-of-sample performance. Beyond Treasury yield curve, the model can also be useful for other assets such as corporate bond and volatility. Moreover, the model also suggests generalized duration components corresponding to the level, slope, and curvature risk factors. The dynamic Nelson-Siegel model can be estimated via a one-step procedure, like the Kalman filter, which can also easily accommodate other variables of interests. Alternatively, we could estimate the model through a two-step process by fixing one parameter and estimating with ordinary least squares. The model is flexible and capable of replicating a variety of yield curve shapes: upward sloping, downward sloping, humped, and inverted humped. Forecasting the yield curve is achieved through forecasting the factors and we can impose either a univariate autoregressive structure or a vector autoregressive structure on the factors.

Keywords: Term structure, Yield curve, Factor model, Nelson-Siegel curve, State-space model

Chapter 40: The Intertemporal Relation Between Expected Return and Risk On Currency

The literature has so far focused on the risk-return trade-off in equity markets and ignored alternative risky assets. This chapter examines the presence and significance of an intertemporal relation between expected return and risk in the foreign exchange market. This chapter tests the existence and significance of a daily risk-return trade-off in the FX market based on the GARCH, realized, and range volatility estimators. Our empirical analysis relies on the maximum likelihood estimation of the GARCH-in-mean models, as described in Appendix A. We also use the seemingly unrelated (SUR) regressions and panel data estimation to investigate the significance of a time-series relation between expected return and risk on currency.

Keywords: GARCH, GARCH-in-mean, Seemingly unrelated regressions (SUR), Panel data estimation, Foreign exchange market, ICAPM, High-frequency data, Time-varying risk aversion, High-frequency data, Daily realized volatility

Chapter 41: Quantile Regression and Value-at-Risk

This chapter studies quantile regression (QR) estimation of Value-at-Risk (VaR). VaRs estimated by the QR method display some nice properties. In this chapter, different QR models in estimating VaRs are introduced. In particular, VaR estimation based on quantile regression of the QAR models, Copula models, ARCH models, GARCH models, and the CaViaR models is systematically introduced. Comparing the proposed QR method with traditional methods based on distributional assumptions, the QR method has the important property that it is robust to non-Gaussian distributions. Quantile estimation is only influenced by the local behavior of the conditional distribution of the response near the specified quantile. As a result, the estimates are not sensitive to outlier observations. Such a property is especially attractive in financial applications since many financial data like, say, portfolio returns (or log returns), are usually not normally distributed. To highlight the importance of the QR method in estimating VaR, we apply the QR techniques to estimate VaRs in International Equity Markets. Numerical evidence indicates that QR is a robust estimation method for VaR.

Keywords: ARCH, Copula, GARCH, Non-normality, QAR, Quantile regression, Risk management, Robust estimation, Time series, Value-at-risk

Chapter 42: Earnings Quality and Board Structure: Evidence from South East Asia

Using a sample of listed firms in Southeast Asia countries, this chapter examines the association among board structure and corporate ownership structure in affecting earnings quality. The econometric method employed is regressions of panel data. In a panel data setting, I address both cross-sectional and time-series dependence. Following Gow et al. (2010), I employ the two-way clustering method where the standard errors are clustered by both firm and year in my regressions of panel data.

Keywords: Earnings quality, Board structure, Corporate ownership structure, Panel data regressions, Cross-sectional and time-series dependence, Two-way clustering method of standard errors

Chapter 43: Rationality and Heterogeneity of Survey Forecasts of the Yen-Dollar Exchange Rate: A Reexamination

This chapter examines the rationality and diversity of industry-level forecasts of the yen-dollar exchange rate collected by the Japan Center for International Finance. We compare three specifications for testing rationality: the "conventional" bivariate regression, the univariate regression of a forecast error on a constant and other information set variables, and an error correction model (ECM). We extend the analysis of industry-level forecasts to a SUR-type structure using an innovative GMM technique (Bonham and Cohen 2001) that allows for forecaster cross-correlation due to the existence of common shocks and/or herd effects. Our GMM tests of micro-homogeneity uniformly reject the hypothesis that forecasters exhibit similar rationality characteristics.

Keywords: Rational expectations, Unbiasedness, Weak efficiency, Micro-homogeneity, Heterogeneity, Exchange rate, Survey forecasts, Aggregation bias, GMM, SUR

Chapter 44: Stochastic Volatility Structures and Intra-day Asset Price Dynamics

This chapter uses conditional volatility estimators as special cases of a general stochastic volatility structure. The theoretical asymptotic distribution of the measurement error process for these estimators is considered for particular features observed in intraday financial asset price processes. Specifically, I consider the effects of (i) induced serial correlation in returns processes, (ii) excess kurtosis in the underlying unconditional distribution of returns, (iii) market anomalies such as market opening and closing effects, and (iv) failure to account for intraday trading patterns. These issues are considered with applications in option pricing/trading strategies and the constant/dynamic hedging frameworks in mind. The methodologies used in this chapter are ARCH, maximum likelihood method, and unweighted GARCH.

Keywords: ARCH, Asymptotic distribution, Autoregressive parameters, Conditional variance estimates, Constant/dynamic hedging, Excess kurtosis, Index futures, Intraday returns, Market anomalies, Maximum likelihood estimates, Misspecification, Mis-specified returns, Persistence, Serial correlation, Stochastic volatility, Stock/futures, Unweighted GARCH, Volatility co-persistence

Chapter 45: Optimal Asset Allocation Under VaR Criterion: Taiwan Stock Market

This chapter examines the riskiness of the Taiwan stock market by determining the VaR from the expected return distribution generated by historical simulation. Value-at-risk (VaR) measures the worst expected loss over a given time horizon under normal market conditions at a specific level of confidence. VaR is determined by the left tail of the cumulative probability distribution of expected returns. Our result indicates the cumulative probability distribution has a fatter left tail, compared with the left tail of a normal distribution. This implies a riskier market. We also examined a two-sector asset allocation model subject to a target VaR constraint. The VaR-efficient frontier of the TAIEX traded stocks recommended, mostly, a corner portfolio.

Keywords: Value-at-risk, Asset allocation, Cumulative probability distribution, Normal distribution, VaR-efficient frontier, Historical simulation, Expected return distribution, Two-sector asset allocation model, Delta, gamma, Corner portfolio, TAIEX

Chapter 46: Alternative Methods for Estimating Firm's Growth Rate

The most common valuation model is the dividend growth model. The growth rate is found by taking the product of the retention rate and the return on equity. What is less well understood are the basic assumptions of this model. In this paper, we demonstrate that the model makes strong assumptions regarding the financing mix of the firm. In addition, we discuss several methods suggested in the literature on estimating growth rates and analyze whether these approaches are consistent with the use of using a constant discount rate to evaluate the firm's assets and equity. The literature has also suggested estimating growth rate by using the average percentage change method, compound-sum method, and/or regression methods. We demonstrate that the average percentage change is very sensitive to extreme observations. Moreover, on average, the regression method yields similar but somewhat smaller estimates of the growth rate compared to the compound-sum method. We also discussed the inferred method suggested by Gordon and Gordon (1997) to estimate the growth rate. Advantages, disadvantages, and the interrelationship among these estimation methods are also discussed in detail.

Keywords: Compound sum method, Discount cash flow model, Growth rate, Internal growth rate, Sustainable growth rate

Chapter 47: Econometric Measures of Liquidity

A security is liquid to the extent that an investor can trade significant quantities of the security quickly, at or near the current market price, and bearing low transaction costs. As such, liquidity is a multidimensional concept. In this chapter, I review several widely used econometrics or statistics-based measures that researchers have developed to capture one or more dimensions of a security's liquidity (i.e., limited dependent variable model (Lesmond et al. 1999) and autocovariance of price changes (Roll 1984)). These alternative proxies have been designed to be estimated using either low-frequency or high-frequency data, so I discuss four liquidity proxies that are estimated using low-frequency data and two proxies that require high-frequency data. Low-frequency measures permit the study of liquidity over relatively long time horizons; however, they do not reflect actual trading processes. To overcome this limitation, high-frequency liquidity proxies are often used as benchmarks to determine the best low-frequency proxy. In this chapter, I find that estimates from the effective tick measure perform best among the four low-frequency measures tested.

Keywords: Liquidity, Transaction costs, Bid-ask spread, Price impact, Percent effective spread, Market model, Limited dependent variable model, Tobin's model, Log-likelihood function, Autocovariance, Correlation analysis

Chapter 48: A Quasi-Maximum Likelihood Estimation Strategy for Value-at-Risk Forecasting: Application to Equity Index Futures Markets

The chapter uses GARCH model and quasi-maximum likelihood estimation strategy to investigate equity index futures markets. We present the first empirical evidence for the validity of the ARMA-GARCH model with tempered stable innovations to estimate 1-day-ahead value-at-risk in futures markets for the S&P 500, DAX, and Nikkei. We also provide empirical support that GARCH models based on the normal innovations appear not to be as well suited as infinitely divisible models for predicting financial crashes. In our empirical analysis, we forecast 1 % value-at-risk in both spot and futures markets using normal and tempered stable GARCH models following a quasi-maximum likelihood estimation strategy. In order to determine the accuracy of forecasting for each specific model, backtesting using Kupiec's proportion of failures test is applied.

Keywords: Infinitely divisible models, Tempered stable distribution, GARCH models, Value-at-risk, Kupiec's proportion of failures test, Quasi-maximum likelihood estimation strategy

Chapter 49: Computer Technology for Financial Service

This chapter examines the core computing competence for financial services. Securities trading is one of the few business activities where a few seconds of processing delay can cost a company big fortune. Grid and Cloud computing will be briefly described. How the underlying algorithm for financial analysis can take advantage of Grid environment is chosen and presented. One of the most popular practiced algorithms Monte Carlo Simulation is used in our cases study for option pricing and risk management. The various distributed computational platforms are carefully chosen to demonstrate the performance issue for financial services.

Keywords: Financial service, Grid and cloud computing, Monte Carlo simulation, Option pricing, Risk management, Cyberinfrastructure, Random number generation, High end computing, Financial simulation, Information technology

Chapter 50: Long-Run Stock Return and the Statistical Inference

This chapter introduces the long-run stock return methodologies and their statistical inference. The long-run stock return is usually computed by using a holding strategy more than 1 year but up to 5 years. Two categories of long-run return methods are illustrated in this chapter: the event-time approach and calendar-time approach. The event-time approach includes cumulative abnormal return, buy-and-hold abnormal return, and abnormal returns around earnings announcements. In former two methods, it is recommended to apply the empirical distribution (from the bootstrapping method) to examine the statistical inference, whereas the last one uses classical *t*-test. In addition, the benchmark selections in the long-run return literature are introduced. Moreover, the calendar-time approach contains mean monthly abnormal return, factor models, and Ibbotson's RATS, which could be tested by time-series volatility.

Keywords: Long-run stock return, Buy-and-hold return, Factor model, Event-time, Calendar-time, Cumulative abnormal return, Ibottson's RATS, Conditional market model, Bootstrap, Zero-investment portfolio

Chapter 51: Value-at-Risk Estimation via a Semi-Parametric Approach: Evidence from the Stock Markets

This study utilizes the parametric approach (GARCH-based models) and the semi-parametric approach of Hull and White (1998) (HW-based models) to estimate the Value-at-Risk (VaR) through the accuracy evaluation of accuracy for the eight stock indices in Europe and Asia stock markets. The measure of accuracy includes the unconditional coverage test by Kupiec (1995) as well as two loss functions, quadratic loss function and unexpected loss. As to the parametric approach, the parameters of generalized autoregressive conditional heteroskedasticity (GARCH) model are estimated by the method of maximum likelihood and the quantiles of asymmetric distribution like skewed generalized student's t (SGT) can be solved by composite trapezoid rule. Sequentially, the VaR is evaluated by the framework proposed by Jorion (2000). Turning to the semi-parametric approach of Hull and White (1998), before performing the traditional historical simulation, the raw return series is scaled by a volatility ratio where the volatility is estimated by the same procedure of parametric approach.

Keywords: Value-at-risk, Semi-parametric approach, Parametric approach, Generalized autoregressive conditional heteroskedasticity, Skewed generalized student's *t*, Composite trapezoid rule, Method of maximum likelihood, Unconditional coverage test, Loss function

Chapter 52: Modeling Multiple Asset Returns by a Time-Varying *t* Copula Model

This chapter illustrates a framework to model joint distributions of multiple asset returns using a time-varying Student's *t* copula model. We model marginal distributions of individual asset returns by a variant of GARCH models and then use a Student's *t* copula to connect all the margins. To build a time-varying structure for the correlation matrix of *t* copula, we employ a dynamic conditional correlation (DCC) specification. We illustrate the two-stage estimation procedures for the model and apply the model to 45 major US stocks returns selected from nine sectors. As it is quite challenging to find a copula function with very flexible parameter structure to account for difference dependence features among all pairs of random variables, our time-varying *t* copula model tends to be a good working tool to model multiple asset returns for risk management and asset allocation purposes. Our model can capture time-varying conditional correlation and some degree of tail dependence, while it also has limitations of featuring symmetric dependence and inability of generating high tail dependence when being used to model a large number of asset returns.

Keywords: Student's *t* copula, GARCH models, Asset returns, U.S. stocks, Maximum likelihood, Two-stage estimation, Tail dependence, Exceedance correlation, Dynamic conditional correlation, Asymmetric dependence

Chapter 53: Internet Bubble Examination with Mean-Variance Ratio

This chapter illustrates the superiority of the mean-variance ratio (MVR) test over the traditional SR test by applying both tests to analyze the performance of the S&P 500 index and the NASDAQ 100 index after the bursting of the Internet bubble in 2000s. This shows the superiority of the MVR test statistic in revealing short-term performance and, in turn, enables investors to make better decisions in their investments. The methodologies used in this chapter are mean-variance ratio, Sharpe ratio, hypothesis testing, and uniformly most powerful unbiased test.

Keywords: Mean-variance ratio, Sharpe ratio, Hypothesis testing, Uniformly most powerful unbiased test, Internet bubble, Fund management

Chapter 54: Quantile Regression in Risk Calibration

This chapter uses the CoVaR (Conditional VaR) framework to obtain accurate information on the interdependency of risk factors. The basic technical elements of CoVaR estimation are two levels of quantile regression: one on market risk factors; another on individual risk factor. Tests on the functional form of the two-level quantile regression reject the linearity. A flexible semi-parametric modeling framework for CoVaR is proposed. A partial linear model (PLM) is analyzed. In applying the technology to stock data covering the crisis period, the PLM outperforms in the crisis time, with the justification of the backtesting procedures. Moreover, using the data on global stock markets indices, the analysis on marginal contribution of risk (MCR) defined as the local first order derivative of the quantile curve sheds some light on the source of the global market risk.

Keywords: CoVAR, Value-at-risk, Quantile regression, Locally linear quantile regression, Partial linear model, Semi-parametric model

Chapter 55: Strike Prices of Options for Overconfident Executives

This chapter uses Monte Carlo simulation to investigate the impacts of managerial overconfidence on the optimal strike prices of executive incentive options. Although it has been shown that optimally managerial incentive options should be awarded in-the-money, in practice, most firms award them at-the-money. We show that the optimal strike prices of options granted to overconfident executive are directly related to their overconfidence level, and that this bias brings the optimal strike prices closer to the institutionally prevalent at-the-money prices. The Monte Carlo simulation procedure uses a Mathematica program to find the optimal effort by managers and the optimal (for stockholders) contract parameters. An expanded discussion of the simulations, including the choice of the functional forms and the calibration of the parameters, is provided.

Keywords: Overconfidence, Managerial effort, Incentive options, Strike price, Simulations, Behavioral finance, Executive compensation schemes, Mathematica optimization, Risk aversion, Effort aversion

Chapter 56: Density and Conditional Distribution Based Specification Analysis

This chapter uses densities and conditional distributions analysis to carry out consistent specification testing and model selection among multiple diffusion processes. In this chapter, we discuss advances to this literature introduced by Corradi and Swanson (2005), who compare the cumulative distribution (marginal or joint) implied by a hypothesized null model with corresponding empirical distributions of observed data. In particular, parametric specification tests in the spirit of the conditional Kolmogorov test of Andrews (1997) that rely on block bootstrap resampling methods in order to construct test critical values are discussed. The methodologies used in this chapter are continuous time simulation methods, single process specification testing, multiple process model selection, and multi-factor diffusion process, block bootstrap, and jump process.

Keywords: Multifactor diffusion process, Specification test, Out-of-sample forecasts, Conditional distribution, Model selection, Block bootstrap, Jump process

Chapter 57: Assessing the Performance of Estimators Dealing with Measurement Errors

This chapter describes different procedures to deal with measurement error in linear models, and assess their performance in finite samples using Monte Carlo simulations, and data on corporate investment. We consider the standard instrumental variables approach proposed by Griliches and Hausman (1986) as extended by Biorn (2000) [OLS-IV], the Arellano and Bond (1991) instrumental variable estimator, and the higher-order moment estimator proposed by Erickson and Whited (2000, 2002). Our analysis focuses on characterizing the conditions under which each of these estimators produces unbiased and efficient estimates in a standard “errors in variables” setting. In the presence of fixed effects, under heteroscedasticity, or in the absence of a very high degree of skewness in the data, the EW estimator is inefficient and returns biased estimates for mismeasured and perfectly measured regressors. In contrast to the EW estimator, IV-type estimators (OLS-IV and AB-GMM) easily handle individual effects, heteroskedastic errors, and different degrees of data skewness. The IV approach, however, requires assumptions about the autocorrelation structure of the mismeasured regressor and the measurement error. We illustrate the application of the different estimators using empirical investment models.

Keywords: Investment equations, Measurement error, Monte Carlo simulations, Instrumental variables, GMM, Bias, Fixed effects, Heteroscedasticity, Skewness, High-order moments

Chapter 58: Realized Distributions of Dynamic Conditional Correlation and Volatility Thresholds in the Crude Oil, Gold, and Dollar/Pound Currency Markets

This chapter proposes a modeling framework for the study of co-movements in price changes among crude oil, gold, and dollar/pound currencies that are conditional on volatility regimes. Methodologically, we extend the Dynamic Conditional Correlation (DCC) multivariate GARCH model to examine the volatility and correlation dynamics depending on the variances of price returns involving a threshold structure. The results indicate that the periods of market turbulence are associated with an increase in co-movements in commodity (gold and oil) prices. The results imply that gold may act as a safe haven against major currencies when investors face market turmoil.

Keywords: Dynamic conditional correlation, Volatility threshold, Realized distribution, Currency market, Gold, Oil

Chapter 59: Pre-IT Policy, Post-IT Policy, and the Real Sphere in Turkey

We estimate Two SVECM (Structural Vector Error Correction) Models for the Turkish economy based on imposing short run and Long-run restrictions that accounts for examining the behavior of the real sphere in the Pre-IT policy (before Inflation-Targeting adoption) and Post-IT policy (after Inflation-Targeting Adoption). Responses reveals that an expansionary interest policy shock leads to a decrease in price level, a fall in output, an appreciation in the exchange rate, an improvement in the share prices in the very short run for the most of Pre-IT period.

Keywords: SVECM models, Turkish economy, Short run, Long run, Restrictions, Inflation targeting, Pre-IT policy, Post-IT policy, Share prices, Exchange rate, Monetary policy shock, Output, Price level, Real sphere

Chapter 60: Determination of Capital Structure: A LISREL Model Approach

In this chapter, we employ structural equation modeling (SEM) in LISREL system to solve the measurement errors problems in the analysis of the determinants of capital structure and find the important factors consistent with capital structure theory by using date from 2002 to 2010. The purpose of this chapter is to investigate whether the influences of accounting factors on capital structure change and whether the important factors are consistent with the previous literature. The methodologies discussed in this chapter are structural equation modeling (SEM), multiple indicators and multiple causes (MIMIC) model, LISREL system, simultaneous equations, and SEM with confirmatory factor analysis (CFA) approach.

Keywords: Capital structure, Structural equation modeling (SEM), Multiple indicators and multiple causes (MIMIC) model, LISREL system, Simultaneous equations, Latent variable, Determinants of capital structure, Error in variable problem

Chapter 61: Evaluating the Effectiveness of Futures Hedging

This chapter examines the Ederington hedging effectiveness (EHE) comparisons between unconditional OLS hedge strategy and other conditional hedge strategies. It is shown that OLS hedge strategy outperforms most of the optimal conditional hedge strategies when EHE is used as the hedging effectiveness criteria. Before concluding that OLS hedge is better than the others; however, we need to understand under what circumstances the result is derived. We explain why OLS is the best hedge strategy under EHE criteria in most cases, and how most conditional hedge strategies are judged as inferior to OLS hedge strategy by an EHE comparison.

Keywords: Futures hedging, Portfolio management, Ederington hedging effectiveness, Variance estimation, Unconditional variance, Conditional variance, OLS hedging strategy, GARCH hedging strategy, Regime-switching hedging strategy, Utility-based hedging strategy

Chapter 62: Evidence on Earning Management by Integrated Oil and Gas Companies

This chapter uses Jones Model (1991) which projects the expected level of discretionary accruals and demonstrates specific test methodology for detection of earnings management in the oil and gas industry. This study utilized several parametric and nonparametric statistical methods to test for such earnings management. By comparing actuals versus projected accruals, we are able to compute the total unexpected accruals. We also correlate unexpected total accruals with several difficult to manipulate indicators that reflect company's level of activities.

Keywords: Earning management, Jones (1991) model, Discretionary accruals, Income from operations, Nonrecurring items, Special items, Research and development expense, Write-downs, Political cost, Impression management, Oil and gas industry

Chapter 63: A Comparative Study of Two Models SV with MCMC Algorithm

This chapter examines two asymmetric stochastic volatility models used to describe the volatility dependencies found in most financial returns. The first is the autoregressive stochastic volatility model with Student's t-distribution (ARSV-t), and the second is the basic Svol of JPR (1994). In order to estimate these models, our analysis is based on the Markov Chain Monte Carlo (MCMC) method. Therefore, the technique used is a Metropolishastings (Hastings 1970), and the Gibbs sampler (Casella and George 1992; Gelfand and Smith 1990; Gilks et al. 1993). The empirical results concerned on the Standard and Poor's 500 composite Index (S&P), CAC40, Nasdaq, Nikkei, and Dow-Jones stock price indexes reveal that the ARSV-t model provides a better performance than the Svol model on the Mean Squared Error (MSE) and the Maximum Likelihood function.

Keywords: Autoregression, Asymmetric stochastic volatility, MCMC, Metropolishastings, Gibbs sampler, Volatility dependencies, Student's t-distribution, SVOL, MSE, Financial returns, Stock price indexes

Chapter 64: Internal Control Material Weakness, Analysts' Accuracy and Bias, and Brokerage Reputation

This chapter uses the Ordinary Least-Squares (OLS) methodology in the main tests to examine the impact of internal control material weaknesses (ICMW hereafter) on sell side analysts. We match our ICMW firms with non-ICMWs based on industry, sales, and assets. We re-estimate the models using rank regression technique to assess the sensitivity of the results to the underlying functional form assumption made by OLS. We use Cook's distance to test the outliers.

Keywords: Internal control material weakness, Analyst forecast accuracy, Analyst forecast bias, Brokerage reputation, Sarbanes-Oxley act, Ordinary least squares regressions, Rank regressions, Fixed effects, Matching procedure, Cook's distance

Chapter 65: What Increases Banks' Vulnerability to Financial Crisis: Short-Term Financing or Illiquid Assets?

This chapter applies Logit and OLS econometric techniques to analyze the Federal Reserve Y-9C report data. We show that short-term financing is a response to the adverse economic shocks rather than a cause of the recent crisis. The likelihood of financial crisis actually stems from the illiquidity and low creditworthiness of the investment. Our results are robust to endogeneity concerns when we use a difference-in-differences (DiD) approach with the Lehman bankruptcy in 2008 proxying for an exogenous shock.

Keywords: Financial crisis, Short-term financing, Debt maturity, Liquidity risk, Deterioration of bank asset quality

Chapter 66: Accurate Formulae for Evaluating Barrier Options with Dividends Payout and the Application in Credit Risk Valuation

This chapter approximates the discrete dividend payout by a stochastic continuous dividend yield, so the post dividend stock price process can be approximated by another log-normally diffusive stock process with a stochastic continuous payout ratio up to the ex-dividend date. Accurate approximation analytical pricing formulae for barrier options are derived by repeatedly applying the reflection principle. Besides, our formulae can be applied to extend the applicability of the first passage model – a branch of structural credit risk model. The stock price falls due to the dividend payout in the option pricing problem is analog to selling the firm's asset to finance the loan repayment or dividend payout in the first passage model. Thus, our formulae can evaluate vulnerable bonds or the equity values given that the firm's future loan/dividend payments are known.

Keywords: Barrier option, Option pricing, Stock option, Dividend, Reflection principle, Lognormal, Credit risk

Chapter 67: Pension Funds: Financial Econometrics on the Herding Phenomenon in Spain and the United Kingdom

This chapter uses the estimated cross-sectional standard deviations of betas to analyze if manager's behavior enhances the existence of herding phenomena and the impact of the Spanish and UK pension funds investment on the market efficiency. We also estimate the betas with an econometric technique less applied in the financial literature: state-space models and the Kalman filter. Additionally, in order to obtain a robust estimation, we apply the Huber estimator. Finally, we apply several models and study the existence of herding toward the market, size, book-to-market, and momentum factors.

Keywords: Herding, Pension funds, State-space models, Kalman filter, Huber estimation, Imitation, Behavioral finance, Estimated cross-sectional standard deviations of betas, Herding toward the market, Herding toward size factor, Herding toward book-to-market factor, and Herding toward momentum factor

Chapter 68: Estimating the Correlation of Asset Returns: A Quantile Dependence Perspective

This chapter uses the *Copula Quantile-on-Quantile Regression* (C-QQR) approach to construct the correlation between the conditional quantiles of stock returns. This new approach of estimating correlation utilizes the idea that the condition of a stock market is related to its return performance, particularly to the conditional quantile of its return, as the lower return quantiles reflect a weak market while the upper quantiles reflect a bullish one. The C-QQR approach uses the copula to generate a regression function for modeling the dependence between the conditional quantiles of the stock returns under consideration. It is estimated using a two-step quantile regression procedure, where in principle, the first step is implemented to model the conditional quantile of one stock return, which is then related in the second step to the conditional quantile of another return.

Keywords: Stock markets, Copula, Correlation, Quantile regression, Quantile dependence, Business cycle, Dynamics, Risk management, Investment, Tail risk, Extreme events, Market uncertainties

Chapter 69: Multi-criteria Decision Making for Evaluating Mutual Funds Investment Strategies

This chapter uses the criteria measurements to evaluate investment style and investigate multiple criteria decision-making (MCDM) problem. To achieve this objective, first, we employ factor analysis to extract independent common factors from those criteria. Second, we construct the evaluation frame using hierarchical system composed of the above common factors with evaluation criteria, and then derive the relative weights with respect to the considered criteria. Third, the synthetic utility value corresponding to each investment style is aggregated by the weights with performance values. Finally, we compare with empirical data and find that the model of MCDM predicts the rate of return.

Keywords: Investment strategies, Multiple Criteria Decision Making (MCDM), Hierarchical system, Investment style, Factor analysis, Synthetic utility value, Performance values

Chapter 70: Econometric Analysis of Currency Carry Trade

This chapter investigates carry trade strategy in the currency markets whereby investors fund positions in high interest rate currencies by selling low interest rate currencies to earn the interest rate differential. In this chapter, we first provide an overview of the risk and return profile of currency carry trade; second, we introduce two popular models, the regime-switch model and the logistic smooth transition regression model, to analyze carry trade returns because the carry trade returns are highly regime dependent. Finally, an empirical example is illustrated.

Keywords: Carry trade, Uncovered interest parity, Markov chain Monte Carlo, Regime-switch model, Logistic smooth transition regression model

Chapter 71: Analytical Bounds for Treasury Bond Futures Prices

This study employs a maximum likelihood estimation technique presented by Chen and Scott (1993) to estimate the parameters for two-factor Cox-Ingersoll-Ross models of the term structure. Following the estimation, the factor values are solved for by matching the short rate with the cheapest-to-deliver bond price. Then, upper bounds and lower bounds for Treasury bond futures prices can be calculated. This study first shows that the popular preference-free, closed-form cost of carry model is an upper bound for the Treasury bond futures price. Then, the next step is to derive analytical lower bounds for the futures price under one- and two-factor Cox-Ingersoll-Ross models of the term structure.

Keywords: Treasury bond futures, Delivery options, Cox-Ingersoll-Ross models, Bounds, Maximum likelihood estimation, Term structure, Cheapest-to-deliver bond, Timing options, Quality options, Chicago board of trade

Chapter 72: Rating Dynamics of Fallen Angels and Their Speculative Grade-Rated Peers: Static Versus Dynamic Approach

This study adopts the survival analysis framework (Allison 1984) to examine issuer-heterogeneity and time-heterogeneity in the rating migrations of fallen angels (FAs) and their speculative grade-rated peers (FA peers). Cox's hazard model is considered the pre-eminent method to estimate the probability that an issuer survives in its current rating grade at any point in time t over the time horizon T. In this study, estimation is based on two Cox's hazard models, including a proportional hazard model (Cox 1972) and a dynamic hazard model. The first model employs a static estimation approach and time-independent covariates, whereas the second uses a dynamic estimation approach and time-dependent covariates. To allow for any dependence among rating states of the same issuer, the marginal event-specific method (Wei et al. 1989) was used to obtain robust variance estimates. For validation purpose, the Brier score (Brier 1950) and its covariance decomposition (Yates 1982) were applied to assess the forecast performance of estimated models in forming time-varying survival probability estimates for issuers out-of-sample.

Keywords: Survival analysis, Hazard model, Time-varying covariate, Recurrent event, Brier score, Covariance decomposition, Rating migration, Fallen angel, Markov property, Issuer-heterogeneity, Time-heterogeneity

Chapter 73: Creation and Control of Bubbles: Managers Compensation Schemes, Risk Aversion, and Wealth and Short Sale Constraints

This chapter takes an alternative approach of inquiry – that of using laboratory experiments – to study the creation and control of speculative bubbles. The following three factors are chosen for analysis: the compensation scheme of portfolio managers, wealth and supply constraints, and the relative risk aversion of traders. Under a short investment horizon induced by a tournament compensation scheme, speculative bubbles are observed in markets of speculative traders and in mixed markets of conservative and speculative traders. The primary method of analysis is to use live subjects in a laboratory setting to generate original trading data, which are compared to their fundamental values. Standard statistical techniques are used to supplement analysis in explaining the divergence of asset prices from their fundamental values.

Keywords: Speculative bubbles, Laboratory experimental asset markets, Fundamental asset values, Tournament, Market efficiency, Behavioral finance, Ordinary least squares regression, Correlation

Chapter 74: Range Volatility: A Review of Models and Empirical Studies

In this chapter, we survey the significant development of range-based volatility models, beginning with the simple random walk model up to the conditional autoregressive range (CARR) model. For the extension to range-based multivariate volatilities, some approaches developed recently are adopted, such as the dynamic conditional correlation (DCC) model, the double smooth transition conditional correlation (DSTCC) GARCH model, and the copula method. At last, we introduce different approaches to build bias-adjusted realized range to obtain a more efficient estimator.

Keywords: Range, Volatility forecasting, Dynamic conditional correlation, Smooth transition, Copula, Realized volatility, Risk management

Chapter 75: Business Models: Applications to Capital Budgeting, Equity Value, and Return Attribution

This chapter describes a business model in a contingent claim modeling framework. The chapter then provides three applications of the business model. Firstly, the chapter determines the optimal capital budgeting decision in the presence of fixed operating costs, and shows how the fixed operating cost should be accounted by in an NPV calculation. Secondly, the chapter determines the values of equity value, the growth option, the retention option as the building blocks of primitive firm value. Using a sample of firms, the chapter illustrates a method in comparing the equity values of firms in the same business sector. Thirdly, the chapter relates the change in revenue to the change in equity value, showing how the combined operating leverage and financial leverage may affect the firm valuation and risks.

Keywords: Bottom-up capital budgeting, Business model, Capital budgeting, Contingent claim model, Equity value, Financial leverage, Fixed operating cost, Gross return on investment (GRI), Growth option, Market performance measure, NPV, Operating leverage, Relative value of equity, Retention option, Return attribution, Top-down capital budgeting, Wealth transfer

Chapter 76: VAR Models: Estimation, Inferences, and Applications

This chapter provides a brief overview of the basic Vector autoregression (VAR) approach by focusing on model estimation and statistical inferences. VAR models have been used extensive in finance and economic analysis. Applications of VAR models in some finance areas are discussed, including asset pricing, international finance, and market microstructure. It is shown that such approach provides a powerful tool to study financial market efficiency, stock return predictability, exchange rate dynamics, and information content of stock trades and market quality.

Keywords: VAR, Granger-causality test, Impulse response, Variance decomposition, Co-integration, Asset return predictability, Market quality, Information content of trades, Informational efficiency

Chapter 77: Model Selection for High-Dimensional Problems

This chapter introduces penalized least squares, which seek to keep important predictors in a model, while penalizing coefficients associated with irrelevant predictors. As such, under certain conditions, penalized least squares can lead to a sparse solution for linear models and achieve asymptotic consistency in separating relevant variables from irrelevant ones. We then review independence screening, a recently developed method for analyzing ultrahigh-dimensional data where the number of variables or parameters can be exponentially larger than the sample size. Independence screening selects relevant variables based on certain measures of marginal correlations between candidate variables and the response. Finally, we discuss and advocate multistage procedures that combine independence screening and variable selection and that may be especially suitable for analyzing high-frequency financial data.

Keywords: Model selection, Variable selection, Dimension reduction, Independence screening, High-dimensional data, Ultrahigh-dimensional data, Generalized correlations, Penalized least squares, Shrinkage, Statistical learning, SCAD penalty, Oracle property

Chapter 78: Hedonic Regression Models

The chapter examines three specific, different hedonic specifications: the linear, semi-log, and Box-Cox transformed hedonic models and applies them to real estate data. It also discusses recent innovations related to hedonic models and how these models are being used in contemporary studies. This provides a basic overview of the nature and variety of hedonic empirical pricing models that are employed in the economics literature. It explores the history of hedonic modeling and summarizes the field's utility-theory-based, microeconomic foundations. It also provides a discussion of and potential solutions for common problems associated with hedonic modeling.

Keywords: Hedonic models, Regression, Real estate, Box-Cox, Pricing, Price indexes, Semi-log, Least squares, Housing, Property

Chapter 79: Optimal Payout Ratio Under Uncertainty and the Flexibility Hypothesis: Theory and Empirical Evidence

We theoretically extend the proposition of DeAngelo and DeAngelo's (2006) optimal payout policy in terms of the flexibility dividend hypothesis. We also introduce growth rate, systematic risk, and total risk variables into the theoretical model. We use a panel data collected in the USA from 1969 to 2009 to empirically investigate the impact of growth rate, systematic risk, and total risk on the optimal payout ratio in terms of the fixed-effects model. Furthermore, we implement the moving estimates process to find the empirical breakpoint of the structural change for the relationship between the payout ratio and risks and confirm that the empirical breakpoint is not different from our theoretical breakpoint. Our theoretical model and empirical results can therefore be used to identify whether flexibility or the free cash flow hypothesis should be used to determine the dividend policy.

Keywords: Dividends, Payout policy, Optimal payout ratio, Flexibility hypothesis, Free cash flow hypothesis, Signaling hypothesis, Fixed effect, Clustering effect, Structural change model, Moving estimates processes, Systematic risk, Total risk, Market perfection

Chapter 80: Modeling Asset Returns with Skewness, Kurtosis, and Outliers

This chapter uses an exponential generalized beta distribution of the second kind (EGB2) to model the returns on 30 Dow-Jones industrial stocks. The model accounts for stock return characteristics, including fat tails, peakedness (leptokurtosis), skewness, clustered conditional variance, and leverage effect. The goodness-of-fit statistic provides supporting evidence in favor of EGB2 distribution in modeling stock returns. The EGB2 distribution used in this chapter is a four parameter distribution. It has a closed-form density function, and its higher-order moments are finite and explicitly expressed by its parameters. The EGB2 distribution nests many widely used distributions such as normal distribution, log-normal distribution, Weibull distribution, and standard logistic distribution.

Keywords: Expected stock return, Higher moments, EGB2 distribution, Risk management, Volatility, Conditional skewness, Risk premium

Chapter 81: Does Revenue Momentum Drive or Ride Earnings or Price Momentum?

This chapter performs dominance test to show that revenue surprises, earnings surprises, and prior returns, each lead to significant momentum returns that cannot be fully explained by the others, suggesting that each convey some exclusive and unpriced information content. Also, the joint implications of revenue surprises, earnings surprises, and prior returns are underestimated by investors, particularly when information variables point in the same direction. Momentum cross-contingencies are observed in that momentum profits driven by firm fundamental information positively depend on the accompanying firm market information, and vice versa. A three-way combined momentum strategy may offer monthly return as high as 1.44%.

Keywords: Earnings surprises, Momentum strategies, Post-earnings-announcement drift, Revenue surprises

Chapter 82: A VG-NGARCH Model for Impacts of Extreme Events on Stock Returns

This chapter compares two types of GARCH models, namely, the VG-NGARCH and the GARCH-jump model with autoregressive conditional jump intensity, i.e., the GARJI model, to make inferences on the log of stock returns when there are irregular substantial price fluctuations. The VG-NGARCH model imposes a nonlinear asymmetric structure on the conditional shape parameters in a variance-gamma process, which describes the arrival rates for news with different degrees of influence on price movements, and provides an ex ante probability for the occurrence of large price movements. On the other hand, the GARJI model, a mixed GARCH-jump model proposed by Chan and Maheu (2002), adopts two independent autoregressive processes to model the variances corresponding to moderate and large price movements, respectively.

Keywords: VG-NGARCH model, GARCH-jump model, Autoregressive conditional jump intensity, GARJI model, Substantial price fluctuations, Shape parameter, Variance-gamma process, Ex ante probability, Daily stock price, Goodness-of-fit

Chapter 83: Risk-Averse Portfolio Optimization via Stochastic Dominance Constraints

This chapter presents a new approach to portfolio selection based on stochastic dominance. The portfolio return rate in the new model is required to stochastically dominate a random benchmark. We formulate optimality conditions and duality relations for these models and construct equivalent optimization models with utility functions. Two different formulations of the stochastic dominance constraint, primal and inverse, lead to two dual problems which involve von Neuman–Morgenstern utility functions for the primal formulation and rank dependent (or dual) utility functions for the inverse formulation. We also discuss the relations of our approach to value-at-risk and conditional value-at-risk.

Keywords: Portfolio optimization, Stochastic dominance, Stochastic order, Risk, Expected utility, Duality, Rank dependent utility, Yaari's dual utility, Value-at-risk, Conditional value-at-risk

Chapter 84: Implementation Problems and Solutions in Stochastic Volatility Models of the Heston Type

This chapter compares three major approaches to solve the numerical instability problem inherent in the fundamental solution of the Heston model. In this chapter, we used the fundamental transform method proposed by Lewis to reduce the number of variables from two to one and separate the payoff function from the calculation of the Green function for option pricing. We show that the simple adjusted-formula method is much simpler than the rotation-corrected angle method of Kahl and Jäckel and also greatly superior to the direct integration method of Shaw if taking computing time into consideration.

Keywords: Heston, Stochastic volatility, Fourier inversion, Fundamental transform, Complex logarithm, Rotation-corrected angle, Simple adjusted formula, Green function

Chapter 85: Stochastic Change-Point Models of Asset Returns and Their Volatilities

This chapter considers two time-scales and uses the "short" time-scale to define GARCH dynamics and the "long" time-scale to incorporate parameter jumps. This leads to a Bayesian change-point ARX-GARCH model, whose unknown parameters may undergo occasional changes at unspecified times and can be estimated by explicit recursive formulas when the hyperparameters of the Bayesian model are specified. Efficient estimators of the hyperparameters of the Bayesian model can be developed. The empirical Bayes approach can be applied to the frequentist problem of partitioning the time series into segments under sparsity assumptions on the change-points.

Keywords: ARX-GARCH, Bounded complexity, Contemporaneous jumps, Change-point models, Empirical Bayes, Frequentist segmentation, Hidden Markov models, Hyperparameter estimation, Markov chain Monte Carlo, Recursive filters, Regression models, Stochastic volatility

Chapter 86: Unspanned Stochastic Volatilities and Interest Rate Derivatives Pricing

This chapter first reviews the recent literature on the Unspanned Stochastic Volatilities (USV) documented in the interest rate derivatives markets. The USV refers to the volatilities factors implied in the interest rate derivatives prices that have little correlation with the yield curve factors. We then present the result in Li and Zhao (2006) that a sophisticated DTSM without USV feature can have serious difficulties in hedging caps and cap straddles, even though they capture bond yields well. Furthermore, at-the-money straddle hedging errors are highly correlated with cap-implied volatilities and can explain a large fraction of hedging errors of all caps and straddles across moneyness and maturities. We also present a multifactor term structure model with stochastic volatility and jumps that yields a closed-form formula for cap prices from Jarrow et al. (2007). The three-factor stochastic volatility model with Poisson jumps can price interest rate caps well across moneyness and maturity. The econometric methods in this chapter include extended Kalman filtering, maximum likelihood estimation with latent variables, local polynomial method, and nonparametric density estimation.

Keywords: Term structure modeling, Interest rate volatility, Heath-Jarrow-Morton model, Nonparametric density estimation, Extended Kalman filtering

Chapter 87: Alternative Equity Valuation Models

This chapter examines alternative equity valuation models and their ability to forecast future stock prices. We use simultaneous equations estimation technique to investigate the stock price forecast ability of Ohlson's model, Feltham and Ohlson's Model, and Warren and Shelton's (1971) model. Moreover, we use the combined forecasting methods proposed by Granger and Newbold (1973) and Granger and Ramanathan (1984) to form combined stock price forecasts from individual models. Finally, we examine whether comprehensive earnings can provide incremental price-relevant information beyond net income.

Keywords: Ohlson model, Feltham and Ohlson model, Warren and Shelton model, Equity valuation models, Simultaneous equations estimation, Fundamental analysis, Financial statement analysis, Financial planning and forecasting, Combined forecasting, Comprehensive earnings, Abnormal earnings, Operating earnings, Accounting earnings

Chapter 88: Time Series Models to Predict the Net Asset Value (NAV) of an Asset Allocation Mutual Fund VWELX

This research examines the use of various forms of time-series models to predict the total net asset value (NAV) of an asset allocation mutual fund. The first set of model structures included simple exponential smoothing, double exponential smoothing, and the Winter's method of smoothing. The second set of predictive models used represented trend models. They were developed using regression estimation. They included linear trend model, quadratic trend model, and an exponential model. The third type of method used was a moving average method. The fourth set of models incorporated the Box-Jenkins method, including an autoregressive model, a moving average model, and an unbounded autoregressive and moving average method.

Keywords: NAV of a mutual fund, Asset allocation fund, Combination of forecasts, Single exponential smoothing, Double exponential smoothing, Winter's method, Linear trend model, Quadratic trend model, Exponential trend model, Moving average method, Autoregressive model, Moving average model, Unbounded autoregressive moving average model

Chapter 89: Discriminant Analysis and Factor Analysis: Theory and Method

This chapter discusses three multivariate techniques in detail: discriminant analysis, factor analysis, and principal component analysis. In addition, the stepwise discriminant analysis by Pinches and Mingo (1973) is improved using a goal programming technique. These methodologies are applied to determine useful financial ratios and the subsequent bond ratings. The analysis shows that the stepwise discriminant analysis fails to be an efficient solution as the hybrid approach using the goal programming technique outperforms it, which is a compromised solution for the maximization of the two objectives, namely, the maximization of the explanatory power and the maximization of discriminant power.

Keywords: Multivariate technique, Discriminant analysis, Factor analysis, Principle component analysis, Stepwise discriminant analysis, Goal programming, Bond ratings, Compromised solution, Explanatory power, Discriminant power

Chapter 90: Implied Volatility: Theory and Empirical Method

This chapter reviews the different theoretical methods used to estimate implied standard deviation and to show how the implied volatility can be estimated in empirical work. The OLS method for estimating implied standard deviation is first introduced and the formulas derived by applying a Taylor series expansion method to Black-Scholes option pricing model are also described. Three approaches of estimating implied volatility are derived from one, two, and three options, respectively. Because of these formulas with the remainder terms, the accuracy of these formulas depends on how an underlying asset is close to the present value of exercise price in an option. The formula utilizing three options for estimating implied volatility is more accurate rather than other two approaches. In this chapter, we use call options on S&P 500 index futures in 2010 and 2011 to illustrate how MATLAB can be used to deal with the issue of convergence in estimating implied volatility of future options.

Keywords: Implied volatility, Implied standard deviation (ISD), Option pricing model, MATLAB, Taylor series expansion, Ordinary least-squares (OLS), Black-Scholes Model, Options on S&P 500 index futures

Chapter 91: Measuring Credit Risk in a Factor Copula Model

This chapter uses a new approach to estimate future credit risk on target portfolio based on the framework of CreditMetricsTM by J.P. Morgan. However, we adopt the perspective of factor copula and then bring the principal component analysis concept into factor structure to construct a more appropriate dependence structure among credits. In order to examine the proposed method, we use real market data instead of a virtual one. We also develop a tool for risk analysis which is convenient to use, especially for banking loan businesses. The results show the fact that people assume dependence structures are normally distributed will indeed lead to risks underestimate. On the other hand, our proposed method captures better features of risks and shows the fat-tail effects conspicuously even though assuming the factors are normally distributed.

Keywords: Credit risk, Credit VaR, Default correlation, Copula, Factor copula, Principal component analysis

Chapter 92: Instantaneous Volatility Estimation by Nonparametric Fourier Transform Methods

This chapter conducts some simulation tests to justify the effectiveness of the Fourier transform method. Malliavin and Mancino (2009) proposed a nonparametric Fourier transform method to estimate the instantaneous volatility under the assumption that the underlying asset price process is a semi-martingale. Two correction schemes are proposed to improve the accuracy of volatility estimation. By means of these Fourier transform methods, some documented phenomena such as volatility daily effect and multiple risk factors of volatility can be observed. Then, a linear hypothesis between the instantaneous volatility and VIX derived from Zhang and Zhu (2006) is investigated.

Keywords: Information content, Instantaneous volatility, Fourier transform method, Bias reduction, Correction method, Local volatility, Stochastic volatility, VIX, Volatility daily effect, Online estimation

Chapter 93: A Dynamic CAPM with Supply Effect: Theory and Empirical Results

This chapter first theoretically extends Black's CAPM, and then uses price, dividend per share, and earnings per share to test the existence of supply effect with US equity data. A simultaneous equation system is constructed through a standard structural form of a multi-period equation to represent the dynamic relationship between supply and demand for capital assets. The equation system is exactly identified under our specification. Then, two hypotheses related to supply effect are tested regarding the parameters in the reduced-form system. The equation system is estimated by the Seemingly Unrelated Regression (SUR) method, since SUR allows one to estimate the presented system simultaneously while accounting for the correlated errors.

Keywords: CAPM, Asset, Endogenous supply, Simultaneous equations

Chapter 94: A Generalized Model for Optimum Futures Hedge Ratio

This chapter proposes the generalized hyperbolic distribution as the joint log-return distribution of the spot and futures. Using the parameters in this distribution, we derive several most widely used optimal hedge ratios: minimum variance, maximum Sharpe measure, and minimum generalized semivariance. To estimate these optimal hedge ratios, we first write down the log-likelihood functions for symmetric hyperbolic distributions. Then, we estimate these parameters by maximizing the log-likelihood functions. Using these MLE parameters for the generalized hyperbolic distributions, we obtain the minimum variance hedge ratio and the optimal Sharp hedge ratio. Also based on the MLE parameters and the numerical method, we can calculate the minimum generalized semivariance hedge ratio.

Keywords: Optimal hedge ratio, Generalized hyperbolic distribution, Martingale property, Minimum variance hedge ratio, Minimum generalized semi-invariance, Maximum Sharp measure, Joint-normality assumption, Hedging effectiveness

Chapter 95: Instrument Variable Approach to Correct for Endogeneity in Finance

This chapter reviews the instrumental variables (IV) approach to endogeneity from the point of view of a finance researcher who is implementing instrumental variable methods in empirical studies. This chapter is organized into two parts. Part I discusses the general procedure of the instrumental variable approach, including Two-Stage Least Square (2SLS) and Generalized Method of Moments (GMM), the related diagnostic statistics for assessing the validity of instruments, which are important but not used very often in finance applications, and some recent advances in econometrics research on weak instruments. Part II surveys corporate finance applications of instrumental variables. We found that the instrumental variables used in finance studies are usually chosen arbitrarily, and very few diagnostic statistics are performed to assess the adequacy of IV estimation. The resulting IV estimates thus are questionable.

Keywords: Endogeneity, OLS, Instrumental variable (IV) estimation, Simultaneous equations, 2SLS, GMM, Overidentifying restrictions, Exogeneity test, Weak instruments, Anderson-Rubin statistic, Empirical corporate finance

Chapter 96: Application of Poisson Mixtures in the Estimation of Probability of Informed Trading

This research first discusses the evolution of probability of informed trading in the finance literature. Motivated by asymmetric effects, e.g., return and trading volume in up and down markets, this study modifies a mixture of the Poisson distribution model by different arrival rates of informed buys and sells to measure the probability of informed trading proposed by Easley et al. (1996). By applying the expectation–maximization (EM) algorithm to estimate the parameters of the model, we derive a set of equations for maximum likelihood estimation and these equations are encoded in a SAS Macro utilizing SAS/IML for implementation of the methodology.

Keywords: Probability of informed trading (*PIN*), Expectation–maximization (EM) algorithm, A mixture of Poisson distribution, Asset-pricing returns, Order imbalance, Information asymmetry, Bid-ask spreads, Market microstructure, Trade direction, Errors in variables

Chapter 97: CEO Stock Options and Analysts' Forecast Accuracy and Bias

This chapter uses ordinary least squares estimation to investigate the relations between CEO stock options and analysts' earnings forecast accuracy and bias. Our OLS models relate forecast accuracy and forecast bias (the dependent variables) to CEO stock options (the independent variable) and controls for earnings characteristics, firm characteristics, and forecast characteristics. In addition, the models include controls for industry and year. We use four measures of options: new options, existing exercisable options, existing unexercisable options, and total options (sum of the previous three), all scaled by total number of shares outstanding, and estimate two models for each dependent variable, one including total options and the other including new options, existing exercisable options, and existing unexercisable options. We also use both contemporaneous as well as lagged values of options in our main tests.

Keywords: CEO stock options, Analysts' forecast accuracy, Analysts' forecast bias, CEO compensation, Agency costs, Investment risk taking, Effort allocation, Opportunistic earnings management, Opportunistic disclosure management, Forecasting complexity

Chapter 98: Option Pricing and Hedging Performance Under Stochastic Volatility and Stochastic Interest Rates

This chapter fills this gap by first developing an implementable option model in closed form that admits both stochastic volatility and stochastic interest rates and that is parsimonious in the number of parameters. Based on the model, both delta-neutral and single-instrument minimum variance hedging strategies are derived analytically. Using S&P 500 option prices, we then compare the pricing and hedging performance of this model with that of three existing ones that, respectively, allow for (i) constant volatility and constant interest rates (the Black-Scholes), (ii) constant volatility but stochastic interest rates, and (iii) stochastic volatility but constant interest rates. Overall, incorporating stochastic volatility and stochastic interest rates produces the best performance in pricing and hedging, with the remaining pricing and hedging errors no longer systematically related to contract features. The second performer in the horse-race is the stochastic volatility model, followed by the stochastic interest rates model and then by the Black-Scholes.

Keywords: Stock option pricing, Stochastic volatility, Stochastic interest rates, Hedge ratios, Hedging, Pricing performance, and Hedging performance

Chapter 99: The Le Châtelier Principle of the Capital Market Equilibrium

This chapter purports to provide a theoretical underpinning for the problem of the Investment Company Act. The theory of the Le Chatelier Principle is well known in thermodynamics: The system tends to adjust itself to a new equilibrium as far as possible. In capital market equilibrium, added constraints on portfolio investment in each stock can lead to inefficiency manifested in the right-shifting efficiency frontier. According to the empirical study, the potential loss can amount to millions of dollars coupled with a higher risk-free rate and greater transaction and information costs.

Keywords: Markowitz model, Efficient frontiers, With constraints, Without constraints, Le Chatelier principle, Thermodynamics, Capital market equilibrium, Diversified mutual funds, Quadratic programming, Investment company act

Experience, Information Asymmetry, and Rational Forecast Bias

2

April Knill, Kristina L. Minnick, and Ali Nejadmalayeri

Contents

Abstract

We use a Bayesian model of updating forecasts in which the bias in forecast endogenously determines how the forecaster's own estimates weigh into the posterior beliefs. Our model predicts a concave relationship between accuracy in forecast and posterior weight that is put on the forecaster's self-assessment.

We then use a panel regression to test our analytical findings and find that an analyst's experience is indeed concavely related to the forecast error.

This study examines whether it is ever rational for analysts to post biased estimates and how information asymmetry and analyst experience factor into the decision. Using a construct where analysts wish to minimize their forecasting error, we model forecasted earnings when analysts combine private information with consensus estimates to determine the optimal forecast bias, i.e., the deviation from the consensus. We show that the analyst's rational bias increases with information asymmetry, but is concavely related with experience. Novice analysts post estimates similar to the consensus but as they become more experienced and develop private information channels, their estimates become biased as they deviate from the consensus. Highly seasoned analysts, who have superior analytical skills and valuable relationships, need not post biased forecasts.

Keywords

Financial analysts • Forecast accuracy • Information asymmetry • Forecast bias • Bayesian updating • Panel regressions • Rational bias • Optional bias • Analyst estimation • Analyst experience

2.1 Introduction

Extant evidence suggests an intimate link between an analyst's experience and her forecasting performance. Analysts who are experienced and highly specialized often forecast better than others (Clement and Tse 2005; Bernhardt et al. 2006). One way they do so is by posting an optimistic bias (Mest and Plummer 2003; Gu and Xue 2007). Novice analysts with limited resources tend to herd with others, which results in almost no bias (Bernhardt et al. 2006). In theory, superior forecasters produce better estimates either by resolving information asymmetry or by offering a better assessment. Lim (2001) suggests that analysts can improve forecast accuracy by strategically biasing their forecasts upwards, which placates management, and in essence purchases additional information.[1] Analysts with

[1]Beyer (2008) argues that, even without incentives to appease management, analysts may still post forecasts that exceed median earnings because managers can manipulate earnings upward to prevent falling short of earnings forecasts. Moreover, Conrad et al. (2006) find support for the idea that analysts' "... recommendation changes are "sticky" in one direction, with analysts reluctant to downgrade." Evidence also indicates that analysts rarely post sell recommendations for a stock, suggesting that losing a firm's favor can be viewed as a costly proposition. At the extreme, firms even pursue legal damages for an analyst's unfavorable recommendations. In a 2001 congressional hearing, president and chief executive officer of the Association for Investment Management and Research told the US House of Representatives Committee on Financial Services, Capital Markets Subcommittee, that "...In addition to pressures within their firms, analysts can also be, and have been, pressured by the executives of corporate issuers to issue favorable reports and recommendations. Regulation Fair Disclosure notwithstanding, recent history...has shown that companies retaliate against analysts who issue 'negative'

long histories of examining firms in a particular industry can also offer a unique perspective, and they signal their ability by posting biased estimates to signal superior ability (Bernhardt et al. 2006).

Of course, analysts do not indefinitely and indiscriminately bias forecasts to appease the firm or signal their ability. This is mainly because analysts can learn from the forecasts of other analysts (Chen and Jiang 2006). By incorporating information from other forecasts, analysts can improve the accuracy of their own forecasts without posting biased estimates. The important question then is: given the analyst's own assessment ability and her efficacy in procuring private information versus using consensus information, how should she construct an optimal forecast? Does that optimal forecast ever include bias, and how does information asymmetry affect this decision? We address these questions by analytically and empirically examining how an analyst's experience and information asymmetry affect her forecasting. In so doing, we also account for the role of the consensus estimate in an analyst's forecast. We begin by modeling the problem of optimal forecasting. To be specific, we combine key features of current rational forecasting models by Lim (2001) and Chen and Jiang (2006). As in Chen and Jiang (2006), analysts in our model form rational (i.e., minimum squared error) forecasts by weighing both public and private information.[2] Following Lim (2001), our analysts post rational forecasts that deviate from the consensus to purchase private information from managers. Motivated by Lim (2001) and Bernhardt et al. (2006), we also allow analysts to post biased forecasts because they have more expertise than the consensus. The novelty of our approach is that we directly model how information asymmetry and analyst experience combine to affect the purchase of private information for use in the forecast deviation. We are also able to model how analysts with different levels of experience, i.e., novice, moderately experienced, and highly seasoned analysts, construct their forecast.

We analytically derive the optimal deviation from the consensus as one that minimizes the mean squared error while allowing for rational Bayesian updating based on public and private knowledge. Our analysis shows that even in a rational forecast framework, analysts' forecast deviation depends on the observed consensus deviation of other analysts. When analysts observe others deviating from the consensus (especially those with more experience), they gain enough insight to avoid posting a large deviation themselves. Our results confirm the findings of both Bernhardt et al. (2006) and Chen and Jiang (2006) – that analysts can *rationally* herd. In the presence of the informative consensus, analysts choose to herd with each other, rather than post estimates that are biased.

Our theory suggests that the likelihood of posting biased estimates, conditional on the consensus, is significantly influenced by the analyst's ability to process

recommendations by denying them direct access to company executives and to company-sponsored events that are important research tools. Companies have also sued analysts personally, and their firms, for negative coverage...."

[2]See also Han et al. (2001).

information. Consistent with Hong et al. 2000), we show that novice analysts essentially herd. Without either honed analytical abilities or valuable relationships, these analysts follow the premise that the consensus is more accurate than their own private information. Second, we show that a moderately experienced analyst relies more on her sources inside the firm than her analytical skills. This manifests itself as a biased forecast since she must appease management to tap into those sources. This link between experience and deviation is not monotonic. Highly seasoned analysts do not purchase as much additional information (or they purchase the information at a reduced price), either because they possess superior analytical skills or because their valuable relationships with firms afford them beneficial information without the optimistic forecast. This preferential treatment is akin to that which is afforded to companies in relationship lending with banks (Petersen and Rajan 1994). Indeed, Carey et al. (1998) argue that the relationship lending of banks can also be ascribed to some nonbank financial intermediaries. Although the firms that an analyst covers are not necessarily financial, the same relationship could certainly exist and is based on information asymmetry.

We further demonstrate that as the analyst-firm information asymmetry increases, so does the bias. Similar to the results found in Mest and Plummer (2003), analysts find private channels and analytical ability valuable mitigating factors when faced with information asymmetry. Moderately experienced analysts, who begin to tap into reliable private channels without the valuable relationships that might afford preferential treatment, post larger deviations with the hope of ascertaining better information. This suggests that both information asymmetry and experience interactively affect the way analysts balance public and private information to form forecasts. Our model also shows that the effect of information asymmetry and analyst experience on rational deviation depends on the dispersion of and the correlation between public and private signals. The quality of private information channels, the informativeness of consensus, and the connectedness of public and private signals significantly affect how analysts form forecasts.

To examine the validity of our analytical findings, we empirically investigate how analyst experience and information asymmetry affect forecast deviation from the consensus.[3] Our empirical results confirm our theoretical predictions that rational bias (i.e., deviation from the consensus) is concavely related to analyst experience and positively associated with information asymmetry. Novice analysts and highly seasoned analysts post forecasts with smaller bias, while moderately seasoned analysts post estimates that deviate further from the consensus. Moderately seasoned analysts can benefit from a positive bias if they have the confidence to separate from the herd and access reliable private sources of information.

[3]Clement and Tse (2005) are the closest to our analysis; however while they admit that the observed link between inexperience and herding can be a complex issue that might have other roots than just career concerns, they do not provide detailed insight as to what and how this complexity develops.

These results are stronger for earlier forecasts versus later ones. As analysts become highly seasoned, with external information networks and superior skills in forecasting, they find appeasing management to purchase information less useful (or less costly in the same way that relationship lending affords firms cheaper capital). As one might expect, when information asymmetry increases, rational deviation from the consensus also increases. The degree of information asymmetry faced by seasoned analysts has a significant positive effect on the forecast deviation (information asymmetry also affects novice analysts but not as extensively).

This study contributes to a growing literature on rational bias in analyst forecasting. Motivated by recent works by Bernhardt et al. (2006), Beyer (2008), Chen and Jiang (2006), Lim (2001), and Mest and Plummer (2003), we take an integrated modeling approach to arrive at a rational forecast bias, which is based on Bayesian updating of public consensus and endogenously acquired private information. Our approach is unique in that the forecast bias affects how public and private information are combined. Specifically, analysts can use bias to improve forecast accuracy by purchasing private information but can also learn from other analysts by following the consensus. Our analytical findings, which are empirically confirmed, show that unlike behavioral models, analysts can rationally herd. Unlike signaling models, seasoned analysts do not always post biased estimates. It also shows the value of the relationships that both moderately experienced and highly seasoned analysts leverage to gain reliable private information. These results are of practical interest because they provide evidence that analysts can and may optimally bias their earnings estimates and that this optimal bias differs across both analyst experience and information asymmetry. This knowledge may be useful to brokerage houses for training purposes and/or evaluation of analyst performance, particularly across industries with different levels of information asymmetry.

2.2 Theoretical Design

Recent studies show that earnings forecasts reflect public information and private assessments (Boni and Womack 2006; Chen and Jiang 2006; Lim 2001; Ramnath 2002). As Bernhardt et al. (2006) note, analysts' forecasts of public information partly relate to the consensus, common information, and unanticipated market-wide shocks. We thus model analyst earnings forecasts using two components of earnings information: common and idiosyncratic, with some uncertainty about each component. In doing so, we also assume, as does Lim (2001), that the idiosyncratic component directly relates to the private information analysts can obtain from the firm by posting an optimistic view of the firm's prospects (Nutt et al. 1999). Our typical analyst also observes a previously posted forecast whereby the analyst can learn about both the common and idiosyncratic components of earnings by incorporating previously disclosed information. Since we assume analysts are Bayesians, they can learn from previous forecasts as an alternative to posting a positive deviation to purchase private signals from the firm. Since these prior estimates partially reflect private information, the analysts may heavily weigh them into their assessment, depending on the perceived information asymmetry and experience of the previous analysts.[4]

In this section, we model analyst earnings forecasting in the presence of forecast uncertainty. Following recent studies (Lim 2001; Ramnath 2002), our analyst has an unconditional estimate, $E = X + \varepsilon$, about earnings, $X \sim N(0, \sigma^2)$, with some uncertainty, $\varepsilon \sim N(0, {\tau_e}^{-2})$. As in Chen and Jiang (2006), our analyst also observes a noisy consensus forecast, $E_c = X + \varepsilon_c$, with a consensus uncertainty, $\varepsilon_c \sim N(0, {\tau_c}^{-2})$. As a Bayesian, our analyst forms a conditional forecast, $F = w\,E + (1 - w)\,E_c$, by combining her unconditional estimate with the consensus. The optimal weight in her conditional forecast minimizes her squared forecast error.[5]

As in Lim (2001), the optimal forecasting, however, is endogenous to private information acquisition. Our analyst's forecast precision relates to the private information analysts can obtain from the firm by posting an optimistic view of the firm's prospects. That is to say, while forecast precision, τ_e, consists of a self-accuracy component, τ_0, reflecting the analyst expertise, the forecast precision can be improved by $\tau(b)$ through placating managers by posting positively biased, b, forecasts. The marginal precision per bias, $\partial\tau/\partial b$, reflects the analyst's information asymmetry. This is because an analyst faced with greater information asymmetry should derive a larger marginal benefit from a biased forecast. Since the conditional forecast partially reflects private information, the analyst's optimal rational forecast (and forecast bias) depends on the analyst's expertise and information asymmetry. As noted before, the objective of the analyst is to minimize her squared forecast error, $F - X$:

$$\min_{w|b} \mathbf{E}\left[(F - X)^2\right] = \min_{w|b} \left[(wE + (1 - w)E_c)^2\right] \tag{2.1}$$

where $\mathbf{E}[\bullet]$ is the expectation operator. Let's assume that the analyst's estimate and the consensus are correlated, $\mathbf{E}[\varepsilon, \varepsilon_c] = \rho\ (\tau\ \tau_c)^{-1}$. This correlation reflects the extent to which the analyst uses common private channels. The analyst objective, Eq. 2.1, can be rewritten as

[4]Here, we focus only on the case of one-period sequential forecasting. However, we believe that the main implications of our model hold true for a multi-period sequential forecasting setting. Since we assume that the probabilistic characteristics of different components are known and analysts can gauge each others' experience and the amount of information asymmetry perfectly, there would be no incentive to deviate from posting commensurate optimal, rational forecasts. If expert analysts intentionally deviate from their optimal forecasts, no other analyst can compensate for their experience or information asymmetry [for more discussion, see Trueman (1990)].

[5]For more details on Bayesian methods of inference and decision making, see Winkler (1972).

$$\min_{w|b}\left[w^2(\tau_0+\tau(b))^{-2}+(1-w)^2\tau_c{}^{-2}+2\rho w(1-w)(\tau_0+\tau(b))^{-1}\tau_c^{-1}\right]. \quad (2.2)$$

The optimal weight which solves the aforementioned objective function is

$$w=\frac{(\tau_0+\tau(b))^2-\rho\tau_c(\tau_0+\tau(b))}{(\tau_0+\tau(b))^2+\tau_c^2-2\rho\tau_c(\tau_0+\tau(b))} \quad (2.3)$$

Proposition 1 *Assuming positively biasing forecasts have increasing but diminishing returns*, i.e., $\partial\tau/\partial b > 0$ *and* $\partial^2\tau/\partial b^2 < 0$, *the optimal weight on analyst's own unconditional estimate is concavely related to the analyst's expertise* (i.e., *self-accuracy*, τ_0). *For analysts with self-accuracy less* (*more*) *than* $-\tau(b)+0.5\ \rho^{-1}\ \tau_c$, *the optimal weight on the analyst's own unconditional estimate increases* (*decreases*) *with the expertise. At the optimal weight*, *the analyst's conditional precision*, $\tau_0+\tau(b)$, *equals* $0.5\ \rho^{-1}\ \tau_c$.

Proof See the Appendix 1.

As the analyst's expertise, τ_0, increases, her unconditional estimate precision rises relative to the consensus estimate precision. The analyst would then gain more accuracy by placing more weight on her own assessment, consistent with the findings of Chen and Jiang (2006). Forecast bias, however, affects how the analyst's own unconditional estimate weighs into the optimal forecast. As forecast bias increases, the analyst relies more on her own assessment because larger bias improves precision through more privately acquired information. However, this reliance on private information is limited. When the precision of private information reaches a certain limit, $0.5\ \rho^{-1}\ \tau_c$, the analyst starts to reduce her reliance on her own assessment. Since the consensus contains information, an analyst does not need to rely solely on private information to improve her overall accuracy.

Interestingly, the threshold on the reliance of private information is inversely related to the correlation between analyst's own and consensus precisions. When the signals from the consensus and analyst are highly correlated, the analyst need not post largely biased forecasts to improve her accuracy. At low correlations, however, the analyst almost exclusively relies on her own assessment and uses private channels heavily by posting biased forecasts. As Mest and Plummer (2003) show, when uncertainty about the company is high, management becomes a more important source of information. This confirms Bernhardt et al. (2006) contention that signal "correlatedness" affects analyst forecasting.

Proposition 1 has an interesting testable implication. As noted, following previous studies (Lim 2001; Chen and Jiang 2006), our analysts minimize the squared error to arrive at the optimal bias. In a cross section of analysts, this implies that as long as all analysts follow the squared-error-minimization rule, then the implication of Proposition 1 holds empirically: there would be a concave relation between experience and the weight an analyst places on her own unconditional assessment. However, since the weighted average of self-assessment and consensus belief is theoretically identical with forecast error, this then also implies that in the cross section, analysts' forecast errors and their experience are also related concavely.

Note that our analysts choose how to combine their own unconditional forecast and the consensus forecast to arrive at their reported forecast. They do so by accounting for the inherent error in each of these forecasts and choose a weight that minimizes the squared forecast error: the difference between reported forecast (i.e., conditional forecast) and the observed earnings. So for a novice analyst, the choice is what weight to put on her unconditional forecast knowing that the forecasts reported by other analysts contain much more experience and perhaps less information asymmetry. In the extreme case, where the novice analyst has no confidence on her own assessment, the optimal weight for her unconditional forecast is zero. She will fully herd. A highly seasoned analyst does the same thing: she also chooses the weight she puts on her assessment vis-à-vis consensus. In the alternate extreme case, where the highly seasoned analyst has utmost confidence on her assessment, she puts 100 % weight on her unconditional forecast. Moderately seasoned analysts thus fall somewhere in between; the weight they put on their own unconditional forecasts is between zero and one. In such a setting, all analysts arrive at their own squared-error-minimizing forecast. From the onset, however, as econometricians, we can only observe their reported conditional forecast. This means that we can only focus on the implication of analyst squared-error-minimizing exploiting cross-sectional differences in the data. As noted, the observed error is equal to the weighted average of unconditional forecast and the consensus belief. This implies that observed error is directly linked with the unobservable weight. However from Proposition 1, we know that the unobservable optimal weight is concavely related to experience, which in turn, implies that, in the cross section of analysts, the observed forecast error is concavely linked with the experience as well.

Proposition 2 *Assuming positively biasing forecasts have increasing but diminishing returns*, i.e., $\partial\tau/\partial b > 0$ *and* $\partial^2\tau/\partial b^2 < 0$, *the optimal weight on an analyst's own unconditional estimate increases monotonically with information asymmetry* (i.e., *the marginal accuracy for bias*, $\partial\tau/\partial b$).

Proof See the Appendix 1.

As the efficacy of the analyst's private information acquisition increases, that is, as $\partial\tau/\partial b$ rises, the analyst gains more precision with every cent of bias. More resourceful analysts, such as those employed by large investment houses, either have better private channels or can gain more from the same channels (see, e.g., Chen and Jiang 2006; Clement and Tse 2005). As such, these analysts' estimates become more accurate more rapidly as they bias their forecasts to purchase information from the firm. From proposition 1, we know that at the optimal weight, the sum of the analyst's own estimate and consensus precision is constant.

As information asymmetry increases, i.e., marginal precision per bias rises, a larger bias is needed to obtain the optimal weight of the analyst's estimate and the consensus. Interestingly, as an analyst becomes more experienced, her optimal weight on her own estimate becomes less sensitive to information asymmetry.

2.3 Empirical Method

We empirically test selected comparative statics to draw conclusions about the validity of our analytical results. We focus our attention on analytical predictions that result directly from the endogeneity of private information acquisition. Specifically, we test three of our model's implications: (1) whether analyst experience and forecast deviation are concavely related, (2) whether information asymmetry and analyst forecast deviation are positively related, and (3) whether there is interplay between the effects of experience and information asymmetry. We follow Chen and Jiang (2006) and empirically define bias as the difference between an analyst's forecast and the consensus estimate. We calculate consensus using only the most recent estimate from each analyst and include only those estimates that are less than 90 days old (Lim 2001).

We first examine the impact of analyst experience on forecast deviation. As analysts become more experienced, they post a more positive (i.e., increasing) deviation to improve their information gathering, resulting in better forecasts. Proposition 1 from the theoretical model suggests that this relationship is nonlinear. Highly seasoned analysts achieve forecast accuracy on their own without relying on procured information, or they possess valuable relationship with management that does not necessitate purchasing information, causing this nonlinearity. Empirically, we expect the relationship between deviation and experience to be concave (i.e., a positive coefficient on experience and a negative coefficient on experience squared). To test our contentions, we estimate the following OLS panel regression:

$$\begin{aligned}\mathrm{DFC}_{i,t} = {} & \alpha_0 + \eta_0\,\mathrm{Experience}_{i,t} + \eta_1\,\mathrm{Experience}_{i,t}{}^2 + \beta_0\,\mathrm{Num\ Revisions}_{i,t} \\ & + \beta_1\mathrm{Same\ Quarter}_{i,t} + \beta_2\,\mathrm{Reg.FD}_{i,t} + \boldsymbol{\Phi}_0\mathbf{X}_{t-4} + \boldsymbol{\Phi}_1\mathbf{I} + \boldsymbol{\Phi}_2\mathbf{t} + \varepsilon,\end{aligned} \tag{2.4}$$

where DFC is the Deviation from the consensus for analyst i in quarter t. We have several analyst-specific controls: Experience, Experience squared, and the NumRevisions. Following our analytical model, analysts with more experience should be better at forecasting earnings and should have better channels of private information. Following Leone and Wu (2007), we measure Experience in two ways: using an absolute measure (the natural log of the quarters of experience) and a relative measure (the natural log of the quarters of experience divided by the average of this measure for analysts following firms in the same industry). We include Experience^2 to test for a nonlinear relationship between Deviation and Experience. To control for varying degrees of accuracy due to intertemporal Bayesian updating, we include NumRevisions, which is the number of times the analyst revises her estimate. Studies such as Givoly and Lakonishok (1979) suggest that information has been acquired (i.e., purchased). This suggests a positive relationship between the number of revisions and the resulting deviation; thus we expect the coefficient, β_0, to be positive. Same quarter is an indicator variable for horizon value, where the variable is equal to one if the estimate occurs in the same quarter as the actual earnings report is released and zero otherwise. Including Same quarter can help us understand whether analysts are more likely to be optimistic early in the period than late in the period (Mikhail et al. 1997; Clement 1999; Clement and Tse 2005).[6] We expect the coefficient on this variable, β_1, to be negative. Reg. *FD* is an indicator variable equal to one if the quarter date is after Reg. FD was passed (October 23, 2000), and zero otherwise.[7] Although extant literature is divided on whether or not Reg. FD has decreased the information asymmetry for analysts, if information asymmetry is decreased and more public information available, analysts will be less likely to purchase private information, and the coefficient on Reg. FD, β_2, would be negative. Indeed, Zitzewitz (2002) shows that although private information has decreased post Reg. FD, the amount of public information has improved. Both Brown et al. (2004) and Irani (2004) show that information asymmetry decreased following Reg. FD.[8]

We control for firm effects through the inclusion of firm-specific variables such as Brokerage reputation, Brokerage size, Accruals, Intangible assets, and Return st. dev. (vector X in Eq. 2.4). Following Barber et al. (2000), we use the number of companies a brokerage house follows per year in total as a proxy for brokerage size. Brokerage house reputation may play an integral role in accessing to private information (Agrawal and Chen 2012). To calculate broker reputation, we start with the Carter and Manaster (1990), Carter et al. (1998) and the Loughran and Ritter (2004) rankings. When a firm goes public, the prospectus lists all of the firms that are in the syndicate, along with their shares. More prestigious underwriters are listed higher in the underwriting section. Based upon where the underwriting brokerage firm is listed, they are assigned a value of 0–9, where nine is the highest ranking. As Carter and Manaster (1990) suggest that prestigious financial institutions provide a lower level of risk (i.e., lower information asymmetry), we include control variables for these characteristics of the firm and expect the relationships to be negative.[9]

---

[6]Horizon value and the NumRevisions are highly correlated at 65 %. We therefore orthogonalize horizon value in the equation to ensure that multicollinearity is not a problem between these two variables.

[7]http://www.sec.gov/rules/final/33-7881.htm.

[8]See Lin and Yang (2010) for a study of how Reg. FD affects analyst forecasts of restructuring firms.

[9]Brokerage reputation and Brokerage size are highly correlated at 67 %. We therefore orthogonalize brokerage reputation in the equation to ensure that multicollinearity is not a problem between these two variables.

As suggested by Bannister and Newman (1996) and Dechow et al. (1998), companies that consistently manage their earnings are easier to forecast. We include Accruals (in $ millions) to control for the possibility that earnings are easier to forecast for companies that manage their earnings, resulting in less information "bought" from the company.[10] We expect the coefficient on this control variable to be negative. We include Intangible assets based on the fact that companies with greater levels of intangible assets are more difficult to forecast based on uncertainty of future performance (Hirschey and Richardson 2004).[11] Thus, we expect the coefficient to be positive. We include Return standard deviation to proxy for firm risk. More volatile firms are less likely to voluntarily issue public disclosures, making it necessary for analysts to purchase private information (Waymire 1986). The standard deviation is defined as the monthly standard deviation of stock returns over a calendar year. All firm-level variables are lagged one year (i.e., four quarters). We include both industry (one-digit SIC code) and time indicators to control for industries/times where it is easier to forecast (see Kwon (2002) and Hsu and Chiao (2010), e.g., to see how analyst accuracy differs across industry).[12] Finally, a formal fixed effects treatment around analysts is taken to ensure that standard errors are not understated.

Our theoretical analysis also examines the effect of information asymmetry on forecast deviation. In an environment with high information asymmetry, analysts without adequate, reliable resources need to post a positive deviation to access information, as shown in Proposition 2. We expect a positive coefficient on Information asymmetry. We test this relationship by estimating the following OLS panel regression:

$$\begin{aligned}\mathrm{DFC}_{\mathrm{i,t}} = {} & \alpha_0 + \lambda_0\,\text{Information Asymmetry}_{i,t} + \beta_0\,\text{Num Revisions}_{\mathrm{i,t}} + \beta_1\,\text{Same Quarter}_{\mathrm{i,t}} \\ & + \beta_2\,\text{Reg.FD}_{\mathrm{i,t}} + \boldsymbol{\Phi}_0\mathbf{X}_{t-4} + \boldsymbol{\Phi}_1\mathbf{I} + \boldsymbol{\Phi}_2\mathbf{t} + \varepsilon,\end{aligned} \tag{2.5}$$

where t is the quarter in which we measure deviation and i denotes the ith analyst. We define Information asymmetry three different ways: (1) the inverse of analyst coverage, i.e., 1/(number of brokerage houses following the firm), (2) the standard deviation of the company's forecasts ($\times 10^2$), and (3) the relative firm size, i.e., the difference between the firm's assets and the quarterly median assets for the industry. These definitions are constructed such that the direction of the expected marginal coefficient is congruent with that of information asymmetry.

[10]Following Stangeland and Zheng (2007), we measure Accruals as income before extraordinary items (Data #237) minus cash flow from operations, where cash flow from operations is defined as net cash flow from operating activities (Data #308) minus extraordinary items and discontinued operations (Data #124).

[11]Following Hirschey and Richardson (2004), we calculate Intangibles as intangible assets to total assets (Data 33/Data #6).

[12]As an alternate proxy for industry fixed effects, Fama-French 12-industry classifications (Fama and French 1997) are used. Results using these proxies are available upon request.

The first definition, the inverse of analyst coverage, is based on evidence that the level of financial analyst coverage affects how efficiently the market processes information (Bhattacharya 2001). Analyst coverage proxies for the amount of public and private information available for a firm and, therefore, captures a firm's information environment (Zhang 2006). The second definition, Forecast dispersion, is supported in papers such as Krishnaswami and Subramaniam (1998) and Thomas (2002), among others. Lastly, we use Relative firm size as a proxy for information asymmetry. This is equally supported by the literature, including but not limited to Petersen and Rajan (1994) and Sufi (2007). The firm-specific control variables are the same as in Eq. 2.4, and a fixed effects treatment around analysts is taken.

As previously explained, our model allows for the interaction of experience and information asymmetry; the concavity of the relationship between experience and Deviation may change at different levels of information asymmetry. Thus, we estimate Eq. 2.4 for analysts with both high and low levels of information asymmetry (i.e., based on relation to the industry-quarter median forecast dispersion). We expect the coefficients on Experience and Experience squared to increase when there is more information asymmetry.

Similarly, we demonstrate that experience affects the link between information asymmetry and deviation. While the deviation of the novice and highly seasoned analysts is only marginally affected by information asymmetry, the deviation of the moderately experienced analyst is highly affected by information asymmetry. Since Proposition 2 suggests that information asymmetry will affect analysts differently based on their experience, we segment our sample into three groups: novice, moderately experienced, and highly seasoned analysts. To form these experience groups, we create quarterly terciles of analysts based on their experience. The bottom third comprises the novice analysts; the middle third, moderately seasoned analysts; and the top third, highly seasoned analysts. We examine the model in Eq. 2.5 separately for our three experience subsamples. The coefficient on information asymmetry should be larger for experienced analysts.

It is possible that a resolution of idiosyncratic uncertainty makes deviation insensitive to both analyst experience and information asymmetry. Regulations such as Reg. FD were enacted to reduce the uncertainty around companies (De Jong and Apilado 2008). If Reg. FD reduced firm-specific uncertainty more than common uncertainty, then the coefficients on Experience, Experience squared, and information asymmetry should be smaller after Reg. FD. In other words, if Reg. FD was effective in "leveling the playing field" for analysts with regard to preferential treatment of some analysts over others, the implications of this model should no longer exist.

Extant evidence suggests that by prohibiting exclusive private communication of pertinent information, Reg. FD would cause overall earnings uncertainty to decline (Baily et al. 2003). In Eqs. 2.4 and 2.5, we simply control for any effect that Reg. FD might have. By using interactive terms, however, we can explore this relationship more fully by offering a comparison of the relationship between Experience/ Information asymmetry and Deviation both with and without Reg. FD. If most of the decrease in uncertainty comes from improving the common component of earnings (or equivalently, reducing the amount of private information), then the enactment of Reg. FD should make any remaining private information even more valuable and should lead to an increase in the importance of information asymmetry on deviation. Further, this effect should be disparate based on analyst experience. Specifically, experienced analysts (moderately experienced more so than highly seasoned) should see a drop in their deviation from consensus based on an increase in information asymmetry since their private information is no longer quite so private, i.e., there is less information to buy. Novice analysts, on the other hand, will likely be relatively unaffected since they depend mostly on consensus anyway. In short, since the intent of the regulation is to even the playing field for analysts, the effect of Reg. FD on the impact of experience could be a reduction in its importance. This would especially be the case with relative experience. If Reg. FD achieved what it set out to achieve, we should see a reduction (i.e., flattening) of the concavity of the experience relationship with deviation from consensus.

2.4 Data

Consistent with Brown and Sivakumar (2003) and Doyle et al. (2003), we define earnings as the First Call reported actual earnings per share.[13] Our sample includes companies based in the United States with at least two analysts, consists of 266,708 analyst-firm-quarter forecasts from 1995 to 2007, and includes all analysts' revisions. Variables are winsorized at the 1 % level to ensure that results are not biased by outliers.

First Call data is well suited for examining analyst revisions because most of the analysts' estimates in the data have the date that they were published by the broker. These revisions are reflected daily, which aids in understanding the changes in deviation based on changes in the information environment. One limitation with First Call data is that it identifies only brokerage houses, not individual analysts. Following Leone and Wu (2007), we make the assumption that for each firm quarter there is only one analyst in each brokerage house following the firm. It is noteworthy that this biases our study against finding a nonlinear impact for analyst's experience.

Panel A of Table 2.1 shows the summary statistics of the variables used in our analysis. The average Deviation from the consensus is 5.16¢. However, there is wide dispersion, from −54.67¢ to 112.50¢, as compared to an average Forecast error of −3.79¢, with a range of −131–72¢. The analysts in our sample have on average 12.71 quarters of Experience (the most experienced analyst has 13 years experience, and the least experienced analyst has no prior experience following the firm). Analysts revise their estimates 2.49 times per quarter. The companies they

[13]As a robustness test, we use I/B/E/S data. Results may be found in Appendix 2.

Table 2.1 Data characteristics

Panel A. Summary statistics

Analyst information comes from First Call for the term 1995–2007. Company information comes from Compustat/CRSP. DFC is the bias, defined as the difference between an analyst's forecast and the consensus estimate, where we calculate consensus using only the most recent estimate from each analyst and include only those estimates that are less than 90 days old. Quarters follow is the number of quarters a brokerage firm has been following a company. Experience is the natural log of the quarters of experience. Relative experience is the natural log of the quarters of experience divided by the average of this measure for analysts following firms in the same industry. Analyst coverage^{-1} is equal to 1/(number of brokerage houses following the firm), and forecast dispersion is the standard deviation of the company's forecasts ($\times 10^2$). Relative firm size is the difference between the firm's assets and the quarterly median assets for the industry. Forecast error is the difference between the estimate and the actual earnings. Same quarter is a dummy variable equal to one if the estimate is in the same quarter as the actual and zero otherwise. Brokerage reputation is a ranking of brokerage reputation, where 0 is the worst and 9 is the best. Brokerage size is the natural log of the number of companies per quarter a brokerage house follows. Reg. FD is an indicator variable that takes on a value of 1 if Reg. FD is in effect and 0 otherwise. NumRevisions is the total number of revisions the analyst made during the quarter for the quarter-end earnings. Accruals are income before extraordinary items minus cash flow from operations, where cash flow from operations is defined as net cash flow from operating activities minus extraordinary items and discontinued operations. Intangible assets are intangible assets to total assets. Return std. dev. is the standard deviation of the 12-month returns. Panel A shows the univariate statistics and Panel B shows the pairwise correlations

Asterisks in Panel A represent statistical significance relative to zero

Bolded numbers in Panel B represent 5 % or 1 % significance follow have a Return standard deviation of 13 %, Intangibles of 14 %, and Accruals of −$0.44 (in millions) on average.

Panel B of Table 2.1 shows the correlation matrix for the variables used in the analysis. There exists notable significant relation in the variables: Forecast error and Experience with Deviation from consensus. The relation actually foreshadows one of the main results of the paper, which is that private information can be used to decrease forecast error. The correlation found in this table, −0.89, is not a problem econometrically because fitted values are used in the specification found in Table 2.5. The only other correlations that would be considered a problem econometrically are for variables not used in the same specification, i.e., Experience and Relative experience.

2.5 Empirical Findings

Table 2.2 presents the results of our estimation from Eq. 2.4, which examines how analyst experience affects analyst deviation from the consensus. The coefficients on our control variables all exhibit the expected signs. There is a negative relation between the horizon value (Same quarter) and Deviation, which suggests that analysts are more likely to be optimistic early in the period than late in the period. Supporting the contentions of Carter and Manaster (1990), there is a negative relationship between the brokerage characteristics – Reputation and Size – with Deviation. There is also a negative relationship between Reg. FD and Deviation, suggesting that the enactment of Reg. FD and its mandatory indiscriminant information revelation have made forecasting easier. NumRevisions is positively related to Deviation; revisions are made when valuable information content is received (Givoly and Lakonishok 1979), suggesting that private information is paid for through incremental deviation of their forecasts over time. We find that higher Accruals lead to less deviation from the consensus. Firms who actively manage earnings make forecasting easier; thus analysts do not have to purchase private information. The positive sign on Intangible assets is expected as more intangible assets make forecasting more difficult, necessitating the procurement of private information. Finally, as the standard deviation of Returns increases, future firm performance is more difficult to predict.

Turning to our variables of interest, we find that there is a highly significant positive relationship between Experience and Deviation, as evidenced by a 0.829¢ increase in deviation for every additional unit of experience (specification 1) and a 0.581¢ increase in deviation for every additional unit of relative experience (specification 2).[14] The results in specifications (3) and (4) confirm our contention that this relationship is not linear. The squared Experience variable

[14]Inasmuch as the Experience variable is transformed using the natural logarithm, one unit of experience is approximately equal to two quarters of experience. For tractability, we refer to this as a unit in the empirical results.

Table 2.2 presents the results of our estimation from Eq. 2.4. Experience is the natural log of the number of quarters the analyst has followed the firm for which forecast error is calculated. Relative experience is the analyst experience scaled by the average analyst experience (same industry). Information asymmetry (IA) is proxied based on the forecast dispersion – the standard deviation of estimates. Same quarter is a dummy variable equal to one if the estimate is in the same quarter as the actual and zero otherwise. Same quarter is orthogonalized (on NumRevisions) to ensure that multicollinearity is not a problem between these two variables. NumRevisions is the total number of revisions the analyst made during the quarter for the quarter-end earnings. Reg. FD is an indicator variable that takes on a value of 1 if Reg. FD is in effect and 0 otherwise. X is a vector of firm-specific variables including Broker reputation, Broker size, Accruals, Intang. assets, and Return std dev. Brokerage reputation is a ranking of brokerage reputation, where 0 is the worst and 9 is the best. Brokerage size is the natural log of the number of companies per quarter a Brokerage house follows. Brokerage reputation is orthogonalized (on brokerage size) to ensure that multicollinearity is not a problem between these two variables. Accruals are the accrued revenue/liabilities utilized for earnings smoothing. Intang. assets are the covered firm's intangible assets value relative to its total assets. Return std. dev. is the standard deviation of the covered firm's return. I is a vector of one-digit SIC industry dummies. T is a vector of time dummies. A formal fixed effects treatment around analysts is employed. Standard errors are reported in brackets

*, **, and *** indicate significance levels of 10 %, 5 %, and 1 %, respectively (two-tailed test). In columns 1–4 we use the full sample. In columns 5–8, we use the median value of horizon value to divide the firms into early (columns 5–6) and late estimates (7–8) groups to perform the analysis. In columns 9–12, we use the median value of forecast dispersion to divide the firms into low information asymmetry (columns 9–10) and high information asymmetry (11–12) groups to perform the analysis (both definitions) is significantly and negatively related to Deviation (−0.595¢ in specification 3 for Experience and −1.735¢ in specification 4 for Relative experience). Confirming the analytical results, the empirical results suggest that there exists a trade-off between public and private information. The results suggest that when analysts first begin to follow a firm and gain experience, they are more likely to post small deviations, indicating that they weigh public information (i.e., previous forecasts and the consensus), more heavily than private information. A possible explanation is that they have not yet acquired the preferred access to information that long-term relationships afford experienced analysts or the analytical expertise to wade through noisy information. As analysts gain confidence in their analytical ability and relationships with key personnel within the firm, however, they are more likely to post large deviations to gain private information. Highly seasoned analysts put almost no weight on the consensus in creating their earnings forecasts and rely almost exclusively on their own private information. This information costs them very little, either because they have honed their analytical ability so well that they don't need the information or because the cost of said information is reduced due to their preferential relationship with the firm.

If our hypotheses are true, we would expect that analysts are more optimistic early in the period and less so (and perhaps even pessimistic) later in the period (shortly before earnings are announced).[15] In order to test this, we segment our sample by the median horizon value into two categories, early estimates (i.e., longer horizon) and late estimates (i.e., shorter horizon). The results are substantially stronger for earlier estimates as compared to late estimates. The coefficient on the Experience variable is 6.751 when the horizon value in long and 1.945 when there is a short horizon value (specification 5 vs. 7). The coefficients on the squared Experience variable are also more extreme for the earlier analysts (−1.341 vs. −0.360), showing that the concavity of the function is more pronounced early in the forecasting period and less so later. This pronounced concavity suggests that the distinction between moderately experienced analysts and novice/highly experienced analysts is more pronounced earlier in the estimation period. Essentially, for every additional quarter of experience, there is a 5.410¢ increase in deviation when horizon is long and a 1.585¢ increase in deviation when horizon is short. Results for Relative experience are qualitatively identical, albeit with a reduced difference between early and late. Results are qualitatively identical when we divide horizon into terciles and define early as the highest quartile and late as the lowest. We can conclude from these results that analysts are indeed more optimistic earlier in the estimation period.

Next, we rerun the model in Eq. 2.4 on low and high information asymmetry subsamples (using forecast dispersion and segmenting at the median), shown in Table 2.2, columns 9–12. As Proposition 2 suggests, the empirical results indicate that the impact of experience on optimal deviation is smaller for analysts when information asymmetry is low. One additional quarter of Experience increases the

[15]We are grateful to an anonymous referee for this point.

analyst deviation by 0.950¢ (specification 9) in a low information asymmetry environment versus 4.745¢ (specification 11) in a high information asymmetry environment. One additional unit of Relative experience increases the analyst Deviation by 1.781¢ (specification 10) in a low information asymmetry environment versus 5.572¢ (specification 12) in a high information asymmetry environment. We note once again that this relationship is not linear, as evidenced by the statistically significant negative squared term. This implies that moderately experienced analysts post higher deviations from consensus than do their less and more experienced colleagues.

Table 2.3 provides alternate specifications around the Reg. FD control variable. Specifications (1) through (4) exclude the Reg. FD control to ensure that results are not reliant on its inclusion. Overall, results from Table 2.2 remain consistent. That said, we note that Relative experience in Specification (2) is no longer statistically significant. The substantiation of the nonlinearity of this proxy for Experience in Specification (4), albeit muted, suggests that this is likely due to the fact that we are no longer controlling for the impact of Reg. FD on the deviation from consensus, which we would expect would affect Relative Experience more so than experience (i.e., no longer benefitting highly seasoned analysts for the preferred relationships through better access to information) through the concavity of the function. In other words, without controlling for Reg. FD independently, the "average" impact of the proxy (i.e., before and after Reg. FD) is muted.

Specifications (4) through (8) explore further the effect Reg. FD has on the relationship between Experience and Deviation. We first note that the nonlinearity of the relationship between Experience and forecast deviation (Deviation) is intact, indicating that leveling the playing field through Reg. FD has not (completely) changed how forecasts are fundamentally linked with the information. Focusing on the more potent results, we look to the Relative experience results (Specifications 7 and 8), and we note that Reg. FD *is* effective in reducing the private information component, which in turn reduces the importance of relative experience. Empirically, this translates into a reduction in the concavity of the impact of Relative experience; the "leveling of the playing field" flattens out that curve. We see this in the Reg. FD interaction terms: specifically, a positive and significant marginal effect on (Reg. FD * Relative experience) and negative and significant marginal effect on (Reg. FD * Relative experience^2). More concretely stated, when access to private information is reduced, the relationship-based competitive advantage of relative experience – preferential access to private information – is taken away.

These results highlight a distinction between precision and the value of preferential relationships between veteran analysts and management of the firm. Since all analysts gain analytical expertise over time following the firm (though the marginal effect of this would seem to wane for the most experienced, thus explaining the maintained nonlinearity), but only some may gain preferential treatment by the firm, one could argue that Experience is a better proxy for analytical precision from the model and Relative experience is a better proxy for the preferential treatment provided to veteran analysts that possess valuable relationships with top management of the firms they are covering (i.e., management will provide private

Table 2.3 provides alternate specifications around the Reg. FD control variable. Experience is the natural log of the number of quarters the analyst has followed the firm for which forecast error is calculated. Relative experience is the analyst experience scaled by the average analyst experience (same industry). Reg. FD is an indicator variable that takes on a value of 1 if Reg. FD is in effect and 0 otherwise. Control variables included in the analysis but not shown above include same quarter, NumRevisions, Reg. FD, Broker reputation, Broker size, Accruals, Intang. assets, and Return std. dev. Same quarter is a dummy variable equal to one if the estimate is in the same quarter as the actual and zero otherwise. Same quarter is orthogonalized (on NumRevisions) to ensure that multicollinearity is not a problem between these two variables. NumRevisions is the total number of revisions the analyst made during the quarter for the quarter-end earnings. Brokerage reputation is a ranking of Brokerage reputation, where 0 is the worst and 9 is the best. Brokerage size is the natural log of the number of companies per quarter a brokerage house follows. Brokerage reputation is orthogonalized (on brokerage size) to ensure that multicollinearity is not a problem between these two variables. Accruals are the accrued revenue/liabilities utilized for earnings smoothing. Intang. assets are the covered firm's intangible assets value relative to its total assets. Return standard deviation is the standard deviation of the covered firm's return. I is a vector of one-digit SIC industry dummies. T is a vector of time dummies. A formal fixed effects treatment around analysts is employed. Standard errors are reported in brackets

*, **, and *** indicate significance levels of 10 %, 5 %, and 1 %, respectively (two-tailed test) information to only analysts with the oldest relationships). In short, Reg. FD reduces the importance of the competitive advantage of preferential treatment (proxied by Relative experience) while retaining the importance of analytical ability (proxied by Experience). This is seen empirically in the insignificant change in concavity of Experience and a decrease in the concavity of Relative experience. In this light, we see that the impact of Reg. FD is what we would expect, both with regard to Experience (seen in Specifications 5 and 6) and Relative experience.

Panel A of Table 2.4 shows the results of Eq. 2.5, which examines directly how Information asymmetry affects Deviation, controlling for firm, analyst, and regulatory factors. Specifications (1) through (3) look at the effects of Information asymmetry on the full sample of analysts, using the inverse of Analyst coverage, Forecast dispersion, and Relative firm size, respectively. The first proxy (specification 1) is the inverse of Analyst coverage. As predicted in the theoretical section, Information asymmetry is positively related to Deviation. With fewer resources at their disposal, analysts post greater deviations as a means to purchase private information. This supplements the marginally valuable public information available, leading to more accurate forecasts. When information asymmetry is measured by Analyst coverage, a unit increase in the information asymmetry measure leads to a 0.630¢ additional Deviation. When using Forecast dispersion as the proxy, a one-unit increase in the information asymmetry measure leads to a 0.630¢ increase in Deviation. Lastly, using Relative firm size as the proxy for information asymmetry, a one-unit increase in the information asymmetry measure leads to 0.006¢ additional Deviation. From the multivariate analysis, it is evident that Forecast dispersion is the best proxy for Deviation from the consensus. The specifications where information asymmetry is proxied by Forecast dispersion have approximately two times the predictive power of the analyst coverage and size proxy (R-Squared of 0.15 vs. 0.06 and 0.08, respectively).

In specifications (4)–(6) of Table 2.4, we include indicator variables for the three experience terciles (suppressing the constant term in the model) to examine whether information asymmetry affects analysts in a different manner based on experience. We first note that the marginal effect on Information asymmetry remains positive as in the first three specifications. Looking to the marginal effect of novice analysts – the least experienced third of analysts in a given quarter – they find sticking closer to the herd a better alternative (Zhou and Lai 2009). The cost of acquiring precise information for an inexperienced analyst who lacks necessary resources would be prohibitively large, i.e., the analyst would need to post an outrageously optimistic (positively deviated) forecast. The marginal effect on moderately experienced analysts – the middle third in experience in a given quarter – suggests that they post deviations that are more positive than the average analyst in an effort to purchase valuable private information. The marginal effect for the tercile of highly seasoned analysts suggests that they post a deviation with a smaller magnitude. This nonlinear relationship exists regardless of the proxy for information asymmetry. Controlling for the information asymmetry in the estimation environment, these results fall in line with our prediction of nonlinearity for Experience and our conjecture that highly seasoned analysts possess both superior

Table 2.4 (continued)

Panel B: Experience subsamples			
Dependent variable = DFC (deviation from consensus)			
Information asymmetry=	Coverage	Forecast dispersion	Relative firm size
	1	2	3
Novice = Moderate?	2,780***	7,709***	2,421***
Moderate = Highly seasoned?	1,978***	5,862***	3,742***

Table 2.4 shows the results of Eq. 2.5. We create three groups of experience: the bottom third is the novice analysts, the middle third are the moderately seasoned analysts, and the top third are the highly seasoned analysts. Information asymmetry is defined in three ways: Analyst coverage^{-1}, Forecast dispersion, and Relative firm size. Analyst coverage^{-1} is the inverse of the number of analyst covering the firm. Forecast dispersion is the standard deviation of estimates. Relative firm size is equal to the covered firm size minus industry-quarter median firm size (in $billions). Control variables included in the analysis but not shown above include Same quarter, NumRevisions, Reg. FD, Broker reputation, Broker size, Accruals, Intang. assets, and Return std. dev. Same quarter is a dummy variable equal to one if the estimate is in the same quarter as the actual and zero otherwise. Same quarter is orthogonalized (on NumRevisions) to ensure that multicollinearity is not a problem between these two variables. NumRevisions is the total number of revisions the analyst made during the quarter for the quarter-end earnings. Brokerage reputation is a ranking of brokerage reputation, where 0 is the worst and 9 is the best. Brokerage size is the natural log of the number of companies per quarter a brokerage house follows. Brokerage reputation is orthogonalized (on brokerage size) to ensure that multicollinearity is not a problem between these two variables. Accruals are the accrued revenue/liabilities utilized for earnings smoothing. Intang. assets are the covered firm's intangible assets value relative to its total assets. Return standard deviation is the standard deviation of the covered firm's return. I is a vector of one-digit SIC industry dummies. T is a vector of time dummies. A formal fixed effects treatment around analysts is employed. Panel A Specifications 1–3 use the full sample and do not suppress the constant. Panel A Specifications 4–6 suppress the constant so we can include the three experience indicator variables. To test whether the coefficients on the experience indicator variables are statistically different, we use a Wald test for significance. Panel B shows the results of the same analysis using experience-based subsamples. We use a Hausman estimation to test whether there is statistical significance between each experience estimation. Standard errors are reported in brackets

*, **, and *** indicate significance levels of 10 %, 5 %, and 1 %, respectively (two-tailed test)

analytical abilities, which would suggest that perhaps they have to purchase less information to achieve precision, and valuation relationships, which allow them to purchase information at reduced "costs" (i.e., deviation from consensus). To ensure that the marginal effects are significantly different, we perform Wald tests to confirm that the differences between the coefficients are statistically significant. As can be seen at the bottom of Panel A, the differences are statistically significant in every case.

In Panel B, we examine experience-based subsamples to see more intricately how experience affects the impact of Information asymmetry on Deviation. Results confirm that Experience affects the link between Information asymmetry and Deviation. The moderately experienced analyst is the most affected by an increase in information asymmetry, regardless of the definition of information asymmetry. It is interesting to note that the results for Analyst coverage and Forecast dispersion are much stronger than Relative firm size. We use a Hausman test of statistical significance and find that the experience estimations are all statistically different.

These empirical results nicely complement the theoretical predictions of our model. Taken collectively, the results suggest that analysts' rational forecast deviation from the consensus is a result of analysts maximizing their objective function of minimizing error while taking into consideration the information environment in which they operate.

To provide evidence that the deviation from the consensus discussed in the rest of the paper is indeed rationale, we test whether an analyst posting an estimate with the optimal deviation from consensus, empirically represented by the fitted value of either Eqs. 2.4 or 2.5, achieves a lower forecast error (defined as estimate minus actual earnings). Here, a negative association between fitted Deviation from consensus (DFC*) and Forecast error (FE) is indicative of optimal forecasting. Chen and Jiang (2006) argue that a positive (negative) association between observed Deviation from consensus (DFC) and Forecast error (FE) is indicative of an analyst overweighting (underweighting) her own assessment. This is because if analysts follow a Bayesian updating rule and minimize squared forecast error, there should be no link between observed deviation from forecast and forecast error. They find that analysts, on average, overweigh their own belief, and thus the link between observed deviation from consensus and forecast error is positive. In this paper, we extend Chen and Jiang's model to allow for rational biasing of forecasts, similar to Lim (2001). As such, we find that there should be a concave relationship between Experience and Deviation from consensus. If our theory is correct and if our empirical model of deviation from consensus truly captures the essence of rational forecasting that occurs among analysts, the fitted Deviation from consensus should be devoid of analysts' overconfidence about their own information processing. In fact, if fitted Deviation reflects the tendency toward more rational forecasting, we should find a *negative* relationship between fitted Deviation and Forecast error.

Looking to the results, which are found in Table 2.5, Panel A, we see that this is indeed what we find. In all specifications, the fitted Deviation (DFC) is negatively related with Forecast error. All specifications lead to a significant decline in the forecast error of analyst estimation. Specifically, we find that a 1¢ increase in bias

Table 2.5 Panel A presents the results of regressing forecast error on the regressors specified in each column. Experience is the natural log of the number of quarters the analyst has followed the firm for which forecast error is calculated. Relative experience is the analyst experience scaled by the average analyst experience (same industry). NumRevisions is the total number of revisions the analyst made during the quarter for the quarter-end earnings. Reg. FD is an indicator variable that takes on a value of 1 if Reg. FD is in effect and 0 otherwise. Controls are vector of firm-specific variables including Same quarter, Broker reputation, Broker size, Accruals, Intang. assets, and Return std dev. Same quarter is a dummy variable equal to one if the estimate is in the same quarter as the actual and zero otherwise. Same quarter is orthogonalized (on NumRevisions) to ensure that multicollinearity is not a problem between these two variables. Brokerage reputation is a ranking of brokerage reputation, where 0 is the worst and 9 is the best. Brokerage size is the natural log of the number of companies per quarter a brokerage house follows. Brokerage reputation is orthogonalized (on brokerage size) to ensure that multicollinearity is not a problem between these two variables. Accruals are the accrued revenue/liabilities utilized for earnings smoothing. Intang. assets are the covered firm's intangible assets value relative to its total assets. Return standard deviation is the standard deviation of the covered firm's return. I is a vector of one-digit SIC industry dummies. T is a vector of time dummies. Panel B presents the fitted values of DFC from each specification for each experience level. A formal fixed effects treatment around analysts is employed. Standard errors are reported in brackets

Analyst information comes from First Call (except in Specifications (10)–(12)). Company information comes from Compustat/CRSP. Experience is the natural log of the number of quarters the analyst has followed the firm for which forecast error is calculated. Relative experience is the analyst experience scaled by the average analyst experience (same industry). Same quarter is a dummy variable equal to one if the estimate is in the same quarter as the actual and zero otherwise. Same quarter is orthogonalized (on NumRevisions) to ensure that multicollinearity is not a problem between these two variables. Forecast dispersion is the standard deviation of estimates. X is a vector of firm-specific variables including Broker reputation, Broker size, Accruals, Intang. assets, and Return std dev. Brokerage reputation is a ranking of brokerage reputation, where 0 is the worst and nine is the best. Brokerage size is the natural log of the number of companies per quarter a brokerage house follows. Brokerage reputation is orthogonalized (on brokerage size) to ensure that multicollinearity is not a problem between these two variables. Accruals are the accrued revenue/liabilities utilized for earnings smoothing. Intang. assets are the covered firm's intangible assets value relative to its total assets. Return standard deviation is the standard deviation of the covered firm's return. I is a vector of one-digit SIC industry dummies. T is a vector of time dummies. Specifications (1)–(3) include only original estimates (i.e., no revisions). Specifications (4)–(6) include only firms with one analyst following the firm. Specifications (7)–(9) use random effects. Specifications (10)–(12) use I/B/E/S data. A formal fixed effects treatment around analysts is employed unless otherwise noted. Standard errors are reported in brackets.

*, **, and *** indicate significance levels of 10 %, 5 %, and 1 %, respectively

†In sample derived from I/B/E/S data, this is actually the number of analysts

*, **, and *** indicate significance levels of 10 %, 5 %, and 1 %, respectively

leads to a decrease in Forecast error from a low of 1.029 (specification 3) to 1.081¢ (specification 1), depending upon the specification. Considering that the sample average Forecast error is −3.79¢, this is a significant decrease, suggesting that posting such deviations is indeed rational.

Given the high marginal effect and considering the nonlinearity of the impact of experience on deviation from consensus, we further test a squared term of the fitted deviation from consensus variable. It would make sense that continually adding a penny to one's estimate would cease to increase the precision of the resulting estimation at some point. In doing so, we see that the linear effect is reduced considerably. The forecast error is decreased to less than half of a penny on average and this reduction is decreasing with every marginal penny of bias.

Finally, we examine the fitted values of Deviation from consensus for the different terciles of analyst experience, shown in Table 2.5, Panel B. For all five specifications, we see evidence of nonlinearity with these fitted values. Once again, the moderately experienced analyst is found to have the highest "optimal" deviation. This confirms nicely both the theoretical and previous empirical results and helps us to come full circle.

2.6 Robustness

To check for consistency in the results, we reexamine specifications (3) and (4) from Table 2.2 and specification (2) from Table 2.4 on subsamples, altering our empirical methodology and using a different data source. We analyze two subsamples: (1) excluding revisions and (2) including only firms covered by one analyst. We alter our empirical methodology by using random effects as opposed to the fixed effect treatment used in the base specification of the paper. Lastly, we alter our data source by using I/B/E/S data. Because the main empirical tests use First Call data, which only looks at brokerage houses, one potential concern is that perhaps we might not be able to control for analysts' fixed effects effectively. Given our specifications and variables we include in the model, we find that there are only 130 unique brokerage houses. Since I/B/E/S reports analysts rather than brokerage houses, we use their data and find results hold when individual analysts fixed effect (7,708 unique analysts) are included. Due to the nature of IBES data, we cannot, however, control for broker reputation and size. Results are qualitatively identical across all robustness tests and are included in Appendix 2.

For brevity, we only use one information asymmetry proxy in Table 2.5. We choose forecast dispersion as our proxy for information asymmetry since it provides the best model fit (i.e., Model R^2) of the three proxies. To show that our results are robust to the other two information asymmetry proxies, we rerun Table 2.5 using these alternate proxies. Our results are qualitatively identical and are shown in Appendix 3.

In results not reported, we examine three final robustness tests. To address any concerns about the power of our empirics based on the number of observations, we examine the subsample of manufacturing firms. While this subsample is less than half of the original, the economic and statistical significance of coefficients remains, providing support for our empirical results. We include alternate industry dummies using Fama-French industry classifications (SIC codes are used for classification in the base specifications). Results once again remain. Finally, to address any concerns about sample selection problems and the dependence of the power of our empirics on the number of brokerage houses, we run the estimations not including Broker reputation (which reduces our sample to 130 houses) and have 315 brokerage houses. Our results remain. These results are available upon request. The congruence of the results from both the included and unreported robustness tests provides further credence to the conclusions of this study.

2.7 Conclusions

To understand the exact role experience and information asymmetry play in forming a rational deviation, we offer an integrated framework in which an optimum forecast is derived from weighing public and private information, where the resulting forecast bias (i.e., deviation from the consensus) improves accuracy through the acquisition of private information. We study how information asymmetry and analyst experience affect the efficacy of the feedback from bias on private information acquisition. Our construct enables a realistic optimization, where rational forecast bias emerges as an outcome of a trade-off between public and private information while minimizing forecast squared error. We show both analytically and empirically that this trade-off and the resulting rational deviation are determined by experience and information asymmetry. While the optimal bias and information asymmetry are monotonically positively related, the optimal bias and experience are concavely linked. Moderately experienced analysts find it optimal to purchase private information with a positively biased deviation from the consensus. The superior analytical skills and access to private information (at a lower cost) of highly seasoned analysts leads them to optimally rely on private information.

We use Reg. FD as an experiment to further illuminate the relationship between experience and forecast bias and to make a distinction between access to private information and analytical expertise. We find that, as we would expect, the biases of experienced analysts, who weigh private information more heavily, are affected more. The extent to which information asymmetry and analyst experience play a role in determining the analyst's bias is directly affected by the dispersion of the common and idiosyncratic signals of all analysts as well as the extent of their correlation with each other.

Our results may help to paint a clearer picture of the types of information produced by analysts. Institutions may be able to use these results to design continuing education programs and to make hiring/firing decisions. Our results can also help to explain why and how changes in the information environment caused by regulatory changes (e.g., Reg. FD), index inclusions, and public disclosures affect the role of analysts as information processors.

Appendix 1: Proofs

The Objective Function

Given that the analyst's forecast is a weighted average of the analyst's unconditional estimate and the consensus, $F = wE + (1 - w)E_c$, the objective function can be expressed as

$$\min_{w|b}\left[w^2(\tau_0+\tau(b))^{-2}+(1-w)^2\tau_c^{-2}+2\rho w(1-w)(\tau_0+\tau(b))^{-1}\tau_c^{-1}\right] \tag{2.6}$$

The first-order condition then is

$$\begin{aligned}&2w(\tau_0+\tau(b))^{-2}-2(1-w)\tau_c^{-2}+2\rho(1-w)(\tau_0+\tau(b))^{-1}\tau_c^{-1}\\&-2\rho w(\tau_0+\tau(b))^{-1}\tau_c^{-1}\equiv 0\end{aligned}$$

By collecting terms, we then have

$$w\left\{(\tau_0+\tau(b))^{-2}+\tau_c^{-2}-2\rho(\tau_0+\tau(b))^{-1}\tau_c^{-1}\right\}=\tau_c^{-2}-\rho(\tau_0+\tau(b))^{-1}\tau_c^{-1}$$

This means that the optimal weight is

$$w=\frac{(\tau_0+\tau(b))^2-\rho\tau_c(\tau_0+\tau(b))}{(\tau_0+\tau(b))^2+\tau_c^2-2\rho\tau_c(\tau_0+\tau(b))} \tag{2.7}$$

Proof of Proposition 1

By taking the derivative of Eq. 2.7 with respect to τ_0, we have

$$\frac{\partial w}{\partial\tau_0}=\frac{2\tau_c^2(\tau_0+\tau(b))-2\rho\tau_c(\tau_0+\tau(b))^2-\rho\tau_c^3}{\left[(\tau_0+\tau(b))^2+\tau_c^2-2\rho\tau_c(\tau_0+\tau(b))\right]^2} \tag{2.8}$$

Clearly, since the denominator of $\partial w/\partial\tau_0$ is positive, then the sign is only a function of the numerator. This implies that the sign changes when the numerator, $2\tau_c(\tau_0 + \tau(b)) - 2\rho(\tau_0 + \tau(b))^2 - \rho\tau_c^2$, is at maximum. To find the maximum, we solve for τ_0 that satisfies the first-order conditions of the numerator. The first-order condition yields $\tau_c - 2\rho(\tau_0 + \tau(b)) \equiv 0$. Thus, at optimal weight $\tau_0 + \tau(b) = 0.5\rho^{-1}\tau_c$.

Proof of Proposition 2

By taking the derivative of Eq. 2.7 with respect to bias, we have

$$\frac{\partial w}{\partial b} = \frac{\left[2\tau_c^2(\tau_0 + \tau(b)) - 2\rho\tau_c(\tau_0 + \tau(b))^2 - \rho\tau_c^3\right]\frac{\partial \tau}{\partial b}}{\left[(\tau_0 + \tau(b))^2 + \tau_c^2 - 2\rho\tau_c(\tau_0 + \tau(b))\right]^2} \tag{2.9}$$

Clearly, since the denominator of $\partial w/\partial b$ is positive, then the sign is only a function of the numerator. This implies (1) that since $\partial \tau/\partial b$ is positive, then the optimal weight would be monotonically increasing with $\partial \tau/\partial b$ or information asymmetry, and (2) that the optimal weight is nonlinearly, concavely related to private information precision. Since the first term in the numerator is a quadratic function of analyst's own precision, the maximum in the function is the point at which the numerator changes sign. This point, however, is exactly the same point at which $\partial w/\partial \tau_0$ maximizes. For biases at which $\tau_0 + \tau(b)$ falls below $0.5\rho^{-1}\tau_c$., then so long as bias increases so does the optimal weight.

Appendix 2: Alternate Samples

See Table 2.6.

Appendix 3: Alternate Proxies for Information Asymmetry for Table 2.5

See Table 2.7.

Appendix 3 presents the results of regressing forecast error on the regressors specified in each column. Inf. asymmetry is analyst coverage in Panel A and relative firm size in Panel B. Same quarter is a dummy variable equal to one if the estimate is in the same quarter as the actual and zero otherwise. Same quarter is orthogonalized (on NumRevisions) to ensure that multicollinearity is not a problem between these two variables. Controls is a vector of firm-specific variables including broker reputation, broker size, accruals, intang. assets, and return std dev. Brokerage reputation is a ranking of brokerage reputation, where 0 is the worst and 9 is the best. Brokerage size is the natural log of the number of companies per quarter a brokerage house follows. Brokerage reputation is orthogonalized (on brokerage size) to ensure that multicollinearity is not a problem between these two variables. Accruals are the accrued revenue/liabilities utilized for earnings smoothing. Intang. assets are the covered firm's intangible assets value relative to its total assets. Return standard deviation is the standard deviation of the covered firm's return. I is a vector of one-digit SIC industry dummies. T is a vector of time dummies.

An Appraisal of Modeling Dimensions for Performance Appraisal of Global Mutual Funds

3

G.V. Satya Sekhar

Contents

Abstract

A number of studies have been conducted to examine investment performance of mutual funds of the developed capital markets. Grinblatt and Titman (1989, 1994) found that small mutual funds perform better than large ones and that performance is negatively correlated to management fees but not to fund size or expenses. Hendricks, Patel, and Zeckhauser (1993), Goetzmann and Ibbotson (1994), and Brown and Goetzmann (1995) present evidence of persistence in mutual fund performance. Grinblatt and Titman (1992) and Elton, Gruber,

and Blake (Journal of Financial Economics 42:397–421, 1996) show that past performance is a good predictor of future performance. Blake, Elton, and Grubber (1993), Detzler (1999), and Philpot, Hearth, Rimbey, and Schulman (1998) find that performance is negatively correlated to fund expense, and that past performance does not predict future performance. However, Philpot, Hearth, and Rimbey (2000) provide evidence of short-term performance persistence in high-yield bond mutual funds. In their studies of money market mutual funds, Domian and Reichenstein (1998) find that the expense ratio is the most important factor in explaining net return differences. Christoffersen (2001) shows that fee waivers matter to performance. Smith and Tito (1969) conducted a study into 38 funds for 1958–1967 and obtained similar results. Treyner (1965) advocated the use of beta coefficient instead of the total risk.

Keywords
Financial modeling • Mutual funds • Performance appraisal • Global investments • Evaluation of funds • Portfolio management • Systematic risk • Unsystematic risk • Risk-adjusted performance • Prediction of price movements

3.1 Introduction

Performance of financial instruments is basically dependent on three important models derived independently by Sharpe, Jensen, and Treynor. All three models are based on the assumptions that (1) all investors are averse to risk and are single-period expected utility of terminal wealth maximizers, (2) all investors have identical decision horizons and homogeneous expectations regarding investment opportunities, (3) all investors are able to choose among portfolios solely on the basis of expected returns and variance of returns, (4) all transactions costs and taxes are zero, and (5) all assets are infinitely divisible.

3.2 Performance Evaluation Methods

The following paragraphs indicate a brief description of the studies on "performance evaluation of mutual funds."

Friend et al. (1962) offered the first empirical analysis of mutual funds performance. Sharpe (1964), Treynor and Mazuy (1966), Jensen (1968), Fama (1972), and Grinblatt and Titman (1989, 1994) are considered to be classical studies in performance evaluation methods. Sharpe (1964) made a significant contribution in the methods of evaluating mutual funds. His measure is based on capital asset prices, market conditions with the help of risk and return probabilities. Sharpe (1966) developed a theoretical measure better known as reward to variability ratio that considers both average return and risk simultaneously in its ambit. It tested efficacy through a sample of 34 open-ended funds considering annual returns and standard deviation of annual return risk surrogate for the period for 1954–1963.

The average reward to variability ratio of 34 funds was considerably smaller than Dow Jones portfolio and considered enough to conclude that average mutual funds performance was distinctly inferior to an investment in Dow Jones Portfolio.

Treynor (1965) advocated the use of beta coefficient instead of the total risk. He argues that using only naïve diversification, the unsystematic variability of returns of the individual assets in a portfolio typically average out of zero. So he considers measuring a portfolio's return relative to its systematic risk more appropriate.

Treynor and Mazuy (1966) devised a test of ability of the investment managers to anticipate market movements. The study used the investment performance outcomes of 57 investment managers to find out evidence of market timing abilities and found no statistical evidence that the investment managers of any of the sample funds had successfully outguessed the market. The study exhibited that the investment managers had no ability to outguess the market as a whole but they could identify under priced securities.

Michael C. Jensen (1967) conducted an empirical study of mutual funds during the period 1954–1964 for 115 mutual funds. His results indicate that these funds are not able to predict security prices well enough to outperform a buy-the-market-and-hold policy. His study ignores the gross management expenses to be free. There was very little evidence that any individual fund was able to do significantly better than which investors expected from mere random chance. Jensen (1968) measured the performance as the return in excess of equilibrium return mandated by capital asset pricing model. Jensen's measure is based on the theory of the pricing of capital assets by Sharpe (1964), Linter (1965), and Treynor.

Smith and Tito (1969) conducted a study into 38 funds for 1958–1967 and published results relating to performance of mutual funds. However, Mc Donald (1974) examined 123 mutual funds for 1960–1969 measures to be closely correlated; more importantly, he found that on an average, mutual funds perform about as well as native "buy and hold" strategy.

Fama (1972) suggested alternative methods for evaluating investment performance with somewhat finer breakdowns of performance on the stock selection, market timing, diversification, and risk bearing. It devised mechanism for segregation part of an observed investment return due to managers' ability to pick up the best securities at a given level of risk from part that is due to the prediction of general market price movements.

Dunn and Theisen (1983) study is about ranking by the annual performance of 201 institutional portfolios for the period 1973 through 1982 without controlling for fund risk. They found no evidence that funds performed within the same quartile over the 10-year period. They also found that ranks of individual managers based on 5-year compound returns revealed no consistency.

Eun et al. (1991) reported similar findings. The benchmarks used in their study were the Standard and Poor's 500 Index, the Morgan Stanley Capital International World Index, and a self-constructed index of US multinational firms. For the period 1977–1986, the majority of international funds outperformed the US market.

However, they mostly failed to outperform the world index. The sample consisted of 19 US-based international funds, and the Sharpe measure was used to assess excess returns.

Barua and Varma (1993b) have examined the relationship between the NAV and the market price on Mastershares. They conclude that market prices are far more volatile than what can be justified by volatility of NAVs. The prices also show a mean reverting behavior, thus perhaps providing an opportunity for discovering a trading rule to make abnormal profits in the market. Such a rule would basically imply buying Mastershares whenever the discount from NAV was quite high and selling Mastershares whenever the discount was low.

Droms and Walker (1994) used a cross-sectional/time-series regression methodology. Four funds were examined over 20 years (1971–1990), and 30 funds were analyzed for a 6-year period (1985–1990). The funds were compared to the Standard and Poor's 500 Index, the Morgan Stanley Europe, Australia, and Far East Index (EAFE) which proxies non-US stock markets, and the World Index. Applying the Jensen, Sharpe, and Treynor indices of performance, they found that international funds have generally underperformed the US market and the international market. Additionally, their results indicated that portfolio turnover, expense ratios, asset size, load status, and fund size are unrelated to fund performance.

Bauman and Miller (1995) studied the persistence of pension and investment fund performance by type of investment organization and investment style. They employed a quartile ranking technique, because they noted that "investors pay particular attention to consultants' and financial periodicals' investment performance rankings of mutual funds and pension funds." They found that portfolios managed by investment advisors showed more consistent performance (measured by quartile rankings) over market cycles and that funds managed by banks and insurance companies showed the least consistency. They suggest that this result may be caused by a higher turnover in the decision-making structure in these less consistent funds. This study controls for the effects of turnover of key decision makers by restricting the sample to those funds with the same manager for the entire period of study.

Volkman and Wohar (1995) extend this analysis to examine factors that impact performance persistence. Their data consists of 322 funds over the period 1980–1989 and shows performance persistence is negatively related to size and negatively related to levels of management fees.

Elton et al. (1996) examined the predictability of stock mutual funds performance based on risk-adjusted future performance. It also demonstrated application of modern portfolio techniques on past data to improve selection, which permitted construction of portfolio funds that significantly outperformed a rule based on the past rank alone. The portfolio so selected was reported to have small, but statistically significant, positive risk-adjusted returns during a period when mutual funds in general had negative risk-adjusted returns.

Jayadeve (1996) paper enlightens performance evaluation based on monthly returns. His paper focuses on performance of two growth-oriented mutual funds

(Mastergain and Magnum Express) on the basis of monthly returns compared to benchmark returns. For this purpose, risk-adjusted performance measures suggested by Jensen and Treynor and Sharpe are employed.

Carhart (1997) shows that expenses and common factors in stock returns such as beta, market capitalization, 1-year return momentum, and whether the portfolio is value or growth oriented "almost completely" explain short-term persistence in risk-adjusted returns. He concludes that his evidence does not "support the existence of skilled or informed mutual fund portfolio managers."

Yuxing Yan (1999) examined performance of 67 US mutual funds and the S&P 500 Index with 10-year daily return data from 1982 to 1992. The S&P index was used as benchmark index. Daily data are transformed into weekly data for computational reasons. In the calculations, it was assumed that the S&P 500 market index is a good one, i.e., it is efficient and its variance is constant.

Redmand et al.'s (2000) study examines the risk-adjusted returns using Sharpe's Index, Treynor's Index, and Jensen's alpha for five portfolios of international mutual funds during 1985–1994. The benchmarks for competition were the US market proxied by the Vanguard Index 500 mutual fund and a portfolio of funds that invest solely in US stocks. The results show that for 1985 through 1994 the portfolio of international mutual funds outperformed the US market and the portfolio of US mutual funds.

Rahul Bhargava et al. (2001) evaluated the performance of 114 international equity managers over the January 1988 to December 1997 period. Performance tests are conducted using Sharpe and Jensen performance methodologies. Three major findings are reported. First, international equity managers, on an average, were unable to outperform the MSCI world market proxy during the sample period. Second, geographic asset allocation and equity style allocation decisions enhanced the performance of international managers during the sample period. Third, separately managed funds were outperformed mutual funds.

Sadhak's (2003) study is an attempt to evaluate the performance of Indian mutual funds with the help of data pertaining to (a) trends in income and expenses, (b) investment yield and risk-associated returns, and (c) returns of Indian mutual funds vis-à-vis returns of other emerging markets.

Bala Ramasamy and Yeung's (2003) survey focused on Malaysia where the mutual fund industry started in the 1950s but only gained importance in the 1980s with the establishment of government-initiated program. The sample size consisting of 56 financial advisors representing various life insurance and mutual fund companies resulted in 864 different profiles of mutual funds. The cojoint analysis was employed to generate the questionnaire and analyze its results. The results of this survey point to three important factors which dominate the choice of mutual funds. These are consistent past performance, size of funds, and costs of transaction.

Chang et al. (2003) identified hedging factor in the equilibrium asset pricing model and used this benchmark to construct a new performance measure. Based on this measure, they are able to evaluate mutual fund managers hedging timing ability in addition to more traditional security selectivity and timing. While security selectivity performance involves forecasts of price movements of selected individual stock, market timing measures the forecasts of next period realizations of the market portfolio. The empirical evidence indicates that the selectivity measure is positive on average and the market timing measure is negative on average.

Obeid (2004) has suggested a new dimension called "modified approach for risk-adjusted performance of mutual funds." This method can be considered as more powerful, because it allows not only for an identification of active resources but also for identification of risk. He observed two interesting results: first, it can be shown that in some cases, a superior security selection effect is largely dependent on taking higher risks. Second, even in the small sample analyzed in the study, significant differences appear between each portfolio manager's styles of selection.

Gupta OP and Amitabh Gupta (2004) published their research on select Indian mutual funds during a 4-year period from 1999 to 2003 using weekly returns based on NAVs for 57 funds. They found that fund managers have not outperformed the relevant benchmark during the study period. The funds earned an average return of 0.041 per week against the average market return of 0.035 %. The average risk-free rate was 0.15 % per week, indicating that the sample funds have not earned even equivalent to risk-free return during the study period.

Subash Chander and Japal Singh (2004) considered selected funds during the period from November 1993 to March 2003 for the purpose of their study. It was found that the Alliance Mutual Fund and Prudential ICICI Mutual Funds have posted better performance for the period of study in that order as compared to other funds. Pioneer ITI, however, has shown average performance and Templeton India mutual fund has staged a poor show.

Amit Singh Sisodiya (2004) makes comparative analysis of performance of different mutual funds. He explains that a fund's performance when viewed on the basis of returns alone would not give a true picture about the risk the fund would have taken. Hence, a comparison of risk-adjusted return is the criteria for analysis.

Bertoni et al. (2005) analyzed the passive role that, implicitly, would place institutional investors in such a context. The study was conducted in Italy using empirical evidence from the Italian stock exchange (Comit Index). This study finds that three factors reduce the freedom of institutional investors to manage their portfolio – the market target size, the fund structure, and the benchmarking.

Sudhakar and Sasi Kumar (2005) made a case study of Franklin Templeton mutual fund. The sample consists of a total of ten growth-oriented mutual funds during the period from April 2004 to March 2005. NIFTY based on NSE Index was used as the proxy for the market index, and each scheme is evaluated with respect to the NSE index to find out whether the schemes were able to beat the market or not. It was found that most of the growth-oriented mutual funds have been able to deliver better returns than the benchmark indicators. In the sample study, all the funds have positive differential returns indicating better performance and diversification of the portfolio, except two funds with negative differential returns, viz., Franklin India Bluechip Fund and Templeton India Income Fund.

Martin Eling (2006) made a remarkable contribution to the theory of "performance evaluation measures." In this study, data envelopment analysis (DEA) is presented as an alternative method for hedge fund performance measurement. As an optimization result, DEA determines an efficiency score, which can be interpreted as a performance measure. An important result of the empirical study is that completely new rankings of hedge funds compared to classic performance measures.

George Comer (2006) examined the stock market timing ability of two samples of hybrid mutual funds. The results indicate that the inclusion of bond indices and a bond timing variable in a multifactor Treynor-Mazuy model framework leads to substantially different conclusion concerning the stock market timing performance of these funds relative to the traditional Treynor-Mazuy model find less stock timing ability over the 1981–1991 time period provide evidence of significant stock timing ability across the second fund sample during the 1999–2000 period.

Yoon K. Choi (2006) proposed an incentive-compatible portfolio performance evaluation measure. In this model, a risk-averse portfolio manager is delegated to manage a fund, and his portfolio construction (and information-gathering) effort is not directly observable to investors, in which managers are to maximize investors' gross returns net of managerial compensation. He considers the effect of organizational elements such as economics of scale on incentive and thus on performance.

Ramesh Chander (2006) study examined the investment performance of managed portfolios with regard to sustainability of such performance in relation to fund characteristics, parameter stationarity, and benchmark consistency. The study under consideration is based on the performance outcome of 80 investment schemes from public as well as private sectors for the 5-year period encompassing January 1998 through December 2002. The sample comprised 33.75 % of small, 26.75 % of medium, 21.25 % of large, and 18.75 % of the giant funds.

Ramesh Chander (2006a) study on market timing abilities enables us to understand how well the manager has been able to achieve investment targets and how well risk has been controlled in the process. The results reported were unable to generate adequate statistical evidence in support of manager's successful market timing. It persisted across measurement criteria, fund characteristics, and the benchmark indices. However, absence of performance is noted for alternative sub-periods signifying the negation of survivorship bias.

Beckmann et al. (2007) found that Italian female professionals do not only assess themselves as more risk averse than their male colleagues, they also prefer a more passive portfolio management compared to the level they are allowed to. Besides, in a competitive tournament scenario near the end of the investment period, female asset managers do not try to become the ultimate top performer when they have outperformed the peer group. However in case of underperformance, the risk of deviating from the benchmark makes female professionals more willing than their male colleagues to seize a chance of catching up.

Gajendra Sidana (2007) made an attempt to classify hundreds of mutual funds employing cluster analysis and using a host of criteria like the 1-year-old return, 2-year annualized return, 3-year annualized return, 5-year annualized return, alpha, and beta. The data is obtained from value research. The author finds inconsistencies between investment style/objective classification and the return obtained by the fund.

Coates and Hubbard (2007) reviewed the structure, performance, and dynamics of the mutual fund industry and showed that they are consistent with competition. It was also found that concentration and barriers to entry are low, actual entry is common and continuous, pricing exhibits no dominant long-term trend, and market shares fluctuate significantly. Their study also focused on "effects of competition on fee" and "pricing anomalies." They suggested legal interventions are necessary in setting fee in mutual funds of United States.

Subha and Bharati's (2007) study is carried out for open-ended mutual fund schemes and 51 schemes are selected by convenient sampling method. NAVs are taken for a period of 1 year from 1 October 2004 to 30 September 2005. Out of the 51 funds, as many as 18 schemes earned higher returns than the market return. The remaining 33 funds however generated lower returns than the market.

Sondhi's (2007) study analyzes the financial performance of 36 diversified equity mutual funds in India, in terms of rates of return, comparison with risk-free return, benchmark comparison, and risk-adjusted returns of diversified equity funds. Fund size, ownership pattern of AMC, and type of fund are the main factors considered in this study. The study reveals that private sector is dominating public sector.

Cheng-Ru Wu et al.'s (2008) study adopts modified Delphi method and the analytical hierarchy process to design an assessment method for evaluating mutual fund performance. The most important criteria for mutual fund performance should be "mutual fund style" followed by "market investment environment." This result indicates investor's focus when they evaluate the mutual fund performance.

Eleni Thanou's (2008) study examines the risk-adjusted overall performance of 17 Greek Equity Mutual Funds between the years 1997 and 2005. The study evaluated performance of each fund based on the CAPM performance methodology, calculating the Treynor and Sharpe Indexes for the 9-year period as well as for three sub-periods displaying different market characteristics. The results indicated that the majority of the funds under examination followed closely the market, achieved overall satisfactory diversification, and some consistently outperformed the market, while the results in market timing are mixed, with most funds displaying negative market timing capabilities.

Kajshmi et al. (2008) studied a sample of schemes in the 8-year period. This study considers performance evaluation and is restricted to the schemes launched in the year 1993 when the industry was thrown open to private sector under the regulated environment by passing the SEBI (Mutual Funds) Regulations 1993. The performance of the sample schemes were in line with that of the market as evident from the positive beta values. All the sample schemes were not well diversified as depicted by the differences in the Jensen alpha and Sharpe's differential return.

Massimo Masa and Lei Zhang (2008) found the importance of organizational structure on Asset Management Company of mutual fund. Their study found that more hierarchical structures invest less in firms located close to them and deliver lower performance. An additional layer in hierarchical structure reduces the average performance by 24 basis points per month. At the same time, more hierarchical structures leads to herd more and to hold less concentrated portfolios.

Manuel Ammann and Michael Verhofen (2008) examined the impact of prior performance on the risk-taking behavior of mutual fund managers. Their sample taken from US funds started in January 2001 and ended in December 2005. The study found that prior performance in the first half of the year has, in general, a positive impact on the choice of the risk level in the second half of the year. Successful fund managers increase the volatility and the beta and assign a higher proportion of their portfolio to value stocks, small firms, and momentum stocks in comparison to unsuccessful fund managers.

Onur et al. (2008) study evaluates the performance of 50 large US-based international equity funds using risk-adjusted returns during 1994–2003. This study provides documentation on the risk-adjusted performance of international mutual funds. The evaluation is based on objective performance measures grounded in modern portfolio theory. Using the methodology developed by Modigliani and Miller in 1997, the study reports the returns that would have accrued to these mutual funds for a 5-year holding period as well as a 10-year holding period. It is evident from the empirical results of this study that the funds with the highest average returns may lose their attractiveness to investors once the degree of risk embedded in the fund has been factored into the analysis.

Qiang Bu and Nelson Lacey (2008) examined the determinants of US mutual fund terminations and provided estimates of mutual fund hazard functions. Their study found that mutual fund termination correlates with a variety of fund-specific variables as well as with market variables such as the S&P 500 Index and the short-term interest rate. This was tested with the underlying assumptions of the semi-parametric Cox model and reject proportionality. They also found that different fund categories exhibit distinct hazard functions depending on the fund's investment objectives.

David M. Smith (2009) discussed the size and market concentration of the mutual fund industry, the market entry and exit of mutual funds, the benefits and costs of mutual fund size changes, the principal benefits and costs of ownership from fund shareholders' perspective, etc. This study is based on data from Morningstar (2009) about US mutual fund industry, which was composed of 607 fund families.

Baker et al. (2010) investigated the relation between the performance and characteristics of 118 domestic actively managed institutional equity mutual funds. The results showed that the large funds tend to perform better, which suggests the presence of significant economies of scale. The evidence indicates a positive relation between cash holding and performance. They also found evidence in a univariate analysis that expense ratio class is an important determinant of performance, and the results are significant in a multivariate setting using Miller's active alpha as a performance metric.

Khurshid et al. (2009) studied the structure of the mutual fund industry in India and analyzed the state of competition among all the mutual funds in private sector and public sector. The levels of competition and their trends have been obtained for the periods March 2003–March 2009. This study found overall mutual fund industry is facing a high competitive environment. An increasing trend of competition was observed within bank institution, private sector foreign, and private sector joint venture mutual funds.

Mohit Gupta and Aggarwal's (2009) study focused on the portfolio creation and industry concentration of 18 ELSS schemes during April 2006 to April 2007. Mutual fund industry concentration was the variable used in classification or cluster creation. This exercise was repeated each month for the period under study. Finally portfolio performance was compared with index fund, portfolio of three randomly picked funds of the previous month, and the return and risk parameters of ELSS category as a whole.

Talat Afza and Ali Rauf's (2009) study aims to provide guidelines to the managers of open-ended Pakistani mutual funds and benefit small investors by pointing out the significant variables influencing the fund performance. An effort has been made to measure the fund performance by using Sharpe ratio with the help of pooled time-series and cross-sectional data and focusing on different fund attributes such as fund size, expenses, age, turnover, loads, and liquidity. The quarterly sample data are collected for all the open-ended mutual funds listed on Mutual Fund Association of Pakistan (MUFAP), for the years 1999–2006. The results indicate that among various funds attributes are: lagged return, liquidity and had significant impact on fund performance.

Amar Ranu and Depali Ranu (2010) critically examined the performance of equity funds and found out the top 10 best performing funds among 256 equity mutual fund schemes in this category. They considered three factors for selection: (a) mutual funds having 5 years of historical performance, (b) fund schemes having a minimum of Rs.400 crore of assets under management, and (c) funds which have average return more than 22.47. They found that HDFC TOP 200 (Growth) option was outperforming among the top 10 best performing equity funds.

Sunil Wahal and Albert Wang (2010) found impact of the entry of new mutual funds on incumbents using the overlap in their portfolio holdings as a measure of competitive intensity. Their study revealed that funds with high overlap also experience quantity competition through lower investor flows, have lower alphas, and higher attrition rates. These effects only appeared after the late 1990s, at which point there appears to be endogenous structural shift in the competitive environment. Their concluding remark is that "the mutual fund market has evolved into one that displays the hallmark features of a competitive market."

Sukhwinder Kaur Dhanda et al.'s (2012) study considered the BSE-30 as a benchmark to study the performance of mutual funds in India. The study period has been taken from 1 April 2009 to 31 March 2011. The findings of the study reveal that only three schemes have performed better than benchmark. In the year 2009, HDFC Capital Builder has the top performer. It was 69.18 returns and 26.37 SD and 0.78 beta. HDFC Capital Builder scheme has given the reward for variability and volatility. HDFC Top 200 Fund and Birla Sun Life Advantage Funds are on second and third position in terms of return. HDFC Top 200 Fund has shown better performance than Birla Sun Life Advantage Fund in terms of SD, beta, Sharpe ratio, and Treynor ratio. Birla Sun Life Advantage Fund has more risk than the benchmark. Kotak Select Focus Fund has the poorer performer in terms of risk and return. Except two schemes all other schemes have performed better than benchmark. Except Kotak Select Focus Fund all other schemes are able to give reward for variability and volatility.

3.3 A Review on Various Models for Performance Evaluation

3.3.1 Jensen Model

Given the additional assumption that the capital market is in equilibrium, all three models yield the following expression for the expected one-period return on any security (or portfolio) *j*:

$$\mathrm{E}\left(R_j\right) = R_F + \beta_J[\mathrm{E}(R_m) - R_F] \tag{3.1}$$

$R_F =$ the one-period risk-free interest rate.

$\beta_J = \mathrm{Cov}(j\,R_J, R_M)/\sigma^2\,R_M =$ the measure of risk (hereafter called systematic risk) which the asset pricing model implies is crucial in determining the prices of risky assets.

$E(R_M)$ = the expected one-period return on the “market portfolio” which consists of an investment in each asset in the market in proportion to its fraction of the total value of all assets in the market. It implies that the expected return on any asset is equal to the risk-free rate plus a risk premium given by the product of the systematic risk of the asset and the risk premium on the market portfolio.

3.3.2 Fama Model

In Fama’s decomposition performance evaluation measure of portfolio, overall performance can be attributed to selectivity and risk. The performance due to selectivity is decomposed into net selectivity and diversification. The difference between actual return and risk-free return indicates overall performance:

$$\mathrm{R_p} - \mathrm{R_f} \tag{3.2}$$

wherein

R_p is actually return on the portfolio, which is monthly average return of fund and

R_f is monthly average return on treasury bills 91 days.

The overall performance further can be bifurcated into performance due to selectivity and risk.

Thus,

$$\mathrm{R}_p - \mathrm{R}_f = \left[R_p - R_p\left(\beta_p + R_p\left(\beta_p - R_f\right)\right]\right. \tag{3.3}$$

In other words, overall performance = selectivity + risk

3.3.3 Treynor and Mazuy Model

Treynor and Mazuy developed a prudent and exclusive model to measure investment managers' market timing abilities. This formulation is obtained by adding squared extra return in the excess return version of the capital asset pricing model as given below:

$$\left(R_{pt} - R_{ft}\right) = \alpha + \beta_p\left(R_{mt} - R_{ft}\right) + yp\left(R_{mt} - R_{ft}\right)^{2+} e_{pt} \tag{3.4}$$

where R_{pt} is monthly return on the fund, R_{ft} is monthly return on 91 days treasury bills, R_{mt} is monthly return on market index, and E_{pt} is error term.

This model involves running a regression with excess investment return as dependent variable and the excess market return and squared excess market return as independent variables. The value of coefficient of squared excess return acts as a measure of market timing abilities that has been tested for significance of using *t*-test. Significant and positive values provide evidence in support of the investment manager's successful market timing abilities.

3.3.4 Statman Model

Statman measured mutual funds using the following equation (Statman 2000):

eSDAR (excess standard deviation and adjusted return)

$$= R_f + \left(R_p - R_f\right)\left(S_m/S_p\right) - R_m \tag{3.5}$$

In this formulae, R_f = monthly return on 3-month treasury bills, R_p = monthly return on fund portfolio, R_m = monthly return on the benchmark index, S_p = standard deviation of portfolio *p*'s return, and S_m = standard deviation of return on the benchmark index.

This model is used for short-term investment analysis. The performance is compared with it benchmark on monthly basis.

3.3.5 Choi Model

Choi provides a theoretical foundation for an alternative portfolio performance measure that is incentive-compatible. In this model, a risk-averse portfolio manager is delegated to manage a fund, and his portfolio construction (and information-gathering) effort is not directly observable to investors. The fund manager is paid on the basis of the portfolio return that is a function of effort, managerial skill, and organizational factors. In this model, the effect of institutional factors is described by the incentive contractual form and disutility (or cost) function of managerial efforts in fund operations. It focuses on the cost function as an organizational factor (simply, scale factor). It was assumed that the disutility function of each fund is determined by the unique nature of its operation (e.g., fund size) and is an increasing function of managerial effort at an increasing rate.

3.3.6 Elango Model

Elango's model also compares the performance of public sector funds vs private sector mutual funds in India. In order to examine the trend in performance of NAV during the study period, growth rate in NAV was computed. The growth rate was computed based on the following formula (Elango 2003):

$$\text{Growth rate: } R_g = (Y_t - Y_0/Y_0) \times 100 \tag{3.6}$$

R_g: growth rate registered during the current year
Y_t: yield in current year
Y_0: yield in previous year

In order to examine whether past is any indicator of future growth in the NAV, six regression analyses were carried out. NAV of base year was considered as the dependent variable and current year as in the independent variable.

$$\text{Equation: } Y = \mathrm{A} + \mathrm{b}\,X \tag{3.7}$$

Dependent variable: $Y =$ NAV of 1999–2000
Independent variable: $X =$ NAV of 2000–2001

In the same way, the second regression equation computed using NAVs of 2000–2001 and 2001–2002, as dependent and independent variables.

3.3.7 Chang, Hung, and Lee Model

The pricing model adopted by Jow-Ran Chang, Nao-Wei Hung, and Cheng-Few Lee is based on competitive equilibrium version of intemporal asset pricing model derived in Campbell. The dynamic asset pricing model incorporates hedging risk as well as market. This model uses a log-linear approximation to the budget constraint to substitute out consumption from a standard intertemporal asset pricing model. Therefore, asset risk premia are determined by the covariances of asset returns with the market return and with news about the discounted value of all future market returns. Formally, the pricing restrictions on asset i imported by the conditional version of the model are

$$E_t r_{i,\,t+1} - rf_{\,,t+1} = -V_{iI}/2 + \gamma V_{im} + (\gamma - 1)V_{ih} \tag{3.8}$$

where
$E_t r_{i,\,t+1}$, log return on asset; $rf,_{t+1}$, log return on riskless asset; V_{ii} denotes $\mathrm{Var}_t\,(r_{i,t+1})$; γ is the agent's coefficient of relative risk aversion; V_{im} denotes $\mathrm{Cov}_t\,(r_{i,\,t+1}, r_{m,t+1})$ and $V_{ih} = \mathrm{Cov}_t\,(r_{i,t+1}, (E_{t+1} - E_t), \_\infty j = 1\ \rho_j\ r_{m,t+1+j})$; the parameter, $\rho = 1 - \exp(c - w)$; and $c - w$ is the mean log consumption to wealth ratio.

This states that the expected excess log return in an asset, adjusted for a Jensen's inequality effect, is a weighted average of two covariances: the covariance with the return from the market portfolio and the covariance with news about future returns on invested wealth. The intuition in this equation that assets are priced using their covariances with the return on invested wealth and future returns on invested wealth.

3.3.8 MM Approach

Leah Modigliani and Franco Modigliani are better known as M^2 in the investment literature. This measure is developed adjusting portfolio return. This adjustment is carried on the uncommitted (cash balances) part of the investment portfolio at the riskless return so as to enable all portfolio holdings to participate in the return generation process. This adjustment is needed to bring out the level playing field for portfolio risk-return and vis-à-vis market return. The effect of this adjustment is reported below (Modigliani and Modigliani 1997):

$$\mathrm{M}^2 = {}^*\mathrm{Rp} - \mathrm{Rm} \tag{3.9}$$

$$^*\mathrm{Rp} = (\mathrm{Rf}^*(1 - \mathrm{Sdm}/\mathrm{Sdp})) + (\mathrm{Rp}^*\mathrm{Sdm}/\mathrm{Sdp}) \tag{3.10}$$

In this formulae * Rp = expected return, Rf = risk-free return, Sdm = standard deviation of market portfolio, and Sdp = standard deviation of managed portfolio.

In case the managed portfolio has twice the standard deviation of the market, then, the portfolio would be half invested in the managed portfolio and the remaining half would be invested at the riskless rate. Likewise, in case the managed portfolio has lower standard deviation than the market portfolio, it would be levered by borrowing money and investing the money in managed portfolio. Positive M^2 value indicates superior portfolio performance, while negative indicates actively managed portfolio manager's inability to beat the benchmark portfolio performance.

3.3.9 Meijun Qian's Stage Pricing Model

Meijun Qian's (2009) study reveals about the staleness, which is measured prices imparts a positive statistical bias and a negative dilution effect on mutual fund performance. First, evaluating performance with non-synchronous data generates

Table 3.1 Overview of different measures

Measures	Description	Interpretation
Sharpe ratio	Sharpe ratio = fund return in excess of risk-free return/standard deviation of fund. Sharpe ratios are ideal for comparing funds that have a mixed asset classes	The higher the Sharpe ratio, the better the fund returns relative to the amount of risk taken
Treynor ratio	Treynor ratio = fund return in excess of risk-free return/beta of fund. Treynor ratio indicates relative measure of market risk	The higher the Treynor ratio shows higher returns and lesser market risk of the fund
Jensen measure	This shows relative ratio between alpha and beta	Jensen measure is based on systematic risk. It is also suitable for evaluating a portfolio's performance in combination with other portfolios
M^2 measure	It matches the risk of the market portfolio and then calculate appropriate return for that portfolio	A high value indicates that the portfolio has outperformed and vice versa
Jensen model	$E(R_j) = R_F + \beta_J[E(R_m) - R_F]$	The expected one-period return on the "market portfolio" which consists of an investment in each asset in the market in proportion to its fraction of the total value of all assets in the market
Fama model	$R_p – R_f = [R_p - R_p(\beta_p + R_p(\beta_p – R_f)]$	Overall performance = selectivity + risk
Treynor and Mazuy model	$(R_{pt} – R_{ft}) = \alpha + \beta_p\ (R_{mt} - R_{ft}) + yp\ (R_{mt} - R_{ft})^{2+} e_{pt}$	This model involves running a regression with excess investment return as dependent variable and the excess market return and squared excess market return as independent variables
Statman model	eSDAR $= R_f + (R_p - R_f)(S_m/S_p) – R_m$	This model used for short-term investment analysis. The performance is compared with it benchmark on monthly basis
Elango model	$R_g = (Y_t - Y_0/Y_0) \times 100$	In order to examine whether past is any indicator of future growth in the NAV, six regression analyses were carried out. NAV of base year was considered as the dependent variable and current year as in the independent variable

a spurious component of alpha. Second, stale prices create arbitrage opportunities for high-frequency traders whose trades dilute the portfolio returns and hence fund performance. This paper introduces a model that evaluates fund performance while controlling directly for these biases. Empirical tests of the model show that alpha net of these biases is on average positive although not significant and about 40 basis points higher than alpha measured without controlling for the impacts of stale pricing. The difference between the net alpha and the measured alpha consists of three components: a statistical bias, the dilution effect of long-term fund flows, and the dilution effect of arbitrage flows. Thus, assuming that information generated in time t is not fully incorporated into prices until one period later, the observed fund return becomes a weighted average of true returns in the current and last periods:

$$r_t = \alpha + \beta r_{mt} + \varepsilon_t, \tag{3.11}$$

$$r_t^* = \eta r_{t-1} + (1 - \eta) r_t, \tag{3.12}$$

where r_t denotes the true excess return of the portfolio with mean μ and variance σ_2 and r_{mt} denotes the excess market return with mean μ_m and variance σ_m. Both r_t and r_{mt} are i.i.d, and the error term ε_t is independent of r_{mt}. R_t* is the observed excess return of the portfolio with zero flows, while η is the weight on the lagged true return. That is, the higher the η, the staler the prices. Assumedly, arbitrage traders can earn the return r_t*, by trading at the fund's reported net assets values (Table 3.1).

3.4 Conclusion

This paper is intended to examine various performance models derived by financial experts across the globe. A number of studies have been conducted to examine investment performance of mutual funds of the developed capital markets. The measure of performance of financial instruments is basically dependent on three important models derived independently by Sharpe, Jensen, and Treynor. All three models are based on the assumption that (1) all investors are averse to risk and are single-period expected utility of terminal wealth maximizers, (2) all investors have identical decision horizons and homogeneous expectations regarding investment opportunities, (3) all investors are able to choose among portfolios solely on the basis of expected returns and variance of returns, (4) all transactions costs and taxes are zero, and (5) all assets are infinitely divisible.

Abstract

Financial economists have three primary research tools at their disposal: theoretical modeling, statistical analysis, and computer simulation. In this chapter, we focus on using simulation to gain insights into trading and market structure topics, which are growing in importance for practitioners, policy-makers, and academics. We show how simulation can be used to gather data on trading decision behavior and to analyze performance in securities markets under controlled yet competitive conditions. We find that controlled simulations with participants are a flexible and reliable research tool when it comes to studying issues involving traders and market architecture. The role of the discrete event simulation model we have developed is to create a backdrop, or a controlled stochastic environment, for running market experiments with live subjects. Simulations enable us to gather data on trading participants' decision making and to ascertain the ability of incentives and market structures to influence outcomes. The statistical methods we use include experimental design and careful controls over experimental parameters such as the instructions given to participants. Furthermore, results are assessed both at the *individual* level to understand how participants respond to incentives in a trading setting and also at the *market* level to know whether the predicted outcomes are achieved and how well the market operated.

There are two statistical methods described in the chapter. The first is discrete event simulation and the model of computer-generated trade order flow that we describe in Sect. 4.3. To create a realistic, but not ad hoc, market background, we use draws from a log-normal returns distribution to simulate changes in a stock's fundamental value, or P*. The model uses price-dependent Poisson distributions to generate a realistic flow of computer-generated buy and sell orders whose intensity and supply-demand balance vary over time. The order flow fluctuations depend on the difference between the current market price and the P* value. In Sect. 4.4, we illustrate the second method, which is experimental control to create groupings of participants in our simulations that have the same trading "assignment." The result is the ability to make valid comparisons of traders' performances in the simulations.

Trading simulations • Market microstructure • Order flow models • Random walk models • Experimental economics • Experimental control

4.1 Studying Market Structure

Financial economists have three major research methods at their disposal: theoretical modeling, statistical analysis, and simulation. We will focus on using simulation to gain insights into trading and market structure. In so doing, we show how simulation can be used to analyze participant behavior in a security market. We find that controlled simulations with participants are a flexible and reliable research tool when it comes to studying trading behavior and market architecture.

Using good experimental design we can draw statistically valid conclusions from simulations at both the *individual* level to understand how participants respond to incentives in a trading setting and also at the *market* level to know whether the predicted outcomes are achieved and how well the market operated. We begin by considering the interaction between the three tools.

4.2 The Interaction Between Theoretical Modeling, Empirical Analysis, and Simulation

A theoretical formulation based on a limited number of abstract assumptions enables complex reality to be translated into a simplified representation that can be rigorously analyzed. As such, theoretical modeling typically provides the underpinnings for both empirical and simulation analysis. Theory alone, however, can take us only so far. One cannot expect that every detailed aspect of reality can be analyzed from a theoretical vantage point (Clemons and Weber 1997). Moreover, in light of the literature on behavioral economics, it is clear that not all human behavior follows the dictates of rational economic modeling.

We turn to empirical analysis both to provide confirmation of a theoretical model and to describe aspects of reality that theoretical analysis has not been able to explain (Zhang et al. 2011). But necessary data may not be available and empirical analysis, like theoretical modeling, has its limitations. Variability in important variables, such as differences across time or traded instruments, is difficult for empiricists to control (Greene 2011; Kennedy 2008). Moreover, empirical variables may change in correlated ways, yet this should not be mistaken for a causal mechanism. When we seek insights that neither theory nor empirical analysis can provide, simulation has an important role to play (Parker and Weber 2012). An example will help explain.

4.2.1 An Application: Call Auction Trading

Consider an electronic call auction. At a call, submitted orders are batched together for simultaneous execution at a single clearing price. For the batching, buy orders are cumulated from the highest price to the lowest to produce a function that resembles a downward sloping demand curve, and sell orders are cumulated from the lowest price to the highest to produce a function that resembles an upward sloping supply curve. The algorithm generally used for determining the clearing price at the time that the market is called finds the price which maximizes the number of shares that execute. In an abstract, theoretical model, the number of shares that trade is maximized at the price where the downward sloping buy curve crosses the upward sloping sell curve. Consequently, with continuous order functions, the clearing price which maximizes the number of shares that trade in a call auction is uniquely determined by the point where the two curves cross, and this price, in economics parlance, is an equilibrium value.

All told, this call auction procedure has excellent theoretic properties, and one might expect that designing a well-functioning call would be a straightforward task. This is not the case, however. In reality, as the saying goes, "the devil is in the details."

For theoretical modeling, we might for analytic convenience assume a large enough number of participants so that no one individual has any market power. We might further assume that the cumulated buy and sell curves are continuous functions and that the call auction is the only trading facility available. In reality, however, the buy and sell curves are step functions and some players' orders will be large enough to impact a call's clearing price.

To illustrate, assume an exact match of 40,000 shares to buy and 40,000 shares to sell at a price of $50 and that, at the next higher price of $50.10, sell orders totaling 50,000 shares and buy orders totaling 30,000 shares exist. A buyer could move the price up by entering more than 10,000 shares at $50.10 or greater.

Notice also that the real-world buy and sell curves are step functions (neither price nor quantity is a continuous variable) and thus that the cumulated buy orders may not exactly match the cumulated sell orders at the price where the two curves cross. Moreover, many exchange-based call auctions are offered along with continuous trading in a hybrid environment. These realities of the marketplace affect participants' order placement decisions and, consequently, impact market outcomes for both price and the number of shares that trade. In response, participants will enter their orders *strategically* when coming to the market to trade.

These strategic interactions and the decisions that market participants make depend on the call auction's rules of order disclosure (i.e., its transparency) and its rules of order execution which apply when an exact cross is not obtained. What guidance do market architects have in dealing with questions such as these other than their own, hopefully educated, speculation? The questions being raised may be too context specific for theory to address and, if a new market structure is being considered, the data required for empirical analysis will not yet exist. This is when simulation analysis can be used to good advantage.

Regarding transparency, alternative call auction structures include full transparency (i.e., display the complete set of submitted orders), partial transparency (e.g., display an indicated clearing price and any order imbalance at that price), or no transparency at all (i.e., be a dark pool). Regarding the procedure for dealing with an inexact cross, the alternatives for rationing orders on the "heavy" side of the market include pro rata execution, the application of time priority to orders at the clearing price exactly, and the application of time priority to all orders at the clearing price and better (i.e., to higher priced buys or to lower priced sells). These and other decisions have been debated in terms of, for instance, the ability to game or to manipulate an auction, the incentive to enter large orders, and the incentive to submit orders early in the book building period before the auction is called. But definitive answers are difficult to come by. This is when valuable guidance can be (and has been) obtained via the use of simulation analysis.

4.2.2 An Application: The Search for an Equilibrium Price and Quantity

In this section, we consider another application of simulation as a research tool: the search for an equilibrium price and quantity in a competitive marketplace. Determining equilibrium values for a resource's unit price and quantity traded is a keystone of economic analysis. In the standard formulation, equilibrium is determined by the intersection of market demand and supply curves, with scant consideration given to just how the buy and sell orders of participants actually meet in a marketplace. In fact, the "marketplace" is typically taken to be nothing more than a mystical, perfectly frictionless environment, and the actual discovery of equilibrium values for price and quantity is implicitly assumed to be trivial.

Real-world markets are very different. In the non-frictionless environment, a panoply of transaction costs interact to make price and quantity discovery an imperfect process. In this far more complex setting, two further issues need to be analyzed: (1) the trading decisions that market participants make when confronted by the imperfections (frictions) that characterize real-world markets and (2) the determination of actual prices and quantities based on the decisions of the individual participants. Both issues are ideally suited for simulation analysis.

We consider this further in this section of the chapter, with particular reference to one specific market: the secondary market for trading equity shares of already issued stock. Underlying the simulation analysis is an economic model that is based on the following assumptions:

1. The decision maker qua investor is seeking to maximize his/her expected utility of wealth as of the end of a single holding period.
2. The investor is risk averse.
3. There are just two assets, one risk-free (cash) and one risky (equity shares).
4. There are no explicit trading cost (i.e., there are no commissions or borrowing costs, and short selling is unrestricted).
5. Share price and share holdings are continuous variables.
6. A brief trading period (T_0 to T_1) that is followed by a single investment period (T_1 to T_2).
7. The participant's expectation of price at T_2 is exogenous (i.e., independent of the stock's current price).
8. The investor is a perfect decision maker when it comes to knowing his/her demand curve to hold shares of the risky asset.

From this set of assumptions, and following the derivation described in Ho et al. (1985) and Francioni et al. (2010), we can obtain a participant's demand to hold shares of the risky asset. The participant's demand is described by two simple, linear functions:

$$P^0 = a - 2bN \quad (\text{an ordinary demand curve})$$

and

$$P^R = a - bN \quad (\text{a reservation price demand curve})$$

where P^0 denotes price with respect to the ordinary curve, P^R denotes a reservation price, and N is the number of shares held.

The ordinary curve shows that if, for instance, the price of shares is P^0_1, the participant maximizes expected utility by holding N_1 shares; if alternatively price is P^0_2, the participant maximizes expected utility by holding N_2 shares; and so on. Values given by the reservation curve show that at a quantity N_1, the maximum the participant would pay is P^R_1 when the alternative is to hold no shares at all; or, at a quantity N_2, the maximum the participant would pay is P^R_2 when the alternative is to hold no shares at all; and so on. Identifying the reservation price demand curve enables us to obtain easily a monetary measure of the gains from trading.

To facilitate the exposition, assume for the moment that the participant initially holds no shares. Then if, for instance, N_1 shares are acquired, we have

$$\text{Surplus} = N_1\left(P^R - P\right)$$

where "Surplus" denotes the gains from buying N_1 shares and P is the price at which the N_1 shares were bought (note that, for a purchase, we have Surplus > 0 for $P < P^R$). The participant controls P via the price of his/her order but knows neither the price at which the order will execute (if price improvement is possible) nor whether or not the order will, in fact, execute. Because P is not known with certainty, Surplus is not known with certainty and thus the investor seeks to maximize the expected value of Surplus. It follows from the derivations cited above that the maximization of the expected value of Surplus is consistent with the maximization of the expected utility of the end of the holding period wealth (i.e., at time T_2).

With the demand curves to hold shares established, it is straightforward to obtain linear functions that describe the investor's propensity to buy and to sell shares in relation to both ordinary and reservation prices. If the investor's initial position is zero shares, the buy curve is the same as the downward sloping demand curve. By extending the demand curve up and through the price intercept (a) into the negative quadrant, we see that at prices higher than the intercept, a, the investor will want to hold a negative number of shares (i.e., establish a short position by selling shares that he/she does not currently own). By flipping the portion of the demand to hold curve that is in the negative quadrant into the positive quadrant (and viewing a negative shareholdings adjustment as a *positive* sell), we obtain a positively inclined (vertical) mirror image that is the sell function.

The procedure just described can easily be replicated for any initial share holdings (either a long or a short position). The individual buy and sell curves can be aggregated across investors and, following standard economic theory, the intersection of the aggregate buy curve with the aggregate sell curve establishes the equilibrium values of share price and the number of shares that trade. This equilibrium would be achieved if all participants were, simultaneously, to submit their complete demand functions to the market, as they presumably would in a perfect, frictionless environment.

Continue to assume that investors know their continuous, negatively inclined demand curves to hold shares of the risky asset, but let us now consider how they might operate in a non-frictionless marketplace where they cannot all simultaneously submit their complete and continuous, downward sloping buy functions and upward sloping sell functions. What specific orders will they send to the market, and how will these orders interact so as to be turned into trades? Will equilibrium values for price and quantity be achieved? This highly complex issue might best be approached by observing participant behavior and, to this end, simulation can be used as the research tool. Here is how one might go about it.

Let participants compete with each other in a networked, simulated environment. Each participant is given a demand curve to hold shares of a risky stock, and each is asked to implement that demand curve by submitting buy or sell orders to the market. The participants are motivated to place their orders strategically given their demand curves, the architectural structure of the marketplace, and the objective against which their performance is assessed – namely, the maximization of expected surplus.

The simulation can be structured as follows. Give all of the participants in a simulation run the same demand curve,

$$P = 20 - 0.5N_0$$

where N_0 represents the number of shares initially held. Divide the participants into two equal groups, A and B, according to the number of shares they are initially holding, with $N_{0A} = 4$ for group A players and $N_{0B} = 8$ for group B players. Accordingly, the buy curve for each individual in group A is

$$P = 18 - 0.5Q$$

and the sell curve for each individual in group B is

$$P = 16 + 0.5Q$$

where Q is the number of shares bought or sold. The associated reservation curves are

$$P^R = 18 - 0.25Q \quad (\text{for the buyers})$$

and

$$P^R = 16 + 0.25Q \quad (\text{for the sellers})$$

From the ordinary (as opposed to the reservation) buy and sell curves, and recalling that the groups A and B are of equal size, we obtain an equilibrium price of 17 and an equilibrium quantity traded of 2 (per participant). From the reservation buy and sell curves, we see that if each participant bought or sold two shares, the surplus for each would be

$$2(17.50 - 17.00) = \$1.00 \ \ \text{(for the buyers)}$$

and

$$2(17.00 - 16.50) = \$1.00 \ \ \text{(for the sellers)}$$

Participants, however, do not know the distribution of initial shareholdings across the other investors, and thus they know neither the buy and sell functions of all the other traders, nor the equilibrium price and quantity for the market. It is up to each of them individually to submit their orders wisely, and it is up to all of them collectively to find the equilibrium price along with the quantity to trade at that price. How do they operate? How well do they do? How quickly and successfully can they collectively find equilibrium values for P and Q? And how are participant decisions and market outcomes affected by different market structures? With regard to each of these issues, important insights can be obtained through the use of simulation as a research tool.

4.2.3 The Realism of Computer-Generated Data Versus Canned Data

A live equity trading simulation can either depend exclusively on person-to-person interaction or add computer-driven order flow; we focus on the latter. Most experimental economics research is based on the former. Computer-driven simulations can be based on either canned data or on data that the computer itself generates; we focus on the latter. Canned data have two major limitations. First, participants in the simulation cannot affect the stream of prices that they are trading against and, consequently, the dynamic, two-way interaction between live participants and the marketplace is absent. Second, canned data cannot be used to analyze new market structure because, quite simply, it is exclusively the product of the actual market within which it was generated.

On the other hand, a simulation model based on computer-generated data faces a formidable challenge: capturing the dynamics of a real-world market. Canned data does not face this problem – it is, after all, generated in a real marketplace. We discuss the challenge of realism in this section of the chapter with specific reference to an equity market.

It has been well established in the financial economics literature that, in an equity market which is fully efficient, security prices follow random walks. “Efficiency” in this financial markets context is generally understood as referring to “informational efficiency,” by which we mean that market prices reflect all existing information. In a nutshell, the raison d’être of a stock’s price following a random walk in a fully informationally efficient market can be understood as follows. If all (and we mean *all*) information about a security is reflected in a stock's market price, then only totally new, totally unanticipated information can cause the stock's price to change. But totally new and thus totally unanticipated information can be either bullish or bearish with equal probability and thus, with equal probability, can lead to either positive or negative price changes (returns). Thus, the argument goes, in an informationally efficient market, returns are not predictable and stock prices follow random walks.

It would be relatively straightforward to structure an equity market simulation based on machine-driven prices that follow a random walk. One would start a simulation run with an arbitrarily selected seed price and have that price evolve as the simulation progresses according to random draws from a (log-normal) returns distribution with arbitrary variance and a zero mean. Real-world prices do not evolve in this fashion, however. In a world characterized by trading costs, imperfect information, and divergent (i.e., nonhomogeneous) expectations based on publicly available information, prices do not follow simple random walks. Rather, price changes (returns) in relatively brief intervals of time (e.g., intraday) evolve in dynamic ways that encompass complex patterns of first-order and higher-order correlations. Structuring a computer simulation to produce prices that capture this dynamic property of real-world markets is the objective. In the next session of this chapter, we set forth the major properties of a machine-driven trading simulation, TraderEx, which we have formulated so as to achieve this goal.

4.3 An Equity Market Trading Simulation Model

In this section, we focus on a key conceptual foundation of the TraderEx simulation model: how the machine-generated order flow is structured. Above all else, it is this modeling that captures the dynamic property of trades and prices and, in so doing, that enables our software to compete with canned data in terms of realism. First, we present a brief overview of the functions the computer performs.

Looking under the hood, the TraderEx software can be thought of, first and foremost, as a package of statistical distributions. The prices and sizes of the machine-driven orders that power the TraderEx simulation are determined by draws from these distributions. The software also maintains and displays an order book or set of dealer quotes, drives a ticker tape that displays trade prices and sizes, computes summary statistics for each simulation run (e.g., a stock's volume-weighted average price and participant performance measures such as profit or loss), and provides post trade analytics (both statistics and graphs). The simulation game can be played either individually (i.e., one person interacting with the machine-driven order flow in a solitaire environment) or as a group (i.e., in a networked environment that also includes machine-driven order flow).

While our machine-driven order flow, as we have said, is powered by random draws from distributions, we are able to tell meaningful economic stories about these statistical draws. These stories involve exogenous information change and three different economic agents: informed traders, liquidity traders, and noise traders. Interestingly, while the simulation requires this tripartite division, it has also been established in the academic microstructure literature that, for an equity market not to fail, informed traders must interact with liquidity traders, and noise traders must also be part of the mix.

4.3.1 Informed Orders

In TraderEx, orders submitted by informed traders are specified with reference to an exogenous variable we call P* that can be viewed as an equilibrium price. That is, at the value P*, the aggregate flow of buy and sell orders is in balance (much as, in economic analysis, buy and sell orders are in balance at the price where a demand curve crosses a supply curve). More specifically, the TraderEx market is in equilibrium when the lowest posted offer is greater than P* and the highest posted bid is less than P*. When this equilibrium is achieved, no informed orders are submitted to the market, and an incoming (liquidity) order can be from a buyer or a seller with equal probability. On the other hand, if P* is greater than the lowest posted offer, informed orders kick in and the probability of an incoming order being from a buyer is raised to 0.6 (a parameter that can, of course, be adjusted). Equivalently, if P* is lower than the highest posted bid, informed orders again kick in and the probability of an incoming order being from a seller is raised to 0.6. This asymmetry between the buy and sell orders that exists when P* is not within the quotes keeps the quotes loosely linked to P*.

P* evolves as the simulation progresses according to a Poisson arrival process. Each jump in P* symbolizes informational change. The size of the change in P* at each new arrival is determined by a draw from a log-normal returns distribution with a zero mean and a variance that is a controllable parameter.

4.3.2 Liquidity Orders

The second component of the order flow, liquidity orders, is also modeled as a Poisson arrival process, but with one important difference: at any point of time, the probability of the newly arriving liquidity order being a buy equals the probability of its being sell equals 0.5. All liquidity orders are priced, with the price determined by a draw from a double triangular distribution that is located with reference to the best posted bid and offer quotes.

A new liquidity order is entered on the book as a limit order if it is a buy with a price lower than the best posted offer or if it is a sell with a price higher than the best posted bid. A new liquidity order with a price equal to or more aggressive than the best posted offer (for a buy) or the best posted bid (for a sell) is executed immediately as a market order. Liquidity orders can (randomly) cause the market's bid and ask quotes to drift away from the equilibrium value, P*. When this occurs, informed orders that are entered as market orders pull market prices back towards P*.

4.3.3 Momentum Orders

The third component of the order flow is orders entered by noise traders. TraderEx activity includes just one kind of noise trader – a momentum player – and it operates as follows: whenever three or more buy orders (or sell orders) arrive sequentially, the conditional probability is increased that the next arriving order will also be a buy (or a sell).

As in the microstructure literature, noise traders are needed in the simulation model to keep participants from too easily identifying price movements that have been caused by informed orders responding to a change in P*. This is what our momentum orders achieve. For instance, assume that P* jumps several ticks above the best posted offer. An accelerated arrival of informed buy orders would be triggered and prices on the TraderEx book would rise over a sequence of trades, causing a pattern of positively autocorrelated price movements that can, with relative ease, be detected by a live participant. But, to obscure this, the momentum orders create faux price trends that mimic, and therefore obfuscate, the information-induced trends.

Momentum orders play a further role in the TraderEx simulations. They systematically cause transaction prices to overshoot P*. Then, as informed orders kick in, prices in the simulation mean revert back to P*. This mean reversion and its associated accentuated short-run volatility encourage the placement of limit orders. This is because overshooting causes limit orders to execute, and limit order placers profit when price then mean reverts. To see this, assume that the stock is currently trading at the $23.00 level and that P* jumps from $23.00 to $24.00. As price starts to tick up to $24.00, momentum orders join the march and carry price beyond $24.00–$24.20. Assume a limit order to sell is on the book at $24.20 and that it executes. The limit order placer then benefits from having sold at $24.20 when the momentum move ends and when a P* of $24.00 exerts its influence and price mean reverts back towards $24.00.

4.4 Simulation in Action

Since the earliest version of TraderEx was developed in 1995, we have run hundreds of "live market" simulations with students in our trading and market microstructure electives and with executive education participants. In addition, we have developed training modules on trading for new hires at a number of global banks. We have also run controlled experimental economics studies of trading decision making and alternative market structures (Schwartz and Weber 1997).

To illustrate the potential for research from using market simulation, we will examine the data generated by simulation participants' behavior in a number of settings. In a January 2011 class session of the "Trading and Financial Market Structure" elective at London Business School, a simulation was run which covered

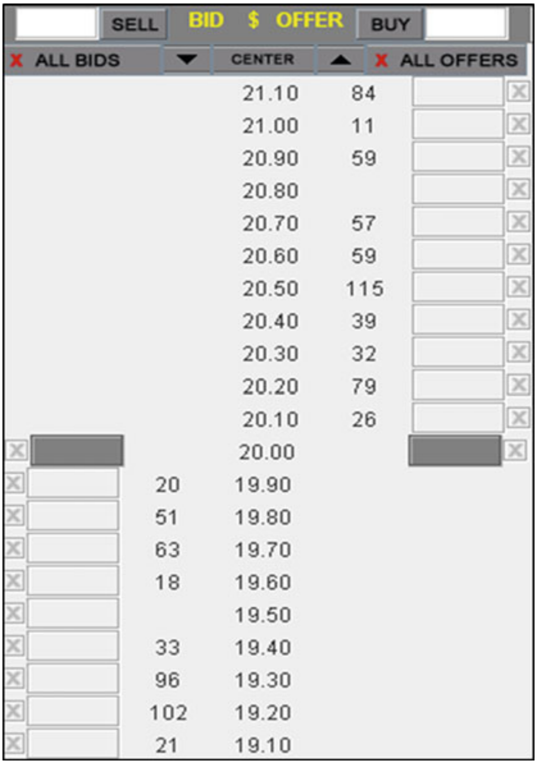

Fig. 4.1 Initial order book at start of simulated trading day. Limit orders to buy are on the *left* and limit orders to sell on the *right*. Participants enter buy and sell market orders in the *white boxes* at the *top* of the book. Limit orders are entered by clicking on the *gray rectangles* at the price level the user selects

1 day of trading in an order-driven market structure. In it, 42 graduate students were divided into 21 teams of two. The order book maintained price and time priority over limit orders. The price increment was 10 cents, and the order book at the open looked similar to Fig. 4.1 below.

4.4.1 Trading Instructions: Simulation A

Eight teams were each given the instruction to sell 1,500 units, and seven teams were each asked to buy 1,300. Five other teams had the role of either day traders or proprietary trading desks. Three of these five teams were instructed to buy 900 then sell 900 and to have a closing position of 0. Two teams were asked to sell 800, then buy 800, and to close with a flat position. A trial simulation was run, and performance metrics were discussed before the simulation began. The teams with a sell instruction were told they would be assessed on the basis of the *highest* average selling price, while buying teams competed on the basis of the *lowest* average buying price. The “prop” teams were told that maximizing closing P&L was their objective but that they should finish flat and have no “overnight risk.” A screen similar to the one the participants saw is shown in Fig. 4.2.

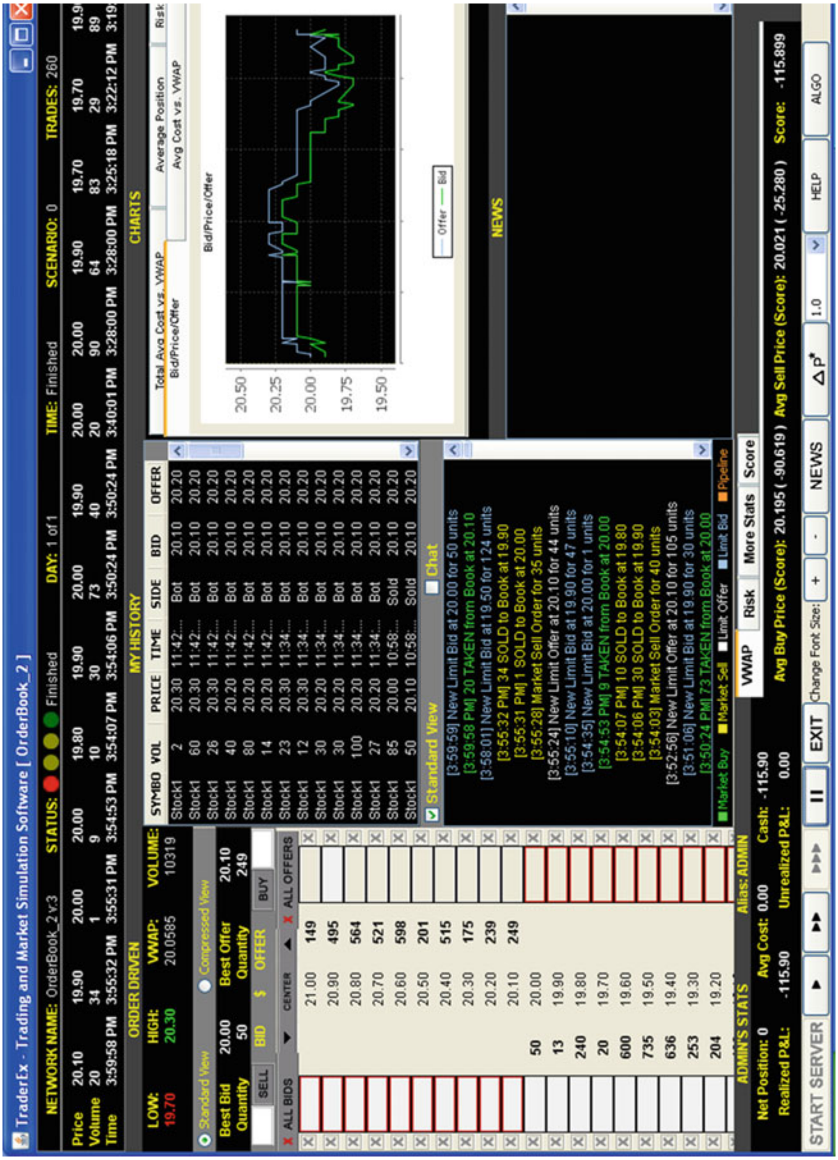

Fig. 4.2 End of a trading day in a networked order book simulation from the screen used by the instructor or simulation administrator

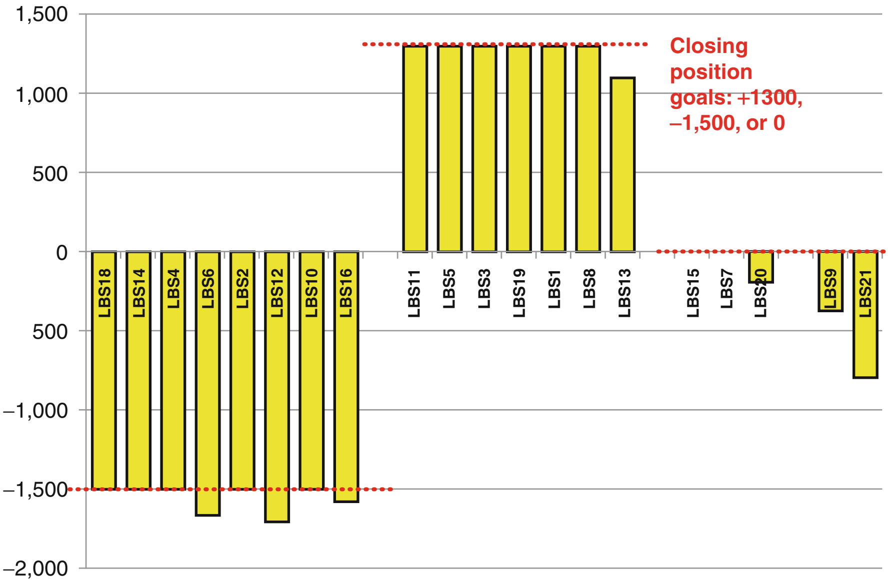

Fig. 4.3 Final positions of 21 trading teams. Teams were supposed to end with holdings of either −1,500 (sellers), +1,300 (buyers), or flat (0, prop-day traders)

One of the first lessons of behavioral studies of trading done via simulation is that following instructions is *not simple* for participants. As Fig. 4.3 shows, seven of the 21 teams did not end the simulation with the position they were instructed to have. Three of the selling teams sold more than instructed and three of the proprietary trading teams had short, nonzero positions at the end of the day. Of course, the noncompliant teams had excuses – "*the end of the day came too fast*," or "*there were not enough willing buyers in the afternoon*," or "*we didn't want to pay more than the VWAP price on the screen*." These complaints could, of course, also apply in a real equity market.

In the simulation, the market opened at £20.00. The day's high was £23.60, the low £18.80, and the last trade of the day was at £21.50. The £4.80 high-low range (24 %) reflects a volatile day. The day's volume-weighted average price (VWAP) was £20.03. Trading volume was 42,224 units and 784 trades took place. Although the teams were in the same market, and had the same buying or selling instructions with the same opportunities, there were vast differences in performance. As Fig. 4.4 shows, the best buying team paid £19.68, or £0.35 less than both the worst team and VWAP, adding nearly 2 % to the investment return. The best selling team received £0.95 more per share than VWAP and £1.23 per share more than the worst selling team. This outcome would add almost 5 % to one selling investor's return relative to the average. The conclusion is clear: trading performance has a substantial impact on investors' returns.

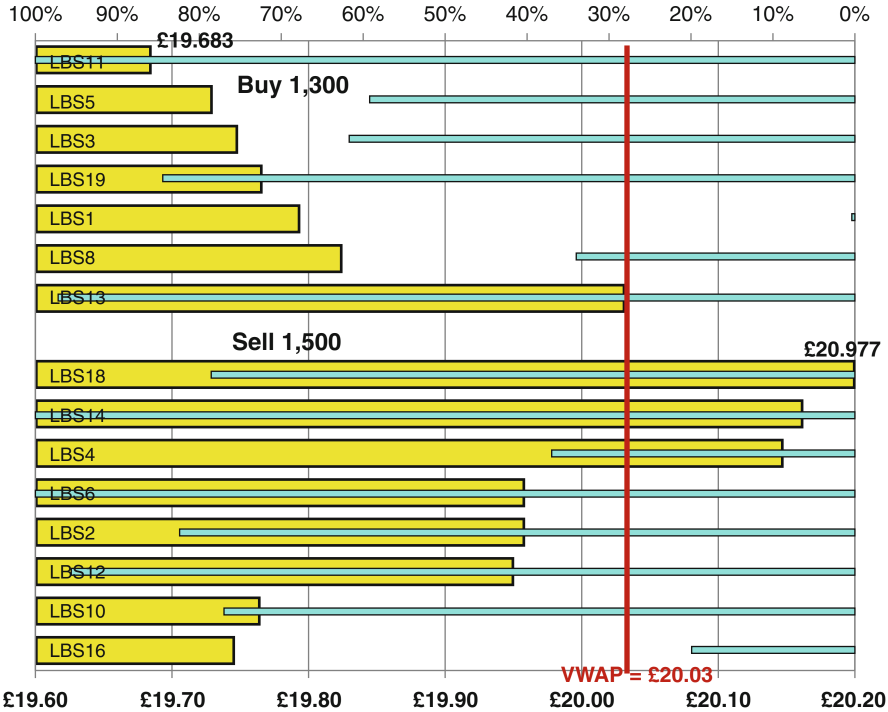

Fig. 4.4 Performance of trading teams as measured by average buying or selling price (scale shown on *bottom* of figure reading *left* to *right*) and the percentage of teams' trading done via limit orders (scale shown on *top* of figure reading *right* to *left*)

Also shown in Fig. 4.4 is the team's use of limit orders. Again, there is substantial variation, with the best buying team trading exclusively with limit orders and the best selling team completing 79 % of its trading with limit orders. Note that, as the chart shows, a higher use of limit orders did not assure good trading outcomes.

Note in Fig. 4.4 that the buying teams all matched or improved on VWAP, while only three of the selling teams were able to for more than VWAP. Teams' trading was completed with a varied combination of limit orders and market orders, with the best team, for instance, selling its 1,500 with 77 % limit orders and 23 % market orders. No significant correlation existed between order choice and performance.

As Fig. 4.5 shows, among the five proprietary trading teams, the largest loss was generated by the team (LBS21) that also had the largest risk as measured by average absolute value of their inventory position during the trading day. The greatest profit came from LBS15, a team that only took a moderate level of risk. Again, the simulation reveals substantial variation and behavioral differences across traders.

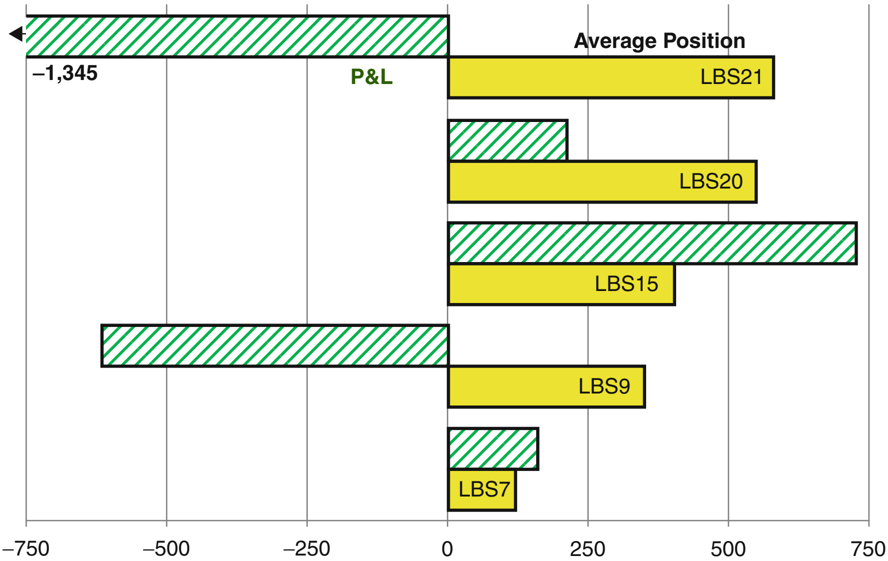

Fig. 4.5 Performance of 5-day trading teams. Collectively the proprietary traders lost money, and only two teams returned to a zero position

4.4.2 Trading Instructions: Simulations B-1 and B-2

A quote-driven market structure was used in two other simulations with the same graduate students. The underlying order flow and P* model simulated by the computer is the same as in the order-driven market. The students were put into 22 teams, and two markets (i.e., two separate networks) with 11 teams each were run. In each of the networks, seven teams were market makers, and the other teams were given large orders to fill over the course of the day.

In B-1, the market opened at 20.00, and the day's high and low prices were 21.00 and 18.70, respectively. The last trade was 19.50, and the VWAP was 20.00, with 706 trades generating a volume of 39,875 units. Participants were told that a unit represented 1,000 shares and that those with buy or sell instructions were handling institutional-sized orders that could affect prices.

In their trading, four of the market makers generated a positive profit; as a group they earned 1.4 pence per share, or seven basis points, in their trading. As Fig. 4.6 shows, only three of the dealers (LBS1, LBS3, LBS2) ended the day with a flat (either zero or no more than ±35 units) closing position. The chart shows the seven dealers' average inventory position, closing profit or loss, and their closing inventory position. LBS4, for instance, had an average position over the day of +797, a loss of 674, and a closing position of +1,431.

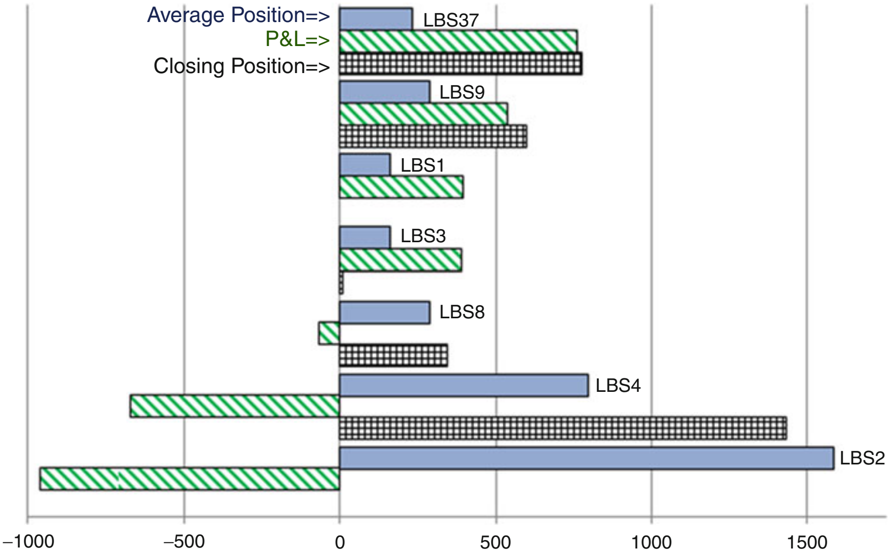

Fig. 4.6 Performance of seven market maker trading teams. The teams that controlled risk by keeping their average absolute value of their positions below 350 were able to make profits. Teams LBS4 and LBS2 incurred large losses and held large risk positions

In the B-2 market, the simulation started at 20.00, and the day's high and low prices were 22.30 and 19.00, respectively. The last trade was 22.20, and the VWAP was 20.22, with 579 trades generating volume of 36,161 units. Reflecting higher volatility, only two market makers generated a positive profit and, as a group, they lost 2.7 pence per share, or −13 basis points, in their trading. Figure 4.7 shows that three of the six dealers (LBS31, LBS25, LBS3) had a flat position at the end of the day. The other dealers had short positions reflecting the P* (equilibrium price) increases and buying pressure that drove the prices up during the simulation.

4.4.3 Trading Instructions: Simulation C

An order-driven market structure was used to study trading when participants are given either an *upward sloping supply curve* or a *downward sloping demand curve*. Rather than being instructed to buy a fixed quantity of shares, buyers and sellers are asked to maximize their surplus or profit, which is the number of shares bought or sold times the amount their *reservation price* differs from the average price they paid. The reservation prices for buyers are decreasing in the quantity they hold in their position, a demand curve. The reservation prices for sellers are increasing in the quantity they have sold, a supply curve. Our interest is in whether a group of trading participants will trade the optimal quantity in the market or whether in the absence of explicit order quantities they overtrade, or trade too little.

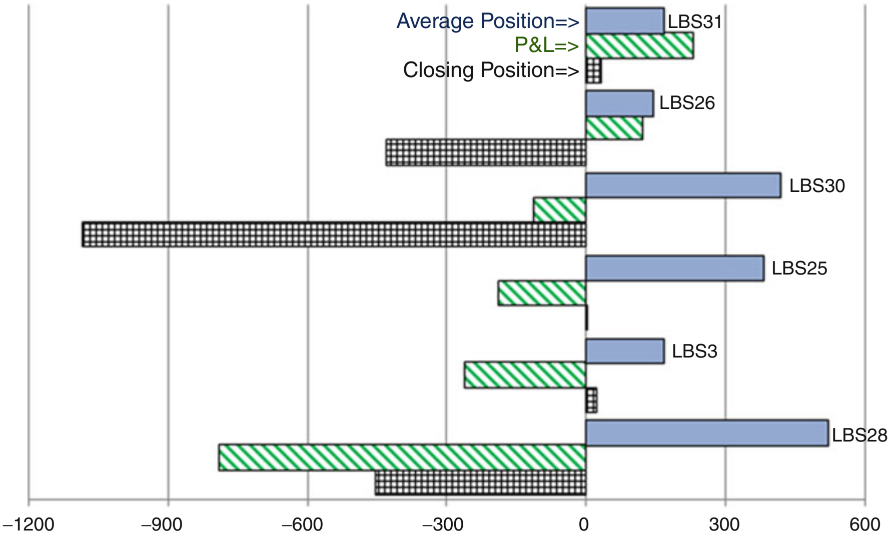

Fig. 4.7 Performance of six market maker trading teams. Only two teams, LBS #31 and #26, were able to make profits, and the teams that allowed their average position to exceed 300 had the largest losses

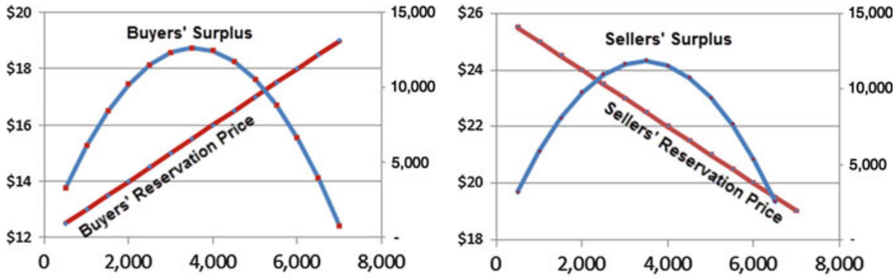
In the example below, we provide the buyers' reservation price function, which starts at $26.00 but decreases by one for each 1,000 shares bought. If a participant buys 6,000 shares over the course of the simulation, for instance, the reservation price is $20.00. If they paid on average $18, then the surplus generated is 12,000.

<u>Reservation BUY curve:</u>	P^R = \$26 – (X units/1,000)	
# shares bought	=	__________
P^R = 26 – (# shares bought/1,000)	=	__________
Average buy price	=	__________
Surplus = (# shares) × (P^R – Avg buy price)	=	__________

The sellers' reservation price function is below. It starts at $12.00 but increases by one for each 1,000 shares bought. If a participant sells 2,000 shares, the reservation price is $14.00. If the sellers' average selling price is $18, for instance, the surplus is 16,000.

<u>Reservation SELL curve:</u>	P^R = \$12 + (X units/1,000)	
# shares sold	=	__________
P^R = 12 + (# shares sold/1,000)	=	__________
Average sell price	=	__________
Surplus = (# shares) × (Avg sell price – P^R)	=	__________



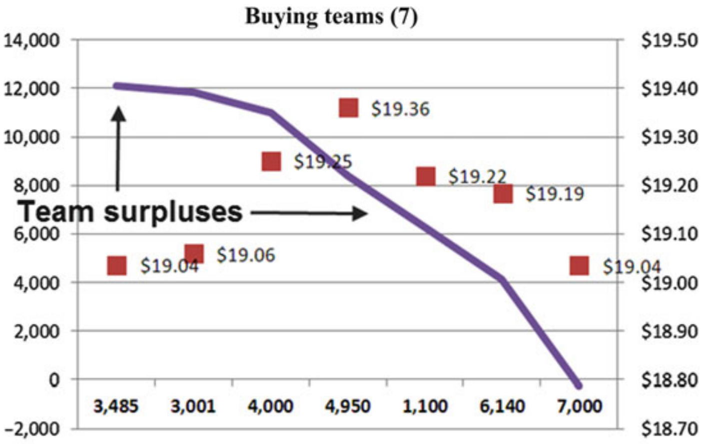
Avg Price=	$ 19.11	$12.00	$26.00	BUY	SELL
	500	$ 12.50	$ 25.50	3,195	3,305
	1,000	$ 13.00	$ 25.00	5,890	6,110
	1,500	$ 13.50	$ 24.50	8,085	8,415
	2,000	$ 14.00	$ 24.00	9,780	10,220
	2,500	$ 14.50	$ 23.50	10,975	11,525
Optimal	3,000	$ 15.00	$ 23.00	11,670	12,330
Quantity:	**3,500**	$ 15.50	$ 22.50	**11,865**	**12,635**
	4,000	$ 16.00	$ 22.00	11,560	12,440
	4,500	$ 16.50	$ 21.50	10,755	11,745
	5,000	$ 17.00	$ 21.00	9,450	10,550
	5,500	$ 17.50	$ 20.50	7,645	8,855
	6,000	$ 18.00	$ 20.00	5,340	6,660
	6,500	$ 18.50	$ 19.50	2,535	3,965
	7,000	$ 19.00	$ 19.00	-	770

Fig. 4.8 Trading experiment with supply and demand functions and surplus calculations based on a participant trading at the market average price over the day of $19.11. The optimal trading strategy was to end with a position of 3,500 long (buyer) or short (seller)

We provided the surplus functions above to a group of 28 participants. The group was split into teams of two, with seven buying teams and seven selling teams. Although the teams were not aware of the other teams' curves, the equilibrium price was $19, and the maximum surplus was achieved by participants that built a position of 3,500 and bought at the lowest possible prices or sold at the highest prices (see Fig. 4.8). In our experiment, average per share trade price was $19.11.

In the experiment, participants in the 14 teams built positions ranging from 1,100 to 7,500 (see Fig. 4.9). There was a substantial dispersion of performance, yet the market's trade prices converged to within $0.11 of the $19.00 equilibrium price. The average ending position was 4,001, so participants were within 15 % of the optimal position implicit in the reservation price functions. The teams with the greatest surpluses were able to come close to the optimal position of 3,500 and to buy below the average price and sell at greater than the average price.

As these three simulation exercises show, a number of insights can be gained into the effect of market structure on participant behavior and market outcomes (the quality of price and quantity discovery) by running "live market" simulations. First, participants' performance varied widely despite being in the same environment with the same trading instructions. Second, markets are complicated and not



BUYERS	Name	Qty	Avg Price	P r	Surplus
	Mustafa	3,485	$ 19.04	$ 22.52	**12,124**
	Thilo	3,001	$ 19.06	$ 23.00	11,821
	George	4,000	$ 19.25	$ 22.00	10,996
	Frank	4,950	$ 19.36	$ 21.05	8,366
	Pietro	1,100	$ 19.22	$ 24.90	6,248
	Oliver	6,140	$ 19.19	$ 19.86	4,145
	Jung	7,000	$ 19.04	$ 19.00	-245

	Maja	3,400	$ 19.09	$ 15.40	12,546
	Fredrick	2,750	$ 18.98	$ 14.75	11,633
	Jim	2,500	$ 19.00	$ 14.50	11,250
	Marcus	5,293	$ 19.08	$ 17.29	9,459
	Harald	1,500	$ 18.78	$ 13.50	7,920
	Ulrich	7,500	$ 19.05	$ 19.50	-3,405

Fig. 4.9 Even when provided with reservation price functions, the live participants in the markets traded near the equilibrium and showed little inclination to "overtrade." The average position was only 501 units away from the optimal closing position of 3,500

perfectly liquid; filling large orders, while competing to outperform price benchmarks, is challenging. Participants often did not complete their instructions even though completion was part of their assessment. Third, trading can add (or subtract) value for investment managers. Even in fairly simple simulation games, performance varied widely across participant teams. Finally, risk was not well controlled by the (admittedly inexperienced) trading participants. Although given specific position limits as guidelines, many participants had large average positions and suffered substantial losses from adverse price movements.

Market architects today combine different trading systems designs (Zhang et al. 2011). Beyond studies of trading decision making, the live simulations provide a method for comparing alternative market structures. For instance, implicit trading costs incurred in handling a large order over a trading day can be contrasted in markets with and without dealers, and with and without a dark liquidity pool. Live simulations, by extending what can be learned with analytical modeling and empirical data analytics, provide a laboratory for examining a broad set of questions about trading behavior and market structures.

4.5 Conclusion

Simulation is a powerful research tool that can be used in conjunction with theoretical modeling and empirical research. While simulation can enable a researcher to delve into issues that are too detailed and specific for theory to handle, a simulation structure must itself be based on a theoretical model. We have illustrated this with reference to TraderEx, the simulation that we have developed and used to analyze details of market structure and trading in an equity market.

One further research methodology incorporates simulation: experimental economics. This application applies the simulated market in a laboratory where multiple players are networked together. With a well-defined performance measure and carefully crafted alternative market structure and/or information environments, a simulation-based experimental application can yield valuable insights into the determinants of market outcomes when market structure affects individual behavior and when behavioral economics along with theoretically rational decision making characterizes participant actions.

Appendix

Modeling Securities Trading

The simulation methodology was chosen for its ability to accommodate critical institutional features of the market mechanism and off-exchange dealers' operations. While higher level abstractions and simplifications could yield an analytically tractable model, it is not consistent with the goals of this chapter. These complexities included here are the specialist's role, the use of large and small order sizes, and the limit and market orders.

Earlier market structure research provides useful insights, but missing institutional details prevent it from determining the effect of third markets. Garman's (1976) model of an auction market identifies a stochastic order arrival process and a market structure consistent with negative serial autocorrelations or the tendency of price changes to reverse themselves. Garman's model has no specialist role, and an analytic solution is obtained only for the case with one possible price. He notes "the practical difficulties of finding analytic solutions in the general case are considerable, and numerical techniques such as Monte Carlo methods suggest themselves." Mendelson (1987) derives analytic results that provide a comparison of market consolidation or fragmentation on market performance. The work provides numerous insights into market design trade-offs. As a simplification, however, all orders from traders are for one unit of the security.

Simulation has yielded useful results in other microstructure research. Garbade (1978) investigated the implications of interdealer brokerage (IDB) operations in a competing dealer market with a simulation model and concluded that there are benefits to investors from IDBs through reduced dispersion of quotes and transaction prices closer to the best available in the market. Cohen et al. (1985) used simulation to analyze market quality under different sets of trading priority rules. They showed that systems that consolidate orders and that maintain trading priorities by an order's time of arrival in the market increase the quality of the market. Hakannson et al. (1985) studied the market effects of alternative price-setting and own-inventory trading policies for an NYSE-style specialist dealer using simulation. They found that pricing rules "independent of the specialist's inventories break down."

Further Details on Simulation Model and Environment

Our simulation model has been used in experiments with subject-traders to test hypotheses concerning market structures. The simulation model is dynamic, with informational changes occurring in a way that creates the possibility of realizing trading profits from close attention to price changes and careful order handling. In our human-machine interactive environment, the computer generates orders from an unlimited number of "machine-resident" traders and investors. This enables us easily to satisfy the conditions for an active, competitive market.

To be useful and valid, simulation models must reflect real-world dynamics without being burdened by unnecessary real-world detail. A simulation model also requires a strong theoretical foundation. The advantage of simulation over theoretical modeling is that "theorizing" requires abstracting away from some of the very details of market structure that exchange officials and regulators wish to study. Consequently, theoretical modeling can give only limited insight into the effects of market design changes on the behavior of market participants. The advantage of simulation vis-à-vis empirically testing of new market structures is that the simulated experiments can be run at much lower cost and across a broader range of alternatives.

The objective of our computer simulation is to provide a backdrop for assessing the decisions of live participants. Trading in the model is in a single security and is the result of "machine-generated" order flow interacting with the order placement decisions of the live participants. Assumptions are made about the arrival process of investors' orders, changes to a price, p*, which is an "equilibrium value" at which the expected arrival rate of buy orders equals the expected arrival rate of sell orders.

P* follows a random walk jump process. In other words, the equilibrium value jumps randomly from one level at interarrival times based on sampling an exponential distribution. After a shift in p*, the orders of the informed traders pull the quotes and transaction prices up or down, causing them to trend towards the new p* level. Occasionally, market prices can also trend away from p* because of the orders of momentum traders or the chance arrival of a string of buy or sell liquidity orders. However, movements away from p* are unsustainable; eventually the imbalanced order flow causes a price reversal and market prices gravitate back towards p*.

Little work in experimental economics has used computers to create background order flow into which participants individually enter orders (Smith and Williams 1992; Friedman 1993). Our test environment does. We use discrete event computer simulation to do the following:

- Generate a background public order flow that can (1) be placed on a public limit order book for later execution, or (2) execute as market orders immediately against the public limit order book.
- Give the live participants the opportunity to trade a quantity of stock. Depending on the market structure, the live participants can (i) place them in a public limit order book and wait for a trade to occur or (ii) execute them against the public limit order book immediately. Variants of the simulation model include market makers, or call auctions, or dark liquidity pools to facilitate transactions.
- Maintain the screen which displays (i) orders on the public limit order book, (ii) a time-stamped record of all transaction sizes and prices for each trading session, and (iii) the users' position, risk, and profit performance data.
- Capture information concerning (i) the live participants' decisions and (ii) market quality measures such as bid-ask spreads.

In summary, with this realistic and theory-based model and the ability in the simulation to control the level of transparency provided, we have a rigorous environment to assess trading decisions and the effects of different market rules.

Components of the Market Model

In the simulation model, assumptions are made about the arrival process of investors' orders, elasticity of supply and demand, and order placement strategies, price volatility, and the proportions of market and limit orders.

Order Arrival. Orders arrive according to a price-dependent Poisson function. Using time-stamped transactions data on six stocks traded on the London Stock Exchange, a Kolmogorov-Smirnov goodness-of-fit test fails to reject the null hypothesis of exponential interarrival in 17 out of 22 sample periods at the 0.10 level of significance. We would expect to reject in just over two cases due to random realizations. The fit is not perfect in part because transactions tend to

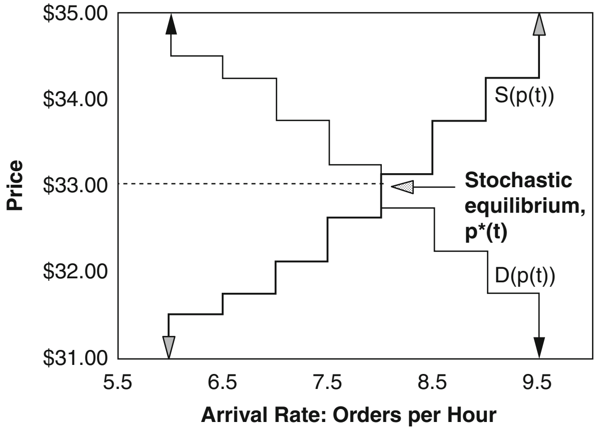

Fig. 4.10 Buy and sell order arrival rates. At market prices greater than p*, sell orders will arrive with greater intensity than buy orders. At market prices less than p*, buy orders will arrive with greater intensity than sell orders

cluster somewhat more than predicted by the theoretical model (Weber 1991). Given the shortcoming of using empirical distributions in simulations (Law and Kelton 1989), the Poisson assumption appears sufficiently justified for capturing the typical behavior of the order arrival process.

The Poisson interarrival time, T, is exponentially distributed with β_t equal to the mean interarrival time at time *t*. The mean interarrival time is set at the beginning of each experiment and assumed to hold constant. A realization at time t is thus $T_t = \Psi(\beta)$. The supply and demand structure follows closely those previously developed in the market microstructure literature (Garbade and Silber 1979), in which buy and sell arrival rates are step functions of the difference between the quoted price and the equilibrium value of the security Fig. 4.10.

Garman (1976) termed the intersection of the supply and demand functions a "stochastic equilibrium."

Demand/buy orders, D(p):

$$\begin{aligned}
&\lambda_B(p_i, p^*) = a_1 \quad \text{for} \quad {p_t}^* < p_i \\
&\lambda_B(p_i, p^*) = a_1 + a_2({p_t}^* - p_i) \quad \text{for} \quad p_i = {p_t}^* + \alpha \\
&\quad \text{with} \quad \alpha = \text{tick size}, 2(\text{tick size}), 3(\text{tick size}), \ldots \delta \\
&\lambda_B(p_i, p^*) = a_1 + a_2\delta \quad \text{for} \quad {p_t}^* - p_i > \delta
\end{aligned}$$

Supply/sell orders, S(p):

$$\begin{aligned}
&\lambda_S\left(p_j, p^*\right) = a_1 \quad \text{for} \quad {p_t}^* > p_i \\
&\lambda_S\left(p_j, p^*\right) = a_1 + a_2\left(p_j - {p_t}^*\right) \quad \text{for} \quad p_j = {p_t}^* - \alpha \\
&\quad \text{with} \quad \alpha = \text{tick size}, 2(\text{tick size}), 3(\text{tick size}), \ldots \delta \\
&\lambda_S\left(p_j, p^*\right) = a_1 + a_2\delta \quad \text{for} \quad p_j - {p_t}^* > \delta
\end{aligned}$$

The constant a_1 reflects the proportion of arrivals that are market orders. The coefficient a_2 determines the arrival rate of limit orders with reservation prices. Limit order traders are sensitive to discrepancies between available prices and the equilibrium value. The parameter, δ, is the range around the equilibrium value from which limit prices for limit orders are generated. At a price p_i lower than the equilibrium value at the time, p_t^*, the arrival rate of buy orders will exceed the rate of sell order arrivals. The resulting market buy orders and limit order bids will exceed the quantity of sell orders for below-equilibrium values. The arrival rate discrepancy will cause prices to rise since in expectation, orders will trade against the lowest offer quotes, and add new, higher priced bid quotes.

Order Size. Orders are between one and 250 units of the security. This reflects a convenient normalization that is consistent with the empirically observable range of order sizes. A unit may represent, for instance, three round lots, or 300 shares. Beyond 250 units, we assume the trade would be handled as a block trade, and negotiated outside of the standard market design, or arrive in the market in smaller broken-up pieces. Large orders can have "market impact," and can move prices up for large buyers, and force them down for larger sellers. The functioning of the market for large orders is consistent with observed trade discounts for large sell orders and premiums for large buy orders.

Order Placement Strategies. The machine-generated order flow consists of liquidity, informed, and momentum trading orders. The liquidity orders are either limited price orders or market (immediately executable) orders. Market orders execute on arrival but are "priced" to reflect a maximum acceptable premium or discount to the current bid or offer. If the market order is large enough, its price impact (the need to hit successive lower priced bids or lift higher priced offers) will exceed the acceptable discount or premium, and the remaining order quantity will become a limit order after partially executing against the limit order book.

Information Generation. Idiosyncratic information events occur that change the share value, p*, at which buying and selling order arrival rates are balanced. Information event occurs according to a Poisson arrival process. When an information innovation occurs, the price will have a random walk jump.

Price Random Walk. Idiosyncratic information events occur that change the share value, p*, at which the arrival rate of buy orders equals the arrival rate of sell orders. The time between information change is assumed to be exponentially distributed with mean, 12 h. Empirical validation is difficult, because informatio-n affects the share values in unobservable ways. When there is a change in information that will shift the "balance price," p* evolves according to a random walk without return drift. To assure nonnegative prices, the natural log of price is used, yielding a log-normal distribution for the equilibrium price. The white noise term, et, is normally distributed with variance linear in the time since the last observation. This is consistent with the price diffusion models used in the financial economics literature (Cox and Rubinstein 1985):

$\ln p_t * = \ln p_t - T * + e_t$ where, $et \sim N(0, T\sigma^2)$
where $p_t * \sim LN(\ln pt - T *, T\sigma^2)$

The natural logarithm of the current price is an unbiased estimator of the natural logarithm of any subsequent price:

$$E(\ln\ p_t + T^* \mid pt^*) = \ln \quad p_t *$$

Empirical validation for the random walk model comes from numerous tests, whose results "are remarkably consistent in their general finding of randomness . . . serial correlations are found to be small" (Malkiel 1987).

Information Effects. If the bid and offer quotes straddle p*, there is no informed order flow and buying and selling order arrival rates will be equal. When p* is outside of the bid-offer range, additional one-sided market orders will be generated according to a Poisson process.

that the market favorably views the issue announcement of these bonds that we refer to as bonds with European put options or European putable bonds. This response is in contrast to the response documented by the literature to other bond issues (straight, convertible, and most studies examining poison puts) and to the response documented in the current paper to the issue announcements of poison put bonds. Our results suggest that the market views issuing European putable bonds as helping mitigate security mispricing. Our study is an application of important statistical methods in corporate finance, namely, *event studies* and the use of general method of moments for cross-sectional regressions.

5.1 Introduction

This paper examines the motivations for issuing putable bonds in which the embedded option is not contingent upon company-related events. The option entitles bondholders to sell the bond back to the firm on the exercise date (usually 3–10 years after the bond is issued) at a predetermined price (usually at par). We refer to these bonds as bonds with European put options or European putable bonds. Unlike the poison put bonds (i.e., bonds with event risk covenants) that have been studied by the literature,[1] the exercise of the option in a putable bond is **not** contingent upon a company-related event. This distinction is important because a poison put protects the bondholder from a specific event (e.g., a takeover) and may be designed to help prevent that event. In contrast, putable debt provides protection to the bondholder against any deterioration in the value of her claim. This distinction is important also because the two types of embedded put options may serve different purposes. Crabbe and Nikoulis (1997) provide a good overview of the putable bond market.

Corporate managers determine which contingent claims the company issues to finance its activities. This choice includes the debt-equity mix and the specific design of the debt. The design of the debt includes its maturity, seniority, collateral, and the type of embedded options included in the bond contract. The theoretical corporate finance literature indicates that including convertible, callable, and/or putable bonds in the capital structure may help mitigate agency costs and reduce asymmetric information. Haugen and Senbet (1981) theoretically demonstrate that the optimal combination of embedded call and put options should eliminate the

[1]See for example, Crabbe (1991), Bae et al. (1994, 1997), Cook and Easterwood (1994), and Roth and McDonald (1999), Nash et al. (2003). Billett et al. (2007) find that 5 % of corporate bonds of their sample have a non-poison putable option.

asset substitution problem. Bodie and Taggart (1978) and Barnea et al. (1980) show that bonds with call options can mitigate the underinvestment problem. Robbins and Schatzberg (1986) demonstrate that the increased interest cost of callable bond can be used to convey the true value of the firm to the market.[2]

The literature has not empirically examined the motivation and equity valuation impact of issuing debt with European put options. We fill this gap in the literature in several ways. First, we examine the stock price reaction around the announcement dates of the two types of putable bond issues: bonds with European put options and bonds with poison puts. Further, we consider four alternative motivations for incorporating either a European or a poison put option in a bond contract and test the hypotheses that putable debt is issued to reduce security mispricing, agency costs of debt, management entrenchment, and myopia. The first possible motivation for issuing putable debt is asymmetric information. Consider a company that is undervalued by the market. The market should also undervalue its risky straight-debt issue. However, if this firm were to issue putable bonds, the put option would be overvalued. (Recall that put options are negatively related to the value of the underlying asset.) Consequently, the market value of bonds with a put option is less sensitive to asymmetric information than straight bonds, minimizing market mispricing of these debt securities. Additionally, if the market overestimates the risk of the bond, it may overvalue the embedded put option at issuance, thereby increasing bond proceeds and benefiting the shareholders.[3] The second possible motivation is mitigating agency costs of debt. For example, the existence of a put option mitigates the advantage to stockholders (and the loss to bondholders) from risk shifting, thereby reducing the incentive to shift risk. Risk shifting hurts putable bondholders less than holders of straight bonds because the value of the put option (which is held by bondholders) is an increasing function of the firm's risk. The third possible motivation is the relatively low coupon rate (a myopic view that ignores the potential liability to the firm due to the put option). The fourth possible motivation is that the put option may serve to entrench management. This fourth motivation is most relevant for firms issuing poison puts since these put options are exercisable contingent upon company-related events that are usually related to a change in ownership.

We find that the market reacts favorably to the issue announcement of European put bonds. We also examine the relationship between the abnormal returns around the put issue announcement date and firm characteristics that proxy for asymmetric information problems, potential agency costs (i.e., risk-shifting ability and the level of free cash flow), and management myopia. The empirical evidence is consistent with the view that the market considers issuing putable bonds as mitigating security mispricing caused by asymmetric information. The results do not support the idea

[2]Other benefits posited by the literature include minimizing tax liabilities. See for example, Brick and Wallingford (1985), and Brick and Palmon (1993).

[3]Brennan and Schwartz (1988) offer a similar argument to explain the benefits of issuing convertible bonds.

that putable bonds are issued to obtain lower coupon rates (i.e., management myopia). Our empirical findings are robust to a number of alternate specifications.

In contrast to European putable bonds, and consistent with the management entrenchment hypothesis (see Cook and Easterwood (1994) and Roth and McDonald (1999)), we find that the market reacts unfavorably to the issue announcement of poison put bonds. However, consistent with Bae et al. (1994) who argue that poison put bonds are useful in mitigating agency cost problems, we find that the abnormal returns around the issue announcement of poison put bonds are positively related to the protection level of the event risk covenant. Thus, our results are consistent with the view that European put bonds are effective in mitigating security mispricing problems, but, in contrast, poison put bonds are related to management entrenchment or mitigating agency cost problems.

The paper's organization is as follows. In the next section we summarize the previous literature. Section 5.3 develops the empirical hypotheses. We describe the data and empirical methodology in Sect. 5.4. The empirical results are summarized in Sect. 5.5. We offer concluding remarks in Sect. 5.6.

5.2 Literature Review

The theoretical corporate finance literature concludes that the firm's financing decision may affect its equity value for several reasons. First, issuing debt increases firm value because it decreases its tax liabilities.[4] Second, issuing debt may be, in part, a signaling mechanism that informs the market of private information. For example, Ross (1977) and Ravid and Sarig (1991) demonstrate that the manager of a firm with better prospects than the market perceives has an incentive to signal her firm's quality by issuing a greater amount of debt than issued in a symmetric information environment. Third, prudent level of debt can reduce the agency costs arising from the conflict of interest between managers and shareholders as demonstrated by Jensen and Meckling (1976). For example, Jensen (1986) demonstrates that leverage can minimize the deleterious effect of free cash flow on the firm.[5] However, leverage is also shown to generate other

[4]See, for example, Modigliani and Miller (1963), Scott (1976) and Kim (1978). In contrast, Miller (1977) suggests that the tax benefit of interest is marginal. However, Mackie-Mason (1990) empirically demonstrates the significant impact of corporate taxes upon the observed finance choices of firms.

[5]Hence, empirically, we would expect that as firms announce increased levels of debt, the stock price should increase. However, studies by Dann and Mikkelson (1984), Mikkelson and Partch (1986), Eckbo (1986), and Shyam-Sunder (1991) indicate that there is no systematic relationship between the announcement of firm's debt financing and its stock price or that this relationship is weakly negative. One potential explanation for this result is that the market can predict future debt offerings as argued by Hansen and Chaplinsky (1993). Another potential explanation, as suggested by Miller and Rock (1985) and documented by Hansen and Crutchley (1990), is that raising external capital may indicate a cash shortfall.

agency problems because of the conflict of interest between stockholders and bondholders. These agency problems include underinvestment and risk shifting (or asset substitution).[6]

Other studies indicate that these agency problems can be mitigated or eliminated by optimal security design. For example, Haugen and Senbet (1981) demonstrate that the optimal combination of embedded call and put options completely eliminates the asset substitution problem. Bodie and Taggart (1978) and Barnea et al. (1980) show that the call options of bonds can mitigate the underinvestment problem. Similarly, Green (1984) demonstrates that including convertible bonds in the capital structure may also mitigate the underinvestment problem.

The literature has also demonstrated that an appropriate debt security design may alleviate asymmetric information problems. For example, Robbins and Schatzberg (1986) demonstrate that the increased interest cost of callable bond can be used to signal the value of the firm. Moreover, as similarly stated for the case of convertible bonds by Brennan and Schwartz (1988), the inclusion of a put option can minimize the mispricing of debt securities if the market overestimates the risk of default. Chatfield and Moyer (1986) find that putable bonds may be issued by financial institutions for asset-liability management in a period of volatile interest rates. Tewari and Ramanlal (2010) find that callable-putable bonds provide protection to bondholders and improved returns to stockholders.

The literature examines the equity valuation impact of a special type of putable bond known as the poison put bond. In poison put bonds, the put option is exercisable contingent upon a company-related event such as a leveraged restructuring, takeover, or downgrading the debt credit rating to speculative grade. David (2001) shows that puts may have higher strategic value than intrinsic value. Crabbe (1991) finds that such event-related covenant put bonds reduce the cost of borrowing to the firm. Bae et al. (1994) conclude that stockholders benefit from the inclusion of event-related (risk) covenants. Furthermore, Bae et al. (1997) empirically document that the likelihood of a firm to include event risk covenants is positively related to the firm's agency costs of debt. In contrast, Cook and Easterwood (1994) and Roth and McDonald (1999) find that the inclusion of poison put bonds benefits both management and bondholders at the expense of stockholders.

In contrast to these studies of poison put options, our study examines debt issues in which the embedded put option is equivalent to a European put with a fixed exercise date that is usually 3–10 years after the issue date. That is, bondholders may exercise the put option only at the exercise date, and their ability to do so is not contingent upon any particular company-related event. Thus, we believe that issuing bonds with an embedded put option that is not contingent upon a company-related event (such as a change in ownership) is not likely to be motivated by

[6]Myers (1977) demonstrates that shareholders may avoid some profitable net present value projects because the benefits accrue to the bondholders. Jensen and Meckling (1976) demonstrate that leverage increases the incentives for managers, acting as agents of the stockholders, to increase the risk of the firm.

management entrenchment. Consequently, we consider the security mispricing motivation and two other possible motivations: mitigating agency costs and the myopic behavior on the part of the management.

5.3 Hypotheses

In this section, we describe four alternative motivations for incorporating a put option in a bond contract and outline their empirical implications.

The first motivation is **reduction in the level of security mispricing due to asymmetric information**. Consider a company that is undervalued by the market.[7] The market should also undervalue its risky straight-debt issue. However, if this firm were to issue putable bonds, the put option would be overvalued. Consequently, the market value of bonds with put option is less sensitive to asymmetric information than the market value of straight bonds, minimizing market mispricing of these debt securities. Additionally, the overvaluation of the implicit put option increases the debt proceeds at the issuance thereby benefiting the shareholders. This possible motivation has the following empirical implications. *First*, issuing bonds with put option should be associated with an increase in equity value. *Second*, this increase in firm value should be negatively related to the accuracy with which the firm's value has been estimated prior to the bond issue. *Third*, because the value of the put option is directly related to the magnitude of firm undervaluation, the increase in equity value should be directly related to the value of the put option.

The second possible motivation is **mitigating the bondholder-stockholder agency costs**.[8] The value of a put option is an increasing function of the firm's risk. Thus, its existence mitigates the gains to stockholders from, and hence their incentives for, risk shifting. This possible motivation has the following empirical implications. *First*, the benefit to a firm from incorporating a put option in the bond contract should be directly related to the firm's ability to shift risk in a way that increases the value of stockholders claims at the expense of bondholders. *Second*, the inclusion of a put option should help restrain management from taking on negative net present value projects in the presence of Jensen's (1986) free cash flow problem.[9] In the absence of a put option, undertaking negative net present value projects should reduce security prices for both stockholders and bondholders.

[7]We assume that managers of companies that are overvalued have no incentive to resolve security mispricing. Consequently, managers of undervalued firms could send a credible signal to the market of the firm's undervaluation with the inclusion of a put feature. Overvalued firms should not be able to mimic since the put option represents a potential liability that is greater to these firms than of the undervalued firms.

[8]The bondholders-stockholders agency conflict has been found to be important in security design by Bodie and Taggart (1978), Barnea et al. (1980), Haugen and Senbet (1981), Jung et al. (1996), and Lewis et al. (1998).

[9]Equivalently, the inclusion of a put option should restrain management from consuming a suboptimal amount of perquisites or nonpecuniary benefits.

In contrast, giving bondholders the option to put the bond back to the firm at face value shifts more of the negative price impact of undertaking negative net present value projects to the stockholders. This negative stock price impact may reduce management compensation that is tied to equity performance and/or induce tender offers that will ultimately help replace the current management. These increased costs to stockholders and management should induce management to refrain from undertaking negative net present value projects. Thus, we hypothesize that the benefit to the stockholders from incorporating a put option in the bond contract should be directly related to the level of free cash flow. *Third*, the gain in firm value should be related to the magnitude of the agency cost problem that the firm faces. The valuation of the put option by the market (assuming market efficiency and symmetric information) should be positively related to the magnitude of the agency cost problem faced by the company. Thus, the benefit to the firm should also be directly related to the aggregate value of the implied put option of the issue (scaled by firm size). *Fourth*, for our sample of poison put bonds, the benefit to shareholders should increase with the strength of the event risk covenant, since the greater the strength of the event risk covenant, the less likely management will engage in value decreasing activities. Bae et al. (1994) tested a similar set of hypotheses for a sample of poison put bonds.[10]

The third possible motivation is the low coupon rate (compared to the coupon rates of straight or callable debt issues). This motivation reflects **management myopia** as it ignores the potential liability to the firm due to the put option.[11] That is, myopic management may not fully comprehend the increased risk to the firm's viability that is posed by the put option. In particular, bondholders would have the right to force the firm to (prematurely) retire its debt at a time that is most inconvenient to the firm, which in turn can precipitate a financial crisis. Further, if the cost of financial distress is significant, given rational markets and myopic management, issuing putable debt may negatively impact the value of equity. This possible motivation has the following empirical implications. *First*, because management myopia implies that management pursues suboptimal policies, the issuance of putable debt should be associated with a decline in equity value.[12] *Second*, the decline should be more severe the larger is the aggregate value of the implied put option. *Third*, because expected costs of financial distress are

[10]Although bonds become due following formal default, hence all bonds in a sense become putable, bondholders usually recover substantially less than face value following formal default because equity value has already vanished. In contrast, a formal inclusion of put option may allow bondholders to recover the face value at the expense of shareholders when financial distress is not imminent but credit deterioration has occurred.

[11]Other studies that have examined managerial myopia include Stein (1988), Meulbroek et al. (1990), Spiegel and Wilkie (1996), and Wahal and McConnell (2000).

[12]Haugen and Senbet (1978, 1988) theoretically demonstrate that the organizational costs of bankruptcy are economically insignificant. However, if the putable bonds increase the potential of technical insolvency, then it will increase potential agency costs that are not necessarily insignificant.

negatively related to the financial stability of the company, the decline should be more severe the lower the credit rating of the bond.

The fourth possible motivation is that the use of put options enhances **management entrenchment**. This hypothesis is relevant for firms issuing poison but not European put bonds. In particular, many bonds with event risk covenants (i.e., poison puts) place restrictions on the merger and acquisition activity of the issuing firms, thereby strengthening the hands of management to resist hostile takeover bids. This possible motivation has the following empirical implications. *First*, issuing bonds with put options should be followed by a decrease in equity value. *Second*, in contrast to the **mitigating agency costs hypothesis**, the abnormal returns of equity around the issue announcement date should be inversely related to the level of event-related covenant protection offered to the bondholder.

5.4 Data and Methodology

Our sample of bonds with put options is taken from the *Warga Fixed Income Database*. The database includes pricing information on bonds included in the Lehman Brothers Bond Indices from January 1973. Using this database we select all bonds with fixed exercise date put option (i.e., not event contingent), issued between January 1973 and December 1996, excluding issues by public utilities, multilateral agencies (such as the World Bank), and sovereign issues. In our sample we keep only those issues for which we find announcement dates in the *Dow Jones News Retrieval Service*. This resulted in a sample of 158 bonds of which the earliest bond is issued in 1979. Our final sample of bonds is selected according to the following criteria:

(a) The issuing company's stock returns are available on the CRSP tapes. For 20 companies CRSP data are not available, resulting in 138 issues. To reduce confounding effects, all repeat issues by the same company within a year of a sample issue are eliminated. We also eliminated observations for which we find other contemporaneous corporate events. This further reduced our sample to 104 issues.
(b) Furthermore, we eliminate from the sample companies that do not have sufficient accounting data, credit rating, issue size, and industry code in either the *Compustat* tapes, Moody's *Industrial Manuals*, or the Warga's *Fixed Income* database. This reduces our sample size by 13 firms.
(c) We eliminate one more company for which we found no I/B/E/S data, thus yielding a final sample of 90 firms.

The list of these firms and the characteristics of these bonds are reported in Appendix 1. The maturity of these put bonds ranges from 5 to 100 years, with an average initial maturity of 24 years. The put exercise dates ranges from 2 to 30 years, with an average put expiration period of 7 years.[13]

[13]Four bonds have multiple put exercise dates.

For the sake of comparison, we also construct a sample poison put bonds.[14] The issue announcements of poison put bonds are taken from *Dow Jones Interactive*. We also searched *LexisNexis* but did not find any new announcements.[15] This search resulted in 67 observations. Our final sample of bonds with poison put feature is further refined using criteria (a), (b), and (c) described above. Criterion (a) reduces the sample size to 57 observations, and applying criterion (b) further reduces it to 47 observations. The list of these firms and the characteristics of these bonds are reported in the Appendix 2.

For these issues, we collect *CRSP* daily returns for our event study.[16] We calculate the abnormal returns (*AR*) on equity for each firm around the date of the issue announcement, assuming that the stochastic process of returns is generated by the market model. We define the announcement date to be the earlier of the date on which the bond is issued and the date on which the issue information appears in the news wires, or published in the *Wall Street Journal*, as depicted by the *Dow Jones Interactive*. Our final sample includes only bonds whose issue announcement explicitly mentions the inclusion of a put option. We estimate the market model coefficients using the time period that begins 200 trading days before and ends 31 trading days before the event, employing the CRSP value-weighted market index as the benchmark portfolio. We use these coefficients to estimate abnormal returns for days −30 to +30. We calculate the t-statistics for the significance of the abnormal and cumulative abnormal returns using the methodology employed by Mikkelson and Partch (1986). See Appendix 3 for details.

We examine the abnormal returns and their determinants for the sample of issuers of bonds with European put options. First, we test whether issuing these bonds significantly affects equity values. The stock price should, on average, react positively to the issue announcement if either reducing debt security mispricing due to asymmetric information or mitigating agency costs is a major motivation for issuing putable bonds. On the other hand, the stock price should, on average, react negatively to the issue announcement if management myopia (i.e., the relatively low coupon rate compared to straight or callable debt issues) is a major motivation of management in issuing putable bonds and if costs of financial distress are significant.

Second, we estimate the following cross-sectional regression equation that relates the cumulative abnormal return of the issuing firm's equity to firm

[14]Unlike the European put bond sample which we were able to obtain from *Warga's Fixed Income Database*, we obtained our sample of poison puts from *Dow Jones Interactive* by using keywords such as poison put, event risk, and covenant ranking. Warga's database does not include an identifiable sample of poison put bonds.

[15]We were only able to find a sample of poison put bonds with issue announcements using *Dow Jones Interactive* and *LexisNexis* for the period between 1986 until 1991. We did use these news services for the periods between 1979 and 2000.

[16]The event study methodology was pioneered by Fama et al. (1969).

characteristics that proxy for agency costs, asymmetric information problems, and managerial myopia:

$$\begin{aligned} CAR3_i = \beta_0 + \beta_1 FCF_i + \beta_2 RISK_i + \beta_3 SIZE_i + \beta_4 INTSAVED_i \\ + \beta_5 ANALYSTS_i + \beta_6 FINS_i + \varepsilon_i, \end{aligned} \tag{5.1}$$

where $CAR3_i$ is the 3-day (i.e., $t = -1, 1$) cumulative abnormal return for firm I. The variables, *FCF*, *RISK*, *SIZE*, *INTSAVED*, and *ANALYSTS* proxy for agency costs, information asymmetry, or management myopia. *FINS* is a dummy variable that indicates whether the company is a financial institution.

FCF is the level of free cash flow of the firm for the fiscal year prior to the issue announcement of putable bonds. We construct two alternative measures of *FCF* which are similar to the definition employed by Lehn and Poulsen (1989) and Bae et al. (1994). *FCF1* is defined as [Earnings before Interest and Taxes – Taxes – Interest Expense – Preferred Dividend Payments – Common Stock Dividend Payments]/Total Assets. *FCF2* is defined as [Earnings before Interest and Taxes – Taxes – Interest Expense]/Total Assets.[17] The inclusion of a put option in the bond contract should help restrain management from misusing its cash flow resources. We therefore expect β_1 to be positive if reducing agency cost is a major motivation for issuing putable bonds.

RISK is a dummy variable that equals 1 if the putable bond is rated by **Standard and Poor's** as BBB+ or below and zero otherwise.[18] The impact of issuing putable bonds on equity value may be associated with the variable *RISK* because of two alternative hypotheses. First, the level of agency costs due to the asset substitution problem is positively related to the probability of financial distress. We use this dummy variable as a proxy for the firm's ability and incentive to shift risk. According to the agency cost motivation, we expect β_2 to be positive. Second, the greater the probability of financial distress, the more likely are bondholders to exercise their put option and force the firm to prematurely retire the debt at a time that is most inconvenient to the firm. Thus, according to the management myopia hypothesis, we expect β_2 to be negative.

SIZE is the natural logarithm of the total asset level of the issuing firm at the end of the fiscal year preceding the issue announcement date. *SIZE* may have two contrasting impacts on *CAR3*. First, *SIZE* may be interpreted as a proxy for the level of asymmetric information. We expect that the degree of asymmetric information is inversely related to *SIZE*. Hence, according to the debt security mispricing motivation, we expect the putable bond issue announcement to have a larger positive impact on small firms than on large firms. Consequently, we expect

[17]Note that *FCF1* is the actual free cash flow of the firm while *FCF2* is the (maximum) potential free cash flow if dividends are not paid. We do not subtract capital expenditures from the free cash flow variables because they maybe discretionary and maybe allocated suboptimally to satisfy management's interests.

[18]Had we assigned the value of 1 to only junk bonds, the number of observations with the risk variable equal to one would be too small for statistical inference.

β_3 to be negative. On the other hand, we also expect that the risk of default is inversely related to firm size. The higher the probability of default, the lower the probability that the firm will be in existence and be able to pay its obligations (including the par value of the bond if the put option is exercised) at the exercise date of these European put options. Thus, size may be an indirect proxy of the aggregate value of the put option. In this case, we expect β_3 to be positive.

INTSAVED is the scaled (per $100 of assets for the fiscal year prior to the issue announcement date) annual reduction in interest expense due to the incorporation of a European put option in the bond contract. The annual interest expense reduction is calculated as the product of the dollar amount of the putable bond issue and the yield difference between straight and putable bonds. These yield differences are calculated by subtracting the yields to maturity of the putable bond from the yield to maturity of an equivalent non-putable bond, also taken from Warga's *Fixed Income Database*. The equivalent bond has similar maturity, credit rating, and call feature as the putable bond. The equivalent non-putable bond is selected from the issuing firm if, at the issue date of the putable debt, the issuing firm has an appropriate (in terms of maturity, credit rating, and call feature) outstanding non-putable bond. Otherwise, we choose an appropriate equivalent bond from a firm of the same industry code as given by the Warga's *Fixed Income* database. We posit that value of the embedded put option is directly related to the (present) value of *INTSAVED*. If the benefits of mitigating either agency costs or security mispricing are a major reason for issuing European put bonds, and if these benefits are directly related to the value of the embedded option, then β_4 should be positive. In contrast, if managerial myopia is a major reason for issuing European put bonds, and if the expected reduction in equity value due to the cost of financial distress is related to the value of the option, then β_4 should be negative. The β_4 coefficient may be negative also because it proxies for a loss of interest tax shield due issuing putable rather than straight bonds.

The variable *ANALYSTS*, defined as the natural logarithm of one plus the number of analysts who follow the issuing firm for the quarter prior to the putable bond issue announcement date, is another proxy for the degree of asymmetric information.[19] We obtain the number of analysts following each firm, for the year prior to the bond announcement, from the *I/B/E/S* tapes. We hypothesize that the degree of asymmetric information is negatively related to *ANALYSTS*. Thus, if asymmetric information motivation is a major motivation for issuing putable debt, we expect β_5 to be negative.

We note that the European put and the poison put samples vary in their proportion of financial service companies. The European put sample contains 25 (out of 90) financial service companies, while the poison put contains only one. To control for the potential sector impact, we introduce the dummy variable *FINS* which equals one if the company is a financial institution and zero otherwise

[19]An alternative measure of the degree of asymmetric information is the number of analysts. The empirical results are robust to this alternative measure.

Table 5.1 A summary of expected signs of abnormal returns and their determinants for issuers of bonds with European put options

	Agency cost	Security mispricing	Managerial myopia
Abnormal returns	***Positive***	***Positive***	*Negative*
FCF	*Positive*	*No prediction*	*No prediction*
RISK	*Positive*	*No prediction*	*Negative*
SIZE	*No prediction*	*Ambiguous*	*No prediction*
INTSAVED	***Positive***	***Positive***	*Negative*
ANALYSTS	*No prediction*	***Negative***	*No prediction*

The determinants of abnormal returns are: *RISK* is a dummy variable equal to one if the bond issue has an S&P bond rating of BBB+ or below and zero otherwise. *FCF* is defined in two separate ways. *FCF1* and *FCF2* are the two free cash flow measures as described in the text. In particular, *FCF1* is defined as [Earnings before Interest and Taxes – Taxes – Interest Expense – Preferred Dividend Payments – Common Stock Dividend Payments]/Total Assets. *FCF2* is defined as [Earnings before Interest and Taxes – Taxes – Interest Expense]/Total Assets. *INTSAVED* measures the relative amount of aggregate interest expense saved per $1,000 of total assets of the issuing firm. *ANALYSTS* is the natural logarithm of one plus the number of analysts who follow the issuing firm for the year prior to the putable bond issue announcement date. Those predictions that are confirmed by our empirical study are in bold letters, and those that are significantly different from zero are also underlined

for our regression analysis of the European put sample.[20] Table 5.1 provides a summary of the expected signs of the regression coefficients for the sample of European put bonds.

We estimate our regressions using the general method of moments (GMM) procedure. See Appendix 4. The procedure yields unbiased White t-statistics estimates that are robust to heteroscedasticity.[21] Note that because our instruments are the regressors themselves, the parameter estimates from OLS and GMM are identical. This is also discussed in Appendix 3.

We test the robustness and appropriateness of our specification by estimating alternative specifications that include additional variables. First, we include a dummy variable for the existence of a call feature to take into account the effectiveness of the call feature to mitigate agency costs. Second, we include a dummy variable to indicate that the bond's put option expires within 5 years because effectiveness of the put bond in mitigating agency costs may be related to

[20] In the next section, we report the regression results when we exclude financial service companies from our European put sample. Essentially, the basic results of our paper are not affected by the inclusion or exclusion of financial services company.

[21] The violation of the homoscedastic assumption for OLS does not lead to biased regression coefficients estimators but potentially biases the computed t-statistic. The GMM procedure provides an asymptotically unbiased estimation of the t-statistics without specifying the heteroscedastic structure of the regression equation. The t-statistics obtained using GMM are identical to those obtained using ordinary least squares (OLS) in the absence of heteroscedasticity.

time to expiration of the put option. Third, we also include interaction variables between these dummy variables and *FCF*, *SPRISK*, *INTSAVE*, and *ANALYSTS*.

In alternative specifications, we include interest rate volatility measures to take into account the potential sensitivity of the value of the put option to interest rate volatility. It should be noted that the value of the put option depends on the volatility of the corporate bond yield. This volatility may be due to factors specific to the company (such as corporate mismanagement and asymmetric information about firm's value) and macroeconomic factors relating to the stability and level of market-wide default-free interest rates. Our independent variables in Eqs. 5.1 and 5.2 control for firm-specific yield volatility. To incorporate the possible impact of market-wide interest rate volatility, we include several alternative variables. We measure interest rate volatility as the standard deviation of the monthly 5-year Fama-Bliss discount rate from CRSP. The standard deviation is alternatively measured during a period of 60 months and 24 months immediately prior and after the announcement date. Alternatively, we use the level of the Fama-Bliss discount rate as a proxy for interest rate volatility.

We repeat the analysis for the sample of issuers of poison put bonds. As with the sample of bonds with an embedded European put option, we first examine the abnormal returns and their determinants for the sample of issuers of poison putable bonds. In essence, we test whether issuing these bonds significantly affects equity value. The stock price should, on average, react positively to the issue announcement if either mitigating agency costs or reducing debt security mispricing due to asymmetric information is a major motivation for issuing poison bonds. On the other hand, the stock price should, on average, react negatively to the issue announcement if management myopia (i.e., the relatively low coupon rate compared to straight or callable debt issues) or management entrenchment is a major motivation of management in issuing putable bonds.

We use two alternative specifications for the cross-sectional study that relates the abnormal returns of the poison putable bond sample to firm characteristics. The first is described by Eq. 5.1 The second includes a variable, COVRANK, that equals the S&P event risk ranking on a scale of 1–5. S&P event risk ranking of one implies that the embedded put option provides the most protection to bondholders against credit downgrade events. Event risk ranking of five offers the least protection to bondholders against credit downgrade events. Thus, the second specification is:

$$CAR3_i = \beta_0 + \beta_1 FCF_i + \beta_2 RISK_i + \beta_3 SIZE_i + \beta_4 INTSAVED_i + \beta_5 ANALYSTS_i + \beta_6 COVRANK_i + \varepsilon_{i.} \tag{5.2}$$

If mitigating agency costs was a major motivation for issuing poison put bonds as suggested by Bae et al. (1994), then we would expect regression coefficients β_1, β_2, and β_4 to be positive. We also expect β_6 to be negative because COVRANK is negatively related to extent of bondholder protection, and this protection should deter management from asset substitution activities.

In contrast, if, as Cook and Easterwood (1994) and Roth and McDonald (1999) argue, management entrenchment is a major motivation behind for issuing putable bonds, then we expect β_1 to be negative since we expect the potential loss of value due to management entrenchment to be positively related to free cash flow and β_6 to be positive.[22]

5.5 Empirical Results

This section presents the empirical results for tests of our hypotheses discussed above. Panel A of Table 5.2 provides summary statistics of issuers of bonds with a European put option. The average annual sales, long-term debt, and total assets for the fiscal year prior to the issue announcement date are \$14.66 billion, \$4.21 billion, and \$30.79 billion, respectively. The mean leverage ratio, defined as the long-term debt to total assets, is 18.6 %. The average issue size of the putable bond is \$190 million and represents, on average, 2.7 % of the firm's assets. As measured by *RISK*, 24 % of putable bonds are rated below A-. The average free cash flow of the firm as a percentage of the firm's total assets is below 4 %. The average amount of interest saved (*INTSAVED*) due to the inclusion of a put option feature in the bond issue is approximately 0.03 % of the total assets of the issuing firm. The maximum interest expense saved is as high as \$1.23 per \$100 of total assets.[23] However, *INTSAVED* is negative for ten observations, which may be due to the lack of a closely matched straight bond. To guard against this error-in-variable problem, we estimate our regression Eq. 5.1 using two alternative samples: the entire sample and a sample comprising of positive *INTSAVED* observations. The number of analysts following a company ranges from 1 to 41. Panel B of Table 5.2 provides the corresponding summary statistics for the sample of issuers of poison put bonds. We note that these firms are smaller than the issuers of bonds with European put options. Additionally, issuers of poison puts have a smaller number of following analysts, and the bonds tend to be somewhat riskier than the issuers of bonds with European put options.

Panel A of Table 5.3 presents the average daily abnormal performance of the equity of issuers of bonds with European put options in our sample for $t = -30$ to $t = 30$. These abnormal returns are obtained from a market model. Please note that the t-statistics presented in Table 5.3 are based on standardized abnormal returns. In an efficient market, we expect the market to impound the economic informational impact of the new bond issue on the day of the announcement ($t = 0$). The average abnormal return at $t = 0$ is almost 0.33 % and is significantly positive at the 1 % level.

[22]If a major motivation for issuing putable bonds is to enhance management entrenchment, then we expect that the value of entrenchment is directly related to the level of free cash flow which management can misappropriate.

[23]Crabbe (1991) demonstrates that bonds with poison puts reduce the cost of borrowing for firms.

Table 5.2 Summary statistics of putable bond issuing firms

Variable	Mean	Std dev	Minimum	Maximum
Panel A: Sample of 90 issuers of bonds with European put options

INTSAVED	0.011	0.044	−0.070	0.216

Sales, long-term debt, total assets, and EBIT are in millions of dollars and are for the fiscal year prior to the putable bond issue announcement. Leverage ratio is the ratio of the long-term debt to total assets. Issue size is the dollar amount of putable bond issue in millions of dollars. ISSUE is the ratio of issue size to the total assets of the issuing firm as of the fiscal year prior to the issue announcement date. *RISK* is a dummy variable equal to one if the bond issue has an S&P bond rating of BBB+ or below and zero otherwise. *FCF1* and *FCF2* are the two free cash flow measures as described in the text. In particular, *FCF1* is defined as [Earnings before Interest and Taxes – Taxes – Interest Expense – Preferred Dividend Payments – Common Stock Dividend Payments]/Total Assets. *FCF2* is defined as [Earnings before Interest and Taxes – Taxes – Interest Expense]/Total Assets. *Number of analysts* is the number of analysts who follow the issuing firms for the year prior to the putable bond issue. *INTSAVED* measures the relative amount of aggregate interest expense saved per $100 of total assets of the issuing firm

This suggests that the market views favorably the announcement of putable bonds. This may be due to mitigating agency costs or resolving asymmetric information. However, for the 3-day window ($t = -1, 1$), the abnormal return is 0.19 % but is not statistically significant from zero.

Table 5.3 The average daily abnormal returns for firms issuing putable bonds from 30 days prior to the putable bond issuance announcement to 30 days after the announcement. The t-statistics are based on standardized abnormal returns. CAR is the cumulative abnormal return

This table reports the regression coefficients and their t-statistics of the following regression equation:

$CAR3_i = \beta_0 + \beta_1 FCF_i + \beta_2 RISK_i + \beta_3 SIZE_i + \beta_4 INTSAVED_i + \beta_5 ANALYSTS_i + \beta_6 FINS + \varepsilon_i$

CAR3 is the cumulative abnormal return measured from the day before the announced issue to the day after the announced issue; *FCF1* and *FCF2* are the two free cash flow measures as described in the text; *RISK* is a dummy variable equal to one if the bond issue has an S&P bond rating of BBB+ or below and zero otherwise; SIZE is the natural logarithm of the total assets of the issuing firm at the end of the fiscal year prior to the issue announcement; *INTSAVED* measures the relative amount of aggregate interest expense saved per $100 of total assets of the issuing firm; *ANALYSTS* is the natural logarithm of one plus the number of analysts following the firm; and *FINS* is equal to one if the parent company is a financial institution and is equal to zero otherwise. The p-values assume a two-tail test. All the t-ratios are heteroscedasticity consistent

Panel B of Table 5.3 presents the corresponding results for the issuers of poison put bonds. Note that the abnormal return at $t = 0$ is −0.28 % with a t-statistic of −1.38. Furthermore, during the 3-day (i.e., $t = -1, 1$) window, the abnormal return is negative (−0.52 %) and is significantly different than zero (t-statistic of −2.03). This negative abnormal return is consistent with the view that poison put bonds help entrench the current management. The cumulative abnormal returns of the two sample types of embedded put option are also depicted in Fig. 5.1. The patterns of CARs around the issue announcement dates clearly show the positive trend of CARs for bonds with European puts versus the negative trend of CARs for bonds with poison puts.

Next, to test our hypotheses, we examine what determines the cross-sectional variations in the CARs for the sample of European and poison put bonds. Table 5.4 reports the parameter and t-statistic estimates for regression Eq. 5.1 for the sample of issuers of bonds with European put options. The four regressions reported in Table 5.4 differ by the sample that is used and by the specification used for the free cash flow variable. The regression in the top left panel uses the entire sample of 90 observations and the variable *FCF1*. The regression in the top right panel reports the results using only the 80 observations in which the variable *INTSAVED* is positive. The regressions reported in the bottom panels use *FCF2* instead of *FCF1*.

First note that our estimates are robust to these alternative specifications. The Wald test of the hypothesis that all five independent variables are jointly zero is rejected at the 1 % significance level for all four regression specifications. The regression coefficients on the *ANALYSTS* variable, β_5, are negative and significantly different from zero for all four regressions. These estimates are consistent with the reduction in security mispricing motivation for issuing putable bonds. In contrast, the regression coefficients for *FCF* and *RISK* are not significantly different from zero, indicating a lack of empirical support for the mitigating agency cost hypothesis. The regression coefficients for the *INTSAVED* variables are positive and are significantly different from zero in all four regressions. This result is again consistent with the security mispricing motivation and inconsistent with the management myopia motivation. Additionally, the regression coefficient β_3 for the size variable is also positive and significantly different from zero, a result more consistent with size being related to the probability of survivorship of the firm. In summary, announcement of bonds with European puts is associated with positive abnormal returns which are related to our proxies for potential benefits from mitigating security mispricing.

Panel A of Table 5.5 presents the corresponding estimates for the sample of issuers of poison put bonds, while panel B of Table 5.5 presents the estimates of Eq. 5.2 for the same sample. The estimates reported in Table 5.5 are different from those in Table 5.4. The coefficients of the *ANALYSTS* variable, β_5, are significantly positive for the full sample. The coefficients for *Size* are significantly negative for the full sample. All the other variables are not significantly different than zero. The estimates of Eq. 5.2 indicate that the coefficients of the variable *COVRANK* are negative and significantly different from 0.

Our results so far indicate that the equity abnormal returns around the issue announcement dates of poison put bonds are negative, consistent with the managerial entrenchment evidence in Cook and Easterwood (1994) and Roth and McDonald (1999). Additionally, the positive and significant coefficient of the *ANALYSTS* variable may also be consistent with the management entrenchment hypothesis because it appears that the market negative response to the issuance of poison putable bonds arises from the less followed firms, where the management

Panels A reports the regression coefficients and their t-statistics of the following regression equation:
$CAR3_i = \beta_0 + \beta_1 FCF_i + \beta_2 RISK_i + \beta_3 SIZE_i + \beta_4 INTSAVED_i + \beta_5 ANALYSTS_i + \varepsilon_i$
Panel B reports the regression coefficients the regression coefficients and their t-statistics of the following regression equation:
$CAR3_i = \beta_0 + \beta_1 FCF_i + \beta_2 RISK_i + \beta_3 SIZE_i + \beta_4 INTSAVED_i + \beta_5 ANALYSTS_i + \beta_7 COVRANK_i + e_i$
CAR3 is the cumulative abnormal return measured from the day before the announced issue to the day after the announced issue; *FCF1* and *FCF2* are the two free cash flow measures as described in the text; *RISK* is a dummy variable equal to one if the bond issue has a S&P bond rating of BBB+ or below, and zero otherwise; SIZE is the natural logarithm of the total assets of the issuing firm at the end of the fiscal year prior to the issue announcement; *INTSAVED* measures the relative amount of aggregate interest expense saved per $100 of total assets of the issuing firm; *ANALYSTS* is the natural logarithm of one plus the number of analysts following the firm; and *COVRANK* equals the S&P Event Risk Ranking on a scale of 1–5. The p-values assume a two-tail test. All the t-ratios are heteroscedasticity consistent

strategy may not be as well known prior to the bond issuance. However, these returns are negatively related to the event risk covenant ranking consistent with the agency cost evidence in Bae et al. (1994). The negative abnormal returns experienced by issuers of poison puts and the different coefficients on *SIZE*, *INTSAVED*, and *ANALYSTS* indicate that the European put bonds are viewed differently than poison put bonds.

In summary, the results reported in Tables 5.2–5.5 are consistent with the view that European put bonds, where the put option does not depend on a specific company event, are more effective in mitigating problems that are associated with security mispricing. Furthermore, there is no empirical support for the hypothesis that European put bonds are used as a vehicle for management entrenchment. In contrast, the evidence for poison put bonds is consistent with both management entrenchment and mitigating agency costs.

We now discuss several robustness checks of our basic results. Note that, as reported in Table 5.4, the regression coefficient of the financial industry dummy variable, β_6, is negative and significantly different from zero. To verify that the differing results between the European put bond sample (where 25 out of 90 firms

are from the financial service sector) and the poison put sample (where only one firm is from the financial service sector), we replicate the regressions of Tables 5.4 and 5.5 excluding all financial service companies. The estimates for the subsample of European put bonds are reported in Table 5.6. Note that the coefficients and significance levels are very similar to those reported in Table 5.4. Because only one poison put company is from the financial sector and because the estimates of the corresponding subsample of poison put bonds are very similar to those reported in Table 5.5, we do not report these estimates. Thus, we conclude that the differences between poison and European put bonds are not due to the different sector composition of our samples.

This table reports the regression coefficients and their t-statistics of the following regression equation: $CAR3_i = \beta_0 + \beta_1 FCF_i + \beta_2 RISK_i + \beta_3 SIZE_i + \beta_4 INTSAVED_i + \beta_5 ANALYSTS_i + \beta_6 FINS + \beta_7 EXPLT5 + \varepsilon_i$ *CAR3* is the cumulative abnormal return measured from the day before the announced issue to the day after the announced issue; *FCF1* and *FCF2* are the two free cash flow measures as described in the text; *RISK* is a dummy variable equal to one if the bond issue has a S&P bond rating of BBB+ or below and zero otherwise; SIZE is the natural logarithm of the total assets of the issuing firm at the end of the fiscal year prior to the issue announcement; *INTSAVED* measures the relative amount of aggregate interest expense saved per $100 of total assets of the issuing firm; *ANALYSTS* is the natural logarithm of one plus the number of analysts following the firm; *FINS* is equal to one if the parent company is a financial institution and is equal to zero otherwise; and *EXPLT5* is equal to one if the expiration of the embedded option is less than 5 years from the issue date and is equal to zero otherwise. The p-values assume a two-tail test. All the t-ratios are heteroscedasticity consistent

Next, we examine whether the term to expiration of European put bonds affects our estimates.[24] Table 5.7 repeats the regressions of Table 5.4 when we introduce an additional explanatory dummy variable, *EXPLT5*, that is equal to one if the

[24]Recall that by definition the option of poison put bonds does not have an expiration date.

expiration date of the embedded European put option is less than 5 years from the issue date and zero otherwise. We find that *INTSAVE* is still positive but is no longer significant and the regression coefficient for *EXPLT5* is positive and is significantly different from zero at the 10 % level for the full sample. The estimates and the significance of the other coefficients are largely unaffected. We conclude that these results still confirm the security mispricing hypothesis because the regression coefficients for *ANALYSTS* are significantly negative.

Our results are robust to alternative specifications we described at the end of the previous section. In particular, including a dummy variable for the existence of a call feature, interaction variables and alternative measures of interest rate volatility do not affect our results. These results are not reported here but are available upon request.

Finally, we test for multicollinearity by examining the eigenvalues of the correlation matrix for (non-dummy) independent variables. For orthogonal data the eigenvalue, λ, for each variable should equal 1, and $\Sigma 1/\lambda$ = the number of regressors (i.e., five for our study). For our sample of bonds with an embedded European put option, this sum is 7.14 when FCF1 is used, and this sum = 7.19 when FCF2 is used, indicating a lack of significant multicollinearity. Similar results are obtained for the poison put sample. Therefore, our findings are robust to alternate specifications and are not driven by multicollinearity.

5.6 Concluding Remarks

This paper examines the motivations and equity valuation impact of issuing European putable bonds, a bond containing an embedded European put option held by bondholders. The option entitles them to sell the bond back to the firm on the exercise date at a predetermined price. Unlike a poison put bond which has been studied by the literature, the exercise of the put option in a European putable bond is not contingent upon a company-related event.

We find that the market reacts favorably to the issue announcement of such putable bonds. We consider three alternative motivations for incorporating a European put option in a bond contract: reducing the security mispricing impact of asymmetric information, mitigating agency costs, and the relatively low coupon rate (a myopic view that ignores the potential liability to the firm due to the put option). We test these hypotheses by conducting a cross-sectional empirical study of the impact of putable debt issue announcements on the equity value of the issuing companies. Our results indicate that the market favorably views putable bonds as a means to reduce security mispricing. We also find that the market reaction to poison put announcements differs from the market reaction to issue announcements for bonds with European put options.

Appendix 3: Estimating the Standard Abnormal Returns and the White t-Statistic

Fama et al. (1969) introduced the event study methodology when they analyzed the impact of stock dividend announcements upon stock prices. Essentially, they used the Market Model to estimate the stochastic relationship between stock returns and the market portfolio. In particular, we estimate the following regression:

$$R_{i,t} = \alpha_i + \beta_i R_{m,t} + \varepsilon_{i,t} \tag{5.3}$$

We estimate the market model coefficients using the time period that begins 200 trading days before and ends 31 trading days before the event, employing the CRSP value-weighted market index as the benchmark portfolio. We use these coefficients to estimate abnormal returns for days −30 to +30. The abnormal return is defined as

$$AR_{i,t} = R_{i,t} - \alpha_i - \beta_i R_{m,t}. \tag{5.4}$$

The mean abnormal return for the sample of *i* firms, AR_t, at time t is found by

$$AR_t = \sum_{i=1}^{n} AR_{i,t}/n. \tag{5.5}$$

In order to conduct tests of significance, we must ensure that $AR_{i,t}$ has identical standard deviation. Assuming that the forecast values are normally distributed, we can scale $AR_{i,t}$ by the standard deviation of the prediction, S_{it}, given by Eq. 5.4 In particular,

$$S_{it} = \left\{\sigma_i^2 + (1/ED) + \left[\left(R_{mt} - \overline{R}_m\right)^2 / \Sigma\left(R_{mi} - \overline{R}_m\right)^2\right]\right\}^{1/2} \tag{5.6}$$

where σ^2_i is the variance of the error term of Eq. 5.3, ED is the number of days to estimate the market model for firm I, R_{mt} is the return of the market portfolio, and R_m is the mean market return in the estimation period.

Hence the standardized abnormal return, $SAR_{i,t}$, is equal to $AR_{i,t}/S_{it}$. $SAR_{i,t}$ is distributed normally with a mean of zero and a standard deviation equal to one. The mean standardized abnormal return for time t, SAR_t, is the sum of the $SAR_{i,t}$ divided by n. SAR_t is normally distributed with a mean of zero and a standard deviation of the square root of l/n. The cumulative abnormal returns for days 1 to k, CAR*k*, is the sum of mean abnormal returns for $t = 1$ to k. The standardized cumulative mean excess returns for the *k* days after month $t = 0$, *SCARt*, is equal to the sum of SAR_t for days 1 to k. *SCART* is normally distributed with a standard deviation of square root of k/n. Please see Campbell et al. (1996) for a detailed discussion of these tests as well as event studies in general.

In our cross-sectional regressions where we regress the CARs on firm-specific variables, we estimate the model using GMM. However, since we are not interested in conditional estimates, our regressors are the instruments. Therefore our parameters estimates are the same that would be obtained by OLS. However, we use the White (1980) heteroscedastic-consistent estimator. In the standard regression model,

$$Y = X\beta + \varepsilon \tag{5.7}$$

The OLS estimator of $\beta = (X'X)^{-1}(X'y)$ with the covariance matrix

$$\mathrm{VaR}(\beta) = (X'X)^{-1}(X'\Omega X)(X'X)^{-1} \tag{5.8}$$

When the errors are homoscedastic, $\Omega = \sigma^2 I$ and the variance reduces to $\sigma^2(X'X)^{-1}$.

However when Ω is unknown as shown by White (1980), Eq. 5.8 can be used using a consistent estimator of Ω. White showed that can be done using the residual from Eq. 5.7.

So when the heteroscedasticity is of the unknown form,

$$\text{Using } (X'X)^{-1}\left(X'\mathrm{diag}\left(\varepsilon^2\right)X\right)(X'X)^{-1} \tag{5.9}$$

gives us heteroscedastic-consistent White standard errors and White t-statistics.

Appendix 4: Generalized Method of Moments (GMM)

GMM is a generalization of the method of moments developed by Hansen (1982). The moment conditions are derived from the model. Suppose Y_t is a multivariate independently and identically distributed (i.i.d.) random variable. The econometric model specifies the relationship between Y_t and the true parameters of the model (θ_0). To use GMM there must exist a function $f(Y_t, \theta_0)$ so that

$$m(\theta_0) \equiv E[f(Y_t, \theta_0)] = 0. \tag{5.10}$$

In GMM, the theoretical expectations are replaced by sample analogs:

$$g(\theta, Y_t) = 1/T \sum f(Y_t, \theta). \tag{5.11}$$

The law of large numbers ensures that the RHS of above equation is the same as

$$E[f(Y_t, \theta_0)]. \tag{5.12}$$

The sample GMM estimator of the parameters may be written as (see Hansen 1982)

$$\Theta = \arg\min \left[1/T \sum f(Y_t, \theta)\right]' W_T 1/T \sum f(Y_t, \theta)]. \tag{5.13}$$

So essentially GMM finds the values of the parameters so that the sample moment conditions are satisfied as closely as possible. In our case for the regression model,

$$y_t = X_t{}'\beta + \varepsilon_t. \tag{5.14}$$

The moment conditions include

$$E[(y_t - X_t{}'\beta)x_t] = E[\varepsilon_t x_t] = 0 \text{ for all t}. \tag{5.15}$$

So the sample moment condition is

$$1/T \sum (y_t - X_t{}'\beta)x_t$$

and we want to select β so that this is as close to zero as possible. If we select β as $(X'X)^{-1}(X'y)$, which is the OLS estimator, the moment condition is exactly satisfied. Thus, the GMM estimator reduces to the OLS estimator and this is what we estimate. For our case the instruments used are the same as the independent variables. If, however, there are more moment conditions than the parameters, the GMM estimator above weighs them. These are discussed in detail in Greene (2008, Chap. 15).

The GMM estimator has the asymptotic variance

$$\left(X'Z\,(Z'\Omega Z)^{-1}Z'X\right)^{-1} \tag{5.16}$$

In our case Z = X since we use the independent variables as the instruments Z. The White robust covariance matrix may be used for Ω as discussed in Appendix 3 when heteroscedasticity is present. Using this approach, we estimate GMM with White heteroscedasticity consistent t-stats.

Multi-Risk Premia Model of US Bank Returns: An Integration of CAPM and APT

6

Suresh Srivastava and Ken Hung

Contents

Abstract

Interest rate sensitivity of bank stock returns has been studied using an augmented CAPM, a multiple regression model with market returns and interest rate as independent variables. In this paper, we test an asset-pricing model in which the CAPM is augmented by three orthogonal factors which are proxies for the innovations in inflation, maturity risk, and default risk. The model proposed

C.-F. Lee, J. Lee (eds.), *Handbook of Financial Econometrics and Statistics*,
DOI 10.1007/978-1-4614-7750-1_6,

is an integration of CAPM and APT. The results of the two models are compared to shed light on sources of interest rate risk.

Our results using the integrated model indicate the inflation beta to be statistically significant. Hence, innovations in short-term interest rates contain valuable information regarding inflation premium; as a result the interest rate risk is priced with respect to the short-term interest rates. Further, it also indicates that innovations in long-term interest rates contain valuable information regarding maturity premium. Consequently the interest rate risk is priced with respect to the long-term interest rates. Using the traditional augmented CAPM, our investigation of the pricing of the interest rate risk is inconclusive. It shows that interest rate risk was priced from 1979 to 1984 irrespective of the choice of interest rate variable. However, during the periods 1974–1978 and 1985–1990, bank stock returns were sensitive only to the innovations in the long-term interest rates.

6.1 Introduction

Interest rate sensitivity of commercial bank stock returns has been the subject of considerable academic research. Stone (1974) proposed a multiple regression model incorporating both the market return and interest rate variables as return-generating independent variables. While some studies have found the interest rate variable to be an important determinant of common stock returns of banks (Fama and Schwert 1977; Lynge and Zumwalt 1980; Christie 1981; Flannery and James 1984; Booth and Officer 1985), others have found the returns to be insensitive (Chance and Lane 1980) or only marginally explained by the interest rate factor (Lloyd and Shick 1977). A review of the early literature can be found in Unal and Kane (1988). Sweeney and Warga (1986) used the APT framework and concluded that the interest rate risk premium exists but varies over time. Flannery et al. (1997) tested a two-factor model for a broad class of security returns and found the effect of interest rate risk on security returns to be rather weak. Bae (1990) examined the interest rate sensitivity of depository and nondepository firms using three different maturity interest rate indices. His results indicate that depository institutions' stocks are sensitive to actual and unexpected interest rate changes, and the sensitivity increases for longer-maturity interest rate variables. Song (1994) examined the two-factor model using time-varying betas. His results show that both market beta and interest rate beta varied over the period 1977–1987. Yourougou (1990) found the interest rate risk to be high during a period of great interest rate volatility (post-October 1979) but low during a period of stable interest rates (pre-October 1979). Choi et al. (1992) tested a three-factor model of bank stock returns using market, interest, and exchange rate variables. Their findings about interest rate risk are consistent with the observations of Yourougou (1990).

The issue of interest rate sensitivity remains empirically unresolved. Most of the studies use a variety of short-term and long-term bond returns as the interest rate factor without providing any rationale for their use. The choice of bond market index seems to affect the pricing of the interest rate risk. Yet, there is no consensus on the choice of the interest rate factor that should be used in testing the two-factor model. In this paper, we provide a plausible explanation of why pricing of interest rate risk differs with the choice of interest rate variable. We also suggest a hybrid return-generating model for bank stock returns in which the CAPM is augmented by three APT-type factors to account for unexpected changes in the inflation premium, the maturity-risk premium, and the default-risk premium. The use of three additional factors provides a better understanding of the interest rate sensitivity and offers a plausible explanation for the time-varying interest rate risk observed by other investigators. Our empirical investigation covers three distinction economic and bank regulatory environments: 1974–1978, a period of increasing but only moderately volatile interest rates in a highly regulated banking environment; (2) 1979–1984, a period characterized by high level of interest rates with high volatility, in which there was gradual deregulation of the banking industry; and (3) 1985–1990, a low interest rate and low-volatility period during which many regulatory changes were made in response to enormous bank loan losses and bankruptcies. The results of the multifactor asset-pricing model are compared with those from the two-factor model in order to explain the time-varying interest rate risk.

The rest of this paper is divided into five sections. In Sect. 6.2, we describe the two-factor model of the bank stock return and the pricing of the interest rate risk. The multi-risk premia model and the specification of the factors are discussed in Sect. 6.3. The data for this analysis is described in Sect. 6.4. Section 6.5 presents empirical results, and Sect. 6.6 concludes the paper.

6.2 Multiple Regression Model of Bank Return

Stone (1974) proposed the following two-variable bank stock return-generating model:

$$R_{jt} = \alpha_j + \beta_{1j} R_{mt} + \beta_{2j} R_{It} + \varepsilon_{jt} \tag{6.1}$$

where R_{jt} is the bank common stock return, R_{mt} is the market return, and R_{It} is the innovation in the interest rate variable. Coefficients α_j and β_{1j} are analogous to the alpha and beta coefficients of the market model, and β_{2j} represents interest rate risk. Since then, numerous researchers have studied the pricing of interest rate risk with varying results. While Stone (1974) and others did not place an a priori restriction on the sign of β_{2j}, the nominal contracting hypothesis implies that it should be positive. This is because the maturity of bank assets is typically longer than that of liabilities.[1] Support for this hypothesis was found by Flannery and James (1984) but not by French et al. (1983).

An important issue in the empirical investigation of the two-factor model is the specification of an appropriate interest rate factor. Theoretical consideration of factor analysis requires that two factors, R_{mt} and R_{It}, be orthogonal whereby choice of the second factor (R_{It}) would not influence the first factor loading (β_{1j}). The resolution of this constraint requires a robust technique for determining the unexpected changes in the interest rate that is uncorrelated with the market return. There are three approaches to specify the interest rate factor (Appendix 2). In the first approach, the expected change in the interest rate is estimated using the high correlation between the observed interest rate and the market rate. The residual – difference between observed and estimated rates – is used as the interest rate factor. The second approach is to identify and estimate a univariate ARMA model for the interest rate variable and use the residuals from the ARMA model as the second factor. In the third approach, the interest rate variable (R_{It}) and the market return (R_{mt}) are treated as the components of a bivariate vector, which is modeled as a vector ARMA process. The estimated model provides the unanticipated change in interest rate variable to be used as the second factor in the augmented CAPM, Eq. 6.1. Srivastava et al. (1999) discuss the alternate ways of specifying the innovations in the interest rate variable and its influence on the pricing of the interest rate risk. In this paper, the error term from the regression of interest rates on market returns is used as the orthogonal interest rate factor in Eq. 6.1.

6.2.1 Pricing of Interest Rate Risk

In addition to changes in the level of expected or unexpected inflation, changes in other economic conditions produce effects on interest rate risk. For example, according to the intertemporal model of the capital market (Merton 1973; Cox et al. 1985), a change in interest rates alters the future investment opportunity set; as a result, investors require additional compensation for bearing the risk of such changes. Similarly, changes in the investor's degree of risk aversion, default risk, or maturity risk of bank financial assets cause additional shifts in the future investment opportunities for the bank stockholders. The specific choice of the bond market index for the two-variable model determines what unexpected change is captured by the coefficient $\beta_{2j.}$

The nominal return on a debt security, R, is expressed as

$$R = R_{rf} + MRP + DRP + LP \tag{6.2}$$

where R_{rf} is the real risk-free rate plus an inflation premium, DRP is the default-risk premium, MRP is the maturity-risk premium, and LP is the liquidity-risk premium.

[1]The sign of β_{2j} is negative when changes in bond yields and not the bond market return are used as the interest rate variable (see Sweeney and Warga 1986).

A change in nominal return consists of changes in the risk-free, liquidity-risk, default-risk, and maturity-risk rate. A change in the short-term risk-free rate can be attributed to changes in real rate or short-term inflation. A sizeable change in the real rate takes place over a longer time horizon. Therefore, it should not significantly impact monthly stock returns and cause the interest rate risk.[2] However, Fama and Gibbons (1982) suggested that changes in real rate may cause changes in the magnitude of interest risk from period to period. Fama and Schwert (1977) argued that, in equilibrium, the risk premium in the short-term interest rate is compensation to the investor for changes in the level of *expected* inflation. However, French et al. (1983) pointed out that the interest rate risk is due to the *unexpected* changes in inflation. More specifically, the interest rate risk can be viewed as the compensation for expected or unexpected changes in the level of short-term inflation. Maturity risk is associated with the changes in the slope of the yield curve that caused a number of economic factors, such as supply and demand of long-term credit, long-term inflation, and risk aversion. Estimates of β_{2j} using short-term T-bill returns as the second factor account for the changes in short-term inflation, whereas estimates of β_{2j} using long-term T-note returns account for the unexpected changes in long-term inflation as well as maturity risk. The inflation expectation horizon approximates that of the maturity of the debt security. Estimating coefficient β_{2j} using BAA bond returns as the interest rate factor explains the fluctuations in bank stock return due to unexpected changes in long-term inflation, maturity-risk premium, default-risk premium, or a combination of risk premia.[3]

As the risk premia are additive, in Eq. 6.2, the magnitude β_{2j} depends on the choice of the interest rate index. A priori expectations about the relative size of β_{2j} are:

$$\begin{aligned} \beta 2j\{\text{6-month T-bill}\} &> \beta 2j\{\text{3-month T-bill}\} \\ \beta_{2j}\{\text{7-year T-note}\} &> \beta_{2j}\{\text{6-month T-bill}\} \\ \beta_{2j}\{\text{BAA-rated bond}\} &> \beta_{2j}\{\text{7-year T-note}\} \end{aligned} \tag{6.3}$$

where the debt security within the brackets identifies the choice of the bond market index. A number of researchers have indicated that bank stock returns are sensitive to unexpected changes in long-term but not short-term interest rates. This observation is consistent with the expectations expressed in Eq. 6.3. However, we are unable to isolate and identify which component of the interest rate risk is being

[2]Federal Reserve's intervention changes the short-term interest rates. These rate changes take place after considerable deliberation and are often anticipated by financial markets. Hence, it neither generates interest rate innovations nor produces interest rate risk.

[3]Liquidity premium is ignored in our discussion and subsequent model construction because our sample does not include financially distressed banks, so there are insufficient variations in the liquidity premium.

priced when a long-term bond return is used. It is feasible to observe a significant change in stock returns due to unexpected changes in default-risk premium (or maturity-risk premium), whether or not nominal contracting hypothesis is valid. The two-factor model can ascertain the pricing of interest rate risk without identifying the source. Commercial banks have a variety of nominal assets and liabilities with different sensitivities to unexpected changes in short-term inflation, maturity risk, and default risk. In the next section, we propose an asset-pricing model in which the interest rate factor of the two-factor model is replaced by three factors, each of which represents a different risk component of the bond return.[4]

6.3 Multi-Risk Premia Asset-Pricing Model

We propose a hybrid asset-pricing model to investigate the interest rate sensitivity of bank stock returns.[5] The traditional CAPM is augmented by three additional APT-type factors to account for unexpected changes in the inflation premium, the maturity-risk premium, and the default-risk rating. Hence, the proposed return-generating model is written as

$$\begin{aligned} R_{jt} = \alpha_j + \beta_{1j}R_{mt} + \beta_{2Pj}\Delta P_t + \beta_{2Mj}\Delta MR_t \\ + \beta_{2Dj}\Delta DR_t + \varepsilon_{jt} \end{aligned} \tag{6.4}$$

where ΔP_t, ΔMR_t, and ΔDR_t are the proxies for the innovations in inflation, maturity risk, and default risk, respectively (specification of these principal component factors consistent with APT is discussed in the Appendix). Coefficients β_1, β_{2P}, β_{2M}, and β_{2D} are the measures of market risk, inflation risk, maturity risk, and default risk, respectively. The expected return is given by CAPM:

$$E\left(R_j\right) = \alpha_j + \beta_{1j}E(Rm) \tag{6.5}$$

However, systematic risk is determined by the integrated model:

$$\begin{aligned} \text{Total systematic risk} = \text{market risk} + \text{inflation risk} + \text{maturity risk} \\ + \text{default risk} \end{aligned} \tag{6.6}$$

[4]An appropriate interest rate variable that should be used to examine the pricing of the interest rate risk in the two-variable framework is not easily available. However, one could construct an index composed of long-term US bonds and corporate bonds with duration equal to the net duration of bank assets and appropriate default risk. This interest rate variable will identify the true pricing of the interest rate risk.

[5]This model's conceptual framework is provided by Chen et al. (1986). However, their factors are not orthogonal.

The three APT-type factors have managerial implications regarding bank's asset and liability management. The first factor, ΔP_t, has implications pertaining to the management of the treasury securities portfolio held by the bank. The value of this portfolio is sensitive to the changes in the short-term interest rate. In addition, these changes impact the short-maturity funding gap. The null hypothesis $\beta_{2P} = 0$ implies that management has correctly anticipated future changes in short-term inflation and has taken steps to correctly hedge the pricing risk through the use of derivative contracts and minimize the short-maturity funding gap.

The second factor, ΔMR_t, has implications regarding the bank's long-term assets and liabilities. The market value of a bank's net worth is very sensitive to changes in the slope of the term structure. The null hypothesis $\beta_{2M} = 0$ conjectures that management has correctly anticipated future changes in the slope of the term structure and has immunized the institution's net worth by a sensible allocation assets in the loan portfolio, sale of loans to the secondary markets, securitization of loans, and the use of derivative contracts. The third factor, ΔDR_t, relates to the management of loan losses and overall default-risk rating of bank assets. The null hypothesis $\beta_{2D} = 0$ infers that management has correctly anticipated future loan losses due to changes in exogenous conditions, and subsequent loan losses, however large, will not adversely affect the stock returns.

6.4 Data Description

Month-end yield for 3-month T-bill, 6-month T-bill, 1-year T-note, 7-year T-note, and BAA corporate bonds, for the period January 1974 to December 1990, were obtained, and monthly returns were calculated.[6] Return on the CRSP equally weighted index of NYSE stocks was used as the market return. Month-end closing prices and dividends for a sample of 88 banks were obtained from Compustat's Price, Dividend, and Earning (PDE) data tape, and monthly returns were calculated. Availability of continuous data was the sole sample selection criteria. This selection criterion does introduce a survivorship bias. However, it was correctly pointed out by Elyasiani and Iqbal (1998) that the magnitude of this bias could be small and not affect the pricing of interest risk. Equally weighted portfolios of bank returns were calculated for this study. The total observation period is divided into three contrasting economic and bank regulatory periods: (1) an increasing but moderately volatile interest rate period from January 1974 to December 1978 in a highly regulated environment; (2) a high interest rate and high-volatility period from January 1979 to December 1984, during which there was gradual deregulation of the industry; and (3) a low interest rate and low-volatility period from January 1985 to December 1990, during which many regulatory changes were made in response to banks loan loss problems. The descriptive statistics of the sample are

[6]The return on a bond index is calculated from the yield series as $R_{It} = -(Y_{It} - Y_{I,t-1})/Y_{It}$ where Y_{It} is the bond index yield at time t.

Table 6.1 Summary statistics of portfolio returns and interest rate yields

	1974–1978	1979–1984	1985–1990
Bank portfolio return	9.66%[a]	22.28%	6.48%
	(5.95%)[b]	(4.93%)	(6.17%)
Portfolio beta[c]	0.7091	0.7259	1.0102
CRSP market return	22.05%	22.05%	8.58%
	(7.63%)	(5.39%)	(5.36%)
3-month T-bill yield	6.21%	10.71%	6.92%
	(1.27%)	(2.41%)	(1.00%)
6-month T-bill yield	6.48%	10.80%	7.02%
	(1.27%)	(2.21%)	(0.95%)
1-year T-note yield	7.05%	11.70%	7.62%
	(1.25%)	(2.27%)	(1.00%)
7-year T-note yield	7.23%	11.91%	8.67%
	(0.54%)	(1.79%)	(1.09%)
BAA bond yield	9.66%	14.04%	10.84%
	(0.68%)	(1.97%)	(0.98%)
Monthly inflation[d]	0.78%	0.46%	0.25%
	(0.69%)	(0.50%)	(0.23%)
Maturity-risk premium[e]	0.68%	0.20%	1.05%
	(0.88%)	(1.32%)	(0.72)
Default-risk premium[f]	1.94%	2.13%	2.17%
	(0.77%)	(0.76%)	(0.46%)

[a]Average returns and yields are reported on annualized basis
[b]Standard deviation is in parenthesis
[c]Estimated using single-index market model
[d]Measured by the relative change in consumer price index
[e]Yield differential between 7-year T-note and 1-year T-note
[f]Yield differential between BAA-rated corporate bond and 7-year T-note

summarized in Table 6.1. The average monthly inflation, as measured by the relative change in the consumer price index, was highest during 1974–1978 and lowest during 1985–1990. The average default-risk premium was of the same order of magnitude for all the three periods. The average maturity-risk premium was high during 1985–1990 indicating a steeper yield curve. For the period 1979–1984, the average maturity-risk premium was low, but its standard deviation was high. This indicates a relatively less steep but volatile yield curve.

The bank portfolio's average return (9.66 %), for the period 1974–1978, was much smaller than the average market return (22.05 %). For the period 1979–1984, both returns increased dramatically; the portfolio's average return (22.28 %) was about the same as the average market return (22.05 %). For the period 1985–1990, the portfolio and markets average return both dropped dramatically to 6.48 % and 8.58 %, respectively. The estimated portfolio beta increased from about 0.7 in the two earlier periods to about 1.0 in the latest period.

6.5 Empirical Results

6.5.1 Two-Variable Regression Model and Pricing of Interest Rate Risk

The estimated coefficients of the two-variable regression model are presented in Table 6.2.[7] For the period 1974–1978, a period characterized by low and stable interest rates, the interest rate beta was statistically insignificant with all the interest rate factors except the 7-year T-note returns. For the period 1979–1984,

[7]Test of two-variable model for the period 1991–2007 indicated that interest rate risk is not priced. Tables can be provided to interested readers.

the interest rate beta was statistically significant with all the interest factors, and its magnitude varied substantially. This period was characterized by a relatively flat but volatile yield curve. For the period 1985–1990, the interest rate beta was statistically significant only with the 7-year T-note returns as the interest rate factor. In general, the estimated value of β_{2j} for the periods 1974–1978 and 1985–1990 is smaller and less statistically significant than the value for the period 1979–1984.

The magnitude of interest rate beta, whether significant or not, varies with the choice of the interest rate variable. The size of β_{2j} increases with the choice of securities in the following order: 3-month T-bill, 6-month T-bill, 1-year T-note, 7-year T-note, and BAA-rated bond (except β_{2j} estimated using BAA bond return for the period 1974–1978 and the 6-month T-bill return in 1985–1990). This observation validates inequality (6.3) in all the periods and suggests the expanding nature of the investment opportunity set with increased horizon (Merton 1973). As stated earlier, the difference between β_{2j} estimated using 7-year T-note returns and that using 3-month T-bill returns measures the effect on the bank stock returns due to the unexpected changes in the maturity-risk premium. Further, difference between β_{2j} estimated using BAA bond returns and that using 7-year T-note returns measures the effect on the bank stock returns due to the unexpected changes in the default-risk premium.

The fact that bank stock returns are more sensitive to the long-term interest rates than to short-term interest rates is consistent with our expectation about the size of β_2 expressed in inequalities (6.3). Similar results were reported by other researchers (such as Unal and Kane (1988) and Chen et al. (1986)). A shift of focus from short-term to long-term inflation expectation could explain this result. An alternative explanation is that bank balance sheet returns are better approximated by long-term than by short-term bond returns. To the extent that balance maturity mismatches occur, they should be related to long-term bond returns. The reason is simply that long-term bond returns include the present value of more future period returns than do short-term bond returns. That is, long-term bond returns include price changes not included in short-term bond returns. The price changes in the long-term bond returns represent price changes in long-term bank contracts. The most representative term equals the term of assets or liabilities, whichever is longer. If the maturity mismatch is a net asset (liability) position, then the long-term bond maturity would reflect the asset (liability) maturity. The estimate of a large, positive coefficient (β_{2j}) for 7-year T-notes and BAA bonds implies that banks mismatch in favor of assets with relatively long maturities.

The plausible causes for the change in the interest risk from period to period are (1) changes in real returns, as reported by Fama and Gibbons (1982), (2) unexpected changes in short-term and long-term inflation expectation, (3) shift of focus from short-term to long-term inflation expectation, (4) unexpected changes in risk aversion, (5) unexpected changes in the default risk of bank's nominal contracts, and (6) structural instability of the systematic interest rate equation used to extract interest rate innovations. The estimated coefficients of multi-risk premia model will shed some light on this issue.

6.5.2 Multi-risk Premia Model

The estimates of the first systematic interest rate Eq. 6.11, which specifies innovations in the short-term default-free bond returns, are reported in Table 6.3. The ordinary least square (OLS) estimates were rejected because of the presence of serial autocorrelation as indicated by the Durbin-Watson statistic (see Woolridge 2009). A Durbin-Watson statistic equal to 2 indicates the absence of any serial autocorrelation. The generalized least square (GLS) estimates seemed more appropriate because the Durbin-Watson statistic was approximately equal to 2 and the value of R^2 was higher. Results reported in Table 6.3 exhibit a significant correlation between market return and short-term interest rate variable in the period 1974–1978, but not in the periods 1979–1984 and 1985–1990. However, a low value of R^2 indicates that the relationship expressed in Eq. 6.4 is not as robust as one would have preferred. This approach of extracting changes in short-term inflation was used by Fama and Schwert (1977) and French et al. (1983). Their estimation period overlapped our estimation period 1974–1978 but not the later ones. In Table 6.4 we present the results of the second systematic interest rate Eqs. 6.12a and 6.12b. The estimated coefficient, θ_1, determined the average slope of the yield curve during the estimation period. The OLS estimates were rejected because of the presence of serial correlation indicated by the Durbin-Watson statistics. The term structure coefficient θ_1 was significant in all the periods for *Specifications a* and *b*. However, coefficients θ_2 of *Specification b* was

significant only during 1985–1990. The errors from Specification a for periods 1974–1978 and 1979–1984 and from *Specification b* for the period 1985–1990 were used to specify the second risk factor ΔMR_t. Estimates of the third systematic interest rate Eqs. 6.13a and 6.13b are presented in Table 6.5. As before, the GLS estimates were deemed appropriate. The errors from *Specification a* for the periods 1974–1978 and 1979–1984 and from *Specification b* for the period 1985–1990 were used to specify the unexpected change in default risk, ΔDR_t.

Results of the multi-risk premia model are presented in Table 6.6. The inflation beta is statistically significant in the periods 1979–1984 and 1985–1990 but not in the period 1974–1978. It was shown in Table 6.3 that quasi-differenced short-term interest rates were correlated with the market return for the period 1974–1978 but not for the periods 1979–1984 and 1985–1990. Hence, one could argue that when short-term interest rates are correlated with the market return (i.e., 1974–1978), the error term from Eq. 6.8 contains no systematic information. This results in the inflation beta being insignificant and the interest rate risk not priced with respect to the short-term rates within the context of the two-factor model. A corollary is that, when short-term interest rates are uncorrelated with the market return (i.e., 1979–1984 and 1985–1990), the error term from Eq. 6.11 contains valuable information leading to the inflation beta being significant. The maturity beta was found

to be statistically significant in the periods 1974–1978 and 1979–1984 but not for the period 1985–1990. Results in Table 6.4 (Specification b) showed that long-term interest rates were correlated with the market return for the period 1985–1990 but not for the periods 1974–1978 and 1979–1984. Hence, we posit that when long-term interest rates are correlated with the market return (i.e., 1985–1990), the error term from Eq. 6.12b contains no systematic information. This results in the maturity beta being insignificant. A corollary is that, when long-term interest rates are uncorrelated with the market return (i.e., 1974–1978 and 1979–1984), the error term from Eq. 6.12b contains valuable information producing a significant maturity beta and the interest rate risk is priced with respect to the long-term rates within the context of the two-factor model. The default beta was found to be statistically significant in the period 1985–1990 but not for the periods 1974–1978 and 1979–1984. The economic factors that lead to significant correlation between market returns and long-term interest rates (Eq. 6.12b) or between market returns and BAA-rated bond returns (Eq. 6.13b) caused the interest rate risk to be priced with respect to the long-term rates within the context of the two-factor model (1985–1990). Since the correlation between market return and interest rate changes over time, the interest rate risk also changes over time.

Portfolio beta estimated using single-index model are 0.7091, 0.7259, and 1.0102 for the periods 1974–1978, 1979–1984, and 1985–1990, respectively

[a]Generalized least square estimates

[b]t-statistics are in the parenthesis

Negative inflation and maturity betas for the period 1985–1990 need some explanation because it is contrary to a priori expectation. For the period 1985–1990, the bank portfolio and market return both dropped dramatically to 6.48 % and 8.58 %, respectively. However, the estimated portfolio beta increased from about 0.7 in the two earlier periods to about 1.0 in this period (beta estimated independently by the single-index model). Consequently, the market factor alone will overestimate the bank portfolio's expected return. The negative values of inflation beta and maturity beta (though insignificant) correct the overestimation. Economic factors and regulatory changes that fuelled M&A activities during this period must have been such that they increased the portfolio beta without increasing the *ex-post* portfolio return. Some of these unidentifiable factors are negatively correlated with the interest rates. One of the shortcomings of the factor analytic approach is that factors are at times unidentifiable. In spite of difficulties in explaining some of the results for the period 1985–1990, the multi-risk premia model does provide greater insight into the pricing of interest rate risk.

6.6 Conclusions

In this paper, we examine the interest rate sensitivity of commercial bank returns covering three distinct economic and regulatory environments. First, we investigate the pricing of the interest rate risk within the framework of the two-factor model.

Our results indicate that interest rate risk was priced during 1979–1984 irrespective of the choice of interest rate variable. However, during the periods 1974–1978 and 1985–1990, bank stock returns were sensitive only to the unexpected changes in the long-term interest rates. Next, we tested to an asset-pricing model in which the traditional CAPM is augmented by three additional factors to account for unexpected changes in the inflation, the maturity premium, and default premium. Our results show that the inflation beta was significant for the periods 1979–1984 and 1985–1990, but not for the period 1974–1978; the maturity beta was significant for the periods 1974–1978 and 1979–1984 but not for the period 1985–1990; and the default beta was significant for the period 1985–1990 but not for the periods 1974–1978 and 1978–1984.

We can infer that when short-term interest rates are correlated with the market return, the innovations in short-term interest rate are indeed white noise. However, innovations in short-term interest rates contain valuable information when short-term interest rates are uncorrelated with the market return. This will lead to a significant inflation beta and the interest rate risk will be priced with respect to the short-term rates within the context of the two-factor model. We can also infer that when long-term interest rates are correlated with the market return, the innovations in long-term interest rate are indeed white noise. However, innovations in long-term interest rates contain valuable information when long-term interest rates are uncorrelated with the market return. This results in a significant maturity beta and priced interest rate risk with respect to the long-term rates within the context of the two-variable model.

Appendix 1: An Integration of CAPM and APT

The traditional CAPM is augmented by three additional APT-type principal component factors (Johnson and Wichern 2007) to account for unexpected changes in the inflation premium, the maturity-risk premium, and the default-risk rating. Hence, the proposed return-generating model is written as

$$R_{jt} = \alpha_j + \beta_{1j}R_{mt} + \beta_{2Pj}\Delta P_t + \beta_{2Mj}\Delta MR_t + \beta_{2Dj}\Delta DR_t + \varepsilon_{jt} \tag{6.7}$$

where ΔP_t, ΔMR_t, and ΔDR_t are the proxies for the innovations in inflation, maturity risk, and default risk, respectively. Coefficients β_1, β_{2P}, β_{2M}, and β_{2D} are the measures of systematic market risk, inflation risk, maturity risk, and default risk, respectively, and are consistent with APT.

Principal Component Factor Specification

An important issue in the empirical investigation of this model is the specification of an appropriate inflation and maturity-risk and default-risk factors. Being innovations in economic variables, these factors cannot be predicted using past information. Hence, they must meet the following conditions:

$$\begin{aligned} E(\Delta P_t|t-1) &= 0 \\ E(\Delta MR_t|t-1) &= 0 \\ E(\Delta DR_t|t-1) &= 0 \end{aligned} \tag{6.8}$$

where $E(.|t-1)$ is the expectation based on available information at $t-1$. Theoretical consideration dictates that the choice of a factor (say ΔMR_t) should not influence any other factor loadings (say $\exists_{1j}$). Hence, there should not be any contemporaneous cross-correlations between the factors. Hence,

$$\begin{aligned} E(\Delta P_t.\Delta MR_t) &= 0 \\ E(\Delta P_t.\Delta DR_t| &= 0 \\ E(\Delta R_t.\Delta DR_t) &= 0 \end{aligned} \tag{6.9}$$

In addition, there are no common market shocks that may influence any of the risk factors. So the following conditions

$$\begin{aligned} E(R_{mt}.\Delta P_t) &= 0 \\ E(R_{mt}.\Delta MR_t) &= 0 \\ E(R_{mt}.\Delta DR_t) &= 0 \end{aligned} \tag{6.10}$$

must be satisfied. We use a generated regressor approach to construct orthogonal inflation-risk, maturity-risk, and default-risk factors.

Economic factors that lead to changes in the equity market return also induce term structure movements. This leads to a significant correlation between the stock market index and the bond market index. Hence, we use the stock market return to forecast systematic changes in the short-term interest rates. The innovations in the short-term default-free bond return specify the unexpected changes in inflation. Hence, the first systematic interest rate equation is written as

$$R_{ST,t} = \delta_0 + \delta_1 R_{mt} + \varepsilon_{It} \tag{6.11}$$

where R_{mt} is the return on the stock market index and $R_{ST,t}$ is the return on the short-term default-free bond return. The error term in Eq. 6.11, ε_{It}, specifies the unexpected change in inflation and is the generated regressor which serves as a proxy for factor ΔP_t. Fama and Schwert (1977) and French et al. (1983) employ similar approaches to specify a proxy for changes in inflation.

The yield differential between short-term and long-term default-free bond represents the slope of the yield curve. The relationship used to construct the maturity-risk factor is given by the second systematic interest rate equation:

$$R_{LT,t} = \theta_0 + \theta_1 R_{ST,t} + \varepsilon_{Mt} \tag{6.12a}$$

where θ_1 measures the average slope of the yield curve. Alternately, we will also test the following systematic interest rate equation:

$$R_{LT,t} = \theta_0 + \theta_1 R_{ST,t} + \theta_2 R_{mt} + \varepsilon_{Mt} \tag{6.12b}$$

Inclusion of the independent variable, R_{mt}, will control for the stock–bond market linkage. The estimated coefficient θ_1 measures the slope of the yield curve, and it determines the maturity-risk premium on long-term assets and liabilities. The error term in Eqs. 6.12a or 6.12b, ε_{Mt}, specifies the unexpected change in maturity risk and will be used as the generated regressor which serves as a proxy for factor ΔMR_t.

The portfolio of commercial banks used for this study consisted of money center and large national and regional banks. Most of these banks were well capitalized and had acquired a balanced portfolio of assets. The average default-risk rating of the portfolio of banks should be close to the default-risk rating of a high-grade corporate bond. Hence, the yield differential between BAA corporate bond and long-term treasury security is used to construct the default-risk factor. Our third systematic interest rate equation is written as

$$R_{BAA,t} = \varphi_0 + \varphi_1 R_{LT,t} + \varepsilon_{Dt} \tag{6.13a}$$

Alternately, we will also test the following systematic interest rate equation:

$$R_{BAA,t} = \varphi_0 + \varphi_1 R_{LT,t} + \varphi_2 R_{mt} + \varepsilon_{Dt} \tag{6.13b}$$

where φ_1 measures the average default risk on BAA corporate bond. Inclusion of the independent variable, R_{mt}, will control for the stock–bond market linkage. The error term in Eqs. 6.13a or 6.13b, ε_{Dt}, specifies the unexpected change in default risk and serves as the generated regressor which will be used as the proxy for factor ΔDR_t.

Appendix 2: Interest Rate Innovations

An important issue in the empirical investigation of the two-factor model is the specification of an appropriate interest rate factor. Theoretical consideration of factor analysis requires that two factors, R_{mt} and R_{It}, be orthogonal whereby choice of the second factor (R_{It}) would not influence the first factor loading (β_{Ij}). The resolution of this constraint requires a robust technique for determining the unexpected changes in the interest rate that is uncorrelated with the market return. The three approaches to specify the interest rate factor are presented here.

Orthogonalization Procedure

Economic factors producing changes in the market return also induced term structure movements. This leads to a high correlation between the market factor and the interest rate factor. Hence, market return can be used as an instrument variable to forecast the expected changes in the interest rates. To find the unexpected component of interest rates, the expected interest rate is purged by regressing R_{It} on R_{mt} and using the residuals. The systematic interest rate risk equation is

$$R_{It} = \delta_0 + \delta_1 R_{mt} + \varepsilon it \tag{6.14}$$

The residuals, εit, are the unsystematic interest rates and are used to replace R_{It} in Eq. 6.14. The validity of this approach has been questioned on methodological grounds. It is pointed out that this orthogonalization procedure produces biased estimates of coefficients (intercept and β_{1j} in Eq. 6.14) and that the deficiency of β_{2j} is not improved. On the other hand, use of an unorthogonal interest rate factor leads to the errors-in-variable problem, i.e., the estimated coefficient β_{2j} also captures some of the effects responsible for changing the market factor, and hence, it is not a true measure of the interest rate risk. Another problem using an unorthogonal interest rate factor stems from the fact that interest rate (R_{It}) is usually autoregressive. Therefore, residuals, εit, from Eq. 6.14 are autocorrelated unless GLS parameter estimation procedure is employed. To use the GLS procedure, a variance-covariance matrix has to be specified, which is not an easy task.

Univariate ARMA Model

The second approach is to identify and estimate an ARMA model for the interest rate variable, R_{It} (Flannery and James (1984)). The unanticipated change in interest rate from the estimated model (i.e., residuals) is used to replace R_{It} in Eq. 6.14. In general, the ARMA model of order (p, q) for the univariate time series, R_{It}, is written as

$$R_{It} = \phi_1 R_{It-1} + \phi_2 R_{It-2} + \ldots + \phi_p R_{It-p} + \mu - \theta_1 e_{I,t-1} - \ldots - \theta_q \varepsilon_{1,t-q} + \varepsilon_{It} \tag{6.15}$$

where ε_{It}, $\varepsilon_{I,t-1}$, ... are identically and independently distributed random errors with mean zero. The ARMA procedure for the modeling of time series data is outlined in Box and Jenkins (1976). The modeling is usually done in three steps. First, a tentative parsimonious model is identified. Second, the parameters are estimated, and diagnostic (Box-Pierce Q) statistics and residual auto correlation plots are examined. The model is acceptable if the time series of residuals is white noise and the Box-Pierce Q statistics are significant.

This approach leads to unbiased estimates of all the coefficients in Eq. 6.14. The shortcoming of the univariate ARMA approach is that valuable information contained in the stock and bond market linkage is ignored. Consequently, coefficient β_{2j} captures some of the effects of economic factors producing stock market changes.

Vector ARMA Model

In recent years vector autoregressive moving average (VARMA) models have proved to be useful tools to describe the dynamic relationship between economic variables. A vector autoregressive moving average model of order (p, q) for k-dimensional time series, $Rt = (R_{1t}, R_2t, \ldots R_{kt})^T$, is generated by the following equation:

$$\Phi(\mathbf{B})R_t = \Theta(\mathbf{B})\varepsilon_t \tag{6.16}$$

$$\Phi(\mathbf{B}) = \left(\mathbf{I} - \phi_1\mathbf{B} - \phi_2\mathbf{B}^2 - \ldots - \phi_p\mathbf{B}^p\right) \tag{6.17}$$

$$\Theta(\mathbf{B}) = \left(\mathbf{I} - \theta_1\mathbf{B} - \theta_2\mathbf{B}^2 - \ldots - \theta_q\mathbf{B}^q\right) \tag{6.18}$$

where **B** is the back shift operator, **I** is kxk unit matrix, and ε_t is a sequence of an independent k-dimensional vector with zero mean and positive definite covariance matrix. The interest rate variable R_{It} and the market return R_{mt} are treated as the components of a bivariate vector. Then vector $(R_{It}, R_{mt})^T$ is modeled as a vector AR process. The estimated model provides the unanticipated change in interest rate variable to be used as the second factor in the augmented CAPM model.

Nonparametric Bounds for European Option Prices

7

Hsuan-Chu Lin, Ren-Raw Chen, and Oded Palmon

Contents

Abstract

There is much research whose efforts have been devoted to discovering the distributional defects in the Black-Scholes model, which are known to cause severe biases. However, with a free specification for the distribution, one can only find upper and lower bounds for option prices. In this paper, we derive a new nonparametric lower bound and provide an alternative interpretation of Ritchken's (1985) upper bound to the price of the European option. In a series of numerical examples, our new lower bound is substantially tighter than previous lower bounds.

This is prevalent especially for out-of-the-money (OTM) options where the previous lower bounds perform badly. Moreover, we present that our bounds can be derived from histograms which are completely nonparametric in an empirical study. We first construct histograms from realizations of S&P 500 index returns following Chen, Lin, and Palmon (2006); calculate the dollar beta of the option and expected payoffs of the index and the option; and eventually obtain our bounds. We discover violations in our lower bound and show that those violations present arbitrage profits. In particular, our empirical results show that out-of-the-money calls are substantially overpriced (violate the lower bound).

7.1 Introduction

In a seminal paper, Merton (1973) presents for the first time the no-arbitrage bounds of European call and put options. These bounds are nonparametric and do not rely on any assumption.[1] Exact pricing formulas such as the Black and Scholes (1973) model and its variants, on the other hand, rely on strong assumptions on the asset price process and continuous trading. Due to the discreteness of actual trading opportunities, Perrakis and Ryan (1984) point out that option analyses in continuous time limit the accuracy and applicability of the Black-Scholes and related formulas. Relying on Rubinstein's (1976) approach, the single-price law, and arbitrage arguments, they derive upper and lower bounds for option prices with both a general price distribution and discrete trading opportunities. Their lower bound is tighter than that of Merton.

Levy (1985) applies stochastic dominance rules with borrowing and lending at the risk-free interest rate to derive upper and lower option bounds for all unconstrained utility functions and alternatively for concave utility functions. The derivation of these bounds can be applied to any kinds of stock price distribution as long as the stock is "nonnegative beta," which is identical to the assumption of Perrakis and Ryan (1984). Moreover, Levy claims that Perrakis and Ryan's bounds can be obtained by applying the second-degree stochastic dominance rule. However, Perrakis and Ryan do not cover all possible combinations of the risky asset with the riskless asset, and their bounds are therefore wider than those of Levy. Levy also applies the first-degree stochastic dominance rule (FSDR) with riskless assets to prove that Merton's bounds are in fact FSDR bounds and applies the second-degree stochastic dominance rule to strengthen Merton's bounds on the option value. At the same time, Ritchken (1985) uses a linear programming methodology to derive option bounds based on primitive prices in incomplete markets and claims that his bounds are tighter than those of Perrakis and Ryan (1984).

[1]The only assumption is that both option and its underlying stock are traded securities.

With an additional restriction that the range of the distribution of the one-period returns per dollar invested in the optioned stock is finite and has a strictly positive lower limit, Perrakis (1986) extends Perrakis and Ryan (1984) to provide bounds for American options. Instead of assuming that no opportunities exist to revise positions prior to expiration in Levy (1985) and Ritchken (Ritchken 1985), Ritchken and Kuo (1988) obtain tighter bounds on option prices under an incomplete market by allowing for a finite number of opportunities to revise position before expiration and making more restrictive assumptions on probabilities and preferences. The single-period linear programming option model is extended to handle multiple periods, and the stock price is assumed to follow a multiplicative multinomial process. Their results show that the upper bounds are identical to those of Perrakis, while the lower bounds are tighter. Later, Ritchken and Kuo (1989) also add suitable constraints to a linear programming problem to derive option bounds under higher orders of stochastic dominance preferences. Their results show that while the upper bounds remain unchanged beyond the second-degree stochastic dominance, the lower bounds become sharper as the order of stochastic dominance increases.[2]

Claiming that Perrakis and Ryan (1984), Levy (1985), Ritchken (1985), and Perrakis (1986) are all parametric models, Lo (1987) derives semi-parametric upper bounds for the expected payoff of call and put options. These upper bounds are semi-parametric because they depend on the mean and variance of the stock price at maturity but not on its entire distribution. In addition, the derivation of corresponding semi-parametric upper bounds for option prices is shown by adopting the risk-neutral pricing approach of Cox and Ross (1976).[3] To continue the work of Lo (1987), Zhang (1994) and De La Pena et al. (2004), both of which assume that the underlying asset price must be continuously distributed, sharpen the upper option bounds of Lo (1987). Boyle and Lin (1997) extend the results of Lo (1987) to contingent claims on multiple underlying assets. Under an intertemporal setting, Constantinides and Zariphopoulou (2001) derive bounds for derivative prices with proportional transaction costs and multiple securities. Frey and Sin (1999) examine the sufficient conditions of Merton's bounds on European option prices under random volatility. More recently, Gotoh and Konno (2002) use the semi-definite programming and a cutting plane algorithm to study upper and lower bounds of European call option prices. Rodriguez (2003) uses a nonparametric method to derive lower and upper

[2]To further explore the research work of Ritchken and Kuo (1989) under the decreasing absolute risk aversion dominance rule, Basso and Pianca (1997) obtain efficient lower and upper option pricing bounds by solving nonlinear optimization problem. Unfortunately, neither model provides enough information of their numerical examples for us to compare our model with. The Ritchken-Kuo model provides no Black-Scholes comparison, and the Basso-Pianca model provides only some partial information on the Black-Scholes model (we find the Black-Scholes model under 0.2 volatility to be 13.2670 and under the 0.4 volatility to be 20.3185, which are different from what are reported in their paper (12.993 and 20.098, respectively)) which is insufficient for us to provide any comparison.

[3]Inspired by Lo (1987), Grundy (1991) derives semi-parametric upper bounds on the moments of the true, other than risk-neutral, distribution of underlying assets and obtains lower bounds by using observed option prices.

bounds and contributes a new tighter lower bound than previous work. Huang (Huang 2004) puts restrictions on the representative investor's relative risk aversion and produces a tighter call option bound than that of Perrakis and Ryan (1984). Hobson et al. (2005) derive arbitrage-free upper bounds for the prices of basket options. Peña et al. (2010) conduct static-arbitrage lower bounds on the prices of basket options via linear programming. Broadie and Cao (2008) introduce new and improved methods based on simulation to obtain tighter lower and upper bounds for pricing American options. Lately, Chung et al. (2010) also use an exponential function to approximate the early exercise boundary to obtain tighter bounds on American option prices. Chuang et al. (2011) provide a more complete review and comparison of theoretical and empirical development on option bounds.[4]

In this paper we derive a new and tighter lower bound for European option prices under a nonparametric framework. We show that Ritchken's (1985) upper bound is consistent with our nonparametric framework. Both bounds are nonparametric because the price distribution of underlying asset is totally flexible, can be arbitrarily chosen, and is consistent with any utility preference.[5] We compare our lower bound with those in previous studies and show that ours dominate those models by a wide margin. We also present the lower bound result on the model with random volatility and random interest rates (Bakshi et al. 1997; Scott 1997) to demonstrate how easily our model can be made consistent with any parametric structure.[6] Finally, we present how our bounds can be derived from histograms which are nonparametric in an empirical study. We discover violations of our lower bound and show that those violations present arbitrage profits.[7] In particular, our empirical results show that out-of-the-money calls are substantially overpriced (violate the lower bound).

7.2 The Bounds

A generic and classical asset pricing model with a stochastic kernel is

$$S_t = E_t\left[M_{t,T} S_T\right], \tag{7.1}$$

where $M_{t,T}$ is the marginal rate of substitution, also known as the pricing kernel that discounts the future cash flow at time T; $E_t[.]$ is the conditional expectation

[4]Since our paper only provides a nonparametric method on examining European option bounds, our literature review is much limited. For a more complete review and comparison on prior studies of option bounds, please see Chuang et al. (2011).

[5]Christoffersen et al. (2010) provide results for the valuation of European-style contingent claims for a large class of specifications of the underlying asset returns.

[6]Given that our upper bound turns out to be identical to Ritchken's (1985), we do not compare with those upper bound models that dominate Ritchken (e.g., Huang (2004), Zhang (1994) and De La Pena et al. (2004)). Also, we do not compare our model with those models that require further assumptions to carry out exact results (e.g., Huang (2004) and Frey and Sin (1999)), since it is technically difficult to do.

[7]For the related empirical studies of S&P 500 index options, see Constantinides et al. (2009, 2011).

under the physical measure $\mathbb{P}$ taken at time t; and S_t is the value of an arbitrary asset at time t. The standard kernel pricing theory (e.g., Ingersoll (1989)) demonstrates that

$$D_{t,T} = E_t\left[M_{t,T}\right], \tag{7.2}$$

where $D_{t,T}$ is the risk-free discount factor that gives the present value of $1 over the period (t,T). The usual separation theorem gives rise to the well-known risk-neutral pricing result:

$$\begin{aligned} S_t &= E_t\left[M_{t,T}S_t\right] \\ &= E_t\left[M_{t,T}\right]\hat{E}_t^{(T)}[S_T], \\ &= D_{t,T}\hat{E}_t^{(T)}[S_T] \end{aligned} \tag{7.3}$$

If the risk-free interest rate is stochastic, then $\hat{E}_t^{(T)}[.]$ is the conditional expectation under the T-forward measure $\hat{\mathbb{P}}^{(T)}$. When the risk-free rate is non-stochastic, then the forward measure reduces to the risk-neutral measure $\hat{\mathbb{P}}$ and will not depend upon maturity time, i.e., $E_t^{(T)}[\cdot] \rightarrow \hat{E}_t[\cdot]$.[8]

Note that Eqs. 7.1 and 7.3 can be applied to both the stock and the option prices. This leads to the following theorem which is the main result of this paper.

Theorem 7.1 The following formula provides a lower bound for the European call option $\underline{C}_t$:

$$\underline{C}_t = D_{t,T}E_t[C_T] + \beta_C\left\{S_t - D_{t,T}E_t[S_T]\right\} \tag{7.4}$$

where $\beta_C = \frac{\text{cov}[C_T, S_T]}{\text{var}[S_T]}$.

Proof By Eq. 7.1, the option price must follow $C_t = E_t[M_{t,T}\, C_T]$, and hence

$$\begin{aligned} C_t &= E_t\left[M_{t,T}C_T\right] \\ &= E_t\left[M_{t,T}\right]E_t[C_T] + \text{cov}\left[M_{t,T}, C_T\right] \\ &= D_{t,T}E_t[C_T] + \text{cov}\left[M_{t,T}, C_T\right] \end{aligned} \tag{7.5}$$

or

$$C_t - D_{t,T}E_t[C_T] = \text{cov}\left[M_{t,T}, C_T\right]. \tag{7.6}$$

Similarly,

$$S_t - D_{t,T}E_t[S_T] = \text{cov}\left[M_{t,T}, S_T\right]. \tag{7.7}$$

[8] Without loss of generality and for the ease of exposition, we take non-stochastic interest rates and proceed with the risk-neutral measure $\hat{\mathbb{P}}$ for the rest of the paper.

Hence, to prove Eq. 7.4, we only need to prove

$$\operatorname{cov}\left[M_{t,T}, C_T\right] \geq \beta_C \operatorname{cov}\left[M_{t,T}, S_T\right]. \tag{7.8}$$

Note that cov$[M_{t,T}, C_T]$ = cov$[M_{t,T}, \max\{S_T - K, 0\}]$ is monotonic in strike price K and has a minimum value when $K = 0$ in which case cov$[M_{t,T}, C_T]$ = cov$[M_{t,T}, S_T]$ and a maximum value when $K \to \infty$ in which case cov$[M_{t,T}, C_T] = 0$. Hence, cov$[M_{t,T}, S_T] \leq$ cov$[M_{t,T}, C_T]$ which is less than 0. Note that $0 < \beta_C < 1$ (see the proof in the following Corollary). In Appendix 1, it is proved that cov$[M_{t,T}, C_T] \geq \beta_C$ cov$[M_{t,T}, S_T]$.

The put lower bound takes the same form and is provided in the following corollary:

Corollary 7.1 The lower bound of the European put option $\underline{P}_t$ can be obtained by the put-call parity and satisfies the same functional form in Theorem 7.1:

$$\underline{P}_t = D_{t,T} E_t[P_T] + \beta_P \{S_t - D_{t,T} E_t[S_T]\} \tag{7.9}$$

where $\beta_P = \dfrac{\operatorname{cov}[P_T, S_T]}{\operatorname{var}[S_T]}$.

[Proof] By the Put-Call Parity:

$$P_t = C_t + D_{t,T} K - S_t \geq \underline{C}_t + D_{t,T} K - S_t = \underline{P}_t. \tag{7.10}$$

We then substitute in the result of Theorem 7.1 to get

$$\begin{aligned}
\underline{P}_t &= D_{t,T} E_t[C_T] + \beta_C \{S_t - D_{t,T} E_t[S_T]\} + D_{t,T} K - S_t \\
&= D_{t,T} E_t[S_T + P_T - K] + \beta_C \{S_t - D_{t,T} E_t[S_T]\} + D_{t,T} K - S_t \\
&= D_{t,T} E_t[P_T] + \beta_P \{S_t - D_{t,T} E_t[S_T]\}
\end{aligned} \tag{7.11}$$

where $\beta_P = \beta_C - 1$. Note that $\beta_P < 0 < \beta_C$. This also implies that $\beta_c < 1$. Finally, it is straightforward to show that $\beta_P = \frac{\operatorname{cov}[P_T, S_T]}{\operatorname{var}[S_T]}$ using the put-call parity.

Therefore, for both call and put options, since the relationship between the pricing kernel M and stock price S is convex, the theorem provides a lower bound.[9] Merton (1973) shows that the stock price will be the upper bound for the call option and the strike price should be the upper bound for the put option; otherwise, arbitrage should occur. Ritchken (1985) provides a tighter upper bound[10] than that of Merton, which is stated in the following theorem, although we provide an alternative proof to Ritchken that is consistent with our derivation of the lower bound.

[9] In the Appendix, $\varepsilon > 0$.

[10] Perrakis and Ryan (1984) and Ritchken (1985) obtain the identical upper bound.

Theorem 7.2 The following formulas provide upper bounds for the European call and put options (Ritchken (1985))[11]:

$$\begin{aligned}\overline{C}_t &= \frac{S_t}{E_t[S_T]}E_t[C_T]\\ \overline{P}_t &= \frac{S_t}{E_t[S_T]}E_t[P_T] + \left(D_{t,T} - \frac{S_t}{E_t[S_T]}\right)K.\end{aligned} \tag{7.12}$$

Proof Similar to the proof of the lower bound, the upper bound of the call option is provided as follows:

$$\begin{aligned}\frac{S_t}{E_t[S_T]}E_t[C_T] &= \frac{E_t\left[M_{t,T}S_T\right]}{E_t[S_T]}E_t[C_T]\\ &= \frac{E_t\left[M_{t,T}S_TC_T\right] - \mathrm{cov}\left[M_{t,T}S_T, C_T\right]}{E_t[S_T]}\\ &> \frac{E_t\left[M_{t,T}S_TC_T\right]}{E_t[S_T]}\\ &= C_t\frac{E_t^{(C)}[S_T]}{E_t[S_T]}\\ &> C_t.\end{aligned} \tag{7.13}$$

The third line of the above equation is a result from the fact that $\mathrm{cov}[M_{t,T}S_T, C_T] < 0$. The fourth line of the above equation is a change of measure with the call option being the numeraire. The last line of the above equation is a result based upon $E_t^{(C)}[S_T]/E_t[S_T] > 1$.[12]

By the put-call parity, we can show that the upper bound of the put option requires an additional term:

$$\begin{aligned}\overline{P}_t &= \overline{C}_t + D_{t,T}K - S_t = \frac{S_t}{E_t[S_T]}E_t[P_T + S_T - K] + D_{t,T}K - S_t\\ &= \frac{S_t}{E_t[S_T]}E_t[P_T] + \left(D_{t,T} - \frac{S_t}{E_t[S_T]}\right)K.\end{aligned} \tag{7.14}$$

The lower and upper bounds we show in this paper have two important advantages over the existing bounds. The bounds will converge to the true value of the option if:

- The expected stock return, $\frac{E_t[S_T]}{S_t}$, approaches the risk-free rate.
- The correlation between the stock and the call or put option (ρ_{SC} or ρ_{SP}) approaches 1 or -1.

[11]This is same as Proposition 3-i (Eq. 7.26) in Ritchken (1985).

[12]By the definition of measure change, we have $E_t[C_TS_T] = E_t[C_T]E_t^{(C)}[S_T]$ which implies $E_t^{(C)}[S_T]/E[S_T] = E_t[C_TS_T]/\{E_t[C_T]E_t[S_T]\} > 1$.

These advantages help us identify when the bounds are tight and when they are not. The first advantage indicates that the bounds are tight for low-risk stocks and not tight for high-risk stocks. The second advantage indicates that the bounds are tighter for in-the-money options than out-of-the-money options.

7.3 Comparisons

The main purpose of this section is to compare our lower bound to several lower bounds in previous studies, namely, Merton (1973), Perrakis and Ryan (1984), Ritchken (1985), Ritchken and Kuo (1988), Gotoh and Konno (2002), and Rodriguez (2003) using the Black-Scholes model as the benchmark for its true option value. We also compare Ritchken's upper bound (which is also our upper bound) with more recent works by Gotoh and Konno (2002) and Rodriguez (2003).

The Black-Scholes model has five variables: stock price, strike price, volatility (standard deviation), risk-free rate (constant), and time to maturity. In addition to the five variables, the lower bound models need the physical expected stock return. The following is the base case for the comparison:

Current stock S_0	50
Strike K	50
Volatility σ	0.2
Risk-free rate r	0.1
Time to maturity T	1
Stock expected return μ	0.2

In the Black-Scholes model, stock price (S) evolution follows a log normal process:

$$dS = \mu S dt + \sigma S dW \tag{7.15}$$

where instantaneous expected rate of stock return μ and volatility of stock price σ are assumed to be constants and where dW is a wiener process. The call option price is computed as

$$C = S_0 N(d_+) - e^{-rT} K N(d_-) \tag{7.16}$$

where

$$d_{\pm} = \frac{\ln S_0 - \ln K + (r \pm 0.5\sigma^2)T}{\sigma\sqrt{T}}.$$

The lower bound is computed by simulating the stock price using Eq. 7.15 via a binomial distribution approximation:

$$S_j = S_0 u^j d^{n-j}. \tag{7.17}$$

As n approaches infinity, S_j approaches the log normal distribution, and the binomial model converges to the Black-Scholes model. Under the risk-neutral measure, the probability associated with the jth state is set as

$$\widehat{\Pr}[j] = \binom{n}{j} \hat{p}^j (1 - \hat{p})^{n-j} \tag{7.18}$$

where

$$\hat{p} = \frac{e^{r\Delta t} - d}{u - d},$$

$$u = e^{\sigma\sqrt{\Delta t}},$$

$$d = e^{-\sigma\sqrt{\Delta t}},$$

and $\Delta t = T/n$ represents the length of the partition. Under the actual measure, the formula will change to

$$\Pr[j] = \binom{n}{j} p^j (1 - p)^{n-j} \tag{7.19}$$

where

$$p = \frac{e^{\mu\Delta t} - d}{u - d}.$$

Finally, the pricing kernel in our model is set as

$$M_{0T}[j] = \frac{\widehat{\Pr}[j]}{\Pr[j]} e^{-rT}. \tag{7.20}$$

In our results, we let n be great enough so that the binomial model price is 4-digit accurate to the Black-Scholes model. We hence set n to be 1,000. The results are reported in Table 7.1. The first panel presents the results for various moneyness levels, the second panel presents the results for various volatility levels, the third panel presents the results for various interest rates, the fourth panel presents the results for various maturity times, and the last presents the results for various stock expected returns. In general, the lower bounds are tighter (for all models) when the moneyness is high (in-the-money), volatility is high, risk-free rate is high, time to maturity is short, and the expected return of stock is low.

This table presents comparisons between our lower bound and existing lower bounds by Merton (1973), Perrakis and Ryan (1984), and Ritchken (1985). The base case parameter values are:

- Stock price = 50
- Strike price = 50
- Volatility = 0.2
- Risk-free rate = 10 %
- Time to maturity = 1 year
- Stock expected return (μ) = 20 %

The highlighted rows represent the base case.

As we can easily see, universally our model for the lower bound is tighter than any of the comparative models. One result particularly worth mentioning is that our lower bound performs better than the other lower bound models in out-of-the-money options. For example, our lower bound is much better than Ritchken's (1985) lower bound when the option is 20 % out-of-the-money and continues to show value when Ritchken's lower bound returns to 0 (see the first panel of Table 7.1).

While Ritchken and Kuo (1988) claim to obtain tighter lower bounds than Perrakis (1986) and Perrakis and Ryan (1984), they do not show direct comparisons in their paper. Rather, they present through a convergence plot (Figure 3 on page 308 in Ritchken and Kuo (1988)) of a Black-Scholes example with the true value being \$5.4532 and the lower bound approaching roughly \$5.2. The same parameter values with our lower bound show a lower bound of \$5.4427, which demonstrates a substantial improvement over the Ritchken and Kuo model.

The comparisons with more recent studies of Gotoh and Konno (2002) and Rodriguez (2003) are given in Tables 7.2 and 7.3.[13] Gotoh and Konno use semi-definite programming and a cutting plane algorithm to study upper and lower bounds of European call option prices. Rodriguez uses a nonparametric method to derive lower and upper bounds. As we can see in Tables 7.2 and 7.3, except for very few upper bound cases, none of the bounds under the Gotoh and Konno's model and Rodriguez's model are very tight, compared to our model. Furthermore, note that our model requires no moments of the underlying distribution.[14]

The base case parameter values are:

- Stock price = 40
- Risk-free rate = 6 %
- Stock expected return (μ) = 20 %

[13] We also compare with the upper bound by Zhang (1994), which is an improved upper bound by Lo (1987), and show overwhelming dominance of our upper bound. The results (comparison to Tables 7.1, 7.2, and 7.3 in Zhang) are available upon request.

[14] The upper bounds by the Gotoh and Konno model perform well in only in-the-money, short maturity, and low volatility scenarios, and these scenarios are where the option prices are close to their intrinsic values, and hence the percentage errors are small.

Table 7.1 Lower bound comparison

Note: *S* is the stock price; *vol* is the volatility; *rate* is the risk-free rate; *Mu* (μ) is the expected rate of return of stock; *Blk-Sch* is the Black-Scholes (1973) solution; *Merton* is the Merton (1973) model; *PR* is Perrakis and Ryan (1984) model; *Ritch.* is the Ritchken (1985) model; *Our* is our model; *$error* is error in dollar; *%error* is error in percentage

The base case parameter values are:

- Strike price = 50
- Volatility = 0.2
- Risk-free rate = 10 %
- Time to maturity = 1 year
- Stock expected return (μ) = 20 %

7.4 Extensions

In addition to a tight lower bound, another major contribution of our model is that it makes no assumption on the distribution of the underlying stock (unlike Lo (1984) and Gotoh and Konno (2002) who require moments of the underlying distribution) or any assumption on interest rates and volatility (unlike Rodriguez (2003) who requires constant interest rates). As a result, our lower bound can be used with models that assume random volatility and random interest rates or any arbitrary specification of the underlying stock. Note that our model needs only the dollar beta of the option and expected payoffs of the stock and the option.[15] In this section, we extend our numerical experiment to a model with random volatility and random interest rates.

Option models with random volatility and random interest rates can be derived with closed form solutions under the Scott (1997) and Bakshi et al. (1997)

[15]The term "dollar beta" is originally from Page 173 of Black (1976). Here we mean β_c and β_p.

specifications. However, here, given that there is no closed form solution to the covariance our model requires, we shall use Monte Carlo to simulate the lower bound. In order to be consistent with the lower bound, we must use the same Monte Carlo paths for the valuation of the option. For the ease of exposition and simplicity, we assume the following joint stochastic processes of stock price S, interest rate r, and volatility V under the actual measure, respectively:

$$\begin{aligned} dS &= \mu S dt + \sqrt{V} S d\hat{W}_2 \\ dr &= \alpha(\theta - r)dt + v d\hat{W}_2 \\ dV &= \eta V d\hat{W}_2 \end{aligned} \tag{7.21}$$

where dW is a wiener process, $dW_i dW_j = 0$, μ, α, θ, υ, and η are constants. The processes under the actual measure are used for simulating the lower and upper bounds. The Monte Carlo simulations are performed under the risk-neutral measure in order to compute the option price:

$$\begin{aligned} dS &= rS dt + \sqrt{V} S d\hat{W}_1 \\ dr &= \alpha(\theta - r)dt + v d\hat{W}_2 \\ dV &= \eta V d\hat{W}_3. \end{aligned} \tag{7.22}$$

To simplify the problem without loss of generosity, we assume that investors charge no risk premiums on interest rate risk and volatility risk, i.e., $dW_2 = d\hat{W}_2$ and $dW_3 = d\hat{W}_3$.

The simulations are done by the following integrals under the actual (top equation) and risk-neutral (bottom equation) measures:

$$
\begin{aligned}
S_t &= S_0 \exp\left(\int_0^t \mu_u du - \int_0^t ½ V_u du + \int_0^t \sqrt{V_u} dW_u\right) \\
\hat{S}_t &= S_0 \exp\left(\int_0^t r_u du - \int_0^t ½ V_u du + \int_0^t \sqrt{V_u} d\hat{W}_u\right).
\end{aligned} \tag{7.23}
$$

The no-arbitrage price of the call option is computed under the risk-neutral measure as

$$
C = E\left[\exp\left(-\int_0^t r_u du\right) \max\{\hat{S}_t - K, 0\}\right]. \tag{7.24}
$$

Table 7.4 Lower bound under the random volatility and random interest rate model

S	BCC/Scott	Our	\$error	%error
25	1.9073	1.1360	0.7713	40.44

60	21.1082	20.5539	0.5543	2.63
65	25.0292	24.7251	0.3040	1.21
70	29.3226	29.0742	0.2484	0.85

Note: *S* is the stock price; *BCC/Scott* are Bakshi et al. (1997) and Scott (1997) models; *Our* is our model; *\$error* is error in dollar; *%error* is error in percentage

The bounds are computed under the actual measure. For example,

$$E[C_t] = E[\max\{S_t - K, 0\}]. \tag{7.25}$$

Given that $dW_i dW_j = 0$, we can simulate the interest rates and volatility separately and then simulate the stock price. That is, conditional on known interest rates and volatility, under independence, the stock price is log normally distributed.

We perform our simulations using 10,000 paths over 52 weekly periods. The parameters are given as follows:

Strike K	50
Time to maturity T	1
Stock expected return μ	0.2
Reverting speed α	0.5
Reverting level θ	0.1
Interest rate volatility υ	0.03
Initial interest rate r_0	0.1
Initial variance V_0	0.04[16]
Volatility on variance η	0.2

Note that implicitly we assume the price of risk for both interest rate process and volatility process to be 0, for simplicity and without loss of generality. The results are shown in Table 7.4. Compared to the model of the Black-Scholes (i.e., the first panel of Table 7.4), the lower bound performs similarly in the random volatility and random interest rate model. Take the base case as an example where the Black-Scholes price is 6.6322, the Bakshi-Cao-Chen/Scott price is 13.6180 as a result of extra uncertainty in the stock price due to random volatility and interest

[16]This is so because the initial volatility is 0.2.

rates. The error of the lower bound of our model is 0.7510 in the Bakshi-Cao-Chen/Scott case as opposed to 0.4398 in the Black-Scholes case.[17] The percentage error is 5.52 % in the Bakshi-Cao-Chen/Scott case versus 6.63 % in the Black-Scholes case. The in-the-money options have larger percentage errors than those of the out-of-the-money options.

The parameters are given as follows:

Strike price	50
Time to maturity	1
Stock expected return	0.2
Reverting speed	0.5
Reverting level	0.1
Interest rate volatility	0.03
Price of risk	0
Initial interest rate	0.1
Initial volatility	0.2
Volatility on volatility	0.2

The Monte Carlo paths are 10,000. The stock price, volatility, and interest rate processes are assumed to be independent

7.5 Empirical Study

In this section, we test the lower and upper bounds against data. Charles Cao has generously provided us with the approximated prices of S&P 500 index call option contracts, matched levels of S&P 500 index, and approximated risk-free 90-day T-Bill rates for the period of June 2, 1988 through December 31, 1991.[18] For each day, the approximated option prices are calculated as the average of the last bid and ask quotes. Index returns are computed using daily closing levels for the S&P 500 index that are collected and confirmed using data obtained from Standard and Poor's, CBOE, Yahoo, and Bloomberg.[19]

The dataset contains 46,540 observations over 901 days (from June 2, 1988, to December 31, 1991). Hence, on average there are over 50 options for various maturities and strikes. The shortest maturity of the dataset is 7 days and the longest is 367 days. 15 % of the data are less than 30 days to maturity, 32 % are between

[17]This Black-Scholes case is from the highlighted row in the first panel of Table 7.1.

[18]The data are used in Bakshi et al. (1997).

[19]The (ex-dividend) S&P 500 index we use is the index that serves as an underlying asset for the option. For option evaluation, realized returns of this index need not be adjusted for dividends unless the timing of the evaluated option contract is correlated with lumpy dividends. Because we use monthly observations, we think that such correlation is not a problem. Furthermore, in any case, this should not affect the comparison of the volatility smile between our model and the Black-Scholes model.

30 and 60 days, 30 % are between 60 and 180 days, and 24 % are more than 180 days to maturity. Hence, these data do not have maturity bias.

The deepest out-of-the-money option is -18.33 %, and the deepest in-the-money option is 47.30 %. Roughly half of the data are at-the-money options (46 % of the data are within 5 % in-the-money and out-of-the-money). 10 % are deep-in-the-money (more than 15 % in-the-money), but less than 1 % of the data are deep-out-of-the-money (more than 15 % out-of-the-money). Hence, the data have disproportional fraction of in-the-money options. This is clearly a reflection of the bull market in the sample period.

The best way to test the lower and upper bounds derived in this paper is to use a nonparametric, distribution-free model. Note that the lower bound in Theorem 7.1 requires only the expected return of the underlying stock and the covariance between the stock and the option. There is no further requirement for the lower and the upper bounds. In other words, our lower bound model can permit any arbitrary distribution of the underlying stock and any parametric specification of the underlying stock such as random volatility, random interest rates, and jumps. Hence, to best test the bounds with a parsimonious empirical design, we adopt the histogram method introduced by Chen et al. (2006) where the underlying asset is modelled by past realizations, i.e., histogram.

We construct histograms from realizations of S&P 500 index (SPX) returns. We calculate the price on day t of an option that settles on day T using a histogram of S&P 500 index returns for a holding period of T–t, taken from a 5-year window immediately preceding time t.[20] For example, an x-calendar-day option price on any date is evaluated using a histogram of round$\left[\frac{252}{365}x\right]$ -trading-day holding period returns where round [.] is rounding the nearest integer.[21] The index levels used to calculate these returns are taken from a window that starts on the 1260th ($\approx 5 \times 252$) trading day before the option trading date and ends 1 day before the trading date. Thus, this histogram contains $1,260 - \text{round}\left[\frac{252}{365}x\right]$ -trading-day return realizations. Formally, we compute histogram of the (unannualized) returns by the following equation:

$$R_{t,\,t+x,\,i} = \ln S_{t-i-x} - \ln S_{t-i}, \tag{7.26}$$

where each i is an observation in time and t is the last i. For example, if t is 1988/06/02 and x is 15 calendar days (or ten business days). We further choose our histogram horizon to be 5 years or 1,260 business days. Fifteen business days after 1988/06/02 is 1988/06/17. To estimate a distribution of the stock return for 1988/06/17, we look back a series of 10-business-day returns. Since we choose a 5-year historical window, or 1,260-business-day window, the histogram will contain

[20]We use three alternative time windows, 2-year, 10-year, and 30-year, to check the robustness of our procedure and results.

[21]The conversion is needed because we use trading-day intervals to identify the appropriate return histograms and calendar-day intervals to calculate the appropriate discount factor.

1,260 observations. The first return in the histogram, $R_{1933/06/02,1933/06/07,1}$, is the difference between the log of the stock price on 1988/06/01, ln S_{t-1}, and the log of the stock price 15 calendar days (ten business days) earlier on 1988/05/17, ln $S_{t-1-\alpha}$. The second observation in the histogram, $R_{1933/06/02/1933/06/07,2}$ is computed as ln S_{t-2}–ln $S_{t-2-\alpha}$.

After, we complete the histogram of returns, we then convert it to the histogram of prices by multiplying every observation in the histogram by the current stock price:

$$S_{t+x,\,i} = S_t R_{t,\,t+x,\,i}. \tag{7.27}$$

The expected option payoff is calculated as the average payoff where all the realizations in the histogram are given equal weights. Thus, $E_t[C_{T,T,K}]$ and $E_t[S_T]$ are calculated as

$$\begin{cases} E_t\left[C_{T,T,K}\right] = \dfrac{1}{N}\sum_{i=1}^{N} \max\left\{S_{T,\,i} - K, 0\right\} \\ E_t[S_T] = \dfrac{1}{N}\sum_{i=1}^{N} S_{T,\,i} \end{cases}, \tag{7.28}$$

where N is the total number of realized returns and $C_{t,T,K}$ is the price observed at time t, of an option that expires at time T with strike price K. Substituting the results in Eq. 7.28 in the approximation pricing formula of Eq. 7.4, we obtain our empirical model:

$$\begin{aligned} \underline{C}_t &= P_{t,T}E_t\left[C_{T,T,K}\right] + \beta_C\left\{S_t - P_{t,T}E_t[S_T]\right\} \\ &= P_{t,T}\frac{1}{N}\sum_{i=1}^{N} \max\left\{S_{T,\,i} - K, 0\right\} + \beta_C\left\{S_t - P_{t,T}\frac{1}{N}\sum_{i=1}^{N} S_{T,\,i}\right\} \end{aligned} \tag{7.29}$$

where the dollar beta is defined as $\beta_C = \frac{\mathrm{cov}[C_T, S_T]}{\mathrm{var}[S_T]}$ as defined in Eq. 7.4.

Note that option prices should be based upon projected future volatility levels rather than historical estimates. We assume that investors believe that the distribution of index returns over the time to maturity follows the histogram of a particular horizon with a projected volatility. In practice, traders obtain this projected volatility by calibrating the model to the market price. We incorporate the projected volatility, $v^*_{\mathrm{t,T,K}}$, into the histogram by adjusting its returns:

$$R^*_{t,T,K,\,i} = \frac{v^*_{t,T,K}}{v_{t,T}}\left(R_{t,T,\,i} - \overline{R}_{t,T}\right) + \overline{R}_{t,T}.., \quad i = 1, \cdots, N, \tag{7.30}$$

where the historical volatility $v_{t,T}$ is calculated as the standard deviation of the historical returns as follows:

$$v^2_{t,T} = \frac{1}{N-1}\sum_{i=1}^{N}\left(R_{t,T,\,i} - \overline{R}_{t,T}\right)^2 \tag{7.31}$$

where $R_{t,T,i} = S_{T,i}/S_t$ and $\overline{R}_{t,T} = \frac{1}{N}\Sigma_{i=1}^{N} R_{t,T,\,i}$ is the mean return.

Note that the transformation from R to R^* changes the standard deviation from $v_{t,T}$ to $\nu^*_{t,T,K}$, but does not change the mean, skewness, or kurtosis. In our empirical study, we approximate the true volatility by the Black-Scholes implied volatility. For the upper bound calculations, we also need an expected mean return of the stock. In our empirical study, we simply use the histogram mean for it.

The selection of the time horizon is somewhat arbitrary. Empiricists know well that too long horizons reduce the impact of recent events and yet too short understate the impact of long time effects. Given that there is no consensus on a most proper horizon, we perform our test over a variety of choices, namely, 5-year, 10-year, and 30-year, and the results are similar. To conserve space, we provide the results on the 10-year and leave the others available on request.

The results are shown in Table 7.5. Columns (1) and (2) define the maturity and moneyness buckets. Short maturity is less than 30 days to maturity, medium is between 31 and 90 days, long is between 91 and 180 days, and real long is over 180 days to maturity. At-the-money is between 5 % in-the-money and 5 % out-of-the-money (or −5 %), near-in-the-money/near-out-of-the-money is between 5 % and 15 %, and deep-in-the-money/deep-out-of-the-money is over 15 %. Moneyness is defined as $S/K-1$. Column (3) is a frequency count of the number of observations in each bucket. Column (4) represents the average value of the ratios of the lower bound over the market price of the option. Column (5) shows the number of violations when the lower bound is higher than the market price.

Out of the entire sample (46,540 observations), on average, the lower bound is 9.57 % below the market value and the upper bound is 9.28 % above the market value. When we look into subsamples, the performances vary. In general, the lower bound performs better in-the-money than out-of-the-money and medium maturity than other maturities. The best lower bound performance is when the option is near-in-the-money and short-term maturity (2.83 % below market value).

To visualize the upper and lower bounds, we plot selected contracts in Fig. 7.1. In Fig. 7.1, we plot at-the-money (ATM) options from four maturities, 1 month (Fig. 7.1a), 2 months (Fig. 7.1b), 3 months (Fig. 7.1c), and 6 months (Fig. 7.1d). As we move from short maturity to long maturity, the number of observations drops (51, 38, 21, 15 observations, respectively). The bounds are wider as we move from short maturity to long maturity, consistent with the analysis in the previous sections.

As we can see, in general, the lower bound using histograms is best for in-the-money and short-dated options and worst for out-of-the-money options. On average the lower bound is 9.57 % below the market value (the ratio is 90.43 %). However, there are violations. For example, medium-term, near-out-of-the-money options have five violations of the lower bound, and there are a total of 4,233 violations. Theoretically, there should be arbitrage opportunities when the bounds are violated. To test the lower bound does imply arbitrage opportunities, we

Table 7.5 Empirical results on the lower bound

(1)	(2)	(3)	(4)	(5)
Maturity	Money	Total	% lbdd	Violation
Short	Deep out	0		0
Medium	Deep out	0		0
Long	Deep out	84	57.26	0
Real long	Deep out	295	61.18	0
Short	Near out	145	65.33	0
Medium	Near out	1,925	69.27	5
Long	Near out	3,554	82.29	30
Real long	Near out	3,317	86.88	271
Short	At	4,106	89.73	492
Medium	At	7,732	92.45	962
Long	At	5,650	92.82	380
Real long	At	3,857	92.61	584
Short	Near in	2,220	97.17	218
Medium	Near in	3,924	97.08	785
Long	Near in	2,951	94.50	234
Real long	Near in	2,018	90.31	130
Short	Deep in	660	92.48	0
Medium	Deep in	1,296	94.52	29
Long	Deep in	1,352	93.14	46
Real long	Deep in	1,454	89.42	67
Total		46,540	90.43	4,233

Note:
1. This is based upon 2,520 business-day (10 years) horizon. Results of other horizons are similar and are available on request
2. Columns (1) and (2) define the maturity and moneyness buckets. Short maturity is less than 30 days to maturity, medium is between 31 and 90 days, long is between 91 and 180 days, and real long is over 180 days to maturity. At-the-money is between 5 % in-the-money and 5 % out-of-the-money (or −5 %), near-in-the-money/near-out-of-the-money is between 5 % and 15 %, and deep-in-the-money/deep-out-of-the-money is over 15 %. Moneyness is defined as $S/K - 1$. Column (3) is a frequency count of the number of observations in each bucket. Column (4) represents the average value of the ratios of the lower bound over the market price of the option. Column (5) shows the number of violations when the lower bound is higher than the market price
3. The best lower bound performance is when the option is near-in-the-money and short-term maturity (2.83 % below market value)
The underlying stock return distribution is a 10-year historical return histogram with the volatility replaced by the Black-Scholes implied volatility

perform a simple buy and hold trading strategy. If the lower bound is violated, we will buy the option and hold it till maturity. For the 4,233 (out of 46,540) violations, the buy and hold strategy generated \$22,809 or an average of \$5.39 per contract. Given that the buy and hold strategy can be profitable simply due to the bull market, we compute those that had no violation of the lower bound. For the 42,307 cases that violated no lower bound, the average profit is \$1.83. Hence, the options that violated the lower bound imply a trading profit 200 % above the average.

7.6 Conclusion

In this paper, we derive a new and tighter lower bound for European option prices comparing with those of previous studies. We further reinterpret Ritchken's (1985) upper bound under a nonparametric framework. Our model contributes to the literature in two different ways. First, our bounds require no parametric assumption of the underlying stock or the moments of the distribution. Furthermore, our bounds require no assumptions on interest rates or volatility. The only requirements of our model are the dollar beta of the option and expected payoffs of the stock and the option. Hence, our bounds can be applied to any model such as the random volatility and random interest rate model by Bakshi et al. (1997) and Scott (1997). Second, despite of much looser and flexible assumptions, our bounds are significantly tighter than the existing upper and lower bound models. Most importantly, our bounds are tighter for the out-of-the-money options that cannot be bounded efficiently by previous models. Finally, we apply our model to real data using histograms of the realized stock returns. The results show that nearly 10 % of the observations violate the lower bound. These violations are shown to generate significant arbitrage profits, after correction of the bull market in the sample period.

Appendix 1

In this appendix, we prove Theorem 7.1. Without loss of generality, we prove Theorem 7.1 by a three-point convex function. The extension of the proof to multiple points is straightforward but tedious. Let the distribution be trinomial and the relationship between the pricing kernel M and the stock price S be convex. In the following table, $x \leq 0$; $y > \varepsilon \geq 0$.

Probability	M	S	$C = \max\{S - K, 0\}$
p^2	$M + x$	$S + y > K$	$S + y - K$
$2p(1 - p)$	M	$S - \varepsilon < K$	0
$(1 - p)^2$	$M - x$	$S - y < K$	0

When $\varepsilon = 0$, the relationship between the pricing kernel M and stock price S is linear, and we obtain equality. When $\varepsilon > 0$, the relationship is convex. We first calculate the mean values:

$$\begin{aligned} &E[M] = M - x + 2px \\ &E[S] = S - y + 2p(y - \varepsilon) + 2p^2\varepsilon \\ &E[C] = p^2(S + y - K). \end{aligned}$$

The three covariances are computed as follows:

$$\begin{aligned} &\mathrm{cov}[M, S] = 2p(1 - p)x(y + \varepsilon(2p - 1)) \\ &\mathrm{cov}[M, C] = 2p^2(1 - p)x(S + y - K) \\ &\mathrm{cov}[S, C] = 2p^2(1 - p)(S + y - K)(y + p\varepsilon). \end{aligned}$$

The variance of the stock price is more complex:

$$\mathrm{var}[S] = 2p(1 - p)z$$

where

$$z = \left(y^2 + \varepsilon^2\left(1 - 2p + 2p^2\right) + 2\varepsilon y(2p - 1)\right) > 0.$$

As a result, it is straightforward to show that

$$\begin{aligned} \frac{\mathrm{cov}[S, C]}{\mathrm{var}[S]}\mathrm{cov}[M, S] &= \frac{2p^2(1 - p)(S + y - K)(y + p\varepsilon)}{2p(1 - p)z} 2p(1 - p)x(y + \varepsilon(2p - 1)) \\ &= 2p^2(1 - p)x(S + y - K)\frac{(y + p\varepsilon)(y + \varepsilon(2p - 1))}{z} \\ &= 2p^2(1 - p)x(S + y - K)\left[1 + \frac{\varepsilon(1 - p)(y - \varepsilon)}{z}\right] \\ &\leq 2p^2(1 - p)x(S + y - K) =: \mathrm{cov}[M, C]. \end{aligned}$$

The fourth line is obtained because cov$[M,C] < 0$ and $1 + \frac{\varepsilon(1-p)(y-\varepsilon)}{z} > 1$. Note that the result is independent of p since all it needs is $0 < p < 1$ for $1 + \frac{\varepsilon(1-p)(y-\varepsilon)}{z}$ to be greater than 1. Also note that when $\varepsilon = 0$ the equality holds.

Abstract

Research in structuring asset return dependence has become an indispensable element of wealth management, particularly after the experience of the recent financial crises. In this paper, we evaluate whether constructing a portfolio using time-varying copulas yields superior returns under various weight updating strategies. Specifically, minimum-risk portfolios are constructed based on various copulas and the Pearson correlation, and a 250-day rolling window technique is adopted to derive a sequence of time-varied dependencies for each dependence model. Using daily data of the G7 countries, our empirical findings suggest that portfolios using time-varying copulas, particularly the Clayton dependence, outperform those constructed using Pearson correlations. The above results still hold under different weight updating strategies and portfolio rebalancing frequencies.

Keywords

Copulas • Time-varying dependence • Portfolio optimization • Bootstrap • Out-of-sample return • Performance evaluation • GARCH • Gaussian copula • Student's *t*-copula • Gumbel copula • Clayton copula

8.1 Introduction

The return of a portfolio depends heavily on its asset dependence structure. Over the past decade, copula modeling has become a popular alternative to Pearson correlation modeling when describing data with an asymptotic dependence structure and a non-normal distribution.[1] However, several critical issues attached to the applications of copulas emerge: Do portfolios using time-varying copulas outperform those constructed with Pearson correlations? How does the risk return of copula-based portfolios change over the business cycle? The estimation of parameters has become particularly critical for finance academics and professionals on the heels of the recent financial crises. In this chapter, we model the time-varying dependence of an international equity portfolio using several copula functions and the Pearson correlation. We investigate whether a portfolio constructed with copula dependence yields superior returns as compared to a portfolio constructed using a Pearson correlation under various weight updating strategies.

This paper extends the existing literature in two ways. First, we estimate our time-varying copulas using a rolling window of the latest 250 trading days. It is well accepted that the dependencies between asset returns are time varying (Kroner and Ng 1998; Ang and Bekaert 2002). Differing from the regime-switching type used in Rodriguez (2007) and Okimoto (2008) or the time-evolving type GARCH model used in Patton (2006a), we estimate time-varying copulas via a rolling window

[1]See Chan et al. (1999), Dowd (2005), Patton (2006a), Engle and Sheppardy (2008), Chollete et al. (2009), Bauer and Vorkink (2011).

based on daily data from the previous year. The rolling window method has several benefits. First, it is a method frequently adopted by practitioners. Second, the rolling window method considers only the past year's information when forming dependencies, thus avoiding disturbances that may have existed in the distant past. Several studies have applied this technique, such as Aussenegg and Cech (2011). However, Aussenegg and Cech (2011) considered only the daily Gaussian and Student's *t*-copulas in constructing models, and it is reasonable to consider monthly and quarterly frequencies, given that portfolio managers do not adjust their portfolios on a daily basis. Our research also extends Aussenegg and Cech's (2011) study by including the Archimedean copulas to govern the strength of dependence.

Second, our study investigates how the choice of copula functions affects portfolio performance during periods of economic expansion and recession. The expansion and recession periods we define are based on announcements from the National Bureau of Economic Research (NBER). While the use of copula functions in financial studies has grown enormously, little work has been done in comparing copula dependencies under different economic states.

Using daily US dollar-denominated Morgan Stanley Capital International (MSCI) indices of the G7 countries, our empirical results suggest that the copula-dependence portfolios outperform the Pearson-correlation portfolios. The Clayton-dependence portfolios, for most scenarios studied, deliver the highest portfolio returns, indicating the importance of lower-tail dependence in building an international equity portfolio. Moreover, the choice of weight updating frequency matters. As we increase the weight updating frequency from quarterly to monthly, the portfolio returns for the full sample and recession periods also increase, regardless of the choice of dependence measure. Our finding supports the value of active portfolio reconstruction during recession periods.

This paper is organized as follows. Section 8.2 reviews the literature on copula applications in portfolio modeling. Section 8.3 describes the empirical models. Section 8.4 presents the data used. The main empirical results are reported in Sect. 8.5. Section 8.6 concludes.

8.2 Literature Review

Copulas, implemented in either static or time-varying fashion, are frequently seen in options pricing, risk management, and portfolio selection. In this section, we review some copula applications in portfolio selection. Patton (2006a) pioneered time-varying copulas by modifying the copula functional form to allow its parameters to vary. Patton (2006a) used conditional copulas to examine asymmetric dependence in daily Deutsche mark (DM)/US dollar (USD) and Japanese yen (Yen)/US dollar (USD) exchange rates. His empirical results suggest that the correlation between DM/USD and Yen/USD exchange rates is stronger when the DM and Yen are depreciating against the dollar. Hu (2006) adopted a mixture of a Gaussian copula, a Gumbel copula, and a Gumbel survival copula to examine the various dependence structures of four stock indices. His results demonstrate the underestimation problem due to multivariate normality correlations and the importance of incorporating both the structure and the degree of dependence into the portfolio evaluation. Kole et al. (2007) compared the Gaussian, Student's *t*, and Gumbel copulas to illustrate the importance of selecting an appropriate copula to manage the risk of a portfolio composed of stocks, bonds, and real estate. Kole et al. (2007) empirically demonstrated that the Student's *t*-copula, which considers the dependence both in the center and the tail of the distribution, provides the best fit for the extreme negative returns of the empirical probabilities under consideration.

Rodriguez (2007) studied financial contagions in emerging markets using switching Frank, Gumbel, Clayton, and Student's *t*-copulas. Rodriguez (2007) found evidence that the dependence structures between assets change during a financial crisis and that a good asset allocation strategy should allow dependence to vary with time. Chollete et al. (2009) modeled asymmetric dependence in international equity portfolios using a regime-switching, canonical vine copula approach, which is a branch of the copula family first described by Aas et al. (2007). Chollete et al. (2009) documented that the canonical vine copula provides better portfolio returns and that the choice of copula dependencies affects the VaR of the portfolio return. Chollete et al. (2011) investigated international diversification benefits using the Pearson correlation and six copula functions. Their results show that dependence increases over time and that the intensity of the asymmetric dependence varies in different regions of the world.

While some existing studies have applied copulas to the optimization of portfolio selection, most have tended to focus on portfolio risks, i.e., value at risk, rather than portfolio returns. Empirically, however, investors pay at least equal attention to portfolio returns. Our study is among the few that have focused on equity portfolio returns using time-varying copulas.

8.3 Empirical Methods

8.3.1 Copulas

A copula C is a function that links univariate distribution functions into a multivariate distribution function. Let F be an n-dimensional joint distribution function and let $U = (u_1, u_2, \ldots, u_n)^{\mathrm{T}}$ be a vector of n random variables with marginal distributions $F_1, F_2, \ldots, F_n$. According to Sklar's (1959) theorem, if the marginal distributions $F_1, F_2, \ldots, F_n$ are continuous, then a copula C exists, where C is a multivariate distribution function with all uniform (0,1) marginal distributions.[2] That is,

$$F(u_1, u_2, \ldots, u_n) = C(F_1(u_1), F_2(u_2), \ldots, F_n(u_n)), \text{ for all } u_1, u_2, \ldots, u_n \in \mathbb{R}^n. \quad (8.1)$$

[2]For detailed derivations, please refer to Cherubini et al. (2004), Demarta and McNeil (2005), Embrechts et al. (2003), Embrechts et al. (2005), Franke et al. (2008), Nelson (2006), and Patton (2009).

Table 8.1 The characteristics of different copulas

Dependence model	Tail dependence	Parameter range
Pearson correlation	No	$\rho \in (-1, 1)$
Gaussian copula	No	$\rho \in (-1, 1)$
Student's *t*-copula	Yes (symmetry)	$\rho \in (-1, 1)$, $v > 2$
Gumbel copula	Yes (upper tail)	$\delta \in (0, 1)$
Clayton copula	Yes (lower tail)	$\alpha \in [-1, \infty)\backslash\{0\}$

For a bivariate case, the model can be defined as

$$F(x, y) = C(F_X(\mathrm{x}), F_Y(\mathrm{y})) \tag{8.2}$$

8.3.2 Copula Specifications

In this paper, we consider four copula functions: the Gaussian, Student's *t*, Gumbel, and Clayton. The Gaussian copula focuses on the center of the distribution and assumes no tail dependence. The Student's *t*-copula stresses both the center of the distribution and symmetric tail behaviors. The Clayton copula emphasizes lower-tail dependence, while the Gumbel copula focuses on upper-tail dependence. Table 8.1 summarizes the characteristics of each copula in detail.

8.3.3 Gaussian Copula

The Gaussian copula is frequently seen in the finance literature due to its close relationship to the Pearson correlation. It represents the dependence structure of two normal marginal distributions. According to Nelson (2006), the bivariate Gaussian copula can be expressed as

$$\begin{aligned} C(x, y) &= \int_{-\infty}^{\Phi^{-1}(x)} ds \int_{-\infty}^{\Phi^{-1}(y)} dt \frac{1}{2\pi\sqrt{1-\rho^2}} \exp\left\{-\frac{s^2 - 2\rho st + t^2}{2(1-\rho^2)}\right\} \\ &= \Phi_\rho\left(\Phi^{-1}(x), \Phi^{-1}(y)\right), \end{aligned} \tag{8.3}$$

where Φ denotes the univariate standard normal distribution function and Φ_ρ is the joint distribution function of the bivariate standard normal distribution with correlation coefficient $-1 \le \rho \le 1$. The Gaussian copula has no tail dependence unless $\rho = 1$.

8.3.4 Student's *t*-Copula

Unlike the Gaussian copula, which fails to capture tail behaviors, the Student's *t*-copula depicts the dependence in the center of the distribution as well as in the tails. The Student's *t*-copula is defined using the multivariate t distribution and can be written as

$$C^t_{v,\rho}(x,y) = \int_{-\infty}^{t_v^{-1}(x)}\int_{-\infty}^{t_v^{-1}(y)} \frac{1}{2\pi\sqrt{1-\rho^2}}\left\{1+\frac{s^2-2\rho st+t^2}{v(1-\rho^2)}\right\}^{-\frac{v+2}{2}} dsdt$$
$$= t^2_{v,r}\left(t_v^{-1}(x), t_v^{-1}(y)\right), \tag{8.4}$$

where $t^2_{v,r}$ indicates the bivariate joint t distribution, $t_v{}^{-1}$ is the inverse of the distribution of a univariate t distribution, v is the degrees of freedom, and ρ is the correlation coefficient of the bivariate t distribution when $v > 2$.

8.3.5 Archimedean Copulas

According to Embrechts et al. (2005), the coefficient of upper-tail dependence (λ_u) of two series, X and Y, can be defined as

$$\lambda_u(x,y) = \lim_{q-1^-} P\left[Y > F_y^{\leftarrow}(q) \middle| X > F_x^{\leftarrow}(q)\right]. \tag{8.5}$$

The upper-tail dependence presents the probability that Y exceeds its qth quantile given that X exceeds its qth quantile, considering the limit as q goes to its infinity. If the limit $\lambda_u \in [0,1]$ exists, then X and Y are said to show upper-tail dependence. In the same manner, the coefficient of lower-tail dependence (λ_1) of X and Y is described as

$$\lambda_l(x,y) = \lim_{q-0^+} P\left[Y \le F_y^{\leftarrow}(q) \middle| X \le F_x^{\leftarrow}(q)\right]. \tag{8.6}$$

Since both F_{U_1} and F_{U_2} are continuous density functions, the upper-tail dependence can be presented as

$$\lambda_u = \lim_{q-0^-} \frac{P\left[Y > F_y^{\leftarrow}(q) \middle| X > F_x^{\leftarrow}(q)\right]}{P\left[X > F_x^{\leftarrow}(q)\right]}. \tag{8.7}$$

For lower-tail dependence, it can be described as

$$\lambda_l = \lim_{q-0^+} \frac{P\left[Y \le F_y^{\leftarrow}(q) \middle| X \le F_x^{\leftarrow}(q)\right]}{P\left[X \le F_x^{\leftarrow}(q)\right]}. \tag{8.8}$$

8.3.5.1 Gumbel Copula

The Gumbel copula is a popular upper-tail dependence measure as suggested in Embrechts et al. (2005). The Gumbel copula can be written as

$$\mathrm{c}(x,y) = \exp\left[-\left\{\left(-\ln(\mathrm{x})^{\frac{1}{\delta}} + (-\ln(\mathrm{y})^{\frac{1}{\delta}}\right\}^{\delta}\right], \tag{8.9}$$

where $0 < \delta \leq 1$ measures the degree of dependence between X and Y. When $\delta = 1$, X and Y do not have upper-tail dependence (i.e., X and Y are independent at upper tails), and when $\delta \to 0$, X and Y have perfect dependence.

8.3.5.2 Clayton Copula

The Clayton copula is used to measure lower-tail dependence. The Clayton copula is defined as

$$\mathrm{c}(x, y) = \max\left[(\mathrm{x}^{-\alpha} + \mathrm{y}^{-\alpha} - 1)^{-\frac{1}{\alpha}}, 0\right], \tag{8.10}$$

where α describes the strength of dependence. If $\alpha \to 0$, X and Y do not have lower-tail dependence. If $\alpha \to \infty$, X and Y have perfect dependence.

8.3.6 Portfolio Construction

The selection of optimal portfolios draws on the seminal work of Markowitz (1952). Specifically, we adopt the variance minimization strategy with no short selling and transaction cost assumptions.[3] An optimal portfolio allocation can be found by solving the following optimization problem:

$$\mathrm{Min}_{\{w\}} w' V w$$

$$\text{Subject to} \sum \mathrm{w_i} = 1, \mathrm{w}_i \geq 0, \tag{8.11}$$

where w_i is the weight of asset i, and V is the covariance matrix of asset returns.

Because dependence is a time-varying parameter, the data from a subset of 250 trading days prior to the given sample date t is used to derive the dependence for date t. With 1,780 daily data points in our sample, we calculate a total of 1,531 dependencies for each copula method and the Pearson correlation. With these dependencies, optimal portfolio weightings can be obtained by solving a quadratic function subject to specified constraints. The optimal weightings for time t are used to calculate the realized portfolio returns for $(t + 1)$.[4]

In practice, portfolio managers periodically reexamine and update the optimal weights of their portfolios. If the asset allocation of an existing portfolio has deviated from the target allocation to a certain degree and if the benefit of updating exceeds its costs, a portfolio reconstruction action is executed. In this paper, we construct a comprehensive study of portfolio returns by varying the state of

[3]Short selling usually involves other service fees, which vary depending on the creditability of the investors. Because the focus of this study is on the effect of the dependence structure on portfolio performance, we assume that short selling is not allowed to simplify the comparison.

[4]For example, we use return data from t_1 to t_{250} to calculate the optimal portfolio weights with dependencies estimated from the copulas and the Pearson correlation. The optimal portfolio weights are applied to the return data at t_{251} to calculate the realized portfolio returns.

Table 8.2 The summary statistics of the G7 indices

	Canada	France	Germany	Italy	Japan	UK	USA
Mean (%)	0.0301	0.0064	0.0082	0.0003	−0.0017	−0.0039	−0.0082
Std. dev.	0.0164	0.0171	0.0178	0.0161	0.0155	0.0159	0.0144
Skewness	−0.8781	0.0740	0.0666	0.0477	−0.1475	−0.0535	−0.1365
Kurtosis	14.1774	10.7576	8.6920	12.9310	7.4592	12.9143	12.1182
Jarque-Bera	9494	4465	2404	7315	1481	7290	6171
JB P-value	0.0000	0.0000	0.0000	0.0000	0.0000	0.0000	0.0000
Observations	1780	1780	1780	1780	1780	1780	1780

The results indicate that the daily returns of the G7 indices are not normally distributed

the economy (i.e., expansion or recession), the dependence structure, and the frequency of weight updating, i.e., quarterly, monthly, and daily. Quarterly updating allows investors to update the optimal weights on the first trading days of March, June, September, and December; monthly updating allows investors to update the optimal weights on the first trading days of each month. Under daily updating, investors update the optimal weights every trading day.

8.4 Data

The data are the US dollar-denominated daily returns of the Morgan Stanley Capital International (MSCI) indices for the G7 countries, including Canada, France, Germany, Italy, Japan, the UK, and the USA. The sample period covers from the first business day in June 2002 to the last business day in June 2009, for a total of 1,780 daily observations. Based on the definitions provided by the National Bureau of Economic Research, we separate the data into an expansion period from June 2002 to November 2007 and a recession period from December 2007 to June 2009.

Table 8.2 presents the descriptive statistics. Among the G7 countries, Canada had the highest daily returns, while the USA had the lowest. Germany, however, experienced the most volatile returns. All return series exhibit high kurtosis, suggesting fat tails on return distributions. The results of the Jarque-Bera test reject the assumption that the G7 indices have normal distributions.

8.5 Empirical Results

8.5.1 Dependence

Using 1,780 daily data points from the G7 countries, for each dependence model, we estimate 21 dependence pairs, each containing a sequence of 1,531 dependencies. The parameters for the Gaussian, Student's *t*, Gumbel, and Clayton copula functions are estimated using the two-stage *inference for the margins* (IFM) method proposed by Joe and Xu (1996) and Joe (1997).

The dependencies from the Pearson correlation are calculated using the standard method. Appendix 1 shows the maximum and the minimum of the 21 dependence pairs of each dependence model.

The graphs in Fig. 8.1 show the dependencies between the USA and other countries as estimated via the various copulas and the Pearson correlation. In general, the Gaussian copula estimation is similar to that of the corresponding Pearson correlation, but the Student's *t*-copulas show significant jumps over time. For our sample period, Japan shows a low dependence with the US market as compared to other economies.

8.5.2 Average Portfolio Returns

Table 8.3 presents the average portfolio returns for the full sample period, the expansion period, and the recession period for the quarterly, monthly, and daily weight updating strategies. Under the quarterly weight updating, the Clayton-dependence portfolios have the highest average returns at 6.07 % in the expansions and −12.52 % in the recessions, and the Pearson-correlation portfolios have the lowest average returns, 5.48 % in the expansions and −14.25 % in the recessions. The order of portfolio performance, in the form of its dependence model regardless of the state of economy, is as follows: the Clayton copula, the Gumbel copula, the Student's *t*-copula, the Gaussian copula, and the Pearson correlation. Because both the Clayton and Gumbel copulas highlight the tail dependence between assets, the empirical evidence suggests that with a quarterly weighting strategy, tail dependence, particularly lower-tail dependence, is important for obtaining superior average portfolio returns across different states of the economy.

As we increase the updating frequency from quarterly to monthly, similar empirical results are observed. That is, the Clayton-copula portfolios yield the highest average returns, while the Pearson-correlation portfolios provide the lowest average returns. In the expansion periods, the order of portfolio performance, in the form of its dependence model, is as follows: the Clayton copula, the Student's *t*-copula, the Gaussian copula, the Gumbel copula, and the Pearson correlation. In recession periods, the order of portfolio performance, in the form of its dependence model, is as follows: the Clayton copula, the Gumbel copula, the Student's *t*- copula, the Gaussian copula, and the Pearson correlation. According to Kole et al. (2007), the Gaussian copula, which does not consider lower-tail dependence, tends to be overly optimistic on the portfolio's diversification benefits, and the Gumbel copula, which focuses on the upper tail and pays no attention to the center of the distribution, tends to be overly pessimistic on the portfolio's diversification benefits. We verify this argument by observing that the Gumbel-copula portfolio outperforms only the Pearson-correlation portfolio in the expansion periods, while the Gaussian-copula-dependence portfolio outperforms the Pearson-correlation portfolio only in recession periods. Interestingly, as we increase the weight updating frequency from quarterly to monthly, the average portfolio returns for the full sample and recession periods also

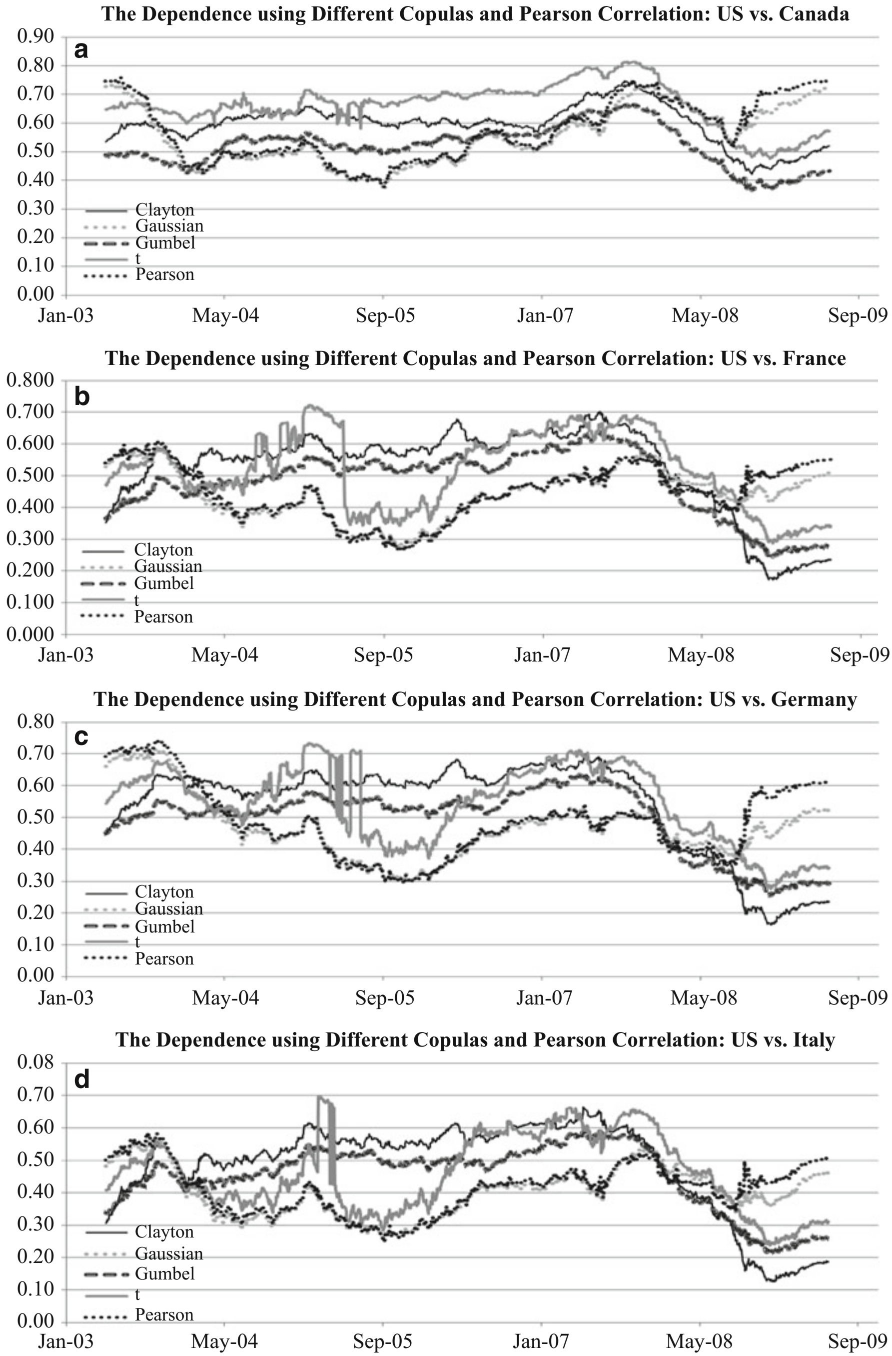

Fig. 8.1 (continued)

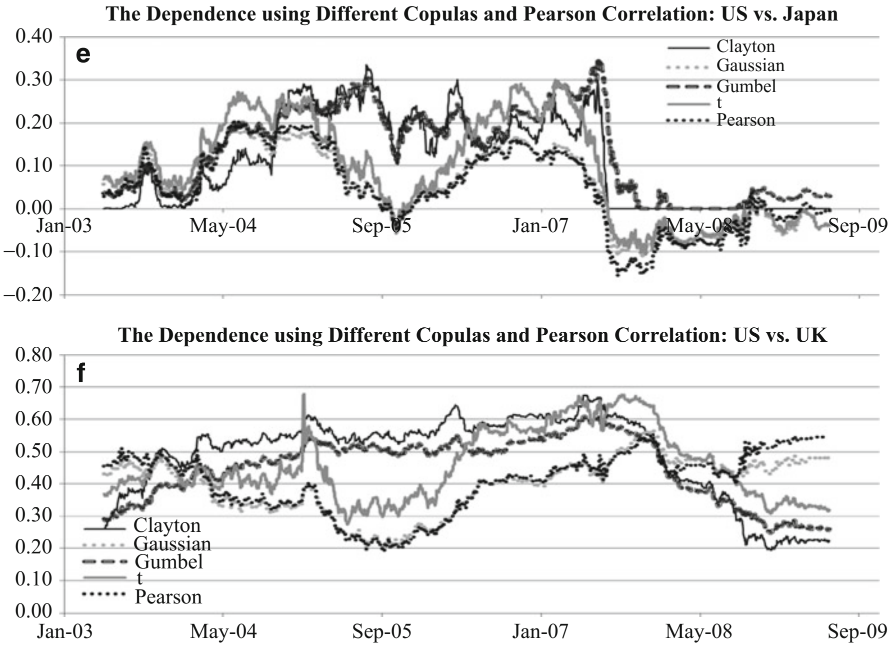

Fig. 8.1 The dependence using different copulas and Pearson correlation. Panel (**a**) USA versus Canada. Panel (**b**) USA versus France. Panel (**c**) USA versus Germany. Panel (**d**) USA versus Italy. Panel (**e**) USA versus Japan. Panel (**f**) USA versus UK

increase, regardless of the choice of dependence measures. Thus, the empirical results seem to support the need for active portfolio reconstruction during recessions.

As the weight updating frequency increases to daily, the Clayton copula delivers only the highest average portfolio returns during the expansion period. The Student's *t*-copula, by contrast, generates the highest portfolio average returns for the full sample and recession periods. The influence of the lower-tail dependence seems to diminish under daily weight reconstruction. The Gaussian-copula portfolio delivers the worst portfolio performance in both expansion and recession periods.

8.5.3 Testing Significance of Return Difference

The results reported in the previous section show the average portfolio returns for different dependencies and weight updating frequencies. One issue with average returns is that if extreme values exist over the examined period, the empirical results may be biased and relatively high-standard deviations will be reported. Previous methods of examining the robustness of portfolio performance usually build on the data normality assumption (Jobson and Korkie 1981; Memmel 2003), which goes against the empirical facts.

Table 8.3 Average portfolio returns

	Clayton	Gaussian	Gumbel	Student's t	Pearson
Panel A: quarterly adjustments					
Full sample returns	1.44 %	0.91 %	1.16 %	1.11 %	0.57 %

	(2.0375)	(2.0355)	(2.0474)	(2.0247)	(1.1708)
Panel C: daily adjustments					
Full sample returns	1.34 %	0.85 %	1.16 %	1.47 %	1.03 %
	(1.1737)	(1.1651)	(1.1749)	(1.1733)	(1.0253)
Expansion returns	5.84 %	5.35 %	5.59 %	5.70 %	5.39 %
	(0.6733)	(0.6859)	(0.6839)	(0.6766)	(0.6367)
Recession returns	−12.27 %	−12.74 %	−12.22 %	−11.34 %	−12.14 %
	(2.0382)	(2.0053)	(2.0277)	(2.0346)	(1.7280)

The average portfolio returns are presented in an annualized, percentage format. Three weight updating frequencies are considered: quarterly, monthly, and daily. Within each frequency, we report the returns for the full sample period, the expansion period, and the recession period. The numbers in the parentheses are standard errors

To cope with this problem, Ledoit and Wolf (2008) proposed an alternative testing method using the inferential studentized time-series bootstrap. Ledoit and Wolf's (2008) method is as follows.[5] Let a and b be two investment strategies, and let r_{at} and r_{bt} be the portfolio returns for strategies a and b, respectively, at time t, where t ranges from 1 to i. The mean vector μ and the covariance matrix Σ for the return pairs $(r_{a1},r_{b1})',\ldots,(r_{at},r_{bt})'$ are denoted by

$$\mu = \begin{pmatrix} \mu_a \\ \mu_b \end{pmatrix} \text{ and } \sum = \begin{pmatrix} \sigma_a^2 & \sigma_{ab} \\ \sigma_{ab} & \sigma_b^2 \end{pmatrix}. \tag{8.12}$$

The performance of strategies a and b can be examined by checking whether the difference between the Sharpe ratios for strategies a and b are statistically different from 0. That is,

$$\Delta = S_a - S_b = \frac{\mu_a}{\sigma_a} - \frac{\mu_b}{\sigma_b} \tag{8.13}$$

[5]For detailed derivations and computer codes, please refer to Ledoit and Wolf (2008).

and

$$\hat{\Delta} = \widehat{S_a} - \widehat{S_b} = \frac{\widehat{\mu_a}}{\widehat{\sigma_a}} - \frac{\widehat{\mu_b}}{\widehat{\sigma_b}}, \tag{8.14}$$

where Δ is the difference between the two Sharpe ratios, and S_a and S_b are the Sharpe ratios for strategies a and b, respectively.

Let the second moments of the returns from strategies a and b be denoted by γ_a and γ_b. Then $\gamma_a = E({\gamma_{at}}^2)$ and $\gamma_b = E({\gamma_{bt}}^2)$. Let υ and $\hat{\upsilon}$ be $(\mu_a, \mu_b, \gamma_a, \gamma_b)$' and $(\hat{\mu_a}, \hat{\mu_b}, \hat{\gamma_a}, \hat{\gamma_a})'$, respectively. Then Δ and $\hat{\Delta}$ can be expressed as

$$\Delta = f(\upsilon) \text{ and } \hat{\Delta} = f(\hat{\upsilon}) \tag{8.15}$$

where $f(\upsilon) = \frac{\mu_a}{\sqrt{\gamma_a - \mu_a^2}} - \frac{\mu_b}{\sqrt{\gamma_b - \mu_b^2}}$ and $\sqrt{i}(\hat{\upsilon} - \upsilon) \xrightarrow{d} N(0; \Psi)$.

For time-series data, Ledoit and Wolf (2008) have argued that Ψ can be evaluated by the studentized bootstrap as $\widehat{\Psi}^* = \frac{1}{\vartheta}\sum_{j=1}^{\vartheta} \xi_j \xi'_j$, where $\xi_j = \frac{1}{\sqrt{b}}\sum_{t=1}^{b} y^*_{(j-1)b+t}\, t = 1, \ldots, \vartheta. \vartheta$ is the integer part of the fraction of the total observations divided by the blocks b. Also,

$$y_t^* = \left(r_{ta}^* - \hat{\mu}_a^*, r_{tb}^* - \hat{\mu}_b^*, r_{ta}^{*2} - \hat{\gamma}_a^*, r_{tb}^{*2} - \hat{\gamma}_b^*\right) t = 1, \ldots, i. \tag{8.16}$$

Following Ledoit and Wolf's (2008) method, we examine the significance of 60 pairs of portfolio performance. The size of the bootstrap iteration is 10,000 to ensure a sufficient sample.[6] Table 8.4 presents the results from Ledoit and Wolf's (2008) portfolio performance test.

The results indicate that during the recession periods and using quarterly weight updating, the Pearson correlation underperforms all the copula dependencies at a confidence level of 90 % or greater. During recession periods and adopting monthly weight updating, the superiority of the copula dependencies jumps to a 99 % confidence level. Moreover, during the recession periods and assuming daily updating, the Student's t-copula outperforms the Pearson correlation at the 99 % confidence level.

Overall, Ledoit and Wolf's (2008) empirical tests illustrate the superiority of copulas during recession periods, regardless of the frequency of weight updating. During a bullish market, this advantage seems not as statistically significant as during a bearish market.

[6]Ledoit and Wolf (2008) suggested that 5,000 iterations guarantee a sufficient sample. We adopt a higher standard of 10,000 iterations to strengthen our testing results.

Table 8.4 Ledoit and Wolf portfolio performance test

Panel A: quarterly adjustments					
	CL-GA	CL-GU	CL-PE	CL-t	GA-GU

The performance tests are conducted using the approach suggested by Ledoit and Wolf (2008). The tests examine whether the returns from two portfolios are significantly different at the 95 % level

CL stands for the Clayton copula, *GA* stands for the Gaussian copula, *GU* stands for the gumbel copula, *PE* stands for Pearson correlation, and *t* stands for the Student's *t*-copula

[a]Represents 90 % statistical significance

[b]Represents 95 % statistical significance

[c]Represents 99 % statistical significance

8.6 Conclusions

In this paper, we study whether adopting time-varying copulas as a measure of dependence of asset returns can improve portfolio performance. This study was motivated by the fact that the traditional Pearson correlation is inadequate in describing most financial returns. Moreover, the robustness of copula functions has not been fully examined under different states of the economy and weight updating scenarios. We evaluate the effectiveness of various copulas in managing portfolios while considering portfolio rebalance frequencies and the business cycle. The significance of return difference is tested using the studentized time-series bootstrap method suggested by Ledoit and Wolf (2008).

The main findings are as follows: first, an international equity portfolio modeled using the Pearson correlations underperforms those modeled using copula-based dependencies, especially during recession periods. Our findings remain robust regardless of the rebalancing frequency. Second, the importance of lower-tail behaviors in portfolio modeling is highlighted by the higher average portfolio returns of the Clayton-dependence portfolios. Third, the choice of weight updating frequency affects portfolio returns. The portfolios using monthly weight updating frequency provide better portfolio returns than those using quarterly and daily weight adjustments.

We add to the current literature by thoroughly evaluating the effectiveness of asymmetric conditional correlations in managing portfolio risk. This paper synthesizes the major concepts and modi operandi of previous research and maximizes the practicality of applying copulas under a variety of scenarios. Future research into copulas can be extended to the contagion of various asset classes and interest rates and evaluations of the impact of certain economic events.

Appendix 1

Appendix 1 illustrates the dependence of the G7 countries from different dependence models. Note that to ease the comparison between dependencies, we transform Gumbel dependencies by $(1 - \delta)$. Therefore, the range for the Clayton and the Gumbel copulas is between 0 and 1, with 0 meaning no dependence and 1 standing for perfect dependence. The range for the Gaussian copula, the Student's t-copula, and the Pearson correlation is -1 to 1, with 0 meaning no dependence and 1 or -1 standing for complete dependence.

Abstract

Individual investors are actively involved in stock market and are making investment decision based on publicly available and nonproprietary information, such as corporate earnings forecasts from the management and the financial analyst. Also, the management forecast is another important index investors might use.

To examine the accuracy of the earnings forecasts, the following test methodology have been conducted. **Multiple regression models** are used to examine the effect of six factors: firm size, market volatility, trading volume turnover, corporate earnings variances, type of industry, and experience. If the two-sample groups are related, **Wilcoxon two-sample test** will be used to determine the relative earnings forecast accuracy.

The results indicate that firm size has no effect on management forecast, voluntary management forecast, mandatory management forecast, and analysts' forecast. There are some indications that forecasting accuracy is affected by market ups and downs. The results also reveal that relative accuracy of earnings forecasts is not a function of trading volume turnover. However, management's earnings forecast and analysts' forecasts are sensitive to earnings variances.

Readers are well advised and referred to the chapter appendix for methodological issues such as sample selection, variable definition, regression model, and Wilcoxon two-sample test.

Keywords

Multiple regression • Wilcoxon two-sample test • Corporate earnings • Forecast accuracy • Management earnings • Firm size • Corporation regulation • Volatility • Trade turnover • Industry

9.1 Introduction

In recent times, individual investors are actively involved in stock market and are making investment decision based on publicly available and nonproprietary information. Corporate earnings forecasts are an important investment tool for investors. Corporate earnings forecasts come from two sources: the company management and financial analyst. As an insider, the management has the advantage of possessing more information and hence provides a more accurate earnings forecast. However, because of the existing relationship of the company with its key investor group, the management may have a tendency to take an optimistic view and overestimate its future earnings. In contrast, the financial analysts are less informed about the company and often rely on management briefings. They have more experiences in the overall market and economies and are expected to analyze companies objectively. Hence, analysts should provide reliable and more accurate earnings forecast.

Whether investors should rely on the earnings forecast made by the management or by the analyst is a debatable issue. Many researchers have examined the accuracy of such earnings forecasts. Because there are differences in methodologies, sample selections and time horizons, the findings and conclusions from the previous studies are conflicting and inconclusive. This motivated us to do a new analysis by using a different methodology.

According to *Regulations for Publishing Corporate Earnings Forecast* imposed by the Department of Treasury,[1] publicly traded Taiwanese companies have to publish their earnings forecasts under the following situations:

1. To issue new stocks or acquired liabilities;
2. When more than one third of the board has been changed;
3. When one of the situations as listed in section 185 of the corporation regulations happens;
4. Merger and acquisitions;
5. Profit gain/loss up to one third of its annual revenue due to an unexpected event;
6. Revenue loss over 30 % compared to last year;
7. Voluntarily publish its earnings forecast

Since management earnings forecasts are mandatory or voluntary, the focus of this research is to examine the accuracy of management's overall earnings forecast, management voluntary earnings forecast, management mandatory earnings forecast, and financial analyst earnings forecast.

9.2 Literature Review

Jaggi (1980) examined the impact of company size on forecast accuracy using management's earnings forecasts from the Wall Street Journal and analysts' earnings forecasts from Value Line Investment Service from 1971 to 1974. He argued that because a larger company has strong financial and human capital resources, its management's earnings forecast would be more accurate than the analyst's. The sample data were classified into six categories based on the size of the firms' total revenue to examine the factors that attribute to the accuracy of management's earnings forecast with the analyst's. The result of his research did not support his hypothesis that management's forecast is more accurate than the analyst's.

Bhushan (1989) assumed that it is more profitable trading large companies' stocks because large companies have better liquidity than the small ones. Therefore, the availability of information is related to company size. His research results support his hypothesis that the larger the company size, the more information is available to financial analysts and the more accurate their earnings forecasts are. Kross and Schreoder (1990) proposed that brokerage firm's characteristics influence analysts' earnings forecasting accuracy. In their analysis, sample analysts'

[1]Securities Regulation Committee, Department of Treasury, series 00588, volume #6, 1997

earnings forecasts from 1980 to 1981 were obtained from Value Line Investment, and the market value of a firm is used as the size of the firm. The results of this study on analysts' earnings forecasts did not find a positive relation between the company size and the analyst's forecast accuracy. Xu (1990) used the data range from 1986 to 1990 and the logarithm of average total revenue as a proxy of company earnings and examined factors associated with the accuracy of analysts' earnings forecast. The hypothesis that the larger the firm size is, the more accurate the analysts' earnings forecast would be was supported.

Su (1996) focuses on comparison of relative accuracy of management and analysts' earnings forecasts by using cross-sectional design method. Samples selection includes forecast data during the time period from 1991 to 1994. The company's "book value" of its total assets is used as a proxy for the size of the company in the regression analysis. The author believes that analysts are more attracted to larger companies, and there are more incentives for them to follow large companies than small companies in their forecasting. Therefore, the size of a company will affect the relative accuracy of analyst earnings forecast. On the other hand, large companies possess excessive human and financial resources and information which analysts have no access to, to allow managers to anticipate the corporate future earnings with high accuracy. The study results show that analyst and voluntary earnings forecast accuracy for larger companies are higher than forecast accuracy for small companies.

Yie (1996) examines the factors influencing management and financial analyst earnings forecasting accuracy. Data used in this study are the earnings forecasts during the years 1991–1995. She uses the company's total assets and market value of the company's equity as proxies for company size. The finding of this research reveals that the relative earnings forecast accuracy (management, voluntary management, mandatory management, and analyst) is not affected by the size of the company when the company's total assets are used as the proxy of company size. The result also indicates that mandatory management's earnings forecast and analysts' earnings forecasts are influenced by company size if market value of company's equity is used.

Xu (1990) examines the relative accuracy of analysts' earnings forecasts, a hypothesis that market volatility is one of factors that influence the relative accuracy of analyst earnings forecast. In upmarket situation, a vast amount of information regarding corporate earnings and overwhelming trading activities may hinder the analyst from getting realistic and objective information; thus, overoptimistic forecast might be a result. In contrast, when market is experiencing a downturn, individual investors are less speculative and more rational; thus, information about corporate earnings tends to be more accurate. Under these circumstances, the analyst tends to provide earnings forecasts with a higher level of accuracy. The results of this study support the author's hypothesis. Jiang (1993) examines the relative accuracy between management's earnings forecast and analyst earnings forecast. He hypothesizes that analysts' earnings forecast has a higher degree of accuracy in down market compared to upmarket situation. He uses samples forecast data from years 1991 to 1993 in his analysis and finds that the result of this research supports his argument.

Das et al. (1998) used a cross-sectional approach to study the optimistic behavior of financial analysts. Especially, they focused on the predicative accuracy of past information analysts' earnings forecast associated with magnetite of the bias in analysts' earnings forecasts. The sample selection covers the time period from 1989 to 1993 with 274 companies' earnings forecasts information. A regression method was used in this research. The term "optimistic behavior" is referred to as the optimistic earnings forecasts made by financial analysts. The authors hypothesize the following scenario: there is higher demand for nonpublic information for firms whose earnings are more difficult to predict than for firms whose earnings can be accurately forecasted using public information. Their finding supports the hypothesis that analysts will make more optimistic forecasts for low-predictability firms with an assumption that optimistic forecast facilitates access to management's nonpublic information. Clement (1999) studies the relation between the quality and forecast accuracy of analysts' reports. It also identifies systematic and time persistence in analysts' earnings forecast accuracy and examines the factors associated with degree of accuracy. Using the I/B/E/S database, the author has found that earnings forecast accuracy is positively related with analysts' experience (a surrogate for analyst ability and skill) and employer size (a surrogate for resources available) and inversely related with the number of firms and industries followed by the analyst. The sample selection covers the time horizon from 1983 to 1994 with earnings forecasts of 9,500 companies and 7,500 analysts. The author believes that as the analyst's experience increases, his earnings forecast accuracy will increase, which implies that the analyst has a better understanding of the idiosyncrasies of a particular firm's reporting practices or he might establish a better relationship with insiders and therefore gain better access to the managers' private information. An analyst's portfolio complexity is also believed to have association with his earnings forecast accuracy. He hypothesizes that forecast accuracy would decrease with the number of industries/firms followed. The effect of available resources impacts analyst's earnings forecast in such a way that analysts employed by a larger broker firm supply more accurate forecasts than smaller ones. The rationale behind this hypothesis is that the analyst hired by a large brokerage firm has better access to the private information of managers at the companies he follows. Large firms have more advanced networks that allow the firms to better disseminate their analyst's recommendations into the capital markets. The results of this research support the hypothesis made by the author.

Xiu (1992) studies the relative accuracy of management and analysts' earnings forecasts using Taiwan database covering the period 1986–1990. The management and analyst's earnings forecasts used in the study are from Business News, Finance News, Central News Paper, and The United Newspaper. The research methodology is to examine management's earnings forecast accuracy with prior and posterior analyst's earnings forecasts. The result reveals that a management's forecast is superior to prior analyst's forecast, but less accurate than posterior analyst's earnings forecasts.

Jiang (1993) examined the determinants associated with analysts' earnings forecast and management and analyst's earnings accuracy under different assumptions. A sample of Taiwan corporations is collected from the Four Seasons newspaper. Jiang uses cross-sectional regression analysis to investigate the relations between the forecast accuracy and firm's size, rate of earnings deviation, forecasting time horizon, market situation, and rate of annual trading volume turnover. His results show that earnings forecasts provided by analysts are more accurate than management earnings forecasts. Chia (1994) focuses a study on mandatory management earnings forecasts and the rate of trading volume turnover in an unpublished thesis.

9.3 Testable Hypotheses

9.3.1 Firm Size

The size of a firm is believed to have influence on the accuracy of analyst's and management's earnings forecast. Jaggi (1980), Bhushan (1989), and Clement (1999) found that the larger the company is, the more accurate the earnings forecast will be. They believe that holding other factors constant, larger companies have more financial and human resources available that allow the management to draw more precise earnings forecast than smaller companies. Thus, forecasts and recommendations supplied by larger firms are more valuable and accurate than the smaller firms:

H1: The accuracy of management's earnings forecast increases with the size of the firm.

H2: The accuracy of management's voluntary earnings forecast increases with the size of the firm.

H3: The accuracy of management's mandatory earnings forecast increases with the size of the firm.

H4: The accuracy of analysts' earnings forecast increases with the size of the firm.

9.3.2 Volatility of Market

The accuracy of earnings forecast will be affected by market situation. When market is very volatile and unstable, investors who are looking for the opportunities to profit will act more, speculative about what would be the next for the market. In this situation, it is more difficult for analysts to figure out the real useful information for their forecasts; they might have a tendency to overoptimistically forecast the earnings and provide recommendations. When a market is in a relative stable period, investors tend to be rational about the next movement of the market; there is less biased information regarding corporate earnings among the general investors; thus, the information accessed by analysts will allow them to be more objective in the earnings forecast. In contrast, the management has the insights on what is really happening in the aspects of operation, finance, top management changes, and profitability of the business. Even if they are less vulnerable regardless of what the market situation is, voluntary management's earnings forecast might be affected by market volatility to some extent:

H5: Management's earnings forecast will not be affected by volatility of market.

H6: Voluntary management's earnings forecast is a function of the of market volatility.

H7: Mandatory management's earnings forecast is not affected by market volatility.

H8: Accuracy of analysts' earnings forecast is affected by market volatility.

9.3.3 Volume Turnover

The relationship between trading volume turnover and accuracy of earnings forecast can be examined based on the hypothesis that daily stock trading volume represents the public investors' perception about a company. Larger trading volume during a day for a particulate stock reflects a higher degree of divergence on confidence about the company's stock, and vice versa. This public perception on a stock might distract management's and analysts' judgment; they need more time and strive extra efforts in order to prove accurate earnings forecasts:

H9: Trading volume turnover affects the accuracy of management's earnings forecast.

H10: Trading volume turnover affects the accuracy of voluntary management's earnings forecast.

H11: Trading volume turnover affects the accuracy of mandatory management's earnings forecast.

H12: Trading volume turnover affects the accuracy of analysts' earnings forecast.

9.3.4 Corporate Earnings Variance

Corporate earnings surprises are an important aspect of analysts' earnings forecast. The larger the earnings surprise is, the less useful the past information will be in earnings forecasting and the harder it is to make accurate forecasts. Corporate earnings variances represent the earnings surprises a company has in the past; it would affect the accuracy of management and analysts' earnings forecasts:

H13: Corporate earnings variances affect the accuracy of management's earnings forecast.

H14: Corporate earnings variances affect the accuracy of voluntary management's earnings forecast.

H15: Corporate earnings variances affect the accuracy of mandatory management's earnings forecast.
H16: Corporate earnings variances affect the accuracy of analysts' earnings forecast.

9.3.5 Type of Industry

There may exist a relationship between the type of industry and earnings forecast accuracy. They hypothesize that the difference between different industries may result in different levels of accuracy on earnings forecast. Some analysts may not possess adequate knowledge necessary in the forecasting in a particular industry; therefore, their forecast may not be as accurate as management's earnings forecast. Hence, the following hypotheses can be tested:
H17: Type of industries influences the accuracy of management's earnings forecast.
H18: Type of industries affects the accuracy of voluntary management's earnings forecast.
H19: Type of industries affects the accuracy of mandatory management's earnings forecast.
H20: Type of industries affects the accuracy of analysts' earnings forecast.

9.3.6 Forecasting Experience

Analysts' accuracy of earnings forecast will improve as their experience and knowledge about companies increase. They learn from their previous forecasts and make the next forecast more accurate. A similar argument can be made about the management's earnings forecast. Hence, the following hypotheses can be tested:
H21: Forecasting experience influences the accuracy of management's earnings forecast.
H22: Forecasting experience affects the accuracy of voluntary management's earnings forecast.
H23: Forecasting experience affects the accuracy of mandatory management's earnings forecast.
H24: Forecasting experience affects the accuracy of analysts' earnings forecast.

9.4 Empirical Results

9.4.1 Comparison of Management and Analyst's Earnings Forecast

To compare the relative accuracy of management and analysts' earnings forecasts, we focus on four major aspects regarding the relative accuracy of earnings forecasts. First, management versus analysts' earnings forecasts is made to compare the relative accuracy of the forecasts. Secondly, a comparison is made between voluntary management's forecasts and analysts' forecasts. Thirdly, mandatory management's forecasts are compared with analysts' forecasts to determine the relative accuracy of the forecasts. Finally, tests of hypothesis have been made to further prove the relative accuracy of management and analysts' earnings forecasts.

Table 9.1 provides descriptive statistics of management and financial analysts' earnings forecasts based from 1987 to 1999. It can be observed that absolute errors of management earnings forecasts are less than the analyst's in the years 1992, 1993, 1995, 1996, 1997, and 1997. It indicates that management's earnings forecasts are superior to analysts during that time period. But, in other time periods, the absolute errors for management's earnings forecast are higher than analysts', indicating analysts provide higher forecast productions. Overall, it is less obvious to conclude who has higher predicate ability for providing more precise earnings forecast.

The last three rows of Table 9.1 list the mean absolute errors of earnings forecasts by management and analysts during three different time periods. From 1988 to 1992, management's forecast absolute mean error is 1.796, whereas analyst's earnings forecast absolute mean error is 1.503. From 1993 to 1999, management's earnings forecast absolute mean error is 2.031, while analysts' forecast absolute mean error shows higher value of 2.236. If we look at the entire time period from 1987 to 1999, the absolute mean error for management's forecast is less than the absolute mean error for analysts' earnings forecast, which is 1.969 and 2.043 respectively. A conclusion can be drawn from the above results that management's earnings forecasts are more accurate than analysts' forecasts from the early 1990s, but less accurate during the late 1980s.

Table 9.2 shows the results of the Wilcoxon signed-rank test used to test the relative accuracy of managements' forecast and analysts' forecast. Comparing the negative ranks and positive ranks in Table 9.2, management's forecasts are less accurate than analysts' forecasts in the years 1987, 1988, 1989, 1990, and 1999, but more accurate in the years 1995 and 1998. There is no significant difference in the absolute errors between management's forecasts and analysts' forecasts.

If we examine the z-values of the test for the entire time period (1986–1999), the z-value for Wilcoxon signed-rank test is −0.346, which is not significant enough to tell the difference between the two samples. This supports the hypothesis H1 that there are no significant differences between management's forecast accuracy and analysts' forecast accuracy. This also agrees with the findings suggested by Imhoff and Pare (1982) and Baretley and Cameron (1991). They believe the reason for that is due to the similar abilities of forecasters and comparable networks to access company information (public/private) between management and analysts; it is possible that both can provide relative accurate earnings forecasts.

If the entire time period is divided into two subsamples, one is from 1987 to 1992 and the other is from 1993 to 1999, the latter subsample shows a significant level of 0.05 with a z-value of −2.138, which indicates that management's forecasts are less reliable than analysts' forecasts. For the former subsample, it shows no contradiction with the results by Imhoff and Pare (1982) and Baretley and Cameron (1991).

Negative ranks: absolute error of management's earnings forecast < absolute error of analyst earnings forecast
Positive ranks: absolute error of management's earnings forecast > absolute error of analyst earnings forecast
Tie: absolute error of management's earnings forecast = absolute error of analyst earnings forecast
*Significant level = 0.1, ** significant level = 0.05, *** significant level = 0.01

9.4.2 Factors Influencing the Absolute Errors of Earnings Forecast

9.4.2.1 Firm Size

We argue that the management possesses the relative advantage of having private insights that the analyst cannot access, and that a larger company has stronger human and financial resources. Therefore, the management forecasts of corporate earnings are much more precise. On the other hand, a larger company tends to draw attentions and is more likely to attract and be followed by financial analysts; analysts' forecasts can be objective and accurate as well; however, the results from our research do not support this argument. Table 9.4 shows that the p-value of t-parameter for the size of a company (0.478) does not reach a significant level, indicating the size of a company is not associated with the accuracy of management's earnings forecast. This result does not support the hypothesis H1: management's earnings forecast accuracy increases with the size of company. Tables 9.5 and 9.6 show results of the regression analysis for two subsamples representing the time period of 1987–1992 and 1993–1999 to investigate the relationship between company size and accuracy of management's earnings forecast.

Table 9.3 Taiwan stock market volatility from 1987 to 1999

Year	Rm (%)	R_f (%)	$R_m - R_f$ (%)	Market volatility
1999	27	4	23	Upmarket
1998	−13	6	−19	Down market
1997	14	5	9	Upmarket

1988	124	4	120	Upmarket
1987	138	4	134	Upmarket

Market volatility measure, Rm, suggested by Pettengill et al. (1995), is the last month's market return minus the first month's market return divided by the first month's market return in a given year. R_f is the risk-free rate

9.4.2.2 Volatility of Market

In Table 9.4, the p-value of t-parameter in column 4 for the *volatility of market* of a company (0.075) does not reach a significant level, which implicates the accuracy of management's earnings forecast is not positively associated with the volatility of market. This result supports the hypothesis H1: management's earnings forecast accuracy will not change with market volatility. Further examining the two sub-tables of Tables 9.4, 9.5, and 9.6, p-value of parameter for the volatility of market of a company (0.310) indicates that management's earnings forecast accuracy will not change with market volatility during 1987–1999. But the t-parameter for the volatility of market is −2.569, indicating the management can provide accurate forecast during upmarket, but less accurate forecast during down market.

9.4.2.3 Trading Volume Turnover

The p-values of t-parameter in column 4 for the trading volume turnover of a company in all three tables do not reach a significant level. The regression analysis does not support the hypothesis H8 that trading volume turnover will affect management earnings forecast accuracy.

9.4.2.4 Corporate Earnings Variances

In Table 9.4, the p-values of t-parameter (2.74) in column 4 for the rate of earnings divination of a company is 0.01, which shows corporate earnings variances affect management's earnings forecast accuracy. Positive value of t-parameter means management earnings forecast accuracy decreases as corporate earnings variance

increases. This supports the hypothesis H12 that corporate earnings variance has an effect on management earnings forecast accuracy. From the examination for Tables 9.5 (1993–1999) and 9.6 (1987–1992), management earnings forecast accuracy is affected by corporate earnings variances during the recent years (1993–1999).

9.4.2.5 Type of Industry

To determine whether and which industry will influence the forecast accuracy, 18 industries are selected and represented by a dummy variable I_j. From Table 9.4, I_8 is the only industry that has a significant level for the p-values of t-parameter of 14.73. According to our assumption, I_8 represents the chemical industry. Thus, we conclude that management's forecasts are reliable for most of the industries studied in this research, except for the chemical industry.

9.4.2.6 Forecasting Experience

The results of regression analyses for investigating the relationship of forecasting experience and management's earnings forecast accuracy are shown in Tables 9.4, 9.5, and 9.6. All three p-values of t-parameter in column 4 for forecasting experience indicate that management earnings forecast accuracy is not affected by previous forecasting experiences. This conclusion does not support the hypothesis H20 that forecasting experiences affect management's forecast accuracy. Test of other hypotheses indicates similar results.

9.5 Conclusions

The results of our research indicate that company size has no effect on any of the following: management forecast, voluntary management forecast, mandatory

Table 9.6 Regression model for the absolute errors of management earnings forecasts dating from 1978 to 1992

management forecast, and analysts' forecast. This result agrees with Jaggi (1980) and Kross and Schreoder (1990) that analyst's earnings forecast accuracy is not related with the size of company, but differs from the results suggested by Bhushan (1989), Das et al. (1998), Clement (1999), Xu (1990), and Jiang (1993) that company size does influence the relative precision of management or analysts' earnings forecasts.

It can be seen that the relative accuracy of management's earnings forecast and analyst's earnings forecast is not affected by market situation across the entire range of sampled forecasts. There are some indications that forecasting accuracy is affected by market ups and downs. For instance, the relative accuracy of voluntary management's earnings forecast during the entire time period, accuracy of management's forecast, and analysts' earnings forecasts during the years 1978 through 1992 are more accurate when market is up and are less accurate during the down market. This result agrees with what Su has suggested – earnings forecast accuracy is affected by market volatility, but in different ways. We believe that due to the fact that more individual investors who are most likely to chase the market when it is up saturate the Taiwan stock market. They examine corporate earnings with more caution, so their expectations for companies in general are more realistic and rational. Therefore, overall earnings forecast accuracy is increased, and vice versa.

The results of this study reveal that relative accuracy of all four kinds of earnings forecasts is not the functions of trading volume turnover. This agrees with the results obtained by Chai, but it disagrees with the results of Jiang (1993). Results of regression analysis indicate that management's earnings forecast and analysts' forecasts are sensitive to the corporate earnings variances. This conclusion proves the hypothesis supports H13 through H16 and supports the theories of Kross and Schreoder (1990) and Jiang (1993). We postulate that corporate earnings variance of earnings surprises is an important indicator for a company's profitability and its earnings in the future. The management and analysts use past year's earnings surprises to forecast that future earnings, with an assumption of higher forecast inaccuracy, are a result of a high degree of earnings deviation. Therefore, they will need to exercise their highest ability in making earnings forecast more accurate. But we found that the higher the corporate earnings variance is, the lower the forecast accuracy will be for both the management and for analysts. Corporate earnings variances should not be used as an important indicator as how a company is operating, but it represents a complicated business environment it operates in. The higher the complicity of the business environment is, the less accurate the prediction/forecast will be.

Analyst earnings forecast and management's earnings forecast are biased for the chemical industry over the entire time period of sampled forecast; voluntary management's earnings forecasts for textile, electrical machinery, and paper manufacturing industries are inaccurate during 1993–1999. Mandatory management's earnings forecasts are very inaccurate for the food industry, textile industry, and travel industry in the time period of 1993–1999. This supports Kross and Schreoder (1990) who concluded that analyst's earnings forecast is affected by the type of industry he/she follows.

The results reveal that the relative accuracy of management's earnings forecast and analyst's earnings forecast do not respond to the differences of forecasters' previous experiences. But, the relative accuracy of mandatory management's earnings forecast for forecasters affect the entire time period and the subsampled voluntary management's forecast previous earnings forecast experiences. This conclusion agrees with Clement's (1999) finding.

We rationalize that forecast accuracy is positive related to the forecasting experiences as hypotheses H21 through H24 state. The results from this study indicate otherwise. The forecast accuracy of mandatory and voluntary management's earnings forecast has a negative relationship with previous forecasting experiences. We argue that it is because of (1) mis-quantifying variable as a proxy of forecasting experiences and (2) only using the past mandatory management's earnings forecasts as the base of future focusing without paying attention to ways on how to reduce the forecasting errors in those forecasts. Therefore, the more forecasting experiences the forecaster has, the less accurate the forecast will be.

Methodology Appendix

Sample Selection

This research uses cross-sectional design to examine the relative accuracy of management and analysts' earnings forecast. Due to the disclosure regulation in Taiwan, management's earnings forecast is classified as two categories: mandatory earnings forecast and voluntary earnings forecast[1]. Samples used are management's and analysts' earnings forecasts at all publicly traded companies during the time period of 1987–1999. The forecasts are compared with actual corporate earnings on an annual basis. Voluntary and mandatory management's forecast and analysts' forecast are then used to compare with actual corporate earnings to evaluate the effects of management motivation and behaviors on their earnings forecasts.

Management and analysts' pretax earnings forecast data are collected from "Taiwan Business & Finance News" during the time period of 1987–1999. Actual corporate earnings are collected from the Department of Education's "AREMOS" database. Only those firms were included in the samples whose stocks were traded on the Taiwan Stock Exchange before December 31, 1999. Also, forecasts made after accounting year and before announcement of earnings were excluded from the sample.

Management's earnings forecast and analysts' earnings forecast samples for this research are selected to cover the time period from 1987 to 1999. Available database, over the 13-year period, consisted of 5,594 management's earnings forecasts, in which 2,894 management forecasts are voluntary and 2,700 management' forecasts are mandatory. A total of 17,783 analysts' forecasts are in the database. The selected samples, presented in Table 9.7, consist of 2,941 management earnings forecasts, of which 2,046 are voluntary and 1,679 mandatory forecasts and 3,210 analysts' earnings forecasts. Table 9.7 shows that the average number of analysts' earnings forecasts is more than the number of management's earnings forecasts. A higher frequency of analysts' earnings forecasts is expected as an analyst may cover more than one firm. Most of management's earnings forecasts are made after 1991; it may be attributed by the amendment of "Regulation of Financial Report of Stock Issuer" imposed by the Taiwanese government in 1991. In the new regulation, a new section dealing with earnings forecast was added requiring company's management to disclose its earnings forecasts to the general public. Comparing the number of management voluntary forecasts and mandatory forecasts, the latter is about 1.5 times more than the former except during the years 1991–1993.

Table 9.7 Sample of earnings forecasts by management and analysts from Taiwan database selected for the study

Year	Management voluntary	Management mandatory	Management	Analysts
1999	407	236	319	479
1998	408	238	335	430
1997	384	227	288	376
1996	328	201	223	322
1995	281	193	218	279
1994	219	135	112	247
1993	172	137	84	225

1989	123	123	NA	130
1988	112	112	NA	106
1987	87	87	NA	87
Total	2,941	2,046	1,679	3,210

[a]Mandatory forecast requirement was introduced in 1991

Variable Definition

Absolute Earnings Errors

The mean value of total corporate earnings before tax is used as proxy of earnings forecast. Using earnings before tax in the analysis will eliminate other factors, such as raising cash for capital investment, earnings retention for capital investment, and stock distribution from paid in capital that might impact the accuracy of the analysis. Absolute earnings (before tax) forecast error is used to compare the relative accuracy of management and analysts' earnings forecasts.

Management's forecasts errors are calculated as follows:

$$MF_{m,i,t} = \frac{1}{N} \times \sum_{j=1}^{n} FE_{m,i,j,t}$$

$$MF1_{m,i,t} = \frac{1}{N} \times \sum_{j=1}^{n} FE1_{m,i,j,t}$$

$$MF2_{m,i,t} = \frac{1}{N} \times \sum_{j=1}^{n} FE2_{m,i,j,t}$$

$$AFE_{m,i,t} = \left|\left(MF_{m,i,t} - AE_{i,t}\right)/AE_{i,t}\right|$$

$$AFE1_{m,i,t} = \left|\left(MF1_{m,i,t} - AE_{i,t}\right)/AE_{i,t}\right|$$

$$AFE2_{m,i,t} = \left|\left(MF2_{m,i,t} - AE_{i,t}\right)/AE_{i,t}\right|$$

where,

$MF_{m,i,t}$: mean management's pretax earnings forecast for company i at time t

$MF1_{m,i,t}$: mean management's voluntary pretax earnings forecast for company i at time t

$MF2_{m,i,t}$: mean management's mandatory pretax earnings forecast for company i at time t

$FE_{m,i,j,t}$: management's jth pretax earnings forecast for company i at time t

$FE1_{m,i,j,t}$: voluntary management's jth pretax earnings forecast for company i at time t

$FE2_{m,i,j,t}$: mandatory management's jth pretax earnings forecast for company i in year t

$AFE_{m,i,t}$: absolute error of management's pretax earnings forecast for company i at time t

$AFE1_{m,i,t}$: absolute error of voluntary management's pretax earnings forecast for company i at time t

$AFE2_{m,i,t}$: absolute error of mandatory management's pretax earnings forecast for company i at time t

$AE_{i,t}$: actual pretax EPS for company i at time t

Analysts forecast errors are calculated as follows:

$$MF_{f,i,t} = \frac{1}{n} \times \sum_{j=1}^{n} FE_{f,i,j,t}$$

$$AFE_{f,i,t} = \left|\left(MF_{f,i,t} - AE_{i,t}\right)/AE_{i,t}\right|$$

where

$MF_{f,i,t}$: mean analysts' pretax earnings forecast for company at time t

$FE_{f,i,j,t}$: analysts' jth pre-tax earnings forecast for company i at time t;

$AFE_{f,i,t}$: absolute error of analyst's pre-tax earnings forecast for company i at time t;

$AE_{i,t}$: actual pre-tax EPS for company i at time t.

Company Size

Unlike other previous researchers who used market value of company's equity as a indication of size of a company, in this study, a company's last year's total revenue is used as the size of the company. The reason is because Taiwanese market is not efficient and investors are not informed fully with information they need during their investment decision-making process; speculations among individual investors are the main cause of the stock market volatility; thus, market value of company's equity cannot fully represent a company's real size.In order to better control the company size for our regression analysis, a logarithm of company's last year's total revenue is used as the following:

$$\mathrm{SIZE}_{i,t} = \ln\left(\mathrm{TA}_{i,t-1}\right)$$

where

$\mathrm{SIZE}_{i,t}$: the size of company i at time t;

$\mathrm{TA}_{i,t-1}$: total revenue of company i at time t−1.

Market Volatility

This study adapts what Pettengill, Glenn N, Sundaram, Sridhar, and Mathur and Ike used in their research to measure market volatility. Market volatility is measured as upmarket or down market by using market-adjusted return. This return is calculated as $R_m - R_f$, in which R_m is the last month's market return minus the last first month's market return divided by the first month's market return in a given year. R_f is the risk-free interest rate in the same year:

$$\mathrm{Return}_{(\mathrm{Market-adjusted})} = R_m - R_f$$

where

Upmarket if Return (Market-adjusted) >0

Down market if Return (Market-adjusted) <0

A dummy variable is used to identify market volatility. Market volatility is set to 1 if a year's Return $_{(\mathrm{Market-adjusted})}$ is greater than 0 and set to 0 otherwise. Table 9.3 reports the market volatility of Taiwan market.

Trading Volume Turnover

Trading volume turnover is defined as the value of a company's stock daily trading volume divided by the company's number of shares outstanding. To make this proxy better fit in the regression analysis, a logarithm is applied to the value and multiplies by 1,000:

$$AV_{i,t} = \frac{1}{N}\sum_{j=1}^{n} V_{i,j,t}$$

$$TR_{i,t} = \ln\left(1,000 \times \frac{AV_{i,t-1}}{CS_{i,t-1}}\right)$$

where

$V_{i,j,t}$: daily trading volume in day j at time t for company i
$AV_{i,t}$: mean daily trading volume at time t for company i
$CS_{i,t-1}$: number of shares outstanding at time t−1 for company i
$TR_{i,t}$: rate of trading volume turnover at time t for company i

Corporate Earnings Variance

In this research, we only consider the past 3 years' historical earnings surprises as a proxy of a company's corporate earnings variances. Thus, the corporate earnings variance is defined as the following:

$$CV_{i,t} = LN\left(\frac{\sigma(X)}{|\overline{X}|}\right)$$

$$\sigma(X) = \sqrt{\frac{\sum_{t=1}^{n}\left(X_t - \overline{X}\right)^2}{n-1}}$$

$$\overline{X} = \frac{1}{3}\sum_{t=1}^{3} Y_t$$

where

$CV_{i,t}$: corporate earnings variance at time t for company i
$\sigma(x)$: actual corporate earnings variance for company i
X_t: actual earnings at time t for company i
$\overline{X}$: mean EPS (before tax) for company i
Y_t: actual EPS at time t for company i

Type of Industry

There are two major ways to classify industries:

(i) "Industry classification of Republic of China" by State Council in 1987
(ii) Industry classification used by stock exchange house

In this research, we use the latter one to classify industries, and a variable I_j is set to represent nineteen different industries: cement, food, plastic, textile, electrical machinery, electronic equipment and cable, chemical, glass and ceramic, paper manufacturing, steel, rubber, auto, electronics, construction, transportation, travel, insurance, and others.

Proxy for Experience

According to research done by previous researchers, although earnings forecast accuracy is positively related to management and analysts' previous forecasting experiences, it is difficult to quantify the experiences. In this research, we argue that the accuracy of nth management and analyst's earnings forecast depends on their (n − 1)th forecasting experience. Therefore, the proxy of experience is defined as the following:

$$E_{m,i,t} = \sum_{j=1}^{n} E_{m,i,j,t-1}$$

$$E1_{m,i,t} = \sum_{j=1}^{n} E1_{m,i,j,t-1}$$

$$E2_{m,i,t} = \sum_{j=1}^{n} E2_{m,i,j,t-1}$$

$$E_{f,i,t} = \sum_{j=1}^{n} E_{f,i,j,t-1}$$

where

$E_{m,i,t}$: total number of times of management's earnings forecasting experience at time t for company i

$E1_{m,i,t}$: total number of times of voluntary management's earnings forecasting experience at time t for company i

$E2_{m,i,t}$: total number of times of mandatory management's earnings forecasting experience at time t for company i

$E_{f,i,t}$: total number of times of analysts' earnings forecasting experience at time t for company i

Regression Model

A multiple regression model is used to examine the effect of six factors: firm size, market volatility, trading volume turnover, corporate earnings variances, type of industry, and experience.

Regression model for management's forecast absolute error percentage:

$$\begin{aligned}\mathrm{AFE}_{m,i} = {} & a_0 + a_1(\mathrm{SIZE}_i) + a_2 I_{i,1} \\ & + a_3(\mathrm{TR}_i) + a_4(\mathrm{CV}_i) + a_5\left(E_{m,i}\right) \\ & + \sum_{k=6}^{23} a_k I_{i,k-4} + \varepsilon_i\end{aligned} \tag{9.1}$$

Regression model for voluntary management's forecast absolute error percentage:

$$\begin{aligned}\mathrm{AFE1}_{m,i} = {} & b_0 + b_1(\mathrm{SIZE}_i) + b_2 I_{i,1} \\ & + b_3(\mathrm{TR}_i) + b_4(\mathrm{CV}_i) + b_5\left(E1_{m,i}\right) \\ & + \sum_{k=6}^{23} b_k I_{i,k-4} + \varepsilon_i\end{aligned} \tag{9.2}$$

Regression model for mandatory management's forecast absolute error percentage:

$$\begin{aligned}\mathrm{AFE2}_{m,i} = {} & c_0 + c_1(\mathrm{SIZE}_i) + c_2 I_{i,1} \\ & + c_3(\mathrm{TR}_i) + c_4(\mathrm{CV}_i) + c_5\left(E2_{m,i}\right) \\ & + \sum_{k=6}^{23} c_k I_{i,k-4} + \varepsilon_i\end{aligned} \tag{9.3}$$

Regression model for analysts' forecast absolute error percentage:

$$\begin{aligned}\mathrm{AFE}_{f,i} = {} & d_0 + d_1(\mathrm{SIZE}_i) + d_2 I_{i,1} \\ & + d_3(\mathrm{TR}_i) + d_4(\mathrm{CV}_i) + d_5\left(E_{f,i}\right) \\ & + \sum_{k=6}^{23} d_k I_{i,k-4} + \varepsilon_i\end{aligned} \tag{9.4}$$

where

$\mathrm{AFE}_{m,i}$: absolute error percentage of management's forecast for company i

$\mathrm{AFE1}_{m,i}$: absolute error percentage of voluntary management's forecast for company i

$\mathrm{AFE2}_{m,i}$: absolute error percentage of mandatory management's forecast for company i

$\mathrm{AFE}_{f,i}$: absolute error percentage of analysts' forecast for company i

SIZE_i: size of company i

$I_{i,1}$: market volatility (1 if market is upmarket, 0 if market is down market)

TR_i: rate of trading volume turn over for company i
CV_i: corporate earnings variances for company i
$E_{m,i}$: management's earnings forecasting experience for company i
$E_{1m,i}$: voluntary management's earnings forecasting experience for company i
$E2_{m,i}$: mandatory management's earnings forecasting experience for company i
$E_{f,i}$: analyst earnings forecasting experience for company i
$I_{i,2-19}$: type of industry for company i

Wilcoxon Two-Sample Test

If the two-sample groups are related, Wilcoxon two-sample test will be used to determine the relative earnings forecast accuracy:

$$Z = \frac{W - E(W)}{\sqrt{V(W)}}$$

where

W1: rank sum of absolute error percentage for management's earnings forecasts
W2: rank sum of absolute error percentage for analysts' earnings forecasts
W: smaller value between W1 and W2
E(W): expected values of W-distribution
$\sqrt{V(W)}$: deviation of W-distribution

Contents

Abstract

The purpose of this study is to provide evidence drawn from publicly traded companies in Greece as far as some of the standard models of accounting earnings and returns relations mainly collected through the literature. Standard models such as earnings level and earnings changes have been investigated in this study. Models that fit better to the data drawn from companies listed on the Athens Stock Exchange have been selected employing autoregressive integrated moving average with exogenous variables (ARIMAX) models. Models I (price on earnings model), II (returns on change in earnings divided by beginning-of-period price and prior period), V (returns on change in earnings over opening market value), VII (returns deflated by lag of 2 years on earnings over opening market value), and IX (differenced-price model) have statistically significant coefficients of explanatory variables. In addition, model II (returns on change in earnings divided by beginning-of-period price and prior period with MSE (minimum squared error)

loss function in ARIMAX (2,0,2)) is prevalent. These models take place with backward-looking information instead of forward-looking information that recent literature is assessed. Application of generalized autoregressive conditional heteroscedasticity (GARCH) models is suggested for further future research.

Keywords

Market-based accounting research • Price on earnings model • Earnings level • Earnings change • Return models • Autoregressive-moving average with exogenous variables • Minimum value of squared residuals (MSE loss function) • Unit root tests • Stationarity • Dickey-Fuller test

10.1 Introduction

The relationship between accounting earnings and stock prices has been discussed both in the accounting and financial literature. In a consideration of market-based accounting research, the association between returns and earnings has been very low due to (i) poor specification of the estimating equation, (ii) poor informational properties of reported earnings, (iii) inappropriate choice of the assumed proxy for expected earnings, and (iv) the availability of more timely sources of the value-relevant information in earnings statement (Strong and Walker 1993). This has been resolved by allowing for time-series and cross-sectional variation in the regression parameters, by including an earnings yield and partitioning all-inclusive earnings into pre-exceptional, exceptional, and extraordinary components. Yet, empirical evidence on returns-earnings association in certain applications is very strong (Easton and Harris 1991; Kothari and Zimmerman 1995). Standard empirical models, that is, price-earnings association, and returns-earnings association (earnings level and earnings changes) have been investigated in the USA and UK with no empirical evidence from at least the rest of Europe. The purpose of this paper is to develop an empirical background by investigating whether some of the standard models that have been collected through the literature would be relevant for evaluating accounting earnings/returns associations in a stock market being in transition from an emerging to a matured one. In other words, we purport to select those models that better fit to available data. The rationale of the Greek stock market response is one major objective, while the other is to make some comparisons with other findings presented in the literature.

The Athens stock exchange has been established on 1876. It was an emerging market some years ago and has run up to a mature one. It is a normal market with no surprises, and investments are not only a place for corporations to get financing; more importantly it is a place to create wealth. Registered companies are young, growth-oriented to long-established enterprises. The Greek stock market has played a great role in the economic development of the country in the last half of the twentieth century. Facts that have influenced the ASE is the inclusion of the country in the Economic and Monetary Union and the **crash** of 1999 that affected the life of many Greek families. The ASE operates in a country which has been in deep recession since 2008.

The paper is organized as follows: Literature is discussed in Sect. 10.2. Methodology and model building process are described in Sect. 10.3. Section 10.4 discusses the sample design. Section 10.5 presents empirical findings. Conclusions are summarized in last Sect. 10.6.

10.2 Review of the Literature

Common interest of both accounting and finance scholars and users of financial statements (primarily, financial analysts and investors) is to obtain concrete and increased knowledge of the association between accounting earnings and stock prices for a more or less predictive ability explanation. An evaluation of the informational content of, at least, the most basic accounting numbers contributes to the improvement of models. Among the various treatments of the relation between accounting earnings and stock prices, the seminal work of Ball and Brown (1968) is precedent. Their work indicates that accounting earnings and some of its components exhibit an information content drawn through stock prices. Later on, Brown et al. (1985) worked on the relative ability of the current innovation in annual earnings and the revision in next year's earnings forecasts to explain changes in stock prices. However, it has empirically been tested (Fama et al. 1969; Fama 1970). Successive changes in individual common stocks are very nearly independent because of an efficient market in which adjustments to new information are rapidly made (Mandelbrot 1966; Samuelson 1965). Beaver (1970) and Rosenberg and Marathe (1975) worked to discover financial statement components that are related to risk and, thus, predict expected stock returns. They maintain that financial statements constitute an assured source of information (and can be prepared in a short time period) and, consequently, the direction of 1-year-ahead earnings changes affects stock prices. Their results indicate that the summary measure robustly predicts future stock returns.

Beaver et al. (1980) developed a model known as BLM theory. They followed the traditional price-earnings relation and tested for the information content of prices with respect to future earnings. BLM regress percentage change in price which may contain information about future earnings not reflected in the current earnings. Lev and Ohlson (1982) describe price and return models as complementary. Given that stock prices are associated with accounting earnings, analysts forecast the reported accounting numbers, and as Brown et al. (1985) maintain, analysts use their 1-year-ahead forecasts to convey their expectations about permanent earnings. In all the above treatments of the subject matter referring to accounting earnings and stock prices, the more and more prevailing role of managerialism could be more or less emphatic. Trueman (1986) explained why managers would be willing to disclose forecasts of higher or lower than expected earnings. Undoubtedly, the disclosure of favorable accounting numbers or the disclosure of forecasts of favorable expected earnings contributes to an increase of the market value of the firm. Hirst et al. (2008) assert that managers often issue earnings forecasts to correct information asymmetry problems and, thus, influence their firm's stock price.

Lipe and Kormendi (1987) found that stock returns were considered as a function of the revisions in expectations of earnings. They show that the stock return reaction to earnings is a function of (1) the time-series properties of earnings, (2) the interest rate used to discount expected future earnings, and (3) the relative ability of earnings. Furthermore, Freeman (1987) maintains that the relation between security prices and firm-specific information is associated with the market value of a firm's common equity and concludes that the magnitude of the abnormal returns related to earnings is a decreasing function of firm size. Of much interest is a hypothesis tested by Freeman (1987) which implies that (i) the abnormal security returns related to accounting earnings occur earlier for large than for small firms and (ii) abnormal returns are lower for large firms and higher for small firms. The information content theorists consider size as an important conditioning variable when testing the information content of prices with respect to future earnings and contemporaneous price changes.

Beaver et al. (1987), Collins et al. (1987), Collins and Kothari (1989), and many others show that unexpected earnings for a year are correlated with returns from a prior year. Christie (1987) concludes that while return and price models are economically equivalent, return models are econometrically less problematic. Meanwhile, Holthausen and Verrecchia (1988) worked on price changes when information is announced. Landsman and Magliolo (1988) argue that price models are superior to return models for certain applications. According to Cornell and Landsman (1989), stock prices respond to earnings announcements. Alternatively stated, unexpected increases in earnings are associated with a rise in stock prices, and unexpected decreases in earnings are associated with a fall in stock prices. Relating unexpected accounting earnings and security prices aims to assess the information content of the latter (Collins and Kothari 1989). Conservative proponents support the view that financial statement ratios are the basic tools for evaluating and predicting accounting earnings and, consequently, security prices. Ou and Penman (1989) maintain that the relationship of financial statement characteristics to value is not apparent. Easton and Zmijewski (1989) and that of Board and Walker (1990) analyze a coefficient that measures the response of stock prices to accounting earnings coefficient. They measure the response of stock prices to accounting earnings announcements, and they empirically show that the higher this coefficient, the smaller the stock price changes.

Lipe (1990) worked on the relation between stock returns and accounting earnings, assuming that market observes current-period information other than earnings. In the process of relating stock prices to accounting earnings, (i) a coefficient which measures the stock-return response to a one dollar earnings changes as a function of both "predictability" and "persistence" of earnings, and (ii) the variance of stock price changes during the reporting of earnings has been tested in the literature (Cho and Jung 1991; etc.). Easton and Harris (1991) presented models relating earnings variables and security returns, concluding that both current earnings level and the earnings change variables play a role in the security valuation. They are in fact correlated. Strong and Walker (1993) used a panel regression approach to examine the association between annual stock price returns and reported earnings figures of industrial companies in the UK and proved through an analysis of earnings components that models of the relation between earnings and returns that focus exclusively on the deflated first difference of earnings are misspecified. Kahya et al. (1993) showed that earnings growth rates are predictable using past earnings growth rates, stock price returns are predictable using past earnings growth rates as well as stock price returns, and firm size has no incremental explanatory power with respect to equity prices.

Kothari and Zimmerman (1995) provide empirical results confirming that price models' earnings response coefficients are less biased and argue that the price specification suffers more from heteroscedasticity/misspecification problems than the return model. They conclude that in some research contexts, the combined use of both price and return models may be useful. Chen et al. (2001) obtain evidence of value relevance of accounting information in China based on a return and a price model according to both the pooled cross section and time-series regressions or the year-by-year regressions, and find that value relevance is higher for companies using only A shares to domestic investors despite of the lack of alternative information sources (i.e., earnings forecasts, financial analysts), the lack of a sufficient level of corporate governance, and the even recent new phenomenon of independent auditing in China. Lundholm and Myers (2002) examined how a firm's disclosures affect the mix of earnings information reflected in its annual stock return and found that increased disclosure activity "brings the future forward" into current stock returns. Chen et al. (2011) examined the properties of accounting numbers of listed firms in China by investigating the interplay between accounting earnings and stock prices. They found that core earnings (or operating income) have a greater association with contemporaneous stock returns than nonoperating revenues and expenses, and they also found that different types of firm ownership may have different impacts on the information content of earnings components.

10.3 Methodology and Models Used

Literature concerning accounting earnings and stock prices has been formulated in the framework of an earnings-based valuation model expanded with the dividend irrelevance proposition. These standard models which have also been tested by Easton and Harris (1991) and Zimmerman and Kothari (1995) are as follows:

I. Price on earnings

$$P_{i,j} = a + bA_{i,j} + e_{i,j}. \tag{10.1}$$

II. Returns on change in earnings divided by beginning-of-period price and prior period earnings divided by the price at the beginning of the return period

$$\left[\left(A_{i,j}/P_{i,j-1}\right)\right] = a_{i,j} + b_{i,j}\left(A_{i,j} - A_{i,j-1}\right)/P_{i,j-1} + \left(A_{i,j-1}/P_{i,j-1}\right)\right] \tag{10.2}$$

III. Returns on earnings over opening market value

$$\left[\left(P_{i,j} - P_{i,j-1}\right) + d_{i,j}\right]/P_{i,j-1} = a_{i,j} + b_{i,j}\left(A_{i,j}/P_{i,j-1}\right) + e_{i,j} \tag{10.3}$$

IV. Returns on prior earnings model over opening market value

$$\left[\left(P_{i,j} - P_{i,j-1}\right) + d_{i,j}\right]/P_{i,j-1} = a_{i,j} + b_{i,j}\left(A_{i,j-1}/P_{i,j-1}\right) + e_{i,j} \tag{10.4}$$

V. Returns on change in earnings over opening market value

$$\left[\left(P_{i,j} - P_{i,j-1}\right) + d_{i,j}\right]/P_{i,j-1} = a_{i,j} + b_{i,j}\left[\left(A_{i,j} - A_{i,j-1}\right)/P_{i,j-1}\right] + e_{i,j} \tag{10.5}$$

VI. Returns on change in earnings over opening market value and on earnings over opening market value

$$\begin{aligned}\left[\left(P_{i,j} - P_{i,j-1}\right) + d_{i,j}\right]/P_{i,j-1} = a &+ b_{1i,j}\left[\left(A_{i,j} - A_{i,j-1}\right)/P_{i,j-1}\right] \\ &+ b_{2i,j}\left[\left(A_{i,j}/P_{i,j-1}\right) + e_{i,j}\right]\end{aligned} \tag{10.6}$$

VII. Returns (deflated by lag of 2 years) on earnings over opening market value

$$\left[\left(P_{i,j} - P_{i,j-1}\right) + d_{i,j}\right]/P_{i,j-2} = a_{i,j} + b_{i,j}\left(A_{i,j}/P_{i,j-1}\right) + e_{i,j} \tag{10.7}$$

VIII. Return model regressed on earnings over opening market value

$$P_{i,j}/P_{i,j-1} = a + b_{1i,j}A_{i,j}/P_{i,j-1} \tag{10.8}$$

IX. Differenced-price model

$$P_{i,j} - P_{i,j-1} = A_{i,j} - A_{i,j-1} \tag{10.9}$$

where
$P_{i,j}$ = stock price (per share) of firm i in period j
$A_{i,j}$ = earnings per share of firm i in period j
$d_{i,j}$ = dividend per share of firm i in period j
a = a constant in a linear relationship(intercept parameter)
b_1,b_2 = a slope parameter or a coefficient in a linear regression
i = cross-selection item, j = time-series item

To be familiar and consistent with the existing literature, some requirements are stressed. For example, earnings per share divided by price at the beginning of the return period ($A_{i,j}/P_{i,j-1}$) refers to current earnings level variable. Change in earnings divided by beginning-of-period price refers to earnings change variable [($A_{i,j} - A_{i,j-1}$)/$P_{i,j-1}$]. Thus far, the models that have been selected to be tested express the following:

Model I: Expresses price as a multiple of earnings.

Model II: Expresses historical price-earnings ratios with an earnings change versus earnings levels explanation form.

Model III: From an earnings valuation perspective, earnings levels(divided by beginning-of-period price) will be associated with returns.
Model IV: Illustrates a linear relation between prior earnings divided by beginning-of-period price and security returns over that period.
Model V: Regresses annual security returns on change in earnings divided by beginning-of-period price.
Model VI: Expresses the contribution of change in earnings versus earnings levels in the explanation of stock returns.
Model VII: Returns (deflated by lag of 2 years) on earnings over opening market value.
Model VIII: Expresses returns on earnings level divided by beginning-of-period price.
Model IX: Expresses differenced-price model.

As in Easton and Harris (1991), the models under investigation have been based on either the book value valuation model or the earnings valuation model.

The book value valuation model indicates that

$$P_{ij} = BV_{ij} + u_{ij} \tag{10.10}$$

Taking first differences we have

$$\Delta P_{ij} = \Delta BV_{ij} + u_{ij} \tag{10.11}$$

But in general

$$\Delta BV_{ij} = A_{ij} - d_{ij} \tag{10.12}$$

Substituting (3) into (2), rearranging and dividing by P_{ij-1} yields
$(\Delta P_{ij} + d_{ij})/P_{ij-1} = A_{ij}/P_{ij-1} + u_{ij}$ (model III)
On the other hand,

$$P_{ij} = \rho A_{ij} + u_{ij} \tag{10.13}$$

Given the dividends irrelevance proposition, we have

$$P_{ij} + d_{ij} = \rho A_{ij} + u_{ij} \tag{10.14}$$

It follows that $(\Delta P_{ij} + d_{ij})/P_{ij-1} = \rho(\Delta A_{ij}/P_{ij-1}) + u_{ij}$ (model V)

ARIMAX (autoregressive integrated moving average with exogenous variables) as a suitable technique for nonstationarity time-series modeling is employed in this study.

10.4 Sample Selection

The whole population containing all Greek-listed companies in the Athens Stock Exchange is investigated in this study. The total number of companies amounts to 513 companies. The main source of data is the Athens Stock

Exchange Annual Yearbook, the annual statistical bulletin, and the Internet. Total number of companies refers to the time period 1974 up to 2005 (the most recently available data when writing the paper). The full sample (1974–2005) is separated in two samples (1974–1999 and 2000–2005) which correspond to two-time periods, that is, before the Euro currency and the Euro era. As in Kothari and Zimmerman (1995), to avoid any undue influence of extreme observations, the largest and the lowest 1 % of observations is excluded from the sample. EPS take positive or zero values. All firms have a December fiscal year-end. Annual earnings include those from discontinued operations and extraordinary items.

10.5 Empirical Findings

For each year, a nonconstant number of companies is available. We define the total number of companies at each year t as n_t. We would like to estimate the following nine models for the period from 1974 to 2005:
Model I

$$P_t = a + bA_t + e_t, \quad \textbf{for} \quad e_t \sim N\left(0, \sigma^2\right), \tag{10.15}$$

where $P_t = {n_t}^{-1}\sum_{i=1}^{n_t} P_{i,t}$ and $A_t = {n_t}^{-1}\sum_{i=1}^{n_t} A_{i,t}$.

Model II

$$\frac{A_t}{P_{t-1}} = a + b_1\frac{A_t - A_{t-1}}{P_{t-1}} + b_2\frac{A_{t-1}}{P_{t-1}} + e_t, \quad \textbf{for} \quad e_t \sim N\left(0, \sigma^2\right), \tag{10.16}$$

where $\frac{A_t}{P_{t-1}} = {n_t}^{-1}\sum_{i=1}^{n_t}\frac{A_{i,t}}{P_{i,t-1}}$, $\frac{A_t - A_{t-1}}{P_{t-1}} = {n_t}^{-1}\sum_{i=1}^{n_t}\frac{A_{i,t} - A_{i,t-1}}{P_{i,t-1}}$, and $\frac{A_{t-1}}{P_{t-1}} = {n_t}^{-1}\sum_{i=1}^{n_t}\frac{A_{i,t-1}}{P_{i,t-1}}$.

Model III

$$\frac{P_t - P_{t-1} + d_t}{P_{t-1}} = a + b_1\frac{A_t}{P_{t-1}} + e_t, \quad \textbf{for} \quad e_t \sim N\left(0, \sigma^2\right), \tag{10.17}$$

where $\frac{P_t - P_{t-1} + d_t}{P_{t-1}} = {n_t}^{-1}\sum_{i=1}^{n_t}\frac{P_{i,t} - P_{i,t-1} + d_{i,t}}{P_{i,t-1}}$ and $\frac{A_t}{P_{t-1}} = {n_t}^{-1}\sum_{i=1}^{n_t}\frac{A_{i,t}}{P_{i,t-1}}$.

Model IV

$$\frac{P_t - P_{t-1} + d_t}{P_{t-1}} = a + b_1 \frac{A_{t-1}}{P_{t-1}} + e_t, \ \ \textbf{for} \ \ e_t \sim N\left(0, \sigma^2\right), \tag{10.18}$$

where $\frac{P_t - P_{t-1} + d_t}{P_{t-1}} = {n_t}^{-1} \sum_{i=1}^{n_t} \frac{P_{i,t} - P_{i,t-1} + d_{i,t}}{P_{i,t-1}}$ and $\frac{A_{t-1}}{P_{t-1}} = {n_t}^{-1} \sum_{i=1}^{n_t} \frac{A_{i,t-1}}{P_{i,t-1}}$.

Model V

$$\frac{P_t - P_{t-1} + d_t}{P_{t-1}} = a + b_1 \frac{A_t - A_{t-1}}{P_{t-1}} + e_t, \ \ \textbf{for} \ \ e_t \sim N\left(0, \sigma^2\right), \tag{10.19}$$

where $\frac{P_t - P_{t-1} + d_t}{P_{t-1}} = {n_t}^{-1} \sum_{i=1}^{n_t} \frac{P_{i,t} - P_{i,t-1} + d_{i,t}}{P_{i,t-1}}$ and $\frac{A_t - A_{t-1}}{P_{t-1}} = {n_t}^{-1} \sum_{i=1}^{n_t} \frac{A_{i,t} - A_{i,t-1}}{P_{i,t-1}}$.

Model VI

$$\frac{P_t - P_{t-1} + d_t}{P_{t-1}} = a + b_1 \frac{A_t - A_{t-1}}{P_{t-1}} + b_2 \frac{A_t}{P_{t-1}} + e_t, \ \ \textbf{for} \ \ e_t \sim N\left(0, \sigma^2\right), \tag{10.20}$$

where $\frac{P_t - P_{t-1} + d_t}{P_{t-1}} = {n_t}^{-1} \sum_{i=1}^{n_t} \frac{P_{i,t} - P_{i,t-1} + d_{i,t}}{P_{i,t-1}}$, $\frac{A_t - A_{t-1}}{P_{t-1}} = {n_t}^{-1} \sum_{i=1}^{n_t} \frac{A_{i,t} - A_{i,t-1}}{P_{i,t-1}}$, and $\frac{A_t}{P_{t-1}} = {n_t}^{-1} \sum_{i=1}^{n_t} \frac{A_{i,t}}{P_{i,t-1}}$.

Model VII

$$\frac{P_t - P_{t-1} + d_t}{P_{t-2}} = a + b_1 \frac{A_t}{P_{t-1}} + e_t, \ \ \textbf{for} \ \ e_t \sim N\left(0, \sigma^2\right), \tag{10.21}$$

where $\frac{P_t - P_{t-1} + d_t}{P_{t-2}} = {n_t}^{-1} \sum_{i=1}^{n_t} \frac{P_{i,t} - P_{i,t-1} + d_{i,t}}{P_{i,t-2}}$ and $\frac{A_t}{P_{t-1}} = {n_t}^{-1} \sum_{i=1}^{n_t} \frac{A_{i,t}}{P_{i,t-1}}$.

Model VIII

$$\frac{P_t}{P_{t-1}} = a + b_1 \frac{A_t}{P_{t-1}} + e_t, \ \ \textbf{for} \ \ e_t \sim N\left(0, \sigma^2\right), \tag{10.22}$$

where $\frac{P_t}{P_{t-1}} = {n_t}^{-1} \sum_{i=1}^{n_t} \frac{P_{i,t}}{P_{i,t-1}}$ and $\frac{A_t}{P_{t-1}} = {n_t}^{-1} \sum_{i=1}^{n_t} \frac{A_{i,t}}{P_{i,t-1}}$.

Table 10.1 The ARIMAX (p,d,q) specification for each of the nine models and the relative MSE loss functions

Model I	ARIMAX(1,0,1)	2.766371
Model II	ARIMAX(2,0,2)	0.003763
Model III	ARIMAX(2,0,2)	0.741482
Model IV	ARIMAX(2,0,2)	0.719591
Model V	ARIMAX(0,1,1)	0.732002
Model VI	ARIMAX(2,0,2)	0.584564
Model VII	ARIMAX(2,1,1)	0.888239
Model VIII	ARIMAX(2,0,2)	0.762231
Model IX	ARIMAX(2,1,2)	2.245854

Model IX

$$(P_t - P_{t-1}) = a + b_1(A_t - A_{t-1}) + e_t, \quad \textbf{for} \quad e_t \sim N\left(0, \sigma^2\right), \tag{10.23}$$

where $(P_t - P_{t-1}) = {n_t}^{-1}\sum_{i=1}^{n_t}\left(P_{i,t} - P_{i,t-1}\right)$ and $(A_t - A_{t-1}) = {n_t}^{-1}\sum_{i=1}^{n_t}\left(A_{i,t} - A_{i,t-1}\right)$.

The nine aforementioned models are characterized by autocorrelated and heteroscedastic residuals. Thus, the models are expanded in the ARIMAX (autoregressive integrated moving average) framework (for details about ARIMAX modeling, the interested reader is referred to Box and Jenkins (1976)) in order to model the autocorrelated residuals. Moreover, we take into consideration White's (1980) heteroscedasticity-consistent covariance matrix estimator which provides correct estimates of the coefficient covariances in the presence of heteroscedasticity of unknown form.

The ARIMAX (p,d,q) models are estimated in the following form:

$$\begin{gathered}(1 - L)^d y_t = \mathbf{X}_t\beta + e_t \\ \left(1 - \sum_{i=1}^{p} c_i L^i\right) e_t = \left(1 + \sum_{i=1}^{q} d_i L^i\right)\varepsilon_t \\ \varepsilon_t \sim N(0, \sigma^2),\end{gathered} \tag{10.24}$$

where y_t is the dependent variable, $\mathbf{X}_t$ is the vector of explanatory variables, L is the lag operator, and β is a vector of parameters to be estimated. c_i, for $i = 1,\ldots,p$, and d_i, for $i = 1,\ldots,q$, are also parameters to be estimated.

For each of the nine models, the ARIMAX (p,d,q) specification is estimated for $p = 0,1,2$, $d = 0,1,2$ and $q = 0,1,2$. Therefore, for each model, 27 ARIMAX specifications are estimated. The ARIMAX (p,d,q) specification with the minimum value of squared residuals (MSE loss function) is selected as the most appropriate. The following Table presents the selected specifications for each model (Table 10.1).

Hence, the estimated models are the following:

Model I

$$\begin{aligned} P_t &= 8.5 - 5.1A_t + e_t \\ e_t &= 1.05e_{t-1} + \varepsilon_t - 1.46\varepsilon_{t-1} \\ \varepsilon_t &\sim N(0, \sigma^2). \end{aligned} \tag{10.25}$$

Model II

$$\begin{aligned} \frac{A_t}{P_{t-1}} &= -0.004 + 0.99\frac{A_t - A_{t-1}}{P_{t-1}} + 1.04\frac{A_{t-1}}{P_{t-1}} + e_t \\ e_t &= 1.5e_{t-1}0.84e_{t-2} + \varepsilon_t - 1.14\varepsilon_{t-1} + 0.52\varepsilon_{t-2} \\ \varepsilon_t &\sim N(0, \sigma^2). \end{aligned} \tag{10.26}$$

Model III

$$\begin{aligned} \frac{P_t - P_{t-1} + d_t}{P_{t-1}} &= 0.28 - 0.21\frac{A_t}{P_{t-1}} + e_t \\ e_t &= 0.32e_{t-1} + 0.46e_{t-2} + \varepsilon_t + 0.92\varepsilon_{t-1} - 1.16\varepsilon_{t-2} \\ \varepsilon_t &\sim N(0, \sigma^2). \end{aligned} \tag{10.27}$$

Model IV

$$\begin{aligned} \frac{P_t - P_{t-1} + d_t}{P_{t-1}} &= -0.47 + 2.48\frac{A_{t-1}}{P_{t-1}} + e_t \\ e_t &= 0.21e_{t-1} + 0.36e_{t-2} + \varepsilon_t - 0.68\varepsilon_{t-1} - 1.42\varepsilon_{t-2} \\ \varepsilon_t &\sim N(0, \sigma^2). \end{aligned} \tag{10.28}$$

Model V

$$\begin{aligned} (1-L)\frac{P_t - P_{t-1} + d_t}{P_{t-1}} &= 0.055 - 0.5\frac{A_t - A_{t-1}}{P_{t-1}} + e_t \\ e_t &= \varepsilon_t - 1.52\varepsilon_{t-1} \\ \varepsilon_t &\sim N(0, \sigma^2). \end{aligned} \tag{10.29}$$

Model VI

$$\begin{aligned} \frac{P_t - P_{t-1} + d_t}{P_{t-1}} &= -0.33 - 2.6\frac{A_t - A_{t-1}}{P_{t-1}} + 2.4\frac{A_t}{P_{t-1}} + e_t \\ e_t &= 0.4e_{t-1} + 0.3e_{t-2} + \varepsilon_t 0.37\varepsilon_{t-1} - 1.9\varepsilon_{t-2} \\ \varepsilon_t &\sim N(0, \sigma^2). \end{aligned} \tag{10.30}$$

Model VII

$$\begin{aligned} (1-L)\frac{P_t - P_{t-1} + d_t}{P_{t-2}} &= 0.2 - 0.76\frac{A_t}{P_{t-1}} + e_t \\ e_t &= 0.1e_{t-1} + 0.3e_{t-2} + \varepsilon_t - 1.7\varepsilon_{t-1} \\ \varepsilon_t &\sim N(0, \sigma^2). \end{aligned} \tag{10.31}$$

Model VIII

$$\begin{gathered}\frac{P_t}{P_{t-1}} = 1.3 - 0.22\frac{A_t}{P_{t-1}} + e_t \\ e_t = 0.31e_{t-1} + 0.46e_{t-2} + \varepsilon_t + 0.94\varepsilon_{t-1} - 1.1\varepsilon_{t-2} \\ \varepsilon_t \sim N(0, \sigma^2).\end{gathered} \tag{10.32}$$

Model IX

$$\begin{gathered}(1 - L)(P_t - P_{t-1}) = 0.16 - 5.54(A_t - A_{t-1}) + e_t \\ e_t = -0.25e_{t-1} + 0.13e_{t-2} + \varepsilon_t - 1.2\varepsilon_{t-1} - 0.64\varepsilon_{t-2} \\ \varepsilon_t \sim N(0, \sigma^2).\end{gathered} \tag{10.33}$$

In the sequel, for the models being estimated, the estimates of the coefficients, their standard errors, the t-ratios, and their p-values are presented. According to the t-statistics, computed as the ratio of the coefficients to their standard errors, the coefficients of the explanatory variables are statistically significant in models I (price on earnings), II (returns on change in earnings divided by beginning-of-period price and prior period earnings divided by the price at the beginning of the return period), V (returns on change in earnings over opening market value), VII (returns (deflated by lag of 2 years) on earnings over opening market value, and IX (differenced-price model).

Thus, we conclude that these models explain the relationship between dependent and explanatory variables, whereas the models III (returns on earnings over opening market value), IV (returns on prior earnings model over opening market value), VI (returns on change in earnings over opening market value, and on earnings over opening market value), and VIII (return model regressed on earnings over opening market value) fail to explain any strong relationship for the variables under investigation.

10.5.1 Unit Root Tests: Testing for Stationarity

We estimate the augmented Dickey and Fuller (1979) test in order to investigate the null hypothesis of a unit root or nonstationarity of the time series under investigation, i.e., y_t. The Dickey-Fuller test is carried out by estimating:

$$\Delta y_t = a_0 + a_1 y_{t-1} + a_2 t + \sum_{i=1}^{l} b_i \Delta y_{t-i} + \varepsilon_t \tag{10.34}$$

where $\varepsilon_t \sim N(0,\sigma^2)$, and Δ is the difference operator, or $\Delta = (1 - L)$. The lag order l of $\sum_{i=1}^{l} b_i \Delta y_{t-i}$ is selected based on the Schwarz (1978) information criterion. The null and the alternative hypotheses may be written as

$$\begin{aligned} H_0 &: a_1 = 0 \\ H_A &: a_1 \neq 0. \end{aligned} \tag{10.35}$$

A rejection of the null hypothesis indicates that the series y_t is stationary. The Eq. 10.20 is estimated in three different versions: (i) for $a_0 = a_2 = 0$, (ii) for $a_2 = 0$, and (iii) for $a_0 \neq 0$ and $a_2 \neq 0$. The variables we are interested in are

P_t in model I; A_t in model I; $\frac{A_t}{P_{t-1}}$ in models II, III, VI, VII, and VIII; $\frac{A_t - A_{t-1}}{P_{t-1}}$ in models II, V, VI; $\frac{A_{t-1}}{P_{t-1}}$ in models II and IV; $\frac{P_t - P_{t-1} + d_t}{P_{t-1}}$ in models III, IV, V, and VI; $\frac{P_t - P_{t-1} + d_t}{P_{t-2}}$ in model VII; $\frac{P_t}{P_{t-1}}$ in model VIII; $(P_t - P_{t-1})$ in model IX; and $(A_t - A_{t-1})$ in model IX.

The test statistics and the relative p-values from testing 21 for the Eq. 10.20 for $a_0 = a_2 = 0$ are the following:

Variable	Test statistic	p-value
P_t	−2.256635	0.0254
A_t	−3.414078	0.0013
$\frac{A_t}{P_{t-1}}$	−5.218131	0.00
$\frac{A_t - A_{t-1}}{P_{t-1}}$	−6.010163	0.00
$\frac{A_{t-1}}{P_{t-1}}$	−3.238033	0.00
$\frac{P_t - P_{t-1} + d_t}{P_{t-1}}$	−4.363369	0.00
$\frac{P_t - P_{t-1} + d_t}{P_{t-2}}$	−5.920676	0.00
$\frac{P_t}{P_{t-1}}$	−2.698176	0.0087
$(P_t - P_{t-1})$	−7.122593	0.00
$(A_t - A_{t-1})$	−7.294227	0.00

The test statistics and the relative p-values from testing 21 for the Eq. 10.20 for $a_2 = 0$ are the following:

Variable	Test statistic	p-value
P_t	−3.625190	0.0109
A_t	−5.722834	0.00
$\frac{A_t}{P_{t-1}}$	−5.587381	0.00
$\frac{A_t - A_{t-1}}{P_{t-1}}$	−6.107705	0.00
$\frac{A_{t-1}}{P_{t-1}}$	−5.774024	0.00
$\frac{P_t - P_{t-1} + d_t}{P_{t-1}}$	−4.399238	0.0016
$\frac{P_t - P_{t-1} + d_t}{P_{t-2}}$	−6.043400	0.00
$\frac{P_t}{P_{t-1}}$	−4.345041	0.0018
$(P_t - P_{t-1})$	−6.998199	0.00
$(A_t - A_{t-1})$	−7.157803	0.00

The test statistics and the relative p-values from testing 21 for the Eq. 10.20 for $a_0 \neq 0$ and $a_2 \neq 0$ are the following:

Variable	Test statistic	p-value
P_t	−3.565939	0.0497
A_t	−5.698735	0.0003
$\frac{A_t}{P_{t-1}}$	−5.667882	0.0004
$\frac{A_t - A_{t-1}}{P_{t-1}}$	−6.213167	0.0001
$\frac{A_{t-1}}{P_{t-1}}$	−5.673596	0.0003
$\frac{P_t - P_{t-1} + d_t}{P_{t-1}}$	−4.332965	0.0092
$\frac{P_t - P_{t-1} + d_t}{P_{t-2}}$	−5.931949	0.0002
$\frac{P_t}{P_{t-1}}$	−4.290153	0.0102
$(P_t - P_{t-1})$	−6.875067	0.00
$(A_t - A_{t-1})$	−7.024534	0.00

In all the cases, the p-values are less than a 5 % level of significance. Therefore, the null hypothesis is rejected at any case. Hence, the series are defined, by the augmented Dickey-Fuller tests, to be stationary.

10.5.2 Forecasting Dependent Variables

For the following models, the dependent variable is predicted for the year 2006, after adding in the dataset the values of the explanatory variables for the year 2006:
Model I

$$\begin{gathered} P_t = 8.5 - 5.1A_t + e_t \\ e_t = 1.05e_{t-1} + \varepsilon_t - 1.46\varepsilon_{t-1} \\ \varepsilon_t \sim N(0, \sigma^2). \end{gathered} \tag{10.36}$$

Model II

$$\begin{gathered} \frac{A_t}{P_{t-1}} = -0.004 + 0.99\frac{A_t - A_{t-1}}{P_{t-1}} + 1.04\frac{A_{t-1}}{P_{t-1}} + e_t \\ e_t = 1.5e_{t-1}0.84e_{t-2} + \varepsilon_t - 1.14\varepsilon_{t-1} + 0.52\varepsilon_{t-2} \\ \varepsilon_t \sim N(0, \sigma^2). \end{gathered} \tag{10.37}$$

Model III

$$\begin{gathered} \frac{P_t - P_{t-1} + d_t}{P_{t-1}} = 0.28 - 0.21\frac{A_t}{P_{t-1}} + e_t \\ e_t = 0.32e_{t-1} + 0.46e_{t-2} + \varepsilon_t + 0.92\varepsilon_{t-1} - 1.16\varepsilon_{t-2} \\ \varepsilon_t \sim N(0, \sigma^2). \end{gathered} \tag{10.38}$$

Table 10.2 The 1-year-ahead forecasts (year 2006) of the dependent variables for the nine models

Number of model	Best model	Forecast of the dependent variable
Model I	ARIMAX(1,0,1)	−1.066527
Model II	ARIMAX(2,0,2)	0.010287
Model III	ARIMAX(2,0,2)	−0.094187
Model IV	ARIMAX(2,0,2)	−0.236392
Model V	ARIMAX(0,1,1)	−0.715401
Model VI	ARIMAX(2,0,2)	0.059651
Model VII	ARIMAX(2,1,1)	0.372343
Model VIII	ARIMAX(2,0,2)	0.833744
Model IX	ARIMAX(2,1,2)	−4.755135

Model IV

$$\begin{gathered}\frac{P_t - P_{t-1} + d_t}{P_{t-1}} = -0.47 + 2.48\frac{A_{t-1}}{P_{t-1}} + e_t \\ e_t = 0.21e_{t-1} + 0.36e_{t-2} + \varepsilon_t - 0.68\varepsilon_{t-1} - 1.42\varepsilon_{t-2} \\ \varepsilon_t \sim N(0, \sigma^2).\end{gathered} \tag{10.39}$$

Model V

$$\begin{gathered}(1-L)\frac{P_t - P_{t-1} + d_t}{P_{t-1}} = 0.055 - 0.5\frac{A_t - A_{t-1}}{P_{t-1}} + e_t \\ e_t = \varepsilon_t - 1.52\varepsilon_{t-1} \\ \varepsilon_t \sim N(0, \sigma^2).\end{gathered} \tag{10.40}$$

Model VI

$$\begin{gathered}\frac{P_t - P_{t-1} + d_t}{P_{t-1}} = -0.33 - 2.6\frac{A_t - A_{t-1}}{P_{t-1}} + 2.4\frac{A_t}{P_{t-1}} + e_t \\ e_t = 0.4e_{t-1} + 0.3e_{t-2} + \varepsilon_t 0.37\varepsilon_{t-1} - 1.9\varepsilon_{t-2} \\ \varepsilon_t \sim N(0, \sigma^2).\end{gathered} \tag{10.41}$$

Model VII

$$\begin{gathered}(1-L)\frac{P_t - P_{t-1} + d_t}{P_{t-2}} = 0.2 - 0.76\frac{A_t}{P_{t-1}} + e_t \\ e_t = 0.1e_{t-1} + 0.3e_{t-2} + \varepsilon_t - 1.7\varepsilon_{t-1} \\ \varepsilon_t \sim N(0, \sigma^2).\end{gathered} \tag{10.42}$$

Model VIII

$$\begin{gathered}\frac{P_t}{P_{t-1}} = 1.3 - 0.22\frac{A_t}{P_{t-1}} + e_t \\ e_t = 0.31e_{t-1} + 0.46e_{t-2} + \varepsilon_t + 0.94\varepsilon_{t-1} - 1.1\varepsilon_{t-2} \\ \varepsilon_t \sim N(0, \sigma^2).\end{gathered} \tag{10.43}$$

Model IX

$$\begin{gathered}(1-L)(P_t-P_{t-1})=0.16-5.54(A_t-A_{t-1})+e_t\\ e_t=-0.25e_{t-1}+0.13e_{t-2}+\varepsilon_t-1.2\varepsilon_{t-1}-0.64\varepsilon_{t-2}\\ \varepsilon_t\sim N(0,\sigma^2).\end{gathered}\tag{10.44}$$

See Table 10.2

10.6 Conclusions and Suggestions for Further Future Research

This study denotes whether some standard models of market-based accounting research can explain stock returns in a different country than the USA and UK. In other words, in the Greek stock market, there is a memory of earnings in stock returns. Models I (price on earnings), II (returns on change in earnings divided by beginning-of-period price and prior period earnings divided by the price at the beginning of the return period), V (returns on change in earnings over opening market value), VII (returns deflated by lag of 2 years on earnings over opening market value), and IX (differenced-price model) have statistically significant coefficients of explanatory variables. In addition, model II with MSE (minimum squared error) loss function in ARIMAX (2,0,2) is prevalent. ARIMAX (2,0,2) is a representation of the ARIMAX (p,d,q) with two lags in autoregressive, after being differenced 0 times, with two lags in residuals.

Unlike the US market, in the Athens Stock Exchange, there is a far lower ratio of professional analysts per registered company, and management earnings forecasts are only recently and very rarely made publicly available which as fact makes earnings change and earnings level as determinant factor in stock returns. Further analysis in earnings components and revenues from sales may explain more satisfactorily the returns and earnings association. This is in the due course. The issuance of a law on 1985 (Presidential Decree 360/1985) for the publication of semiannual reports and the issuance of a law (2533/1997) for the publication of quarterly reports seem to have no effect on the main accounting moments employed in this study. Even the institutional changes such as liberalization of the auditing profession, corporate tax cuts, and the change in currency seem to have no effect on the models under investigation. The different business environment that is going to be formed with forecasted financial statements and the IAS(IFRS) may make the model selection a different task. Besides application of generalized autoregressive conditional heteroscedasticity (GARCH) models is suggested for further future research.

Contents

Abstract

In credit risk modeling, factor models, either static or dynamic, are often used to account for correlated defaults among a set of financial assets. Within the realm of factor models, default dependence is due to a set of common systemic factors. Conditional on these common factors, defaults are independent. The benefit of a factor model is straightforward coupling with a copula function to give an analytic formulation of the joint distribution of default times. However, factor models fail to account for the contagion mechanism of defaults in which a firm's

default risk increases due to their commercial or financial counterparties' defaults. This study considers a mixture of the dynamic factor model of Duffee (*Review of Financial Studies 12*, 197–226, 1999) and a contagious effect in the specification of a Hawkes process, a class of counting processes which allows intensities to depend on the timing of previous events (Hawkes. *Biometrika 58*(1), 83–90, 1971). Using the mixture factor-contagious-effect model, Monte Carlo simulation is performed to generate default times of two hypothesized firms.

The goodness-of-fit of the joint distributions based on the most often used copula functions in literature including the normal, *t*-, Clayton, Frank, and Gumbel copula, respectively, is assessed against the simulated default times. It is demonstrated that as the contagious effect increases, the goodness-of-fit of the joint distribution functions based on copula functions decreases, which highlights the deficiency of the copula function approach.

Static factor model • Dynamic factor model • Correlated defaults • Contagious effect • Hawkes process-Monte • Carlo simulation • Normal copula • *t*-copula • Clayton copula • Frank copula • Gumbel copula

11.1 Introduction

An understanding of correlated defaults of the underlying assets is fundamental to portfolio management and the pricing of credit derivatives such as a CDS contract, a CDO contract, or a basket default swap contract (Hull and White 2001; Zhou 2001; Das et al. 2006). There exist, however, different ways of introducing correlations when modeling assets' defaults. In Schönbucher (2003), a good modeling framework for correlated defaults should include (1) being able to produce default correlations of a realistic magnitude, (2) being able to model the timing of defaults, (3) being capable of reproducing default clustering periods, and (4) easily calibrated and implemented by keeping the number of parameters under control without growing dramatically with the number of assets.

In responding to these properties, two types of factor models coupled with a set of small number of common systemic factors have been followed in literature to account for default correlations. The first type of factor model is static in the sense that the modeling of default correlations among a set of I assets is based on the creditworthiness indices $X_1, \ldots, X_I$ at a specific time point T, which is analogous to Merton's structural model (1974) in which an asset defaults when its creditworthiness index falls below some threshold at a specific time point. The static factor model has been widely used for the computation of joint default and loss probability distribution in a portfolio (Vasicek 1997; Koyuoglu and Hickman 1998; Finger 2000; Schönbucher 2003). Portfolio credit risk models fit within this framework include CreditMetrics (1997) of JP Morgan, Credit Risk$^+$ of Credit Suisse Financial Products (1997), and KMV's portfolio manager (Kealhofer 1995).

In the static factor model, default dependence among a set of I assets is introduced by the correlations between the creditworthiness $X_1, \ldots, X_I$ and a set of common systemic economic factors. Conditional on these common systemic factors, the creditworthiness $X_1, \ldots, X_I$ are independent. Depending on the distributions imposing on these common systemic factors, a specific type of copula function can be used to obtain an analytical expression for the joint distribution of the default times for the I assets (Li 1999, 2000; Schönbucher 2003; Gregory and Laurent 2005).

The second type of factor models uses a more consistent framework to model correlated defaults via assets' default intensities that describe the evolution of instantaneous default probabilities dynamically over time. In parallel to the static factor model, the dynamic factor model generates default dependency among assets through a set of common factors. Conditioned to the realization of these common factors, the assets' defaults are independent. However, being different from the static factor model in which common factors affect assets' creditworthiness at a specific time horizon, the common factors in dynamic factor models affect assets' default intensities dynamically over time (Duffee 1999; Yu 2005; Driessen 2005; Elizalde 2005).

The benefit of a factor model, either static or dynamic, is its straightforward conjunction with a copula function to give an analytic formulation of the joint distribution of default times (Li 1999, 2000; Schönbucher and Schubert 2001; Schönbucher 2003; Gregory and Laurent 2005). In this way, model parameters can be readily inferred from the common systemic factors and individual assets' default times. The main drawback of a factor model, however, is that the likelihood of an asset's default does not change due to the defaults of any other assets, i.e., the default of one asset does not trigger the defaults of other related assets. While this might be adequate for production firms, it may be inadequate for studying the default risk of a financial institution with large positions in a few assets whose default can trigger the failure of other financial institutions (Lucas 1995; Jarrow and Yu 2001; Nagpal and Bahar 2001; Das et al. 2006). Under such circumstance, correlated defaults are due to counterparties' default risk. For this reason, the contagious default models in which the default intensity of an asset depends on the status (default/not default) of the other assets are proposed (Davis and Lo 2001; Jarrow and Yu 2001). These contagious default models allow extra-default dependence to be introduced compared to the factor models.

This study uses a mixture of a dynamic factor model by Duffee (1999) with a contagious effect as a benchmark model to generate simulated default times of two assets. Various copula functions that are often used in credit risk modeling, including the normal copula, t-copula, Clayton copula, Frank copula, and Gumbel copula, are employed to calibrate the simulated default times. As the contagious effect increases, the simulated default times show that the goodness-of-fit of the aforementioned copula functions decreases.

The paper is organized as follows. Section 11.2 introduces the static factor model and its link to the copula function approach. Section 11.3 introduces the dynamic factor model in a point process. Section 11.4 introduces the contagious effect model based on mutually exciting point processes. The theoretical foundations of the copula function approach are given in Sect. 11.5. A simulation study is given in Sect. 11.6. Section 11.7 concludes.

11.2 Dependence Structure in Static Factor Model

In a static factor model, the creditworthiness indices $X_1, \ldots, X_I$ of I assets at times $0 < t_1, \ldots, t_I \leq T$ are explained by 1 or a set of common systemic risk factors $Y_1, \ldots, Y_K$ in the form

$$X_i = \sum_{j=1}^{K} \rho_{ij} Y_j + \rho_{i(K+1)} \varepsilon_i$$

where ρ_{ij} determines the relative importance of asset i to the common factor Y_j and $\rho_{i(K+1)}$ the relative weight of idiosyncratic factor ε_i for asset i. To the extent that the creditworthiness indices are related to the common systemic factors $Y_1, \ldots, Y_K$, the likelihood of joint default events across assets varies accordingly. Here the common factors $Y_1, \ldots, Y_K$ and the idiosyncratic factors $\varepsilon_1, \ldots, \varepsilon_I$ are independent. In the following, for simplicity, we will consider a single factor Y and the ith asset's creditworthiness index:

$$X_i = \rho_i Y + \sqrt{1 - \rho_i^2}\, \varepsilon_i. \tag{11.1}$$

Equation 11.1 is the one-factor model adopted in CreditMetrics (Gupton et al. 1997). Since the default environment is completely determined by creditworthiness indices $X_1, \ldots, X_I$ at times $t_1, \ldots, t_I$, respectively, the factor model is static in that the dynamics of the firms' credit quality that evolves during the time horizon $[0, T]$ is ignored.

Suppose default of the ith asset occurs if the creditworthiness index X_i falls below a certain threshold u_i at time t_i and the marginal distribution functions

$$F_1(t_1) = \Pr(\tau_1 \leq t_1), \ldots, F_I(t_I) = \Pr(\tau_I \leq t_I)$$

of the default times $\tau_1, \ldots, \tau_I$ are given. The threshold u_i and the joint distribution of the default times $\tau_1, \ldots, \tau_I$ satisfy $F_i(t_i) = \Pr(X_i \leq u_i)$ and $\mathrm{F}(t_1, \ldots, t_I) = \Pr(X_1 \leq u_1, \ldots, X_I \leq u_I)$, respectively. By noting that conditional on the common factor Y, the creditworthiness indices $X_1, \ldots, X_I$ are independent and therefore

$$\Pr(X_1 \leq U_1, \ldots, X_I \leq U_I) = \int \left[\prod_{i=1}^{I} P(X_i \leq u_i | y) \right] f(y) dy.$$

If assuming the latent common factors Y and idiosyncratic factors $\varepsilon_1, \ldots, \varepsilon_I$ are standard normally distributed, then the creditworthiness indices X_i are also standard normally distributed. Therefore, the conditional probability

$$P(X_i \leq u_i|y) = \Phi\left(\frac{\Phi^{-1}(F_i(t_i)) - \rho_i y}{\sqrt{1-\rho_i^2}}\right)$$

And the joint distribution $F(t_1, \ldots, t_I)$ of default times $\tau_1, \ldots, \tau_I$ is linked to a one-factor normal copula function in the form

$$F(t_1,\ldots,t_I) = \int\left[\prod_{i=1}^{I}\Phi\left(\frac{\Phi^{-1}(F_i(t_i)) - \rho_i y}{\sqrt{1-\rho_i^2}}\right)\right]\phi(y)dy \tag{11.2}$$

where ϕ is the standard normal density function. Alternatively, one can assume that the latent common factor Y is Gamma distributed with parameter $1/\theta$ and let

$$P(X_i \leq u_i|y) = \exp\left(-y\varphi^{-1}(F_i(t_i))\right)$$

where $\varphi^{-1}(s) = s^{-\theta} - 1$ and φ is the generator. Then the joint distribution $F(t_1, \ldots, t_I)$ is linked to a one-factor Clayton copula function in the form

$$F(t_1,\ldots,t_I) = \int\left[\prod_{i=1}^{I}\exp\left(-y\varphi^{-1}(F_i(t_i))\right)\right]\phi(y)dy. \tag{11.3}$$

The Clayton copula function and its generator φ are given in Definition 2.7 of Appendix 2.

11.3 Dependence Structure in Dynamic Factor Model Using Intensity Function

In the dynamic factor model, as in the reduced-form model put forward by Jarrow and Turnbull (1995), Lando (1998), and Duffie and Singleton (1999a), default is treated as an unpredictable jump of a firm's value and the default time τ is treated as the time of the unpredictable jump. Often the unpredictable jump or default is considered as triggered by an exogenous event that occurs with an instantaneous likelihood specified by the intensity function of the first jump in a point process. The formal definition of a point process and properties of its intensity function are given in Definitions 1.1–1.2 of Appendix 1.

In the dynamic factor model, the intensity function of a default depends on certain exogenously determined stochastic common systemic factors X_t which induce correlated defaults among assets (Duffee 1999; Driessen 2005; Elizalde 2005; Yu 2005). In contrast to the static factor model, the evolution of these common factors over time is modeled, and conditional on the evolution of these common factors X_t, defaults are independent. The formulation of the default intensity as such is referred as a doubly Poisson point process (Lando 1998). In Definition 1.3, the properties of a point process and a (doubly) Poisson process are given. An example of a dynamic factor model is given in Duffee (1999), in which the default intensity of asset i is

$$\lambda_{i,t} = a_{0,i} + a_{1,i}\left(X_{1,t} - \overline{X}_1\right) + a_{2,i}\left(X_{2,t} - \overline{X}_2\right) + \lambda^*_{i,t}\psi$$

where $a_{0,i}$, $a_{1,i}$, and $a_{2,i}$ are constants and $X_{1,t}$ and $X_{2,t}$ are two latent factors interpreted as the slope and level of the default-free yield curve, i.e., the risk-free interest rate

$$r_t = a_r + X_{1,t} + X_{2,t}.$$

The asset's specific intensity $\lambda^*_{i,t}$, independent across assets, is assumed to obey a mean-reversion process

$$d\lambda^*_{i,t} = \kappa_i\left(\theta_i - \lambda^*_{i,t}\right)dt + \sigma_i^{\lambda}\sqrt{\lambda^*_{i,t}}\,dW_{i,t} \tag{11.4}$$

where $W_{1,t}, \ldots, W_{\mathrm{I},t}$ are independent Brownian motions. To introduce more default correlation, Duffie and Singleton (1999b) incorporate joint as well as idiosyncratic jumps in the default intensity $\lambda_{i,t}$.

In Das et al. (2007), the hypothesis whether default events can be modeled as a doubly Poisson point process that solely depends on "exogenous" factors is tested. Based on a time series of US corporate defaults, they strongly rejected the hypothesis that defaults can be modeled as a doubly Poisson point process. Instead of a factor model, in the following, the contagious model in which default status of other firms will affect the default intensity of the underlying asset will be considered.

11.4 Contagious Model: Mutually Exciting Intensity Function

Examples of contagious models include the infectious default model by Davis and Lo (2001) in which the intensity function follows a piecewise deterministic Markov process and the propensity model by Jarrow and Yu (2001). In the propensity model, firms are divided into K primary and I-K-1 secondary firms: the default intensities $\lambda_{1,t}, \ldots, \lambda_{K,t}$ of primary firms are determined by some exogenously common factors, while those of the secondary firms depend on the status (default or not) of the primary firms but not the other way around (asymmetric dependence). Specifically, the default intensity of the ith secondary firm is given by

$$\lambda_{i,t} = \overline{\lambda}_{i,t} + \sum_{j=1}^{K} a_{i,t}^{j} 1_{\{\tau_j \leq t\}} \tag{11.5}$$

where $K + 1 \leq i \leq I$. Here $\overline{\lambda}_{i,t}$ represents the part of secondary firm i's hazard rate independent of the default status of other firms.

Recently, Hawkes process, a class of counting processes which allow intensities to depend on the timing of previous events (Hawkes 1971), had been adopted to model the aggregate default intensity of a portfolio (Azizpour and Giesecke 2008; Errais et al. 2010). In Errais et al. (2010), the cumulated default intensity of n firms is specified by

$$\lambda(t) = \lambda_0 + \sum_{j=1}^{n} a e^{-\beta(t-\tau_j)} 1_{\{\tau_j \leq t\}}. \tag{11.6}$$

In Lando and Nielsen (2010), a total of 2,557 firms with an average of 1,142 and a minimum of 1,007 firms at any time throughout the sample period from January 1982 to December 2005 are used to calibrate the goodness-of-fit of an extended dynamic factor model that includes exogenously determined common factors as well as a contagion effect in terms of a Hawkes process. During the sampling period, 370 firms default and a contagious effect is concluded.

In this study, we simulate the default times of two firms using a mixture model based on a dynamic factor model of Duffee (1999) together with a contagious effect in the specification of a Hawkes process. Various commonly used copula functions are calibrated against simulated default times to demonstrate the copula functions in the modeling of credit default risk.

11.5 Copula Functions

Copulas, introduced by Sklar (1959), have been extensively applied in areas such as actuarial science using survival data. It was adopted by Li (2000) and Gregory and Laurent (2005) to the application in modeling the joint distribution of the default times $\tau_1, \ldots, \tau_I$ of a set of I firms. According to Sklar (1959), for any continuous joint distribution $F(t_1, \ldots, t_I)$, there exists a uniquely determined I-dimensional copula $C_F(u_1, \ldots, u_I)$, where $u_i = F(t_i)$, $1 \leq i \leq I$, such that for all $(t_1, \ldots, t_I)$ in R^I,

$$F(t_1, \ldots, t_I) = C_F(F_1(t_1), \ldots, F_I(t_I)). \tag{11.7}$$

In Definition 2.1, the formal definition of a copula is given. The theorem by Sklar (1959) is given in Appendix 2.

According to Sklar (1959), as the existence of the copula function C_F is guaranteed, the joint distribution F of default times $\tau_1, \ldots, \tau_I$ can be obtained via Eq. 11.7 given the marginal distributions $F_1, \ldots, F_I$ of individual default times. However, the analytic formulation of the specific copula function C_F is usually unknown and even intractable. For this reason, some copula functions are chosen in an ad hoc way in credit risk modeling. The most often used copulas are the normal copulas (Li 2000; Frey et al. 2001; Gregory and Laurent 2005). However, normal copula presents no tail dependency and has been criticized for not assigning enough probability for the occurrence of extreme events.

To account for tail dependency, the double-*t*-copula or a member of the Archimedean-type copulas can be used. The *t*-copula is radically symmetric in that its lower and upper tail dependence is the same. In case lower tail dependence is desired, the Clayton copula should be used, while a Gumbel copula should be used for upper tail dependence. However, the Gumbel copula does not allow for negative dependence. To compare these copulas, three indices to measure the dependence structure between two random variables introduced by the copula function are given in Definitions 2.3–2.4, respectively. The three dependence measures include the global dependent measure, i.e., Kendall's tau, and two tail dependent measures, i.e., the upper/lower tail dependence coefficients.

Instead of tail dependence, this study focused on the dependent structure of the firms' default times due to contagious effects. Schönbucher and Schubert (2001) study the dynamics of default intensities and show that a Clayton copula, a member of the Archimedean copula family, is related to the contagious models of Davis and Lo (2001) and Jarrow and Yu (2001). In the following simulation study based on a mixture of the dynamic factor model of Duffee (1999) and a contagious effect specified by a Hawkes process, the aforementioned copula functions are calibrated against the simulated default times generated by the mixture model to test the goodness-of-fit of the copulas when contagious effect is present.

11.6 Simulation Study

A simulation based on a mixture of the dynamic factor model of Duffee (1999) incorporated with contagious effect specified by a Hawkes process is performed here. In Duffee (1999), a firm's default intensity is determined by two factors $X_{1,t}$ and $X_{2,t}$, where $X_{1,t}$ and $X_{2,t}$ are the two latent components of the risk-free interest rate $r_t = a_r + X_{1,t} + X_{2,t}$. The latent components $X_{j,t}$, $j = 1, 2$, obeys the mean-reversion process:

$$dX_{j,t} = \eta_j\left(\mu_j - X_{j,t}\right)dt + \sigma_j^X\sqrt{X_{j,t}}dW_{j,t}^X \tag{11.8}$$

where $W_{1,t}^X$ and $W_{2,t}^X$ are two independent Wiener processes. To account for counterparty default risk, however, a modification is made on the default intensity in Eq. 11.8 by including the default status of the other firm(s). For the two-firm case, the default intensities are, respectively,

Table 11.1 Parameter specification for mixture model

Panel a:			
i	κ_i	θ_i	σ_j^λ
1	0.023	0.0036	0.051
2	0.600	0.1407	0.104
Panel b:			
j	a_r	$\eta_j\mu_j$	σ_j^X
1	−10.474	1.003	0.0134
2	−10.032	0.060	0.0449
Panel c:			
i	$a_{0,i}$	$a_{1,i}$	$a_{2,i}$
1	0.0132	–0.142	0.001
2	0.0196	0.001	0.062

This table reports the parameter values of the proposed mixture model. In Panel a, the parameter values in the mean-reversion process in Eq. 11.4 for the two firms ($i = 1,2$), respectively, are given. In Panel b, parameter values of the latent components $X_{j,t}$ ($j = 1,2$) in Eq. 11.8 are given. In Panel c, parameter values of default intensities $\lambda_i(i = 1,2)$ in Eqs. 11.9 and 11.10, respectively, are given

$$\lambda_{1,t} = a_{0,1} + a_{1,1}\left(X_{1,t} - \overline{X}_1\right) + a_{2,1}\left(X_{2,t} - \overline{X}_2\right) + \lambda_{1,t}^* + \alpha e^{-\beta(t-\tau_2)} 1_{\{\tau_2 \le t\}} \tag{11.9}$$

$$\lambda_{2,t} = a_{0,2} + a_{1,2}\left(X_{1,t} - \overline{X}_1\right) + a_{2,2}\left(X_{2,t} - \overline{X}_2\right) + \lambda_{2,t}^* + \alpha e^{-\beta(t-\tau_1)} 1_{\{\tau_1 \le t\}} \tag{11.10}$$

where τ_1 and τ_2 are the default times of the 1st and 2nd firm, respectively. The firm's specific default intensities $\lambda_{1,t}^*$ and $\lambda_{2,t}^*$ are assumed to follow the mean-reversion processes in Eq. 11.4.

The values of the parameters κ_i, θ_i, η_j, μ_j, $a_{0,i}$, $a_{1,i}$, $a_{2,i}$, σ_j^X, $1 \le i \le 2$, $1 \le j \le 2$ are from Duffee (1999), in which month-end prices of noncallable corporate bonds from January 1985 to December 1995 across 161 firms, with majority of investment grade bonds, are used to calibrate default intensity process. In Table 11.1, the parameter values used are given. Two cases with different contagious effects are considered in the study. In the first case, the parameter α that specifies the contagious effect is set to 0.1, while the α value is 0.25 in the second case. For each case, 10,000 pairs of simulated default times for the two firms are generated.

Five different copula functions are considered to fit the empirical joint distribution of the default times τ_1 and τ_2. They are the normal, *t*-, Clayton, Frank, and Gumbel copula, respectively. For the normal and *t*-copula, the parameter ρ is set to the empirical correlation coefficient of the simulated default times. Minimum mean squares error is used to obtain the estimated parameter values of the degree of freedom v in *t*-copula and θ in Clayton, Frank, and Gumbel copula, respectively.

In Table 11.2, the estimated parameters for the five copula functions and the corresponding sum squares of errors (SSE) are given. As can be seen in Table 11.2,

Table 11.2 Parameter estimation of copula functions

Case I: $\alpha = 0.1$		
Copula type	SSE	Parameter estimation
Normal	0.2394	$\rho = 0.2137$
t-copula	0.1650	$\rho = 0.2137$, d.f. $= 10$
Clayton	0.6043	$\theta = 0.51$
Frank	0.1695	$\theta = 1.70$
Gumbel	0.1591	$\theta = 1.15$
Case II: $\alpha = 0.25$		
Copula type	SSE	Parameter estimation
Normal	0.3867	$\rho = 0.4687$
t-copula	0.2213	$\rho = 0.4687$, d.f. $= 3$
Clayton	1.4439	$\theta = 1.51$
Frank	0.4525	$\theta = 3.75$
Gumbel	0.1431	$\theta = 1.45$

This table reports the estimated parameters of the normal, t-, Clayton, Frank, and Gumbel copulas. For the parameter ρ, empirical correlation of the simulated default times is used. SSE is used to obtain the estimates of the degree of freedom (d.f.) for the t-copula and the parameter θ for the Clayton, Frank, and Gumbel copula, respectively

the normal copula is outperformed by the t-, Frank, and Gumbel copulas when $\alpha = 0.10$, while outperformed by the t- and Gumbel copulas only when $\alpha = 0.25$. It can also be seen that as the contagious effect parameter α increases from 0.10 to 0.25, except the Gumbel copula, the SSEs also increase significantly for the normal, t-, Clayton, Frank, and Gumbel copulas. In both cases, i.e., $\alpha = 0.10$ and $\alpha = 0.25$, the Gumbel copula performs the best while the Clayton copula performs the worst among the five copula approximations.

In Figs. 11.1 and 11.2, the contour plots of the differences between the empirical and copula-based joint distribution functions when the contagious effect parameter $\alpha = 0.10$ and $\alpha = 0.25$, respectively, are given. For the normal copula, as can be seen in Fig. 11.1 (panel a), larger deviations from the empirical joint distribution occur when the default times τ_1 and τ_2 are in the range from 5 to 10 years when $\alpha = 0.10$. When $\alpha = 0.25$, as illustrated in Fig. 11.2 (panel a), larger deviations occur in the range from 5 to 15 years. For the t-copula, larger deviations from the empirical joint distribution occur when the default times τ_1 and τ_2 are in the range from 5 to 10 years when $\alpha = 0.10$. However, in panel b of Fig. 11.2 where $\alpha = 0.25$, in addition to the range between 5 and 10 years, the t-copula fails to approximate the empirical joint distribution well for small default times τ_1 and τ_2. This implies that as the contagious effect increases, the t-copula does not explain the lower tail dependence well. In panel d of Figs. 11.1 and 11.2, when using the Gumbel copula, larger deviations occur when the default times τ_1 and τ_2 are in the range from 2 to 7 years. This indicates that the Gumbel copula does not approximate well for smaller default times.

Taken together, the goodness-of-fit of the normal, t-, Clayton, Frank, and Gumbel copula, respectively, decreases as the contagious effect parameter α increases. This phenomenon is more apparent for the Frank copula. The contour plots of the

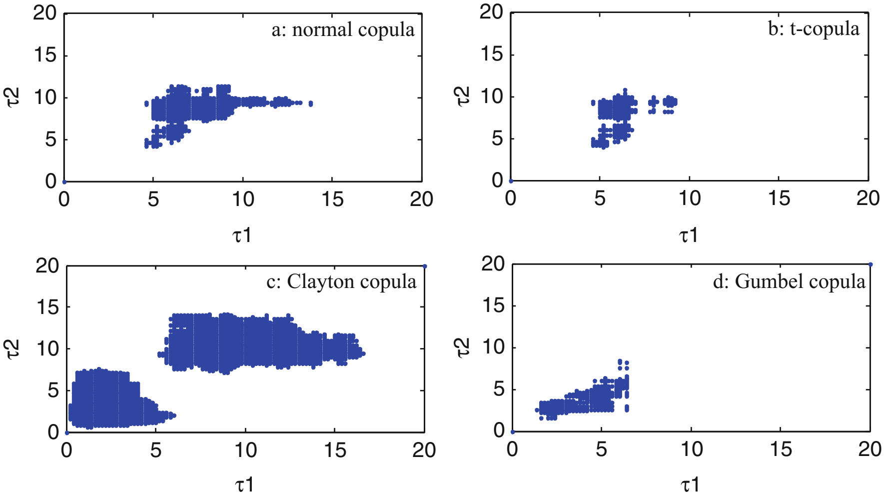

Fig. 11.1 Contours of Differences between Empirical Joint Distribution and Copula Approximation. Note Panels a-d show the contours of differences with absolute values exceeding 0.01 for normal, t-Clayton, and Gumbel copula, respectively. The contagious effect parameter a is 0.1

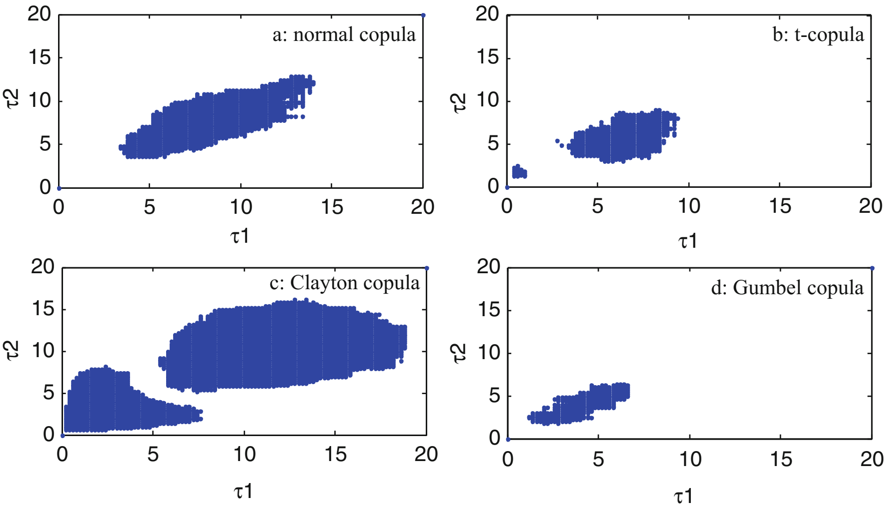

Fig. 11.2 Contours of Differences between Empirical Joint Distribution and its Copula Approximation. Note Panels a-d show the contours of differences with absolute values exceeding 0.01 for normal, t-Clayton, and Gumbel copula, respectively. The contagious effect parameter a is 0.25

differences between the empirical and Frank copula-based joint distribution functions when the contagious effect parameter $\alpha = 0.10$ and $\alpha = 0.25$, respectively, are given in Panel a–b of Fig. 11.3. As can be seen in Fig. 11.3, when $\alpha = 0.10$, the Frank copula fails to approximate the empirical distribution well only for small default

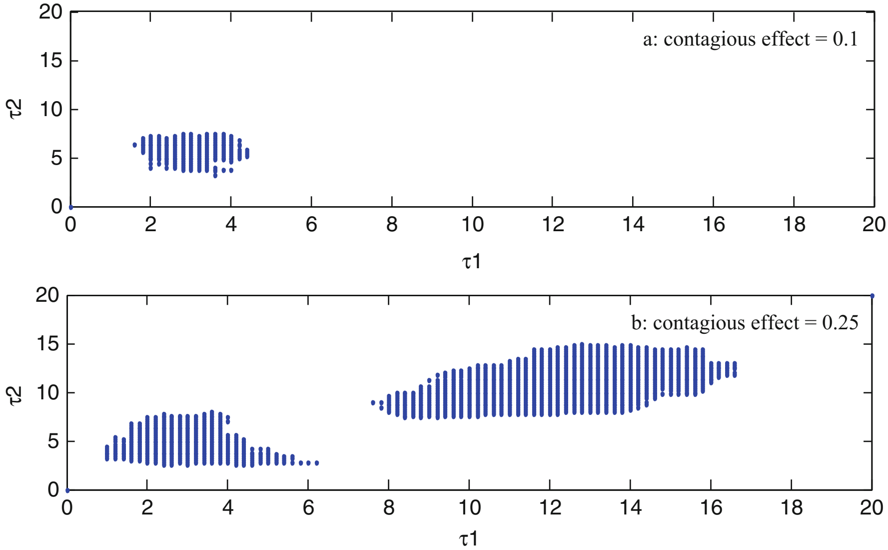

Fig. 11.3 Contours of Differences between Empirical Joint Distribution and its Frank Copula Approximation. Note Panels a–d show the contours of differences with absolute values exceeding 0.01 for normal, t-Clayton, and Gumbel copula, respectively. The contagious effect parameter a is 0.1 and 0.25

times τ_1 and τ_2. As the contagious effect parameter $\alpha = 0.25$, however, the Frank copula fails to approximate the empirical distribution well not only for small default times τ_1 and τ_2 but also larger τ_1 and τ_2. This can also be seen in Table 11.2, where the SSE increases from 0.1695 to 0.4525 as α increases from 0.10 to 0.25.

11.7 Conclusion

As a firm's default determines the economic opportunities available, it is very likely that the status of firms' defaults will affect one another. That is, a firm's default might have contagious effect on other firms' defaults. As a result, one often observes firms' default simultaneously. This study demonstrates that the copula functions from literature do not necessarily, and most unlikely, match the joint distribution F of the correlated default times $\tau_1, \ldots, \tau_I$ of a set of I firms as the contagious effect is increasing.

Five of the most often used copula functions in literature, namely, the normal, *t*-, Clayton, Frank, and Gumbel copulas, are under study. Among the five copula functions, the Clayton copula performs the worst, whereas the Gumbel copula performs the best. Except the Gumbel copula, the goodness-of-fit of the other four copulas decreases as the contagious effect increases. This suggests further advanced statistical tool for the modeling of contagious defaults in a more consistent and accurate way is in need.

Appendix 1: Point Process and Its Intensity

Let (Ω, H, P) be a probability space, where P is a physical measure. A formal definition of a point process is given below.

Definition 1.1 A point process N with stopping times $\tau_1, \tau_2, \ldots . \in [0,T]$ is a counting measure on the probability space (Ω, H, P) in that for any Borel subset $E \subseteq [0,T]$, the counting measure $N(E)$ represents the number of time points $\tau_1, \tau_2, \ldots$, in E.

Let $\{H_t: t \in [0, T]\}$ be a filtration on (Ω, P) so that H_t contains the accumulated information generated by a point process N till time t. The notion of the compensator of the point process N is given below.

Definition 1.2 Define the compensator A of the point process N as the unique random measure on (Ω, P) such that:

i. A is H_t-predictable.

ii. For every nonnegative H_t-predictable process H,

$$E\left(\int_0^T HdN\right) = E\left(\int_0^T HdA\right).$$

The characterization of the compensator A is essential to the statistical inference of the point process N in that the compensated process $M(t) = N(t) - A(t)$, $t \in [0,T]$ is a martingale under P. In this case a positive, H_t-predictable process $\lambda(t)$ exists so that

$$A(t) = \int_0^t \lambda(s)ds.$$

Then $\lambda(t)$ is called the intensity process of the point process N. The H_t-predictable intensity has the x dt, the probability one of the stopping time τ_k that occurs during $(t\text{-}dt,t]$ is

$$P[N(t-dt,t] = 1|H_t-] = \lambda(t)dt + \mathrm{o}(dt).$$

Definition 1.3 If the compensator process $A(t)$ is continuous and deterministic, then the point process $N(t)$ is a Poisson process. A doubly stochastic Poisson process $M(t)$ is a point process in which the intensity process $\lambda(t)$ is F_t-predictable, where F_t contains the accumulated information generated by the point process M till time t and the entire trajectory $\{\lambda(s): s > 0\}$. Conditioning on one realization of the intensity process $\{\lambda(s): s > 0\}$, the point process $M(t)$ is an inhomogeneous Poisson process.

Appendix 2: Copula Functions

Basically, a copula function C links the joint distribution $F(y_1, \ldots, y_I)$ of I multivariate random variables $Y_1, \ldots, Y_I$ to their univariate marginal distributions $F_1(y_1), \ldots, F_I(y_I)$. A formal definition of a copula function is given as follows.

Definition 2.1 A function C: $[0, 1]^N \rightarrow [0, 1]$ is a copula if there are uniform random variables $U_1, \ldots, U_N$ taking values in [0, 1] such that C is their joint distribution function that satisfies:

1. $C(1, \ldots, 1, u_i, 1, \ldots, 1) = u_i$ for all $i = 1, \ldots, N$ and $u_i \in [0, 1]$.
2. For all $\boldsymbol{u} \in [0, 1]^N$, $C(\boldsymbol{u}) = 0$ if at least one coordinate $u_i = 0$, $i = 1, \ldots, N$.
3. For all $\boldsymbol{u} \in [0, 1]^N$, $\boldsymbol{v} \in [0, 1]^N$ with $u_i \leq v_i$, $i = 1, \ldots, N$, the C volume of the hypercube

$$\sum_{i_1=1}^{2} \cdots \sum_{i=1}^{2} (-1)^{i_1+\ldots+i_N} C(w_{i_1}, \ldots, w_{i_N}) \geq 0$$

where $w_{i_k} = u_k$ if $i_k = 1$ else $w_{i_k} = v_k$.

The theoretical groundwork of applying a copula function is based on Sklar's theorem (Sklar 1959) in the following:

Theorem 2.2 Let $\tau_1, \ldots, \tau_I$ be random variables with marginal distribution functions $F_1, \ldots, F_I$ and joint distribution function F. Then there exists an I-dimensional copula C such that

$$F(t_1, \ldots, t_I) = C(u_1, \ldots, u_I) = C(F_1(t_1), \ldots, F_I(t_I))$$

for all $(t_1, \ldots, t_I)$ in R^I, where $u_i = F(t_i)$, $1 \leq i \leq I$. Moreover, if each F_i is continuous, then the copula C is unique.

In order to calibrate a copula, indices that measure the dependence structure introduced by the choice of the copula function are used. We focus on three dependence measures that depend only on the copula function, not in the marginal distributions. Among the three dependence measures, Kendall's *tau* is the measure of global dependence, while upper/lower tail dependence coefficients are two local measures of dependence.

Definition 2.3 Let F be the joint distribution of two random variables X_1 and X_2 with marginal F_1 and F_2, respectively. Kendall's *tau* is the probability of concordance minus the probability of discordance. Specifically, if (X_1, X_2) and (X_1', X_2') are two realizations of F, then Kendall's *tau* is defined as

$$P\left[\left(X_1 - X_1'\right)\left(X_2 - X_2'\right) > 0\right] - P\left[\left(X_1 - X_1'\right)\left(X_2 - X_2'\right) < 0\right] \qquad (11.11)$$

If C is the copula of the joint distribution F, i.e., $C(u_1, u_2) = C(F_1(x_1), F_2(x_2))$, Kendall's *tau* is

$$tau = 4\int_0^1\int_0^1 C(u,v)dC(u,v) - 1.$$

Definition 2.4 Let $F(X_1, X_2)$ be the joint distribution of two random variables X_1 and X_2, with marginal F_1 and F_2. The coefficients of upper and lower tail dependence are defined, respectively, as

$$\lambda_U = \lim_{u\uparrow 1} \Pr\left[X_1 > F_1^{-1}(u) \middle| X_2 > F_2^{-1}(u)\right]$$
$$\lambda_L = \lim_{u\downarrow 0} \Pr\left[X_1 < F_1^{-1}(u) \middle| X_2 < F_2^{-1}(u)\right].$$

Definition 2.5. (Normal Copula) The I-dimensional normal copula is expressed as

$$C(u_1, \ldots, u_{\boldsymbol{I}}) = \Phi_\Sigma^I\left(\Phi^{-1}(u_1), \ldots, \Phi^{-1}(u_I)\right),$$

where Σ is a positive-definite correlation matrix, Φ_Σ^I is the distribution function of an I-dimensional multivariate normal random vector with correlation matrix Σ, and Φ^{-1} is the inverse of the distribution function of a standard normal random variable. The density function c of $C(u_1, \ldots, u_{\boldsymbol{I}})$ is

$$c(u_1, \ldots, u_{\boldsymbol{I}}) = \frac{1}{|\Sigma|^{1/2}} \exp\left(\frac{1}{2}\boldsymbol{\zeta}'\left(\Sigma^{-1} - \mathrm{I}_{I\times I}\right)\boldsymbol{\zeta}\right)$$

where $\boldsymbol{\zeta}' = (\Phi^{-1}(u_1), \ldots, \Phi^{-1}(u_I))$, and $\mathrm{I}_{I\times I}$ is the unity matrix. For a normal copula, the relationship between the linear correlation coefficient ρ and Kendall's *tau* is

$$\rho = \sin(2\pi \times tau). \tag{11.12}$$

On the other hand, the coefficients of upper and lower tail dependence are both zero, i.e., a normal copula is tail independent.

Definition 2.6 (*t*-Copula) The I-dimensional t-copula is expressed as

$$C(u_1, \ldots, u_{\boldsymbol{I}}) = t_{v,\Sigma}^I\left(t_v^{-1}(u_1), \ldots, t_v^{-1}(u_I)\right)$$

where $t_v{}^{-1}$ denotes the inverse of the distribution function of a univariate t-student random variable with v degrees of freedom and $t_{v,\Sigma}^I$ denotes the distribution function of a multivariate t-distribution with v degrees of freedom and positive-definite dispersion matrix Σ. Its density function is

$$\frac{\left(\Gamma\left(\frac{v}{2}\right)\right)^{I-1}\Gamma\left(\frac{v+I}{2}\right)\left(1+\frac{\boldsymbol{\zeta}'\Sigma^{-1}\boldsymbol{\zeta}}{v}\right)^{-\frac{v+I}{2}}}{\left(\Gamma\left(\frac{v+1}{2}\right)\right)^{I}|\Sigma|^{-\frac{1}{2}}\,{}_{i=1}^{I}\left(1+\frac{\zeta_i^2}{v}\right)^{-\frac{(v+1)}{2}}}$$

where $\boldsymbol{\zeta}' = (t_v^{-1}(u_1), \ldots, t_v^{-1}(u_I))$. For a t-copula, the relationship between the linear correlation coefficient ρ and Kendall's *tau* is the same as Eq. 11.12. The coefficients of upper and lower tail dependence are

$$\lambda_U = \lambda_L = 2 - 2t_v\left(\frac{(v+1)(1-\rho)}{1+\rho}\right)^{1/2}.$$

Definition 2.7 (Archimedean Copula) The I-dimensional Archimedean copula can be expressed as

$$C(u_1, \ldots, u_I) = \phi^{-1}\left(\sum_{i=1}^{I} \phi(u_i)\right) \tag{11.13}$$

where the generator ϕ is a continuous strictly decreasing function from [0, 1] to $[0, \infty]$ satisfying $\phi(0) = \infty$ and $\phi(1) = 0$. In particular, when the generator

$$\phi(u) = \frac{u^{-\theta} - 1}{\theta}, \theta \geq 0$$

then Eq. 11.13 is called a Clayton copula. When the generator

$$\phi(u) = -\ln\left(\frac{e^{-\theta u} - 1}{e^{-\theta} - 1}\right), \theta \neq 0$$

Equation 11.13 is called a Frank copula. When the generator $\phi(u) = (-\ln u)^{\theta}$, $\theta \geq 1$, Eq. 11.13 is a Gumbel copula. In particular, the density function of a Clayton copula is

$$c(u_1, \ldots, u_I) = \left(1 - I + \sum_{i=1}^{I} u_i^{-\theta}\right)^{-I-1/\theta} \prod_{i=1}^{I}\left[u_i^{-\theta-1}((i-1)\theta + 1)\right]. \tag{11.14}$$

For a Clayton copula, Kendall's *tau* and tail dependency measures are

$$tau = 1 + 4\int_0^1 \frac{u^{\theta} - 1}{\theta u^{\theta-1}} du = \frac{\theta}{\theta - 2}$$

$$\lambda_U = 2 - 2\lim_{v \to 0} \frac{\phi'(2v)}{\phi'(v)} = 0$$

$$\lambda_L = 2\lim_{v \to 0} \frac{\phi'(2v)}{\phi'(v)} = 2$$

where the function $\varphi(u) = \phi^{-1}(v)$ is the inverse of the generator ϕ.

Abstract

In the study of economic and financial panel data, it is often important to differentiate between time series and cross-sectional effects. We present two estimation procedures that can do so and illustrate their application by examining international variations in expected equity premia and financial architecture where a number of variables vary across time but not cross-sectionally, while other variables vary cross-sectionally but not across time. Using two different estimation procedures, we find a preference for market financing to be negatively associated with the size of expected premia. However, we also find that US corporate bond spreads negatively determine financial architecture according to the first procedure but not according to the second estimation as US corporate bond spreads change value each year but have the same value across countries. Similarly some measures that change across countries but do not change across time, such as cultural dimensions as well as the index of measures against self-dealing, are significant determinants of financial architecture according second estimation but not according to the first estimation. Our results show that using these two estimation procedures together can assess time series versus cross-sectional variations in panel data. This research should be of considerable interest to empirical researchers.

We illustrate with simultaneous-equation modeling. Following a Hausman test to determine whether to report fixed or random-effects estimates, we first report random-effects estimates based on the estimation procedure of Baltagi (Baltagi 1981; Baltagi and Li 1995; Baltagi and Li 1994). We consider that the error component two-stage least squares (EC2SLS) estimator of Baltagi and Li (1995) is more efficient than the generalized two-stage least squares (G2SLS) estimator of Balestra and Varadharajan-Krishnakumar (1987). For our second estimation procedure, for comparative purposes we use the dynamic panel modeling estimates recommended by Blundell and Bond (1998). We employ the model of Blundell and Bond (1998), as these authors argue that their estimator is more appropriate than the Arellano and Bond (1991) model for smaller time periods relative to the size of the panels. We also use this two-step procedure and use as an independent variable the first lag of the dependent variable, reporting robust standard errors of Windmeijer (2005). Thus, our two different panel estimation techniques place differing emphases on cross-sectional and time series effects, with the Baltagi-Li estimator emphasizing cross-sectional effects and the Blundell-Bond estimator emphasizing time series effects.

12.1 Introduction

Recently, there has been a veritable explosion of studies in a wide variety of areas that employ panel data econometric methodology. Analysis of panel data allows independent variables to vary both cross-sectionally and across time, while panel data econometrics correct for cross-correlations between time series and cross-sectional error terms. In recent years there has been the introduction of a number of new refinements in analyzing panel data (Petersen 2009; Wooldridge 2010), all maintaining the goal of accounting for cross-correlation between time series and cross-sectional error terms when assessing coefficient significance.

However, in the study of economic and financial panel data, it is often important to assess the differential impact of time series versus cross-sectional effects; but panel data techniques are unclear how this may be accomplished. In other words, panel data methodologies typically do not inform us fully regarding which effect (time series or cross-sectional) is more important or more dominant within particular data sets or contexts. In this chapter we employ two contrasting estimation procedures, which, respectively, emphasize cross-sectional versus time series differences, to clarify the impacts of these two influences. We undertake this comparison of econometric methods within a finance-related context which takes into account possible endogeneity.

We illustrate with simultaneous-equation modeling (outlined below). Following a Hausman test to determine whether to report fixed or random-effects estimates, we first report random-effects estimates based on the estimation procedure of Baltagi (1981; Baltagi and Li 1994, 1995). We consider that the error component two-stage least squares (EC2SLS) estimator of Baltagi and Li (1995) is more efficient than the generalized two-stage least squares (G2SLS) estimator of Balestra and Varadharajan-Krishnakumar (1987).

For our second estimation procedure, for comparative purposes we use the dynamic panel modeling estimates recommended by Blundell and Bond (1998). We employ the model of Blundell and Bond (1998), as these authors argue that their estimator is more appropriate than the Arellano and Bond (1991) model for smaller time periods relative to the size of the panels. We also use the two-step procedure, reporting robust standard errors of Windmeijer (2005). Within this modeling we use as an independent variable the first lag of the dependent variable. Thus, our two different panel estimation techniques place differing emphases on cross-sectional and time series effects, with the Baltagi-Li estimator emphasizing cross-sectional effects and the Blundell-Bond estimator emphasizing time series effects.

Regarding the context of this econometric study, recent research suggests that both national variations in the structures of financial intermediation and equity premia are determined by many similar socioeconomic factors so that national variations in equity premia can be expected to influence national variations in the structure of financial intermediation and vice versa. But, until very recently prior literatures in these two areas have ignored each other and the resulting possible endogeneity problems. Recent exceptions include Aggarwal and Goodell (2011a, b), both of which examine the role of financial architecture in determining nations' equity premia. In this chapter we use this economic context to illustrate two differing estimation procedures.

We find that a number of independent variables used in this study significantly determine financial architecture across nations and across time. While a number of our results are consistent across differing estimation procedures, we also document a number of results that differ according to the two estimation procedures. After controlling for outliers and serial correlation in further robustness checks, we find that some significant differences remain, differences that help assess the relative influence of time series versus cross-sectional variations.

We document, using the two different estimation procedures, a preference for market financing to be negatively associated with the size of expected premia, However, after controlling for multicollinearity and serial correlation in robustness checks, we also find that US corporate bond spreads negatively determine financial architecture according to the first procedure but not according to the second estimation as US corporate bond spreads change value each year but have the same value across countries. Similarly some measures that change across countries but do not change across time, such as cultural dimensions as well as the index of measures against self-dealing, are significant determinants of financial architecture according to the second estimation but not according to the first estimation. We conclude from our presented example that the two estimation procedures can produce results with different emphases with regard to cross-sectional and time series effects.

12.2 Literature

12.2.1 Panel Data Estimation Procedures: Time Series Versus Cross-Sectional Effects

In recent years, the development of panel data econometrics has facilitated a large increase in scholarship where panel data models are applicable. This is particularly the case in international finance where data can be described across countries and time as well as across industries and time. The development of panel data methods has followed from the introduction by Hansen (1982) of Generalized Method of Moments (GMM). GMM, including the use of instrumental variables, allows the implementation of consistent estimations based on conditional expectations which are inconsistent with the use of earlier methods such as ordinary least squares regression.

Dynamic effects can render the fixed-effects estimator of panel models biased and inconsistent, especially for data covering finite and short time periods. Among alternative estimators that control for persistence is the system Generalized Method of Moments (GMM) estimator proposed by Blundell and Bond (1998). This procedure addresses econometric problems such as regressor endogeneity, measurement error, and weak instruments while controlling for time-invariant, country-specific effects such as distance or common language. Arellano and Bond (1991) suggest transforming the model, either in the first differences or in orthogonal deviations, to eliminate the fixed effects and to estimate it by using the two-step GMM estimator. The second and higher lags of the endogenous variable in levels are suitable instruments to overcome the estimation problem. However, when data are highly persistent, Blundell and Bond (1998) argue that this procedure can be improved by using the system – GMM estimation – which supplements the equations in the first differences with equations in levels. For the equations in the first differences, the instruments used are the lagged levels, and for the equations in levels, the instruments are the lagged differences.

In addition, the use of simultaneous-equation modeling on the same data set allows us to assess the results using the Blundell and Bond estimation procedure against an alternative. Following a Hausman test to determine whether to report fixed or random-effects estimates, we report random-effects estimates based on the estimation procedure of Baltagi (1981; Baltagi and Li 1994, 1995). We believe that the error component two-stage least squares (EC2SLS) estimator of Baltagi and Li (1995) is more efficient than the generalized two-stage least squares (G2SLS) estimator of Balestra and Varadharajan-Krishnakumar (1987) because of a broader set of transformations of the instruments.

It is very useful to examine the differences obtained with these two estimation procedures. These two panel data estimation procedures have different emphases with regard to cross-sectional versus time series effects. Because of the nature of their construction, while the Baltagi-Li estimator emphasizes cross-sectional effects, the Blundell-Bond estimator emphasizes time series effects.

12.2.2 Financial Architecture, Transactions Costs, and Risks

The channeling of funds from savers to investors, or financial intermediation, is a necessary function in all countries and is generally undertaken primarily through financial institutions and/or through financial markets. Either financing channel must resolve the issues of asymmetric information, adverse selection, and agency costs involved in financing contracts that cover the monitoring and collection of funds provided by savers to investors. Given that all optimal contracts are incomplete, the efficacy and efficiency of overcoming contracting costs depends on the nature of "hold-up" costs in a country, i.e., the ability and willingness of the contracting parties to try and take advantage of each other.

This ability and willingness to take advantage of the other party in incomplete contracts depend not only on industrial structure and the legal environment (reflecting the relative power of the contracting agents and legal constraints on their behavior) but also on ethical and other informal conventions that depend on social and cultural values. As these differ from country to country and given that institutions and markets differ in how they enforce incomplete contracts, financial institutions may be optimal in some combinations of ethical, cultural, and social conditions, while financial markets may be optimal in other conditions, and financial institutions may be favored in some countries, while financial markets are favored in other countries. Recent research notes that national preferences for market financing increase with political stability, societal openness, economic inequality, and equity market concentration and decrease with regulatory quality and ambiguity aversion (e.g., Modigliani and Perotti 2000; Ergungor 2004; Kwok and Tadesse 2006; Aggarwal and Goodell 2009).

Of course, as noted by Coase (1960), in a theoretically ideal and perfect financial system, it would make no difference whether financial intermediation was privately done through banks or publicly through markets. However, in reality many factors must be considered. According to North (1990), the costliness of information needed for measurement and enforcement of exchanges creates "transaction costs." Transaction costs involve costs of defining property rights and costs of enforcing contracts – including costs of information. "Transformation costs" are the costs associated with using technology and the efficiency of factor and product markets and are reflected in transactions costs. Whether institutions lower or raise overall transactions costs has to do in part with the ability of participants to be informed and to understand the nature of the particular institutional environment. This includes not just understanding the nature of contracts and their enforceability but also the temperament and motivations of other participants.

Additional transactions costs may also be associated with market transactions. As noted by Williamson (1988) and others more recently (e.g., Aggarwal and Zhao 2009), Transaction Cost Economics (TCE) suggests that when the costs of market exchange are sufficiently high, firms can obtain cheaper financing through some other means. The alternative to market financing is typically through some sort of a prescribed arrangement, such as a bank loan or, more broadly, through a prescribed transfer of resources through a horizontal or vertical network. Hart (1995, 2001) recognize that the primary transaction costs of market exchanges stem from the uncertainties of contracts. From the point of view of the equity investor, obtaining reliable information about firms is innately costly and, to some degree, fallible. These costs will be shared with the supplier of equity, causing equity financing to be more costly for the firm. This view is supported by Bhattacharya and Thakor (1993) who suggest that a unifying thread among a great number of papers on banking is that "intermediation is a response to the inability of market-mediated mechanisms to efficiently resolve informational problems."

Modigliani and Perotti (2000) theorize that when societies' enforcement regimes are not adequate, bank financing is favored. In this instance the binding of transactions becomes more private than public and reflects longer-term reputations and relationships between the parties, such as those between firms and their banks. Modigliani and Perotti (2000) suggest that when the rights of minority (or outside) investors are not adequate, less equity investment will be available for new enterprises (also see Myers 1977). According to Modigliani and Perotti (2000), in such societies, there will be more bank lendings instead of financing with public equity.

Modigliani and Perotti (2000) also suggest that banks, because of an emphasis on collateral, are less likely or able to differentiate firms with good future prospects versus those with poor future prospects. Alternatively, markets with good governance are better able to distinguish between these types of firms, a view supported by recent literature.[1] However, Rajan (1992) notes that a higher emphasis on

[1]For instance, Shirai (2004) reports that, because of improvements in official oversight for the period 1997–2001, Indian capital markets improved significantly in being able to differentiate high-quality firms from low-quality firms.

collateral can also lead to such an informational advantage for banks such that they can charge excessively high interest rates which can weaken economic development. Underlying Rajan and Zingales (1998) is the notion that when reliable information about firms is too difficult or costly for the general public, banks provide delegated monitoring (see Diamond 1984).

As this brief review of the relevant literature indicates, the international determinants of financial architecture must include national characteristics such as quality of investor protection, cultural and legal variables, and the equity premium. However, there may be an endogeneity problem as financial architecture seems to depend on a number of similar variables and the two variables, financial architecture and equity premia, may influence each other. Our research design includes a resolution of this issue.

12.2.3 Equity Premium as Measure of Equity Risk

We can expect variations in the ex ante equity premia across countries. Equity premia can be expected to reflect the price of risk in equity investments. Depending on national characteristics such as the nature of their institutional structures and their levels of financial development, countries may differ with regard to both the risk involved in equity investments and in the price of such risk. One way to think about this extra risk and its price is to think about how the supply and demand for equity investments may differ across countries, especially as most countries have less than perfect capital markets.

Ibbotson et al. (2006) suggest that because of many obstacles and limitations, the supply and demand for equity in markets may not respond to market forces as would be expected from a theoretical view of efficient markets.[2] For example, the supply of equity may be restricted as bureaucratic rules and regulations may deter the formation and market listing of corporate shares. Similarly, the demand for equity may be limited due to uncertain property rights and the unreliability of public information on potential investments. As the equity premium is the price of equity risk, it is determined by the balance between supply and demand for equity. In order to understand the nature and size of equity premia, it is important to account for the nature of equity demand and supply in actual, imperfect, markets.

While there are no perfect measures of national supply of equity, a number of variables could be used as indirect indicators. For example, stock market capitalization as a ratio of GDP is one such widely used measure. But this ratio by itself is an inadequate proxy because this measure will rise with a rise in valuation (as well as with new listings) and valuation is itself affected by supply. Other arguable measures of equity supply would include the number of shares

[2]Ibbotson et al. (2006) actually start with somewhat of an alternative view to the commonly held notion that prices in capital markets are set by the supply and demand for capital. Instead, they focus on the viewpoint of the supplier of capital (an investor) and suggest that there is a supply and demand for returns and that it is returns that are priced in the marketplace.

listed per unit of population or the number of new shares listed. A more extensive evaluation of how developed an equity market is might include R^2, the degree to which individual stocks move synchronously with the overall equity market in that country (Morck et al. 2000), or the degree to which market capitalization is concentrated in a few firms. Turner (2003) associates the development of nations' private bond markets with the quality of their local investor bases. Regulatory restrictions and lack of accounting standards can inhibit bond trading by institutional investors. So if the quality of local bond markets in some measure reflects the narrowness of the local investor base, then the quality of the bond market might partially and indirectly determine the nonpecuniary (e.g., for control rights) demand for equity.

Similarly, the demand for equity returns is likely to be influenced by a great variety of factors that influence the risk level of equity and society's perceptions, tolerance, or price of equity risk. The nature of legal protection for investors, disclosure requirements, the level of social trust that a particular society believes can be placed in strangers, and the political stability of a country certainly are some factors that come to mind. However, it is also reasonable to suppose that there is correlation among many of the social, cultural, legal, and governance factors that might affect the demand for equity. Ibbotson et al. (2006) suggest that the demand for equity return is potentially also affected by concern for real returns as opposed to nominal returns. Further, Moerman and van Dijk (2010) document evidence that inflation risk is priced in international asset returns – so our investigation of the demand for equity returns also ought to control for inflation variability.

The supply and demand for equity in a country are also likely to be affected by its financial architecture, i.e., the relative importance of the banking sector versus financial markets in a country. It is now well recognized that some countries like Japan and Germany are bank oriented, while other countries, like the Anglo-Saxon countries, depend more on financial markets. For example, it can be expected that equity premia are likely to be lower in countries with well-developed financial and equity markets with a less restricted, and so greater, supply of equity than in bank-oriented countries.

12.3 Methodology

As discussed briefly above, it seems that both national variations in the structures of financial intermediation and equity premia are determined by many similar socio-economic factors so that national variations in equity premia can be expected to influence national variations in the structure of financial intermediation and vice versa. But, until very recently, prior literatures in these two areas have ignored each other and the resulting possible endogeneity problem. Recent exceptions include Aggarwal and Goodell (2011a, b), both of which papers examine the role of financial architecture in partial determining nations' equity premia. This chapter overcomes this limitation of prior research and examines the determinants of international variations in financial architecture, accounting for the relationship between financing architecture and ex ante equity risk premia with different estimation techniques. One estimation technique uses simultaneous-equation estimates that include the equity premium as an instrumental variable along with a number of other relevant institutional, governance, and cultural factors. Another estimation technique uses a dynamic panel data modeling which includes as an independent variable the ex ante equity premium as a predetermined variable. Specifically, this chapter examines the nature of international variations in national financial architecture with a special emphasis on exploring the role of ex ante equity premia.

12.3.1 Estimating the Equity Premium

This chapter uses the abnormal earnings growth (AEG) model to estimate the ex ante equity premium. This model is chosen not just because of its efficacy at predicting ex post values but rather also because it is regarded as a fundamental model upon which other previously used models are based (Penman 2005). In addition, we use AEG estimations rather than alternative estimations in order to avoid assumptions of future payout ratios. Further, the AEG model avoids the problem with some estimation procedures when composite market-to-book ratios for particular country/years are less than one.

Our estimates of ex ante equity premiums are based on data from the period 1996–2006. Consensus of all available individual earnings forecasts are obtained from Institutional Brokers Estimate System (I/B/E/S) of Thomson Financial, as well as data for actual earnings per share, dividends per share, share prices, and the number of shares outstanding. In the interests of consistency, forecasts are collected as of April each year. Most firms end their fiscal years in December, and, typically, values are reported within 90 days of the fiscal year end. If a firm has I/B/E/S earnings forecasts for +1 and +2 years and a 5-year growth forecast, it is retained in the sample. Firm-level data are then aggregated for each year. This paper uses national treasury bill rates as a measure of the risk-free rate. This data is obtained from *International Financial Statistics* of the International Monetary Fund (IMF).

This chapter estimates that abnormal earnings grow at a constant rate after 5 years at a rate equal to the rate of expected nominal GDP growth. Expected GDP growth is modeled according to the following equation:

$$\text{expNomGDPgrowth} = (1 + \text{expInflation}) * (1 + \text{expRealGDPgrowth}) - 1 \tag{12.1}$$

Expected inflation is modeled as the arithmetic average of the current, preceding, and subsequent years' inflation as reported by IFS. Expected real GDP growth is modeled as the arithmetic average of the current, preceding and subsequent years' real GDP growth as reported by *World Development Indicators*. If national treasury bill rates are not available, a 1-year money market rate or a similar country-specific short-term rate is used.

This chapter uses the following AEG model:

$$p_0 = \frac{eps_1}{k}\left(\frac{g_{st} + k\frac{d_1}{eps_1} - g_{lt}}{k - g_{lt}}\right) \tag{12.2}$$

where eps_1 is the next-period forecasted earnings per share (when all firms aggregated, this becomes next year's forecasted earnings), p_0 is the price which when all firms are aggregated becomes aggregate market values, d_1 are the dividends per share which become aggregate dividends, g_{lt} is the long-term growth rate, and g_{st} is the short-term growth rate. We proxy the short-term rate as the geometric average of growth in earnings forecasts up to the fifth forecast. The long-term growth rate is proxied as the rate of expected nominal GDP growth. We do not incorporate the 5-year growth forecast from I/B/E/S in the estimate of the short-term growth rate because of concerns that, by using an average of the 5-year growth forecast from I/B/E/S, a bias will be introduced as a consequence of equal weighting across years.

12.3.2 Estimating the Cross-Border Determinants of Financial Architecture

Besides the use of expected equity premia as an instrumental variable, we also use a number of other independent variables. We control for inflation variability (INFLATION_VOLATILITY) using the variance of the preceding 5 years as reported by IFS. To capture time variation in risk appetite, we include the annual difference from Moody's Baa corporate bond yield and 10-year Treasury yield as reported by the *St Louis Federal Reserve* for the middle of April for each year. STOCK_VOLATILITY is the annualized standard deviation of monthly equity returns of the respective Morgan Stanley Country Index. To account for relative firm size and equity market concentration, we establish a Herfindahl index for each country for each year (CONCENTRATION). A value of CONCENTRATION close to 1 would suggest that most market capitalization for a particular country in a given year is due to a small number of firms. Market capitalization data is obtained from I/B/E/S. Based on Aggarwal and Goodell (2009), we speculate in advance of empirical findings that country/years with high market capitalization concentration will be more market based.

We control for regional differences by including as an independent variable a dummy variable and REGION_EUROPE that receive "1" if the country is Europe. We consider that the European region has historically had a unique relationship with banking (see Rajan and Zingales 2003). We also control for cross-national differences in wealth and wealth inequality by including real GDP and the Gini coefficient from *World Development Indicators*.

In order to assess the cultural impact on financial architecture, we include as independent variables four cultural dimensions of Hofstede (2001):

uncertainty avoidance (UAI), power distance (PDI), masculinity (MAS), and individualism (IDV). Kwok and Tadesse (2006) and others have found that national culture is an important partial determinant of nations' preference for markets versus banks.

We control for regulatory quality using a governance indicator from Djankov et al. (2008) his is the comprehensive index of cross-national differences in protection of investors from self-dealing, the anti-self-dealing index (ANTI_SELF_DEAL). Fligstein (2001) suggests that market participants primarily value stable worlds and that markets are state-directed societal solutions to competition. More efficient regulation and control of corruption will improve transparency and so lower costs of resolving the asymmetry of information inherent with markets. Aggarwal and Goodell (2009), Kwok and Tadesse (2006), and Ergungor (2004) have found that governance impacts financing preferences.

12.3.3 Estimation Methodologies

In order to use the estimator of Baltagi and Li (1995), we design a set of simultaneous equations. With regard to our modeling of simultaneous equations, we suggest that the risk factors and costs generally involved with resolving asymmetric information in markets is reflected in the equity premium. Therefore we model financial architecture as partially determined by the respective country/year equity premium as well as political factors. Our empirical estimation models are based on this set of equations:

$$\mathrm{FIN\_ARCH}_{it} = \alpha_{it} + \sum \beta_{1it} * \mathrm{EQ\_PREM}_{it} + \beta_{2it}\mathrm{X2}_{it} + e_{it} \tag{12.3}$$

$$\mathrm{EQ\_PREM}_{it} = \alpha_{it} + \beta_{1it}\mathrm{FIN\_ARCH}_{it} + \sum \beta_{2it}\mathrm{X1}_{it} + e_{it} \tag{12.4}$$

In Eqs. 12.3 and 12.4, FIN_ARCH is domestic stock market capitalization divided by domestic assets of deposit money banks; this measure is constructed from the data from Beck et al. (2000). EQ_PREM is our estimate of the equity premium, and X1 and X2 represent a number of independent variables, including risk, political, and social factors. Alternatively, as noted earlier, we also use, for the same respective sets of independent variables, the results of Blundell and Bond (1998) dynamic panel estimation procedures.

12.3.4 Data

We analyze data for 41 countries over a recent 11-year period using panel data methods. Specifically, we assess data for the 11-year period, 1996–2006, from

41 countries: Argentina, Australia, Austria, Belgium, Brazil, Canada, Chile, Czech Republic, Denmark, Finland, France, Germany, Greece, India, Indonesia, Ireland, Italy, Hong Kong, Hungary, Israel, Japan, Korea, Malaysia, Mexico, New Zealand, the Netherlands, Norway, Philippines, Pakistan, Peru, Poland, Portugal, Russia, Singapore, South Africa, Spain, Sweden, Thailand, Turkey, the United Kingdom, and the United States.[3] The countries we include here cover much breadth across regions, cultures, legal origins, and difference in national wealth. In selecting independent variables we have tried and managed to avoid excess correlation among them. We estimate models that focus on structural variables and then add in turn a regional variable and then cultural, governance, and security protection variables. All models have variance inflation factors (VIF) of less than 10 for all regressors indicating that any multicollinearity is unlikely to be a problem. Nevertheless, in subsequent robustness checks, we also address other specific correlations among particular pairs of independent variables.

12.4 Results

12.4.1 Descriptive Statistics

Table 12.3 presents the means, and standard deviations of the variables used in our models. Together these independent variables reflect the factors we described earlier that may affect cross-national differences in financing predilections. Column 4 shows the standard deviation divided by the mean. This column suggests that the dummy variable for European region, and our Herfindahl for market concentration are the most variable of the independent variables (1.06, 0.96), while FIN_ARCH, and EQUITY PREMIUM are similarly variable (0.73, 0.40) (Table 12.3).

12.4.2 Results of Baltagi-Li EC2SLS Modeling and Blundell-Bond Modeling

Table 12.4 shows the results of panel regressions using the system of Eqs. 12.3 and 12.4, with our estimate of financial architecture as a dependent variable and our estimate of the equity premium as an instrumented variable. The estimation is carried out using the random-effects EC2SLS estimator proposed by Baltagi and Li (1992, 1995), and Baltagi (2001). Baltagi (2001) suggests the EC2SLS estimator is more

[3]We begin our period of study in 1996 in order to include our measure of market concentration which is a Herfindahl index we construct using data from I/B/E/S. There is insufficient data from I/B/E/S for many countries prior to 1996. Another important reason, however, is that the measures we use for political stability, control of corruption, and regulatory from Kaufmann et al. (2008) are only available from 1996. Generally, our sample is restricted to those country/years which have sufficient data reported by I/B/E/S and are included by Kaufmann et al. (2008). We stop in 2006 to avoid the effects of the global financial crises and recession that started in 2007.

Table 12.1 Mean financial architecture

Country	Mean	Country	Mean
South Africa	2.47	Greece	0.69
The United States	2.35	Israel	0.64
Finland	2.00	Korea	0.60
Hong Kong	1.93	Indonesia	0.59
Sweden	1.72	Spain	0.58
Chile	1.52	Brazil	0.58
Singapore	1.47	Norway	0.57
Russia	1.40	Hungary	0.57
Switzerland	1.36	Ireland	0.57
Argentina	1.31	Belgium	0.56
Malaysia	1.20	New Zealand	0.51
The United Kingdom	1.15	Pakistan	0.49
Australia	1.11	Italy	0.48
Philippines	0.99	Poland	0.45
Canada	0.92	Thailand	0.41
India	0.87	Czech Republic	0.41
Mexico	0.87	Japan	0.40
The Netherlands	0.75	Germany	0.33
Denmark	0.72	Portugal	0.31
France	0.72	Austria	0.18
Turkey	0.71		

This table lists the mean national financial architecture for 41 countries for 1996–2006. Financial architecture is domestic stock market capitalization divided by domestic assets of deposit money banks (this measure is constructed from the data from Beck et al. (2000))

efficient than the usual Balestra and Varadharajan-Krishnakumar (1987) G2SLS estimator because of a broader set of transformations of the instruments. Alternatively Table 12.5 shows, for the same respective sets of independent variables as Table 12.4, the results of Blundell and Bond (1998) dynamic panel estimates.

Table 12.4 reports the results of EC2SLS random-effects estimates, while Table 12.5 reports Blundell and Bond (1998) estimates. Model 1 restricts the independent variables to just the equity premium. In this model EQ_PREM is negatively significant at 5 % in both Tables 12.4 and 12.5. Both estimation procedures suggest in Model 1 an association of lower equity premia with more market-oriented countries.

Model 2 adds to the independent variables that describe the volatility of the financial and economic environment: INFLATION_VOLATILITY and STOCK_VOLATILITY. The equity premium is again negatively significant, at 1 % in Table 12.4 and 10 % in Table 12.5. Equity premium is again negatively significant according to both estimation procedures. INFLATION_VOLATILITY is not significant with regard to either estimation procedure, while STOCK_VOLATILITY is negatively significant in both Tables 12.4 and 12.5.

Table 12.2 Mean equity premia

Country	Mean	Country	Mean
Brazil	−4.24	Finland	7.24
Turkey	1.61	Australia	7.33
Argentina	1.71	Hong Kong	7.37
Hungary	3.08	Germany	7.51
Mexico	3.62	Austria	7.65
Poland	3.75	Canada	7.65
Norway	3.82	France	7.84
India	4.44	Japan	7.85
Indonesia	5.19	Chile	8.03
South Africa	5.54	Greece	8.35
Belgium	6.01	Switzerland	8.38
Denmark	6.08	Portugal	8.38
The United Kingdom	6.24	The Netherlands	8.41
Italy	6.27	Malaysia	8.62
Israel	6.38	Thailand	8.85
Philippines	6.42	Spain	9.07
New Zealand	6.57	Korea	9.27
Singapore	6.64	Pakistan	10.61
Czech Republic	6.84	Ireland	10.65
Sweden	6.84	Russia	39.16
The United States	7.02		

This table lists the mean expected national mean equity premia for 41 countries for 1996–2006. This chapter uses the following AEG model

$$p_0 = \frac{eps_1}{k}\left(\frac{g_{st} + k\frac{d_1}{eps_1} - g_{lt}}{k - g_{lt}}\right)$$

Where eps_1 is the next-period forecasted earnings per share (when all firms aggregated, this becomes next year's forecasted earnings), p_0 is the price which when all firms are aggregated becomes aggregate market values, d_1 are the dividends per share which becomes aggregate dividends, g_{lt} is the long-term growth rate, and g_{st} is short-term growth rate. We proxy the short-term rate as the geometric average of growth in earnings forecasts up to the fifth forecast. The long-term growth rate is proxied as rate of expected nominal GDP growth

Model 3 adds to the other three independent variables CONCENTRATION, REGION_EUROPE, and LN_GDP. This results in CONCENTRATION being positively significant with regard to both estimation procedures. Equity premium is again negatively significant in both tables. A difference in the two tables is that in Table 12.4 REGION_EUROPE is negatively significant, while in Table 12.5 this variable is not significant. STOCK_VOLATILITY is negatively significant in both Tables 12.4 and 12.5, although only at 10 % in Table 12.4.

Model 4 add to the independent variables the Hofstede cultural dimensions UAI, PDI, MAS, and IDV. Model 4 also adds SPREAD, the spread between US corporate bonds and US 10-year Treasuries. This results in differences between

Table 12.3 Summary of data sources used in this study

1	2	3	4	5
Variable	Mean	Standard deviation	Stdev/ mean	Source
FIN_ARCH	0.92	0.67	0.73	Beck et al. (2000)
EQUITY_PREMIUM	7.28	2.91	0.40	Equity premium estimated from the data from I/B/E/S and treasury rate data from *International Financial Statistics*
INFLATION_VOLATILITY	8873.06	296.65	0.03	Variance of preceding 5 years of inflation
STOCK_VOLATILITY	24.49	14.77	0.60	The annualized standard deviation of monthly equity returns of respective Morgan Stanley Country Index
CONCENTRATION	0.18	0.17	0.96	Herfindahl index created for this chapter based on number of firms
REGION_EUROPE	0.47	0.50	1.06	A dummy variable that is assigned "1" if the country is in Europe and "0" otherwise
LN_GDP	9.12	1.24	0.14	PPP GDP per capita from *World Development Indicators*
UAI	62.76	24.88	0.40	Uncertainty Avoidance, Hofstede (2001)
PDI	53.74	21.72	0.40	Power Distance, Hofstede (2001)
MAS	51.22	19.44	0.38	Masculinity, Hofstede (2001)
IDV	51.52	23.83	0.46	Individualism, Hofstede (2001)
SPREAD	2.15	0.53	0.25	Difference from Moody's Baa corporate bond yield and 10-year Treasury yield *St Louis Federal Reserve*
ANTI_SELF_DEAL	0.52	0.24	0.47	Djankov et al. (2008)

Means, standard deviations, and sources of variables used in statistical estimates reported in succeeding tables, 1996–2006

Tables 12.4 and 12.5. SPREAD is significantly negative in Table 12.5 while not significant in Table 12.4. Three cultural variables, PDI, MAS, and IDV, are significant in Table 12.4 while not significant in Table 12.5. In Table 12.4, UAI and MAS are negatively significant at 1 % and 5 %, respectively. In Table 12.4, IDV and PDI are both positively significant at 1 %. However, UAI, MAS, IDV, and PDI are not significant in Table 12.5. In other results, both tables show LN_GDP positively significant, suggesting equity premia are larger in wealthier countries.

Model 5 adds to the independent variables of Model 4, the comprehensive index of anti-self-dealing (ANTI_SELF_DEAL) of Djankov et al. (2008). These result, in Table 12.4, with regulatory efficiency, as reflected in measures against self-dealing being positively significant. In Table 12.5, however, this variable is not significant.

Table 12.4 Cross-national determinants of financial architecture: static panel estimation

12.4.3 Additional Econometric Details

In our results for Table 12.4, we consistently report random-effects estimates. We do this because the results of Hausman tests (Hausman 1978) suggest that random-effects estimates may be used. Reading across the models in Table 12.4, we see that Hausman tests for the models are consistently insignificant. Therefore we do not reject the NULL hypothesis that the estimates are inconsistent (Hausman 1978). In the Appendix we also report the Pearson correlation coefficients (Appendix 1) and the variance inflation factors (Appendix 2) for our five models in Tables 12.4 and 12.5. Examining Appendix 1, we see that the largest correlation among our independent variables is –0.67 between IDV and PDI. The next largest correlation is between PDI and LN_GDP (–0.63). Since PDI is a partner in the two largest correlations in our sample, we exclude this independent variable in robustness tests described in Table 12.6.

In Table 12.4, we report the locally invariant test statistic of Baltagi and Wu (1999) (LBI). The LBI for our models in Table 12.4 are all not close to 2. This may suggest that serial correlation is a problem for these models. However, while commonly used, the significances of LBI are difficult to interpret.

Because the dynamic panel estimator of Blundell and Bond (1998) assumes that there is no autocorrelation in the idiosyncratic errors, we also report in Table 12.5 Arellano-Bond test statistics. The Arellano-Bond test for zero correlation in first-differenced errors is significant for differences of one lag. However, because the first difference of white noise is necessarily autocorrelated, it is only necessary to be concerned with second and higher autocorrelations. Examining the Arellano-Bond test across the models in Table 12.5, we see that the values for lags 2 and 4 are also consistently significant. In subsequent robustness tests described below, we also control for other lags in order to control for serial correlation.

12.4.4 Discussion of Initial Results

With the exception of Model 4 in Table 12.4, EQUITY_PREMIUM is negatively significant in every model of both Tables 12.4 and 12.5. Both modelings point toward a negative association of the size of the expected equity premium with financial architecture (the ratio of stock market size to banking size). It is also intuitively reasonable to expect a lower equity premium in more market-oriented nations. This is consistent with the results of Aggarwal and Goodell (2011a, b).

With the exception of Model 4 in Table 12.4, STOCK_VOLATILITY is negatively significant in every model of both Tables 12.4 and 12.5. CONCENTRATION is positively significant in every model in which it is present in both Tables 12.4 and 12.5. REGION_EUROPE is negatively significant in Models 3 and 4 in Table 12.4, but is not significant in any models in Table 12.5. LN_GPD is positively significant in Models 4 and 5 of both Tables 12.4 and 12.5. SPREAD is negatively significant in Models 4 and 5 in Table 12.5, but is not significant in any models in Table 12.4. ANTI_SELF_DEAL is positively

	1.37(0.170)	1.37(0.171)	1.06(0.289)	1.50(0.133)	1.28(0.201)

This table reports results of tobit regressions for 41 countries, for 1996–2006. FIN_ARCH is stock market capitalization divided by domestic assets of deposit money banks from from Beck, Demirguc-Kunt, Levine (2000), EQUITY PREMIUM is ex ante equity premium estimations from the data from I/B/E/S; INFLATION_VOLATILITY is variance of preceding 5 years of inflation from *International Financial Statistics*; STOCK_VOLATILITY is the annualized standard deviation of monthly equity returns of respective Morgan Stanley Country Index; CONCENTRATION is a Herfindahl index of equity market concentration created for this chapter REGION_EUROPE is a dummy variable that is assigned "1" if market is in Europe and "0" otherwise; LN_GDP is natural log of real GDP per capita;; UAI, PDI MAS, and IDV are cultural dimensions of Hofstede (2001); SREAD is the difference between Moody's Baa corporate bond yield and 10-year Treasury yield from *St Louis Federal Reserve*; ANTI_SELF_DEAL is the index of measures against self-dealing from Djankov et al. (2008)

Variance inflation factors are less than 10 for all variables and models. P values in parentheses. Random-effects, EC2SLS estimates reported for Model 1.
*** Significance at 1 % level, ** significance at 5 % level, * significance at 10 % level Blundell-Bond estimates reported, controlling for three lags

significant (at 10 %) in Model 5 in Table 12.4 but is not significant in Table 12.5. Many of the cultural dimensions of Hofstede (2001) are significant in Table 12.4. For instance, PDI, IDV, and MAS are significant in every model in which they are present, while UAI is significant in Model 4. However, none of these cultural variables are significant in Table 12.5.

Summarizing these differences, both static and dynamic estimation methods find evidence of a negative association of financial architecture with the expected equity premium. This suggests that investors demand less return for holding equity in more market-oriented countries. Both static and dynamic estimation methods find evidence of a negative association of financial architecture with stock volatility. This suggests that less volatile markets are associated with being more market-oriented. Both static and dynamic estimation methods find evidence of a positive association of financial architecture with equity market concentration. This suggests that, despite the widely dispersed, market orientation of the United States, overall, more market-oriented countries have greater concentration of equity ownership into fewer firms. Both static and dynamic estimation methods also find evidence of a positive association of financial architecture with national wealth, suggesting that wealthier countries are more market oriented.

While the two estimation procedures used in Tables 12.4 and 12.5 yield very similar results with respect to a number of independent variables, some differences also exist. For instance, SPREAD is significantly negative in Table 12.5 but not significant in Table 12.4. SPREAD changes value each year but is the same across countries. We consider that the difference between Tables 12.4 and 12.5 with respect to SPREAD may be due to a difference in emphasis between these tables with regard to cross-sectional versus time series effects, with the Baltagi-Li estimator emphasizing cross-sectional effects and the Blundell-Bond estimator emphasizing time series effects. Similarly the cultural dimensions of Hofstede (2001) – as well as ANTI_SELF_DEALING – do not change over our time period. However these variables vary widely across countries. And so the result that these variables are significant in Table 12.4 but not significant in Table 12.5 is consistent with the notion that Table 12.4 emphasizes cross-sectional differences, while Table 12.5 emphasizes time series differences.

12.4.5 Robustness Checks

As noted above, because the dynamic panel estimator of Blundell and Bond (1998) assumes that there is no autocorrelation in the idiosyncratic errors, we also report in Table 12.5 Arellano-Bond test statistics. The Arellano-Bond test for zero correlation in first-differenced errors is significant for differences of one lag. However, because the first difference of white noise is necessarily autocorrelated, it is only necessary to be concerned with second and higher autocorrelations that are higher than 1 for the models in Table 12.5. However, examining the Arellano-Bond test across the models in Table 12.5, the values for lags 2 and 4 are also consistently significant. Therefore, in Table 12.6, we also control for the first three lags of our dependent variable.

Additionally, in order to avoid multicollinearity, we also employ, in Table 12.7, a two-stage model for some variables in order to lower multicollinearity. We note that the Pearson correlation coefficients between IDV and PDI as reported in Appendix 1 is –0.67. Further, the correlation between PDI and LN_GDP is –0.63. We first regress the respective independent variable (either IDV or PDI) on our measure of wealth along with some other cultural variables. Specifically, we regress each variable on wealth (LN_GDP). We then use the residuals from these regressions as our independent variables in Eq. 12.3:

$$\mathrm{IDV}_{it} = \alpha_i + \sum \beta_1 * LN\_GDP_{it} + e_{it} \tag{12.5}$$

$$\mathrm{PDI}_{it} = \alpha_i + \sum \beta_1 * LN\_GDP_{it} + e_{it} \tag{12.6}$$

We then include the residuals from Eqs. 12.5 and 12.6 as substitute independent variables for IDV and PDI, respectively. We refer to these variables as RESID_IDV and RESID_PDI, respectively. This procedure lowers the correlation between IDV (RESID_IDV) and PDI (RESID_PDI) to zero. The correlation between RESID_IDV and RESID_PDI is now lowered to –0.45.

12.4.6 Discussion of Robustness Tests

The models in Table 12.6 are the same as those in Tables 12.4 and 12.5, with the exception of including three lags of the dependent variable. The results of Table 12.6 substantially corroborate the results of Tables 12.5 and 12.4. EQUITY__PREMIUM is negatively significant in every model. CONCENTRATION is positively significant. STOCK_VOLATILITY is generally negatively significant, as in Tables 12.4 and 12.5. However, unlike the previous tables this variable is not significant in Model 5. Like Table 12.5, SPREAD is negatively significant. Overall the results of Table 12.6 suggest that the results of Table 12.5 are not driven by serial correlation in higher lags and/or excessive multicollinearity.

Table 12.7 shows the results of the most comprehensive model (Model 5 in Tables 12.4, 12.5, and 12.6) using three lags of the dependent variable and replacing IDV and PDI with RESID_IDV and RESID_PDI. As seen in Table 12.7, controlling for correlation between PDI and IDV by orthogonalizing both to LN_GDP results in little change to the estimates for our most comprehensive model. Model 1 in Table 12.7 is very similar to Model 5 in Table 12.4. Similarly, Model 2 in Table 12.7 is very similar to Model 5 in Table 12.5.

12.4.7 Discussion of Differences in the Results of the Two Different Modelings

As noted above, while the two estimation procedures used in this study yield very similar results with respect to a number of independent variables, some

		0.05(0.963)
		1.28(0.201)

This table reports results of tobit regressions for 41 countries, for 1996–2006. FIN_ARCH is stock market capitalization divided by domestic assets of deposit money banks from Beck, Demirguc-Kunt, Levine (2000), EQUITY PREMIUM is ex ante equity premium estimations from the data from I/B/E/S; INFLATION_VOLATILITY is variance of preceding 5 years of inflation from *International Financial Statistics*; STOCK_VOLATILITY is the annualized standard deviation of monthly equity returns of respective Morgan Stanley Country Index; CONCENTRATION is a Herfindahl index of equity market concentration created for this chapter; REGION_EUROPE is a dummy variable that is assigned "1" if market is in Europe and "0" otherwise; LN_GDP is natural log of real GDP per capita; UAI, PDI MAS, and IDV are cultural dimensions of Hofstede (2001); SREAD is difference between Moody's Baa corporate bond yield and 10 year Treasury yield from *St Louis Federal Reserve*; ANTI_SELF_DEAL is the index of measures against self-dealing from Djankov et al. (2008)

Variance inflation factors are less than 10 for all variables and models. P values in parentheses. Random-effects, EC2SLS estimates reported for Model 1. Blundell-Bond dynamic panel estimates (Modified to control for three lags) reported in Model 2. *** Significance at 1 % level, ** significance at 5 % level, * significance at 10 % level differences in the results using Blundell-Bond dynamic panel modeling and Baltagi-Li static panel modeling persist. For instance, the variable SPREAD which has a time series aspect but no cross-sectional aspect is significantly negative in the estimation of Blundell-Bond but not significant using Baltagi-Li EC2SLS estimator. We consider that the difference between these two estimators with respect to SPREAD may be due to a difference in emphasis between these estimators with regard to cross-sectional versus time series effects, with the Baltagi-Li estimator emphasizing cross-sectional effects and the Blundell-Bond estimator emphasizing time series effects. Similarly the cultural dimensions of Hofstede (2001) and our index of measures against self-dealing have no time series aspect but these variables vary widely across countries. These variables are significant using Baltagi-Li estimation but not significant using Blundell-Bond estimation. These differences in the results using differing estimation procedures are consistent with the Baltagi-Li estimator emphasizing cross-sectional differences, while Blundell-Bond estimator places greater emphasis on time series differences, due to the fact that the Blundell-Bond modeling includes as an independent variable the one-period lag in the dependent variable and so controls for fixed effects across one-period lags.

12.5 Conclusions

There has been a veritable explosion of studies in a wide variety of areas that employ panel data econometric methodology in recent years. Analysis of panel data allows independent variables to vary both cross-sectionally and across time, while panel data econometrics correct for cross-correlations between time series and cross-sectional error terms. In addition, there has now been the introduction of a number of new refinements in analyzing panel data (Petersen 2009; Wooldridge 2010), all maintaining the goal of accounting for cross-correlation between time series and cross-sectional error terms when assessing coefficient significance.

However, in the study of economic and financial panel data, it is often important to assess the differential impact of time series versus cross-sectional effects; but panel data techniques are unclear how this may be accomplished. In other words, panel data methodologies typically do not inform us fully regarding which effect (time series or cross-sectional) is more important or more dominant within particular data sets or contexts. In this chapter we employ two contrasting estimation procedures, which, respectively, emphasize cross-sectional versus time series differences, to clarify the impacts of these two influences. We undertake this comparison of econometric methods within a finance-related context which takes into account possible endogeneity.

In this chapter we show that a number of independent variables are significant in partially determining financial architecture using either or both of the estimation procedures of Baltagi and Li (1992) and Blundell and Bond (1998). Overall, we find a negative association of the equity premium with financial architecture. A smaller equity premium inclines societies toward being more market oriented. A Herfindahl Index for equity market concentration is positively significant. Generally, when market capitalization is concentrated in fewer firms, societies are more market oriented. We also find that stock volatility is generally negatively significant. This suggests that stock volatility inclines societies away from markets and toward banks.

However, of greater interest for this study, we find that some of our independent variables impact cross-national differences in financial architecture according to Baltagi and Li (1992) estimation, while other independent variables impact financial architecture according to Blundell and Bond (1998) estimation. While the two estimation procedures yield very similar results with respect to a number of independent variables, some differences exist also.

US Corporate bond spreads negatively determine financial architecture according to Blundell and Bond (1998) estimation but not according to Baltagi and Li (1992) estimation. US Corporate bond spreads change value each year but have the same value across countries. Similarly some measures that change across countries but do not change across time, such as the cultural dimensions of Hofstede (2001) as well as the index of measures against self-dealing, are significant determinants of financial architecture according to Baltagi-Li estimation but not according to Blundell-Bond estimation. This is consistent with different estimation techniques placing differing emphasis on cross-sectional and time series effects, with the Baltagi-Li estimator emphasizing cross-sectional effects and the Blundell-Bond estimator emphasizing time series effects.

These are critical findings that have important implications for the use of panel data estimation procedures, especially where it is important to differentiate between time series and cross-sectional influences. Our results show that using the two panel estimation procedures used here together can better differentiate between time series and cross-sectional variations in panel data. Thus, our results should be of much interest to scholars especially in finance and economics.

Appendix 2: Estimation Procedure of Baltagi-Li EC2SLS

Following Baltagi (1981), consider the jth structural equation:

$$\begin{aligned} y_j &= Y_j\alpha_j + X_j\beta_j + u_j = Z_j\delta_j + u_j, j = 1, 2, \ldots, M, \\ y_j &= NT \times 1; Y_j = NT \times \left(M_j - 1\right); X_j = NT \times K_j; \\ Z_j &= \left(Y_j X_j\right); \delta_j' = \left(\alpha_j', \beta_j'\right); n_j = M_j + K_j - 1 \end{aligned} \tag{12.7}$$

The additive error components structure is given by

$$u_j = Z_u u_j + Z_\lambda \lambda_j + v_j, \mathrm{j} = 1, 2, \ldots, \mathrm{M}, \tag{12.8}$$

where $Z_u = I_N \bigotimes e_T$, $\mathrm{Z}_\lambda = e_N \bigotimes I_T$

I_N and I_T are identifying matrices of order N and T, respectively. e_N and e_N are vectors of ones of order N and T, respectively.

$u_j' = (u_{1j}, u_{2j}, \ldots, u_{Nj})$, $\lambda_j' = (\lambda_{1j}, \lambda_{2j}, \ldots, \lambda_{Tj})$, and $v_j' = (v_{1j}, v_{2j}, \ldots, v_{NTj})$ are random vectors with means of zero and the following covariance matrix:

$$E\begin{pmatrix} u_j \\ \lambda_j \\ v_j \end{pmatrix}\left(u_1'\lambda_1'v_1'\right) = \begin{bmatrix} \sigma^2_{u_{jl}} I_N & 0 & 0 \\ 0 & \sigma^2_{\lambda_{jl}} I_T & 0 \\ 0 & 0 & \sigma^2_{v_{jl}} I_{TN} \end{bmatrix} \tag{12.9}$$

for j and l = 1,2,. . . .M. As noted by Baltagi (1981), this implies that the covariance matrix between jth and lth structural equation is

$$\Sigma_{jl} = E\left(u_j u_l'\right) = \sigma^2_{u_{jl}} A + \sigma^2_{\lambda_{jl}} B + \sigma^2_{v_{jl}} I_{NT}, \tag{12.10}$$

where $A = I_N \bigotimes e_T e'_T$, $B = e_N e'_N \bigotimes I_T$

It follows that

$$\Sigma_{ij} = \sigma^2_{3_{jl}} \frac{J_{NT}}{NT} + \sigma^2_{1_{jl}} \left(\frac{A}{T} - \frac{J_{NT}}{NT}\right) + \sigma^2_{2_{jl}} \left(\frac{B}{N} - \frac{J_{NT}}{NT}\right) + \sigma^2_{v_{jl}} Q \tag{12.11}$$

where

$Q = I_{NT} - \frac{A}{T} - \frac{B}{N} + \frac{J_{NT}}{NT}$ and $J_{NT} = e_{NT}e'_{NT}$

also

$\sigma^2_{3_{jl}} = \sigma^2_{v_{jl}} + N\sigma^2_{\lambda_{jl}} + T\sigma^2_{u_{jl}}$ and $\sigma^2_{1_{jl}} = \sigma^2_{v_{jl}} + T\sigma^2_{u_{jl}}$ as well as

$$\sigma^2_{2_{jl}} = \sigma^2_{v_{jl}} + N\sigma^2_{\lambda_{jl}}$$

$\sigma^2_{v_{jl}}, \sigma^2_{1_{jl}}, \sigma^2_{2_{jl}}, \sigma^2_{1_{jl}}$ are the characteristic roots of $\sum_{ij}$ of multiplicity (N−1)(T−1), N−1, T−1, and 1, respectively (Baltagi 1981; Nerlove 1971).

If the rank condition $K \geq K_1 + M_1 - 1$ holds for Eq. 12.7, then we can apply transformation Q_h to Eq. 12.7 to get

$$y_1^{(h)} = Y_1^{(h)}\alpha_1 + X_1^{(h)}\beta_1 + u_1^{(h)} = Z_1^{(h)}\delta_1 + u_1^{(h)} \tag{12.12}$$

$y_1^{(h)} = Q_h y_1, \ldots,; u_1^{(h)} = Q_h u_1$ for h = 1,2,3.

As noted by Baltagi (1981), $u_1^{(h)}$ has a covariance matrix which is a scalar times an identity matrix.

However, Baltagi (1981) applies a 2SLS procedure to Eq. 12.12 in order to correct for simultaneity:

$$X^{h'}y_1^h = X^{h'}Z_1^h\delta_1 + X^{h'}u_1^h \tag{12.13}$$

The resulting estimator of δ_1 is

$$\hat{\delta}^{(h)}_{1,2SLS} = \left[Z_1^{(h)'}P_{\chi^{(h)}}Z_1^h\right]^{-1}\left[Z_1^{(h)'}P_{\chi^{(h)}}y_1^h\right] \tag{12.14}$$

where

$$P_{\chi^h} = X^{(h)}X^{(h)}\left(X^{(h)'}X^{(h)}\right)^{-1}X^{(h)'}$$

The variance components are then estimated by

$$\sigma_{11}^{(h)2} = \left(y_1^{(h)} - Z_1^{(h)}\hat{\delta}^{(h)}_{1,2SLS}\right)'\left(y_1^{(h)} - Z_1^{(h)}\hat{\delta}^{(h)}_{1,2SLS}\right)/n(h) \tag{12.15}$$

As noted by Baltagi (1981), since δ_1 is common to all three transformations of Eq. 12.13, we can apply an Aitken estimation to the following sets of equations (Baltagi 1981):

$$\begin{pmatrix} X^{(1)'}y_1^{(1)} \\ X^{(2)'}y_1^{(2)} \\ X^{(3)'}y_1^{(3)} \end{pmatrix} = \begin{pmatrix} X^{(1)'}Z_1^{(1)} \\ X^{(2)'}Z_1^{(2)} \\ X^{(3)'}Z_1^{(3)} \end{pmatrix}\delta_1 + \begin{pmatrix} X^{(1)'}u_1^{(1)} \\ X^{(2)'}u_1^{(2)} \\ X^{(3)'}u_1^{(3)} \end{pmatrix} \tag{12.16}$$

This results in the following estimator:

$$\hat{\delta}_{1,GLS} = \left(\sum_{h=1}^{3} \left[Z_1^{(h)'} P_{\chi^h} Z_1^{(h)} / \sigma_{11}^{(h)2} \right] \right)^{-1} \left(\sum_{h=1}^{3} \left[Z_1^{(h)'} P_{\chi^h} y_1^{(h)} / \sigma_{11}^{(h)2} \right] \right) \tag{12.17}$$

Substituting the estimate of $\hat{\sigma}_{11}^{(h)2}$ from Eq. 12.15 into Eq. 12.17 yields

$$\hat{\delta}_{1,EC2SLS} = \left(\sum_{h=1}^{3} \left[Z_1^{(h)'} P_{\chi^h} Z_1^{(h)} / \hat{\sigma}_{11}^{(h)2} \right] \right)^{-1} \left(\sum_{h=1}^{3} \left[Z_1^{(h)'} P_{\chi^h} y_1^{(h)} / \hat{\sigma}_{11}^{(h)2} \right] \right)$$

Appendix 3: Estimation Procedure of Blundell and Bond (1998) System GMM Estimation

We consider the first-order autoregressive panel data model:

$$y_{it} = \alpha y_{i,t-1} + u_{it} \tag{12.18}$$

In this case, $u_{it} = \eta_i + v_{it}$
where i = 1, . . . N and t = 2, ... T
As described by Bun and Windmeijer (2010), following Blundell and Bond (1998), we assume that η_i and v_{it} have the error components structure

$$E(\eta_i) = 0; E(v_{it}) = 0; E(v_{it}\eta_i) = 0 \tag{12.19}$$

Additionally

$$E(v_{it}v_{is}) = 0 \text{ for } t \neq s \tag{12.20}$$

Additionally the initial condition satisfies

$$E(y_{i1}v_{it}) = 0. \tag{12.21}$$

It then follows that the following (T – 1)(T – 2)/2 linear moments conditions are valid:

$$E\left(y_i^{t-2}\Delta u_{it}\right) \text{ t} = 3, \ldots, \text{T}, \tag{12.22}$$

where

$$y_i^{t-2} = (y_{i1}, y_{i2}, \ldots, y_{it-2})' \text{ and } \Delta u_{it} = u_{it} - u_{it-1} = \Delta y_{it} - \alpha \Delta y_{it-1}$$

Defining

$$Z_{di} = \begin{bmatrix} y_{i1} & 0 & 0 & \dots & 0 & \dots & 0 \\ 0 & y_{i1} & y_{i2} & \dots & 0 & \dots & 0 \\ . & . & . & \dots & . & \dots & . \\ 0 & 0 & 0 & \dots & y_{i1} & \dots & y_{iT-2} \end{bmatrix}; \Delta u_i = \begin{bmatrix} u_{i3} \\ u_{i4} \\ . \\ . \\ . \\ \Delta u_{iT} \end{bmatrix}$$

This leads to a more efficient representing of the moment conditions:

$$E\left(Z'_{di}\Delta u_i\right) = 0 \tag{12.23}$$

Following Arellano and Bover (1995), the GMM estimator of α is given by

$$\alpha_d = \frac{\Delta y'_{-1} Z_d W_N^{-1} Z'_d \Delta y}{\Delta y'_{-1} Z_d W_N^{-1} Z'_d \Delta y_{-1}}$$

where $\Delta y = (\Delta y'_1, \Delta y^1_2 \dots \Delta y'_N)'$, $\Delta y_i = (\Delta y_{i3} \Delta y_{i4}, \dots, \Delta y_{iT})'$, Δy_{-1} the lagged version of Δy, and $Z_d = (Z'_{d1}, Z'_{d2}, \dots, Z'_{dN})$ ', and W_N is a weight determining the efficiency of the GMM estimator.

α_d is a GMM estimator in the differenced model. As noted by Bun and Windmeijer (2010), this estimator is referred to as the difference GMM estimator.

However, following Blundell and Bond (1998), who follow on Arellano and Bover (1995), we also assume additional conditions:

$$E(\eta_i \Delta y_{i2}) = 0 \tag{12.24}$$

This condition holds when the process is mean stationary:

$$y_{i1} = \frac{\eta_i}{1-\alpha} + \varepsilon_i \tag{12.25}$$

Additionally, $E(\varepsilon_i) = E(\varepsilon_i \eta_i) = 0$.

Further, if Eqs. 12.19, 12.20, 12.21, and 12.24 hold, then further $(T-1)(T-2)/2$ linear moments conditions are valid:

$$E\left(u_{it}\Delta y_i^{t-1}\right) = 0 \quad \text{for } t = 3, \dots, T, \tag{12.26}$$

where

$$y_i^{t-1} = (\Delta y_{i2}, \Delta y_{i3}, \dots, \Delta y_{it-1})'$$

Defining

$$Z_{di} = \begin{bmatrix} \varDelta y_{\mathrm{i}2} & 0 & 0 & \dots & 0 & \dots & 0 \\ 0 & \varDelta y_{\mathrm{i}2} & \varDelta y_{\mathrm{i}3} & \dots & 0 & \dots & 0 \\ . & . & . & \dots & . & \dots & . \\ 0 & 0 & 0 & \dots & \varDelta y_{i2} & \dots & \varDelta y_{iT-1} \end{bmatrix}; \Delta u_i = \begin{bmatrix} u_{i3} \\ u_{i4} \\ . \\ . \\ . \\ \Delta u_{iT} \end{bmatrix}$$

The above moment conditions can be written as

$$E\left(Z_{li}^{'} u_i\right) = 0 \tag{12.27}$$

The GMM estimator based on these estimates is then given by

$$\alpha_l = \frac{y_{-1}^{'} Z_l W_N^{-1} Z_l^{'} y}{y_{-1}^{'} Z_l W_N^{-1} Z_l^{'} y_{-1}}$$

α_l is a GMM estimator in the levels model. This is referred to as the levels' GMM estimator (Bun and Windmeijer 2010).

The full set of linear moments under assumptions (Eqs. 12.19, 12.20, 12.21, and 12.24) is

$$E\left(y_i^{t-2} \Delta u_{it}\right) = 0 \tag{12.28}$$

$$E\left(u_{it} \Delta y_{i,t-1}\right) = 0$$

for $t = 3, \dots, \mathrm{T}$

Following Bun and Windmeijer (2010), this can be resolved as

$$E\left(Z_{si}^{'} p_i\right) = 0, \tag{12.29}$$

where

$$Z_{si} = \begin{bmatrix} \mathrm{Z}_{di} & 0 & \dots & 0 \\ 0 & \varDelta y_{\mathrm{i}2} & \dots & 0 \\ . & . & . & . \\ 0 & 0 & \dots & \varDelta y_{iT} \end{bmatrix}; p_i = \begin{bmatrix} \Delta u_i \\ u_i \end{bmatrix}$$

As noted by Wind, the GMM estimator based on these conditions is

$$\alpha_s = \frac{q_{-1}^{'} Z_s W_N^{-1} Z_s^{'} q}{q_{-1}^{'} Z_s W_N^{-1} Z_s^{'} q_{-1}}$$

where

$$q_i = \left(\Delta y_i^{'} y_i^{'}\right)^{'}$$

α_s is the system GMM estimator of Blundell and Bond (1998).

Does Banking Capital Reduce Risk? An Application of Stochastic Frontier Analysis and GMM Approach

13

Wan-Jiun Paul Chiou and Robert L. Porter

Contents

Abstract

In this chapter, we thoroughly analyze the relationship between capital and bank risk-taking. We collect cross section of bank holding company data from 1993 to 2008. To deal with the endogeneity between risk and capital, we employ stochastic frontier analysis to create a new type of instrumental variable. The unrestricted frontier model determines the highest possible profitability based solely on the book value of assets employed. We develop a second frontier based

on the level of bank holding company capital as well as the amount of assets. The implication of using the unrestricted model is that we are measuring the unconditional inefficiency of the banking organization.

We further apply generalized method of moments (GMM) regression to avoid the problem caused by departure from normality. To control for the impact of size on a bank's risk-taking behavior, the book value of assets is considered in the model. The relationship between the variables specifying bank behavior and the use of equity is analyzed by GMM regression. Our results support the theory that banks respond to higher capital ratios by increasing the risk in their earning asset portfolios and off-balance-sheet activity. This perverse result suggests that bank regulation should be thoroughly reexamined and alternative tools developed to ensure a stable financial system.

Keywords
Bank capital • Generalized method of moments • Stochastic frontier analysis • Bank risks • Bank holding companies • Endogeneity of variables

13.1 Introduction

Bank capital management has become an important issue to both commercial bankers and central bankers after the recent financial crisis. As the subprime mortgage debacle spread, the balkanized regulatory system designed over half a century ago appeared totally inadequate for today's complex financial system. In this study, we evaluate the role of capital in regulatory risk management by examining a wide-range bank holding company data. Historically, both theoretical and empirical papers on the relationship between capital and risk have produced mixed results.[1] Yet a new look at the role of bank capital in risk management is now critical if we are to protect the financial system of the twenty-first century.

This chapter fits into a long history of literature dealing in general with bank risk management and more specifically with the question of what constitutes an adequate level of bank capital. Our contribution consists of the analysis of a large cross section of bank holding companies over the years that the Basle Accords have been implemented. In addition, we introduce a unique, to our knowledge, method to exogenously model an instrumental variable for capital in a regression with risk.

One of the primary goals of bank regulators is to minimize the risk held on and off their balance sheets by financial institutions. In this way, the negative externalities of bank failures and the risk to taxpayers from losses from the federal bank safety net are avoided or reduced. A mandatory bank capital requirement is one of the most important tools historically used by regulators to stabilize the financial industry. The recent financial crisis, however, challenges the effectiveness of these

[1]For detailed discussion, please see Berger et al. (1995); Gatev et al. (2009); Hovakimian and Kane (2000); Shrieves and Dahl (1992); and VanHoose (2007).

mandatory capital requirements. The inherent characteristics of today's banking industry such as rapid financial innovation, high financial leverage, information asymmetry, liquidity creation, and the federal bank safety net all distort incentives and reward risk-taking. If maintaining a certain level of capital is viewed by bank managers only as a necessary evil, then critical questions emerge: How is capital related to specific measures of risk including credit risk, liquidity risk, interest rate risk, off-balance-sheet risk, market risk, and overall bank risk? Do higher levels of capital improve or lower the efficiency of banking? Answers to these questions will help to establish the role of capital in regulatory risk management.

Empirical studies of bank capital and bank risk, however, face an inherent problem. In order to measure the effect of the level of capital on bank risk-taking, it would be useful to regress risk, as the dependent variable, on capital, as the independent variable. However, there is an obvious endogeneity problem. The amount of risk a bank can undertake is dependent on its amount of capital, and the amount of capital needed is dependent on the amount of risk that a bank wants to undertake. In other words, they are jointly determined, much like price and quantity in a basic microeconomic analysis. The solution to this problem is normally either to use a simultaneous equation model or to use instrumental variables. However, a simultaneous equation model must be properly identified, and no one has yet been able to accomplish this in regard to risk and bank capital. Likewise, no one, to our knowledge, has yet found a true instrument for capital that is independent of risk.

We present a methodology for the development of an exogenous instrument for capital in a regression with risk by using stochastic frontier analysis. First, we determine the maximum possible income that can be achieved from a given level of assets. This is referred to as fitting an upper envelope. Such a frontier is obviously exogenous to any specific bank because it is determined by the data from all banks in the sample. The distance from the frontier to any specific bank's actual income can be considered a measure of bank inefficiency. Next, to develop the instrument for capital, we create a second frontier conditioned on bank capital as well as the amount of assets employed. The incremental inefficiency from the second frontier is a function of the bank's capital but independent of the bank's risk, and it is this incremental inefficiency that we propose to use as an instrument for capital.

Our analysis adds to the existing literature in several ways. First, we employ a large panel data set to consider the capital-risk relationship for a wider range of bank holding companies than typically reviewed. Previous empirical studies have commonly used market measures of risk. However, this approach necessarily limits the sample to publically owned banks or bank holding companies. In this study, we acknowledge the importance of small banks and bank holding companies, as well as the largest bank holding companies. This concern is significant since public policy related to the banking industry must consider a broad sample of banks and not only the largest organizations. As a result, we turn to the typical accounting measures of a bank's risk and utilize a large panel data set. In a second contribution, stochastic frontier analysis is applied to exogenously generate the effect of the use of capital in banking.

Finally, the results provide evidence of bank holding companies reacting to higher mandatory capital requirements by increasing the amount of risk the bank holding company accepts. We use the generalized method of moments and look at seven different measures of risk: credit risk, liquidity risk, interest rate risk, off-balance-sheet risk, market risk, overall risk, and leverage risk. In general, many results support the proposition that increased capital requirements reduce risk in BHCs. There are, however, some results that suggest the opposite – that BHCs increase risk as their capital ratios increase. This is obviously an important finding with major public policy implications. If the primary tool used by regulators to ensure a stable financial system is creating perverse results, then alternative tools must be developed.

The rest of the chapter is organized as follows. Section 13.2 summarizes the literature that deals with bank capital regulation. Section 13.3 presents our methodology, and Sect. 13.4 reports the data along with its univariate analysis. In Sect. 13.5, we present our empirical results. Section 13.6 concludes.

13.2 Literature Review

It has been argued that excessively high capital requirements can produce social costs through lower levels of intermediation. In addition, there can be unintended consequences of high capital requirements such as risk arbitrage (increasing risk to offset the increase in capital and thereby maintain the same return on capital), increased securitization, and increased off-balance-sheet activity, all of which could mitigate the benefits of increased capital standards. See Berger et al. (1995) and Santos (2001). The extent to which these unintended consequences played a role in our recent crisis is yet to be determined.

Moral hazard is high on the list of problems receiving attention in this post-financial crisis environment. The presence of a federal safety net creates moral hazard because bank management does not have to worry about monitoring by depositors (see Merton 1977; Buser et al. 1981; Laeven and Levine 2009). Absent depositor monitoring, banks are free to increase risk. If, however, deposit insurance and other elements of a federal safety net are reasons for increases in bank risk, why do they continue to exist? The answer lies in the contemporary theory of financial intermediation. It has been well established in the literature that there is need for both demand deposit contracts and the possibility of bank runs (Diamond and Dybvig 1983; Calomiris and Kahn 1991; Diamond and Rajan 2000; and Santos 2001). If the possibility of bank runs is needed, and bank runs are harmful, then government deposit insurance is an optimal solution. There is a related issue. Banks have a unique ability to resolve information asymmetries associated with risky loans. As a result, bank failures can produce a serious contraction in credit availability, especially among borrowers without access to public capital markets. The federal safety net is needed to avoid this credit contraction. Likewise, if a bank is considered "too big to fail," then the government will always bail the bank out, and there is no reason for bank management to limit risk.

It needs to be noted that not everyone is in agreement that the use of capital requirements is the best way to reduce risk in banking. Marcus (1984) and Keeley (1990) argue that a bank's charter value mitigates against increased risk. Banks operate in a regulated environment, and therefore, a charter to operate contains market power. Excessive risk increases the cost of financial distress, and this can cause a loss of charter value. Kim and Santomero (1988) argue that a simple capital ratio cannot be effective, and any ratio would need to have exactly correct risk weights in a risk-based system. Gorton and Pennacchi (1992) discuss "narrow banking" and propose splitting the deposit services of banks from the credit services. In other words, the financial system would include money market accounts and finance companies. The money market accounts would only invest in short-term high-quality assets and leave the lending to the finance companies that would not take in any deposits.

In Prescott (1997), he reviews the precommitment approach to risk management. Briefly, banks commit to a level of capital, and if that level proves to be insufficient, the bank is fined. This is used currently in the area of capital in support of a trading portfolio but cannot be used for overall capital ratios since a fine against a failed bank is not effective. Esty (1998) studies the impact of contingent liability of stockholders on risk. In the late nineteenth and early twentieth century, bank stockholders were subject to a call or an assessment for more money if needed to meet the claims on a bank. There was a negative relation between increases in risk and the possible call on bank stockholders. Calomiris (1999) makes a strong case for requiring the use of subordinated debt in bank capital structures. The need to issue unguaranteed debt and the associated market discipline would act as an effective limit to the amount of risk a bank would be able to assume. John et al. (2000) argue that a regulatory emphasis on capital ratios may not be effective in controlling risk. Since all banks will have a different investment opportunity set, an efficient allocation of funds must incorporate different risk-taking for different investment schedules. These authors go on to argue that senior bank management compensation contracts may be a more promising avenue to control risk using incentive-compatible contracts to achieve the optimal level of risk.

Marcus and Shaked (1984) show how Merton's (1977) put option pricing formula can be made operational and then used the results to estimate appropriate deposit insurance premium rates. The results of their empirical analysis indicated that the then current FDIC premiums were higher than was warranted by the ex ante default risk of the sample banks. This implies that banks are not transferring excessive risk to the deposit insurance safety net and capital regulation is effectively working.

Duan et al. (1992) address the question of the impact of fixed-rate versus risk-based deposit insurance premiums directly. The authors tested for specific risk-shifting behavior by banks. If banks were able to increase the risk-adjusted value of the deposit insurance premiums, then they had appropriated wealth from the FDIC. This is because the FDIC, at the time, could not increase the insurance premium even though risk had increased. Their empirical findings were that only 20 % of their sample banks were successful in risk-shifting behavior and therefore the problem was not widespread. This also implies that capital management has been effective.

Keeley (1992) empirically studied the impact of the establishment of objective capital-to-assets ratio requirements in the early 1980s. His evidence documents an increase in the book value capital-to-assets ratio of previously undercapitalized banks, and this, of course, was the goal of the new capital regulations. His study, however, is unable to confirm the same result when looking at the market value capital ratios. While the market value capital-to-assets ratios also increased, there was no significant difference between the undercapitalized banks and the adequately capitalized banks. Nevertheless, this was more evidence that capital regulation was working.

Hovakimian and Kane (2000) use the same empirical design as Duan et al. (1992) but for a more recent time period, and they obtain opposite results. They also start with the argument of Merton (1977) that the value of deposit insurance increases in asset return variance and leverage. They regress the change in leverage on the change in risk and find a positive rather than a negative coefficient. The coefficient must be negative if capital regulation forces banks to decrease leverage with increases in risk. In a second test, they regress the change in the value of the deposit insurance premium on the change in the asset return variance. Here again the coefficient must be negative (or zero) if there is any restraint. In this equation, the coefficient measures how much the bank can benefit from increasing the volatility of its asset returns. The option-model evidence presented shows that capital regulation has not prevented risk-shifting by banks and that it was possible for banks to extract a deposit insurance subsidy.

In Hughes et al. (2001), the authors study the joint impact of two functions of bank capital. First is the capital's influence on market value conditioned on risk, and second is its impact on production decisions incorporating endogenous risk. Efficient BHCs are determined according to frontier analysis, and then these BHCs are assumed to be value-maximizing firms. The conclusion is that these value-maximizing firms do achieve economies of scale, but the analysis of production must include capital structure and risk-taking.

Berger et al. (2008) note that US banks hold significantly more equity capital than the minimum amount required by regulators. Their evidence documents the active management of capital levels by BHCs including setting target levels of capital above regulatory minimums and moving quickly to achieve their targets. Over the 15-year period of their study, BHCs regularly used new issues of shares and share repurchase programs to actively manage their capital levels. Several reasons for differing capital ratios among BHCs are given by the authors. Banks with high earnings volatility would likely hold more capital. Banks whose customers are more sensitive to default risk via counterparty exposure may be forced to hold more capital. Firms with high charter values will want to minimize their costs of financial distress by maintaining high capital ratios. On the other hand, larger banks by asset size tend to be more diversified, enjoy scale economies in risk management, have ready access to capital markets, and are possibly viewed as "too big to fail" with attendant implicit government guarantees.

Flannery and Rangan (2008) also document a large increase in bank capital during the 1990s. The authors note the timing correlation with deregulation of the banking industry and the related increase in risk exposure. They suggest that increased diversification may have been offset by the increased risk of the newly permissible activities. As a result, it was counterparty risk that was the driving force for higher capital ratios.

13.3 Methodology

13.3.1 Instrumental Variable for Capital

We differ from previous studies that deal with the endogeneity between risk and capital using traditional methods such as a simultaneous equation approach or two- or three-stage regression analysis.[2] In this study, we follow the method and concept of Hughes et al. (2001, 2003); and others and use stochastic frontier analysis to estimate the inefficiency of our sample of bank holding companies. See Jondrow et al. (1982) for a discussion of fitting production frontier models. We then create a unique instrumental variable for bank capital to be used in regressions of capital and risk. The question we ask is: "How efficient is a bank holding company in converting the resources with which it has to work into profit?" The frontier developed is exogenous to any specific bank since it is based on the results of all banks in the sample. From this frontier, we measure the inefficiency of each bank as the distance between the frontier and that specific bank's pretax income. This measure, however, must be adjusted for those elements that are beyond the control of the bank.

Our unrestricted frontier model determines the highest possible profitability based solely on the book value of assets employed. The unrestricted model is specified as

$$\begin{aligned} &PTI(BVA, \sigma_{\text{BANK}}) = a + b_1 BVA + b_2 (BVA)^2 + e \\ &e = \xi - \varsigma \\ &\xi \sim iid\, N\left(0, \sigma_\xi^2\right), \varsigma(\geq 0) \sim iid\, N\left(0, \sigma_\varsigma^2\right) \end{aligned} \tag{13.1}$$

where *PTI* is pretax income, *BVA* is of book value of assets, ξ is statistical noise, ς is systematic shortfall (under management control), and $\varsigma \geq 0$. A quadratic specification is used to allow for a nonlinear relation between the pretax income and the book value of assets.

Our next step is to develop a second frontier based on the level of bank holding company capital as well as the amount of assets. The implication of using the unrestricted model is that we are measuring the unconditional inefficiency of the banking organization. By also conditioning the model on capital, we can develop a measure of the incremental efficiency or inefficiency of an organization due to its

[2] In Appendix 1, we explain the execution of stochastic frontier in this chapter.

capital level. It is this incremental inefficiency due to a bank's capital level that we propose to use as an instrument for capital in a regression of risk on capital. Specifically, our restricted model, again in a quadratic form, is as follows:

$$\begin{aligned} &PTI(BVA, BVC, \sigma_{\mathrm{BANK}}) = \alpha + \beta_1 BVA + \beta_2 (BVA)^2 + \beta_3 BVC + \varepsilon \\ &\varepsilon = v - u \\ &v \sim iid\, N\left(0, \sigma_v^2\right)\, u(\geq 0) \sim iid\, N\left(0, \sigma_u^2\right) \end{aligned} \tag{13.2}$$

where BVC is the book value of capital, v is statistical noise, and u denotes the inefficiency of a bank considering its use of both assets and capital.

The two assessments of inefficiency allow us to measure the difference in profitability due to the use of capital by calculating the difference in the inefficiency between the restricted and unrestricted model. Specifically,

$$\delta = u - \varsigma \tag{13.3}$$

This becomes our instrumental variable for capital. While any measure of profitability endogenously includes risk, our instrument, the difference between two measures of profitability conditioned only on capital, is related to capital but not to risk which is included in both models.

13.3.2 Generalized Method of Moments

We first apply a generalized method of moments (GMM) regression in this study.[3] There are several reasons why we need to consider the infeasibility of the OLS regression. First, the departure from normality of the variable δ due to the combined error terms should be taken into account in the analysis. There is no theory to support a Gaussian distribution of these variables. Furthermore, in practice, the ranges of the independent and dependent variables are bounded within certain intervals. Unlike other estimators, GMM is robust and does not require information on the exact distribution of the disturbances. We follow Hamilton (1994) to construct our GMM estimation. To control for the impact of size on a bank's risk-taking behavior, the book value of assets is considered in the model (Gatev et al. 2009). The relationship between the variables specifying bank behavior and the use of equity is analyzed by GMM regression. Specifically,

$$y_{k,t} = c_t + b_{k,t}\delta_{i,t} + \gamma_{k,t}\ln(BVA) + \eta_{k,t}, \tag{13.4}$$

where $y_{k,t}$ is one of the measures of risk or behavior (e.g., total equity/total asset) for bank i in year t; c is a constant; $b_{k,t}$ is the coefficient of instrumental

[3] In Appendix 2, we provide the derivation of the GMM model.

variable of capital, $\delta_{i,k}$, for k's regression in year t; $\gamma_{k,t}$ is the coefficient of natural logarithm of bank's book value; and $\eta_{k,t}$ is the error term.

13.4 Data

We obtain our data on bank holding companies from Federal Reserve reports FR Y-9C for the years 1993–2008. Data on risk-weighted assets, tier 1 capital, and tier 2 capital were not included with the FR Y-9C reports from 1993 to 1996. We were graciously provided this missing information by the authors of Berger et al. (2008).

Table 13.1 displays the descriptive statistics of the sample BHCs in our analysis. The total of 24,973 bank-year observations ranges from 2,256 in 2005 to 678 in 2008. From 2005 to 2006, there is an especially large drop in the number of BHCs included in our data. This is primarily due to a change in the reporting criteria for the FR Y-9C report. Starting in 2006, the threshold for required reporting by a BHC was increased from BHCs with $150 million in total assets to BHCs with $500 million in total assets. Note that in spite of the 57 % drop in the number of BHCs reporting in 2006 compared with 2005, the total assets represented in the sample for these 2 years decreased by only 14 %.

Our data start in 1993 because 1992 was the final year in which capital ratios were still adjusting in order to conform to the Basle I Capital Accord. As a result, 1993 represents the first year that does not include any mandated changes in the capital ratios. The entire period of 1993–2008 contains a number of significant events affecting the banking industry. For instance, the Riegle-Neal Interstate Banking and Branching Act was passed in 1994 eliminating geographic restrictions on bank expansion. In 1999 the Gramm-Leach-Bliley Financial Services Modernization Act was passed effectively repealing the Glass-Steagall Act. Together these two acts overturned 65 years of legislation and regulation intended to keep banks financially sound.

From an economic point of view, the early portion of our time period represented a time of recovery from recession. The economy then moved from recovery to growth, and the decade ended in a tech-stock boom followed by a bursting of the tech-stock price bubble and an attendant recession. The new decade brought traditional financial policies intended to stimulate the economy which, in hindsight, probably helped to lay the foundation for the housing price bubble which precipitated the 2007–2009 financial crisis. The time period from 1993 to 2008 seems to be a very appropriate period in which to analyze bank capital ratios.

Previous empirical studies have used market measures of risk and various risk measures derived from a market model based on return data. However, this approach necessarily limits the sample to publically owned banks or bank holding companies. In this study, we wish to determine the impact of capital on various measures of risk and acknowledge the importance of small banks and bank holding companies, as well as the largest bank holding companies. This concern is significant since public policy related to the banking industry must consider the broadest sample and not only the largest organizations. As a result, we utilize a large panel data set and turn to the typical accounting measures of a bank's risk.

Table 13.1 Statistical summary

Year	N	BVA (US$ million) Mean	Max	Min	SD	BE	PTI	ROE	OHE	OBS	RA	Cap	E/A	NPA	Gap
1993	1,525	2,630	216,574	22	12,260	207	43	0.135	4.10	0.120	0.438	0.161	0.085	0.069	0.160

The numbers of bank holding companies (*BHCs*) and statistics of their book value of asset (*BVA*) over sample years are reported. The means of other descriptive statistics are listed: BE, book value of equity; PTI, pretax income; ROE, return of equity; OHE (*overhead efficiency*), noninterest expenses/noninterest income; OBS (*off-balance-sheet activities*), all OBS activities/total assets; RA (*risk-based asset ratio*), total risk-based assets/total assets; Cap (*total risk-based capital ratio*), (tier 1 capital + tier 2 capital)/total risk-based asset; E/A, total equity/total asset; NPA (*nonperforming assets ratio*), nonperforming assets/total equity capital; Gap, (*interest-sensitive gap*) (IS assets – IS liabilities)/total asset. The BVA, BE, and PTI are in million US dollar

13.4.1 Overall Observations of BHC Data

We see the significant events and the economic activity listed above in the statistics in Table 13.1. First, the size of BHCs measured by either their asset values or equity has increased, while the number of banks has decreased. This trend is still evident after adjusting for changes in the reporting criteria for the FR Y-9C report. The government deregulation noted above has resulted in increased concentration in the banking industry. We note also the significant cross-sectional variation in scale of BHCs that suggests the utilization and operation of their resources vary considerably.

When we look in Table 13.1 at the basic leverage ratio of equity to assets (E/A), we see a generally rising ratio. In 1993, the ratio was 8.5 %, while in 2008 it was 9.2 %. These ratios appear to be in line with mandatory capital requirements. We also see variation in this trend consistent with prevailing economic activity. For example, the decline from 9.4 % in 1998 to 8.9 % in 1999 reflects the tech-stock problems of that time period. In Table 13.1, we also see a rising trend in RA, the ratio of risk-based assets to total assets. Here, however, the trend is far more pronounced, rising from 43.80 % in 1993 to 76.00 % in 2008. Confirmation of these two trends comes from the trend in CAP, the ratio of tier 1 plus tier 2 capital to risk-based assets. This ratio declines from 16.10 % in 1993 to 14.50 % in 2008. While these ratios are substantially above the Basle Capital Accord standards, the trend is clearly down.

Another dramatic trend over this time period is the increase in off-balance-sheet activity. In Table 13.1, the off-balance-sheet activities-to-total assets ratio (OBS) has increased from 12.00 % in 1993 to 31.50 % in 2008. While this trend is not a surprise, we need to ask if there is capital to support this expansion and consider the makeup of the components of off-balance-sheet activities. It is unclear whether BHCs use off-balance-sheet activities to decrease or increase risk.

The time-varying overall performance measures of our sample of BHCs such as pretax income (PTI), return on equity (ROE), nonperforming assets ratio (NPA), and the interest-sensitive gap (Gap) are shaped by major economic occurrences and policies. Return on equity has varied in a relatively narrow band over this time period. With the exception of 2007 and 2008, the return on equity ranged from 12.20 % to 13.50 %. In line with the financial crisis that started in 2007, ROE declined to 11.00 % in 2007 and to 8.40 % in 2008. It is also noteworthy that the highest return on equity was in the first year of our sample period, 1993. Nonperforming assets appear to move in concert with economic activity. The recovery and expansion period of 1993–1998 is marked by a steady decrease in the ratio of nonperforming assets to equity. This is followed by an increase in this ratio during the tech-stock bubble and recession after which we see another decline until the crisis of 2007 and 2008.

Since the industrial structure of financial services changes intertemporally, we analyze the risk and use of capital by BHCs year by year. The analysis suggests banks progressively depend more on aggressive funding sources and new product lines over our sample period. Given that financial leverage (e.g., equity/asset ratio) must remain approximately stable due to regulatory requirements, bankers may try to improve their ROE by (1) enhancing overhead efficiency (OHE), (2) engaging in more off-balance-sheet activities (OBS), and (3) using interest-sensitive gap management in an attempt to decrease their total risk-based capital ratio (Cap) while maintaining an attractive ROE. The above developments in the banking industry generate potential improvement in performance but also intensify uncertainties and complexities of bank management. Therefore, a study to investigate the impact of the use of capital on the riskiness of banks is an indispensible element in bank management.

13.4.2 Instrumental Variable

The statistical summary of our instrumental variable, δ, for each year is shown in Table 13.2. Consistent with the findings documented by Hughes et al. (2001), John et al. (2000), Keeley (1990), and Kim and Santomero (1988), the use of equity capital by banks, on average, triggers a loss in efficiency. The dispersion of δ is substantial both cross-sectionally and intertemporally. For our sample, the distribution of δ in the same year tends to be skewed to the left-hand side and leptokurtic (i.e., has positive excess kurtosis). Therefore, we look at nonparametric statistics and use a normality-free regression model in our analysis to avoid the possible errors in estimation.

Table 13.2 Distribution of instrumental variables

	Mean	SD	Skewness	Kurtosis	Max	Min
1993	−0.038	0.106	−0.167	1.936	0.470	−0.494
1994	−0.040	0.112	−0.386	3.394	0.511	−0.805
1995	−0.036	0.114	−0.196	3.791	0.551	−0.753
1996	−0.041	0.111	−0.037	1.852	0.506	−0.557
1997	−0.223	0.162	−2.848	16.357	0.302	−1.253
1998	−0.032	0.112	−0.018	3.332	0.544	−0.744
1999	−0.053	0.144	−0.266	1.274	0.502	−0.714
2000	−0.054	0.144	−0.101	1.358	0.541	−0.761

Descriptive statistics of the instrumental variable for capital over sample years are presented. The instrumental variable $\delta = u - \varsigma$ is a measure of incremental bank inefficiency due to capital level, where the stochastic frontiers are $PTI = a + b_1BVA + b_2(BVA)^2 + e$, $e = \xi - \varsigma$, and $PTI = \alpha + \beta_1BVA + \beta_2(BVA)^2 + \beta_3BVC + \varepsilon$, $\varepsilon = v - u$

13.4.3 Measures of Bank Risk

We investigate the risks faced by banks from various aspects. Table 13.3 displays the measures of risk used in this study: credit risk, liquidity risk, interest rate risk, off-balance-sheet (OBS) risk, market risk, and finally leverage risk. Credit risk is concerned with the quality of a bank's assets. Historically this has focused on a bank's loan portfolio, but recent events have shown the importance of looking at all bank assets in light of potential default risk. Liquidity risk measures the ability of a bank to meet all cash needs at a reasonable cost whenever they arise. Interest rate risk is the extent to which banks have protected themselves from market-driven changes in the level of interest rates. Banks have the opportunity to use asset/liability management tools to mitigate the impact of changes in interest rates on both bank earnings and bank equity. We also collect data on off-balance-sheet activities and investigate their relationship with bank capital. Market risk is the risk of changes in asset prices that are beyond the control of bank management. Finally, leverage risk is the risk arising from the capital structure decisions of the BHC. The first five measures of risk relate to the various elements of business risk confronting bank management. Leverage risk, on the other hand, relates directly to the financial decisions taken in terms of the amount of capital employed. From another perspective, it can be said that minimum capital requirements (i.e., maximum leverage standards) are mandated by regulators to mitigate the various elements of business risk that the BHC accepts.

Table 13.4 displays the Spearman correlation coefficients between bank size and our instrumental variable over the sample period. We look at this nonparametric test due to the non-normal distribution of the instrument and variables. We believe that the generally insignificant correlation between our instrument and the book value of assets in combination with the generally significant correlation of our instrument and the book value of equity justifies the use of delta as an instrument for capital. In addition, Table 13.4 shows that, measured by book value of equity and pretax income, large BHCs tend to suffer a greater loss in efficiency than their smaller counterparts at a statistically significant level. On the other hand, the value of assets does not necessarily demonstrate a negative relation with bank efficiency. These findings suggest that the inefficiency of BHCs comes from the use of equity capital but is not directly led by the expansion of business scale and/or scope. Therefore, a careful investigation of the impact of capital on banking risks is appropriate.

13.5 Empirical Results

We look at seven different measures of risk: credit risk, liquidity risk, interest rate risk, off-balance-sheet risk, market risk, composite risk, and leverage risk. While many of the results support the proposition that increased capital requirements reduce risk in BHCs, there are some very significant results that suggest the opposite – that BHCs increase risk as their capital ratios increase.

Table 13.3 Variables

Symbol	Definition
Overall risk	
Eq/A	Total equity/total asset
RA/A	Total risk-based assets/total assets
RC/RA	Capital requirement ratio (total risk-based capital/total risk-based assets)
Tier 1/RA	Tier 1 capital/total risk-based assets
Tier 2/tier 1	Tier 2 capital/tier 1 capital
Credit risk	
NPL/LL	Nonperforming assets/total loans and leases
NPL/E	Nonperforming assets/total equity capital
Charge-offs/L	Net loan charge-offs/total loans and leases
Provision/L	Annual provision for loan losses/total loans and leases
Provision/E	Annual provision for loan losses/total equity capital
Allowance/L	Allowance for loan losses/total loans and leases
Allowance/E	Allowance for loan losses/total equity capital
Liquidity risk	
STPF/A	Short-term purchased funds (Eurodollars, federal funds, security RPs, large CDs, and commercial paper)/total assets
Cash/A	Cash and due from other banks/total assets
HLA/A	Cash assets and government securities/total assets
FFS/A	(Federal funds sold + reverse RPs – sum of federal funds purchased – RPs)/total assets
FFP/A	(Federal funds purchased + RPs)/total assets
Cash/STPF	Cash and due from other banks/short-term purchased funds (Eurodollars, federal funds, security RPs, large CDs, and commercial papers)
Interest rate risk	
Gap	Interest-sensitive gap (IS assets – IS liabilities)/total assets
Off-balance-sheet risk	
OBS/A	Off-balance-sheet assets/total assets
Der/A	Credit equivalent amount of off-balance-sheet derivative contracts/total assets
Der/RA	Credit equivalent amount of off-balance-sheet derivative contracts/total risk-based assets
IR Der	Notional amount of interest rate derivatives held for trading/notional amount of interest rate derivatives held for other purposes
FX Der	Notional amount of foreign exchange derivatives held for trading/notional amount of foreign exchange derivatives held for other purposes
Eq Der	Notional amount of equity derivatives held for trading/notional amount of equity derivatives held for other purposes
Cmd Der	Notional amount of commodity derivatives held for trading/notional amount of commodity derivatives held for other purposes
OBS/E	Total OBS LC, commitments, credit card lines of credit, and loan/total equity
Der/A	Total derivatives/total assets

(*continued*)

Table 13.3 (continued)

Symbol	Definition
Market risk	
Trading assets	Trading account assets/total assets
Trading A/L	Trading account assets/trading account liabilities
Investment M/B	Market value of investment portfolio/book value of investment portfolio
Performance	
PTI/A	Pretax income/asset
ROE	Return on equity
ROA	Return on asset
ATR	Average tax rate (taxes/pretax income)
Spread	Earning spread (interest income/(loan + investment)−(interest expenses/deposits))
OHE	Overhead efficiency (noninterest expenses/noninterest income)

Our results are displayed in Tables 13.5, 13.6, 13.7, 13.8, 13.9, and 13.10 and provide a number of interesting insights. To enhance robustness, we present both Spearman's rank correlation coefficient between the tested variable and the instrumental variable for capital, δ, and the coefficient of δ in GMM regressions. To control for the size of the bank holding companies, each coefficient of δ is generated by GMM regression with a constant and the natural logarithm of the book value of assets. While the coefficient of the control variable and the constant term are omitted from the tables, they are available upon request. In Table 13.5, we find a positive relationship between ratio of total equity to total assets and our instrument for capital (see Eq/A). The coefficient on our instrument is strictly positive and statistically significant. This is clearly what we would expect. As leverage decreases, so does risk; therefore, higher capital should be associated with higher levels of this risk measure. In other words, it should be a positive relationship, and it is. However, for the ratio of risky assets to total assets, risk increases as the ratio increases. Therefore, higher capital should be associated with lower levels of this risk measure (a negative relationship), and again that is what we find. When we look at just tier 1 capital to total risky assets, we find the expected positive relationship, and when we look at the ratio of tier 2 to tier 1 capital, we find the expected negative relationship.

In Table 13.6, we look at some traditional measures of credit risk. As the ratio of nonperforming loans to total loans increases, so does risk. Therefore, the coefficient on capital should be negative, and they are with several exceptions over the years. Our second measure of credit risk is the ratio of nonperforming loans to total equity. Here again higher levels of the ratio imply higher risk, so we expect to find a negative relationship and we do, and this time without exception and at high levels of significance. When we look at the ratio of loan charge-offs to loans outstanding, we have more exceptions, but in general we find an expected negative relationship.

Spearman's rank correlation coefficients between each risk measure variable with δ, the instrument for capital, are reported for each year in Panel A. In Panel B, the GMM regression coefficients of $b_{k,t}$ for each dependent variable k in each year t are reported. Specifically, $y_{k,t} = c_t + b_{k,t}\delta_{i,t} + \gamma_{k,t}\ln(BVA) + \eta_{k,t}$, where $y_{k,t}$ is one of the measures of risk or performance (e.g., total equity/total asset) for bank i in year t; c is a constant; $b_{k,t}$ is the coefficient of instrumental variable of capital, $\delta_{i,k}$, for k's regression in year t; $\gamma_{k,t}$ is the coefficient of natural logarithm of bank's book value; an $\eta_{k,t}$ is the error term

Please see the description of Table 13.5

The ratio of the provision for loan loss to total loans is an ambiguous measure. A high provision could indicate bank management is expecting high loan losses. On the other hand, a high ratio could indicate conservative bank management that is taking no chances on an underfunded allowance for loan loss. When we look at the provision as a percentage of total equity, we again have the same ambiguous results possible. In general, we find that both of these risk measures produce a negative coefficient on our measure of capital. The ambiguity seems to be resolved in that as the provision for loan losses increases, so does risk. The alternative explanation is that risk should decrease with this ratio, but higher capital levels produce counterintuitive results. The ratio of the allowance for loan loss to total loans moves inversely with capital while the ratio of allowance for loan loss to total equity moves in the opposite direction.

We turn now to the allowance for loan losses. Like the provision for loan loss ratios, we have the same ambiguous expectations, but now we find conflicting results. There is no clear expectation for the impact of this ratio on risk. In other words, both the ratio of the allowance for loan losses to total loans and the ratio of the allowance for loan losses to total equity can be reflecting either high risk or low risk. What we find is that the allowance for loan loss as a percentage of loans produces a positive sign for the coefficient on capital, while the allowance for loan loss as a percentage of equity produces a negative sign on the coefficient.

We find even more consistent counterintuitive results when we look at the relationship between capital and liquidity risk in Table 13.7. Lower capital ratios are generally related to higher levels of short-term purchased liabilities (see STPF/A and FFP/A). Since short-term purchased money is more volatile than core deposits, for example, we would expect high levels of purchased money to be associated with high levels of capital, yet this is not what we find. On the other hand, we do find that higher capital ratios are related to more liquid assets (HLA/A) and better coverage of short-term liabilities (FFS/A). Since both of these ratios imply higher levels of liquidity, we expected them to be related to lower levels of capital. Apparently liquidity risk is not reflected in a BHC's capital level.

When we look at a BHC's exposure to interest rate risk, we again find counterintuitive results. As noted above, Table 13.7 shows that low capital ratios are related to high levels of short-term purchased funds. This can result in a fundamental liquidity problem if some markets for short-term borrowing completely dry up as we have observed in the recent financial crisis. Our more direct measure of interest rate risk is the interest-sensitive gap (gap) which we define as interest-sensitive assets minus interest-sensitive liabilities divided by total assets. Here we find ambiguous results. It is obvious that wider gaps expose banks to more risk if interest rates move against the bank. However, wide gaps can be held in both a positive and negative direction. A high positive gap indicates a BHC has a large amount of interest-sensitive assets in relation to interest-sensitive liabilities and will be hurt by falling interest rates. A high negative gap indicates a BHC has a large amount of interest-sensitive liabilities in relation to interest-sensitive assets and will be hurt if interest rates rise. Our results in Table 13.7 indicate that wider gaps are associated with lower levels of capital, but this is only a true measure if BHCs typically held a positive gap.

In Table 13.8, we turn our attention to BHCs' off-balance-sheet activity. Rather surprisingly, off-balance-sheet exposures seem to be inversely related to capital levels in spite of the Basle Capital Accords. Recall that the Basle Accords require the maintenance of capital in support of off-balance-sheet activity. Yet all of our measures of off-balance-sheet risk are associated with low capital levels with one exception. The notional amount of commodity derivatives held for trading compared with the notional amount of commodity derivatives held for other purposes is associated with a higher level of capital. Our interpretation of the ratios that measure the amount of derivatives held for trading compared with the derivatives held for other purposes is that the derivatives not held for trading are held to hedge an existing position on the books of the BHC. As a result, a high ratio implies more trading activity in relation to hedging activity, and therefore, more capital should be required. However, we again find high OBS ratios associated with low levels of capital.

In Table 13.9, we look at two measures of market risk: the size of the BHCs' trading account and the amount of unrealized gains or losses on the BHCs' investment portfolio. We again find what we believe are counterintuitive results. First, larger trading portfolios inherently contain a larger amount of market risk. On the other hand, a large amount of unrealized gains in the investment portfolio mitigates market risk, at least to some extent. We find, however, low levels of capital associated with higher trading portfolios, while high levels of capital are associated with higher unrealized gains in the investment portfolio.

Our results concerning performance measures are shown in Table 13.10. Here we find evidence of higher capital ratios being associated with higher return on assets ratios and with higher net interest spreads. Since higher returns on earning assets are logically associated with higher risk, it is appropriate that higher capital is used in support of the additional risk. However, while the direction of the causality is not clear, this could be interpreted as more evidence that BHCs increase risk to maintain a target return on equity in the face of higher capital requirements.

13.6 Conclusions

In this study, we thoroughly analyze a large cross section of bank holding company data from 1993 to 2008 to determine the relationship between capital and bank risk-taking. Our sample includes a minimum of almost 700 BHCs in 2008 and a maximum of about 1,500 BHCs in 1993. This produces nearly 25,000 company-year observations of BHCs starting with the year that risk-based capital requirements were first in place. Our data cover a period containing significant changes in the banking industry and varying levels of economic activity. The Riegle-Neal and Gramm-Leach-Bliley acts were passed during this time period, and the tech-stock and housing bubbles both burst with attendant recessions. By including a larger size range of BHCs in our analysis over a long sample period, our results are applicable to relatively small BHCs as well as to the largest 200 or so BHCs traditionally included in empirical studies.

We employ stochastic frontier analysis to create a new type of instrumental variable for capital to be used in regressions of risk and capital, thereby mitigating the obvious endogeneity problem. The instruments are validated to confirm their high correlation with capital and limited correlation with risk. We conclude that they are suitable for use in our models and employ a GMM estimator to acknowledge the non-normal distribution of the instruments.

Our results are consistent with the theory that BHCs respond to higher capital ratios by increasing the risk in the earning asset portfolios. We find an inverse relationship between the proportion of risky assets held by a bank holding company and the amount of capital they hold. We also find lower levels of capital associated with measures of credit risk that indicate a riskier loan portfolio. For example, the amount of nonperforming assets held by the bank holding company is inversely related to the bank holding company's capital.

Our findings also demonstrate a counterintuitive relationship between bank capital and liquidity risk. Less liquid banks tend to have low capital ratios, while more liquid banks tend to have high capital ratios. These same results suggest that a higher level of interest rate risk is also related to lower levels of capital. Our direct measure of the mismatch between interest-sensitive assets and liabilities provides additional evidence, although somewhat ambiguously, of higher interest rate risk being associated with lower capital. High levels of off-balance-sheet activity and of market risk exposure are likewise surprisingly related to low capital levels. Finally, we note the association of high levels of capital with high return on asset ratios. This association at least suggests that bank holding companies do increase the risk of their earning assets in order to provide an adequate return on their capital.

Our analysis adds to the existing literature with three contributions. First, we employ a large panel data set to consider the capital-risk relationship for a wider range of bank holding companies than previously reviewed. Second, stochastic frontier analysis is applied to exogenously generate the effect of the use of capital in banking. Finally, our results provide what we believe are important findings with potentially major public policy implications. If the primary tool used by bank regulators to ensure a stable financial system is, instead, creating perverse results, then alternative tools must be developed. Further exploring the relationship between the efficiency of capital and the risk strategy adopted by a bank would be a contribution to this literature.

Appendix 1: Stochastic Frontier Analysis

Stochastic frontier analysis (SFA) is an economic modeling method that is introduced by Jondrow et al. (1982). The frontier without random component can be written as the following general form:

$$PTI_i = TE_i \cdot f(\mathbf{x}_i; b), \tag{13.5}$$

where PTI_i is the pretax income of the bank i, $i = 1,..N$, TE_i denotes the technical efficiency defined as the ratio of observed output to maximum feasible output, $\mathbf{x}_i$ is a vector of J inputs used by the bank i, $f(\mathbf{x}_i, b)$ is the frontier, and b is a vector of technology parameters to be estimated. Since the frontier provides an estimate of the maximum feasible output, we then can measure the shortfall of the observed output from the maximum feasible output. Considering a stochastic component that describes random shocks affecting the production process in this model, the stochastic frontier becomes

$$PTI_i = e^{v_i} \cdot TE_i \cdot f(\mathbf{x}_i; b). \tag{13.6}$$

The shock, e^{v_i}, is not directly attributable to the bank or the technology but may come from random white noises in the economy, which is considered as a two-sided Gaussian distributed variable.

We further describe TE_i as a stochastic variable with a specific distribution function. Specifically,

$$TE_i = e^{-u_i}, \tag{13.7}$$

where u_i is the nonnegative technical inefficiency component, since it is required that $TE_i \leq 1$. Thus, we obtain the following equation:

$$PTI_i = e^{v_i - u_i} \cdot f(\mathbf{x}_i; b). \tag{13.8}$$

We then can describe the frontier according to a specific production model. In our case, we assume that bank's profitability can be specified as the log-linear Cobb-Douglas function:

$$PTI_i = a + \sum_{h=1}^{H} b_h \ln x_{i,h} + v_i - u_i. \tag{13.9}$$

Because both v_i and u_i constitute a compound error term with a specific distribution to be determined, hence the SFA is often referred as composed error model.

In our study, we use the above stochastic frontier with different inputs to generate the net effect of bank capital without mixing the impact of risk. The unrestricted model (without including bank equity) is

$$\begin{array}{l} PTI(BVA, \sigma_{\mathrm{BANK}}) = a + b_1 BVA + b_2 (BVA)^2 + e \\ e = \xi - \varsigma \\ \xi \sim iidN\left(0, \sigma_\xi^2\right), \varsigma \sim iidN\left(0, \sigma_\varsigma^2\right) \end{array}, \tag{13.10}$$

where BVA is the natural logarithm of book value of assets, ξ is statistical noise, ς is systematic shortfall (under management control), and $\varsigma \geq 0$. Our restricted model is as follows:

$$\begin{aligned} &PTI(BVA, BVC, \sigma_{\text{BANK}}) = \alpha + \beta_1 BVA + \beta_2 (BVA)^2 + \beta_3 BVC + \varepsilon. \\ &\varepsilon = v - u \\ &v \sim iidN(0, \sigma_v^2) u \sim iidN(0, \sigma_u^2)\text{'} \end{aligned} \tag{13.11}$$

where BVC is the natural logarithm of book value of capital, v is statistical noise, and u denotes the inefficiency of a bank considering its use of both assets and capital. The difference in the inefficiency between the restricted and unrestricted model,

$$\delta = u - \varsigma, \tag{13.12}$$

is our instrumental variable. The instrumental variable for capital can be used in regressions of various measures of risk, as the dependent variable, on our instrument for capital, as the independent variable, while controlling for BHC size.

Appendix 2: Generalized Method of Moments

Hansen (1982) develops generalized method of moments (GMM) to estimate parameters that its full shape of the distribution function is not known. The method requires that a certain number of moment conditions were specified for the model. These moment conditions are functions of the model parameters and the data, such that their expectation is zero at the true values of the parameters. The GMM method then minimizes a certain norm of the sample averages of the moment conditions.

Suppose the error term $\boldsymbol{\varepsilon}_t = \boldsymbol{\varepsilon}(\mathbf{x}_t, \theta)$ is a $(T \times 1)$ vector that contains T observations of the error term $\boldsymbol{\varepsilon}_t$, where $\mathbf{x}_t$ includes the data relevant for the model and θ is a vector of N_β coefficients. Assume there are N_H instrumental variables in an $(N_H \times 1)$ column vector, $\mathbf{h}_t$ and T observations of this vector form a $(T \times N_H)$ matrix $\mathbf{H}$. We define

$$\mathbf{f}_t(\theta) \equiv \mathbf{h}_t \otimes \boldsymbol{\varepsilon}(\mathbf{x}_t, \theta). \tag{13.13}$$

The notation $\otimes$ denotes the Kronecker product of the two vectors. Therefore, $\mathbf{f}_t\ (\theta)$ is a vector containing the cross product of each instrument in $\mathbf{h}$ with each element of $\boldsymbol{\varepsilon}$. The expected value of this cross product is a vector with $N_\varepsilon N_{\mathrm{H}}$ elements of zeros at the parameter vector:

$$\mathrm{E}[\mathbf{f}_t(\theta_0)] = 0. \tag{13.14}$$

Since we do not observe the true expected values of $\mathbf{f}$, thus we must work instead with the sample mean of $\mathbf{f}$,

$$\mathbf{g}_t(\theta) \equiv T^{-1} \sum_{t=1}^{T} \mathbf{f}_t(\theta) = T^{-1} \sum_{t=1}^{T} \mathbf{h}_t \boldsymbol{\varepsilon}_t(\theta) = T^{-1}\ \mathbf{H}' \boldsymbol{\varepsilon}_t(\theta). \tag{13.15}$$

We can minimize the quadratic form

$$\mathbf{Q}_T(\theta) \equiv \mathbf{g}_T(\theta)' \mathbf{W}_T \mathbf{g}_T(\theta), \tag{13.16}$$

where $\mathbf{W}_T$ is an $(N_H \times N_H)$ symmetric, positive definite weighting matrix. We then find the first-order condition is

$$\mathbf{D}_T\left(\hat{\theta}_T\right)' \mathbf{W}_T \mathbf{g}_T\left(\hat{\theta}_T\right) = 0, \tag{13.17}$$

where $\mathbf{D}_T\ (\theta_T)$ is a matrix of partial derivatives defined by

$$\mathbf{D}_T(\theta_T) = \partial \mathbf{g}_T(\theta_T)/\partial\theta'.$$

Note the above problem is nonlinear; thus, the optimization must be solved numerically.

Applying the asymptotic distribution theory, the coefficient estimate $\hat{\theta}_T$ is

$$\sqrt{T}\left(\hat{\theta}_T - \theta_0\right) \xrightarrow{d} N(0, \Omega), \tag{13.18}$$

where $\Omega = (\mathbf{D}_0{}'\mathbf{W}\mathbf{D}_0)^{-1}\ \mathbf{D}_0{}'\mathbf{W}\mathbf{S}\mathbf{W}\mathbf{D}_0\ (\mathbf{D}_0{}'\mathbf{W}\mathbf{D}_0)^{-1}$. $\mathbf{D}_0$ is a generalization of M_{HX} in those equations and is defined by $\mathbf{D}_0 \equiv \mathrm{E}[\partial \mathbf{f}(\mathbf{x}_t, \theta_0)/\partial\theta_0]$. $\mathbf{S}$ is defined as

$$\mathbf{S} \equiv \lim_{T\to\infty} \mathrm{Var}\left[T^{1/2}\sum_{t=1}^{T} \mathbf{f}_t(\theta_0)\right] = \lim_{T\to\infty} \mathrm{Var}\left[T^{1/2}\mathbf{g}_T(\theta_0)\right]. \tag{13.19}$$

The GMM estimators are known to be consistent, asymptotically normal, and efficient in the class of all estimators that do not use any extra information aside from that contained in the moment conditions. For more discussion of the execution of the GMM, please refer to Campbell et al. (1997) and Hamilton (1994).

Evaluating Long-Horizon Event Study Methodology

14

James S. Ang and Shaojun Zhang

Contents

Abstract

We describe the fundamental issues that long-horizon event studies face in choosing the proper research methodology and summarize findings from existing simulation studies about the performance of commonly used methods. We document in details how to implement a simulation study and report our own findings on large-size samples. The findings have important implications for future research.

We examine the performance of more than 20 different testing procedures that fall into two categories. First, the buy-and-hold benchmark approach uses

a benchmark to measure the abnormal buy-and-hold return for every event firm and tests the null hypothesis that the average abnormal return is zero. Second, the calendar-time portfolio approach forms a portfolio in each calendar month consisting of firms that have had an event within a certain time period prior to the month and tests the null hypothesis that the intercept is zero in the regression of monthly portfolio returns against the factors in an asset-pricing model. We find that using the sign test and the single most correlated firm being the benchmark provides the best overall performance for various sample sizes and long horizons. In addition, the Fama-French three-factor model performs better in our simulation study than the four-factor model, as the latter leads to serious over-rejection of the null hypothesis.

We evaluate the performance of bootstrapped Johnson's skewness-adjusted *t*-test. This computation-intensive procedure is considered because the distribution of long-horizon abnormal returns tends to be highly skewed to the right. The bootstrapping method uses repeated random sampling to measure the significance of relevant test statistics. Due to the nature of random sampling, the resultant measurement of significance varies each time such a procedure is used. We also evaluate simple nonparametric tests, such as the Wilcoxon signed-rank test or the Fisher's sign test, which are free from random sampling variation.

Long-horizon event study • Johnson's skewness-adjusted *t*-test • Weighted least squares regression • Bootstrap test • Calendar-time portfolio approach • Fama-French three-factor model • Johnson's skewness-adjusted *t*-statistic • Large-scale simulations

14.1 Introduction

A large number of papers in finance literature have documented evidence that firms earn abnormal returns over a long time period (ranging from 1 to 5 years) after certain corporate events. Kothari and Warner (2007) report that a total of 565 papers reporting event study results were published between 1974 and 2000 in five leading journals: the *Journal of Business* (JB), *Journal of Finance* (JF), *Journal of Financial Economics* (JFE), *Journal of Financial and Quantitative Analysis* (JFQA), and the *Review of Financial Studies* (RFS). Approximately 200 of the 565 event studies use a maximum window length of 12 months or more.

The evidence of long-horizon abnormal returns contradicts the efficient market hypothesis that stock prices adjust to information fully within a narrow time window (a few days). To reconcile the contradiction, Fama (1998) argues that "Most important, consistent with the market efficiency prediction that apparent anomalies can be due to methodology, most long-term return anomalies tend to disappear with reasonable changes in technique." Several simulation studies such as Kothari and Warner (1997) and Barber and Lyon (1997) document evidence that statistical inference in long-horizon event studies is sensitive to the choice of methodology. Therefore, it is crucial to gain an understanding of the properties and limitations of the available approaches before choosing a methodology for a long-horizon event study.

At the core of a long-horizon event study lie two tasks: the first is to measure the event-related long-horizon abnormal returns, and the second is to test the null hypothesis that the distribution of these long-horizon abnormal returns concentrates around zero. A proper testing procedure for long-horizon event studies has to do both tasks well. Otherwise, two types of error could arise and lead to incorrect inference. The first error occurs when the null hypothesis is rejected, not because the event has generated true abnormal returns, but because a biased benchmark has been used to measure abnormal returns. A biased benchmark shifts the concentration of abnormal returns away from zero and leads to too many false rejections of the null hypothesis. The second error occurs when the null hypothesis is accepted, not because the event has no impact, but because the test itself does not have enough power to statistically discriminate the mean abnormal return from zero. A test with low power is undesirable, as it will lead researchers to reach the incorrect inference that long-term effect is statistically insignificant. Thus, the researchers would want a procedure that minimizes both sources of error or at least choose a balance between them.

Two approaches have been followed in recent finance literature to measure and test long-term abnormal returns. The first approach uses a benchmark to measure the abnormal buy-and-hold return for every event firm in a sample and tests whether the abnormal returns have a zero mean. The second approach forms a portfolio in each calendar month consisting of firms that have had an event within a certain time period prior to the month and tests the null hypothesis that the intercept is zero in the regression of monthly calendar-time portfolio returns against the factors in an asset-pricing model. To follow either approach, researchers need to make a few choices as illustrated in Fig. 14.1. For the calendar-time portfolio approach, researchers choose an asset-pricing model and an estimation technique to fit the model. Among the most popular asset-pricing models are Fama and French's (1993) three-factor model and its four-factor extension proposed by Carhart (1997) that includes an additional momentum-related factor. Two techniques are commonly used to fit the pricing model: the ordinary least squares (OLS) technique and the weighted least squares (WLS) technique. On the other hand, if adopting the buy-and-hold benchmark approach, researchers choose either a reference portfolio or a single control firm as the benchmark for measuring abnormal returns and select either parametric or nonparametric statistic for testing the null hypothesis of zero abnormal return.

Permutations of these choices under both approaches generate a large number of possible testing procedures that can be used in a long-horizon event study. It is neither practical nor sensible to implement all the testing procedures in an empirical study of a financial event. Therefore, it would be very useful to provide guidance on the strength and weakness of the procedures based on simulation results. Simulation study generates large number of repetitions under various circumstances for each testing procedure, which allows the tabulations of these two types of error for comparison.

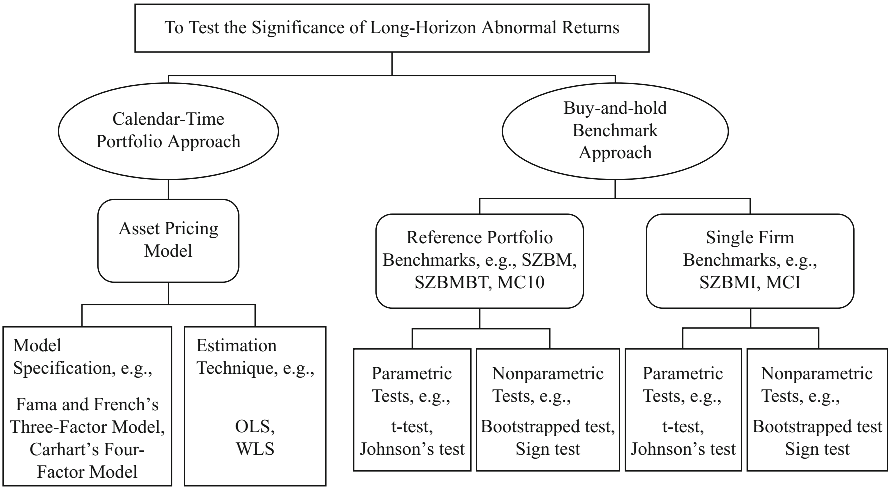

Fig 14.1 Overview of the two approaches to choose a methodology for long-horizon event study

We organize this chapter as follows. Section 14.2 discusses the fundamental issues in long-horizon event studies that have been documented in the literature. Section 14.3 reviews existing simulation studies. Section 14.4 reports results from a simulation study of large-size samples. Section 14.5 contains some suggestions for future research.

14.2 Fundamental Issues in Long-Horizon Event Studies

14.2.1 The Buy-and-Hold Benchmark Approach

The long-term buy-and-hold abnormal return of firm i, denoted as AR_i, is calculated as

$$AR_i = R_i - BR_i, \tag{14.1}$$

where R_i is the long-term buy-and-hold return of firm i and BR_i is the long-term return on a particular benchmark of firm i. The buy-and-hold return of firm i over τ months is obtained by compounding monthly returns, that is,

$$R_i = \prod_{t=1}^{\tau}(1 + r_{it}) - 1, \tag{14.2}$$

where r_{it} is firm i's return in month t. Calculation of the benchmark return BR_i is given below. The benchmark return, BR_i, estimates the return that an event firm would have had if the event had not happened.

Several articles clearly show that long-term abnormal returns are very sensitive to choice of benchmarks; see, e.g., Ikenberry et al. (1995), Kothari and Warner (1997), Barber and Lyon (1997), and Lyon et al. (1999). If wrong benchmarks were used in measuring long-term abnormal returns, inference on the significance of a certain event would be erroneous. Most existing studies use either a single matched firm or a matched reference portfolio as the benchmark. Barber and Lyon (1997) point out that the control firm approach eliminates the new listing bias, the rebalancing bias, and the skewness problem. It also yields well-specified test statistics in virtually all the situations they consider. Further, Lyon et al. (1999) advocate a reference portfolio of firms that match on size and BE/ME. The issue on choice of the benchmark is practically unresolved. Ang and Zhang (2004) additionally argue that the control firm method overcomes another important problem that is associated with the event firm not being representative in important aspects of the respective matched portfolio in the reference portfolio approach. This leads to the matched portfolio return generating a biased estimate of expected firm return. This problem is particularly severe with small firms.

A common practice in computing an event firm's long-term abnormal return is to utilize a benchmark that matches the event firm on size and BE/ME. The practice is often justified by quoting the findings in Fama and French (1992) that size and BE/ME combine to capture the cross-sectional variation in average monthly stock returns and that market beta has no additional power in explaining cross-sectional return differences. However, in a separate paper, Fama and French (1993) demonstrate that expected monthly stock returns are related to three factors: a market factor, a size-related factor, and a book-to-market equity ratio (BE/ME)-related factor. To resolve this issue, Ang and Zhang (2004) show that matching based on beta in addition to size and BE/ME does not improve the performance of the approach.

A recent trend is to use computation-intensive bootstrapping-based tests, such as the bootstrapped Johnson's skewness-adjusted *t*-statistic (e.g., Sutton 1993 and Lyon et al. 1999) and the simulated empirical p-values (e.g., Brock et al. 1992 and Ikenberry et al. 1995). These procedures rely on repeated random sampling to measure the significance of relevant test statistics. Due to the nature of random sampling, the resultant measurement of significance varies every time such a procedure is used. As a consequence, different researchers could reach contradictory conclusions using the same procedure on the same sample of event firms. In contrast, simple nonparametric tests, such as the Wilcoxon signed-rank test or the Fisher's sign test, are free from random sampling variation. Barber and Lyon (1997) examined the performance of the Wilcoxon signed-rank test in a large-scale simulation study. They show that the performance depends on choice of the benchmark. The signed-rank test is well specified when the benchmark is a single size and BE/ME matched firm and misspecified when the benchmark is a size and BE/ME matched reference portfolio. However, Barber and Lyon (1997) present only simulation results for 1-year horizon. *No simulation study in the finance literature has examined the performance of these simple nonparametric tests for 3- or 5-year horizons, which are the common holding periods in long-horizon event studies.*[1]

[1]The sign test has an advantage over the signed-rank test in that it does not require a symmetric underlying distribution, while the signed-rank test does.

Power is an important consideration in statistical hypothesis testing. Lyon et al. (1999) report that bootstrapping-based tests are more powerful than Student's *t*-test in testing 1-year abnormal returns in a large-scale simulation study. However, they do not report evidence on the power of these tests for the longer 3- or 5-year horizon. In statistics literature, bootstrapping is primarily for challenging situations when the sampling distribution of the test statistic is either indeterminate or difficult to obtain and that bootstrapping is less powerful in hypothesis testing than other parametric or simple nonparametric methods when both bootstrapping and other methods are applicable (see, e.g., Efron and Tibshirani 1993, Chap. 16 and Davison and Hinkley 1997, Chap. 4). In a recent study on 5-year buy-and-hold abnormal returns to holders of the seasoned equity offerings, Eckbo et al. (2000) note that bootstrapping gives lower significance level relative to the Student's *t*-test.

Ang and Zhang (2004) find that most testing procedures have very low power for samples of medium size over long event horizons (3 or 5 years). This raises concern about how to interpret long-horizon event studies that fail to reject the null hypothesis. Failure to reject is often interpreted as evidence that supports the null hypothesis. However, when power of the test is low, such interpretation may no longer be warranted. This problem gets even worse when event firms are primarily small firms. They observe that all tests, except the sign test, have much lower power for samples of small firms.

More recently, Schultz (2003) argue via simulation that the long-run IPO underperformance could be related to the endogeneity of the number of new issues. Firms choose to go IPO at the time when they expect to obtain high valuation in the stock market. Therefore, IPOs cluster after periods of high abnormal returns on new issues. In such a case, even if the ex ante returns on IPO are normal, the ex post measures of abnormal returns may be negative on average. Schultz suggests using calendar-time returns to overcome the bias. However, Dahlquist and de Jong (2008) find that it is unlikely that the endogeneity of the number of new issues explains the long-run underperformance of IPOs. Viswanathan and Wei (2008) present a theoretical analysis on event abnormal returns when returns predict events. They show that, when the sample size is fixed, the expected abnormal return is negative and becomes more negative as the holding period increases. This implies that there is a small-sample bias in the use of long-run event returns. Asymptotically, abnormal returns converge to zero provided that the process of the number of events is stationary. Nonstationarity in the process of the number of events is needed to generate a large negative bias.

The issues discussed above are associated with the buy-and-hold approach to testing long-term abnormal returns.[2] In addition, this approach suffers from the cross-correlation problem and the bad model problem (Fama 1998; Brav 1999; Mitchell and Stafford 2000). The cross-correlation problem arises because matching on firm-specific characteristics fails to completely remove the correlation between

[2]Variations of this approach have been used extensively; see, e.g., Ritter (1991); Ikenberry et al. (1995); Ikenberry et al. (1996); and Desai and Jain (1997), among many others.

event firms' returns. The bad model problem arises because no benchmark gives perfect estimate of the *counterfactual* (i.e., what if there was no event) return of an event firm and benchmark errors are multiplied in computing long-term buy-and-hold returns. Therefore, Fama (1998) advocates a calendar-time portfolio approach.[3]

14.2.2 The Calendar-Time Portfolio Approach

In the calendar-time portfolio approach, for each calendar month, an event portfolio is formed, consisting of all firms that have experienced the same event within the τ months prior to the given month. Monthly return of the event portfolio is computed as the equally weighted average of monthly returns of all firms in the portfolio. Excess returns of the event portfolio are regressed on the Fama-French three factors as in the following model:

$$R_{pt} - R_{ft} = \alpha + \beta\left(R_{mt} - R_{ft}\right) + sSMB_t + hHML_t + \varepsilon_t, \tag{14.3}$$

where R_{pt} is the event portfolio's return in month t; R_{ft} is the 1-month Treasury bill rate, observed at the beginning of the month; R_{mt} is the monthly market return; SMB_t is the monthly return on the zero investment portfolio for the common size factor in stock returns; and HML_t is the monthly return on the zero investment portfolio for the common book-to-market equity factor in stock returns.[4] Under the assumption that the Fama-French three-factor model provides a complete description of expected stock returns, the intercept, α, measures the average monthly abnormal return on the portfolio of event firms and should be equal to zero under the null hypothesis of no abnormal performance.

A later modification that has gained popularity is the four-factor model that added a momentum-related factor to the Fama-French three factors:

$$R_{pt} - R_{ft} = \alpha + b\left(R_{mt} - R_{ft}\right) + sSMB_t + hHML_t + pPR12_t + \varepsilon_t, \tag{14.4}$$

where $PR12_t$ is the momentum-related factor advocated by Carhart (1997). Typically, we compute $PR12_t$ by first ranking all firms by their previous 11-month stock return lagged 1 month and then taking the average return of the top one third (i.e., high past return) stocks minus the average return of the bottom one third (i.e., low past return) stocks.

Under the assumption that the asset-pricing model adequately explains variation in expected stock returns, the intercept, α, measures the average monthly abnormal return of the calendar-time portfolio of event firms and should be equal to zero under the null hypothesis of no abnormal performance. If the test concludes that the

[3]Loughran and Ritter (1995), Brav and Gompers (1996), and Brav et al. (2000), among others, have used the calendar-time portfolio approach.

[4]See Fama and French (1993) for details on construction of the mimicking portfolios for the common size and book-to-market equity factors. We thank Eugene Fama for providing us with returns on R_{ft}, R_{mt}, SMB_t, and HML_t.

time series conforms to the asset-pricing model, the event is said to have had no significant long-term effect; otherwise, the event has produced significant long-term abnormal returns. Lyon et al. (1999) report that the calendar-time portfolio approach together with the Fama-French three-factor model, which shall be referred to as the Fama-French calendar-time approach later, is well specified for random samples in their simulation study.

However, we do not know how much power the Fama-French calendar-time approach has. Loughran and Ritter (1999) criticize the approach as having very low power. They argue that reduction in power is caused by using returns on contaminated portfolios as factors in the regression, by weighting each month equally and by using value-weighted returns of the calendar-time portfolios. However, their empirical evidence is based only on one carefully constructed sample of firms and is hardly conclusive. No large-scale simulation study has been done to examine power of the Fama-French calendar-time approach, which we will remedy in this paper.

The Fama-French calendar-time approach, estimated with the ordinary least squares (OLS) technique, could suffer from a potential heteroskedasticity problem due to unequal and changing number of firms in the calendar-time portfolios. The weighted least squares (WLS) technique, which is helpful in addressing the heteroskedasticity problem, has been suggested as a way to deal with the changing size of calendar-time portfolios. When applying WLS, we use the monthly number of firms in the event portfolio as weights.

14.3 A Review of Simulation Studies on Long-Horizon Event Study Methodology

Several papers have documented performance of testing procedures in large-scale simulations. Table 14.1 surveys these papers with reference to testing procedures under their investigation and their simulation settings. The simulation technique was pioneered by Brown and Warner (1980, 1985) to evaluate size and power of testing procedures. In this section, we review these simulation studies.

As shown in Fig. 14.1, there are two approaches for a long-term event study: the calendar-time portfolio approach versus the buy-and-hold benchmark approach. There has been a debate on which approach prescribes the best procedure for long-term event studies. Both approaches have been under criticisms. The buy-and-hold benchmark approach is susceptible to biases associated with cross-sectional correlation, insufficient matching criteria, new equity issues, periodic balancing, and skewed distribution of long-term abnormal returns, while the calendar-time portfolio approach may suffer from an improper asset-pricing model and heteroskedasticity in portfolio returns. See Kothari and Warner (1997), Barber and Lyon (1997), Fama (1998), Loughran and Ritter (1999), Lyon et al. (1999); and others for more detailed discussions. Kothari and Warner (1997) argue that the combined effect of these issues is difficult to specify a priori and, thus, "a simulation study with actual security return data is a direct way to study the joint impact, and is helpful in identifying the potential problems that are empirically most relevant."

Table 14.1 Summary of existing simulation studies

	Procedures under investigation				Validation settings		
	Calendar-time portfolio approach		Buy-and-hold benchmark approach				
Authors (year)	Pricing model	Estimation method	Matching criteria	Test statistics	Simulation design	Evidence on specification at horizon of	Evidence on power at horizon of
Kothari and Warner (1997)	This paper examines procedures that are based on cumulating monthly abnormal returns. Such procedures are severely misspecified in most cases and are not recommended				250 simulated samples of 200 firms each	1 month, 1, 2, and 3 years	1 year
Barber and Lyon (1997)			Size, BE/ME	*t*-test, Wilcoxon test	1,000 simulated samples of 200 firms each	1, 3, and 5 years	1 year
Lyon et al. (1999)	Three-factor model	OLS	Size, BE/ME	*t*-test, Johnson's test, bootstrapped test	1,000 simulated samples of 200 firms each	1, 3, and 5 years	1 year, only for the buy-and-hold approach
Mitchell and Stafford (2000)	Three-factor model	OLS			1,000 simulated samples of 2,000 firms each	3 years	3 years
Cowan and Sergeant (2001)			Size, BE/ME	*t*-test, two-group test with winsorized data	1,000 simulated samples with sample size of 50, 200, and 1,000	1, 3, and 5 years	3 years
Ang and Zhang (2004)	Three-factor model, four-factor model	OLS, WLS	Size, BE/ME, beta, and correlation coefficient	*t*-test, Johnson's test, bootstrapped test, sign test	250 simulated samples with sample size of 200 and 1,000	1, 3, and 5 years	1, 3, and 5 years
Jegadeesh and Karceski (2009)			Size, BE/ME	*t*-test, *t*-test adjusted for heteroskedasticity and serial correlation	1,000 simulated samples of 200 firms each	1, 3, and 5 years	1, 3, and 5 years

In their simulation study, Kothari and Warner (1997) measure the long-term (up to 3 years) impact of an event by cumulative monthly abnormal returns, where monthly abnormal returns are computed against four common models: the market-adjusted model, the market model, the capital asset-pricing model, and the Fama-French three-factor model. They find that tests for cumulative abnormal returns are severely misspecified. They identify sample selection, survival bias, and bias in variance estimation as potential sources of the misspecification and suggest that nonparametric and bootstrap tests are likely to reduce misspecification.

Barber and Lyon (1997) address two main issues in their simulation study. First, they argue that buy-and-hold return is a better measure of investors' actual experience over a long horizon and should be used in long-term event study (up to 5 years). They show simulation evidence that approaches using cumulative abnormal returns cause severe misspecification, which is consistent with the observation in Kothari and Warner (1997). Second, they use simulations to measure both size and power of testing procedures that follow the buy-and-hold benchmark approach. An important finding is that using a single control firm as benchmark yields well-specified tests, whereas using reference portfolio causes substantial over-rejection.

In a later paper, Lyon et al. (1999) report another simulation study (for up to the 5-year horizon) that investigates the performance of both buy-and-hold benchmark approach and calendar-time portfolio approach. They find that using the Fama-French three-factor model yields a well-specified test. However, they advocate a test that uses carefully constructed reference portfolio as benchmark and the bootstrapped Johnson's statistic for testing abnormal returns. They present evidence that this test is well specified and has high power at the 1-year horizon.

Two questions remain unanswered in Lyon et al. (1999). First, how much power does the bootstrap test have for event horizons longer than 1 year (e.g., 3 or 5 years that is common in long-horizon studies)? It is known in statistics literature that a bootstrap test is not as powerful as simple nonparametric tests in many occasions (see Efron and Tibshirani 1993, Chap. 16 and Davison and Hinckley 1997, Chap. 4). It is necessary to know the actual power of such test for event horizons beyond 1 year. Second, is the calendar-time portfolio approach as powerful as the buy-and-hold benchmark approach? Loughran and Ritter (2000) argue that the calendar-time portfolio approach has low power, using simulations and empirical evidence from a sample of new equity issuers. However, they do not measure how much power the approach actually has, which makes it impossible to compare the two approaches directly in more general settings.

Mitchell and Stafford (2000) is the only study that empirically measures power of the calendar-time portfolio approach using simulations. Their main focus is to assess performance of several testing procedures in three large samples of major managerial decisions, i.e., mergers, seasoned equity offerings, and share repurchases (up to 3 years). They find that different procedures lead to contradicting conclusions and argue that the calendar-time portfolio approach is preferred. To resolve Loughran and Ritter's (2000) critique that the calendar-time portfolio approach has low power, they conduct simulations to measure the empirical power and find that the power is actually very high with an empirical rejection rate of 99 % for induced abnormal returns of ±15 % over a 3-year horizon. Since they have a large sample size, this finding is actually consistent with what we document in Table 14.5. However, their simulations focus on only samples of 2,000 firms. Many event studies have much smaller sample sizes, especially after researchers slice and dice a whole sample into subsamples. More evidence is needed in order to have great confidence in applying the calendar-time portfolio approach in such studies.

Cowan and Sergeant (2001) focus on the buy-and-hold benchmark approach in their simulations. They find that using the reference portfolio approach cannot overcome the skewness bias discussed in Barber and Lyon (1997) and that the larger the sample size, the smaller the magnitude of the skewness bias. They also argue that cross-sectional dependence among event firms' abnormal returns increases in event horizon due to partially contemporaneous holding periods, which may cause the overlapping horizon bias. They propose a two-group test using abnormal returns winsorized at three standard deviations to deal with these two biases and report evidence that this test yields correct specifications and considerable power in many situations.

All previous simulation studies use only size and BE/ME to construct benchmarks, which is often justified by the findings in Fama and French (1992) that size and BE/ME together adequately capture the cross-sectional variations in average monthly stock returns. Ang and Zhang (2004) use two other matching criteria to explore whether better benchmarks could be used for future studies. The two criteria are market beta and pre-event correlation coefficient. Using market beta is motivated by the fact that Fama and French's (1993) three-factor model has a market factor, a size-related factor, and a BE/ME-related factor. Matching on the basis of size and BE/ME does not account for the influence of the market factor. The rationale for using pre-event correlation coefficient is that matching on size and BE/ME may fail to control for other factors that could influence stock returns, such as industry factor, seasonal factor, momentum factor, and other factors shared by only firms of the same characteristics, such as geographical location, ownership, and governance structures. Matching on the basis of pre-event correlation coefficient helps remove the effect of these factors on the event firm's long-term return.

The main findings in Ang and Zhang (2004) include the following. First, the four-factor model is inferior to the well-specified three-factor model in the calendar-time portfolio approach in that the former causes too many rejections of the null hypothesis relative to the specified significance level. Second, WLS improves the performance of the calendar-time portfolio approach over OLS, especially for long event horizons. Third, the Fama-French three-factor model has relatively high power in detecting abnormal returns, although power decreases sharply as event horizon increases. Fourth, the simple sign test is well specified when it is applied with a single firm benchmark, but misspecified when used with reference portfolio benchmarks. More importantly, the combination of the sign test and the benchmark with the single most correlated firm consistently has much higher power than any other test in our simulations and is the only testing procedure that performs well in samples of small firms.

Jegadeesh and Karceski (2009) propose a new test of long-run performance that allows for heteroskedasticity and autocorrelation. Previous tests used in Lyon et al. (1999) implicitly assume that the observations are cross-sectionally uncorrelated.

This assumption is frequently violated in nonrandom samples such as samples with industry clustering or with overlapping returns. To overcome the cross-correlation bias in event firms' returns, they recommend a t-statistic that is computed using a generalized version of the Hansen and Hodrick (1980) standard error. Their simulation studies show that the new tests they propose are reasonably well specified in random samples, in samples that are concentrated in particular industries, and also in samples where event firms enter the sample on multiple occasions within the holding period.

In summary, these simulation studies show that testing procedures differ dramatically in performance. Some procedures reject the null hypothesis at an excessively high rate, while others have very low power. These findings confirm the Fama (1998) statement that evidence for long-term return anomalies is dependent upon methodology and suggest that caution must be exercised in choosing the proper methodology for a long-term event study.

14.4 A Simulation Study of Large-Size Samples

A simulation study of large-size samples serves two purposes. First, it is well documented that the distribution of buy-and-hold abnormal returns tends to be skewed to the right. Kothari and Warner (2007) mention that the extent of skewness bias is likely to decline with sample size. It is of interest to provide evidence on how much is the level of right-skewness in the average abnormal returns of large-size samples. Second, although it is expected that testing power increases with sample size, it is of practical interest to know more precisely how much power a test can have in a sample of 1,000 observations. Large sample simulation defines the limits of a procedure.

14.4.1 Research Design

In this simulation study, we construct 250 samples each consisting of 1,000 event firms. To produce one sample, we randomly select, with replacement, 1,000 event months between January 1980 and December 1992, inclusively.[5,6] This allows us to calculate 5-year abnormal returns until December 1997. For each selected event month, we randomly select, without replacement, one firm from a list of qualified firms. The qualified firms satisfy the following requirements: (i) They are publicly traded firms, incorporated in the USA, and have ordinary common shares with Center for Research in Security Prices (CRSP) share codes 10 and 11; (ii) they have return data found in the CRSP monthly returns database for the 24-month period

[5]We use a pseudorandom number generator developed by Matsumoto and Nishimura (1998) to ensure high quality of random sampling.

[6]Kothari and Warner (1997) use 250 samples, each of 200 event months between January 1980 and December 1989 inclusively. Barber and Lyon (1997) use 1,000 samples, each of 200 event months in a much longer period from July 1963 to December 1994. The period under our study, between January 1980 and December 1992, is of similar length to Kothari and Warner's.

prior to the event month; (iii) they have nonnegative book values on COMPUSTAT prior to the event month so that we can calculate their book-to-market equity ratios.

The 250 samples, each of 1,000 randomly selected firms, comprise the simulation setting for comparing the performance of different testing procedures.[7] We apply all testing procedures under our study to the same samples. Such controlled comparison is more informative because it eliminates difference in performance due to variation in the samples.

For the buy-and-hold approach, we compute the long-term buy-and-hold abnormal return of firm i as the difference between the long-term buy-and-hold return of firm i and the long-term return of a benchmark. The buy-and-hold return of firm i over τ months is obtained by compounding monthly returns. In case that firm i does not have return data for all τ months, we replace missing returns by the same-month returns of a size and BE/ME matched reference portfolio.[8] We evaluate a total of five benchmarks and four test statistics in this study. We briefly describe them in the following and give the details in the Appendix.

Three of the benchmarks are reference portfolios. The *first* reference portfolio consists of firms that are similar to the event firm in both size and BE/ME. We follow the same procedure as in Lyon et al. (1999) to construct the two-factor reference portfolio. We use the label "SZBM" for this benchmark. The *second* reference portfolio consists of firms that are similar to the event firm not only in size and BE/ME but also in market beta. We use the label "SZBMBT" for this benchmark. The *third* reference portfolio consists of ten firms that are most correlated with the event firm prior to the event. We use the label "MC10" for this benchmark.

The other two of the five benchmarks consist of a single firm. The *first* single firm benchmark is the firm that matched the event firm in both size and BE/ME. To find the two-factor single firm benchmark, we first identify all firms whose market value is within 70–130 % of the event firm's market value and then choose the firm that has the BE/ME ratio closest to that of the event firm. We use the label "SZBM1" for this benchmark. The *second* single firm benchmark is the firm that has the highest correlation coefficient with the event firm prior to the event. We use the label "MC1" for this benchmark.

We apply four test statistics to test the null hypothesis that the mean long-term abnormal return is zero. They include Student's t-test, Fisher's sign test, Johnson's skewness-adjusted t-test, and the bootstrapped Johnson's t-test. Fisher's sign test is a nonparametric test and is described in details in Hollander and Wolfe (1999, Chap. 3). Johnson's skewness-adjusted t-statistic was developed by Johnson (1978) to deal with the skewness-related misspecification error in Student's t-test. Sutton (1992) proposes to apply Johnson's t-test with a computationally intensive bootstrap resampling

[7]Ang and Zhang (2004) examine two other simulation settings. Under one setting, they have another 250 samples of 200 event firms, a smaller sample size than the setting in this chapter. Under the other setting, they have the sample size of 200 with the requirement that event firms belong to the smallest quintile sorted by NYSE firm size. The second setting is used to examine the effect of small firms.

[8]Filling in missing returns is a common practice in calculating long-term buy-and-hold returns; e.g., see Barber and Lyon (1997), Lyon et al. (1999), and Mitchell and Stafford (2000).

technique when the population skewness is severe and the sample size is small. Lyon et al. (1999) advocate use of the bootstrapped Johnson's *t*-test because long-term buy-and-hold abnormal returns are highly skewed when buy-and-hold reference portfolios are used as benchmarks. We follow Lyon et al. (1999) and set the resampling size in the bootstrapped Johnson's *t*-test to be one quarter of the sample size.

For the Fama-French calendar-time approach, we use both the Fama-French three-factor model and the four-factor model. We apply both ordinary least squares (OLS) and weighted least squares (WLS) techniques to estimate parameters in the pricing model. The WLS is used to correct the heteroskedasticity problem due to the monthly variation in the number of firms in the calendar-time portfolio. When applying WLS, we use the number of event firms in the portfolio as weights.

14.4.2 Simulation Results for the Buy-and-Hold Benchmark Approach

In this section, we examine the performance of testing procedures that follow the buy-and-hold benchmark approach. Implementation of the buy-and-hold benchmark approach involves choosing both benchmark and test statistic. For this reason, rather than focusing on what is the best among all benchmarks, or focusing on what is the best among all test statistics, we address the more practical question of finding the best combination of benchmark and test statistic. Combination of the five benchmarks and the four test statistics yields 20 testing procedures, out of which we look for the best combination.

For each sample of 1,000 abnormal returns, we compute mean, median, standard deviation, interquartile range, skewness coefficient, and kurtosis coefficient. Table 14.2 reports the average of these statistics over 250 samples.

Since these event firms, being randomly selected, may not experience any event or may experience events that have offsetting effects on averaged stock returns, we expect their abnormal returns to concentrate around zero. In Table 14.2, means are close to zero for all five benchmarks at all three holding periods, but medians differ systematically according to the type of benchmark used. Medians are clearly negative under the three reference portfolio benchmarks (i.e., SZBM, SZBMBT, and MC10), but close to zero under the two single firm benchmarks (i.e., SZBM1 and MC1). The evidence suggests that reference portfolio benchmarks overestimate holding period returns of many event firms, resulting in far too many event firms having negative abnormal returns under the portfolio-based benchmarks. The extent of the overestimation bias by portfolio-based benchmarks is quite severe and gets worse as the time horizon lengthens. The bias, as measured by the magnitude of median, ranges from around 4 % at a 1-year horizon to 12 % at a 3-year horizon and to more than 20 % at a 5-year horizon. Bias of this magnitude could cause too many events to be falsely identified as having significant long-term impact.

Volatility of abnormal returns increases with the length of holding period under all five benchmarks. For the same holding period, volatility is higher under the two single firm benchmarks than under the three reference portfolio benchmarks. This is expected

Table 14.2 Descriptive statistics of abnormal returns in samples of *1,000 firms*

	Descriptive statistics					
Benchmark	Mean	Median	Standard deviation	Interquartile range	Skewness coefficient	Kurtosis coefficient
Panel A: 1-year holding period						
SZBM	0.009	−0.032	0.574	0.453	4.332	60.763

MC1	0.036	0.000	2.745	1.834	0.500	50.365

This table reports descriptive statistics that characterize the probability distribution of long-term abnormal returns, in samples of *1,000 firms*. Abnormal return is calculated as the difference in holding period return between the event firm and its benchmark. We use five benchmarks: a reference portfolio matched by size and BE/ME (SZBM); a reference portfolio matched by size, BE/ME, and beta (SZBMBT); a reference portfolio consisting of ten firms, within the event firm's size and BE/ME matched portfolio, whose returns are most correlated with the event firm's MC10; a single firm matched by size and BE/ME (SZBM1); and a single firm, from the event firm's size and BE/ME matched portfolio, whose returns have the highest correlation with the event firm's MC1. We compute mean, median, standard deviation, interquartile range, skewness coefficient, and kurtosis coefficient for abnormal returns in every sample. Since there are 250 samples in the simulation, entries in the table are the average of these statistics over the 250 samples

because reference portfolios have lower volatility due to averaging. As for kurtosis, all five benchmarks produce highly leptokurtic abnormal returns, with kurtosis coefficients ranging from 41.4 to 67.5, which are far greater than three, the kurtosis coefficient of any normal distribution. At last, skewness coefficients for the two single firm benchmarks are close to zero regardless of event horizons, while skewness coefficients for the three portfolio benchmarks are excessively positive.

To sum up, probability distributions of long-term abnormal returns exhibit different properties, depending on whether the benchmark is a reference portfolio or a single firm. Under a reference portfolio benchmark, the distribution is highly leptokurtic and positively skewed, with a close-to-zero mean but a highly negative median. Under a single firm benchmark, the distribution is highly leptokurtic but symmetric, with both mean and median close to zero. Statistical properties of long-term abnormal returns have important bearings on performance of test statistics. Overall, it seems single firm benchmarks have more desirable properties. Between the two single firm benchmarks, MC1 shows better performance than SZBM1, because the abnormal returns based on MC1 have both mean and median being closer to zero and smaller standard deviation.

A superior test should control for the probability of committing two errors. First, it is important to control for the probability of misidentifying an insignificant event as having statistical significance; in other words, the empirical size of the test, which is computed from simulations, is close to the prespecified significance level at which the test is conducted. When this happens, the test is well specified. Second, power of the test should be large, that is, the probability of finding a statistically significant event if one did exist.

Table 14.3 reports empirical size of all 20 tests for three holding periods. Empirical size is calculated as the proportion of 250 samples that rejects the null hypothesis at the 5 % nominal significance level. With only a few exceptions, Student's *t*-test is well specified against the two-sided alternative hypothesis. Despite excessively high skewness in abnormal returns from reference portfolio benchmarks, Student's *t*-test is well specified against two-sided alternative hypothesis because the effect of skewness at both tails cancels out (see, e.g., Pearson and Please 1975). When testing against the two-sided alternative hypothesis, Johnson's skewness-adjusted *t*-test is in general misspecified, but its bootstrapped version is well specified in most situations. The sign test is misspecified when applied to abnormal returns from reference portfolio benchmarks, and the extent of misspecification is quite serious and increases in the length of holding period. This is not surprising because abnormal returns from reference portfolio benchmarks have highly negative medians.

Table 14.4 reports empirical power of testing the null hypothesis of zero abnormal return against the two-sided alternative hypothesis. We follow Brown and Warner (1980, 1985) to measure empirical power by intentionally forcing the mean abnormal return away from zero with induced abnormal returns. We induce nine levels of abnormal returns ranging from −20 % to 20 % at an increment of 5 %. To induce an abnormal return of −20 %, for example, we add −20 % to the observed holding period return of an event firm. Empirical power is calculated as the proportion of 250 samples that rejects the null hypothesis at 5 % significance level.

With a large sample size of 1,000, the power of these tests remains reasonably high at the longer holding period. Ang and Zhang (2004) report that, with the sample size of 200, the power of all tests deteriorates sharply as holding period lengthens from 1 to 3 and to 5 years and is alarmingly low at the 5-year horizon. For example, when the induced abnormal return is −20 % over a 5-year horizon, the highest power of the bootstrapped Johnson's *t*-test is 13.6 % for a sample of 200 firms, whereas the highest power is 62.8 % for a sample of 1,000 firms.

We compare the power of the three test statistics: Student's *t*-test, the bootstrapped Johnson's skewness-adjusted *t*-test, and the sign test. All three test statistics are applied together with the most correlated single firm benchmark. The evidence shows that all three tests are well specified. However, the sign test clearly has much higher power than the other two tests.

This table reports empirical size of testing the null hypothesis of zero abnormal return against two-tailed, lower-tailed, and upper-tailed alternative hypothesis, in samples of *1,000 firms*. Empirical size is calculated as the proportion of 250 samples that reject the null hypothesis at 5 % significance level. Abnormal return is calculated as the difference in holding period return between the event firm and its benchmark. We use *five benchmarks* (a reference portfolio matched by size and BE/ME (SZBM); a reference portfolio matched by size, BE/ME, and beta (SZBMBT); a reference portfolio consisting of ten firms, within the event firm's size and BE/ME matched portfolio, whose returns are most correlated with the event firm's MC10; a single firm matched by size and BE/ME (SZBM1); and a single firm, from the event firm's size and BE/ME matched portfolio, whose returns have the highest correlation with the event firm's MC1) and *four test statistics* (the conventional t-test (t), Fisher's sign test (sign), Johnson's skewness-adjusted t-test (Jt), and the bootstrapped Johnson's skewness-adjusted t-test (BJt)). It is indicated by * that the empirical size is significantly different from the 5 % significance level. The significance is judged against the critical values $0.05 \pm 1.96\sqrt{0.05(1-0.05)/250}$, where 0.05 is the theoretical size, 1.96 is the 97.5th percentile of the standard normal distribution, and 250 is the sample size

Table 14.4 Power of tests in samples of *1,000 firms*

This table reports empirical power of testing the null hypothesis of zero abnormal return against the two-sided alternative hypothesis, in samples of *1,000 firms*. Empirical power is calculated as the proportion of 250 samples that reject the null hypothesis at 5 % significance level. Abnormal return is calculated as the difference in holding period return between the event firm and its benchmark. We use *five benchmarks* (a reference portfolio matched by size and BE/ME (SZBM); a reference portfolio matched by size, BE/ME, and beta (SZBMBT); a reference portfolio consisting of ten firms, within the event firm's size and BE/ME matched portfolio, whose returns are most correlated with the event firm's MC10; a single firm matched by size and BE/ME (SZBM1); and a single firm, from the event firm's size and BE/ME matched portfolio, whose returns have the highest correlation with the event firm's MC1) and *four test statistics* (the conventional *t*-test (t), Johnson's skewness-adjusted *t*-test (Jt), the bootstrapped Johnson's skewness-adjusted *t*-test (BJt), and Fisher's sign test (sign)). We study power at nine levels of induced abnormal return, ranging from −20 % to 20 % at an increment of 5 %

14.4.3 Simulation Results for the Calendar-Time Portfolio Approach

Table 14.5 reports the rejection frequency of the calendar-time portfolio approach in testing the null hypothesis that the intercept is zero in the regression of monthly calendar-time portfolio returns, against the two-sided alternative hypothesis. Rejection frequency is measured as the proportion of the total 250 samples that reject the null hypothesis. We compute rejection frequencies at nine *nominal* levels of induced abnormal returns, ranging from −20 % to 20 % at an increment of 5 %. Since monthly returns of the calendar-time portfolio are used in fitting the model, to examine the power of testing the intercept, we need to induce abnormal returns by

Table 14.5 Rejection frequency of calendar-time portfolio approach in samples of *1,000 firms*

This table reports rejection frequency in testing the null hypothesis that the intercept in the regression of monthly calendar-time portfolio returns is zero, in samples of *1,000 firms*. Both the Fama-French three-factor model and the four-factor model are used in the regression. Model parameters are estimated with both OLS and WLS estimation techniques. Rejection frequency is equal to the proportion of 250 samples that reject the null hypothesis at 5 % significance level. We measure rejection frequency at nine levels of induced abnormal returns. We induce abnormal returns by adding an extra amount to monthly returns of every event firm before forming the calendar-time portfolios. The *effective* induced holding period return of an event firm is equal to the difference in the firm's holding period return between before and after adding the monthly extra amount. The *average* effective induced holding period return is computed over all event firms in the 250 samples

adding an extra amount to actual monthly returns of every event firm before forming the calendar-time portfolios. For example, in order to induce the −20 % nominal level of abnormal holding period return, we add the extra amount of −1.67 % (=−20 %/12) to an event firm's 12 monthly returns for a 1-year horizon, or add the abnormal amount of −0.56 % (= −20 %/36) to the firm's 24 monthly returns for a 3-year horizon, or the abnormal amount of −0.33 % (=−20 %/60) to the firm's 60 monthly returns for a 5-year horizon.

Note that the *nominal* induced holding period return is different from the *effective* induced abnormal holding period return, because adding the abnormal amount each month does not guarantee that an event firm's holding period return will be increased or decreased by the exact nominal level. We measure the *effective* induced holding period return of an event firm as the difference in the firm's holding period return between before and after adding the monthly abnormal amount. The *average* effective induced holding period return is computed over all event firms in the 250 samples. The average induced holding period return allows us to compare power of the buy-and-hold benchmark approach with that of the calendar-time portfolio approach at the scale of holding period return.

We first examine empirical size of the calendar-time portfolio approach, which is equal to the rejection frequency when no abnormal return is induced. In Table 14.5, the empirical size is in the column with zero induced return. It is very surprising that when the four-factor model is used, the test has excessively high rejection frequency at 3-year and 5-year horizons. The rejection frequency, for example, is 94.0 % at the 5-year horizon with the WLS estimation! In contrast, when the Fama-French three-factor model is used, the empirical sizes are not significantly different from the 5 % significance level. The evidence strongly suggests that the three-factor model is preferred for the calendar-time portfolio approach, whereas the four-factor model suffers from overfitting and should not be used.

Table 14.5 shows that, for a sample of 1,000 firms, the power of this approach remains high as event horizon increases. WLS estimation does improve the power of the procedure over the OLS, and the extent of improvement becomes greater as holding period gets longer. By comparing Tables 14.4 and 14.5, we find that the power of the Fama-French calendar-time approach implemented with WLS technique (i.e., FF, WLS) has almost the same power as the buy-and-hold benchmark approach implemented with the most correlated single firm and the sign test (i.e., MC1, sign), at the 1-year horizon, but slightly less at the 3- and 5-year horizons.

14.5 Conclusion

Comparing the simulation results in Sect. 14.4 with those in Ang and Zhang (2004), we find that sample size has a significant impact on the performance of tests in long-horizon event studies. With a sample size of 1,000, a few tests perform reasonably well, including the Fama-French calendar-time approach implemented with WLS technique and the buy-and-hold benchmark approach implemented with the most correlated single firm (MC1) and the sign test. In particular, they have reasonably high power even for the long 5-year holding period. On the contrary, with a sample size of 200, Ang and Zhang (2004) find that the power of most well-specified tests is very low for the 5-year horizon, only in the range of 10–20 % against a high level of induced abnormal returns, while the combination of the most correlated single firm and the sign test stands out with a power of 41.2 %. Thus, the most correlated single firm benchmark dominates for most practical sample sizes, and in addition, the simplicity of the sign test is appealing.

The findings have important implications for future research. For long-horizon event studies with a large sample, it is likely to be more fruitful to spend efforts on understanding the characteristics of the sample firms, than on implementing various sophisticated testing procedures. The simulation results here show that the commonly used tests following both the Fama-French calendar-time approach and the buy-and-hold benchmark approach perform reasonably well. In a recent paper, Butler and Wan (2010) reexamine the long-run underperformance of bond-issuing firms and find that straight debt and convertible debt issuers appear to have systematically better liquidity than benchmark firms, and controlling for liquidity by having an additional matching criterion eliminates the underperformance. This resonates well with Barber and Lyon's (1997) suggestion that "as future research in financial economics discovers additional variables that explain the cross-sectional variation in common stock returns, it will also be important to consider these additional variables when matching sample firms to control firms" (pp. 370–71). One reason why the benchmark with a single most correlated firm performs well in our simulations may be that returns of highly correlated firms are likely to move in tandem in response to changes in risk factors that are well known, such as the market, size, and book-to-market ratio, but also changes in other factors, such as industry, liquidity, momentum, and seasonality.

On the other hand, for long-horizon event studies with a small sample, it may be necessary to use a wide range of tests and interpret their outcome with care. This prompts researchers to continue searching for better test statistics. For example, Kolari and Pynnonen (2010) find that even relatively low cross-correlation among abnormal returns in a short event window causes serious over-rejection of the null hypothesis. They propose both cross-correlation and volatility-adjusted as well as cross-correlation-adjusted scaled test statistics and demonstrate that these statistics perform well in samples of 50 firms. It is an open and interesting question whether these statistics have high power in long-horizon event studies with a small sample.

Appendix

This appendix includes the details on the benchmarks and the test statistics that are used in our simulation studies. We use five benchmarks. The *first benchmark* is a reference portfolio constructed on the basis of firm size and BE/ME. We follow Lyon et al. (1999) to form 70 reference portfolios at the end of June in each year from 1979 to 1997. At the end of June of year t, we calculate the size of every qualified firm as price per share multiplied by shares outstanding. We sort all NYSE firms by firm size into ten portfolios, each having the same number of firms, and then place all AMEX/NASDAQ firms into the ten portfolios based on firm size. Since a majority of NASDAQ firms are small, approximately 50 % of all firms fall in the smallest size decile. To obtain portfolios with the same number of firms, we further partition the smallest size decile into five subportfolios by firm size without regard to listing exchange. We now have 14 size portfolios. Next, we calculate each qualified firm's BE/ME as the ratio of the book equity value (COMPUSTAT data item 60) of the firm's fiscal year ending in year $t-1$ to its market equity value at the end of December of year $t-1$. We then divide each of the 14 portfolios into five subportfolios by BE/ME and conclude the procedure with 70 reference portfolios on the basis of size and BE/ME.

The size and BE/ME matched reference portfolio of an event firm is taken to be the one of the 70 reference portfolios constructed at the month of June prior to the event month that matches the event firm in size and BE/ME. The return on a size and BE/ME matched reference portfolio over τ months is calculated as

$$BR_i^{SZBM} = \prod_{t=0}^{\tau-1}\left[1 + \frac{\sum_{j=1}^{n_t} r_{jt}}{n_t}\right] - 1, \tag{14.5}$$

where month $t = 0$ is the event month, n_t is the number of firms in month t, and r_{jt} is the monthly return of firm j in month t. We use the label “SZBM” for the benchmark that is based on firm size and BE/ME.

The *second benchmark* is a reference portfolio constructed on the basis of firm size, BE/ME, and market beta. The Fama-French three-factor model suggests that expected stock returns are related to three factors: a market factor, a size-related factor, and a BE/ME-related factor. Reference portfolios constructed on the basis of size and BE/ME account for the systematic portion of expected stock returns due to the size and BE/ME factors, but not the portion due to the market factor. Our second benchmark is based on firm size, BE/ME, and market beta to take all three factors into account.

To build a three-factor reference portfolio for a given event firm, we first construct the 70 size and BE/ME reference portfolios as above and identify the one that matches the event firm. Next, we pick firms within the matched portfolio that have returns in CRSP monthly returns database for all 24 months prior to the event month and compute their market beta by regressing the 24 monthly returns on the value-weighted CRSP return index. Lastly, we divide these firms that have market beta into three portfolios by their rankings in beta and pick the one that matches the event firm in beta as the three-factor reference portfolio. The return on a three-factor portfolio over τ months is calculated as

$$BR_i^{SZBMBT} = \prod_{t=0}^{\tau-1}\left[1 + \frac{\sum_{j=1}^{l_t} r_{jt}}{n_t}\right] - 1, \tag{14.6}$$

where month $t = 0$ is the event month, n_t is the number of firms in month t, and r_{jt} is the monthly return of firm j in month t. We use the label “SZBMBT” to indicate that the benchmark is based on firm size, BE/ME, and market beta.

The *third benchmark* is a reference portfolio constructed on the basis of firm size, BE/ME, and pre-event correlation coefficient. The rational for using pre-event correlation coefficient as an additional dimension is that returns of highly correlated firms are likely to move in tandem in response to not only changes in “global” risk factors, such as the market factor, the size factor, and the BE/ME factor in the Fama-French model, but also changes in other “local” factors, such as the industry factor, the seasonal factor, liquidity factor, and the momentum factor. Over a long time period following an event, both global and local factors experience changes that affect stock returns. It is reasonable to expect more correlated stocks would be affected by these factors similarly and should have resulting stock return patterns that are closer to each other. Therefore, returns of a reference portfolio on the basis of pre-event size, BE/ME, and pre-event correlation coefficient are likely to be better estimate of the *status quo* (i.e., what if there was no event) return of an event firm.

To build a reference portfolio on the basis of size, BE/ME, and pre-event correlation coefficient, we first construct the same 70 size and BE/ME reference portfolios as above and identify the combination that matches the event firm. Next, we pick firms within the matched size and BE/ME reference portfolio that have returns in CRSP monthly returns database for all 24 months prior to the event month and compute their correlation coefficients with the event firm over the pre-event 24 months. Lastly, we choose the ten firms that have the highest pre-event correlation coefficient with the event firm to form the reference portfolio. Return of the portfolio over τ months is calculated as

$$BR_i^{MC10} = \sum_{j=1}^{10} \frac{\prod_{t=0}^{\tau-1}\left(1 + r_{jt}\right) - 1}{10}, \tag{14.7}$$

where month $t = 0$ is the event month and r_{jt} is the monthly return of firm j in month t. We use the label "MC10" to indicate that the benchmark consists of the most correlated ten firms. The benchmark return is the return of investing equally in the ten most correlated firms over the τ months beginning with the event month. The benchmark is to be considered as a hybrid between the reference portfolio discussed above and the matching firm approach shown below.

The *fourth benchmark* is a single firm matched to the event firm in size and BE/ME. Barber and Lyon (1997) report that using a size and BE/ME matched firm as benchmark gives measurements of long-term abnormal return that is free of the new listing bias, the rebalancing bias, and the skewness bias documented in Kothari and Warner (1997) and Barber and Lyon (1997). To select the size and BE/ME matched firm, we first identify all firms that have a market equity value between 70 % and 130 % of that of the event firm and then choose the firm with BE/ME closest to that of the event firm. The buy-and-hold return of the matched firm is computed as in Eq. 14.2. We use the label "SZBM1" to represent the single size and BE/ME matched firm.

The *fifth and last benchmark* is a single firm that has the highest pre-event correlation coefficient with the event firm. Specifically, to select the firm, we first construct the 70 size and BE/ME reference portfolios and identify the one that matches the event firm. Next, we pick firms within the matched size and BE/ME reference portfolio that have returns in CRSP monthly returns database for all 24 months prior to the event month and compute their correlation coefficients with the event firm over the pre-event 24 months. We choose the firm with the highest pre-event correlation coefficient with the event firm as the benchmark. The buy-and-hold return of the most correlated firm is computed as in Eq. 14.2. We use the label "MC1" to represent the most correlated single firm.

We apply four test statistics to test the null hypothesis of no abnormal returns: (a) Student's t-test, (b) Fisher's sign test, (c) Johnson's skewness-adjusted t-test, and (d) bootstrapped Johnson's t-test.

(a) Student's t-test

Given the long-term buy-and-hold abnormal returns for a sample of n event firms, we compute Student's t-statistic as follows:

$$t = \frac{\overline{AR}}{s(AR)/\sqrt{n}}, \tag{14.8}$$

where $\overline{AR}$ is the sample mean and $s(AR)$ the sample standard deviation of the given sample of abnormal returns. The Student's t-statistic tests the null hypothesis that the population mean of long-term buy-and-hold abnormal returns is equal to zero. The usual assumption for applying the Student's t-statistic is that abnormal returns are mutually independent and follow the same normal distribution.

(b) Fisher's sign test

To test the null hypothesis that the population median of long-term buy-and-hold abnormal returns is zero, we compute Fisher's sign test statistic as follows:

$$B = \sum_{i=1}^{n} \mathrm{I}(AR_i > 0), \tag{14.9}$$

where $\mathrm{I}(AR_i > 0)$ equals 1 if the abnormal return on the ith firm is greater than zero and 0 otherwise. At the chosen significance level of α, the null hypothesis is rejected in favor of the alternative of nonzero median if $B \geq b(\alpha/2, n, 0.5)$ or $B < [n - b(\alpha/2, n, 0.5)]$, or in favor of positive median if $B \geq b(\alpha, n, 0.5)$, or in favor of negative median if $B < [n - b(\alpha, n, 0.5)]$. The constant $b(\alpha, n, 0.5)$ is the upper α percentile point of the binomial distribution with sample size n and success probability of 0.5. The usual assumption for applying the sign test is that abnormal returns are mutually independent and follow the same continuous distribution. Note that application of the sign test does not require the population distribution to be symmetric. When the population distribution is symmetric, the population mean equals the population median, and the sign test then indicates the significance of the population mean (see Hollander and Wolfe 2000, Chap. 3).

(c) Johnson's skewness-adjusted t-test

Johnson (1978) developed the following skewness-adjusted t-test to correct the misspecification of Student's t-test caused by the skewness of the population distribution. Johnson's test statistic is computed as follows:

$$J = t + \frac{1}{3\sqrt{n}} t^2 \gamma + \frac{1}{6\sqrt{n}} \gamma, \tag{14.10}$$

where t is Student's t-statistic given in Eq. 14.8 and γ is an estimate of the coefficient of skewness given by $\gamma = \sum_{i=1}^{n} \left(AR_i - \overline{AR}\right)^3 / s(AR)^3 n$. Johnson's

t-test is applied to test the null hypothesis of zero mean under the assumption that abnormal returns are mutually independent and follow the same continuous distribution. At the chosen significance level of α, the null hypothesis is rejected in favor of the alternative of nonzero mean if $J > t(\alpha/2, \upsilon)$ or $J < -t(\alpha/2, \upsilon)$, or in favor of positive mean if $J > t(\alpha, \upsilon)$, or in favor of negative mean if $J < -t(\alpha, \upsilon)$. The constant $t(\alpha, \upsilon)$ is the upper α percentile point of the Student's t distribution with the degrees of freedom $\upsilon = n - 1$.

(d) Bootstrapped Johnson's skewness-adjusted t-test
Sutton (1992) proposes to apply Johnson's t-test with a computer-intensive bootstrap resampling technique when the population skewness is severe and the sample size is small. He demonstrates it by an extensive Monte Carlo study that the bootstrapped Johnson's t-test reduces both type I and type II errors compared to Johnson's t-test. Lyon et al. (1999) advocate the bootstrapped Johnson's t-test in that long-term buy-and-hold abnormal returns are highly skewed when buy-and-hold reference portfolios are used as benchmarks. They report that the bootstrapped Johnson's t-test is well specified and has considerable power in testing abnormal returns at the 1-year horizon. In this paper, we document its power at 3- and 5-year horizons.

We apply the bootstrapped Johnson's t-test as follows. From the given sample of n event firms, we draw m firms randomly with replacement counted as one resample until we have 250 resamples. We calculate Johnson's test statistic as in Eq. 14.10 for each resample and end up with 250 J values, labeled as $J_1, \cdots, J_{250}$. Let J_0 denotes the J value of the original sample. To test the null hypothesis of zero mean at the significance level of α, we first determine two critical values, C_1 and C_2, such that the percentage of J values less than C_1 equals $\alpha/2$ and the percentage of J values greater than c_2 equals $\alpha/2$, and then reject the null hypothesis if $J_0 < C_1$ or $J_0 > C_2$. We follow Lyon et al. (1999) to apply the bootstrapped Johnson's t-test with $m = 50$.[9]

intertemporal relation for the US monthly excess returns for 1926:12–2008:12. We reexamine the relation for the sample period studied by Glosten, Jagannathan, and Runkle (Journal of Finance 48, 1779–1801, 1993) and find that their sample period is indeed characterized by a positive (negative) relation under a positive (negative) volatility shock with the effect of a volatility shock incorporated in estimation. We also find a significant link between the asymmetric mean reversion and the intertemporal relation in that the quicker reversion of negative returns is attributed to the negative intertemporal relation under a prior negative return shock.

For estimations we employ the ANST-GARCH model that is capable of capturing the asymmetric volatility effect of a positive and negative return shock. The key feature of the model is the regime-shift mechanism that allows a smooth, flexible transition of the conditional volatility between different states of volatility persistence. The regime-switching mechanism is governed by a logistic transition function that changes values depending on the level of the previous return shock. With a negative (positive) return shock, the conditional variance process is described as a high (low)-persistence-in-volatility regime. The ANST-GARCH model describes the heteroskedastic return dynamics more accurately and generates better volatility forecasts.

Intertemporal risk-return relation • Unexpected volatility shocks • Time-varying rational expectation hypothesis • Stock market overreaction • Expected market risk premium • Volatility feedback effect • Asymmetric mean reversion • Asymmetric volatility response • Time-varying volatility • Volatility regime switching • ANST-GARCH model

15.1 Introduction

The trade-off between risk and return is a core tenet in financial economics. In particular, the intertemporal risk-return relation is a key element to explain the predictable variation of expected asset returns.[1] Despite its importance in asset pricing, there has been a long-standing debate on the empirical sign of the intertemporal relation, with findings that are mixed and inconclusive.

Criticisms of the mixed results often refer to a lack of conditional information. If the predetermined conditional information set does not contain an important variable that affects the risk-return trade-off, the econometric modeling of market expectations suffers from the model misspecification problem and leads to a wrong conclusion on the empirical nature of the intertemporal risk-return relation.

[1]Fama and French (1989) argue that systematic patterns in the predictable variations of expected returns are consistent with the intertemporal asset pricing model by Lucas (1978) and Breeden (1979) and the consumption smoothing idea by Modigliani and Brumberg (1955) and Friedman (1957). Ferson and Harvey (1991) and Evans (1994) also document the relative importance of the time-varying risk premia to the conditional betas to explain predictable variations in expected returns.

In this chapter, we suggest that an unexpected volatility shock is an important risk factor to induce the intertemporal risk-return trade-off, and the conflicting findings on the relation could be attributable to an omitting variable bias resulting from ignoring the effect of an unexpected volatility shock on the relation. Incorporating the effect of an unexpected volatility shock in estimation of the relation, we find a strong *positive* intertemporal relation between the expected market risk premium and the predictable volatility for the US monthly excess returns of market indices for the period of 1926:01–2008:12.

Conventional belief about the intertemporal relation is that a positive risk-return relation is consistent with the time-varying rational expectation hypothesis in the sense that a substantial amount of predictable variations of the expected risk premium is induced by the risk-averse investors' revision of their expectations in responding to changing volatility. For example, Pindyck (1984) empirically shows that much of the decline in stock prices during the 1970s in the US stock market is attributable to the upward shift in risk premium arising from high stock market volatility.[2] Studies that support a positive relation include French et al. (1987), Fama and French (1988), Ball and Kothari (1989), Turner et al. (1989), Harvey (1989), Cecchetti et al. (1990), Haugen et al. (1991), Campbell and Hentschel (1992), Scruggs (1998), Kim et al. (2001), Ghysel et al. (2005), Ludvigson and Ng (2007), Pastor et al. (2008), Bali (2008), Darrat et al. (2011), and Nyberga (2012).

Although a positive intertemporal relation is consistent with Merton's (1980) dynamic CAPM, there is another side to the argument that the equilibrium asset pricing does not necessarily imply a positive relation. Abel (1988) suggests that a positive risk-return relation is consistent with the general equilibrium model only when the coefficient of relative risk aversion is less than one. Barky (1989) suggests that the directional effect of an increase in riskiness on stock prices depends on the curvature of the utility function. Showing evidence of a strong negative relation for their sample period, Glosten et al. (hereinafter GJR) (1993) suggest that both positive and negative intertemporal relations are consistent with the equilibrium asset pricing theory.[3] Among others, Campbell (1987), Pagan and Hong (1989), Breen et al. (1989), Nelson (1991), Backus and Gregory (1993), Harvey (2001), and Ang et al. (2006) support a negative intertemporal relation.[4]

[2]He suggested that a substantial portion of time variation in the expected risk premium is associated with time-varying risk factors in investment opportunities.

[3]They argue that investors may not require a large premium for bearing risk, but rather may reduce the risk premium when they perceive exceptionally optimistic expectations on the future performance of stock prices.

[4]Brandt and Kang (2004) find that the conditional mean and volatility are negatively correlated contemporaneously but positively correlated unconditionally due to the positive lead-lag relation between the two moments of stock returns. Poterba and Summers (1986) suggested that, due to the low level of volatility persistence, the volatility effect on the expected risk premium dissipates so quickly that it cannot have a major effect on stock price movements. Note that there are some studies that report weak evidence of the intertemporal relation. See Baillie and DeGennaro (1990), Whitelaw (1994, 2000), Boudoukh et al. (1997), Yu and Yuan (2011), and Müller et al. (2011).

A price shock generates two sources of forecasting errors: a return forecasting error and a volatility forecasting error. Unlike a return forecasting error, the unanticipated volatility shock has not been paid much attention by the literature. We refer the volatility forecasting error to as an unexpected volatility shock. An unexpected volatility shock is indeed an important risk factor to affect investors' pricing behavior in that rational risk-averse investors revise their expectations in responding not only to an underlying volatility but also to an unexpected volatility shock. This implies that the intertemporal behavior of the expected market risk premium is driven by both the predictable volatility and the unexpected volatility change.

While the underlying return volatility has been widely examined by many studies, the impact of an unexpected volatility shock has not been given much attention by the literature. Almost all of the previous empirical studies on this topic completely ignore the effect of an unexpected volatility shock on the relation, so that their empirical results reflect only a partial intertemporal risk-return relation. Thus, considering an unexpected volatility shock as the conditional information in estimation, we reexamine the nature of the intertemporal relation.

Especially, we examine an asymmetrical effect of a positive and negative unexpected volatility shock on the relation. We conjecture that a higher volatility level than predicted would increase the expected risk premium and induce a stronger positive intertemporal relation. We define a positive (negative) unexpected volatility shock as the case where actual market volatility is higher (lower) than expected. Our estimation results show that a positive unexpected volatility shock (the case in which the actual volatility is higher than expected) causes a stronger positive intertemporal relation than does a negative unexpected volatility shock (the case in which the actual volatility is lower than expected).

The effect of an unexpected volatility shock considered in this chapter is different from the volatility feedback effect proposed by Campbell and Hentschel (1992). While the volatility feedback effect focuses on the *contemporaneous* effect of concurrent volatility shocks on the expected returns, our volatility shock effect implies the consequence of a prior unexpected volatility shock on the intertemporal relation. However, the estimation of their contemporaneous volatility feedback effect is subject to the endogeneity problem, as it is theoretically impossible to obtain the concurrent volatility forecasting error due to an unavailability of the current volatility information.[5]

[5]To avoid the endogeneity problem, French et al. (1987) examined the volatility feedback effect using ex post unexpected volatility changes. They found a strong negative relation between unexpected returns and ex post unexpected volatility changes and interpreted it as evidence supporting a positive intertemporal relation.

15.2 Theoretical Models

Merton (1973) suggests the intertemporal risk-return relation as a function of stock market volatility, which can be specified in the following general form:

$$E\left(R_{mt} - rf_t|\Omega_{t-1}\right) = f\left(\sigma^p_{mt}\right),\ p = 1,2, \tag{15.1}$$

Where $E(\cdot)$ is the expectation operator, $E(R_{mt}-rf_t|\Omega_{t-1})$ is the time-varying expected market risk premium conditional on the information set Ω_{t-1}, R_{mt} is the return on a stock market index portfolio, and rf_t is the risk-free interest rate. The market volatility is represented by either σ_{mt} or σ^2_{mt}, where $\sigma^2_{mt} = E_{t-1}[(R_{mt} - rf_t) - \mathrm{E}_{t-1}(R_{mt} - rf_t)]^2$. Although $\frac{\partial E(R_{mt}-rf_t|\Omega_{t-1})}{\partial \sigma^2_{mt}} > 0$ is consistent with the equilibrium asset pricing theory, there has been a long-standing controversy in the sign of the relation.

The intertemporal relation is driven not only by predictable volatility but also by an unexpected volatility change. We thus consider the intertemporal relation in the following form:

$$E(R_{mt} - rf_t|\Omega_{t-1}) = f_1\left(\hat{\sigma}^2_{mt}\right) + f_2\left(\varepsilon^2_{mt-1} - \hat{\sigma}^2_{mt-1}\right), \tag{15.2}$$

where ε^2_{mt-1} and $\hat{\sigma}^2_{mt-1}$ are the actual realized volatility series and the predicted volatility series, respectively, such that $\varepsilon^2_{mt-1} - \hat{\sigma}^2_{mt-1}$ represents a prior unexpected volatility shock. Many studies employ the GARCH models to conditionally estimate the predictable volatility series $\hat{\sigma}^2_{mt}$. Equation 15.2 implies that $\frac{\partial E(R_{mt}-rf_t|\Omega_{t-1})}{\partial \sigma^2_{mt}}$ consists of two components: $\frac{\partial f_1}{\partial \hat{\sigma}^2_{mt}}$ and $\frac{\partial f_2}{\partial\left(\varepsilon^2_{mt-1}-\hat{\sigma}^2_{mt-1}\right)}$. While the first term $\frac{\partial f_1}{\partial \hat{\sigma}^2_{mt}}$ measures the effect of predictable market volatility on the relation, the second term $\frac{\partial f_2}{\partial\left(\varepsilon^2_{mt-1}-\hat{\sigma}^2_{mt-1}\right)}$ captures the effects of an unexpected volatility shock on the intertemporal relation. However, most of the previous empirical studies on this topic completely ignore the second term and focus only on the first term. Consequently, their empirical results show only a partial intertemporal relation.

Thus, we examine the empirical nature of the full intertemporal relation by considering not only the predictable conditional volatility but also the effect of an unexpected volatility shock on the relation. Especially, we define an unexpected volatility shock in two separate cases of a positive and negative unexpected volatility shock to examine an asymmetrical effect of a positive and negative unexpected shock on the relation, if any. A positive (negative) unexpected volatility shock is denoted as $\varepsilon^2_{mt-1} > \hat{\sigma}^2_{mt-1}$ ($\varepsilon^2_{mt-1} < \hat{\sigma}^2_{mt-1}$), implying that the actual market volatility is higher (lower) than the predicted conditional market volatility. We then examine the sign of intertemporal relation under each case of $\varepsilon^2_{mt-1} > \hat{\sigma}^2_{mt-1}$ and $\varepsilon^2_{mt-1} < \hat{\sigma}^2_{mt-1}$, respectively.

We specify the linear form of intertemporal relation with a dummy variable to capture the asymmetric effect of a positive and negative unexpected volatility shock on the relation

$$R_{mt} - rf_t = \alpha + \lambda_1 \hat{\sigma}_{mt} + \lambda_2 \hat{\sigma}_{mt} \cdot d_t + \varepsilon_{mt}, \tag{15.3}$$

where ε_{mt} is a series of white noise innovations, and $\hat{\sigma}_{mt}$ is the conditional standard deviation of market portfolio. Note that we use $\hat{\sigma}_{mt}$ instead of $\hat{\sigma}^2_{mt}$ as the conditional forecasts of stock market volatility. The use of $\hat{\sigma}_{mt}$ is suggested as the slope of the capital market line by Merton (1980). Also, in estimation, using $\hat{\sigma}_{mt}$ is expected to yield an improvement in the statistical efficiency, mainly due to a reduction in the mean square error of the regression. d_t is the dummy variable for a positive or negative unexpected volatility shock. It takes the value 1 with a prior unexpected positive volatility shock (i.e., $\varepsilon^2_{mt-1} > \hat{\sigma}^2_{mt-1}$) and 0 otherwise. The intertemporal relation is thus measured by $\lambda_1 + \lambda_2$ when $\varepsilon^2_{mt-1} > \hat{\sigma}^2_{mt-1}$ with $d_{\mathrm{t}} = 1$ or by λ_1 otherwise with $d_t = 0$. The asymmetrical effect of a positive and negative unexpected volatility shock on the intertemporal relation, if any, is captured by λ_2. Specifically, $\lambda_2 > 0$ (or $\lambda_1 + \lambda_2 > \lambda_1$) implies that a positive volatility shock has a positive impact on the intertemporal relation.

15.3 Empirical Models

15.3.1 Asymmetric Nonlinear Smooth Transition GARCH Model

To generate the forecast of time-varying market volatility, we employ the asymmetric nonlinear smooth transition (ANST) GARCH model that is capable of capturing the asymmetric volatility effect of a positive and negative return shock. The key feature of the model is the regime-shift mechanism that allows a smooth, flexible transition of volatility between different states of volatility persistence. For monthly excess return series r_t, we specify

$$h_t = \left[a_0 + a_1 \varepsilon^2_{t-1} + a_2 h_{t-1}\right] + \left[b_0 + b_1 \varepsilon^2_{t-1} + b_2 h_{t-1}\right] F(\varepsilon_{t-1}), \tag{15.4}$$

where $F(\varepsilon_{t-1}) = \{1 + \exp[-\gamma(\varepsilon_{t-1})]\}^{-1}$ and $\varepsilon_t = r_t - E(r_t|\Omega_{t-1})$ with $\varepsilon_t|\Omega_{t-1} \sim N(0, h_t)$. Given $\varepsilon_t = v_t \cdot \sqrt{h_t}$, the normalized residuals are distributed as $v_t \overset{iid}{\sim} N(0,1)$. The logistic transition function $F(\varepsilon_{t-1})$ is a smooth and continuous function of ε_{t-1} and the speed parameter γ and takes a value between 0 and 1: $0 < F(\varepsilon_{t-1}) < 0.5$ for $\varepsilon_{t-1} < 0$, $0.5 < F(\varepsilon_{t-1}) < 1$ for $\varepsilon_{t-1} > 0$, and $F(\varepsilon_{t-1}) = 0.5$ for $\varepsilon_{t-1} = 0$. The volatility persistence is measured by $(a_1 + a_2) + (b_1 + b_2)F$, and the condition $b_1 + b_2 < 0$ captures the excess volatility of a negative return shock. For any negative return shock that causes $0 < F(\varepsilon_{t-1}) < 0.5$, the current volatility is described as a *high-persistence-in-volatility regime*. For any positive return shock causing $0.5 < F(\varepsilon_{t-1}) < 1$, the current volatility is described as a *low-persistence-in-volatility regime*. When $\varepsilon_{t-1} = 0$, $F(\varepsilon_{t-1}) = 0.5$, which implies that the current volatility h_t is halfway between the upper and lower volatility regimes. γ governs the speed of transition between volatility regimes. When γ approaches ∞, our model with $b_0 = b_2 = 0$ degenerates into the GJR model.

Note that the volatility transition mechanism in GARCH models has been applied in the several models, such as the modified GARCH model by Glosten et al. (1993), the smooth transition GARCH model by Gonzalez-Rivera (1998), the SVSARCH (sign- and volatility-switching ARCH) model by Fornari and Mele (1997), and the MSVARCH (Markov switching volatility ARCH) model by Turner et al. (1989) and Hamilton and Susmel (1994). For more details, see Harvey (1993), Lutkepol (1993), Hamilton (1994), Campbell et al. (1997), Gourieroux and Monfort (1997), and Rothman (1999).

15.3.2 Empirical Models for the Intertemporal Relation

We examine a simple linear form of the intertemporal relation in the following model for monthly excess return series r_t:

Model 1:

$$\begin{aligned} r_t &= \mu + \phi r_{t-1} + \delta\sqrt{h_t} + \varepsilon_t \\ h_t &= \left[a_0 + a_1\varepsilon_{t-1}^2 + a_2 h_{t-1}\right] + \left[b_0 + b_1\varepsilon_{t-1}^2 + b_2 h_{t-1}\right]F(\varepsilon_{t-1}), \end{aligned} \tag{15.5}$$

where $F(\varepsilon_{t-1}) = \{1 + \exp[-\gamma(\varepsilon_{t-1})]\}^{-1}$. We include the first-order autoregressive term in the mean equation to capture the serial dependence in returns. The intertemporal relation is measured by the coefficient δ.

Model 1, however, ignores the asymmetric effect of an unexpected volatility shock on the intertemporal relation; hence, it suffers from the omitting variable problem. The estimate of δ in Model 1 measures only a partial intertemporal relation. To measure the full intertemporal relation, we present Model 2 in the following specification:

Model 2:

$$\begin{aligned} r_t &= \mu + \phi r_{t-1} + [\delta + \tau M_t)]\sqrt{h_t} + \varepsilon_t \\ h_t &= \left[a_0 + a_1\varepsilon_{t-1}^2 + a_2 h_{t-1}\right] + \left[b_0 + b_1\varepsilon_{t-1}^2 + b_2 h_{t-1}\right]F(\varepsilon_{t-1}), \end{aligned} \tag{15.6}$$

where M_t is a dummy variable to capture the asymmetrical effect of a positive and negative unexpected volatility shock on the intertemporal relation. We define $\hat{\varepsilon}_{t-1}^2 - h_{t-1} > 0 \cdot \left(\hat{\varepsilon}_{t-1}^2 - h_{t-1} < 0\right)$ as a *positive* (*negative*) unexpected volatility shock, which implies that actual volatility is greater (less) than expected. It thus takes a value 1 if $\hat{\varepsilon}_{t-1}^2 > h_{t-1}$ or 0 otherwise.

The sign of the intertemporal relation is measured by the sign of $\delta + \tau$ under a positive volatility shock ($\hat{\varepsilon}_{t-1}^2 > h_{t-1}$), while it is measured by the sign of δ under a negative volatility shock ($\hat{\varepsilon}_{t-1}^2 < h_{t-1}$). Thus, τ captures an asymmetrical effect of a positive and negative volatility shock on the relation. We put an empirical focus on $\tau > 0$ (or $\delta + \tau > \delta$), which indicates a positive impact of a positive unexpected volatility shock on the intertemporal relation.[6]

We specify Model 3 to examine whether allowing the asymmetry for the constant term affects the estimation of the intertemporal relation. A possibility is that the asymmetrical effect of a positive and negative volatility shock on the relation might disappear.

Model 3:

$$\begin{aligned} r_t &= (\mu_1 + \mu_2 M_t) + \phi r_{t-1} + (\delta + \tau M_t)\sqrt{h_t} + \varepsilon_t \\ h_t &= \left[a_0 + a_1 \varepsilon_{t-1}^2 + a_2 h_{t-1}\right] + \left[b_0 + b_1 \varepsilon_{t-1}^2 + b_2 h_{t-1}\right] F(\varepsilon_{t-1}), \end{aligned} \tag{15.7}$$

where $\mu_2 M_t$ captures the asymmetric effect of a prior positive and negative volatility shock on the level of the conditional mean return. In Model 3, we focus on whether the estimated value of τ is still statistically significant even with a presence of $\mu_2 M_t$.

15.4 Empirical Results

15.4.1 The Data

We employ the excess market returns as the expected market risk premiums. To generate the excess returns, we use the monthly nominal returns of the value- and equal-weighted market portfolio index of the NYSE, AMEX, and NASDAQ from the CRSP data files from 1926:01 to 2008:12. The monthly excess return series is constructed by subtracting the 1-month US T-bill returns reported by Ibbotson Associates from the monthly nominal index returns. The excess return series is computed as percentage returns. We employ three sample periods: the full period (1926:01–2008:12), the pre-87 Crash period (1926:01–1987:09), and the GJR period (1951:04–1989:12). Table 15.1 reports the summary statistics for the data. The descriptive statistics indicate that both the nominal and the excess returns series of the two market indexes exhibit significant excess kurtosis and positive first-order autocorrelation, characterizing the nonnormality of the short-horizon stock returns.

15.4.2 Estimation Results, Interpretations, and Diagnostics

We employ the maximum likelihood method with the analytical derivatives of each parameter provided in the Gauss code. All the statistical inferences are based on the Bollerslev-Wooldrige (1992) robust standard errors. Estimation results of

[6]Note that $\tau = 0$ supports the volatility irrelevance argument by Poterba and Summers (1986).

Table 15.1 Summary statistics for monthly nominal and excess returns

	Nominal value-weighted returns		1-monthT-bill rates		Excess value-weighted returns	
Statistics	Full period	Subperiod	Full period	Subperiod	Full period	Subperiod
Observations	996	741	996	741	996	741
Mean ($\times$100)	0.895	0.961	0.303	0.287	0.592	0.674
Std. dev. ($\times$100)	5.352	5.706	0.253	0.276	5.363	5.722
Skewness	0.18	0.368	1.104	1.261	0.227	0.406
Kurtosis	11.221	10.888	4.684	4.624	11.246	10.875
1st order Autocorrelation	0.112 (0.000)	0.107 (0.003)	0.966 (0.000)	0.967 (0.000)	0.115 (0.000)	0.111 (0.002)

The nominal return series are the monthly value-weighted market index returns for NYSE, AMEX, and NASDAQ stocks and were retrieved from the CRSP tapes for the period from 1926:01 to 2008:12. The monthly nominal return series are the value-weighted market indexes retrieved from the CRSP tapes for the same. The monthly excess return series is computed by subtracting 1-month treasury bill returns as reported by Ibbotson Associates from the nominal returns. All returns are computed as percentage value. The analysis employs the full period (1926:01–2008:12) and the pre-87 Crash period (1926:01–1987:09). The value in the parentheses is the p-value for the Ljung-Box Q test

Model 1 for the full period (1926:01–2008:12) and the pre-87 Crash period (1926:01–1987:09) are reported in Table 15.2. Model 1 examines the sign of the simple linear relation between the expected risk premium and the predictable market volatility. Estimation results for Model 1 show that the intertemporal relation in a simple linear form is significantly positive for both the full sample and subsample periods. The estimated value of δ is 0.077 (0.080 for the pre-87 Crash period) and statistically significant at the 1 % level for both sample periods.

With regard to the conditional variance equation, the asymmetric volatility response of a positive and negative return shock is well captured by $b_1 + b_2 < 0$ with a statistical significance. The average estimated value of h_t for the full sample period under a lower volatility regime is 36.37, while it is 24.00 under a higher volatility regime. Also, the estimation results show a high estimated value of the transition parameter γ, which indicates that the transition between volatility regimes occurs very quickly. This implies that the volatility regime is divided into only two extreme regimes: the upper and lower volatility regimes. The upper (lower) regime is induced by any negative (positive) return shock and exhibits a high volatility persistence (a low volatility persistence) in the conditional volatility process.

Estimation results of Model 2 are reported in Table 15.2. There are several notable findings. First, a positive volatility shock has a positive impact on the intertemporal relation. The results show that the estimated value of τ is significantly positive (0.052 for the full period and 0.041 the pre-87 Crash period) and statistically significant at the 1 % level for both sample periods. This implies that an unexpected volatility shock is priced such that, for a positive volatility shock, the expected risk premium for the full sample period increases by 5.2 % (4.1 % for the pre-87 Crash period) of the predicted conditional volatility $\sqrt{h_t}$. Second, the results show that the intertemporal coefficients are all positive for both sample periods. The estimated value for the full period $\delta + \tau = 0.0878$ is (0.093 for the pre-87 Crash period) under prior positive volatility shock, while it is $\delta = 0.035$ for the full period and 0.052 for the pre-87 Crash period under prior negative volatility shock. The results indicate that the sign of the intertemporal relation is indeed positive when the effect of an unexpected volatility shock is incorporated in estimation. Third, the estimation result of $\tau > 0$ indicates that the slope of the capital market line is relatively steeper under a positive volatility shock than under a negative volatility shock. This implies that a positive volatility shock increases the degree of risk aversion.

Estimation results of Model 3 are also reported in Table 15.2. In Model 3, we examine the possibility that the asymmetrical effect of a positive and negative volatility shock may disappear under the presence of asymmetry in the constant term allowed in the conditional mean equation. The estimation results show a positive value of μ_2 for both periods, indicating that a prior positive volatility shock raises the conditional mean returns. This asymmetrical effect of a prior volatility shock on the constant term is more profound for the pre-87 Crash period (μ_2 is 0.351 and statistically significant at the 1 % level). With respect to the intertemporal relation, τ is still positive and statistically

γ	137.382 (2.057)	97.516 (1.090)	123.324 (3.044)	85.377 (1.577)	107.355 (2.380)	99.011 (1.330)

This table presents the maximum likelihood estimates for models 1−3 for monthly excess returns of the value-weighted index for the NYSE, AMEX, and NASDAQ stocks. The estimation employs the full period (1926:01–2008:12) and the pre-87 Crash period (1926:01–1987:09). For the monthly excess return series r_t, each model is specified as follows

Model 1: $r_t = \mu_1 + \phi r_{t-1} + \delta\sqrt{h_t} + \varepsilon_t$

Model 2: $r_t = \mu_1 + \phi r_{t-1} + (\delta + \tau M_t)\sqrt{h_t} + \varepsilon_t$

Model 3: $r_t = \mu_1 + \mu_2 M_t + \phi r_{t-1} + (\delta + \tau M_t)\sqrt{h_t} + \varepsilon_t$,

where the indicator function M_t is specified to capture the asymmetric effect of an unexpected volatility shock on the intertemporal relation, such that $M_t = 1$ if $\hat{\varepsilon}^2_{t-1} > h_{t-1}$ or $M_t = 0$ otherwise. The conditional variance equation for the models is specified as $h_t = [a_0 + a_1\varepsilon^2_{t-1} + a_2 h_{t-1}] + [b_0 + b_1\varepsilon^2_{t-1} + b_2 h_{t-1}]F(\varepsilon_{t-1})$, where the transition function $F(\varepsilon_{t-1})$ is defined as $F(\varepsilon_{t-1})=\{1 + \exp[-\gamma(\varepsilon_{t-1})]\}^{-1}$. The values in parentheses are the Bollerslev-Wooldridge robust t-statistics significant at the 1 % level for both periods (τ_1 is 0.054 for the full period and 0.048 for the pre-87 Crash period). This implies that, even with the asymmetry allowed in the constant term, there still exists a significant asymmetrical effect of a positive and negative volatility shock on the intertemporal relation. Also, δ is still significantly positive for both periods, confirming the positive full intertemporal relation.

Table 15.3 reports the summary of diagnostics for the estimation results, such as skewness, kurtosis, the Jarque-Bera normality test, and the Ljung-Box Q test on the normalized and the squared normalized residuals. The Ljung-Box Q statistics on the normalized residuals checks serial correlation in the residuals. Rejection of the null of no autocorrelation up to a certain lag length indicates that either the dynamics of the conditional mean or the lag structure of the conditional variance process is not well specified or that both equations are not well specified by the model. The Ljung-Box statistics on the *squared* normalized residuals ascertains if the serial dependence in the conditional variance is well captured by the equation.

We also perform the *negative sign bias test* (NSBT) suggested by Engle and Ng (1993) to examine the ability of the model to capture the so-called leverage effect of a negative return shock on the conditional variance process. The negative sign bias test shows insignificant t-values for all estimations and indicates that the asymmetric volatility response to a positive and negative return shock is well captured by the ANST-GARCH model.[7] The Ljung-Box $Q(10)$ test indicates that the serial dependence of the conditional mean and variance is well captured by models 1–3.

15.4.3 GJR Sample Period

Using modified (E)GARCH-M models, Glosten et al. (1993) report a strong negative intertemporal relation for their (GJR) sample period of 1951:04–1989:12. However, they do not consider the effect of an unanticipated volatility shock on the estimation of the relation, so that their results reflect only a partial intertemporal relation. We thus evaluate the full intertemporal relation for their sample period by incorporating the effect of an unexpected volatility shock in the estimation of the relation. Allowing a time dummy in the conditional mean equation to capture the characteristic of the GJR sample period, we specify Model 5 as follows:

[7] The negative sign bias test is performed with the regression equation $v_t^2 = a + bS_{t-1}^{-}\varepsilon_{t-1} + \pi' z_t^* + e_t$, where $v_t^2 = \left(\varepsilon_t/\sqrt{h_t}\right)^2$. $S_{t-1}^{-} = 1$ if $\varepsilon_{t-1} < 0$, and $S_{t-1}^{-} = 0$ otherwise. Also, $z_t^* = \widetilde{h}(\Psi)/h_t$, where $\widetilde{h}(\Psi) = \partial h_t/\partial \Psi$ evaluated at the values of maximum likelihood estimates of parameter Ψ. The test statistic of the NSBT is defined as the t-ratio of the coefficient b in the regression. A statistically significant t-value implies the failure of the model to absorb the effect of sign bias and indicates that the volatility model considered is misspecified.

Table 15.3 Diagnostics of models 1–3

	Model 1		Model 2		Model 3	
	Full period	Subperiod	Full period	Subperiod	Full period	Subperiod
Skewness of v_t	−0.610	−0.372	−0.631	−0.375	−0.628	−0.366
Kurtosis of v_t	4.961	3.909	5.013	3.877	4.983	3.850
JB-Normality	220.845 (0.000)	42.531 (0.000)	233.794 (0.000)	41.003 (0.000)	228.080 (0.000)	38.743 (0.000)
Q(10) on v_t	11.209 (0.341)	17.801 (0.058)	13.368 (0.204)	18.010 (0.055)	13.139 (0.216)	17.663 (0.061)
Q(10) on v_t^2	7.156 (0.711)	12.905 (0.229)	9.660 (0.471)	13.148 (0.215)	9.516 (0.484)	13.639 (0.190)
NSBT on h_t	−1.328 (0.184)	−0.579 (0.563)	−0.526 (0.599)	−1.275 (0.203)	−0.688 (0.492)	−1.365 (0.173)

This table presents a summary of diagnostics on the normalized residuals and the squared normalized residuals from the estimations. The normalized residual series is defined as $v_t = \varepsilon_t/\sqrt{h_t}$. JB-Normality refers to the Jarque-Bera normality test statistic, which is distributed as χ^2 with two degrees of freedom under the null hypothesis of normally distributed residuals. Q(10) is the Ljung-Box Q(10) test statistic for checking serial dependence in the normalized residuals and the squared normalized residuals from the estimations. NSBT refers to the negative sign bias test suggested by Engle and Ng (1993). It is a diagnostic test that examines the ability of the specified model to capture the so-called leverage effect of a negative return shock on the conditional volatility process. The test is performed with the regression equation $v_t^2 = a + bS_{t-1}^{-}\varepsilon_{t-1} + \pi' z_t^* + e_t$, where $v_t^2 = \left(\varepsilon_t/\sqrt{h_t}\right)^2$. S_{t-1}^{-}=1 if $\varepsilon_{t-1} < 0$, and $S_{t-1}^{-} = 0$ otherwise. Also, $z_t^* = \widetilde{h}(\Psi)/h_t$, where $\widetilde{h}(\Psi) = \partial h_t/\partial \Psi$, is evaluated at the values of the maximum likelihood estimates of parameter Ψ. The test statistic of the NSBT is defined as the t-ratio of the coefficient b in the regression. The value in the parentheses is the p-value of the individual test statistics considered

Model 4 (Modified Model 1 for GJR Period):

$$\begin{aligned} r_t &= \mu + \phi r_{t-1} + \left(\delta + \delta^G G_t\right)\sqrt{h_t} + \varepsilon_t \\ h_t &= \left[a_0 + a_1\varepsilon_{t-1}^2 + a_2 h_{t-1}\right] + \theta rf_t \\ &\quad + \left[b_0 + b_1\varepsilon_{t-1}^2 + b_2 h_{t-1}\right]F(\varepsilon_{t-1}), \end{aligned} \tag{15.8}$$

where G_t is a dummy variable that takes a value 1 for the GJR sample period or 0 otherwise. The coefficient δ^G captures the differential effect of the GJR period, if any, on the intertemporal relation, while δ measures the relation for the full period. The negative intertemporal relation reported by Glosten et al. (1993) can be confirmed by $\delta + \delta^G < 0$. One of the important features of the above modified Model 1 is its capacity to distinguish the relation for the GJR sample period from that for the entire sample period. We also estimate the same model with and without the 1-month T-bill returns rf_t included in the conditional variance equation.[8]

Estimation results of Model 4 are reported in Table 15.4. A notable finding is that the estimated value of δ^G is strongly negative (–0.103 with rf_t and –0.092 without rf_t) and highly significant with $\delta + \delta^G < 0$. This result implies that, comparing to the full period, the GJR sample period is especially characterized by a strong negative intertemporal relation, and this result is consistent with that of Glosten et al. (1993).

As mentioned earlier, however, this result does not consider the effect of an unexpected volatility shock on the relation, reflecting only a simple partial intertemporal relation. In order to examine the full relation for the GJR sample period, we specify Model 5 as follows:

Model 5 (Modified Model 2 for GJR Period):

$$\begin{aligned} r_t &= \mu + \phi r_{t-1} + \left[(\delta + \tau M_t) + \left(\delta^G + \tau^G M_t\right)G_t\right]\sqrt{h_t} + \varepsilon_t \\ h_t &= \left[a_0 + a_1\varepsilon_{t-1}^2 + a_2 h_{t-1}\right] + \theta rf_t + \left[b_0 + b_1\varepsilon_{t-1}^2 + b_2 h_{t-1}\right]F(\varepsilon_{t-1}), \end{aligned} \tag{15.9}$$

where G_t is a time dummy variable that takes the value 1 for the GJR period or 0 otherwise. The full intertemporal relation for the GJR period is measured by $\delta + \delta^G + \tau + \tau^G$ under a positive volatility shock and by $\delta + \delta^G$ under a negative volatility shock, such that the differential effect of the GJR period on the full relation is captured by $\delta^G + \tau^G$. We also estimate the same model with and without rf_t included in the conditional variance equation.

Estimation results of Model 5 for the GJR sample period are reported in Table 15.4. It shows that the estimated value of all four important parameters (δ, τ, δ^G, and τ^G) capturing the intertemporal relation are statistically significant at the 1 % level. There are several notable findings. First, the estimation result of

[8]Several studies show that the estimation results are sensitive to the inclusion of 1-month T-bill return in the conditional variance equation. See Campbell (1987), Glosten et al. (1993), and Scruggs (1998).

θ	0.885 (1.065)		0.901 (1.128)	
γ	121.735 (1.944)	217.354 (2.441)	287.546 (2.128)	254.235 (1.963)

The GJR sample period (1951:04–1989:12) is evaluated by incorporating the period as a dummy variable in the mean equation, with the 1-month T-bill rates included or excluded in the conditional variance equation. The modified models to estimate the GJR sample period are as follows
Model 4 (modified Model 1 for GJR period): $r_t = \mu + \phi r_{t-1} + \left(\delta + \delta^G G_t\right)\sqrt{h_t} + \varepsilon_t$
Model 5 (modified Model 2 for GJR period): $r_t = \mu + \phi r_{t-1} + \left[(\delta + \tau M_t) + \left(\delta^G + \tau^G M_t\right) G_t\right]\sqrt{h_t} + \varepsilon_t$
where the indicator function G_t is a dummy variable for the GJR sample period, and rf_t is the yield on 1-month T-bill from Ibbotson Associates. The function M_t is specified to capture the asymmetric effect of an unexpected volatility shock on the relation, such that $M_t = 1$ if $\hat{\varepsilon}^2_{t-1} > h_{t-1}$; otherwise, $M_t = 0$. The conditional variance equation for the two estimation models is specified as $h_t = [a_0 + a_1\varepsilon^2_{t-1} + a_2 h_{t-1}] + [b_0 + b_1\varepsilon^2_{t-1} + b_2 h_{t-1}]F(\varepsilon_{t-1})$, where $F(\varepsilon_{t-1}) = \{1 + \exp[-\gamma(\varepsilon_{t-1})]\}^{-1}$. The values in parentheses are the Bollerslev-Wooldridge robust *t*-statistics

$\delta^G + \tau^G = -0.088$ (–0.065 without rf_t) confirms that the GJR period is indeed characterized by a significant negative relation. Second, the estimation result of $\tau + \tau^G = 0.113$ (0.137 without rf_t) implies that, even for the GJR sample period, there still exists a significant positive effect of a positive volatility shock on the full intertemporal relation. Third, the estimation results of $\delta + \delta^G + \tau + \tau^G = 0.061$ (0.081 without rf_t) and $\delta + \delta^G = -0.052$ (–0.056 without rf_t) imply that the GJR sample period exhibits a positive intertemporal relation under a positive volatility shock and a negative relation under a negative volatility shock. Note the above results are not sensitive to the inclusion of rf_t in estimation.

Diagnostic tests in Table 15.5 indicate that all the estimations pass the Ljung-Box Q(10) test on the normalized and squared normalized residuals. This result implies that there is no serial dependence remaining in the conditional mean and variance processes. The negative sign bias test shows insignificant *t*-values for all estimations, indicating that the estimated conditional variance process well captures the excess volatility response caused by a negative return shock.

Table 15.5 Diagnostics of the models 4 and 5 for the GJR sample period

	Model 4 for GJR sample period		Model 5 for GJR sample period	
	Without *rf*	With *rf*	Without *rf*	Without *rf*

JB-Normality	246.664 (0.000)	217.536 (0.000)	242.89 (0.000)	208.29 (0.000)
Q(10) on v_t	10.190 (0.424)	10.397 (0.406)	10.111 (0.431)	10.846 (0.370)
Q(10) on v_t^2	10.514 (0.397)	10.418 (0.405)	9.7167 (0.466)	10.122 (0.430)
NSBT on h_t	−1.198 (0.231)	−1.162 (0.246)	−1.205 (0.228)	−1.105 (0.269)

This table presents a summary of diagnostics on the normalized residuals and the squared normalized residuals from the estimations. The normalized residual series is defined as $v_t = \varepsilon_t/\sqrt{h_t}$. JB-Normality refers to the Jarque-Bera normality test statistic, which is distributed as χ^2 with two degrees of freedom under the null hypothesis of normally distributed residuals. Q(10) is the Ljung-Box Q(10) test statistic for checking serial dependence in the normalized residuals and the squared normalized residuals from the estimations. NSBT refers to the negative sign bias test suggested by Engle and Ng (1993). It is a diagnostic test that examines the ability of the specified model to capture the so-called leverage effect of a negative return shock on the conditional volatility process. The test is performed with the regression equation $v_t^2 = a + bS_{t-1}^-\varepsilon_{t-1} + \pi' z_t^* + e_t$, where $v_t^2 = \left(\varepsilon_t/\sqrt{h_t}\right)^2$. $S_{t-1}^- = 1$ if $\varepsilon_{t-1} < 0$, and $S_{t-1}^- = 0$ otherwise. Also, $z_t^* = \widetilde{h}(\Psi)/h_t$, where $\widetilde{h}(\Psi) = \partial h_t/\partial\Psi$, is evaluated at the values of the maximum likelihood estimates of parameter Ψ. The test statistic of the NSBT is defined as the t-ratio of the coefficient b in the regression. The value in the parentheses is the p-value of the individual test statistics considered

15.4.4 The Link Between Asymmetric Mean Reversion and Intertemporal Relation

It has been known that the expected market returns exhibit an asymmetric mean-reverting pattern that negative returns are more likely to revert to positive returns than positive returns reverting to negative returns. However, the quicker reversion of negative returns is hardly justified under a positive intertemporal relation. Under a positive intertemporal relation, a negative return shock raises the risk premium to compensate for the excess volatility, and an increase in risk premium reduces the current stock price, which in turn reduces the concurrent stock price. Thus, if a positive intertemporal relation is correct, a negative return should be more likely to be accompanied by another negative return for the subsequent periods.

Nam et al. (2001) suggest that the quicker reversion of a negative return is attributed to a reduction in the expected risk. They show that the intertemporal relation is significantly negative under a prior negative return shock. They argue that a negative return shock generates an optimistic expectation by investors, of the future performance of a stock experiencing a recent price drop, thereby reducing the expected market risk premium. As a reduction in risk premium in turn raises the current stock price, negative returns are more likely to revert to positive returns.

While successfully explaining the link between the asymmetric mean-reverting property and the intertemporal relation, Nam et al. (2001) do not consider the effect of an unexpected volatility shock on the link. In this section, we investigate the impact of an unexpected volatility shock on the observed link. First, we specify the following nonlinear autoregressive model to confirm the asymmetric mean reversion of the expected market risk premium:

Model 6:

$$\begin{aligned} r_t &= [\mu_1 + \mu_2 F(\varepsilon_{t-1})] + [\phi_1 + \phi_2 F(\varepsilon_{t-1})] r_{t-1} + \varepsilon_t \\ h_t &= \left[a_0 + a_1 \varepsilon_{t-1}^2 + a_2 h_{t-1}\right] + \left[b_0 + b_1 \varepsilon_{t-1}^2 + b_2 h_{t-1}\right] F(\varepsilon_{t-1}), \end{aligned} \tag{15.10}$$

where the asymmetry is allowed in both the conditional mean and variance, such that the asymmetry in both processes is controlled by a prior return shock. The return serial correlation varies between ϕ_1 and $\phi_1 + \phi_2$ depending on the value of the transition function $F(\varepsilon_{t-1})$. Under an extreme negative prior return shock that causes $F(\varepsilon_{t-1}) = 0$, serial correlation is measured by ϕ_1, while it is measured by $\phi_1 + \phi_2$ for an extreme positive return shock yielding $F(\varepsilon_{t-1}) = 1$.[9] A quicker reversion of a negative return is captured by $\phi_1 > 0$ (or $\phi_1 + \phi_2 > \phi_1$). Note that the condition $\phi_1 < 0$ (a negative serial correlation under $\varepsilon_{t-1} < 0$) indicates a stronger reverting tendency of a negative return.

Estimation results of Model 6 are reported in Table 15.6. It shows that the estimated value of ϕ_2 is positive and highly significant for both the full period and the pre-87 Crash period. The measured serial correlation is negative ($\phi_1 = -0.078$ and –0.076, respectively, for the two periods) under a prior negative return shock, while it is positive ($\phi_1 + \phi_2 = 0.056$ and 0.094, respectively, for the two periods) under a prior positive return shock. This result confirms the asymmetrical reverting pattern of the expected returns that a negative return reverts more quickly, while a positive return tends to persist.

Secondly, we specify Model 7 to examine if there is a link between the asymmetric mean reversion and the intertemporal relation.

Model 7:

$$\begin{aligned} r_t &= [\mu_1 + \mu_2 F(\varepsilon_{t-1})] + \phi_1 r_{t-1} + [\delta_1 + \delta_2 F(\varepsilon_{t-1})]\sqrt{h_t} + \varepsilon_t \\ h_t &= \left[a_0 + a_1 \varepsilon_{t-1}^2 + a_2 h_{t-1}\right] + \left[b_0 + b_1 \varepsilon_{t-1}^2 + b_2 h_{t-1}\right] F(\varepsilon_{t-1}). \end{aligned} \tag{15.11}$$

The partial intertemporal relation is measured by the estimated value of δ_1 under a prior negative return shock causing $F(\varepsilon_{t-1}) = 0$, while it is measured by $\delta_1 + \delta_2$ under a prior positive return shock causing $F(\varepsilon_{t-1}) = 1$. Thus, δ_2 measures the differential impact of a positive and negative return shock on the partial intertemporal relation.

The estimation results presented in Table 15.6 show two notable findings. First, δ_2 is positive and statistically significant at the 1 % level ($\delta_2 = 0.258$ for the full period and 0.334 for the pre-87 Crash period). This result implies that there is

[9] Stationarity condition of r_t is satisfied with $|\phi_1 + \phi_2 F(\varepsilon_{t-1})| < 1$, i.e., $|\phi_1| < 1$ for $\varepsilon_{t-1} < 0$ or $|\phi_1 + \phi_2| < 1$ for $\varepsilon_{t-1} > 0$.

This table presents the maximum likelihood estimates of models 6–8 for the monthly excess returns of the value-weighted index for the NYSE, AMEX, and NASDAQ stocks over the period of 1926:01–2008:12 and the period of 1926:01–1987:09. For the monthly excess return series r_t, each model is specified as follows

Model 6: $r_t = [\mu_1 + \mu_2 F(\varepsilon_{t-1})] + [\phi_1 + \phi_2 F(\varepsilon_{t-1})] r_{t-1} + \varepsilon_t$

Model 7: $r_t = [\mu_1 + \mu_2 F(\varepsilon_{t-1})] + \phi r_{t-1} + [\delta_1 + \delta_2 F(\varepsilon_{t-1})]\sqrt{h_t} + \varepsilon_t$

Model 8: $r_t = [\mu_1 + \mu_2 F(\varepsilon_{t-1})] + \phi_1 r_{t-1} + [(\delta_1 + \tau_1 M_t) + (\delta_2 + \tau_2 M_t) F(\varepsilon_{t-1})]\sqrt{h_t} + \varepsilon_t$

where the indicator function M_t is specified to capture the asymmetric effect of an unexpected volatility shock on the intertemporal relation, such that $M_t = 1$ if $\hat{\varepsilon}_{t-1}^2 > h_{t-1}$ or $M_t = 0$ otherwise. The conditional variance equation for Models 6–8 is specified as $h_t = [a_0 + a_1 \varepsilon_{t-1}^2 + a_2 h_{t-1}] + [b_0 + b_1 \varepsilon_{t-1}^2 + b_2 h_{t-1}] F(\varepsilon_{t-1})$. The values in parentheses are the Bollerslev-Wooldridge robust t-statistics a strong asymmetry in the partial intertemporal relation under a prior positive and negative return shock. Second, the partial intertemporal relation is indeed negative under a prior negative return shock ($\delta_1 = -0.155$ for the full period and –0.182 for the pre-87 Crash period), while it is positive under a prior positive return shock ($\delta_1 + \delta_2 = 0.103$ for the full period and 0.152 for the pre-87 Crash period). This result implies that while a positive return shock complies with the conventional positive intertemporal relation, a negative return shock indeed induces a negative intertemporal behavior of the expected market returns. More importantly, the results of Models 6 and 7 confirm the highly significant asymmetric link between the mean reversion and the intertemporal relation. The quicker reversion of negative returns is attributed to the negative intertemporal relation under a prior negative return shock.

Model 7 does not incorporate the asymmetrical impact of a positive and negative volatility shock in the estimation of the intertemporal relation. To get empirically more reliable results on the link between the mean reversion and the full intertemporal relation, we propose Model 8 in the following specification.

Model 8:

$$
\begin{aligned}
r_t &= [\mu_1 + \mu_2 F(\varepsilon_{t-1})] + \phi_1 r_{t-1} + [(\delta_1 + \tau_1 M_t) + (\delta_2 + \tau_2 M_t) F(\varepsilon_{t-1})]\sqrt{h_t} + \varepsilon_t \\
h_t &= \left[a_0 + a_1 \varepsilon_{t-1}^2 + a_2 h_{t-1}\right] + \left[b_0 + b_1 \varepsilon_{t-1}^2 + b_2 h_{t-1}\right] F(\varepsilon_{t-1}),
\end{aligned}
\tag{15.12}
$$

where the full intertemporal relation is measured separately under a positive and negative return shock. When a negative return shock causing $F(\varepsilon_{t-1}) = 0$ is realized, the full intertemporal relation is measured by $\delta_1 + \tau_1$, for which τ_1 captures an asymmetrical impact of a prior unexpected volatility shock on the relation. With a prior positive return shock, the relation is measured by $\delta_1 + \delta_2 + \tau_1 + \tau_2$, for which $\tau_1 + \tau_2$ measures an asymmetrical effect of a prior volatility shock on the relation, if any.

The estimation results of Model 8 are reported in Table 15.6. There are several notable findings. First, the results show that three out of the four important parameters (δ_1, τ_1, δ_2, and τ_2) to capture the full intertemporal relation are statistically significant at the 5 % level. Second, the result of $\delta_1 + \tau_1 = -0.181$ (–0.220 for the pre-87 Crash period) and $\delta_1 + \delta_2 + \tau_1 + \tau_2 = 0.020$ (0.057 for the pre-87 Crash period) implies that the full intertemporal relation is still negative (positive) under a prior negative (positive) return shock. Third, more importantly, the results of $\tau_1 = 0.079$ and $\tau_1 + \tau_2 = 0.051$ (0.024 and 0.076 for the pre-87 Crash period) indicate that a positive volatility shock has a positive impact on the intertemporal relation, regardless of the sign of a prior return shock. This implies that a positive unexpected volatility shock consistently induces a positive impact on the intertemporal risk-return relation.

Table 15.7 reports the results of diagnostic tests. The Ljung-Box Q(10) test results on v_t and v_t^2 indicate that serial dependence is well captured by the specified conditional mean and variance processes. The negative sign bias test shows insignificant *t*-values for all estimations, confirming the capability of the ANST-GARCH model to capture the excess volatility response caused by a negative return shock.

Table 15.7 Diagnostics of models 6–8

	Model 6		Model 7		Model 8	
	Full period	Subperiod	Full period	Subperiod	Full period	Subperiod

NSBT on h_t	−1.415 (0.157)	−0.769 (0.442)	−1.058 (0.290)	−0.547 (0.585)	−1.248 (0.212)	−0.334 (0.738)

This table presents a summary of diagnostics on the normalized residuals and the squared normalized residuals from the estimations. The normalized residual series is defined as $v_t = \varepsilon_t/\sqrt{h_t}$. JB-Normality refers to the Jarque-Bera normality test statistic, which is distributed as χ^2 with two degrees of freedom under the null hypothesis of normally distributed residuals. Q(10) is the Ljung-Box Q(10) test statistic for checking serial dependence in the normalized residuals and the squared normalized residuals from the estimations. NSBT refers to the negative sign bias test suggested by Engle and Ng (1993). It is a diagnostic test that examines the ability of the specified model to capture the so-called leverage effect of a negative return shock on the conditional volatility process. The test is performed with the regression equation $v_t^2 = a + bS_{t-1}^-\varepsilon_{t-1} + \pi' z_t^* + e_t$, where $v_t^2 = \left(\varepsilon_t/\sqrt{h_t}\right)^2$. $S_{t-1}^- = 1$ if $\varepsilon_{t-1} < 0$, and $S_{t-1}^- = 0$ otherwise. Also, $z_t^* = \widetilde{h}(\Psi)/h_t$, where $\widetilde{h}(\Psi) = \partial h_t/\partial\Psi$, is evaluated at the values of the maximum likelihood estimates of parameter Ψ. The test statistic of the NSBT is defined as the t-ratio of the coefficient b in the regression. The value in the parentheses is the p-value of the individual test statistics considered

15.5 Conclusions

We suggest that the intertemporal risk-return relation is driven not only by the underlying market volatility but also by an unexpected volatility shock. Most of the previous literature on this topic ignores the effect of an unexpected volatility shock on the relation. Thus, their results reflect only a partial intertemporal relation. With the effect of an unexpected volatility shock incorporated in the estimation of the relation, we find a strong positive intertemporal relation for the US monthly excess returns for the period of 1926:01–2008:12.

We also reexamine the relation for the GJR sample period with the effect of a volatility shock incorporated in estimation. The estimation results show that the GJR sample period is indeed characterized by a strong positive (negative) relation under a positive (negative) volatility shock. This implies that the negative relation reported by Glosten et al. (1993) is attributed to ignoring the effect of an unexpected volatility shock on the relation.

Lastly, we examine the observed link between the mean reversion property and the intertemporal relation under a consideration of the impact of an unexpected volatility shock on the link. We confirm that the quicker reversion of negative returns is attributed to the negative intertemporal relation under a prior negative return shock. We interpret this negative intertemporal relation as reflective of strong optimistic expectations as perceived by investors of the future performance of a stock experiencing a recent price drop.

Appendix 1: Method to Derive the Variance of the Parameters with Restrictions

In estimations, we employ the parameter restrictions for the positivity of the conditional variance process. To get the true variance of the restricted parameter, we apply the following functional transformations:

Case 1. Logistic Function Transformation

Suppose that a parameter $\hat{\beta}$ is restricted to a logistic function of $\hat{b}$ in order to guarantee $0 < \hat{\beta} < 1$.

Hence,

$$\hat{\beta} = f\left(\hat{b}\right) = \frac{1}{1 + e^{-\hat{b}}}, \tag{15.13}$$

where $\hat{b}$ is the actual coefficient estimated from computation, and $\hat{\beta}$ is the true parameter estimate we want to transform from Eq. 15.13. Using Taylor expansion, Eq. 15.13 can be expressed as

$$f\left(\hat{b}\right) = f(b) + f'(b)\left(\hat{b} - b\right), \tag{15.14}$$

or

$$f(\hat{b}) - f(b) = f'(b)(\hat{b} - b). \tag{15.15}$$

Using $f(b) = \frac{1}{1+e^{-b}} = \beta$ and Eq. 15.15 can be expressed as

$$\hat{\beta} - \beta = f'(b) \cdot (\hat{b} - b). \tag{15.16}$$

Then, from Eq. 15.16 we can get $\text{var}(\hat{\beta})$ as follows:

$$\text{var}(\hat{\beta}) = E(\hat{\beta} - \beta)^2 = [f'(b)]^2 \cdot E(\hat{b} - b)^2, \tag{15.17}$$

where the true value of $f'(b)$ is not known. We thus use the MLE of b, $\hat{b}$, to get the value of $f'(b)$. Then the variance of $\hat{\beta}$ can be calculated as follows:

$$\text{var}(\hat{\beta}) = [f'(\hat{b})]^2 \cdot \text{var}(\hat{b}), \tag{15.18}$$

where $f'(\hat{b}) = f(\hat{b})[1 - f(\hat{b})]$.

Case 2. Exponential Function Transformation

Suppose that a parameter $\hat{\beta}$ is restricted to an exponential function of $\hat{b}$ in order to guarantee $0 < \hat{\beta} < 1$. Hence,

$$\hat{\beta} = f(\hat{b}) = e^{-\hat{b}}. \tag{15.19}$$

Using Eq. 15.18,

$$\text{var}(\hat{\beta}) = [f'(\hat{b})]^2 \cdot \text{var}(\hat{b}), \tag{15.20}$$

where $f'(\hat{b}) = [f(\hat{b})]^2 = \hat{\beta}^2$.

Appendix 2: News Impact Curve

We derive the functions of the news impact curve (NIC) for the ANST-GARCH and the GJR models as follows:
ANST-GARCH (1,1) Model:

$$\text{Model}: \quad h_t = (a_0 + a_1\varepsilon_{t-1}^2 + g_1 h_{t-1}) + (b_0 + b_1\varepsilon_{t-1}^2 + b_2 h_{t-1}) \cdot F(\varepsilon_{t-1}) \tag{15.21}$$

$$\text{NIC}: \quad h_t = C + [a_1 + b_1 F(\varepsilon_{t-1})]\varepsilon_{t-1}^2$$

and

$$C = a_0 + b_0 F(\varepsilon_{t-1}) + [g_1 + b_2 F(\varepsilon_{t-1})]\sigma^2, \tag{15.22}$$

$$\text{where } F(\varepsilon_{t-1}) = \{1 + \exp[-\gamma(\varepsilon_{t-1})]\}^{-1}.$$

GJR (1, 1) Model:

$$\text{Model}: \quad h_t = a_0 + a_1\varepsilon_{t-1}^2 + b_1 h_{t-1} + \left(a_2\varepsilon_{t-1}^2\right) \cdot I(\varepsilon_{t-1} > 0), \tag{15.23}$$

$$\text{where } I(\varepsilon_{t-1} > 0) = \left\{\begin{matrix} 1, if\, \varepsilon_{t-1} > 0 \\ 0, if\, \varepsilon_{t-1} < 0 \end{matrix}\right\}.$$

$$\text{NIC}: \quad h_t = \left\{\begin{matrix} (a_0 + b_1\sigma^2) + a_1\varepsilon_{t-1}^2, & if\, \varepsilon_{t-1} > 0 \\ (a_0 + b_1\sigma^2) + (a_1 + a_2)\varepsilon_{t-1}^2, & if\, \varepsilon_{t-1} < 0 \end{matrix}\right\}. \tag{15.24}$$

Appendix 3: Sign Bias Tests

Based on the news impact curve, we perform three diagnostic tests for examining the ability of a model to capture asymmetric effect of news on conditional variance: the *sign bias test* (SBT), the *negative sign bias test* (NSBT), and the *positive sign bias test* (PSBT). These tests are performed by the t-statistic on the coefficient b under the following regression equations:

$$v_t^2 = a + bS_{t-1}^- + \beta' z_t^* + e_t \tag{15.25}$$

$$v_t^2 = a + bS_{t-1}^- \varepsilon_{t-1} + \beta' z_t^* + e_t \tag{15.26}$$

$$v_t^2 = a + bS_{t-1}^+ \varepsilon_{t-1} + \beta' z_t^* + e_t, \tag{15.27}$$

where $v_t^2 = \left(\varepsilon_t/\sqrt{h_t}\right)^2$, $S_{t-1}^- = 1$ if $\varepsilon_{t-1} < 0$ and $S_{t-1}^- = 0$ otherwise, and $S_{t-1}^+ = 1 - S_{t-1}^-$. $z_t^* = \widetilde{h}(\theta)/h_t^*$, where $\widetilde{h}(\theta) = \partial h_t/\partial\theta$ evaluated at the values of maximum likelihood estimates of parameter θ, and h_t^* is the estimated conditional variance by a model considered.

Abstract

This study uses a novel method, the Logical Analysis of Data (LAD), to reverse engineer and construct credit risk ratings which represent the creditworthiness of financial institutions and countries. LAD is a data mining method based on combinatorics, optimization, and Boolean logic that utilizes combinatorial search techniques to discover various combinations of attribute values that are characteristic of the positive or negative character of observations. The proposed methodology is applicable in the general case of inferring an objective rating system from archival data, given that the rated objects are characterized by vectors of attributes taking numerical or ordinal values. The proposed approaches are shown to generate transparent, consistent, self-contained, and predictive credit risk rating models, closely approximating the risk ratings provided by some of the major rating agencies. The scope of applicability of the proposed method extends beyond the rating problems discussed in this study and can be used in many other contexts where ratings are relevant.

We use multiple linear regression to derive the logical rating scores.

16.1 Introduction

16.1.1 Importance of Credit Risk Ratings

Credit ratings published by such agencies as Moody's, Standard & Poor's, and Fitch are considered important indicators for financial markets, providing critical information about the likelihood of future default. The importance of credit ratings is recognized by international bodies, as manifested by the Basel Capital Accord (2001, 2006). The progressively increasing importance of credit risk ratings is driven by the dramatic expansion of investment opportunities associated with the globalization of the world economies. Since these opportunities are often risky, the internationalized financial markets have to rely on agencies' ratings for the assessment of credit risk.

The importance of credit risk rating systems is manifold, as shown below:

- **Credit approval**: the credit risk rating plays a major role in the credit preapproval decisions. Indeed, a binary decision model in which the credit risk rating of the obligor is an explanatory variable is typically used to preapprove the decision to grant or not the credit.
- **Pricing**: in case of loan preapproval, the credit risk rating impacts the conditions (interest rate, covenants, collaterals, etc.) under which the final credit is granted (Treacy and Carey 2000). The credit risk rating is also utilized in the operations subsequent to the preapproval stage.

- **Provisioning**: the credit risk rating is a variable used for calculating the expected losses, which, in turn, are used to determine the amount of economic capital that a bank must keep to hedge against possible defaults of its borrowers. The expected loss of a credit facility is a function of the probability of default of the borrower to which the credit line is granted, as well as the exposure at default and the loss given default associated with the credit facility. Since there is usually a mapping between credit risk rating and the borrower's probability of default, and provided that the rating of a borrower is a key predictor to assess the recovery rate associated with a credit facility granted to this borrower, the importance of the credit risk rating in calculating the amounts of economic capital is evident.
- **Moral hazard**: the reliance upon an objective and accurate credit risk rating system is a valuable tool against some moral hazard situations. Some financial institutions do not use a credit risk rating model but instead let lending officers assign credit ratings based on their judgment. The lending officers are in charge of the marketing of banking services, and their performance and therefore compensation are determined with respect to the "profitability" of the relationships between the bank and its customers. Clearly, the credit risk ratings assigned by the lending officers will affect the volume of the approved loans and the compensation of the officer who, as a result, could have an incentive to assign ratings in a way that is not consistent with the employer's interests. Thus, the use of a reliable credit risk rating system could lead to avoiding such perverse incentive situations.
- **Basel compliance**: the New Basel Capital Accord (Basel II) requires banks to implement a robust framework for the evaluation of credit risk exposures of financial institutions and the capital requirements they must bear. This involves the construction and the cross-validation of accurate and predictive credit risk rating systems.

Financial institutions, while taking into account external ratings (e.g., those provided by Fitch, Moody's, S&P's), have increasingly been developing efficient and refined internal rating systems over the past years. The reasons for this trend are multiple.

First, the work of rating agencies, providing external, public ratings, has recently come under intense scrutiny and criticism, justified partly by the fact that some of the largest financial collapses of the decade (Enron Corp, etc.) were not anticipated by the ratings. At his March 2006 testimony before the Senate Banking Committee, the president and CEO of the CFA Institute[1] highlighted the conflicts of interest in credit ratings agencies (Wall Street Letter 2006). He regretted that credit rating agencies "have been reluctant to embrace any type of regulation over the services they provide" and reported that credit rating agencies "should be held to the highest standards of transparency, disclosure and professional conduct. Instead, there are no standards." The problem is reinforced by the fact that rating agencies, charging fees

[1]Wall Street Letter. 2006. CFA To Senate: Follow Our Lead On Credit Rating.

to rated countries, can be suspected of reluctance to downgrade them, because of the possibility of jeopardizing their income sources. This is claimed, for example, by Tom McGuire, an executive vice-president of Moody's, who states that "the pressure from fee-paying issuers for higher ratings must always be in a delicate balance with the agencies' need to retain credibility among investors."[2] The necessity to please the payers of the ratings opens the door to many possible issues. Kunczik (2001) notes that the IMF fears the danger that "issuers and intermediaries could be encouraged to engage in *rating shopping* – a process in which the issuer searches for the least expensive and/or least demanding rating." The reader is referred to Hammer et al. (2006) for a discussion of some other criticisms (lack of comprehensibility, procyclicality, black box, lack of predictive and crisis-warning power, regional bias, etc.) commonly addressed to rating agencies.

Second, an internal rating system provides autonomy to a bank's management in defining credit risk in line with that bank's core business and best international practices. Internal ratings are also used to report to senior management various key metrics such as risk positions, loan loss reserves, economic capital allocation, and employee compensation (Treacy and Carey 2000).

Third, while the Basel Committee on Banking Supervision of the Bank for International Settlements favored originally (i.e., in the 1988 Capital Accord) the ratings provided by external credit ratings agencies, it is now encouraging the Internal Ratings-Based (IRB) approach under which banks use their own internal rating estimates to define and calculate default risk, on the condition that the robust regulatory standards are met and the internal rating system is validated by the national supervisory authorities. The committee has defined strict rules for credit risk models used by financial institutions and requires them to develop and cross-validate these models in order to comply with the Basel II standard (Basel Committee on Banking Supervision 2001, 2006).

Fourth, aside from the Basel II requirements, banks are developing internal risk models to make the evaluation of credit risk exposure more accurate and transparent. Credit policies and processes will be more efficient, and the quality of data will be improved. This is expected to translate into substantial savings on capital requirements. Today's eight cents out of every dollar that banks hold in capital reserves could be reduced in banks with conservative credit risk policies, resulting in higher profitability.

16.1.2 Contribution and Structure

The above discussion outlines the impact of the credit risk ratings, the possible problems of objectivity and transparency of external (i.e., provided by rating agencies) credit risk ratings, and the importance and need for financial institutions to develop their own, internal credit risk rating systems.

[2] The Economist, July 15, 1995, 62.

In this chapter, we use the novel combinatorial pattern extraction method called the logical analysis of data (LAD) to learn a given credit risk rating system and to develop on its basis a rating system having the following characteristics:

- **Self-containment**: the rating system does not use as predictor variables any other credit risk rating information (non-recursiveness). Clearly, this requirement precludes the use of lagged ratings as independent variables. It is important to note that this approach is in marked contrast with that of the current literature (see Hammer et al. 2006, 2011 for a discussion). The significant advantage of the non-recursive nature of the rating system is its applicability to not-yet-rated obligors.
- **Objectivity**: the rating system only relies on measurable characteristics of the rated entities.
- **Transparency**: the rating system has formal explicit specification.
- **Accuracy**: it is in close agreement with the learned, opaque rating system.
- **Consistency**: the discrepancies between the learned rating system and the constructed one are resolved by subsequent changes in the learned rating system.
- **Generalizability**: applicability of the rating system to evaluate the creditworthiness of obligors at subsequent years or of obligors that were not previously rated.
- **Basel compliance**: it satisfies the Basel II Accord requirements (cross-validation, etc.).

In this study, we derive a rating system for two types of obligors:

- **Countries**: Eliasson (2002) defines **country risk** as the "risk of national governments defaulting on their obligations," while Afonso et al. (2007) state that "sovereign credit ratings are a condensed assessment of a government's ability and willingness to repay its public debt both in principal and in interests on time." Haque et al. (1996) define **country credit risk ratings** compiled by commercial sources as an attempt "to estimate country-specific risks, particularly the probability that a country will default on its debt-servicing obligations."
- **Financial institutions**: bank financial strength ratings represent the "bank's intrinsic safety and soundness" (Moody's 2006).

Two different approaches developed in this chapter for reverse engineering and constructing credit risk ratings will be based on the following:

- **Absolute creditworthiness**, which evaluates the riskiness of individual obligors.
- **Relative creditworthiness**, which first evaluates the comparative riskiness of pairs of obligors; the absolute riskiness of entities is then derived from their relative riskiness using the combinatorial techniques of partially ordered sets.

As was noted in the literature (de Servigny and Renault 2004), banks and other financial service organizations are not fully utilizing the opportunities provided by the significant increase in the availability of financial data. More specifically, the area of credit rating and scoring is lacking in up-to-date methodological advances (Galindo and Tamayo 2000; de Servigny and Renault 2004; Huang et al. 2004). This provides a tremendous opportunity for the application of modern data mining and machine learning techniques, based on statistics (Jain et al. 2000) and combinatorial pattern extraction (Hammer 1986). The above described approaches are implemented using the LAD combinatorial pattern extraction method, and it turns out to be a very conclusive case for the application and the contribution of data mining to the credit risk industry.

This chapter is structured as follows. Section 16.2 provides an overview of LAD (Hammer 1986), which is used to develop a new methodology for reverse engineering and rating banks and countries with respect to their creditworthiness. Section 16.3 details the absolute creditworthiness model constructed for rating financial institutions and describes the obtained results. Section 16.4 is devoted to the description of two relative creditworthiness models for rating countries and contains an extensive description of the results. Section 16.5 provides concluding remarks.

16.2 Logical Analysis of Data: An Overview

The *logical analysis of data* (LAD) is a modern data mining methodology based on combinatorics, optimization, and Boolean logic[3]. LAD can be applied for the analysis and classification of archives containing both binary (Hammer 1986; Crama et al. 1988) and numerical (Boros et al. 1997) data. The novelty of LAD consists in utilizing combinatorial search techniques to discover various combinations of attribute values that are characteristic of the *positive* or *negative* character of observations (such as whether a bank is solvent or not or whether a patient is healthy or sick). Then LAD selects (usually small) subsets of such combinations (usually optimizing a certain quality objective) to construct what is called a model (Boros et al. 2000). We briefly describe below the basic concepts of LAD, referring the reader for a more detailed description to Boros et al. (2000) and Alexe et al. (2007).

Observations in archives analyzed by LAD are represented by n-dimensional real-valued vectors which are called positive or negative based on the value of the additional binary (0,1) attribute called the *outcome* or the *class* of the observation. Consider a dataset as a collection of M points (a^j, z^j) where the outcome z^j of observation j has value 1 for a positive outcome and 0 for a negative one and a^j is an n-dimensional vector. Figure 16.1 illustrates a dataset containing five observations described by three variables. Each component $a^j[i]$ of the $[5 \times 3]$-matrix in

Observation	Variables			Outcome
j	$a[1]$	$a[2]$	$a[3]$	z^j
1	3.5	3.8	2.8	1
2	2.6	1.6	5	1
3	1	2.2	3.7	1
4	3.5	1.4	3.9	0
5	2.3	2.1	1	0

Fig. 16.1 Set of observations

[3]The presentation in this section is partially based on Hammer et al. (2006).

Variables	Observations	a[1]			a[2]		a[3]			Outcome
Cutpoints		$c_{1,1}$	$c_{1,2}$	$c_{1,3}$	$c_{2,1}$	$c_{2,2}$	$c_{3,1}$	$c_{3,2}$	$c_{3,3}$	
		3	2.4	1.5	3	2	4	3	2	
Binary Variables		$y^j_{i,k}$								z^j
	1	1	1	1	1	1	0	0	1	1
	2	0	1	1	0	0	1	1	1	1
	3	0	0	0	0	1	0	1	1	1
	4	1	1	1	0	0	0	1	1	0
	5	0	0	1	0	1	0	0	0	0

Fig. 16.2 Binarized dataset

Fig. 16.1 gives the value taken by variable i in observation j. We will use $a[i]$ to denote the variables corresponding to the components of this dataset. The rightmost column provides the outcome of the observation.

LAD discriminates positive and negative observations by constructing a binary-valued function f depending on the n input variables, in such a way that it closely approximates the unknown actual discriminator. LAD constructs this function f as a weighed sum of combinatorial patterns.

In order to specify how such a function f is found, we first transform the original dataset into a *binarized dataset* in which the variables can only take the values 0 and 1. We shall achieve this goal by using *indicator variables* which show whether the values the variables take in a particular observation are "large" or "small"; more precisely, each indicator variable shows whether the value of a numerical variable does or does not exceed a specified level. This is achieved by defining, for each variable $a[i]$, a set of $K(i)$ values $\{c_{i,k} \mid k = 1,..., K(i)\}$, called *cut points* to which binary variables $\{y_{i,k} \mid k = 1,...,K(i)\}$ are associated. The values of these binary variables for each observation (z^j, a^j) are then defined as:

$$y^j_{i,k} = \begin{cases} 1 & \text{if } a^j[i] \geq c_{i,k} \\ 0 & \text{otherwise} \end{cases}$$

Figure 16.2 provides the binarized dataset corresponding to the data displayed in Fig. 16.1 and shows the values $c_{i,k}$ of the cut points k for each variable $a[i]$ and those of the binary variables $y^j_{i,k}$ associated with any cut point k of variable i in observation j. For example, $y^1_{1,1} = 1$ since $a^1[1 = 3.5$ is greater than $c_{1,1} = 3$.

Positive (*negative*) *patterns* are combinatorial rules obtained as conjunctions of binary variables and their negations, which, when translated to the original variables, constrain a subset of input variables to take values between identified upper and lower bounds, so that:

- All the pattern conditions are satisfied by a sufficiently high proportion of the positive (negative) observations in the dataset.

- At least one of the pattern conditions is violated by a sufficiently high proportion of the negative (positive) observations.

The number of variables the values of which are constrained in the definition of a pattern is called the *degree* of the pattern. The fraction of positive (negative) observations covered by a positive (negative) pattern is called the *prevalence* of it. The fraction of positive (negative) observations among those covered by a positive (negative) pattern is called the *homogeneity* of it. Considering the above example, the pattern

$$y_{1,3} = 0 \text{ and } y_{3,1} = 1$$

is a positive one of degree 2 covering one positive observation and no negative observation. Therefore, its prevalence is equal to 100/3 % and its homogeneity is equal to 100 %. In terms of the original variables, it imposes a strict upper bound (3) on the value of $a[1]$ and a strict lower bound (4) on the value of $a[3]$.

LAD starts its analysis of a dataset by generating the *pandect*, that is, the collection of all patterns in a dataset. Note that the pandect of a dataset of typically occurring dimension can contain exponentially large number of patterns, but many of these patterns are either subsumed by other patterns or similar to them. It is therefore important to impose a number of limitations on the set of patterns to be generated, by restricting their degrees (to low values), their prevalence (to high values), and their homogeneity (to high values); these bounds are known as LAD *control parameters*. The quality of patterns satisfying these conditions is usually much higher than that of patterns having high degrees, or low prevalence, or low homogeneity. Several algorithms have been developed for the efficient generation of large subsets of the pandect corresponding to reasonable values of the control parameters (Boros et al. 2000). The collections of patterns sufficient for classifying the observations in the dataset are called *models*. A model includes sufficiently many positive (negative) patterns to guarantee that each of the positive (negative) observations in the dataset is "covered" by (i.e., satisfies the conditions of) at least one of the positive (negative) patterns in the model. Good models tend to minimize the number of points in the dataset covered simultaneously by both positive and negative patterns in the model. LAD models can be constructed using the Datascope software (Alexe 2002).

LAD classifies observations on the basis of model's evaluation of them in the following way. An observation (contained in the given dataset or not), satisfying the conditions of some of the positive (negative) patterns in the model and not satisfying the conditions of any of the negative (positive) patterns in the model, is classified as *positive* (*negative*). To classify an observation that satisfies both positive and negative patterns in the model, LAD utilizes a discriminant that assigns specific weights to the patterns in the model (Boros et al. 2000). To define the simplest discriminant that assigns equal weights to all positive (negative) patterns, let p and q represent the number of positive and negative patterns in a model, and let h and k represent the numbers of those positive, respectively, negative patterns in the model which cover a new observation ω. Then the discriminant $\Delta(\omega)$ is calculated as

Table 16.1 Classification matrix

	Classification of observations		
Observation classes	Positive	Negative	Unclassified
Positive	a	c	e
Negative	b	d	f

$$\Delta(\omega) = h/p - k/q \tag{16.1}$$

and the corresponding classification is determined by the sign of this expression. LAD leaves *unclassified* any observation for which $\Delta(\omega) = 0$, since in this case either the model does not provide sufficient evidence or the evidence it provides is contradictory. Computational experience with real-life problems has shown that the number of unclassified observations is usually small. The results of classifying the observations in a dataset can be represented in the form of a *classification matrix* (Table 16.1).

Here, the percentage of positive (negative) observations that are correctly classified is represented by a (respectively d). The percentage of positive (negative) observations that are misclassified is represented by c (respectively b). The percentage of positive (negative) observations that remain unclassified is represented by e (respectively f). Clearly, $a + c + e = 100\ \%$ and $b + d + f = 100\ \%$. The quality of the classification is defined by

$$Q = \frac{1}{2}(a + d) + \frac{1}{4}(e + f) \tag{16.2}$$

16.3 Absolute Creditworthiness: Credit Risk Ratings of Financial Institutions

16.3.1 Problem Description

The capability of evaluating the credit quality of banks has become extremely important in the last 30 years given the increase in the number of bank failures: during the period from 1950 to 1980, bank failures averaged less than seven per year, whereas during the period from 1986 to 1991, they averaged 175 per year (Barr and Siems 1994).[4] Curry and Shibut (2000) report that the so-called savings and loan crisis cost around \$123.8 billion. Central banks are afraid of widespread bank failures since they could exacerbate cyclical recessions and result in more severe financial crises (Basel Committee on Banking Supervision 2004). More accurate credit risk models for banks could enable the identification of problematic banks early, which is seen as a necessary condition by the Bank for International Settlements (2004) to avoid failure, and could serve the regulators in their efforts to minimize bailout costs.

[4]The presentation in this section is based on Hammer et al. (2012).

The evaluation and rating of the creditworthiness of banks and other financial organizations is particularly challenging, since banks and insurance companies appear to be more opaque than firms operating in other industrial sectors. Morgan (2002) attributes this to the fact that banks hold certain assets (loans, trading assets, etc.), the risks of which change fast and are very difficult to assess, and it is further compounded by banks' high leverage. Therefore, it is not surprising that the main rating agencies (Moody's and S&P's) disagree much more often about the ratings given to banks than about those given to obligors in other sectors. The difficulty of accurately rating those organizations is also due the fact that the rating migration volatility of banks is historically significantly higher than it is for corporations and countries and that banks tend to have higher default rates than corporations (de Servigny and Renault 2004). Another distinguishing characteristic of the banking sector is the external support (i.e., from governments) that banks receive and other corporate sectors do not (Fitch Rating 2006). A thorough review of the literature pertaining to the rating and evaluation of credit risk of financial institutions can be found in Hammer et al. (2012).

In the next sections, we shall:

- Identify a set of variables that provides sufficient information to accurately replicate the Fitch bank ratings.
- Construct LAD patterns to discriminate between banks with high and low ratings.
- Construct an optimized model utilizing (some of) the LAD patterns which is capable of distinguishing between banks with high and low ratings.
- Define an accurate bank rating system on the basis of the discriminant values provided by the constructed model.
- Cross-validate the proposed rating system.

16.3.2 Data

16.3.2.1 External Credit Risk Ratings of Financial Institutions

This section starts with a brief description of the Fitch individual bank rating system. Long- and short-term credit ratings provided by Fitch constitute an opinion on the ability of an entity to meet financial commitments (interest, preferred dividends, or repayment of principal) on a timely basis (Fitch Ratings 2001). These ratings are comparable worldwide and are assigned to countries and corporations, including banks.

Fitch bank ratings include *individual* and *support* ratings. Support ratings comprise five rating categories which reflect the likelihood that a banking institution will receive support either from the owners or the governmental authorities if it runs into difficulties. The availability of support, though critical, does not reflect completely the likelihood that a bank will remain solvable in case of adverse situations. To complement a support rating, Fitch also provides an individual bank rating to evaluate credit quality separately from any consideration of outside support. This rating is commonly viewed as assessing a bank were it entirely independent and could not rely on external support. It supposedly takes into

Table 16.2 Fitch individual rating system (Fitch Ratings 2001)

Category	Numerical scale	Description
A	9	A very strong bank. Characteristics may include outstanding profitability and balance sheet integrity, management, or operating environment
B	7	A strong bank. There are no major concerns regarding the bank
C	5	An adequate bank which, however, possesses one or more troublesome aspects. There may be some concerns regarding its profitability, balance sheet integrity, management, operating environment or prospects
D	3	A bank which has weaknesses of internal and/or external origin. There are concerns regarding its profitability, management, balance sheet integrity, franchise, operating environment or prospects
E	1	A bank with very serious problems which either requires or is likely to require external support

consideration such factors as profitability and balance sheet integrity, franchise, management, operating environment, and prospects.

We present in Table 16.2 a detailed description of the nine rating categories characterizing the Fitch individual bank credit rating system. Since individual bank credit ratings are comparable across different countries, they will be used in the remaining part of this chapter. In addition, Fitch uses gradations among these five ratings: A/B, B/C, C/D, and D/E, the corresponding numerical values of which being, respectively, 8, 6, 4, and 2. This conversion of the Fitch individual bank ratings into a numerical scale is commonly used (see, e.g., Poon et al. 1999).

16.3.2.2 Variables and Observations

We use the following 14 financial variables (loans, other earning assets, total earning assets, nonearning assets, net interest revenue, customer and short-term funding, overheads, equity, net income, total liability and equity, operating income) and nine representative financial ratios as predictors in our model. The variables are as follows: ratio of equity to total assets (asset quality), net interest margin, ratio of interest income to average assets, ratio of other operating income to average assets, ratio of noninterest expenses to average assets, return on average assets (ROAA), return on average equity (ROAE), cost-to-income ratio (operations), and ratio of net loans to total assets (liquidity). The values of these variables were collected at the end of 2000 and come from the database Bankscope.

As an additional variable, we use in this study the S&P's risk rating of the country where the bank is located. The S&P's country risk rating scale comprises 22 different categories (from AAA to D). We convert these categorical ratings into a numerical scale, assigning the largest numerical value (21) to the countries with the highest rating (AAA). Similar numerical conversions of country risk ratings are also used by Ferri et al. (1999) and Sy (2004). Similarly, Bloomberg has also developed a standard cardinal scale for comparing Moody's, S&P's, and Fitch-BCA ratings.

Our dataset consists of 800 banks rated by Fitch and operating in 70 different countries (247 in Western Europe; 51 in Eastern Europe; 198 in Canada and the USA; 45 in developing Latin American countries; 47 in the Middle East; 6 in Oceania; 6 in Africa; 145 in developing Asian countries; 55 in Hong Kong, Japan, and Singapore).

16.3.3 An LAD Model for Bank Ratings

Our design of an objective and transparent bank rating system on the basis of the LAD methodology is guided by the properties of LAD as a classification system. Therefore, we define a classification problem associated to the bank rating problem, construct an LAD model for it, and then define a bank rating system rooted in this LAD model. We define as *positive observations* the banks which have been rated by Fitch as A, A/B, or B and as *negative observations* those whose Fitch rating is D, D/E, or E.

In the binarization process, cut points were introduced for the 19 of the 24 numerical variables shown in Table 16.3. Actually, the other five numerical variables were also binarized, but since it turned out that they were redundant, only the variables shown in Table 16.3 were retained for constructing the model. Table 16.3 provides all the cut points used in pattern and model construction. For example, two cut points (24.8 and 111.97) are used to binarize the numerical variable "profit before tax" (PbT), that is, two binary indicator variables replace PbT, one telling whether PbT exceeds 24.8 and the other telling whether PbT exceeds 111.97.

The first step of applying the LAD technique to the problem binarized with the help of these variable cut points was the identification of a collection of powerful patterns. One example of such a powerful negative pattern is (i) the country risk rating is strictly lower than A and (ii) the profits before tax are at most equal to €111.96 millions. One can see that these conditions describe a *negative pattern*, since none of the positive observations (i.e., banks rated A, A/B, or B) satisfy both of them, while no less than 69.11 % of the negative observations (i.e., those banks rated D, D/E, or E) do satisfy both conditions. This pattern has degree 2, prevalence 69.11 %, and homogeneity 100 %.

The model we have developed for bank ratings is very parsimonious, consisting of only 11 positive and 11 negative patterns, and is built on a *support set* of only 19 out of the 24 original variables. All the patterns in the model are of degree at most 3, have perfect homogeneity (100 %), and very substantial prevalence (averaging 50.9 % for the positive and 37.7 % for the negative patterns).

16.3.4 LAD Model Evaluation

16.3.4.1 Accuracy and Robustness of the LAD Model

The classification of the banks whose ratings are A, A/B, B, D, D/E, or E with the above LAD model is 100 % accurate. We use ten two-folding experiments to cross-validate the model. In each of those experiments, we randomly assign the

Table 16.3 Cut points

Numerical variables	Cut points	Numerical variables	Cut points	Numerical variables	Cut points
Country risk rating	11, 16, 19.5, 20	Operating income (memo)	1,360.74	Noninterest expenses/ average assets	2.00, 2.77, 3.71, 4.93
Other earning assets	3,809, 9,564.9	Profit before tax	24.8, 111.97	Return on average assets	0.30, 0.80, 1.52
Nonearning assets	364	Equity/total assets	4.90	Return on average equity	11.82, 15.85, 19.23
Total assets	5,735.8	Equity	370.45	Overhead	127, 324
Customer & short-term funding	4,151.3, 9,643.8	Net interest margin	1.87	Net loans/total assets	44.95, 53.90, 59.67, 66.50
Cost-to-income ratio	50.76, 71.92	Net interest revenue/average assets	3.02		
Other operating income	46.8, 155.5, 470.5	Other operating income/ average assets	0.83, 1.28, 1.86, 3.10		

observations to a training and a testing sets of equal size. We use the training set to build the model, and we apply it to classify the observations in the testing set. In the second half of the experiment, we reverse the role of the two sets. The average accuracy and the standard deviation of the accuracy are, respectively, equal to 95.12 % and 0.03. These results highlight the predictive capability and the robustness of the derived LAD model.

We have also computed the correlation between the discriminant values of the LAD model and the bank credit risk ratings (represented on their numerical scale). Despite the fact that the correlation measure takes into account all the banks in the dataset (i.e., not only those which were used in creating the LAD model but also those rated B/C, C, or C/D, which were not used in the learning process), the correlation is very high, equal to 80.70 %, attesting to the strong predictive power of the LAD model. The ten two-folding experiments described above were then used to verify the stability of the correlation between the LAD discriminant values and the bank ratings. The average correlation is equal to 80.04 %, with a standard deviation of 0.04, another testimony of the stability of the close positive association between the LAD discriminant values and the bank ratings.

16.3.4.2 From LAD Discriminant Values to Ratings

The objective of this section is to map the numerical values of the LAD discriminant to the nine bank rating categories (A, A/B, ..., E). This will be accomplished using a nonlinear optimization problem that partitions the interval of the discriminant values into nine subintervals that we associate to the nine rating categories. The partitioning is determined through *cut points* x_i such that $-1 = x_0 \leq x_1 \leq x_2 \leq \ldots\ldots\ldots \leq x_8 \leq x_9 = 1$, where i indexes the rating categories (with one corresponding to E and nine corresponding to A). A bank should be rated i if its discriminant value is in the interval $[x_i, x_{i+1}]$. Since such a perfect partitioning may not exist, we replace the LAD discriminant values d_i by an *adjusted discriminant value* δ_i and find values of δ_i for which such a partitioning exists and which are "as close as possible" to the values d_i. The expression "as close as possible" involves the minimization of the mean square approximation error. Referring to the rating category of bank i by $j(i)$ and to the set of banks by N, we solve the convex nonlinear problem

$$
\begin{aligned}
\text{minimize} \quad & \sum_{i \in N} (\delta_i - d_i)^2 \\
\text{subject to} \quad & \delta_i \leq x_{j(i)+1}, i \in N \\
& x_{j(i)} < \delta_i, i \in N \\
& -1 = x_0 \leq x_1 \leq x_2, \ldots, \leq x_j, \ldots, x_8 \leq x_9 = 1 \\
& -1 \leq \delta_i \leq 1, i \in N
\end{aligned}
\tag{16.3}
$$

on the NEOS server (Czyzyk et al. 1998) with the solver Lancelot to determine the cut points x_j and the adjusted discriminant values δ_i that will be used for rating the banks not only in the training sample but also those which are not. In this case, the bank rating is defined by the particular subinterval containing the LAD discriminant value.

Table 16.4 Discrepancy analysis

	q_k		
k	$N = \{A, A/B, B, D, D/E, E\}$	$N = \{B/C, C, C/D\}$	$N = \{A, A/B, B, B/C, C, C/D, D, D/E, E\}$
0	29.60 %	29.36 %	29.50 %
1	53.28 %	47.71 %	51.00 %
2	12.05 %	18.96 %	14.88 %
3	4.23 %	3.36 %	3.88 %
4	0.85 %	0.61 %	0.75 %
5–6–7–8	0.00 %	0.00 %	0.00 %

As compared to ordered logistic regression, the LAD-based approach has the additional advantage that it can be used for generating any desired number of rating categories. The LAD model can take the form of a binary classification model and can be used to preapprove or not a loan to a bank. The LAD rating approach can also be used to derive models with higher granularity (i.e., more than nine rating categories), which are used by banks to further differentiate their customers and to tailor accordingly their credit pricing policies.

16.3.4.3 Conformity of Fitch and LAD Bank Ratings

In this section, the goal is to investigate to goodness of fit of our rating system and observe to which extent the original LAD discriminant values fit in the identified rating subintervals. We denote by q_k ($k = 0, \ldots, 8$) the fraction of banks whose rating category determined in this way differs from its Fitch rating by exactly k categories. It is worth recalling that the rating cut points were derived using all the banks in the sample but that the LAD discriminant values were obtained by only taking into account the banks rated A, A/B, B, D, D/E, and E. This is why we calculate separately the discrepancy counts for the banks rated A, A/B, B, D, D/E, and E and for these rated B/C, C, and C/D.

Table 16.4 highlights the high goodness of fit of the proposed LAD model. More than 95 % of the banks are rated within two categories of their Fitch rating, with about 30 % of the banks receiving exactly the same rating as in the Fitch rating system and another 51 % being off by exactly one rating category. The very high concordance between the LAD and the Fitch ratings is illustrated by the weighted average distances between the two ratings equal to (i) 0.93 for the categories A, A/B, B, D, D/E, and E; (ii) 0.98 for the categories B/C, C, and C/D; and (iii) 0.95 for all banks in the dataset. The stability of the proposed rating system and its suitability to evaluate the creditworthiness of "new" banks, that is, banks which are not rated by agencies or banks the rater has not dealt with before, are magnified by the fact that the goodness of fit of the ratings of the banks not used in deriving the LAD model is very close to the goodness of fit for the banks used for deriving the LAD model (i.e., those rated A, A/B, B, D, D/E, and E).

In order to appraise the robustness of the proposed rating system, we apply ten times the two-folding procedure described above to derive the average ($\overline{q}_k$)

Table 16.5 Cross-validated discrepancy analysis

	k								
	0	1	2	3	4	5	6	7	8
$\overline{q}_k$	29.01 %	51.18 %	14.10 %	4.36 %	1.14 %	0.20 %	0.01 %	0.00 %	0.00 %

discrepancy counts (Table 16.5) of the bank ratings predicted for the testing sets. The fact that on the average the difference between the Fitch and the LAD ratings is only 0.98 is a very strong indicator of the LAD model's stability and the absence of overfitting.

16.3.4.4 Importance of Variables

While the focus in LAD is on discovering how the interactions between the values of small groups of variables (as expressed in patterns) affect the outcome (i.e., the bank ratings), one can also use the LAD model to learn about the importance of individual variables. A natural measure of importance of a variable in an LAD model is the frequency of its appearance in the model's patterns. The three most important variables in the 22 patterns constituting the LAD model are the credit risk rating of the country where the bank is located, the return on average total assets, and the return on average equity. The importance of the country risk rating variable, which appears in 18 of the 22 patterns, can be explained by the fact that credit rating agencies are reluctant to give an entity a better credit risk rating than that of the country where it is located. Both the return on average assets and the return on average equity variables appear in six patterns. These two ratios, respectively, representing the efficiency of assets in generating profits and that of shareholders' equity in generating profits, are critical indicators of a company's prosperity and are presented by Sarkar and Sriram (2001) as key predictors to assess the wealth of a bank. The return on average equity is also found significant for predicting the rating of US banks (Huang et al. 2004).

16.3.5 Remarks on Reverse Engineering Bank Ratings

The results presented above demonstrate that the LAD approach can be used to derive rating models with varying granularity levels:

- A binary classification model to be used for the preapproval operations
- A model with the same granularity as the benchmarked rating model
- A model with higher discrimination power, that is, with higher granularity than that of the benchmarked rating model, to allow the bank to refine its pricing policies and the allocation of regulatory capital

We show that the LAD model cross-validates extremely well and therefore is highly generalizable and could therefore be used by financial institutions to develop internal, Basel-compliant rating models.

The availability and processing of data have been major obstacles in the way of using credit risk rating models. Until recently, many banks did not maintain such datasets and were heavily dependent on qualitative judgments. It is only after the currency crises of the 1990s and the requirements imposed by the Basel Accord that financial institutions have seen an incentive in collecting the necessary data and maintaining the databases.

The move towards a heavier reliance on rating models is based on the assumption that models produce more consistent ratings and that, over the long haul, operating costs will diminish since less labor will be required to produce ratings. The model proposed in this chapter will reinforce the incentives to develop and rely upon credit risk models in bank operations due to the following:

- The accuracy and predictive ability of the proposed model will guarantee dependable ratings.
- Its parsimony will alleviate the costs of extracting and maintaining large datasets.
- It will result in leaner loan approval operations and faster decisions and could thus reduce the overall operating costs.

16.4 Relative Creditworthiness: Country Risk Ratings

16.4.1 Problem Description

Country risk ratings have critical importance in the international financial markets since they are the primary determinants of the interest rates at which countries can obtain credit.[5] There are numerous examples of countries having to pay higher rates on their borrowing following their rating downgrade, an often cited example being Japan. As mentioned above, another critical aspect of country risk ratings concerns their influence on the ratings of national banks and companies that would make them more or less attractive to foreign investors. That is why the extant literature calls country risk ratings the "pivot of all other country's ratings" (Ferri et al. 1999) and considers them the credit risk ceiling for all obligors located in a country (Eliasson 2002; Mora 2006). Historical record shows the reluctance of raters to give a company a higher credit rating than that of the sovereign where the company operates. Contractual provisions sometimes prohibit institutional investors from investing in debt rated below a prescribed level. It has been demonstrated (Ferri et al. 1999) that variations in sovereign ratings drastically affect the ratings of banks operating in low-income countries, while the ratings of banks operating in high-income countries (Kaminsky and Schmukler 2002; Larrain et al. 1997) do not depend that much on country ratings. Banks, insurance companies, and public institutions frequently assess the amount of exposure they have in each country and establish lending limits taking into account the estimated level of country risk. Credit managers in multinational corporations have to assess evolving conditions in foreign countries in order to decide whether to request letters of credit for particular

[5]The presentation in this section is based on Hammer et al. (2006, 2012).

transactions. Country risk estimates and their updates are utilized on a real-time basis by multinational corporations facing constant fluctuation in international currency values and difficulties associated with moving capital and profits across national boundaries. Financial institutions have to rely on accurate assessments of credit risk to comply with the requirements of the Basel Bank for International Settlements. Feeling the pressure to get higher ratings could lead to fraud attempts. A notorious case was Ukraine's attempt to obtain IMF credits through misleading reporting of its reserve data on foreign exchanges.

The existing literature on country risk, defined by Bourke and Shanmugam (1990) as "the risk that a country will be unable to service its external debt due to an inability to generate sufficient foreign exchange," recognizes both financial/economic and political components of country risk. There are two basic approaches to the interpretation of the reasons for defaulting. The first one is the *debt-service capacity approach* which considers the deterioration of solvency of a country as preventing it from fulfilling its commitments. This approach views country risk as a function of various financial and economic country parameters. The second one is the *cost-benefit approach* which considers a default on commitments or a rescheduling of debt as a deliberate choice of the country. In this approach the country accepts possible long-term negative effects (e.g., the country's exclusion from certain capital markets (Reinhart 2002) as preferable to repayment). Being politically driven, this approach includes political country parameters in addition to the financial and economic ones in country risk modeling (Brewer and Rivoli 1990, 1997; Citron and Neckelburg 1987).

16.4.2 Data

16.4.2.1 Ratings

We analyze in this chapter Standard & Poor's foreign currency country ratings, as opposed to the ratings for local currency debt. The former is the more important problem, since the sovereign government has usually a lower capacity to repay external (as opposed to domestic) debt, and as an implication, the international bond market views foreign currency ratings as the decisive factor (Cantor and Packer 1996). This is manifested by much higher likelihood for international investors to acquire foreign currency obligations rather than domestic ones. In evaluating foreign currency ratings, one has to take into account not only the economic factors but also the country intervention risk, that is, the risk that a country imposes, for example, exchange controls or a debt moratorium. The evaluation of local currency ratings need not take into account this country intervention risk.

Table 16.16 lists the different country risk levels used by S&P's and also provides descriptions associated with these labels. A rating inferior to BB+ indicates that a country is non-investment grade (speculative). A rating of CCC+ or lower indicates that a country presents serious default risks. BB indicates the least degree of speculation and CC the highest. The addition of a plus or minus sign modifies the rating (between AA and CCC) to indicate relative standing within the major rating category. These subcategories are treated as separate ratings in our analysis.

16.4.2.2 Selected Variables

The selection of relevant variables is based on three criteria. The first criterion is the variable's significance (relevance) in assessing countries' creditworthiness. The review of the literature on predictors for country risk ratings (see Hammer et al. 2011) played an important role in defining the set of candidate variables to include in our model. The second criterion is the availability of complete and reliable statistics, to allow us to maintain the significance and the scope of our analysis. The third criterion is the uniformity of data across countries. This is why we decided against incorporating the unemployment rate statistics provided by the World Bank, since it is compiled according to different definitions: there are significant differences between countries in the treatment of temporarily laid off workers, those looking for their first job, and the criteria for being considered as unemployed.

After applying the criteria of relevance, availability, and uniformity described above, the following variables were incorporated in our model: *gross domestic product per capita* (*GDPc*), *inflation rate* (*IR*), *trade balance* (*TB*), *exports*' *growth rate* (*EGR*), *international reserves* (*RES*), *fiscal balance* (*FB*), *debt to GDP* (*DGDP*), *political stability* (*PS*), *government effectiveness* (*GE*), *corruption* (*COR*), *exchange rate* (*ER*), *and financial depth and efficiency* (*FDE*).

In addition to eight economic variables that have already been used in the country credit risk rating literature, a new one, called *financial depth and efficiency* (*FDE*), was added. This variable is measured as the ratio of the domestic credit provided by the banking sector to the GDP. It measures the growth of the banking system since it reflects the extent to which savings are financial. The financial depth and efficiency variable was first considered in Hammer et al. (2006, 2011) for the evaluation of country risk ratings. The reason to include this variable is that it captures some information that is relevant to the assessment of the creditworthiness of a country and that is not accounted for by other variables and in particular by the fiscal balance of a country.

Our analysis utilized the values of these nine economic/financial variables and three political variables taken at the end of 1998. Our dataset included the values of these 12 variables for the 69 countries considered: 24 industrialized countries, 11 Eastern European countries, eight Asian countries, ten Middle Eastern countries, 15 Latin American countries, and South Africa. The dependent variable is the S&P's country risk ratings for these countries at the end of 1998. The sources utilized for compiling the values of the economic/financial variables include the International Monetary Fund (World Economic Outlook Database), the World Bank (World Development Indicators database), and, for the ratio of debt to gross domestic product, Moody's publications. Values of political variables are taken from Kaufmann et al. (1999a, b), whose database is a joint product of the Macroeconomics and Growth, Development Research Group and Governance, Regulation and Finance Institutes affiliated with the World Bank.

16.4.3 Rating Methodologies

In the next subsections, we derive two new combinatorial models for country risk rating by reverse engineering and "learning" from past S&P's ratings. The models are developed using the novel combinatorial-logical technique of logical analysis of data which derives a new rating system only from the qualitative information representing pairwise comparisons of country riskiness. The approach is based on a *relative creditworthiness* concept, which posits that the knowledge of (pre)order of obligors with respect to their creditworthiness should be the sole source for creating a credit risk rating system. Stated differently, only the order relation between countries should determine the ratings. Thus, the inference of a model for the order relation between countries is the objective of this study. This is in perfect accordance with the general view of the credit risk rating industry. Altman and Rijken (2004) state that the objective of rating agencies is "to provide an accurate relative (i.e., ordinal) ranking of credit risk," which is confirmed by Fitch ratings (2006) saying that "Credit ratings express risk in relative rank order, which is to say they are ordinal measures of credit." Bhatia (2002) adds that: "Although ratings are measures of absolute creditworthiness, in practice, the ratings exercise is highly comparative in nature... On one level, the ratings task is one of continuously sorting the universe of rated sovereigns – assessed under one uniform set of criteria – to ensure that the resulting list of sovereigns presents a meaningful global order of credit standing. On another level, the sorting task is constrained by a parallel need to respect each sovereign's progression over time, such that shifting peer comparisons is a necessary condition – but not a sufficient one – for upward or downward ratings action."

A self-contained model of country risk ratings can hardly be developed by standard econometric methods since the dataset contains information *only* about 69 countries, each described by 12 explanatory variables. An alternative at hand possible with combinatorial techniques is to examine the *relative riskiness* of one country compared to another one, rather than modeling the riskiness of each individual country. This approach has the advantage of allowing the modeling to be based on a much richer dataset (2,346 pairs of countries), which consists of the comparative descriptions of all pairs of countries in the current dataset.

The models utilize the values of nine economic and three political variables associated to a country, but do not use directly or indirectly previous years' ratings. This is a very important feature, since the inclusion of information from past ratings (lagged ratings, rating history) does not allow the construction of a self-contained rating system and does not make possible to rate the creditworthiness of not-yet-rated countries. We refer to Hammer et al. (2006, 2011) for a more detailed discussion of the advantages of building a non-recursive country risk rating system. Moreover, the proposed LAD models completely eliminate the need to view the ratings as numbers. Section 16.4.3.1 presents the common features of the two developed LAD models, while Sects. 16.4.3.2 and 16.4.3.3 discuss the specifics of the LAD-based Condorcet ratings and the logical rating scores, respectively.

16.4.3.1 Commonalities

Pairwise Comparison of Countries: Pseudo-observations

Every country $i \in I = \{1, \ldots, 69\}$ in this study is described by the 13-dimensional vector C_i, whose first component is the country risk rating given by Standard & Poor's, while the remaining 12 components specify the values of the nine economic/financial and of the three political variables. A *pseudo-observation* P_{ij}, associated to every pair of countries i, $j \in I$, provides in a way specified below a comparative description of the two countries.

Every pseudo-observations is also described by a 13-dimensional vector. The first component is an indicator which takes the value 1 if the country i in the pseudo-observation P_{ij} has a higher rating than the country j, –1 if the country j has a higher rating than the country i, and 0 if the two countries have the same rating. The other components k, $k = 2, \ldots, 13$ of the pseudo-observation $P_{ij}[k]$ are derived by taking the differences of the corresponding components of C_i and C_j:

$$P_{ij}[k] = C_i[k] - C_j[k], k = 2, \ldots, 13 \tag{16.4}$$

Transformation (16.4) alleviates the problems related to the small size ($| I |$) of the original dataset by constructing a substantially larger dataset containing $| I |*(| I | -1)$ pseudo-observations. While the set of pseudo-observations is not independent, since $P_{hi} + P_{ij} = P_{hj}$, Hammer et al. (2006) show that this does not create any problems for the LAD-based combinatorial data analysis techniques.

We illustrate the construction of pseudo-observations with Japan and Canada. Rows 2 and 3 in Table 16.6 display the values of the 12 economic/financial and political variables, as well as the S&P's rating for Japan and Canada (at the end of December 1998), while rows 4 and 5 report the pseudo-observations $P_{\text{Japan, Canada}}$ and $P_{\text{Canada, Japan}}$ from the country observations C_{Japan} and C_{Canada}. Since Japan and Canada are rated, respectively, AAA and AA + by S&P's at the end of December 1998 and the rating AAA is better than rating AA+, the first component of the pseudo-observation vector is equal to 1. The set of pseudo-observations is antisymmetric.

An advantage of this transformation is that it allows us to avoid the problems posed by the fact that the original dataset contains only a small number ($| I |$) of observations. The transformation (16.4) provides a larger dataset containing $| I |*(| I | -1)$ pseudo-observations.

Construction of Relative Preferences

The LAD-based reverse engineering of Standard & Poor's rating system starts with deriving an LAD model (constructed as a weighed sum of patterns) from the archive of all those pseudo-observations P_{ij}, corresponding to pairs of countries i and j having different S&P's ratings. A model resulting from applying LAD to the 1998 dataset consists of 320 patterns. As an example, let us describe two of these patterns below. The positive pattern

$$FDE > 28.82; GDPc > 1539.135; GE > 0.553$$

Table 16.6 Examples of country and pseudo-observations

	S&P's rating	*FDE*	*RES*	*IR*	*TB*	*EGR*	*GDPc*	*ER*	*FB*	*DGDP*	*PS*	*GE*	*COR*
C_{Japan}	AAA	138.44	5.168	.65	21.7471	−2.54	24314.2	0.839	−7.7	0.47	1.153	0.839	0.724
C_{Canada}	AA+	94.69	1.01964	0.99	55.9177	8.79	24855.7	0.939	0.9	0.5	1.027	1.717	2.055
$P_{\text{Japan, Canada}}$	1	43.75	4.15	−0.34	−34.17	−11.33	−541.5	−0.1	−8.6	−0.03	0.126	−0.878	−1.331
$P_{\text{Canada, Japan}}$	−1	−43.75	−4.15	0.34	34.17	11.33	541.5	0.1	8.6	0.03	−0.126	0.878	1.331

can be interpreted in the following way. If country i is characterized by

(i) A financial depth and efficiency (FDE) exceeding that of country j by at least 28.82, and
(ii) A gross domestic product per capita ($GDPc$) exceeding that of country j by at least 1,539.135, and
(iii) A government efficiency (GE) exceeding that of country j by at least 0.553

then country i is perceived as more creditworthy than country j.

Similarly, the negative pattern

$$GDPc < -4,886.96; ER < 0.195; COR < -0.213$$

can be interpreted in the following way. If country j is characterized by

(i) A gross domestic product per capita ($GDPc$) exceeding that of country i by 4,886.96, and
(ii) An exports growth rate (EGR) exceeding that of country i by 0.195, and
(iii) A level of incorruptibility (CR) exceeding that of country i by 0.213

then country i is perceived as less creditworthy than country j.

The constructed LAD model allows us to compute the discriminant $\Delta(P_{ij})$ for each pseudo-observation $P_{ij}(i \neq j)$. We call the values $\Delta(P_{ij})$ of the discriminant the *relative preferences*. They can be interpreted as measuring how "superior" the country i's rating over that of country j. We call the [69 $\times$ 69]-dimensional antisymmetric matrix Δ, having the relative preferences as components, the *relative preference matrix*. Its components are relative preferences $\Delta(P_{ij})$ $(i \neq j)$ associated with every pair of countries, including those that have the same S&P's ratings, even though only those pseudo-observation P_{ij} for which i and j had different ratings were used in deriving the LAD model.

Classification of Pseudo-observations and Cross-Validation

The dataset used to derive the LAD model contains 4,360 pseudo-observations, with an equal number of positive and negative pseudo-observations, and is antisymmetric ($P_{ij} = -P_{ij}$). The results of applying the LAD model to classify the observations in the dataset are presented in Table 16.7. The overall classification quality of the LAD model (according to Eq. 16.2) is 95.425 %.

This very high classification accuracy may be misleading, since the constructed LAD model can be overfitting the data, that is, it is adapted excessively well to random noise in the training data and thus has an excellent accuracy on this training data, but could perform very poorly on new observations. We therefore utilize a statistical technique known as "jackknife" (Quenouille 1949) or "leave-one-out"

Table 16.7 Classification matrix

	Classified as			
	Positive	Negative	Unclassified	Total
Positive observations	93.90 %	3.72 %	2.38 %	100 %
Negative observations	3.72 %	93.90 %	2.38 %	100 %

Table 16.8 Classification matrix for Δ^{JK}

	Classified as			
	Positive	Negative	Unclassified	Total
Positive observations	93.49 %	3.67 %	2.84 %	100 %
Negative observations	3.67 %	93.49 %	2.84 %	100 %

to show that the achieved high classification accuracy is not due to overfitting. This technique removes from the dataset one observation at a time, learns a model from all the remaining observations, and evaluates the resulting model on the removed observation; then it repeats all these steps for each observation in the dataset. If on the average the predicted evaluations are "close to" the actual ones, then the model is not affected by overfitting.

In the case at hand, it would not be statistically sound to implement the jackknife technique in a straightforward way because of the dependencies among pseudo-observations (Hammer et al. 2006). Indeed, even after explicitly eliminating a single pseudo-observation P_{ij} from the dataset, it would still remain in the dataset implicitly, since $P_{ih} + P_{hj} + P_{ij}$. This problem can be resolved by modifying the above described procedure so that at each step, instead of just removing a single pseudo-observation P_{ij}, all the pseudo-observations which involve a particular country i are removed. Then, the LAD discriminant is derived on the basis of the remaining pseudo-observations and used to evaluate the relative preferences for every removed pseudo-observation, resulting in a row of relative preferences of all pseudo-observations P_{ij} which involve the country i. This modified procedure is repeated for every country in the dataset, and the obtained rows are combined into a matrix of relative preferences denoted by Δ^{JK}. The absence of overfitting is indicated by a very high correlation level of 96.48 % between the matrix Δ^{JK} and the original relative preference matrix Δ.

To further test for overfitting, we use the obtained matrix of relative preferences Δ^{JK} to classify the dataset of 4,360 pseudo-observations. The results of this classification are presented in Table 16.8, and the overall classification quality of the LAD model (according to formula (16.2)) is 95.10 %. The results in Table 16.8 are virtually identical to those shown in Table 16.7, thus proving the absence of overfitting.

Since the derived LAD model does not suffer from overfitting, it is tempting to interpret the signs of relative preferences as indicative of rating superiority and infer that a positive value for $\Delta(P_{i,j})$ indicates that country i is more creditworthy than country j, while a negative one for $\Delta(P_{i,j})$ justifies the opposite conclusion. However, this naïve approach towards relative rating superiority ignores the potential noise in the data and in relative preferences, which would make it difficult to transform classifications of pseudo-observations to a consistent ordering of countries by their creditworthiness. It is shown in Hammer et al. (2006) that the relationship based on the naïve interpretation of the relative preferences can violate the transitivity requirement of an order relation and therefore does not provide a consistent partially ordered set of countries.

The following section is devoted to overcoming this issue by relaxing the overly constrained search for (possibly nonexistent) country ratings whose pairwise orderings are in *precise* agreement with the signs of relative preferences. Instead, we utilize a more flexible search for *a partial order* on the set of countries, which satisfies the transitivity requirements and *approximates* well the set of relative preferences.

16.4.3.2 Condorcet Ratings

The ultimate objective of this section, which is based on the results of Hammer et al. (2006), is to derive a rating system from the LAD relative preferences. This is accomplished in two stages. First, we use the LAD relative preferences to define a partial order on the set of countries which represents their creditworthiness dominance relationship. Then, we extend the derived dominance relationship to two rating systems, respectively, based on the so-called weak Condorcet winners and losers. The number of rating categories in these rating systems is the same and will be determined by the structure of the partial order obtained in the first stage, that is, it is not a priory fixed.

From LAD Relative Preferences to a Partial Order on the Set of Countries

A partial order $\Pi(X)$ is a reflexive, antisymmetric, and transitive binary relation on a set X. Any two distinct elements x and y of X such that $(x, y) \in \Pi(X)$ are said to be comparable and denoted by $x \supset y$. If neither $(x, y) \in \Pi(X)$ nor $(y, x) \in \Pi(X)$, then x and y are called incomparable and denoted by $x \parallel y$.

As was mentioned above, the naïve rating superiority relation based on the LAD model is not transitive. This difficulty can be overcome by defining a strengthened version of the naïve rating superiority relation, to be called the *dominance relationship*. While the former only relies on the sign of the relative preference $\Delta(P_{ij})$, the definition of dominance of a country i over another country j takes into account not only the sign of the relative preference $\Delta(P_{ij})$ but also the values of the relative preferences of each of these two countries i and j over every other country k.

We will need the following notation to define the dominance relationship. Let

$$S_{ij}(k) = \Delta(P_{ik}) - \Delta(P_{jk}) \tag{16.5}$$

define the external preference of country i over country j with respect to country k, let

$$S_{ij} = \frac{\sum_{j \in I} S_{ij}(k)}{|I|} \tag{16.6}$$

define the *average external preference* of i over j, and let

$$\sigma_{ij} = \sqrt{\frac{\sum_{k \in C} \left[\left(\Delta(P_{ik}) - \Delta(P_{jk})\right) - S_{ij}\right]^2}{|I|}} \tag{16.7}$$

define the *standard deviation of the external preference of i over j*.

The dominance relationship of a country i over another country j will be defined by two conditions. The first one requires that $\Delta(P_{ij}) > 0$. It might also seem logical to require that $S_{ij}(k) > 0$ for every country k, $k \neq i, j$. However, this condition is so difficult to satisfy that the resulting partially ordered set is extremely sparse, with very few country pairs that are comparable. Thus, a more relaxed second condition will require that, only at a certain confidence level, the external preference of i over j should be positive. We parameterize the level of confidence by the multiplier η of the standard deviation σ_{ij}. More formally, for a given $\eta > 0$,

- A country i is said to dominate another country j if

$$\begin{cases} \Delta(P_{ij}) > 0 \\ S_{ij} - \eta\sigma_{ij} > 0 \end{cases} \tag{16.8}$$

- A country i is said to be dominated by another country j if

$$\begin{cases} \Delta(P_{ij}) < 0 \\ S_{ij} + \eta\sigma_{ij} < 0 \end{cases} \tag{16.9}$$

- In all the other cases, countries i and j are said to be not comparable; this can be due to the lack of evidence, or to conflicting evidence about the dominance of i over j.

Note that the larger the value of η is, the stronger the conditions are, and the fewer pairs of countries are comparable. If η is sufficiently large, then the dominance relationship is transitive and is a partial order, since it becomes progressively sparser until being reduced to empty. On the other hand, if η is small (and in particular for $\eta = 0$), then the dominance relationship becomes denser, but is not necessarily transitive.

We are looking for a "rich" dominance relationship (applying to as many country pairs as possible) which is transitive. Formally, our objective is to maximize the number of comparable country pairs subject to preserving the transitivity of the dominance relationship.

The richest dominance relationship defined by the two conditions (16.8) and (16.9) in the case of $\eta = 0$ will be called the *base dominance relationship*. If i and j are any two countries comparable in the base dominance relationship, then it is possible to calculate the smallest value of the parameter $\eta_{ij} = |\, S_{ij}/\sigma_{ij} \,|$ such that the i and j are not comparable in any dominance relationship defined by a parameter

Table 16.9 Correlation levels between LAD and canonical relative preferences

	Δ	$d^{S\&P}$	d^{M}	d^{II}	d^{LRS}
Δ	100 %	93.21 %	92.89 %	91.82 %	97.57 %
$d^{S\&P}$	93.21 %	100 %	98.01 %	96.18 %	95.54 %
d^{M}	92.89 %	98.01 %	100 %	96.31 %	95.20 %
d^{II}	91.82 %	96.18 %	96.31 %	100 %	94.11 %
d^{LRS}	97.57 %	95.54 %	95.20 %	94.11 %	100 %

value exceeding or equal to η_{ij}. This calculation is based on the fact that given a value of η, it is possible to check in polynomial time (Tarjan 1972) whether the corresponding dominance relationship is transitively closed. Then the algorithm that determines in polynomial time the minimum value η^* for which the corresponding dominance relationship is still transitive, sorts at most $|I|^2$ numbers η_{ij} in ascending order, and then checks one by one the transitivity of the corresponding dominance relationships. When the dominance relationship becomes transitive for the first time, the algorithm stops and outputs η^* equal to the corresponding value of the parameter η_{ij}. This study utilizes this value η^* and the corresponding dominance relationship between countries, called here the *logical dominance relationship* and denoted by the subscript of LAD (e.g., $\underset{LAD}{\succ}$).

The definition of dominance relationship between countries on the basis of average external preferences bears some similarities to the so-called “column sum methods” (Choo and Wendley 2004) utilized in reconciling inconsistencies resulting from the application of pairwise comparison matrix methods.

Extending Partially Ordered Sets to “Extreme” Linear Preorders

The information about country preferences contained in the economic and political attributes is represented most faithfully by the logical dominance relationship defined above. However, it is impractical to use, since this partial order requires a large amount of data to describe. On the other hand, country preferences can be expressed very compactly by country ratings, since the latter are a very special type of partial orders called linear preorders.

A partial order $\Pi(X)$ is called a *linear preorder* if there exists a mapping $M : X \to \{0,1, \ldots, k\}$ such that $x \supset y$ if and only if $M(x) > M(y)$. Therefore, a linear preorder is completely described by specifying its mapping M. Without loss of generality, one can assume that for every $i \in \{0,1, \ldots, k\}$, there exists $x \in X$ such that $M(x) = i$. Such a linear preorder is said to have $k + 1$ levels.

To make logical dominance of countries practically utilizable, this relationship should be transformed into a linear preorder preserving all the order relations between countries (i.e., is an *extension* of the partial order) and is as close as possible to it. The logical dominance relationship can be extended in a multitude of ways to a variety of linear preorders. In particular, two extreme linear preorders are constructed below that we call the *optimistic* and the *pessimistic* extensions, denoted by OE and PE, respectively. The names are justified since the former assigns to each country the highest level it can expect, while the latter assigns to each country the lowest level it can expect:

- In the first step of *OE* construction, those countries that are not dominated by any other country are assigned the highest level and are then removed from the set of countries under consideration. Iteratively, non-dominated countries in the remaining set of countries are assigned the highest remaining level until every country is assigned a level denoted by OE_i.
- In the first step of *PE* construction, those countries that do not dominate any other country are assigned the lowest level and are then removed from the set of countries under consideration. Iteratively, non-dominating countries in the

remaining set of countries are assigned the lowest remaining level until every country is assigned a level denoted by PE_i.

The method utilized above to construct OE and PE is known as the *Condorcet method*. It represents a specific type of voting system (Gehrlein and Lepelley 1998), and it is often used to determine the winner of an election. The Condorcet winner(s) of an election is generally defined as the candidate(s) who, when compared in turn with every other candidate, is preferred over each of them. Given an election with preferential votes, one can determine *weak Condorcet winners* (Ng et al. 1996) by constructing the *Schwartz set* as the union of all possible candidates such that (i) every candidate inside the set is pairwise unbeatable by any other candidate outside the set (ties are allowed) and (ii) no proper subset of the set satisfies the first property.

The Schwartz set consists exactly of all weak Condorcet winners. The *weak Condorcet losers* are the reverse of the weak Condorcet winners, that is, those losing pairwise to every other candidate. OE assigns the highest level to those countries that are the weak Condorcet winners, that is, better than or incomparable with every other country. PE assigns the lowest level to those countries that are the weak Condorcet losers, that is, worse than or are incomparable with every other country. Note that both OE and PE have the minimum possible number of levels. Indeed, in a directed graph whose vertices are the countries and whose arcs represent comparable countries in the dominance relationship, the length of the longest directed path bounds from below the number of levels in any linear preorder extending the dominance relationship. This length equals the number of levels in OE and PE.

16.4.3.3 Logical Rating Scores

The LAD relative preferences can be utilized in a completely different way (compared to OE or PE) to construct country risk ratings. We describe here how to derive new numerical ratings of all countries, called "logical rating scores" (LRS), by applying multiple linear regression. LRS were defined by Hammer et al. (2011) as numerical values whose pairwise differences approximate optimally the relative preferences over countries as expressed in their risk ratings. A common way to calculate the relative preferences is based on interpreting sovereign ratings as cardinal values (see, e.g., Ferri et al. 1999; Hu et al. 2002; Sy 2004). If the sovereign ratings β are viewed as cardinal values, then one can view the relative preferences Δ as differences of the corresponding ratings:

$$\Delta\left(P_{ij}\right) = \beta_i - \beta_j, \quad \text{for all } i,j \in I, i \neq j \tag{16.10}$$

Since the system (16.10) is not necessarily consistent, it should be relaxed in the following way:

$$\Delta\left(P_{ij}\right) = \beta_i - \beta_j + \varepsilon_{ij}, \quad \text{for all } i,j \in I, i \neq j \tag{16.11}$$

The values of the β's providing the best L_2 approximation of the Δ's can be found by solving the following multiple linear regression problem:

$$\Delta(\pi) = \sum_{k \in I} \beta_k * x_k(\pi) + \varepsilon(\pi), \tag{16.12}$$

where $\pi = \{(i,j)|i,j \in I, i \neq j\}$ and $x_k(i,j) = \begin{cases} 1, & \text{for } k = i \\ -1, & \text{for } k = j \\ 0, & \text{otherwise} \end{cases}$.

The logical rating scores β_k obtained by fitting the regression model are given in Column 8 of Table 16.16.

16.4.4 Evaluation of the Results

In this section, we analyze the results obtained with the proposed rating systems. The evaluation of the results involves the analysis of the following:

- The relative preferences
- The partially ordered set (i.e., the logical dominance relationship)
- The LRS scores and the Condorcet ratings (extremal linear extensions)

with respect to the rating system of S&P's as well as that of Moody's and The Institutional Investor.

16.4.4.1 Canonical Relative Preferences

In this section, we evaluate the quality of the informational content in the matrix Δ of relative preferences. To reach this goal, we first define, for any set of numerical scores s_i representing sovereign ratings, the *canonical relative preferences* $d_{ij} = s_i - s_j$ for each pair of countries. Second, we compare the LAD relative preferences $\Delta(P_{ij})$ with the canonical relative preferences $d^{S\&P}{}_{ij}$, $d^{M}{}_{ij}$, $d^{II}{}_{ij}$, and $d^{LRS}{}_{ij}$ associated, respectively, to the S&P's ratings, Moody's ratings, The Institutional Investor's scores, and the logical rating scores (Hammer et al. 2011). The corresponding matrices of relative preferences are denoted $d^{S\&P}$, d^{M}, d^{II}, and d^{LRS}, respectively. We evaluate the proximity between the LAD relative preferences (Hammer et al. 2006) and the canonical relative preferences based on their correlation levels (Table 16.9).

The high correlation levels show that the LAD relative preferences are in strong agreement with both the ratings of S&P's and those of the other agencies, as well as with the logical rating scores. The superiority of the logical rating scores compared to the relative preferences associated with the LAD discriminant is explained by the filtering of the noise done when deriving the LRS scores.

16.4.4.2 Preference Orders

The logical dominance relationship is compared to the preference orders derived from the S&P's and Moody's ratings (viewed as partially ordered sets) and the partially ordered sets associated with The Institutional Investor's scores and the logical rating scores. The partially ordered sets corresponding to The Institutional Investor's scores and the logical rating scores are obtained as follows:

$$\begin{array}{ll} i \succ j & \text{if } s_i - s_j > \theta \\ i \prec j & \text{if } s_i - s_j < -\theta \\ i \| j & \text{otherwise} \end{array}$$

where θ is the positive number chosen so as to obtain a partially ordered set of the same density as the dominance relationship and s_i represents the numerical score given to country i by the respective rating system. The incomparability between two countries means, for S&P's and Moody's, that the two countries are equally creditworthy, while for the logical dominance relationship, it means that the evidence about the relative creditworthiness of the two countries is either missing or conflicting. The concept of density of a partially ordered set is defined in Hammer et al. (2006) and represents the extent to which a partial order on a set of countries differentiates them by their creditworthiness.

To assess the extent to which the preference orders agree with each other, the following concepts are introduced (Hammer et al. 2006). Given a pair of countries (i, j), two partially ordered sets are:

- In *concordance* if one of the following relations $i \succ j$, $i \prec j$, or $i \| j$ holds for both partially ordered sets
- In *discordance* if $i \succ j$ for one of the partially ordered sets and $i \prec j$ for the other one
- *Incomparable* otherwise, that is, if $i \| j$ for one of the partially ordered sets, and either $i \succ j$ or $i \prec j$ for the other partially ordered set.

We measure the *levels of concordance*, *discordance*, or *incomparability* between two partially ordered sets by the fractions of pairs of countries for which the two partially ordered sets are, respectively, in concordance, discordance, or incomparable. Hammer et al. (2006) have shown that there is a very high level of agreement between the following:

- The logical dominance relationship and the preference orders associated with S&P's and Moody's ratings and The Institutional Investor scores
- The logical dominance relationship and the logical rating scores

16.4.4.3 Discrepancies with S&P's Logical Dominance Relationship

This section is devoted to the study of the discordance between the logical dominance relationship and the preference order of S&P's. We define as a *discrepancy* (Hammer et al. 2006) a country pair for which the logical dominance relationship and the preference order of S&P's are in discordance. The 2.17 % discordance level between the logical dominance relationship and the preference order of S&P's represents 51 discrepancies.

Next, in order to determine the minimum number of countries, for which the S&P's ratings must be changed so that the new *adjusted* S&P's preference order has a 0 % discordance level with the dominance relationship, we solve the integer program below:

$$\min \sum_{i \in I} a_i$$

subject to

$$\left|S_i^* - S_i\right| \le M^* a_i, \quad \text{for all } i \in I \tag{16.13}$$

$$S_i^* \ge S_j^* \quad \text{for every pair } (i, j) \text{ such that } i \underset{LAD}{\succ} j$$

$$a_i \in \{0, 1\}, \quad S_i^* \varepsilon \{0, 1, \ldots, 21\} \qquad \text{for all } i \in I$$

where a_i takes the value 1 if the S&P's rating of country i must be modified and the value 0 if otherwise, S_i is the original S&P's rating of country i, S_i^* is the adjusted S&P's rating of country i, and M is a sufficiently large positive number (e.g., $M = 22$).

The optimal solution of Eq. 16.13 shows that the 0 % discordance level can be achieved by adjusting the S&P's ratings of nine countries: France, India, Japan, Colombia, Latvia, Lithuania, Croatia, Iceland, and Romania. To check the relevance of the proposed rating adjustments, we examine the S&P's ratings posterior to December 1998. We observe that Romania, Japan, and Columbia's S&P's ratings have been modified in the direction suggested by our model. More precisely, Columbia was downgraded by S&P's twice, moving from BBB− in December 1998 to BB+ in September 1999 and then to BB in March 2000. Japan was downgraded to AA+ in February 2001 and AA in November 2001. Romania was upgraded to B in June 2001. The S&P's rating of the other countries (Iceland, France, India, Croatia, Latvia, and Lithuania) has remained unchanged.

Logical Rating Scores

We have already shown that the LRS and the S&P's ratings are in close agreement. However, since LRS and the S&P's ratings are not expressed on the same scale, the comparison of the two scores of an individual country presents a challenge. In order to bring the LRS and the S&P's ratings to the same scale, we apply a linear transformation $a^*\beta_i + c$ to the logical rating scores β_i in such a way that the mean square difference between the transformed LRS and the S&P's ratings is minimized. This is obtained by solving a series of quadratic optimization problems in which the decision variables are a and c. Clearly, the consistency of the LRS and S&P's ratings is not affected by this transformation.

In 1998, it appears that five countries (Columbia, Hong Kong, Malaysia, Pakistan, and Russia) have an S&P's rating that does not fall within the confidence interval of the transformed LRS. The 1-year modification of the S&P's ratings for Columbia, Pakistan, and Russia is in agreement with the 1998 LRS of these countries and highlights the prediction power of the LRS model. Moreover, the evolution of the S&P's ratings of Malaysia and Hong Kong is also in agreement with their 1998 LRS. Indeed, both Malaysia and Hong Kong have been upgraded shortly thereafter, the former moving from BBB- to BBB in November 1999 and the latter from A to A+ in February 2001.

Table 16.10 Correlation analysis

	S&P's	Moody's	II	OE	PE	LRS
S&P's	100 %	98.01 %	96.18 %	94.31 %	95.40 %	95.54 %
Moody	98.01 %	100 %	96.31 %	94.13 %	95.42 %	95.20 %
II	96.18 %	96.31 %	100 %	93.26 %	94.62 %	94.11 %
OE	94.31 %	94.13 %	93.26 %	100 %	99.15 %	99.24 %
PE	95.40 %	95.42 %	94.62 %	99.15 %	100 %	99.10 %
LRS	95.54 %	95.20 %	94.11 %	99.24 %	99.10 %	100 %

16.4.4.4 Optimistic and Pessimistic Extensions

The optimistic and pessimistic extensions of the logical dominance relationship (Table 16.16) comprise 21 levels, while the S&P's rating system contains 22 rating categories. Table 16.10 provides the correlation levels between all the ratings (scores). The analysis reconfirms the high level of agreement between the proposed rating models and that of S&P's. The high correlation levels attest that the LRS approximate very well the S&P's ratings, as well as those of the other rating agencies.

16.4.4.5 Temporal Validity

In this section, we apply the "out-of-time" or "walk-forward" validation approach (Sobehart et al. 2000; Stein 2002) to further verify the robustness and the relevance of our rating models. This involves testing how well the LAD model derived from the 1998 data performs when applied to the 1999 data. To evaluate the "temporal validity" of the proposed models, we proceed as follows: (i) we derive the LAD relative preferences, (ii) we build the logical dominance relationship and run the regression model for the LRS scores, (iii) we calculate the weak Condorcet ratings (pessimistic and optimistic extensions) and the logical rating scores, and (iv) we compare these to the rating systems of the rating agencies (S&P's, Moody's, and The Institutional Investor).

Relative Preferences

Table 16.11 shows that the LAD relative preferences are highly correlated with those of the S&P's rating system, as well as with the logical rating scores. The LAD relative preferences and the LRS were obtained by applying to the 1999 data the models derived from the 1998 data.

The high levels of pairwise correlations between the S&P's 1999 ratings, the relative preferences given by the LAD discriminant, and the canonical relative preferences corresponding to LRS show that the LRS model has a very strong temporal stability and indicate its high predictive power.

Preorders

The logical dominance relationship is compared to the 1999 preference order of the S&P's and the partially ordered set associated with the logical rating scores. Table 16.12 displays the concordance, discordance, and incomparability levels

Table 16.11 Correlation levels between relative preference matrices

	$d^{S\&P}$	Δ	d^{LRS}
$d^{S\&P}$	100 %	91.70 %	94.12 %
Δ	91.70 %	100 %	96.98 %
d^{LRS}	94.12 %	96.98 %	100 %

Table 16.12 Concordance, discordance, and incomparability levels with dominance relationship

	Logical dominance relationship		
	Concordance	Incomparability	Discordance
S&P's	84.21 %	13.15 %	2.64 %
Logical rating score	93.43 %	6.49 %	0.08 %
	Logical rating score		
	Concordance	Incomparability	Discordance
S&P's	83.46 %	12.69 %	3.85 %

between the logical dominance relationship, the preference order of S&P's, and the partial order associated with the logical rating scores and underlines their very strong level of agreement.

Discrepancies with S&P's

The discordance level between the logical dominance relationship obtained using the 1999 data and the preference order of the 1999 S&P's ratings is equal to 2.64 %. The solution of the above integer programming problem (16.13) reveals that the discrepancies would disappear if one modified the ratings of eight countries (France, Japan, India, Colombia, Latvia, Croatia, Iceland, and Hong Kong). The relevance of the ratings obtained with the logical dominance relationship is proven by observing the rating changes published by S&P's subsequent to December 1999.

The identification of the discrepancies between S&P's ratings and the LRS scores requires the derivation of the confidence intervals for the new, 1999 observations and therefore for the transformed LRS of each country (Hammer et al. 2007). We denote by n and p the number of observations and predictors, respectively. The expression $t(1 - \alpha/2, n - p)$ refers to the Student test with $(n - p)$ degrees of freedom, and with upper and lower tail areas of $\alpha/2$, X_j is the p-dimensional vector of the values taken by the observation Y_j on the p predictors, $X_p^{'}$ is the transposed of X_j, and $(X'X)^{-1}$ is the variance-covariance matrix, that is, the inverse of the $[p \times p]$-dimensional matrix $(X'X)$. Denoting by MSE the mean square of errors, the estimated variance $s^2\left[\hat{Y}_j\right] = MSE^*\left[1 + X_j^{'}\left(X^{'}X\right)^{-1}X_j\right]$ of the predicted rating $\hat{Y}_j$ and the $(1-\alpha)$ confidence interval for $\hat{Y}_{j,n}$ are given by

$$\left\{\hat{Y}_{j,n} - t(1 - \alpha/2, n - p)^* s[pred], \hat{Y}_{j,n} + t(1 - \alpha/2, n - p)^* s[pred]\right\} \quad (16.14)$$

Hammer et al. (2007b) say that there is a discrepancy between S&P's rating R_j^{SP} and the logical rating score if

$R_j^{SP} \notin \{\hat{Y}_{j,n} - t(1-\alpha/2, n-p)^* s[pred], \hat{Y}_{j,n} + t(1-\alpha/2, n-p)^* s[pred]\}$ for $\alpha = 0.1$.

Applying the 1998 LRS model to the 1999 data, only two countries (Russia and Hong Kong) have S&P's ratings that are outside the confidence intervals of the corresponding transformed LRS. The creditworthiness of these two countries seems to have been under-evaluated by S&P's in 1998: the ratings of both were upgraded in 1999.

Condorcet Ratings and LRS Scores

The optimistic and pessimistic extensions (Table 16.16) of the logical dominance relationship obtained using the 1999 data both comprise 20 levels, while the S&P's rating system contains 22 rating categories. Table 16.13 provides the correlation levels between the 1999 S&P's ratings, the optimistic and pessimistic extension levels, and the logical rating scores. The high levels of correlation and their comparison with those presented in Table 16.10 provide further evidence of the temporal validity of the proposed models.

16.4.4.6 Predicting Creditworthiness of Unrated Countries

Condorcet Approach

The application of the logical dominance relationship to predict the rating of countries not included in the original dataset, and for years subsequent to 1998, is an additional validation procedure, sometimes referred to as "out-of-universe" cross-validation (Sobehart et al. 2000; Stein 2002). We use the 1998 LAD model to calculate the relative preferences for all pseudo-observations involving one or two of the four "new" countries (Ecuador, Guatemala, Jamaica, Papua New Guinea), which allows us to derive the logical dominance relationship and the computation of the optimistic and pessimistic extensions of previously unrated countries. The levels assigned to these countries by the recalculated optimistic and pessimistic extensions are shown in Table 16.14.

It appears that:

- Guatemala's first S&P's rating (in 2001) was BB. Guatemala's OE/PE levels are the same as Morocco's (the only country with OE = PE = 5), and Morocco's S&P's rating in 1999 was BB.

Table 16.13 Correlation analysis

	S&P's	*OE*	*PE*	*LRS*
S&P's	100.00 %	95.09 %	95.15 %	94.12 %
OE	95.09 %	100.00 %	99.59 %	98.43 %
PE	95.15 %	99.59 %	100.00 %	98.24 %
LRS	94.12 %	98.43 %	98.24 %	100.00 %

Table 16.14 Out-of-universe validation

	Optimistic extension	Pessimistic extension	First S&P's rating	S&P's linear extension
Ecuador	3	2	SD (07/2000)	0
Guatemala	5	5	BB (10/2001)	10
Jamaica	3	2	B (11/1999)	7
Papua New Guinea	3	3	B+ (01/1999)	8

- Jamaica's first S&P's rating (1999) was B. Its OE/PE levels (OE = 3, PE = 2) are identical to these of Paraguay, Brazil, the Dominican Republic, and Bolivia, which had 1999 S&P's ratings of B, B+, B+, and BB-, respectively.
- The first S&P's rating for Papua New Guinea was B+. Its OE/PE levels (OE = 3, PE = 3) are the same as those of Peru and Mexico, which both had 1999 S&P's ratings of BB.
- Ecuador's OE/PE levels (OE = 3, PE = 2) are the same as those of Paraguay, Brazil, the Dominican Republic, and Bolivia, which had 1999 S&P's ratings of B, B+, B+, and BB-, respectively. Interestingly, while the initial S&P's rating of Ecuador was SD (in July 2000), it was upgraded in August 2000 (1 month later) to B.

The striking similarity between the initial S&P's rating of each of the four countries discussed above and the S&P's ratings of those countries which have the same OE/PE levels validates the proposed model, indicating its power to predict the creditworthiness of previously unrated countries.

LRS Approach

The LAD discriminant, which does not involve in any way the previous years' S&P's ratings, allows the rating of previously unrated countries in the following way. First, we construct all the pseudo-observations involving the new countries to be evaluated. Second, we calculate the relative preferences for these pseudo-observations, and we add the resulting columns and rows to the matrix of relative preferences. Third, we determine the new LRS for all the countries (new and old) by running the multiple linear regression model (16.12). Fourth, we apply the linear transformation defined above to the LRS so that the transformed LRS and the S&P's ratings are on the same scale.

The evaluation of the ability of LRS to accurately predict S&P's ratings is carried out by comparing the predicted LRS (obtained as described above) and the S&P's ratings (when they first become available). We compute the confidence intervals (16.14) for the transformed LRS of four countries never rated by S&P's by December 1998. The predictions for Guatemala, Jamaica, and Papua New Guinea correspond perfectly to the first time (subsequent) S&P's ratings. The comparison between the LRS and the first (July 2000) S&P's rating (SD) to Ecuador shows that S&P's rated it too harshly, since 1 month later S&P's raised its rating to B-, justifying the LRS prediction.

16.4.5 Importance of Variables

The methodology developed in this chapter permits the assessment of the importance of the variables in rating countries' creditworthiness. In LAD, the importance of variables is associated with their use in the patterns of the LAD model and is usually measured by the proportion of patterns containing a particular variable. The patterns of the 1998 LAD model show that the three most frequently used variables are financial depth and efficiency, political stability, and gross domestic product per capita (appearing in 47.5 %, 39.4 %, and 35.6 % of the LAD patterns, respectively).

The presence of political stability among the three most significant ones in the selected set justifies the inclusion of political variables in country risk rating models. This result is in agreement with the cost-benefit approach to country risk (i.e., the risk of defaulting is heavily impacted by the political environment, see Brewer and Rivoli 1990, 1997; Citron and Neckelburg 1987; Afonso 2003) which is not a view shared by all (Haque et al. 1996, 1998).

The fact that the LAD approach identifies gross domestic product per capita as significant was expected, for most studies on country risk ratings acknowledge its crucial importance in evaluating the creditworthiness of a country. A key new result is the identification of the *financial depth and efficiency* variable as a major factor for the prediction of country risk ratings.

16.5 Conclusions

The central objective of this study is to develop transparent, consistent, self-contained, and stable credit risk rating models, closely approximating the risk ratings provided by some of the main rating agencies. We use the combinatorial optimization method called LAD and develop a relative creditworthiness approach for assessing the credit risk of countries, while an absolute creditworthiness approach is used for financial institutions.

The evaluation of the creditworthiness of financial organizations is particularly important due to the growing number of banks going bankrupt and the magnitude of losses caused by such bankruptcies, and it is challenging due to the opaqueness of the banking sector and the high variability of banks' creditworthiness. We use the logical analysis of data (LAD) to reverse engineer the Fitch bank credit ratings. The LAD method identifies strong combinatorial patterns distinguishing banks with high and low ratings. These patterns constitute the core of the rating model developed here for assessing the credit risk of banks. The results show that the LAD ratings are in very close agreement with the Fitch ratings. In that respect, it is important to note that the critical component of the LAD rating system – the LAD discriminant – is derived utilizing only information about whether a bank's rating is "high" or "low," without the exact specification of the bank's rating category. Moreover, the LAD approach uses only a fraction of the observations in the dataset. The higher classification accuracy of LAD appears even more clearly when performing cross-validation and applying the LAD model derived by using the banks in the training set to those in the testing one.

This study also shows that the LAD-based approach to reverse engineering bank ratings provides a model that is *parsimonious* and *robust*. This approach allows to derive rating models with varying levels of granularity that can be used at different stages in the credit granting decision process and can be employed to develop internal rating systems that are Basel 2 compliant. Besides impacting the credit risk of a financial institution, the use of the generalizable and accurate credit risk rating system proposed here will also be critical in mitigating the financial institution's operational risk due to breakdowns in established processes and risk-management operations or to inadequate process mapping within business lines. In particular, the reliance on such risk rating system will reduce the losses due to mistakes made in executing transactions, such as settlement failures, failures to meet capital regulatory requirements, or untimely debt collections, or the losses due to the offering of inappropriate financial products or credit conditions, or giving incorrect advice to counterparty.

The evaluation of the creditworthiness of countries is also of utmost importance, since the country's risk rating is generally viewed as the upper bound on the rating that entities within a given country can be assigned. This study proposes an LAD methodology for inducing a credit risk system from a set of country risk rating evaluations. It uses nine economic and three political variables to construct the relative preferences of countries on the basis of their creditworthiness. Two methods are then developed to construct countries' credit rating systems on the basis of their relative creditworthiness. The first one is based on extending the preorder of countries using the Condorcet voting technique and provides two rating systems (weak Condorcet winners and losers), while the second one uses linear regression to determine the logical rating scores.

The proposed rating systems correlate highly with those of the utilized rating system (S&P's) and those of other rating agencies (Moody's and The Institutional Investor) and are shown to be stable, having an excellent classification accuracy when applied to the following years' data or to the ratings of previously unrated countries. Rating changes implemented by the S&P's in subsequent years have resolved most of the (few) discrepancies between the constructed partially ordered set and S&P's initial ratings. This study provides new insights on the importance of variables by supporting the necessity of including in the analysis, in addition to economic variables, also political variables ("political stability"), and by identifying "financial depth and efficiency" as a new critical factor in assessing country risk.

The rating systems proposed here for banks as well as countries are as follows:

- Avoid overfitting as attested by the back-testing analysis (i.e., extremely high concordance between in- and out-of-sample rating predictions calculated using the k-folding and jackknife cross-validation methods).
- Distinguish themselves from the rating models in the existing literature by their *self-contained* nature, that is, by their non-reliance on any information derived from lagged ratings. Therefore, the high level of correlation between predicted

Table 16.15 Standard & Poor's country rating system

	Level	Description
Investment rating	AAA	An obligor rated AAA has extremely strong capacity to meet its financial obligations. AA is the highest issuer credit rating assigned by S&P's
	AA	An obligor rated AA has very strong capacity to meet its financial commitments. It differs from the highest rated obligors only in small degree
	A	An obligor rated A has strong capacity to meet its financial commitments but is somewhat more susceptible to the adverse effects of changes in circumstances and economic conditions than obligors in higher-rated categories
	BBB	An obligor rated BBB has adequate capacity to meet its financial commitments. However, adverse economic conditions or changing circumstances are more likely to lead to a weakened capacity of the obligor to meet its financial commitments
Speculative rating	BB	An obligor rated BB is less vulnerable in the near term than other lower-rated obligors. However, it faces major ongoing uncertainties and exposure to adverse financial or economic conditions which could lead to its inability to meet financial commitments
	B	An obligor rated B is more vulnerable than the obligors rated BB, but, at the time of the rating, it has the capacity to meet financial commitments. Adverse business, financial conditions could likely impair its capacity to meet financial commitments
Default rating	CCC	An obligor rated CCC is vulnerable at the time of the rating and is dependent upon favorable business, financial, and economic conditions to meet financial commitments
	CC	An obligor rated CC is highly vulnerable at the time of the rating
	C	An obligor rated C is vulnerable to nonpayment at the time of the rating and is dependent upon favorable business, financial, and economic conditions to meet financial commitments
	D	An obligor rated D is predicted to default
	SD	An obligor rated SD (selected default) is presumed to be unwilling to repay

and actual ratings cannot be attributed to the reliance on lagged ratings and is a reflection of the predictive power of the independent variables included in these models. An important advantage of the non-recursive nature of the proposed models is their applicability to not-yet-rated obligors.

The scope of the proposed methodology extends beyond the rating problems discussed in this study and can be used in many other contexts where ratings are relevant. The proposed methodology is applicable in the general case of inferring an objective rating system from archival data, given that the rated objects are characterized by vectors of attributes taking numerical or ordinal values.

We have converted the Standard & Poor's rating scale (columns 1 and 4) into a numerical scale (columns 2 and 5). Such a conversion is not specific to us. Bouchet et al. (2003), Ferri et al. (1999), and Sy (2004) proceed similarly. Moreover, Bloomberg, a major provider of financial data services, developed a standard cardinal scale for comparing Moody's, S&P's, and Fitch-BCA ratings (Kaminsky and Schmukler 2002). A higher numerical value denotes a higher probability of default. The numerical scale is referred to in this chapter as Standard & Poor's preorder

Abstract

This paper constructs a six-variable VAR model (including NASDAQ returns, TSE returns, NT/USD returns, net foreign purchases, net domestic investment companies (dic) purchases, and net registered trading firms (rtf) purchases) to examine: (i) the interaction among three types of institutional investors, particularly to test whether net foreign purchases lead net domestic purchases by dic and rtf (the so-called demonstration effect); (ii) whether net institutional purchases lead market returns or vice versa; and (iii) whether the corresponding lead-lag relationship is positive or negative? The results of unrestricted VAR, structural VAR, and multivariate threshold autoregression models show that net foreign purchases lead net purchases by domestic institutions and the relation between them is not always unidirectional. In certain regimes, depending on whether previous day's TSE returns are negative or previous day's NASDAQ returns are positive, we find ample evidence of a feedback relation between net foreign purchases and net domestic institutional purchases. The evidence also supports a strong positive-feedback trading by institutional investors in the TSE. In addition, it is found that net dic purchases negatively lead market returns in Period 4. The MVTAR results indicate that net foreign purchases lead market returns when previous day's NASDAQ returns are positive and have a positive influence on returns.

Readers are well advised to refer to chapter appendix for detailed discussion of the unrestricted VAR model, the structural VAR model, and the threshold VAR analysis.

Keywords

Demonstration effect • Multivariate threshold autoregression model • Foreign investment • Lead-lag relationship • Structural VAR • Block Granger causality • Institutional investors • Domestic investment companies • Registered trading firms • Qualified foreign institutional investors

17.1 Introduction

As financial markets are gradually liberalized in emerging economies, capital investments have been flowing into these countries at increasing rates. Needless to say, such capital movements in terms of bringing in direct investment along with technological know-how can be instrumental in raising a nation's productivity. On the downside, capital inflows directed at investing in the host country's security markets can be disruptive. From a macroeconomics perspective, foreign capital inflows are beneficial in that they provide much-needed capital. From a microeconomics perspective, they also lower the cost of capital and enhance competitiveness. Nevertheless, capital inflows can also be disruptive if arbitrage is their main purpose. When capital flight occurs, as was the case in the 1997 Asian financial debacle and the 1994 Mexican Peso crisis, movements in foreign capital could be extremely disruptive and damaging.

Given the potentially negative impact of foreign investments, Taiwan's Ministry of Finance exercised caution by implementing foreign capital policies in a three-stage

Table 17.1 Inflows and outflows of foreign capital investment in the TSE Unit: millions of US dollars

Period	Securities investment companies		Foreign institutional investors		Natural person		Foreign total
	Inflow	Outflow	Inflow	Outflow	Inflow	Outflow	Net inflow
1991	263	53	448	0	0	0	658
1992	57	61	447	17	0	0	426
1993	653	93	1,859	97	0	0	2,322

Source of data: Securities and Futures Commission, Ministry of Finance, Taiwan

process. First, it directed a number of local trust companies to issue investment funds abroad for the local stock market. Second, qualified foreign investment companies were allowed to invest in Taiwan's stock market. Third, foreign individual as well as institutional investors were permitted to directly participate in trading in the Taiwan Stock Exchange Corporation (hereafter TSE). The first stage took effect from September 1983 until December 29, 1990, when the second stage replaced the first stage with a maximum investment limit of $2.5 billion. In response to the strong demand to invest in the TSE, the ceiling was raised to $5 billion and to $7.5 billion in August 1993 and March 1994, respectively. Foreign investments later increased substantially (see Table 17.1), and as a result the ceiling was lifted entirely in 1996 except for a maximum investment limit to each individual stock.

The relatively slow pace in allowing foreign investment in Taiwan was the result of ongoing debates between the Central Bank of China and the Securities and Futures Commission of the Ministry of Finance regarding the stability of foreign investment. The focus of the discussion was on the following three questions. First, are there differences in the trading behaviors of different type of institutions? One objective of opening up the domestic market to foreign investments is to utilize its advantages in information acquisition, information processing, and trade execution to improve the overall performance of local institutional investors.[1] Second, will

[1]This is because foreign institutions may well have better research teams and buy stocks according to the fundamentals such as the firm's future profitability. In contrast, local institutions and individual investors usually choose stocks based on insider information or what the newspapers write about. However, if stocks bought by foreign investors have a better performance than that of local institutions and individual investors, the latter tend to buy the stocks bought by successful foreign investors the previous day. Hence this gives rise to the so-called "demonstration effect." Such a concept is similar to the "herding" which Lakonishok et al. (1992) referred to as correlated trading across institutional investors. Nonetheless, their definition is close to the contemporaneous correlation rather than the lead-lag relation under study, and as such this leads to the demonstration effect which we documented.

the trades of the three groups of classified institutional investors affect stock returns of the TSE? Third, will the lifting of restrictions on foreign capital contribute to the volatility of both the foreign exchange and stock markets in Taiwan?

The purpose of this paper is to provide answers to two of the aforementioned issues: (1) Are there differences in the trading behaviors of different types of institutions? Typically, we examine interaction among the three types of institutions: qualified foreign institution investors (*qfii*), domestic investment companies (*dic*), and registered trading firms (*rtf*). (2) Does institutional trading "cause" stock returns or do institution investments follow movements in stock prices? The distinction between this paper and previous literature lies in following aspects: (i) Most previous studies uses low-frequency – yearly, quarterly, or at best weekly – data (Nofsinger and Sias 1999; Cai and Zheng 2002; Karolyi 2002). In this paper we employ daily data to help explore these issues in detail and to provide new evidence on the short-term dynamics among institutional investors and stock returns.[2] (ii) Unlike previous studies that used a bivariate VAR model (Froot et al. 2001), we use a six-variable VAR model, which includes three types of institutional trades, stock returns in the TSE, NT/USD exchange rate changes, and NASDAQ index returns to test related relationships. (iii) Improving on the conventional linear VAR analysis in the previous studies, we employ the threshold concept and split data into two regimes based on whether previous trading day's market returns are positive or negative.

A number of studies have examined the relationship between investment flows and stock returns. Brennan and Cao (1997) develop a theoretical model of international equity flows that relies on the informational difference between foreign and domestic investors. The model predicts that if foreign and domestic investors are differently informed, portfolio flows between two countries will be a linear function of the contemporaneous return on all national market indices. Moreover, if domestic investors have a cumulative information advantage over foreign investors about domestic securities, the coefficient of the host market return is expected to be positive.

Nofsinger and Sias (1999) use US annual data to investigate the relationship between stock returns and institutional and individual investors. They identify a strong positive correlation between changes in institutional ownership and stock returns measured over the same period. Their results suggest that (i) institutional investors practiced positive-feedback trade more than individual investors and (ii) institutional herding impacted price more than that by individual investors. Nofsinger and Sias show that institutional herding is positively correlated with lag returns and appears to be related to stock return momentum.

Choe et al. (1999) use order and trade data from November 30, 1996 to the end of 1997 to examine the impact of foreign investors on stock returns. They found strong

[2]Froot et al. (2001) also use daily data, but they examine the behavior of capital flows across countries. In addition, our models and approaches used in the estimation differ drastically from theirs.

evidence of positive-feedback trading and herding by foreign investors before South Korea's economic crisis. During the crisis period, herding lessened and positive- feedback trading by foreign investors mostly disappeared.[3]

Grinblatt and Keloharju (2000) use a Finland data set to analyze it to the extent that past returns determine the propensity to buy and sell. They find that foreign investors tend to be momentum investors, buying past winning stocks and selling past losing ones. Domestic investors, particularly households, tend to be contrarians.

Froot et al. (2001) by making use of daily international portfolio flows (44 countries from 1994 to 1998) along with a bivariate unrestricted VAR model find that lagged returns are statistically significant in predicting future flows. The evidence of the predictability of returns by flows is, however, ambiguous. In developed markets, there is no statistical evidence of stock predictability. For emerging markets, the evidence for predictability is strong, although less so for the Emerging European region. However, they estimate a restricted VAR model that assumes current inflows will affect current prices, and the causality does not run from contemporaneous returns to the flows. They provide the evidence of a positive contemporaneous correlation between current inflows and returns in emerging markets.

Hamao and Mei (2001) investigate the impact of foreign investment on Japan's financial markets. Using monthly data from July 1974 to June 1992, they find that (1) trades of foreign investors tend to increase market volatility more than that by domestic investors; (2) foreign investors have more sophisticated investment technology than do domestic investors; and (3) foreign investors seem to make investment decisions on the basis of not only short-term gains but also long-term fundamentals.

Cai and Zheng (2002) use institutional holding data from the third quarter of 1981 to the last quarter of 1996 in order to examine the lead-lag relationship between portfolio excess returns and the institutional trading. Beyond it, they compute institutional trading as the change of institutional holdings from last quarter to the current quarter. The unrestricted VAR analysis indicates that stock returns Granger-cause institutional trading on quarterly basis, not vice versa. This implies the institutions "herd" on past price behavior instead of being dominant price-setters in the market.

Using weekly data of Japan, Karolyi (2002) find consistent positive-feedback trading among foreign investors before, during and after the Asian financial debacle. Japanese banks, financial institutions, investment trusts and companies are, on the other hand, aggressive contrarian investors. There is no evidence that the trading activity by foreigners destabilized the markets during the crisis.[4]

Griffin et al. (2003) study the daily and intraday relationship between stock returns and trading of institutional as well as individual investors for NASDAQ 100 securities. The daily unrestricted VAR results indicate that the institutional

[3]Lakonishok et al. (1992) refer to the positive-feedback trading or trend chasing as buying winners and selling losers and the negative feedback trading or contrarian as buying losers and selling winners. Cai and Zheng (2002) point out that feedback trading occurs when lagged returns act as the common signal that the investors follow.

[4]Karolyi (2002) reaches such a conclusion because there is little evidence of any impact of foreign net purchases on future Nikkei returns or currency returns.

buy-sell imbalances are positively related to previous day's returns and the institutional buy-sell imbalances (previous day) are not associated with current return. The results are consistent with the finding by Sias and Starks (1997) using US data. Griffin et al. (2003) estimate a structural VAR with the contemporaneous returns in the institutional imbalance equation and discover a strong contemporaneous relationship between daily returns and institutional buy-sell imbalances.

Kamesaka et al. (2003) use Japanese weekly investment flow data over 18 years to investigate the investment patterns and performance of foreign investors, individual investors, and five types of institutional investors. Not surprisingly, they find individual investors perform poorly, while securities firms, banks, and foreign investors perform admirably over the sample period.

Several related studies focus mainly on Taiwan's stock market. Huang and Hsu (1999) detect decreased volatility in the weighted TSE using Levene's F-statistic following market liberalization. Lee and Oh (1995), implementing a vector autoregression (VAR) model, find a reduction in the explanatory power of macroeconomics variables. Wang and Shen (1999) indicate that foreign investments exert a positive impact on the exchange rate with only a limited effect on the TSE. In addition, by using the turnover rate as a proxy for non-fundamental factors and earnings per share for fundamental factors within the framework of a panel data model, Wang and Shen are able to identify that (i) the non-fundamental factors impacted the returns of the TSE before market liberalization and (ii) both the fundamental and non-fundamental factors exerted an impact following market liberalization.

Lee et al. (1999) investigate interdependence and purchasing patterns among institutional investors, large, and small individual investors. Their results, based on 15-min intraday transaction data (3 months for 30 companies), highlight the important role played by large individual investors, whose trading affects not only stock returns but also small individual investors. However, net buys (i.e., the difference between total buy and total sell) by institutional investors have no effect on the TSE returns, and vice versa.

The previous literature is predominantly focused on the relationship between institutional trading and stock returns, rarely on the interaction among institutional investors. For example, the majority of prior studies find evidence of positive-feedback trading by institutions, with the exception of Froot et al. (2001), who discover that in Latin America and emerging East Asian markets, the trading by institutions positively predicts future returns. Karolyi (2002) also detects that foreign investors in Japan are positive-feedback traders, while Japanese financial institution and companies are contrarian investors.

Most of the studies to date on these issues have been on the USA and Japanese markets despite that some of the literature gives scant attention to Taiwan's stock market. When investigating the related issues in large countries such as the USA and Japan, the influence of the foreign sector on the domestic market could be neglected; however, for a small country such as Taiwan, it should not be ignored. This is because the electronics industry in Taiwan is closely connected to the US companies listed on the NASDAQ. Ultimately, after examining the interaction among institutional investors and the dynamic relationship between stock returns and institutional investors, the conclusion may also be affected by whether returns of domestic market are positive or negative.

To circumvent the above problems, this paper employs a six-variable VAR model, which takes into account trades of three types of institutional investors (*qfii*, *dic*, and *rtf*), foreign returns, domestic returns, and changes in the NT/USD exchange rate to jointly test hypotheses under different market conditions. Using daily data, we find that net foreign purchases lead net domestic purchases. However, such a relation is not unidirectional. Under certain conditions (either when previous day's TSE returns are negative or previous day's NASDAQ returns are positive), we identify a feedback relation between net foreign purchases and net domestic purchases. It highlights the well-known argument in Taiwan regarding foreign investors: The demonstration effect on domestic institutional investors is not entirely correct. As for the lead-lag relation between market returns and institutional trading, we find that in most cases market returns at least lead both net foreign and *dic* purchases; however, market returns also lead net *rtf* purchases if the relationship between contemporaneous returns and institutional trading is considered. On the other hand, our results also indicate that net *dic* purchases lead market returns and are negatively associated with market returns in the fourth period. The MVTAR analysis shows that when previous day's NASDAQ returns are positive, net foreign purchases positively lead stock returns.

The remainder of this paper is organized as follows. Section 17.2 describes the sample data and the basic statistics. Section 17.3 investigates the lead-lag relation for three groups of institutional investors in order to explore the issue of whether foreign investments give rise to demonstration effects in Taiwan's stock market and examines the relationship between institutional trading activity and stock returns of the TSE. To further explore the interaction among three types of market participants, the sample is divided into two regimes based on either the sign of the market returns or that of the NASDAQ index returns of previous trading day, respectively. The last section provides a conclusion.

17.2 Sample Data and Basic Statistics

This paper employs daily data from December 13, 1995 to May 13, 2004 for a large sample analysis.[5] The variables considered include purchases (*qfiibuy*) and sales (*qfiisell*) by *qfii*, purchases (*dicbuy*) and sales (*dicsell*) by *dic*, purchases (*rtfbuy*) and sales (*rtfsell*) by *rtf*, TSE daily weighted stock index (p_t), NASDAQ stock index ($nasp_t$), and the NT/USD exchange rate (e_t). The data are from the Taiwan Economic Journal (TEJ). The changes in the exchange rate and the logarithmic returns on TSE and NASDAQ indices are defined as

[5]The data began on December 13, 1995, since the inception of the TEJ.

Table 17.2 Unit root tests for the six time series

Test	$nasr_t$	r_t	Δe_t	$qfiibs_t$	$dicbs_t$	$rtfbs_t$
PP	-44.04^*	-42.76^*	-43.32^*	-28.47^*	-31.12^*	-29.90^*

The sample period starts from December 13, 1995, to May 13, 2004, a total of 1989 observations. $qfiibuy_t$ and $qfiisell_t$ = purchases and sales by qualified foreign institutional investors, and $qfiibs_t = qfiibuy_t\text{-}qfiisell_t$. $dicbuy_t$ and $dicsell_t$ = purchases and sales by domestic investment companies, and $dicbs_t = dicbuy_t\text{-}dicsell_t$. $rtfbuy_t$ and $rtfsell_t$ = purchases and sales by registered trading firms, and $rtfbs_t = rtfbuy_t\text{-}rtfsell_t$. $nasr_t$ are the NASDAQ index returns. r_t is the TSE index return. Δe_t is changes in the NT/USD exchange rate. $qfiibs_t$ is net purchases by *qfii*. $dicbs_t$ is net purchases by *dic*, and $rtfbs_t$ is net purchases by *rtf*. y denotes the level of the variable. Δy denotes the first difference of the variable. * denotes statistical significance at 1 % level

Table 17.3 Summary statistics for the net institutional purchases, stock returns and NT/USD currency returns

	Mean	Median	Maximum	Minimum	Std. dev.
Δe_t	0.0105	0.0000	3.4014	−2.9609	0.3331
r_t	0.0083	−0.0438	8.5198	−12.6043	1.7839
$nasr_t$	0.0302	0.1300	13.2546	−10.4078	2.0210
$qfiibuy_t$	5,386.30	4,130	31,415	151	4,513.78
$qfiisell_t$	4,675.17	3,601	44,000	74	4,027.41
$qfiibs_t$	711.11	372	19,408	−23772	3,171.87
$dicbuy_t$	3,191.66	2,924	14,980	192	1,643.79
$dicsell_t$	3,306.13	3,096	11,854	141	1,556.99
$dicbs_t$	−114.49	−120	10,070	−8,876	1,277.43
$rtfbuy_t$	1,814.00	1,418	10,972	49	1,433.95
$rtfsell_t$	1,837.15	1,504	18,024	32	1,384.79
$rtfbs_t$	−23.15	−36	6,379	−11,177	934.55

For variable definitions, see Table 17.2

$$\Delta e_t = (\log e_t - \log e_{t-1}) \times 100\%,$$
$$r_t = (\log p_t - \log p_{t-1}) \times 100\%$$

$$nasr_t = (\log nasp_t - \log nasp_{t-1}) \times 100\%$$

Net foreign purchases ($qfiibs_t$) are computed as the daily purchases ($qfiibuy_t$) less sales ($qfiisell_t$) of Taiwan stocks by foreigners. Similarly, net *dic* purchases ($dicbs_t$) are computed as the daily purchases ($dicbuy_t$) less sales ($dicsell_t$) of Taiwan stocks by *dic*, and net *rtf* purchases ($rtfbs_t$) are computed as the daily purchases ($rtfbuy_t$) less sales ($rtfsell_t$) of Taiwan stocks by *rtf*. The VAR analysis used here depends on whether the time series are stationary; hence, a unit root test is to be performed in advance to avoid spurious regression. The Phillips and Perron test is applied and the results are illustrated in Table 17.2.

The Phillips and Perron test results indicate that all time series are statistically significant at 1 % level. There is no further differencing needed before applying VAR. Table 17.3 presents the summary statistics for the time series used in this paper.

The average percentage change in the exchange rate on the daily basis is 0.011 %; the average daily TSE return is 0.0083 %; and the average daily NASDAQ return equals 0.0302 %. Overall, *qfii* are net purchasers on average and two other domestic institutional investors are net sellers of equity over the sample period, reflecting different trading strategies adopted by foreign and domestic institutional investors. Such distinct trading activities among institutional investors can also be seen in Fig. 17.1.

Figure 17.1 presents the cumulative net purchases and daily net purchases by *qfii*, *dic*, and *rtf* and how they are associated with the TSE returns, NASDAQ returns, and NT/USD exchange rate. Over the entire period, the cumulative net purchases by *qfii* suggest an upward trend in general, while those of *dic* and *rtf* tend to present a downward trend. Overall, the NASDAQ index is more volatile than the TSE index (1995/12/13 = 100), and it seems that there exists some correlation between the two indices. During the Asia financial crisis in 1997, the NT/USD exchange rate suffered a great upward swing (depreciation of New Taiwan Dollar) followed by a slight downward slide in 1999 and then rose again from 2002 onwards. Over the sample period, the volatility of net purchases by foreigners seemed to have increased since 2002. As for the relationship between net purchases by institutions and stock returns, no clear correlation could be detected as shown in Fig. 17.1. To grasp a better understanding on their linkages, the contemporaneous correlation of net purchases by the three types of institutional investors, stock returns, and currency returns are displayed in Table 17.4.

An inspection of Table 17.4 points out that returns on the NT/USD exchange rate (currency returns) are negatively correlated with both the TSE returns and net purchases by the three types of institutional investors, especially by foreign investors. Such relations are very much in line with the expectation. When stock prices rise following the influx of foreign capital, the local currency is expected to appreciate to a degree and as such negative correlations among them is expected. In addition, we find that returns on the TSE and NASDAQ are positively correlated. It is noteworthy that there exists a positive contemporaneous correlation between net purchases by the three types of institutional investors and the TSE returns with the correlation coefficients ranging from about 0.3 ($qfiibs_t$ and r_t) to 0.4419 ($rtfbs_t$ and r_t). In short, this finding largely echoes the previous results (e.g., Froot et al. 2001; Karolyi 2002).

The greatest correlation between institutional trading and NASDAQ returns is that of $rtfbs_t$ and $nasr_t$ at 0.0938 followed by $dicbs_t$ and $qfiibs_t$, respectively. Owing to the time difference, the TSE returns may be influenced by NASDAQ index returns. If $nasr_{t-1}$ is used instead, a higher correlations between $nasr_{t-1}$ and net purchases by institutions are found: 0.3441 for $qfiibs_t$, 0.2369 for $dicbs_t$, and 0.1428 for $rtfbs_t$, respectively. It implies that previous day's NASDAQ returns exert a greater impact on net purchases by each institutional investor in the TSE than do the current NASDAQ returns.

17.3 Lead-Lag Relation Among the Three Groups of Institutional Investors in the TSE

17.3.1 The Unrestricted VAR Model

Note that prices of many Taiwanese electronics securities are affected by the NASDAQ returns and hence foreign portfolio inflows may induce fluctuations of exchange rate. To investigate interactions emanated from the three types of institutional investors and the relationship between institutional trading activity and stock returns in Taiwan, we employ a six-variable VAR model using the NASDAQ returns ($nasr_t$), currency returns (Δe_t), TSE returns (r_t), net foreign purchases ($qfiibs_t$), net *dic* purchases ($dicbs_t$), and net *rtf* purchases ($rtfbs_t$) as the underlying variables. We attempt to answer the issues pertaining to (i) the interaction among trading activities of the three types of institutions and (ii) the relationship between stock returns and institutional trading. First, we propose a six-variable unrestricted VAR model shown below:

$$\begin{bmatrix} nasr_t \\ \Delta e_t \\ r_t \\ qfiibs_t \\ dicbs_t \\ rtfbs_t \end{bmatrix} = \begin{bmatrix} \phi_{11}(L) & \phi_{12}(L) & \phi_{13}(L) & \phi_{14}(L) & \phi_{15}(L) & \phi_{16}(L) \\ \phi_{21}(L) & \phi_{22}(L) & \phi_{23}(L) & \phi_{24}(L) & \phi_{25}(L) & \phi_{26}(L) \\ \phi_{31}(L) & \phi_{32}(L) & \phi_{33}(L) & \phi_{34}(L) & \phi_{35}(L) & \phi_{36}(L) \\ \phi_{41}(L) & \phi_{42}(L) & \phi_{43}(L) & \phi_{44}(L) & \phi_{45}(L) & \phi_{46}(L) \\ \phi_{51}(L) & \phi_{52}(L) & \phi_{53}(L) & \phi_{54}(L) & \phi_{55}(L) & \phi_{56}(L) \\ \phi_{61}(L) & \phi_{62}(L) & \phi_{63}(L) & \phi_{64}(L) & \phi_{65}(L) & \phi_{66}(L) \end{bmatrix} \times \begin{bmatrix} nasr_{t-1} \\ \Delta e_{t-1} \\ r_{t-1} \\ qfiibs_{t-1} \\ dicbs_{t-1} \\ rtfbs_{t-1} \end{bmatrix} + \begin{bmatrix} \varepsilon_{1t} \\ \varepsilon_{2t} \\ \varepsilon_{3t} \\ \varepsilon_{4t} \\ \varepsilon_{5t} \\ \varepsilon_{6t} \end{bmatrix} \quad (1)$$

where $\phi_{ij}(L)$ is the polynomial lag of the jth variable in the ith equation. To investigate the lead-lag relation among three types of institutional investors, we need to test the hypothesis that each off-diagonal element in the sub-matrix $\begin{bmatrix} \phi_{44}(L) & \phi_{45}(L) & \phi_{46}(L) \\ \phi_{54}(L) & \phi_{55}(L) & \phi_{56}(L) \\ \phi_{64}(L) & \phi_{65}(L) & \phi_{66}(L) \end{bmatrix}$ is zero.

On the other hand, to determine whether the TSE returns of the previous day lead net purchases by the three types of institutional investors, we test the hypothesis that each polynomial lag in the vector $[\,\phi_{43}(L)\phi_{53}(L)\phi_{63}(L)\,]'$ is zero. Conversely, if we want to determine whether previous day's net purchases by institutional investors lead current market returns, we test the hypothesis that each element in the vector $[\phi_{34}(L)\phi_{35}(L)\phi_{36}(L)]$ is zero. Before applying the VAR model, an appropriate lag structure needs to be specified. A 3-day lag is selected based on the Akaike information criterion (AIC). Table 17.5 presents the lead-lag relation among the six time series using block exogeneity tests.

The $\begin{bmatrix} \phi_{44}(L) & \phi_{45}(L) & \phi_{46}(L) \\ \phi_{54}(L) & \phi_{55}(L) & \phi_{56}(L) \\ \phi_{64}(L) & \phi_{65}(L) & \phi_{66}(L) \end{bmatrix}$ block represents the potential interaction among three types of institutional investors. The results indicate that net foreign purchases lead net *dic* purchases and the dynamic relationship between these two variables can be provided by the impulse response function (IRF) in Fig. 17.2a. Clearly, a one-unit standard error shock to net foreign purchases leads to an increase in net *dic* purchases, but this effect dissipates quickly by Period 2. Figure 17.2b, c indicate a feedback relation between net purchases by *qfii* and *rtf*. A one-unit standard error shock to net foreign purchases results in a positive response to net *rtf* purchases over the next two periods, which become negative in Period 3, followed by a positive response again after Period 4. Furthermore, a one-unit standard error shock to net *rtf* purchases also gives rise to an increase in net foreign purchases, which decays slowly over ten-period horizon.

Figure 17.2d shows that net purchases by *dic* lead net *rtf* purchases. A one-unit standard error shock to net *dic* purchases produces an increase in net *rtf* purchases in the first three periods and then declines thereafter. Overall, these impulse responses suggest that previous day's net foreign purchases exert a noticeable impact on net *rtf* purchases, while previous day's net *rtf* purchases also has an impact on net foreign purchases. It implies that not only do foreign capital flows affect the trading activity of domestic institutional investors but also the relation is not unidirectional. To be specific, there is a feedback relation between net *rtf* purchases and net foreign purchases.

As for the effect of the three types of institutional trading activity on stock returns in the TSE, Table 17.5 reveals that net *dic* purchases on previous day lead the TSE returns. We can also see in Fig. 17.2e that after Period 3, net *dic* purchases exert a negative (and thus destabilizing) effect on market returns, while the other two institutional investors do not have such an effect over the sample period. Examining the relationship between market returns and trading activity of the three types of institutional investors, we find that either the net foreign purchases or net *dic* purchases on previous trading day are affected by the previous day's TSE

Table 17.5 Results of Granger causality tests using the unrestricted VAR models

All	$nasr_t$	Δe_t	r_t	$qfiibs_t$	$dicbs_t$	$rtfbs_t$

$\sum_{i=1}^{3} rtfbs_{t-i}$	0.66 (0.88)	0.81 (0.85)	2.33 (0.51)	52.84^{*} (0.00)	0.85 (0.84)	

*, **, and *** denote statistical significance at 1 %, 5 %, and 10 % levels, respectively. Values in parentheses are p values. The optimal lag length of three is selected based on the Akaike information criterion

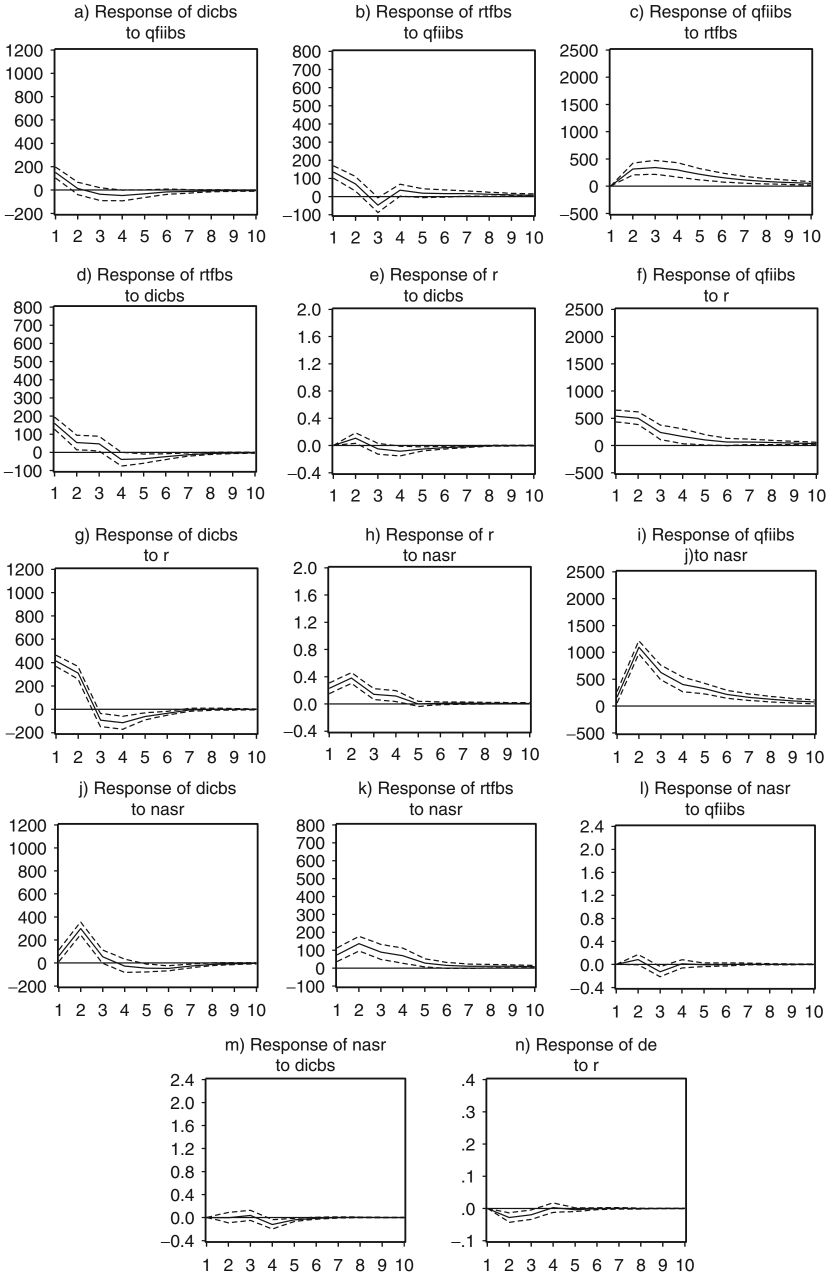

Fig. 17.2 Impulse responses to innovations in the unrestricted VAR models (up to ten periods). Notes: Solid lines represent response path and dotted lines are bands for the 95 % confidence interval around response coefficients. r, TSE returns; nasr, NASDAQ returns; de, exchange rate changes; qfiibs, net *qfii* purchases; dicbs, net *dic* purchases; rtfbs, net *rtf* purchases

returns. Moreover, the IRFs in Fig. 17.2f, g also reveal a significant positive relation between TSE returns and net foreign purchases up to four periods and a significant positive relation between TSE returns and net *dic* purchases for two periods, which becomes negative after Period 3. In other words, foreign investors in the TSE engage in positive-feedback trading, while those of the *dic* tend to change their strategy and adopt negative-feedback trading after Period 3.

On the other hand, Table 17.5 indicates that previous day's NASDAQ returns significantly affect both current TSE returns and net purchases by the three types of institutional investors. The impulse response in Fig. 17.2h–k also confirms that previous day's NASDAQ returns are positively related to both current returns and net purchases by these institutional investors, with the exception that a negative relation between net *dic* purchases and previous day's NASDAQ returns is found after Period 4. Such results are much in sync with the expectation since the largest sector that comprises the TSE-weighted stock index is the electronics industry to which many listed companies on NASDAQ have a strong connection. In addition, although previous day's net *qfii* and *dic* purchases also lead the NASDAQ returns, we find that no significant relation exists except for Period 4 with a significantly negative relation between them.

The liberalization of Taiwan's stock market has ushered in significant amount of short-term inflows and outflows of foreign capital, which have induced fluctuations in the exchange rate. As is seen from Table 17.5, the TSE returns lead currency returns and it appears that the initial significant effect of stock returns on currency returns is negative for the first three periods and then turns to be significantly positive thereafter (Fig. 17.2n). Given that foreign investors are positive-feedback traders, the capital inflows is expected to grow in order to increase their stakes in TSE securities when stock prices rise. Consequently, NT/USD is expected to appreciate.

17.3.2 The Structural VAR Model

The unrestricted VAR model does not consider the effect of current returns on net purchases by institutions. The prior study by Griffin et al. (2003) includes current returns in the institutional imbalance equation and finds a strong contemporaneous positive relation between institutional trading and stock returns.[6] Therefore, to further examine the relationship between institutional trading and stock returns, we introduce the current TSE returns (r_t) in the net purchases equations of the three types of institutional investors and reestimate the VAR model before conducting the corresponding block exogeneity tests. Table 17.6 presents the estimation results.

As indicated in the last row of Table 17.6, we find evidence of a strong contemporaneous correlation between current returns and net institutional

[6]The main purpose of this paper is to improve our understanding on the interaction among institutional investors and the relationship between institutional trading and stock returns. The following discussion will therefore focus on these two issues.

Table 17.6 Results of Granger causality tests using the structural VAR models

SVAR	$nasr_t$	Δe_t	r_t	$qfiibs_t$	$dicbs_t$	$rtfbs_t$
$\sum_{i=1}^{3} nasr_{t-i}$		5.23 (0.16)	103.73* (0.00)	265.94* (0.00)	54.67* (0.00)	6.75*** (0.08)
$\sum_{i=1}^{3} \Delta e_{t-i}$	2.77 (0.43)		2.66 (0.45)	1.85 (0.60)	7.06*** (0.07)	4.45 (0.22)
$\sum_{i=1}^{3} r_{t-i}$	1.26 (0.74)	20.63* (0.00)		98.84* (0.00)	264.71* (0.00)	75.05* (0.00)
$\sum_{i=1}^{3} qfiibs_{t-i}$	12.67* (0.01)	5.81 (0.12)	4.38 (0.22)		14.05* (0.00)	36.64* (0.00)

$\sum_{i=1}^{3} rtfbs_{t-i}$	0.66 (0.88)	0.81 (0.85)	2.33 (0.51)	50.56* (0.00)	0.83 (0.84)	
r_t				332.55* [10.91]	247.47* [18.10]	213.66* [21.43]

The structural VAR model includes current TSE returns in the institutional trading equations to take the contemporaneous correlations into consideration. See also Table 17.5 for definitions

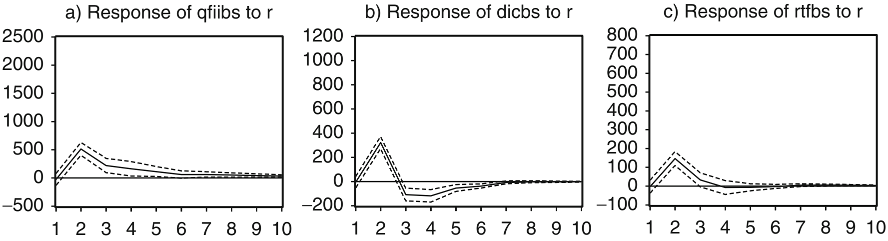

Fig. 17.3 Selected impulse responses to innovations up to ten periods in the structural VAR models. Notes: See also Fig. 17.2

purchases, which confirms the finding by the previous research. Moreover, as shown in Table 17.5, we find no evidence that past returns lead net *rtf* purchases when the unrestricted VAR model is used. In contrast to it, when the contemporaneous impact of stock returns on net institutional purchases is considered, we find that past returns also lead net *rtf* purchases as well as net purchases by *qfii* and *dic* when the structural VAR model is used (Table 17.6). In other words, net purchases by the three types of institutions are affected by past stock returns as was evidenced by previous studies. The corresponding impulse response relations are presented in Fig. 17.3.

Comparing the impulse response relations in Figs. 17.2 and 17.3, it is clear that when the impact of current returns on net institutional purchases is considered, a one-unit standard error shock from r_t does not produce a positive impulse response in institutional trading until Period 2.[7] The responses of foreign investors are rather distinct from those of domestic institutional investors after Period 3. In general, a sustained positive response from foreign investors is observed, while a negative response is witnessed for *dic* and sometimes, an insignificant response for *rtf* manifests itself after Period 3.

17.3.3 The Threshold VAR Analysis

We pool all the data together when estimating either the unrestricted or restricted VAR model; however, the trading activity of institutional investors may depend on whether stock prices rise or fall.[8] A small economy like Taiwan also depends to a large degree on the sign of NASDAQ index returns. Consequently, to investigate institutional trading under distinct regimes based on market returns, we use the multivariate threshold autoregression (MVTAR) model proposed by Tsay (1998)

[7]Figure 17.2f, g show significantly positive responses of $qfiibs_t$ and $dicbs_t$ to r_t in Period 1 if the impact of current returns is not considered.

[8]Recall that both the positive-feedback and negative-feedback trading are associated with the sign of market returns on the previous trading day.

Table 17.7 The $C(d)$ statistic

Threshold variable	Statistic
$nasr_{t-1}$	195.08 (0.00)
r_{t-1}	136.22 (0.08)

Values in parentheses are p values. The delay (d) is assumed to be one

to test the relevant hypotheses. Let $\mathbf{y}_t = [nasr_t,\ \Delta e_t,\ r_t,\ qfiibs_t,\ dicbs_t,\ rtfbs_t]'$ be a 6×1 vector and the MVTAR model can be described as

$$\mathbf{y}_t = \left(\phi_{0,1} + \sum_{i=1}^{p} \phi_{i,1} y_{t-i}\right) \cdot [1 - I(z_{t-d} > c)] + \left(\phi_{0,2} + \sum_{i=1}^{p} \phi_{i,2} y_{t-i}\right) \cdot I(z_{t-d} > c) + \varepsilon_t \tag{2}$$

where $E(\varepsilon) = 0$, $E(\varepsilon\varepsilon') = \mathbf{\Sigma}$, and $I(\cdot)$ is an index function, which equals 1 if the relation in the bracket holds. It equals zero otherwise. z_{t-d} is the threshold variable with a delay (lag) d.

In order to explore whether institutional trading activity would change during different domestic and foreign market return scenarios, the potential threshold variables used are r_{t-1} and $nasr_{t-1}$.[9] Before estimating Eq. 2, we need to test for possible potential nonlinearity (threshold effect) in this equation. Tsay (1998) suggests using the arranged regression concept to construct the $C(d)$ statistic to test the hypothesis $H_o{:}\phi_{i,1} = \phi_{i,2}$, $i = 0, \ldots p$. If H_0 can be rejected, it implies that there exists the nonlinearity in data with z_{t-d} as the threshold variable. Tsay (1998) proves that $C(d)$ is asymptotically a chi-square random variable with $k(pk + 1)$ degrees of freedom, where p is the lag length of the VAR model and k is the number of endogenous variables y_t.[10] Table 17.7 presents the estimation results of the $C(d)$ statistic.

As shown in Table 17.7, the null hypothesis H_0 is rejected using either past returns on the TSE or NASDAQ, suggesting that our data exhibit nonlinear threshold effect. Theoretically, one needs to rearrange the regression based on the size of the threshold variable z_{t-d} before applying a grid search method to find the optimal threshold value c^*. Nonetheless, our goal is to know whether the institutional trading behavior depends on the sign of market returns, as such the threshold is set to zero in a rather arbitrary way.[11] Table 17.8 lists the results of block

[9] Here, we assume that net purchases by institutions are only affected by market returns on the previous trading day.

[10] For more details see Tsay (1998).

[11] A previous study by Sadorsky (1999) also splits data into two regimes based on the sign of the variable to discuss whether variables used would change their behaviors under different regimes.

Table 17.8 Results of Granger causality tests using the MVTAR models with threshold variable r_{t-1}

The results are premised on the condition that when previous day's TSE returns are positive. See also Table 17.5

exogeneity tests for the lead-lag relation in the $r_{t-1} < 0$ and $r_{t-1} \geq 0$ regimes, respectively.

The interaction among institutional investors is depicted in Table 17.8: Current net purchases by foreign investors affect that by domestic institutions when previous day's TSE returns are negative. Note that no such relation is evidenced when previous day's TSE returns are positive. A feedback relation between *rtf* and *qfii* is observed when r_{t-1} is positive or negative. However, *dic* is found to lead *rtf* only when r_{t-1} is positive. Such results reveal different institutional trading strategies under distinct return regimes. The demonstration effect – previous day's net foreign purchases have on domestic institutions using the unrestricted VAR model – seems to surface only when previous day's market returns are negative. Therefore, it may produce misleading results if we fail to consider the sign of previous returns.

The impulse responses in Fig. 17.4 illustrate that the responses of *dic* and *rtf* from the *qfii* shock are quite similar to the ones in Fig. 17.2f, g.[12] As for the impact of previous day's market returns on current net purchases by institutions, it can be shown via the MVTAR model that market returns lead net purchases by *qfii* and *dic* when previous day's market returns are negative, which is consistent with the finding using the one-regime VAR model. When previous day's market returns are positive, market returns lead net purchases by the *dic* only. Obviously, returns have more influence on net institutional purchases when previous day's returns were negative. In addition, we find that net *dic* purchases on the previous day may affect current returns when the one-regime VAR model is used. Actually, the MVTAR analysis reveals that such a relation emerges only when previous day's market returns are positive. The impulse responses depicted in Fig. 17.4 (Panel B) demonstrate that a one-unit standard error shock to net *dic* purchases produces an increase in market returns in Period 2, and then they turns to be negative after Period 4, a result similar to those using the one-regime VAR model.

Among the listed companies on the TSE, the electronics sector has the largest market share, which accounts for more than 60 % of all trades. This being the case, Taiwan's stock market is closely related to the NASDAQ index as is evidenced using the conventional VAR model. To further investigate whether the interaction among institutions and the relationship between institutional trading and stock returns are affected by the sign of previous day's NASDAQ index return, $nasr_{t-1}$ is used as the threshold variable. That is, block Granger causality tests are performed by splitting our data into two regimes based on the sign of the variable $nasr_{t-1}$. Table 17.9 reports the results.

The results indicate that net *qfii* purchases lead to that of two domestic institutional investors regardless of the sign of previous day's NASDAQ returns. Moreover, when $nasr_{t-1} < 0$, net *rtf* purchases lead net *qfii* purchases, which is in line with that using the one-regime VAR model. However, when $nasr_{t-1} \geq 0$, the net purchases by either *dic* or *rtf* lead net *qfii* purchases, and net *qfii* purchases lead net purchases by either *dic* or *rtf*. In other words, we find strong evidence of a feedback

[12]To economize space, only relevant impulse responses are presented here; the remaining are available upon request.

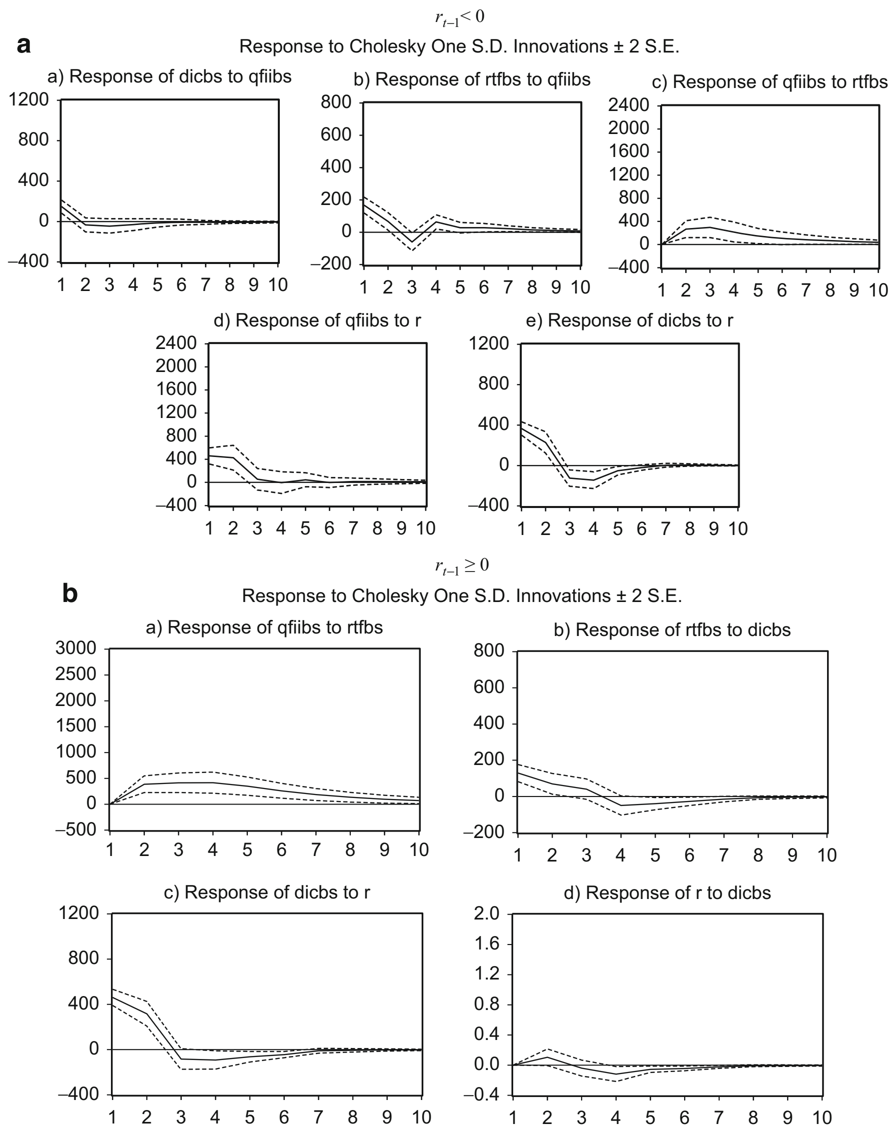

Fig. 17.4 Selected impulse responses to innovations up to ten periods in the MVTAR models. (**a**) $r_{t-1} < 0$, (**b**) $r_{t-1} \geq 0$. Notes: See also Fig. 17.2

relation between net foreign purchases and two domestic net purchases when previous day's NASDAQ returns are positive. The results pertaining to the impact of previous day's returns on institutional trading parallel those using the unrestricted VAR model: Previous day's returns have an impact on the net purchases by *qfii* and *dic*, but not on net purchases by *rtf* regardless of the sign of previous day's NASDAQ returns. As for the impact of net institutional purchases

The results are premised on the condition that when previous day's NASDAQ returns are positive. See also Table 17.5

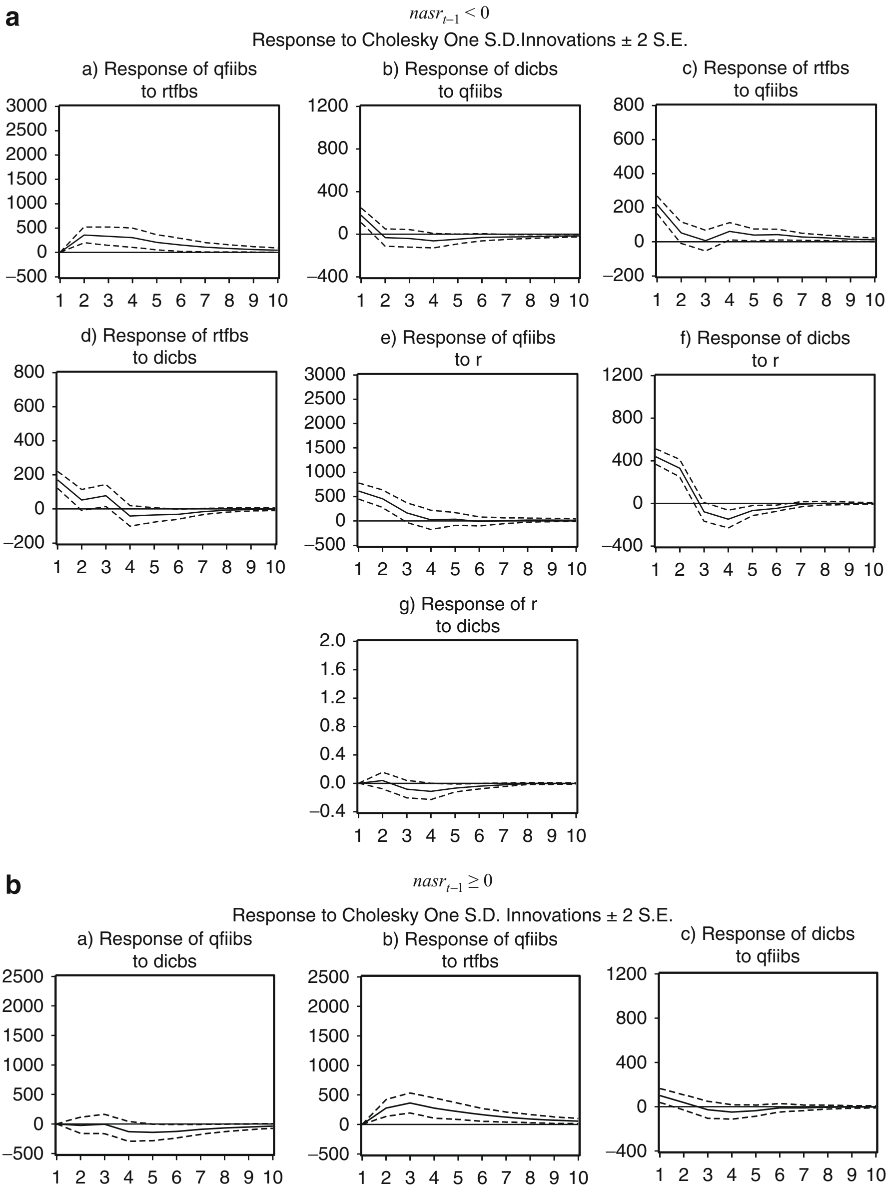

Fig. 17.5 (continued)

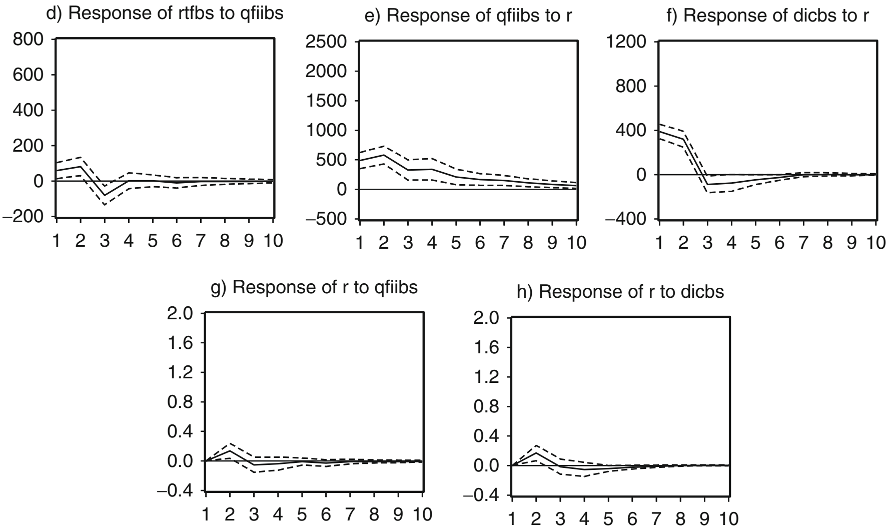

Fig. 17.5 Impulse responses to innovations up to ten periods in the MVTAR models (portion). (**a**) $nasr_{t-1} < 0$, (**b**) $nasr_{t-1} \geq 0$. Notes: See also Fig. 17.2

on previous day's stock returns, only net *dic* purchases still lead stock returns when $nasr_{t-1} < 0$, as was the case in the one-regime model. However, we find that net *qfii* purchases also lead stock returns when $nasr_{t-1} \geq 0$.

The results from Panel B of Fig. 17.5g indicate that a one-unit standard error shock from net *qfii* purchases made on previous days produces a positive response to stock returns in Period 2, but no significantly negative responses are found during other periods. The results of the MVTAR model also capture the phenomenon in the one-regime model: Net *dic* purchases exert a negative impact on market returns. However, such an effect is witnessed when previous day's NASDAQ returns are negative.

17.4 Conclusion

In this paper we investigate whether the trading behavior of foreign investors leads that of Taiwanese institutional investors (i.e., the demonstration effect) and whether institutional trading has a destabilizing effect on the stock market. The reason we select Taiwan in our study is due to her unique role of being gradually opened up to foreign investment and her high stock returns volatility. To provide more information to these issues, this paper has constructed a six-variable VAR model including trading activities of three types of institutional investors, the TSE returns, NASDAQ returns, and currency returns so as to examine the interaction and the dynamic relationship between institutional trading and stock returns using daily data from December 13, 1995 to May 13, 2004.

The results from the conventional unrestricted VAR model indicate that net purchases by foreign investors lead those by domestic institutions (and thus the demonstration effect), while net purchases by *rtf* also lead those by foreign investors. That is, there exists a feedback relation between them. As for the relationship between institutional trading and stock returns, we find that except for *rtf*, both foreign and *dic* net purchases are positively affected by previous day's TSE returns. That is, both the *qfii* and *dic* engage in positive-feedback trading. We also find that previous day's net *dic* purchases first produce a positive and then a negative impact on stock returns. Furthermore, we employ a structural VAR model with the contemporaneous returns included in the three net institutional purchase equations. A comparison of the structural and unrestricted VAR models suggests that the TSE returns positively lead net *rtf* purchases using the structural VAR model, which cannot be observed when the unrestricted VAR model is used. In other words, if the contemporaneous relation between returns and net institutional purchases is taken into account, we find that *rtf* are also positive-feedback traders.

On the other hand, the sign of market returns does affect trading activities of the institutions. As a result, this paper makes use of the MVTAR model introduced by Tsay (1998). By splitting data into two regimes based on the sign of both TSE and NASDAQ returns on the previous trading day, we find that the demonstration effect that foreign investors have on domestic institutions arises only when previous day's TSE returns are negative. In addition, when previous day's TSE returns are negative, stock returns lead both net purchases by *qfii* and *dic*. However, stock returns lead only net *dic* purchases when previous day's TSE returns are positive. Finally, we find the relation that net *dic* purchases lead market returns using the unrestricted VAR model tends to emerge only when previous day's TSE returns are positive.

As for the effect of NASDAQ returns on institutional trading, the results from this paper suggest that when previous day's NASDAQ returns are positive, a feedback relation between net foreign purchases and net domestic purchases prevails. Moreover, it is found that the net *dic* purchases lead the TSE returns, as do the net foreign purchases. The latter, however, exert a positive influence on the TSE returns.

In summary, our results suggest that net foreign purchases do lead net domestic purchases, but more details manifest when the threshold model is applied. When previous day's TSE returns are negative (or previous day's NASDAQ returns are positive), a feedback relation between net foreign purchases and net domestic purchases is observed. It implies that the widespread argument that foreign investors have a demonstration effect on domestic institutions in Taiwan is not entirely correct. In examining the relation between market returns and institutional trading, we find that market returns at least lead net purchases by both *qfii* and *dic* in most cases. Market returns also lead net *rtf* purchases if the relationship of contemporaneous returns and institutional trading is considered. Our analysis also indicates that net *dic* purchases lead market returns and are negatively associated with market returns in Period 4. The results of the MVTAR model suggest that when previous day's NASDAQ returns are positive, net foreign purchases positively lead stock returns and thus will not exert a destabilizing influence on the market.

Appendix 1

The Unrestricted VAR Model

The prices of many Taiwanese electronics securities are affected by the NASDAQ returns and hence foreign portfolio inflows may induce fluctuations of exchange rate. To investigate interactions emanated from the three types of institutional investors and the relationship between institutional trading activity and stock returns in Taiwan, we employ a six-variable VAR model using the NASDAQ returns ($nasr_t$), currency returns (Δe_t), TSE returns (r_t), net foreign purchases ($qfiibs_t$), net *dic* purchases ($dicbs_t$), and net *rtf* purchases ($rtfbs_t$) as the underlying variables. We attempt to answer the issues pertaining to (i) the interaction among trading activities of the three types of institutions and (ii) the relationship between stock returns and institutional trading. First, we propose a six-variable unrestricted VAR model shown below:

$$\begin{bmatrix} nasr_t \\ \Delta e_t \\ r_t \\ qfiibs_t \\ dicbs_t \\ rtfbs_t \end{bmatrix} = \begin{bmatrix} \phi_{11}(L) & \phi_{12}(L) & \phi_{13}(L) & \phi_{14}(L) & \phi_{15}(L) & \phi_{16}(L) \\ \phi_{21}(L) & \phi_{22}(L) & \phi_{23}(L) & \phi_{24}(L) & \phi_{25}(L) & \phi_{26}(L) \\ \phi_{31}(L) & \phi_{32}(L) & \phi_{33}(L) & \phi_{34}(L) & \phi_{35}(L) & \phi_{36}(L) \\ \phi_{41}(L) & \phi_{42}(L) & \phi_{43}(L) & \phi_{44}(L) & \phi_{45}(L) & \phi_{46}(L) \\ \phi_{51}(L) & \phi_{52}(L) & \phi_{53}(L) & \phi_{54}(L) & \phi_{55}(L) & \phi_{56}(L) \\ \phi_{61}(L) & \phi_{62}(L) & \phi_{63}(L) & \phi_{64}(L) & \phi_{65}(L) & \phi_{66}(L) \end{bmatrix}$$

$$\times \begin{bmatrix} nasr_{t-1} \\ \Delta e_{t-1} \\ r_{t-1} \\ qfiibs_{t-1} \\ dicbs_{t-1} \\ rtfbs_{t-1} \end{bmatrix} + \begin{bmatrix} \varepsilon_{1t} \\ \varepsilon_{2t} \\ \varepsilon_{3t} \\ \varepsilon_{4t} \\ \varepsilon_{5t} \\ \varepsilon_{6t} \end{bmatrix}$$

Where $\phi_{ij}(L)$ is the polynomial lag of the *j*th variable in the *i*th equation. To investigate the lead-lag relation among three types of institutional investors, we need to test the hypothesis that each off-diagonal element in the sub-matrix $\begin{bmatrix} \phi_{44}(L) & \phi_{45}(L) & \phi_{46}(L) \\ \phi_{54}(L) & \phi_{55}(L) & \phi_{56}(L) \\ \phi_{64}(L) & \phi_{65}(L) & \phi_{66}(L) \end{bmatrix}$ is zero.

On the other hand, to determine whether the TSE returns of the previous day lead net purchases by the three types of institutional investors, we test the hypothesis that each polynomial lag in the vector $[\phi_{43}(L)\phi_{53}(L)\phi_{63}(L)]'$ is zero. Conversely, if we want to determine whether previous day's net purchases by institutional investors lead current market returns, we test the hypothesis that each element in the vector $[\phi_{34}(L)\phi_{35}(L)\phi_{36}(L)]$ is zero. Before applying the VAR model, an appropriate lag structure needs to be specified. A 3-day lag is selected based on the Akaike information criterion (AIC). Table 17.5 presents the lead-lag relation among the six time series using block exogeneity tests.

The $\begin{bmatrix} \phi_{44}(L) & \phi_{45}(L) & \phi_{46}(L) \\ \phi_{54}(L) & \phi_{55}(L) & \phi_{56}(L) \\ \phi_{64}(L) & \phi_{65}(L) & \phi_{66}(L) \end{bmatrix}$ block represents the potential interaction among three types of institutional investors. The results indicate that net foreign purchases lead net *dic* purchases and the dynamic relationship between these two variables can be provided by the impulse response function (IRF) in Fig. 17.2a. Clearly, a one-unit standard error shock to net foreign purchases leads to an increase in net *dic* purchases, but this effect dissipates quickly by Period 2. Figure 17.2b, c indicate a feedback relation between net purchases by *qfii* and *rtf*. A one-unit standard error shock to net foreign purchases results in a positive response to net *rtf* purchases over the next two periods, which become negative in Period 3, followed by a positive response again after Period 4. Furthermore, a one-unit standard error shock to net *rtf* purchases also gives rise to an increase in net foreign purchases, which decays slowly over ten-period horizon.

Figure 17.2d shows that net purchases by *dic* lead net *rtf* purchases. A one-unit standard error shock to net *dic* purchases produces an increase in net *rtf* purchases in the first three periods and then declines thereafter. Overall, these impulse responses suggest that previous day's net foreign purchases exert a noticeable impact on net *rtf* purchases, while previous day's net *rtf* purchases also has an impact on net foreign purchases. It implies that not only do foreign capital flows affect the trading activity of domestic institutional investors but also the relation is not unidirectional. To be specific, there is a feedback relation between net *rtf* purchases and net foreign purchases.

As for the effect of the three types of institutional trading activity on stock returns in the TSE, Table 17.5 reveals that net *dic* purchases on previous day lead the TSE returns. We can also see in Fig. 17.2e that after Period 3, net *dic* purchases exert a negative (and thus destabilizing) effect on market returns, while the other two institutional investors do not have such an effect over the sample period. Examining the relationship between market returns and trading activity of the three types of institutional investors, we find that either the net foreign purchases or the net *dic* purchases on previous trading day are affected by the previous day's TSE returns. Moreover, the IRFs in Fig. 17.2f, g also reveal a significant positive relation between TSE returns and net foreign purchases up to four periods and a significant positive relation between TSE returns and net *dic* purchases for two periods, which becomes negative after Period 3. In other words, foreign investors in the TSE engage in positive-feedback trading, while those of the *dic* tend to change their strategy and adopt negative-feedback trading after Period 3.

Table 17.5 indicates that previous day's NASDAQ returns significantly affect both current TSE returns and net purchases by the three types of institutional investors. The impulse response in Fig. 17.2h–k also confirms that previous day's NASDAQ returns are positively related to both current returns and net purchases by these institutional investors, with the exception that a negative relation between net *dic* purchases and previous day's NASDAQ returns is found after Period 4.

Such results are much in sync with the expectation since the largest sector that comprises the TSE-weighted stock index is the electronics industry to which many listed companies on NASDAQ have a strong connection. In addition, although previous day's net *qfii* and *dic* purchases also lead the NASDAQ returns, we find that no significant relation exists except for Period 4 with a significantly negative relation between them (Figs. 17.1 and 17.2).

The liberalization of Taiwan's stock market has ushered in significant amount of short-term inflows and outflows of foreign capital, which have induced fluctuations in the exchange rate. As is seen from Table 17.5, the TSE returns lead currency returns and it appears that the initial significant effect of stock returns on currency returns is negative for the first three periods and then turns to be significantly positive thereafter (Fig. 17.2n). Given that foreign investors are positive-feedback traders, the capital inflows is expected to grow in order to increase their stakes in TSE securities when stock prices rise. Consequently, NT/USD is expected to appreciate.

The Structural VAR Model

The unrestricted VAR model does not consider the effect of current returns on net purchases by institutions. The prior study by Griffin et al. (2003) includes current returns in the institutional imbalance equation and finds a strong contemporaneous positive relation between institutional trading and stock returns. Therefore, to further examine the relationship between institutional trading and stock returns, we introduce the current TSE returns (r_t) in the net purchases equations of the three types of institutional investors and reestimate the VAR model before conducting the corresponding block exogeneity tests. Table 17.6 presents the estimation results.

As indicated in the last row of Table 17.6, we find evidence of a strong contemporaneous correlation between current returns and net institutional purchases, which confirms the finding by the previous research. As shown in Table 17.5, we find no evidence that past returns lead net *rtf* purchases when the unrestricted VAR model is used. When the contemporaneous impact of stock returns on net institutional purchases is considered, we find that past returns also lead net *rtf* purchases as well as net purchases by *qfii* and *dic* when the structural VAR model is used (Table 17.6). In other words, net purchases by the three types of institutions are affected by past stock returns as was evidenced by previous studies. The corresponding impulse response relations are presented in Fig. 17.3.

Comparing the impulse response relations in Figs. 17.2 and 17.3, it is clear that when the impact of current returns on net institutional purchases is considered, a one-unit standard error shock from r_t does not produce a positive impulse response in institutional trading until Period 2. The responses of foreign investors are rather distinct from those of domestic institutional investors after Period 3. In general, a sustained positive response from foreign investors is observed, while a negative response is witnessed for *dic* and sometimes, an insignificant response for *rtf* manifests itself after Period 3.

The Threshold VAR Analysis

We pool all the data together when estimating either the unrestricted or restricted VAR model; however, the trading activity of institutional investors may depend on whether stock prices rise or fall. A small economy like Taiwan also depends to a large degree on the sign of NASDAQ index returns. Consequently, to investigate institutional trading under distinct regimes based on market returns, we use the multivariate threshold autoregression (MVTAR) model proposed by Tsay (1998) to test the relevant hypotheses. Let $\mathbf{y}_t = [nasr_t, \Delta e_t, r_t, qfiibs_t, dicbs_t, rtfbs_t]'$ be a 6×1 vector and the MVTAR model can be described as

$$\begin{aligned}\mathbf{y}_t = &\left(\phi_{0,1} + \sum_{i=1}^{p} \phi_{i,1} y_{t-i}\right) \cdot [1 - I(z_{t-d} > c)] \\ &+ \left(\phi_{0,2} + \sum_{i=1}^{p} \phi_{i,2} y_{t-i}\right) \cdot I(z_{t-d} > c) + \varepsilon_t\end{aligned}$$

where $E(\varepsilon) = 0$, $E(\varepsilon\varepsilon') = \mathbf{\Sigma}$, and $I(\cdot)$ is an index function, which equals 1 if the relation in the bracket holds. It equals zero otherwise. z_{t-d} is the threshold variable with a delay (lag) d.

In order to explore whether institutional trading activity would change during different domestic and foreign market return scenarios, the potential threshold variables used are r_{t-1} and $nasr_{t-1}$. Before estimating Eq. 2, we need to test for possible potential nonlinearity (threshold effect) in this equation. Tsay (1998) suggests using the arranged regression concept to construct the $C(d)$ statistic to test the hypothesis H_o:$\phi_{i,1} = \phi_{i,2}$, $i = 0, \ldots p$. If H_0 can be rejected, it implies that there exists the nonlinearity in data with z_{t-d} as the threshold variable. Tsay (1998) proves that $C(d)$ is asymptotically a chi-square random variable with $k(pk + 1)$ degrees of freedom, where p is the lag length of the VAR model and k is the number of endogenous variables $\mathbf{y}_t$. Table 17.7 presents the estimation results of the $C(d)$ statistic.

As shown in Table 17.7, the null hypothesis H_0 is rejected using either past returns on the TSE or NASDAQ, suggesting that our data exhibit nonlinear threshold effect. Theoretically, one needs to rearrange the regression based on the size of the threshold variable z_{t-d} before applying a grid search method to find the optimal threshold value c^*. Nonetheless, our goal is to know whether the institutional trading behavior depends on the sign of market returns, as such the threshold is set to zero in a rather arbitrary way. Table 17.8 lists the results of block exogeneity tests for the lead-lag relation in the $r_{t-1} < 0$ and $r_{t-1} \geq 0$ regimes, respectively.

The interaction among institutional investors is depicted in Table 17.8: Current net purchases by foreign investors affect that by domestic institutions when previous day's TSE returns are negative. Note that no such relation is evidenced when previous day's TSE returns are positive. A feedback relation between *rtf* and *qfii* is observed when r_{t-1} is positive or negative. However, *dic* is found to lead *rtf* only when r_{t-1} is positive. Such results reveal different institutional trading strategies under distinct return regimes. The demonstration effect – previous day's net foreign purchases have on domestic institutions using the unrestricted VAR model – seems to surface only when previous day's market returns are negative. Therefore, it may produce misleading results if we fail to consider the sign of previous returns.

The impulse responses in Fig. 17.4 illustrate that the responses of *dic* and *rtf* from the *qfii* shock are quite similar to the ones in Fig. 17.2f, g. As for the impact of previous day's market returns on current net purchases by institutions, it can be shown via the MVTAR model that market returns lead net purchases by *qfii* and *dic* when previous day's market returns are negative, which is consistent with the finding using the one-regime VAR model. When previous day's market returns are positive, market returns lead net purchases by the *dic* only. Obviously, returns have more influence on net institutional purchases when previous day's returns were negative. In addition, we find that net *dic* purchases on the previous day may affect current returns when the one-regime VAR model is used. Actually, the MVTAR analysis reveals that such a relation emerges only when previous day's market returns are positive. The impulse responses depicted in Fig. 17.4 (Panel B) demonstrate that a one-unit standard error shock to net *dic* purchases produces an increase in market returns in Period 2, and then they turns to be negative after Period 4, a result similar to those using the one-regime VAR model.

To further investigate whether the interaction among institutions and the relationship between institutional trading and stock returns are affected by the sign of previous day's NASDAQ index return, $nasr_{t-1}$ is used as the threshold variable. That is, block Granger causality tests are performed by splitting our data into two regimes based on the sign of the variable $nasr_{t-1}$. Table 17.9 reports the results.

The results indicate that net *qfii* purchases lead that of two domestic institutional investors regardless of the sign of previous day's NASDAQ returns. Moreover, when $nasr_{t-1} < 0$, net *rtf* purchases lead net *qfii* purchases, which is in line with that using the one-regime VAR model. However, when $nasr_{t-1} \geq 0$, the net purchases by either *dic* or *rtf* lead net *qfii* purchases, and net *qfii* purchases lead net purchases by either *dic* or *rtf*. In other words, we find strong evidence of a feedback relation between net foreign purchases and two domestic net purchases when previous day's NASDAQ returns are positive. The results pertaining to the impact of previous day's returns on institutional trading parallel those using the unrestricted VAR model: Previous day's returns have an impact on the net purchases by *qfii* and *dic*, but not on net purchases by *rtf* regardless of the sign of previous day's NASDAQ returns. As for the impact of net institutional purchases on previous day's stock returns, only net *dic* purchases still lead stock returns when $nasr_{t-1} < 0$, as was the case in the one-regime model. However, we find that net *qfii* purchases also lead stock returns when $nasr_{t-1} \geq 0$.

Methods of Denoising Financial Data 18

Thomas Meinl and Edward W. Sun

Contents

Abstract

Denoising analysis imposes new challenges for financial data mining due to the irregularities and roughness observed in financial data, particularly, for instantaneously collected massive amounts of tick-by-tick data from financial markets for information analysis and knowledge extraction. Inefficient decomposition of the systematic pattern (the trend) and noises of financial data will lead to erroneous conclusions since irregularities and roughness of the financial data make the application of traditional methods difficult.

In this chapter, we provide a review to discuss some methods applied for denoising analysis of financial data.

18.1 Introduction

Technical developments allow corporations and organizations to instantaneously collect massive amounts of data, particularly the tick-by-tick data from financial markets. Mining financial data turns to be the foundation for financial informatics and stimulates the research interest in analyzing information conveyed at different frequencies in this data. Financial data have the complex structure of irregularities and roughness that are caused by a large number of instantaneous changes of the markets and trading noises. The noises conveyed in the financial data usually illustrate heavy tailedness, that is, the underlying time series data exhibits a large number of occasional jumps. Ignoring these irregularities can easily lead to erroneous conclusions for data mining and statistical modeling. As consequence, the statistical data mining methods (or models) require a denoising algorithm to clean the data in order to obtain more significant results (see Sun and Meinl (2012)).

Most data cleaning methods focus only on a known type of irregularity. In financial data, the irregularity is manifold, that is, the irregularity varies along with time and changes with different measuring scales (see Fan and Yao (2003) and Sun et al. (2008)). Finding an effective denoising algorithm turns out to be the initial task of financial data mining (see Au et al. (2010) and Meinl and Sun (2012)).

In this chapter we will outline the classic and newly established methods for the denoising analysis (trend extraction) of financial data analysis. We talk about different approaches and a respective classification of them. Based on this classification we focus on nonparametric methods (i.e., linear and nonlinear filters) and examine their pros and cons.

18.2 Denoising (Trend Extraction) of Financial Data

There is no universal definition of *trend* which applies to all application in different fields, and it is generally accepted that a trend is a slowly evolving component that is the main driving force for long-term development beneath the system. Pollock (2001) characterizes trend as being limited to certain low frequencies of the data. This notion excludes any noisy influences and fluctuations from higher frequency levels. However, this notion of trends is not satisfactory for many financial data we encounter in practice.

Some theoretical models (like the Black-Scholes model) do not incorporate aspects like seasonalities or even jumps; they are still widely used today in practice, assuming perfect division between the trend and stochastic fluctuations. It is insufficient for many financial data we measure today, especially, when considering trends over longer time horizon, we perceive significant jumps or steep slopes which cannot be attributed to be part of the persistent stochastic noise. Another example we can observe in electricity markets, where it has been found that jumps occur on such a regular basis that is has been found reasonable to model these by specific stochastic processes; see Seifert and Uhrig-Homburg (2007). These patterns contradict the slow evolving characteristic and the low-frequency notion generally associated with trends and have been considered as an inherent part of them.

A basic model (among others proposed by Fan and Yao (2003)) is stated as follows. Given a time series X_t, $t \geq 0$, this series can be decomposed into

$$X_t = \vartheta_t + s_t + Y_t, \tag{18.1}$$

where ϑ_t represents a *slowly varying function known as trend component*, s_t a single of combination of periodic functions (i.e., seasonal components), and Y_t the stochastic component, assumed to be stationary.

A trend is a mostly slow (in respect to the noise) evolving pattern in a time series, with its driving force not being attributed to any noise present in the signal. Trends may also exhibit edged frontiers (i.e., jumps and sudden regime changes) as well as steep slopes, roofs, and valleys (see Joo and Qiu (2009)), as long as these patterns can be contributed to the long-term dynamics of the time series and do not stem from the noise component responsible for short-term variations.

We note that trend must always be interpreted in respect to the time series at hand (i.e., the period coverage of the financial data) and the goal of the data analysis, that is, on which scale the trend and the noise are relevant. We ignore any distinction between long-, intermediate-, and short-term trends and/or seasonalities, as these usually depend on the context of the financial data.

The question that may now arise is if we consider a trend ϑ to be specified according to Eq. 18.1, how does this agree with the notion that the trend may also exhibit jumps, which clearly contradict this definition? Without going further into this, we only note that this kind of trend would require a different (and more accurate) definition of how trend is to be defined in a time series, than the generally accepted notion in today's literature. While we will not propose a new definition either and leave this task to others, we can point out how jumps enter the trend.

As pointed out by, for example, Tsay (2005), jumps in financial time series data, and particularly in high-frequency data, are attributed to external events, like the increase or drop in interest rates by some governmental financial institution. These events can be considered to happen only occasionally and are very sparse in relation to the frequency the data is measured, that is, the amount of data exhibiting no jumps at all. In the field of high-frequency financial data analysis, jumps are thus assumed to be extreme events that happen with low probability but form nevertheless part of the stochastic distribution and must be considered to be modeled there. Thus, Y will be modeled either by stochastic processes including jump components (see, e.g., Seifert and Uhrig-Homburg (2007)) or by a distribution itself, depending on the model. Such a distribution for high-frequency financial data has then found to be heavy tailed, that is, jumps happen with enough regularity that they cannot simply be discarded as nonrecurring events; see, for example, Rachev (2003).

However, as these extreme events can have an enormous impact on the stochastic variance analysis and its succeeding usage, and furthermore could lead to misleading results in the regions of the signal without any jumps, it is generally preferred to include them into the trend component ϑ rather than the stochastic component Y.

In, for example, Wang (1995), a definition of an α-cusp in a continuous function f at x_0 is given, that is, if there exists an $\varepsilon > 0$ so that

$$|f(x_0 + h) - f(x_0)| \geq K|h|^{\alpha} \tag{18.2}$$

holds for all $h \in [x_0 - \varepsilon, x_0 + \varepsilon]$. For $\alpha = 0$, f is said to have a jump at x_0. It is commonly agreed that the jump should significantly differ from the other fluctuations (i.e., the noise) in the signal. As said above, jumps are just one particular pattern of extreme events we are interested in. Others are steep slopes, roofs, and valleys, which in Joo and Qiu (2009) are defined by at this point having a jump in the first-order derivative of the regression curve.

Other extreme events frequently occurring in many practical applications are spikes and outliers. However, these are usually undesirable features that should not be included in the trend of affect it by any means. This is due to the following reasons. First, in many cases, these outliers or spikes consist only of one or very few points often caused by measurement errors, and it is obvious that they were caused by some factor that plays no vital role in the ongoing time series analysis (unless the focus is on what caused these outliers). Second, while jumps imply a permanent change in the whole time series, outliers do not contribute to this. While we are aware that the distinction between a few (adjacent) outliers and roofs/valleys is not precise, from the context of the time series in most cases, it is evident whether an occurrence should be considered as an outlier that is to be neglected or a significant feature to be included in the trend.

In this work we only consider homogeneous financial time series data. However, in many applications and particularly for high-frequency financial time series data, this data is initially irregularly spaced. Homogeneity in this context means that for a given series X_t, $t \in \mathrm{N}$, holds $t + 1 - t = c$, with a constant $c > 0$, that is, all time steps are equally spaced. As we will see, this is not always the case for empirical time series, especially in the area of financial high-frequency data. In this case, it is necessary to preprocess the inhomogeneous (i.e., irregularly spaced) time series by interpolation methods in order to regularize the raw data. Though there exist models which can handle inhomogeneous time series directly (see Dacorogna (2001), but they also remark that most today's models are suited for regularly spaced time series only), regarding the methods we discuss in the following sections, we restrict ourselves to homogeneous ones.

In this chapter we focus on nonparametric methods for trend extraction. This is due to the reason that in most time series we analyze in this work, we cannot reasonably assume any model for the underlying trend. Yet, as noted in the framework above, in case such assumptions hold, we can expect those models to perform better than nonparametric models, since they exploit information that nonparametric approaches cannot. Furthermore, the commitment to certain parametric time series or trend models can be seen as a restriction when considering the general case, which may lead even to misleading results in case the trend does not match model, as certain patterns might not be captured or considered by the model itself. This can easily be seen at a most basic example, in case a linear trend is expected, which in most cases will only be a poor estimator for any nonlinear trend curve. In this case nonparametric approaches are less restrictive and can more generally be applied, while of course not delivering the same accuracy as parametric models which exactly match the underlying trend, with only their parameters to be calibrated. If, e.g., the trend follows sinusoidal curve, a sinusoidal curve with its parameters being estimated by, e.g., the least-squares method will almost surely provide a better accuracy than any other nonparametric approach. On the other hand, if the underlying trend is linear or even contains only little deviations from a perfect sinusoidal curve, a sinusoidal fit to this trend, it has been shown at simple examples that the parametric sinusoidal approach can lead to confusing results and conclusions.

We further require that the method used for trend extraction be robust, that is, the results are reliable and the error can be estimated or is at least bounded in some way. In many cases (see, e.g., Donoho and Johnstone (1994)), the robustness of a method is shown by proving its asymptotic consistency, that is, its convergence towards a certain value for certain parameters tending towards infinity. It should be remarked that the robustness should be independent of the time series itself and/or any specific algorithm parameter sets, in order to be applicable in practice. Of course this does not exclude specific assumptions on the time series that must be met or parameter ranges for which the algorithm is defined.

Therefore, as we cannot reasonably assume any model for the any time series in general, in this work, we focus on nonparametric approaches only. Within these approaches we focus on two main branches for trend extraction: linear and nonlinear filters. This is for the reason because linear filters are known and have proven to deliver a very smooth trend (given the filtering window size is large enough), while nonlinear filters excel at preserving characteristic patterns in a time series, i.e., especially jumps. Both methods in general require only very few (or none at all) information about the underlying data, besides their configuration of weights and calibration parameters, and are thus applicable to a wide range of time series, independent of the field the data was measured in.

Although there exists a variety of other nonparametric methods, most of these already rely on specific assumptions or choices of parameters which in general cannot easily be derived for any time series data or different analysis goals. Nevertheless, for the sake of completeness, later in this chapter we list some alternative methods, also including parametric approaches, which have been applied in economic, financial, or related time series data.

18.3 Linear Filters

Linear filters are probably the most common and well-known filters used for trend extraction and additive noise removal. We first provide the most general notion of this filter class and then depict the two viewpoints of linear filters and how they can be characterized. While this characterization on the one hand is one of the most distinguishable advantages of linear filters, on the other hand at the same time, it leads to the exact problem we are facing in this work, that is, the representation of sharp edges in otherwise smooth trends.

18.3.1 General Formulation

The filtered output depends linearly from the time series input. Using the notation of Fan and Yao (2003), a linear filter of length $2h + 1$ can be defined as

$$\hat{X}_t = \sum_{i=-h}^{h} w_i X_{t+i}, \tag{18.3}$$

with $\hat{X}_t$ the filtered output and w_i the filter weights. These kinds of filters are also known as (discrete) convolution filters, as the outcome is the convolution of the input signal with a discrete weight function, where often the following notation is used:

$$w^* X_t := \sum_{i=-h}^{h} w_i X_{t-i} = \sum_{i=-h}^{h} w_{t-i} X_i. \tag{18.4}$$

Thus, for every data point X_t, the filtered output $\hat{X}_t$ is the result of weighted summation of data points around t. Applied for the whole time series, this results in weighted average window of size $L = 2h + 1$ which is moved throughout the whole series. The size of this window is also called the *bandwidth* of the filter. It is also common notation to set $h \equiv \infty$ even if the window filter size should be finite, with $w_i = 0$ for $|i| > h$.

The probably best known linear filter is the mean filter, with $w_i = 2h + 1$, that is, all filter weights are uniformly distributed. A more general viewpoint is given by the notion of *kernel filters*. Given a kernel function w.l.o.g. with support $[-1, 1]$, this function assigns the weights according to

$$w_i = \frac{K(i/h)}{\sum_{j=-h}^{h} K(j/h)}. \tag{18.5}$$

Commonly used examples are the *Epanechnikov kernel*

$$K^{\mathrm{E}}(u) = \frac{3}{4}\left(1 - u^2\right) + , \tag{18.6}$$

the *Gaussian kernel*

$$K^{\mathrm{G}}(u) = \frac{1}{\sqrt{2\pi}} \exp\left(\frac{-u^2}{2}\right), \tag{18.7}$$

and the symmetric beta family

$$K_\gamma^{\mathrm{B}}(u) = \frac{1}{B(1/2,\ \gamma+1)} \left(1-u^2\right)^\gamma I_{|u|\leq 1}. \tag{18.8}$$

For the values $\gamma \in \{0, 1, 2, 3\}$, the kernel $K_\gamma^{\mathrm{B}}(u)$ corresponds to the uniform, Epanechnikov, biweight, and triweight kernel functions, respectively.

18.3.2 Transfer Functions: Time Versus Frequency Domain

The previous section depicts the linear filtering method in the time domain, i.e., we look at the time series X_t and its respective filtered output $\hat{X}_t$ and how they evolve over time t. Another perception can be given by taking the frequency domain into account. For all linear filters, we cannot only give its definition as depicted earlier, but also in respect to the frequencies, the filters let pass. This notion can be derived as follows.

While the sequence of filter weights w_i, also called *impulse response sequence*, determines the filtered output in the time domain (or equivalent are the linear filter's time domain representation), via the discrete Fourier transform (DFT), we can derive the *transfer function*

$$\mathcal{W}(f) = \sum_{j=-\infty}^{\infty} w_j e^{-\mathrm{i}2\pi f j}, \tag{18.9}$$

its counterpart in the frequency domain, also called *frequency response function*. Alternatively, if this formulation is given in the beginning, we can also derive the weights via the inverse transform:

$$w_j = \int_{-1/2}^{1/2} \mathcal{W}(f) e^{\mathrm{i}2\pi f j} \mathrm{d}f. \tag{18.10}$$

Obviously, these two formulations are equivalent, as one can be derived from the other, and vice versa. By considering the transfer function's polar representation,

$$\mathcal{W}(f) = |\mathcal{W}(f)| e^{\mathrm{i}\theta(f)}, \tag{18.11}$$

with $|\mathcal{W}(f)|$ the gain function. The magnitude in gain $|\mathcal{W}(f)|$ describes the linear filters behavior in the frequency domain, that is, what kind of frequencies and their respective proportions will let passed or be blocked. For our needs, it satisfies to distinguish between high – and low-pass filters, that is, filters that let pass either the high frequencies and block the lower ones, or vice versa. Of course, other filter types exist; for example, by combining high – and low-pass filters (e.g., in a filter cascade), one can derive band-pass and stop filters, so that the frequency domain output will be located only in a certain frequency range. In this work we are specifically interested in low-pass filters, as they block the high-frequency noise and the output consists of the generally low-frequency trend.

As we assume that the weights w_j are real valued, one can show (see, e.g., Percival and Walden (2006)) that $\mathcal{W}(-f) = \mathcal{W}^*(f)$, and, with $|\mathcal{W}^*(f)| = |\mathcal{W}(f)|$, it follows that $|\mathcal{W}(-f)| = |\mathcal{W}(f)|$. Therefore, the transfer functions are symmetric around zero. Because of its periodicity, we need to consider $\mathcal{W}(f)$ only an interval of unit length. For convenience, this interval is often taken to be $[-1/2, 1/2]$, i.e., $|f| \leq 1/2$. Therefore, with above-depicted symmetry, it suffices to consider $f \in [0, 1/2]$ in order to fully specify the transfer function.

While saying that certain frequencies are blocked and others are passed, this holds only approximately true, since the design of such exact frequency filters is not possible, but always a transition between the blocked and passing frequencies. The goal of many linear filters is either to minimize these transitions (i.e., the range of by this affected frequencies), which, on the other hand, inevitably causes ripples in the other frequencies, that is, they are not any longer blocked, or to let them pass completely (see Bianchi and Sorrentino (2007) and the references therein for further details about this topic).

As we have seen at above examples, linear filters can be designed either from a time or from a frequency perspective. The time domain usually focuses on putting more weights on the surrounding events (i.e., events that recently before or occurred shortly after) and, thus, gives an (economic) interpretation similar to the, for example, ARMA and GARCH models. On the contrary, the frequency domain is based on the point of view that certain disturbances (almost) exclusively are located in a certain frequency range and are thus isolated from the rest of the signal. Also, the slowly evolving trend can be seen to occupy only the lower frequency ranges. Thus, the (economic) meaning lies here in the frequency of events; see, for example, Dacorogna (2001).

Although linear filters can be designed to block or let pass certain frequencies nearly optimal, at the same time this poses a serious problem when facing trends that exhibit jumps or slopes. As these events are also located in the same (or in case of slopes the adjacent) frequency range as the high-frequency noise, this has the effect that jumps and edged frontiers are blurred out, while steep slopes mostly are captured with poor precision only. Hence, from a frequency perspective, a smooth trend and edge preservation are two conflicting goals. This is as the linear filters are not capable to distinguish between the persistent noise and a single events that, while located in the same frequency range, usually have a higher energy and, thus, significantly larger amplitude. Thus, the same filtering rule is applied throughout the whole signal, without any adaption. Note, however, that linear filters still give some weight to undesirable events like outliers, due to their moving average nature. Thus, while some significant features like jumps are not displayed in enough detail, other unwanted patterns, like spikes, still partially carry over to the filtered output. To overcome all these drawbacks for that kind of trends or signals, besides the class of linear filters, the class of nonlinear filters has been developed.

18.4 Nonlinear Filters

As we have seen, linear filters tend to blur out edges and other details though they form an elementary part of the time series' trend. In order to avoid this, a wide range of nonlinear filters has been developed which on one hand preserve those details while on the other try to smooth out as much of the noise as possible. We do not find nonlinear filters only in time series, but they were in many cases developed specifically for two-dimensional signals, specifically images, where the original image, probably corrupted by noise during data transmission, consists mainly of edges, which form the image.

18.4.1 General Perception

While linear filters generally provide a very smooth trend achieved through averaging, two characteristics pose a problem for this class of filters:

- Outliers and spikes
  Single, extreme outliers and spikes can cause the whole long-term trend to deviate in the same direction, though they obviously do not play a part in it.
- Jumps, slopes, and regime changes
  Whenever there occurs a sudden external event in the underlying main driving force, it causes the trend to jump, that is, contrary to spikes it changes permanently onto another plane. While slopes are not that extreme, they also show a similar behavior as they decay or rise with the trend's unusual degree.

The reasons for the deviation sensitivity to these events are given by one of the most favorable linear filters' characteristics themselves: It follows directly from them being characterizable in terms of frequency passbands we explained earlier that all frequencies are treated the same (i.e., filtered according to the same rule) throughout the whole signal. This means that no distinction is made (and even cannot be made) between noise and those patterns, as they are located in approximately the same frequency range. Technically, as long as an outlier or a jump is contained in the weighted moving average filtering window, also a weight is assigned to these outlier data points or the points on the other plane, i.e., before and after the jump. Nonlinear filtering procedures try to avoid this by using a different approach, for example, by considering a single value only (instead of multiple weighted ones) that was selected from an ordered or ranked permutation of the original values in the filtering window.

Although we cannot characterize nonlinear filters in the same way as we do with linear filters (i.e., by transfer functions) besides their characteristics not being classifiable in that way, according to Peltonen et al. (2001), we can divide the whole class of these filters into several subclasses that share the same or similar approaches. Among them, there are stack filters, weighted median filters, polynomial filters, and order statistic filters. Astola and Kuosmanen (1997) provide two different taxonomies for further classification, though they remark that these divisions are not unique. In their work, they extensively show how those different filters behave (i.e., their characteristics) when applied onto different benchmark signals in respect to the mean absolute error (MAE) and mean squared error (MSE) measures.

The behavior of nonlinear filters is generally characterized by their impulse and step response, i.e., the filtered output when the input consists of a single impulse or step only. These impulses generally are given by the sequence $[\ldots, 0, 0, 0, a, 0, 0, 0, \ldots]$ and $[\ldots, 0, 0, 0, a, a, a, \ldots]$, respectively, with $a \neq 0$. Though in most cases no analytical result can be given, these characteristics help us to understand how the nonlinear filter behaves in respect to those patterns, for which the linear filters generally fail to deliver adequate results.

Despite their undoubtedly good ability to preserve outstanding features in a time series while extracting the trend, nonlinear filters also suffer some drawbacks:

1. Insufficient smoothness

   Though most nonlinear filters try to deliver a smooth trend and a good resolution of edged frontiers, beyond the jumps' surrounding regions, they usually fail to deliver a smooth trend as accurate as even simple linear filter (e.g., the mean filter) provides. Yet, by applying further smoothing procedures (e.g., by recursive filters or some kind of linear filtering on the nonlinear output, with a smaller bandwidth, as most of the noise is already smoothed out) comes at the price that the prior preserved details of jumps or slopes tend to get lost.

   This effect is even aggravated when the high-frequency noise present in the signal is extremely high, i.e., the trend which evolves, besides the jumps, quite slowly is dominated by the noise with extremely high amplitudes. Some filters try to counter this effect, but they either:

   - Provide only a tradeoff between an overall smooth signal and poor jump resolution, or a trend still exhibiting ripples but preserved edges, or
   - Rely on further information about the time series itself, that is, the noise component and its structure, the jumps or the trend itself

   This is due to the problem that most filtering rules are applied throughout the whole signal, that is, they do not adapt themselves sufficiently when the filtering window approaches a jump. An overview of these and other nonlinear filters' performance is given by Astola and Kuosmanen (1997), proving again the well-known insight that there cannot exist one solution that performs optimal for all cases. Though the authors also report some approaches that try to incorporate that behavior, these filters provide only dissatisfactory results (see the examples below).

2. Lack of frequency control
Another feature nonlinear filters are lacking is the ability to regulate the filtered output in terms of frequency passbands, as linear filters do. Since Pollock (2001) defines the trend in terms of frequency bands and Ramsey (1999, 2002) points out that frequency analysis is an important aspect in financial time series, so is frequency control. Though not necessary for all applications, the ability to a priori control and regulate the filters output (in contrast to an only a posteriori frequency analysis of the filtered result) may come handy when one wants to ensure that certain frequencies are not contained in the output, that is, when certain information about the noise frequencies is at hand, the analyst can decide before the actual filtering process (and thus, without any try and error procedures) what frequency parts should be filtered out. Although a nonlinear filter can also provide the same or a similar result, no theoretical results or statements are available before the filtering procedure has been carried out completely. This incapacity of the nonlinear filter follows directly from the fact that nonlinear filters do not rely on frequency passbands, as they must be able to filter events, even though they occupy nearly the same frequency range (i.e., noise and jumps), due to different rules.

As Astola and Kuosmanen (1997) classify linear filters to be a subclass of the class of nonlinear filters, above statement does not exactly hold true, i.e., it would mean that a subclass of nonlinear filters can be characterized by their transfer function and frequency output. We, however, separate the classes of linear and nonlinear filters by whether or not a filter can be described by a transfer function or not, which marks a strict division of these two classes.

18.4.1.1 Examples

To illustrate the different courses of action of nonlinear filters and give the reader an idea of their general procedure, in this section we outline several examples of above named subclasses. As this list cannot be exhaustive by any means, of course, we note that we do not take filters into account that already rely on specific assumptions of the systems beneath the time series themselves.

Trimmed Mean Filter

This filter works essentially as the mean filter, with the difference that the extreme values of the *ordered* series $X_{(i)}$ are trimmed. Index t is omitted here as the order is no longer in concordance with time. Therefore, an (r, s)-fold trimmed mean filter is given by

$$\frac{1}{N-r-s}\sum_{i=r+1}^{N-s} X_{(i)}. \tag{18.12}$$

A special case is the choice of $r = s$. A further modification of the trimmed mean filter is not to discard the ordered values beyond $X_{(r)}$ and $X_{(s)}$, but instead replace them by $X_{(r+1)}$ and $X_{(s+1)}$ themselves. This is the Winsorized mean filter:

$$\frac{1}{N}\left(r \cdot X_{(r+1)} \sum_{i=r+1}^{N-s} X_{(i)} + s \cdot X_{(N-s)}\right). \tag{18.13}$$

In these methods, the (r, s) tuple is dependent of the data itself. Other filters consider to make these values independent from the data or dependent from the central sample itself, i.e., nearest neighbor techniques. All those filters have in common that they discard all samples from the ordered series being too far away (respectively) according to some measure.

L-Filters and Weighted Median

L-filters (also called order statistics filters) make a compromise between the weighted moving averages of linear filters and the nonlinear ordering operation. The idea is that the filtered output is generated by weighted averages over the ordered samples, that is,

$$\sum_{i=1}^{N} w_i X_{(i)}, \tag{18.14}$$

with w_i the filter weights. A similar notion is given by weighted median filters, where the weights are assigned to the time ordered sample X_t and where the weights denote a duplication operation, i.e., $w_i \circ X_t = X_{t,1}, \ldots, X_{t,w_i}$. The output is then given by

$$\text{median}\,\{w_1 \circ X_1, \ldots, w_N \circ X_N\}. \tag{18.15}$$

Ranked and Weighted Order Statistic Filters

An rth-ranked-order statistic filter is simply given by taking $X_{(r)}$ as the filter output. Examples are the median, the maximum ($r = N$), and the minimum ($r = 1$) operation. This can also be combined with weights as depicted above, that is,

$$r\text{th order statistic}\{w_1 \circ X_1, \ldots, w_N \circ X_N\}. \tag{18.16}$$

Hybrid Filters

Another approach is the design of nonlinear filters consisting of filter cascades, that is, the repeated application of different filters on the respective outputs. A general formulation is, for example, given by rth-order statistic $F_1(X_1, \ldots, X_n), \ldots, F_M(X_1, \ldots, X_n)$, where $F_1, \ldots, F_M$ can denote any other filtering procedure. A concrete example is the median hybrid filter that combines prior linear filtering procedure with a succeeding median ordering operation, i.e.,

$$\text{median}\left\{(1/k)\sum_{i=1}^{k} X_i,\ \ X_{k+1},\ \ (1/k)\sum_{i=k+2}^{N} X_i\right\}. \tag{18.17}$$

Selective Filters

An interesting approach is given by the principle of switching between different output rules depending on some selection rule, for example, based on the fact that the mean filter delivers a larger (smaller) output than the median filter when the filtering window approaches an upward (downward) jump. Thus, a selection rule would be given by

$$\text{mean}\{X_1, \ldots, X_N\} \geq \text{median}\{X_1, \ldots, X_N\}. \tag{18.18}$$

A certain drawback of this selection rule is that it is one-sided, that is, it considers only the first half of the region around the jump. This is due to the fact that the mean for the second half, after the jump has occurred, is generally smaller (larger) than the median. Other rules can include thresholds and aim at deciding whether there has actually happened a jump or there was an impulse in the signal, which is not caused by the noise distribution, but due to some other explanatory effect.

Above-depicted examples of nonlinear filters should give the reader an overview over the most common methods applied in practice. For detailed information about each filter's characteristics, advantages, and drawbacks, we refer to Astola and Kuosmanen (1997), where there are also the references to the original works to be found. Yet, we see that basically most of these filters rely on some ordered statistics, with their input or output modified prior or afterwards, respectively. Since this basic principle applies to most filters not directly dependent on some specific characteristic or assuming a certain structure of the original series to be filtered, the different methods pointed out above can be combined in numerous ways. In many cases, however, even though we portrait only the very basic methods, we see that almost all of them already incorporate an implicit or explicit choice of additional parameters besides the filter bandwidth, either by weights, rules, or thresholds. These choices introduce further biases into the filtering process. Though some of these parameters can be chosen to be optimal in some sense (i.e., minimize a certain distance measure, e.g., the MSE for the L-filters), they lack the concrete meaning of weights we have for linear filters.

18.5 Specific Jump Detection Models and Related Methods

In this section we list further related methods that are concerned with the estimation of long-term trends exhibiting edged frontiers, i.e., jumps and/or steep slopes. We first review methods being explicitly developed either only for the detection of jumps in a signal corrupted by noise or approaches that also include capturing (i.e., modeling) those very jumps. We show the advantages and limits of applications of these methods, highlighting in which aspects further research is still necessary. We conclude this chapter by listing some of the most in practice well-known methods.

18.5.1 Algorithms for Jump Detection and Modeling

The issue of detecting and modeling jumps in time series has been recognized as an essential task in time series analysis and therefore has already been considered extensively in the literature. Though we introduce wavelet methods in the next chapter only, we list the works based on these methods here as well without going into details. We only note that wavelets, based on their characteristics, make excellent tools for jump and spike detection, as it is this what they were developed for in the first place (see Morlet (1983)).

Generally, the most appreciated procedures in the recent literature can be seen as two different general approaches. One is via wavelets, and the other uses local (linear) estimators and derivatives.

One of the first approaches using wavelets for jump detection in time series, besides the classical wavelet literature, for example, Mallat and Hwang (1992), was given by Wang (1995, 1998). He uses wavelets together with certain data-dependent thresholds in order to determine where in the signal jumps have happened and whether they are significantly different from short-varying fluctuations, and provides several benchmark signals. Assumptions about the noise structure were made according to Donoho and Johnstone (1994), that is, the approach is applicable for white (i.e., uncorrelated) Gaussian noise only. This work was extended by Raimondo (1998) to include even more general cusp definitions. More recent contributions extend these works to stationary noise (Yuan and Zhongjie (2000)) and other distributions (Raimondo and Tajvidi (2004)) and also provide theoretical results about asymptotic consistency. A further application specifically on high-frequency data is given by Fan and Wang (2007).

The other line is given by Qiu and Yandell (1998) who estimate jumps using local polynomial estimators. This work is continued in Qiu (2003) where jumps are not only detected but also represented in the extracted time series. Gijbels et al. (2007) further refine the results by establishing a compromise between a smooth estimation for the continuous parts of a curve and a good resolution of jumps. Again, this work is limited to pure jumps only and, since it uses local linear estimators as the main method, has no frequency interpretation available. Sun and Qiu (2007) and Joo and Qiu (2009) use derivatives to test the signal for jumps and to represent them.

Finally, we note a completely different approach that is presented in Kim and Marron (2006): a purely graphical tool for the recognition of probable jumps (and also areas where almost certainly no jumps occurred). Yet, the authors confess that their work is only to be seen as a complementary approach, and refer to Carlstein et al. (1994) for further thorough investigation.

We note that there exists already a good body of work about how to detect (i.e., estimate their location), and even how to model jumps (i.e., estimate their height), though in most works bounded to strict requirements on the noise or the trend model. However, although most models will also automatically include the detection of steep slopes, they fail at modeling the slope itself. While a jump can easily be presented (either by indicator functions or any other methods used in the cited works above), matters are different with slopes: Since there can be given no general formulation or model of the exact shape of a slope, any parametric approach will fail or deliver only a poor approximation if the model does not fit the occurred slope. Examples of such different kinds of slopes are innumerous: Sine, exponential, and logarithmic decays are only the most basic forms to approximate such events, which in practical examples rarely follow such idealized curves. Naturally, only nonparametric approaches will adapt themselves to the true shape of the underlying trend but generally suffer the same drawbacks as all linear and nonlinear methods pointed out above, i.e., they always have to bargain a tradeoff between bias and signal fidelity.

18.5.2 Further Related Methods

We conclude this section by outlining the most popular and established filtering methods.

18.5.2.1 General Least-Squares Approaches

The most general approach can be seen by setting up a parameterized model and calibrating the model afterwards, generally using some minimization procedure in respect to some error measure. This can be seen as a straightforward approach, requiring only the initialization of an appropriate model and choice of error measure.

An example from the energy market is given by Seifert and Uhrig-Homburg (2007) and Lucia and Schwartz (2002), who set up a trigonometric model in conjunction with indicator functions and minimize the squared error for each time step in order to estimate the deterministic trend as well as values for different seasons and days. Though they find that their model works well in practice, for general cases it might be difficult always finding an appropriate model, especially when there is no information about the trend, its seasonal cycles, and other (deterministic or stochastic) influences. This is especially the case when the data set covers only a short period of time.

When analyzing financial time series data, one could suggest the trigonometric model and the order of the sinusoidal functions; in general it may be difficult to set up such a model or reason, why this model and its estimated trend are appropriate for the respective time series. This requires either a rigorous a priori analysis of the series itself or further information about the external factors (i.e., the system the time series is derived from) and their interaction. In addition to this, the estimation can never be better than the model and to which accuracy it approximates the true trend.

We note another probable critical issue when using indicator functions in combination with least-squares estimation. First, using indicator functions confines the model to jumps only, that is, slopes or similar phenomena cannot be captured by that approach, as the indicator functions automatically introduce jumps in the trend component. Thus, indicator functions excel at modeling jumps but perform poorly with other types of sudden changes. Second, for this approach, it is extremely important to determine the location of the jump as exact as possible, as otherwise the estimated trend in this area may be highly inaccurate.

It is therefore dubious, whether such parametric approaches are appropriate to deal with economic and financial time series, though they will perform very well, if their requirements are met.

18.5.2.2 Smoothing Splines

Smoothing splines, though also utilizing the least-squares methods, on the contrary do not rely on a specific model assumption. Instead, they penalize the regression spline in respect to its roughness, i.e.,

$$\min_{m} \sum_{t=1}^{N} (X_t - m(t))^2 + \omega \int (m''(x))^2 \, dx. \tag{18.19}$$

It follows directly from this definition that for $\omega = 0$ this yields us an interpolation while for $\omega \to \infty$ m will approximate a linear regression.

In practice, there emerges another difficulty: In many cases, the (optimal) choice of ω remains unclear. Although there exist several works that have established some data-dependent rules for this, in many cases, when the assumptions about the noise do not hold or the time series incorporates additional deterministic (e.g., cycles) or stochastic components (e.g., outliers that are part of the system and not due to measurement or other errors), the choice of the penalizing smoothing parameter is a difficult task that has been and is still undergoing extensive research (see Morton et al. (2009), Lee (2003), Hurvich et al. (1998), Cantoni and Ronchetti (2001), Irizarry (2004)). We only mention particularly the cross-validation method which is used to determine the optimal smoothing parameters (see Green and Silverman (1994)). Furthermore, though ω is eventually responsible for the degree of smoothness (i.e., on which scale or level the trend shall be estimated), one can hardly neither impose nor derive any additional meaning on or from this parameter.

18.5.2.3 The Hodrick-Prescott Filter

The Hodrick-Prescott (HP) filter was first introduced by Leser (1961) and later became popular due to the advanced works of Hodrick and Prescott (1997). In order to extract the trend $\tau = [\tau_0, \ldots, \tau_{N+1}]$ from a given time series X, this trend is derived by solving

$$\min_{\tau} \sum_{t=1}^{N} (X_t - \tau_t)^2 + \omega((\tau_{t+1} - \tau_t) - (\tau_t - \tau_{t-1}))^2. \tag{18.20}$$

We note that (besides from not using a spline basis for approximation) this approach can be seen as a discretized formulation of the smoothing spline.

The smoothing parameter ω plays the same role, while the penalized smoothness measure is the discretized version of the second derivative. Thus, though several authors propose explicit rules (of thumb) for choosing ω (see, e.g., Ravn and Uhlig (2002), Dermoune et al. (2008), Schlicht (2005)), some researchers like Harvey and Trimbur (2008) also recognize that in some way this choice still remains kind of arbitrary or problematic for many time series which cannot be associated in the same time terms.

18.5.2.4 The Kalman Filter

Another sophisticated filter was developed by Kalman (1960). It is a state-space system specifically designed to handle unobserved components models and can be used to either filter past events from noise or forecast. Another good introduction to the Kalman filter can be found in Welch and Bishop (1995) and a thorough discussion in Harvey (1989).

The basic Kalman filter assumes that the state $x \in \mathbb{R}^n$ of underlying process in a time series can be described by a linear stochastic difference equation:

$$x_t = Ax_{t-1} + Bu_{t-1} + w_{t-1}, \tag{18.21}$$

with A the state transition model that relates in conjunction with the (optional) control input B, the respective input u_t, and the noise component wt the previous state to the next. In the above equation, A and B are assumed to be constant but may also change over time. Of this model (i.e., the true state x_t), only

$$z_k = Hx_k + v_k \tag{18.22}$$

can be observed. Both noise components are assumed to be independent of one another and to be distributed according to

$$w \sim N(0, Q) \quad \text{and} \quad v \sim N(0, R). \tag{18.23}$$

With A, B, Q, and R assumed to be known, the filter predicts the next state x_t based on x_{t-1} and also provides an estimate of the accuracy of the actual prediction.

Since its first development, the Kalman filter has become popular in many areas; see, for example, Grewal et al. (2001). However, a serious drawback of this Kalman procedure is that many real-world models do not fit the assumptions of the model, for example, above requirement of a linear underlying system is often not met. Though there exist extensions for nonlinear systems (see e.g., Julier and Uhlmann (1997)), there still exists the problem that one or more of the required parameters are unknown. While for many technical systems (e.g., car or missile tracking systems) based on physical laws the state transition model A is exactly known, this becomes a difficult issue in many other application areas, including finance. Additionally, as, e.g., Mohr (2005) notes, the performance of the Kalman filter can be very sensitive to initial conditions of the unobserved components and their variances, while at the same time it requires an elaborate procedure of model selection. He also notes that in macroeconomic time series, the Kalman filter does not work with annual data. Therefore, we see that while the Kalman filter unquestionably delivers excellent results in many areas (and has also applied for financial time series as well, though not without critique), its usage is not convenient for general cases we treat in this work, requiring more assumptions and knowledge about the underlying model.

18.6 Summary

In this chapter we provided an overview of the different tasks of time series analysis in general and the specific challenges of time series trend extraction. We pointed out several methods and outlined their advantages and disadvantages, together with their requirements. The reader should keep in mind the following key points:

- Linear filters provide a very smooth trend but fail to capture sudden changes.
- Nonlinear filters capture jumps extremely well but are very sensitive to higher levels of noise.
- Advanced methods may provide good results depending on the scenario but often rely on very specific assumptions that can yield misleading results, in case they are not completely met.
- The specific task of jump detection and modeling is well understood but lacks appropriate methods for more general changes like steep slopes.
- And the most important: No methods universally perform best for all tasks!

Analysis of Financial Time Series Using Wavelet Methods

19

Philippe Masset

Contents

Abstract

This chapter presents a set of tools, which allow gathering information about the frequency components of a time series. In a first step, we discuss spectral analysis and filtering methods. Spectral analysis can be used to identify and to quantify the different frequency components of a data series. Filters permit to capture specific components (e.g., trends, cycles, seasonalities) of the original time series. Both spectral analysis and standard filtering methods have two main drawbacks: (i) they impose strong restrictions regarding the possible processes underlying the dynamics of the series (e.g., stationarity) and (ii) they lead to a pure frequency-domain representation of the data, i.e., all information from the time-domain representation is lost in the operation.

In a second step, we introduce wavelets, which are relatively new tools in economics and finance. They take their roots from filtering methods and Fourier analysis, but overcome most of the limitations of these two methods. Their principal

advantages derive from (i) combined information from both time domain and frequency domain and (ii) their flexibility as they do not make strong assumptions concerning the data-generating process for the series under investigation.

Keywords
Filtering methods • Spectral analysis • Fourier transform • Wavelet filter • Continuous wavelet transform • Discrete wavelet transform • Multiresolution analysis • Scale-by-scale decomposition • Analysis of variance • Case-Shiller home price indices

19.1 Introduction

The purpose of this chapter is to present a set of methods and tools belonging to the so-called *frequency-domain* analysis and to explain why and how they can be used to enhance the more conventional *time-domain* analysis. In essence, time-domain analysis studies the evolution of an economic variable with respect to time, whereas frequency-domain analysis shows at which frequencies the variable is active. We focus on concepts rather than technicalities and illustrate each method with examples and applications using real datasets.

The usual *time-domain* approach aims at studying the temporal properties of a financial or economic variable, whose realizations are recorded at a predetermined frequency. This approach does not convey any information regarding the frequency components of a variable. Thus, it makes the implicit assumption that the relevant frequency to study the behavior of the variable matches with its sampling frequency. An issue arises, however, if the variable realizations depend (in a possibly complicate manner) on several frequency components rather than just one. In such a case, the time-domain approach will not be able to efficiently process the information contained in the original data series.

In this chapter, we start by discussing methods belonging to the *frequency-domain* analysis. These tools are very appealing to study economic variables that exhibit a cyclical behavior and/or are affected by seasonal effects (e.g., GDP, unemployment). Spectral analysis and Fourier transforms can be used to quantify the importance of the various frequency components of the variable under investigation. In particular, they allow inferring information about the length of a cycle (e.g., business cycle) or a phase (e.g., expansion or recession). The presence of such patterns also imposes the use of appropriate methods when it comes to model the dynamics of the variable. Filtering methods have proven useful in this context. Notably, filters may serve to remove specific frequency components from the original data series.

In a second step, we introduce wavelets. During the last two decades, wavelets have become increasingly popular in scientific applications such as signal processing and functional analysis. More recently, these methods have also started to be applied to financial datasets. They are very attractive as they possess the unique ability to provide a complete representation of a data series from both the time and frequency perspectives simultaneously. Hence, they allow breaking down the activity on the market into different frequency components and to study the dynamics of each of these components separately. They do not suffer from some of the limitations of standard frequency-domain methods and can be employed to study a financial variable, whose evolution through time is dictated by the interaction of a variety of different frequency components. These components may also behave according to nontrivial (noncyclical) dynamics – e.g., regime shifts, jumps, and long-term trends.

For instance, the presence of heterogeneous agents with different trading horizons may generate very complex patterns in the time series of stock prices (see Müller et al. 1995; Lynch and Zumbach 2003). This heterogeneity may in particular induce long memory in stock return volatility. In such a case, studying the properties of a time series and trying to model it from the perspective of a single frequency can be misleading. Much information will be lost because of the naive and implicit aggregation of the different frequency components into a single component. Furthermore, as these components may interact in a complicated manner and may be time varying or even nonstationary, standard methods like Fourier analysis are not appropriate. Therefore, one has to resort to more flexible filtering methods like wavelets.

The remaining of this chapter is structured as follows. In Sect. 19.2, we discuss spectral analysis and filtering methods. Section 19.3 is devoted to the presentation of wavelets, Sect. 19.3.1 explains the relevant theoretical background, Sect. 19.3.2 discusses the implementation of these methods, and Sect. 19.3.3 presents a complete case study. Section 19.4 offers a short conclusion.

19.2 Frequency-Domain Analysis

19.2.1 Spectral Analysis: Some Basics and an Example

Studying the properties of an economic variable in the *time domain* is done through time series analysis. Similarly, the purpose of spectral analysis is to study the properties of an economic variable over the frequency spectrum, i.e., in the *frequency domain*. In particular, the estimation of the population spectrum or the so-called power spectrum (also known as the energy-density spectrum) aims at describing how the variance of the variable under investigation can be split into a variety of frequency components. The subject has been extensively researched during the previous 40 years (see Iacobucci (2003) for a short literature review). Our discussion is based primarily on Hamilton (1994) and Gençay et al. (2002).

19.2.1.1 Fourier Transform

The basic idea of spectral analysis is to reexpress a covariance-stationary process x(t) as a new sequence X(f), which determines the importance of each frequency component f in the dynamics of the original series. This is achieved using the discrete version of the Fourier transform[1]

$$X(\mathrm{f}) = \sum_{t=-\infty}^{\infty} \mathrm{x}(\mathrm{t}) e^{-i2\pi f t}, \tag{19.1}$$

where f denotes the frequency at which X(f) is evaluated. In order to gain a deeper insight into this decomposition, one may think about the De Moivre's (Euler's) theorem, which allows to write $e^{-i2\pi f t}$ as

$$\mathrm{e}^{-\mathrm{i}2\pi f t} = \cos(2\pi f \mathrm{t}) - \mathrm{i}\ \sin(2\pi f t). \tag{19.2}$$

Hence application of formula (19.1) is similar to projecting the original signal x(t) onto a set of sinusoidal functions, each corresponding to a particular frequency component. Furthermore, one can use the inverse Fourier transform to recover the original signal x(t) from X(f):

$$\mathrm{x}(\mathrm{t}) = \frac{1}{2\pi} \int_{-\pi}^{\pi} X(\mathrm{f}) e^{-i2\pi f t} df. \tag{19.3}$$

Equation 19.3 shows that X(f) determines how much of each frequency component is needed to synthesize the original signal x(t).

19.2.1.2 Population Spectrum and Sample Periodogram

Following Hamilton (1994), we define the *population* spectrum of x(t) as

$$s_x(\omega) = \frac{1}{2\pi} \sum_{j=-\infty}^{\infty} \gamma_j e^{-i\omega j}, \tag{19.4}$$

where γ_j is the jth autocovariance of x(t)[2]; $\omega = 2\pi \mathrm{f}$ is a real scalar, which is related to the frequency $\mathrm{f} = 1/\tau$ at which the spectrum is evaluated; and τ is the period length of one cycle at frequency f.[3] One may notice that the right part of Eq. 19.4 is indeed the discrete-time Fourier transform of the autocovariance series. There is also a close link between this expression and the autocovariance generating function, which is defined by

$$g_x(\mathrm{z}) = \sum_{j=-\infty}^{\infty} \gamma_j z^{\mathrm{j}}, \tag{19.5}$$

where z denotes a complex scalar. This implies that one can easily recover the autocovariance generating function from the spectrum. In the same spirit, an

[1]The discrete version of the Fourier transform is used because the time series is recorded at discrete-time intervals.

[2]The jth autocovariance of x(t) is given by $\gamma_j = E[(x(t) - \mu)(x(t - j) - \mu)]$, where μ denotes the expected value of x(t).

[3]As an example, let us consider an economic variable, whose evolution is fully determined by the state of the economy. A complete business cycle lasts on average 36 months and therefore f = 1/36 months.

application of the inverse discrete-time Fourier transform allows a direct estimation of the autocovariances from the population spectrum.

In practice, the sample *periodogram* $\hat{s}_x(\omega)$ can be estimated with either nonparametric or parametric approaches. We briefly describe these two approaches hereafter. The first approach is nonparametric because it infers the spectrum from a sample of realizations of the variable x without trying to assign an explicit structure to the data-generating process underlying its evolution. The estimation of the sample periodogram is straightforward as it is directly related to the squared magnitude of the discrete-time Fourier transform $|X(\mathrm{f})|$ of the time series x(t)

$$\hat{s}_x(\omega) = \frac{1}{2\pi}\frac{1}{T}|X(\mathrm{f})|^2, \tag{19.6}$$

where T is the length of the time series x(t). $|X(\mathrm{f})|^2$ is also known as the power spectrum of x(t). This approach is usually called the "periodogram." As noted in Hamilton (1994), its accuracy seems questionable as the confidence interval for the estimated spectrum is typically very broad. Furthermore, the variance of the periodogram does not tend to zero as the length of the data series tends to infinity. This implies that the periodogram is not a consistent estimator of the population spectrum. Therefore, modified versions of the periodogram have been put forward. For instance, smoothed periodogram estimates have been suggested as a way to reduce the noise of the original estimator and to improve its accuracy. The idea underlying this approach is that $s_x(\omega)$ will be close to $s_x(\lambda)$ when ω is close to λ. This suggests that $s_x(\omega)$ might be estimated with a weighted average of the values of $s_x(\omega)$ for values of λ in a neighborhood around ω, where the weights depend on the distance between ω and λ (Hamilton 1994). The weights are typically determined by a kernel weighting function. Welch's method (Welch 1967) and Childers (1978) constitute another alternative based on a simple idea: instead of estimating a single periodogram for the complete sample, one divides the original sample into subsamples, estimates the periodogram for each subsample, and computes the average periodogram over all subsamples.

The second approach is based on some parameterization of the data-generating process of x(t). Methods belonging to this category are close in spirit to the population spectrum, i.e., to a direct application of Eq. 19.4. Typically some specification based on an ARMA (autoregressive moving average) representation is chosen to represent the temporal dynamics of the variable. The model is then calibrated, i.e., the ARMA coefficients are estimated from the realizations of the process x(t). These estimated coefficients are employed to calculate the spectrum. As long as the autocovariances are reasonably well estimated, the results would also be reasonably close to the true values. A detailed discussion of the various parametric methods (e.g., the covariance, Yule-Walker and Burg methods) is beyond the scope of this introduction, but parametric methods are particularly effective when the length of the observed sample is short. This is due to their ability to distinguish the noise from the information contained in the data.

19.2.1.3 Example

We now turn to the discussion of a simple example. We consider a time series, which has the following dynamic:

$$x(t) = a \cdot \cos\left(\frac{2\pi t}{21}\right) + b \cdot \sin\left(\frac{2\pi t}{63}\right) + \varepsilon(t),$$

where $\varepsilon(t)$ is a random term that follows a normal distribution with mean zero and unit variance. One may observe that the process is driven by two cyclical components, which repeat themselves, respectively, each 21 and 63 units of time.

The full line in Fig. 19.1 shows the first 100 (simulated) realizations of x(t); the dotted lines are for the cos and sin functions. At first glance, it seems difficult to distinguish the realizations of x(t) from a purely random process. Figure 19.2 reports the autocorrelations (left panel) and partial autocorrelations (right panel) of $x(t)$ (upper panel) and of the cos and sin components (bottom panel). Again, it remains difficult, when looking at this figure, to gather conclusive evidence concerning the appropriate model specification for $x(t)$.

On the other hand, results from the Fourier analysis, reported in Fig. 19.3, clearly show that two cyclical components drive the evolution of x(t) and repeat themselves around each 21 and 63 units of time. This demonstrates the effectiveness of Fourier methods for the study of processes featuring cyclical components.

19.2.1.4 Illustration: Home Prices in New York City

We now illustrate how spectral methods can be applied to real economic data series. We consider the Case-Shiller home price index for the city of New York. The dataset covers the period January 1987 to December 2011 on a monthly basis. The upper panel of Fig. 19.4 shows the evolution of the index level over this time period, while the lower panel reports the time series of index returns. Results from the Dickey-Fuller test cannot reject the null hypothesis that the index level series is nonstationary. Application of the Fourier transform requires the series under study to be stationary. We therefore study the spectral properties of the index using the time series of returns rather than the levels themselves.

We also estimate the autocorrelations and partial autocorrelations of the index returns up to 48 lags (i.e., 4 years of observations). These are reported in Fig. 19.5. The structure of both the autocorrelations and the partial autocorrelations indicates that the index returns are significantly autocorrelated and it also suggests a cyclical (or seasonal) behavior of the returns. This observation is in line with previous results from the literature (see Kuo 1996; Gu 2002). In order to gain more insight into the presence of such patterns, we compute the power spectrum of the series using parametric and nonparametric methods displayed in Fig. 19.6. The estimated power spectra returned by the two nonparametric methods (periodogram and Welch) are much noisier than the spectra obtained from the parametric methods (Yule-Walker and Burg). The Welch method also seems to result in an oversmoothed estimate of the power spectrum as compared to the other estimates

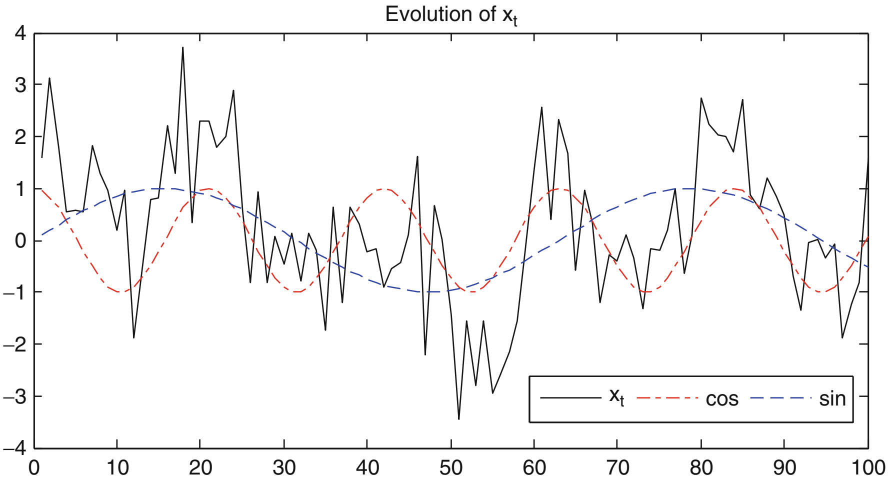

Fig. 19.1 Sample path of $x(t)$

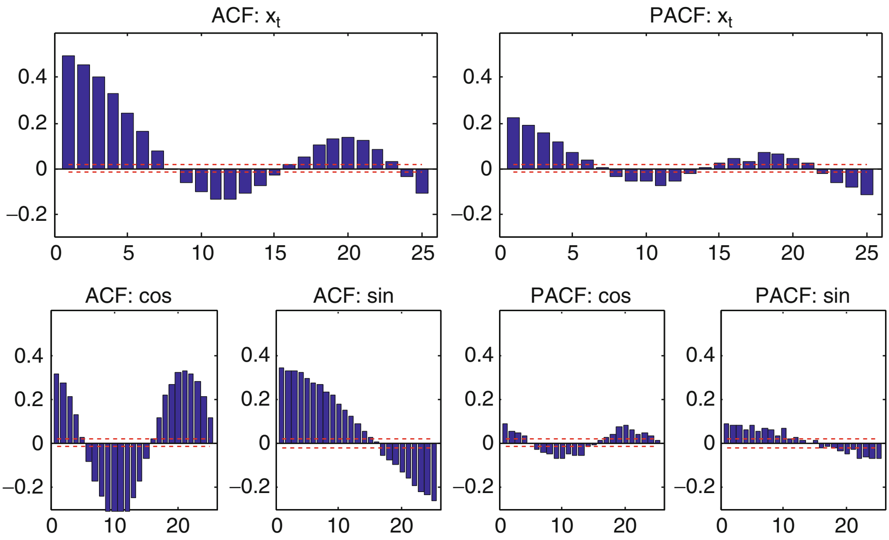

Fig. 19.2 Autocorrelations and partial autocorrelations of $x(t)$. The upper panel reports the autocorrelations (*left panel*) and partial autocorrelations (*right panel*) of $x(t)$. The lower panel shows similar statistics for the cosinus and sinus functions

(e.g., periodogram estimates). On the other hand, the difference between the Yule-Walker and the Burg methods is minimal. Nevertheless, the key message remains remarkably similar: strong seasonalities affect home prices with a frequency of recurrence of 12 months.

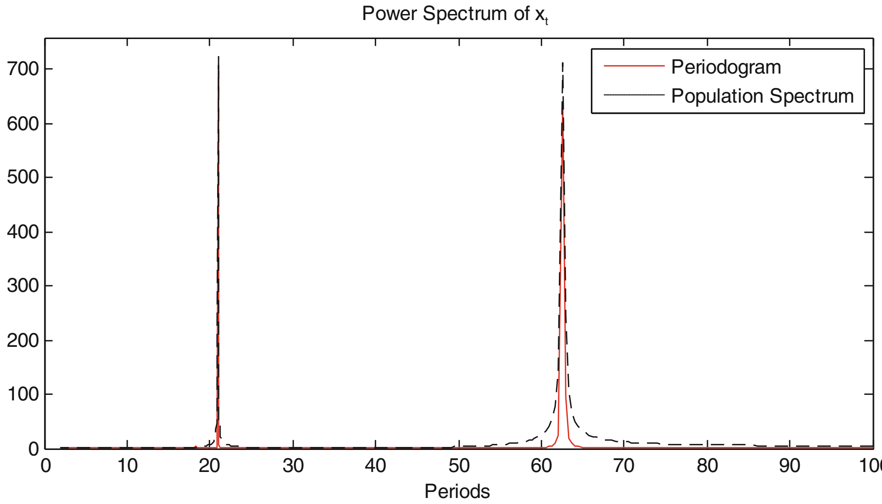

Fig. 19.3 Spectral analysis. The periodogram has been estimated directly from the realizations of $x(t)$. The population spectrum has been estimated on the basis of the theoretical autocovariances of $x(t)$

19.2.2 Filtering Methods

A filter is a mathematical operator that serves to convert an original time series $x(t)$ into another time series $y(t)$. The filter is applied by convolution of the original series $x(t)$ with a coefficient vector w:

$$y(t) = (w * x)(t) = \sum_{k=-\infty}^{\infty} w(k)x(t-k), \tag{19.7}$$

The purpose of this operation is to explicitly identify and to extract certain components from $x(t)$. In the present context, one may want to remove from the original time series some particular features (e.g., trends, business cycles, seasonalities, or noise) that are associated with specific frequency components.

19.2.2.1 Frequency Response Function

Filters in the time domain can be characterized on the basis of their *impulse-response function*, which traces the impact of a one-time unit impulse in $x(t)$ on subsequent values of $y(t)$. Similarly, in the frequency domain, the analysis of the *frequency response function* (or transfer function) of a filter tells us which frequency components the filter captures from the original series. The frequency response function is defined as the Fourier transform of the filter coefficients

$$H(f) = \sum_{k=-\infty}^{\infty} w(k)e^{-i2\pi fk}. \tag{19.8}$$

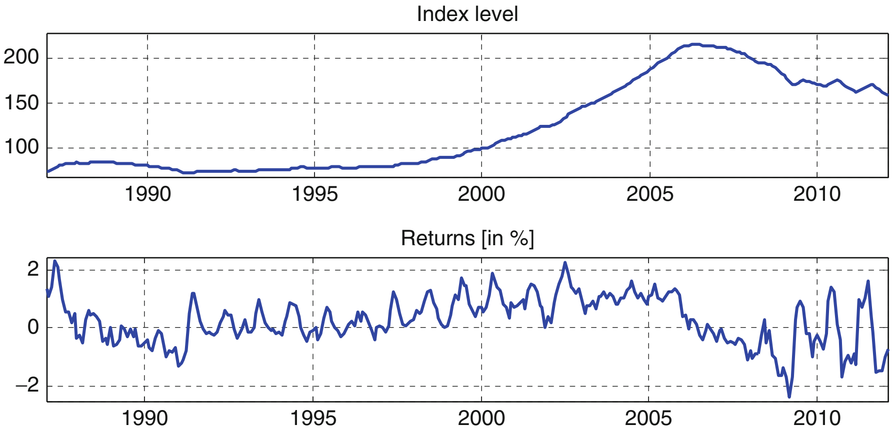

Fig. 19.4 Case-Shiller home price index for the city of New York. Price levels and returns are reported in the *upper* and lower panel respectively.

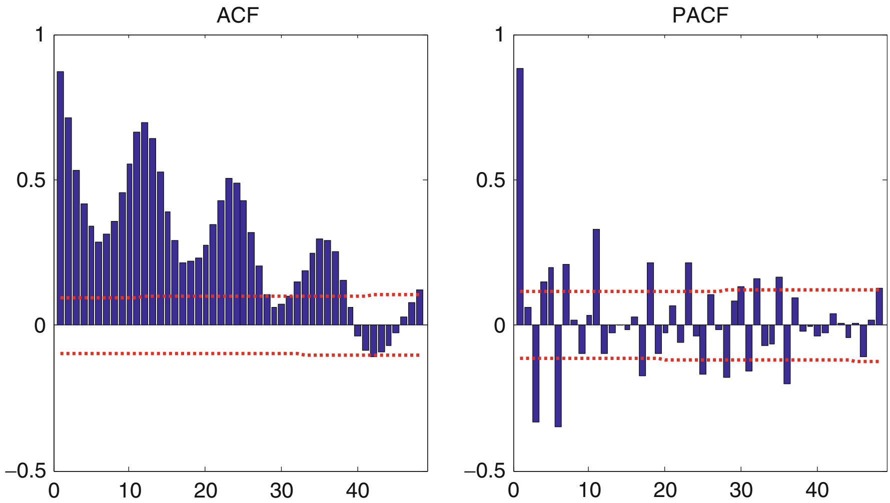

Fig. 19.5 Autocorrelations and partial autocorrelation of the returns on the New York home price index

The frequency response, $H(f)$, can be further split into two parts:

$$H(f) = G(f)e^{i\theta(f)}, \tag{19.9}$$

where $G(f)$ is the *gain* function, $e^{i\theta(f)}$ the *phase* function, and θ the phase angle (or equivalently the argument of $H(f)$). The gain function is the magnitude of the frequency response, i.e., $G(f) = |H(f)|$. If the application of the filter on $x(t)$ results in a phase shift, i.e., if the peaks and lows of $x(t)$ and $y(t)$ have a different timing, the phase angle θ will be different from zero. The use of uncentered moving average

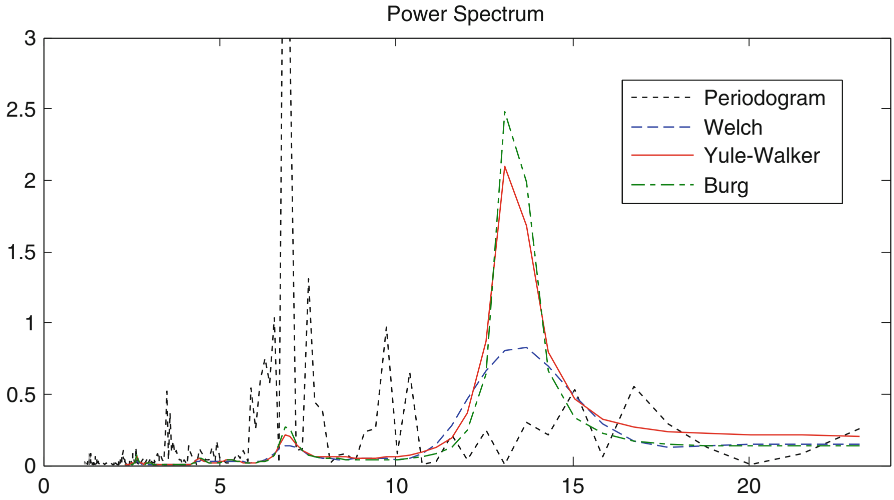

Fig. 19.6 Spectral analysis of the return series. Comparison between parametric (Burg and Yule-Walker) and non-parametric (Periodogram and Welch) methods

filters leads to this (often) undesirable feature because turning points will be recorded earlier in the original series than in the filtered series. On the other hand, centered (symmetric) moving averages have $\theta(f) = 0$; hence, there is no phase shift for this class of filters. For instance, the frequency response of a two-period uncentered moving average filter with coefficients $w(k) = 0.5$ for $k = 0, 1$ is[4]

$$\begin{aligned} H(f) &= \sum\nolimits_{k=0}^{1} 0.5e^{-i2\pi fk} \\ &= 0.5 + 0.5e^{-i2\pi f} \\ &= 0.5\left(e^{i\pi f} + e^{-i\pi f}\right)e^{-i\pi f} \\ &= \cos(\pi f)e^{-i\pi f} \end{aligned}$$

This result shows the existence of a phase shift as the phase angle is $\theta(f) = -\pi f$.[5] Hence, the turning points from the original series will be shifted to the right in the filtered series. On the other hand, a filter with coefficients w(k) = 1/3 for k = −1, 0, 1 has a zero phase angle.

Based on their gain functions, filters can be categorized as follows:

- High-pass filters should be able to capture the high-frequency components of a signal, i.e., the value of their gain function $G(f)$ should equal one for frequencies f close or equal to 1/2.

[4]See also Gençay et al. (2002) who uses a similar example.

[5]In full generality, the phase angle can be computed as $\theta(f) = \arctan\left(\frac{Im[H(f)]}{\mathrm{Re}[H(f)]}\right)$, where $Im[H(f)]$ and $\mathrm{Re}[H(f)]$ are, respectively, the imaginary part and the real part of $H(F)$.

- Low-pass filters should be able to capture the low-frequency components of a signal, i.e., $G(f) = 1$ for f close or equal to 0.
- Band-pass filters should be able to capture a range of frequency components of a signal, i.e., $G(f) = 1$ for $f_{lo} < f < f_{hi}$.
- All-pass filters capture all the frequency components of a signal, i.e., $G(f) = 1$ for $\forall f$. Such filters leave the frequency components of the original signal unaltered.

Filters are commonly used in economics. The Hodrick and Prescott (1997) filter is probably the best known. It has a structure and a gain function which enable it to capture business cycle components.

19.2.2.2 Example

A basic example of a high-pass filter is a filter that takes the difference between two adjacent values from the original series; its coefficients are $w_{hi} = [0.5, -0.5]$. Similarly, the most simple low-pass filter is a 2-period moving average; in this case $w_{lo} = [0.5, 0.5]$. In wavelet theory, $w_{hi}/\sqrt{2}$ and $w_{lo}/\sqrt{2}$ form the Haar wavelet family. In this case, the low-pass filter w_{lo} is basically an averaging filter, while the high-pass filter w_{hi} is a differencing filter. The gain functions for these two filters are reported in Fig. 19.7.

19.2.2.3 Illustration

The full line in the left panels of Fig. 19.8 shows the monthly (unadjusted) returns on the Case-Shiller New York home price index from 1987 to 2011. We add to the top panel the output series resulting from the application of both a centered and an uncentered (causal) 3-period moving average on the original data. The three-filter coefficients have a value of 1/3. This implies that the output series of the centered moving average at time t is basically the average return from months $t - 1$ to $t + 1$. Similarly, the uncentered moving returns the average return from $t - 2$ to t. It is apparent from the figure that the uncentered moving average leads to a phase shift of 1 month. The bottom panel shows the outputs of a 7-period moving average. The filter coefficients are equal to 1/7. Again, we consider both centered and uncentered filters. The use of an uncentered moving average leads to a phase shift of 3 months as compared to the centered moving average.

The right part of the figure reports the gain functions for the 3-period and the 7-period moving averages. The gain function is similar for both the uncentered and the centered moving average. The only element that distinguishes these two filters is indeed their phase function. One may notice that (i) both filters are low-pass filters, and (ii) the longer filter captures more efficiently the low-frequency components of the original signal than the short filter.

19.3 Scale-by-Scale Decomposition with Wavelets

To a large extent, wavelets can be seen as a natural extension to spectral and Fourier analysis as (i) wavelets do not suffer the weaknesses of Fourier analysis, and (ii) wavelets provide a more complete decomposition of the original time series than Fourier analysis does.

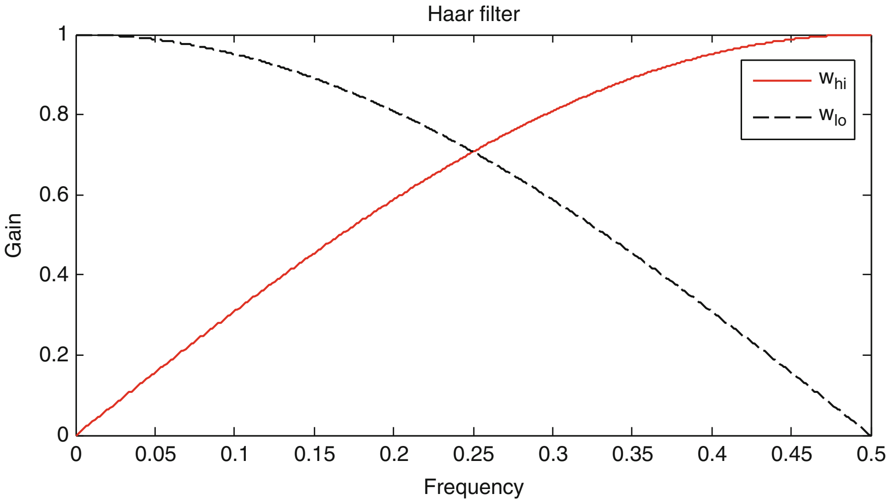

Fig. 19.7 Gain functions of the high-pass (differencing) and low-pass (averaging) Haar filters

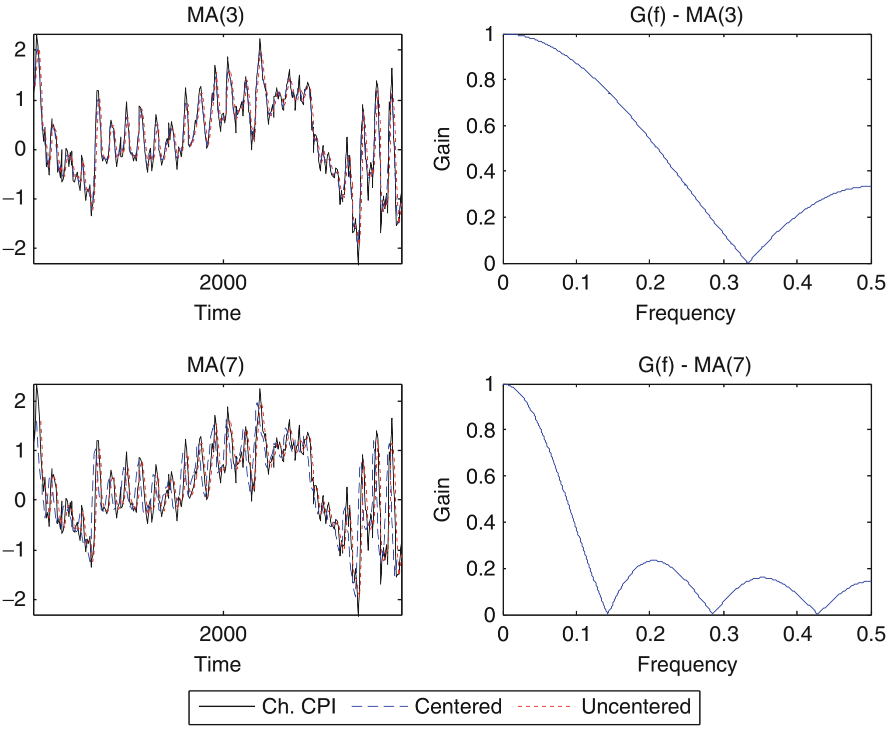

Fig. 19.8 Two moving averages and their frequency responses. *Left panels* show the outputs from a 3-period (*upper panel*) and a 7-period (*lower panel*) moving average filters applied on the returns on the Case-Shiller New York home price index. *Right panels* report the corresponding gain functions

There are some problems with spectral methods and Fourier transforms. Notably, these methods require the data under investigation to be stationary. This is often not the case in economics and finance. In particular, volatility is known to exhibit complicated patterns like jumps, clustering, and long memory. Furthermore, the frequency decomposition delivered by Fourier analysis only makes sense if the importance of the various frequency components remains stable over the sample period. Ex ante, there is good reason to expect this assumption not to hold for a variety of economic and financial variables. For instance, volatility changes are likely to exhibit a different frequency spectrum when trading activity is intense than when the market is quiet. The short-time Fourier transform (which is also known as the Gabor or windowed Fourier transform) has been suggested to overcome these difficulties. The idea is to split the sample into subsamples and to compute the Fourier transform on these subsamples. Hence, this extension achieves a better trade-off between the time and the frequency representation of the original data. Nevertheless, this provides at best a partial solution to the aforementioned issues as the strong restrictions regarding the possible data-generating process over each subsample are maintained.

Wavelets do not make any of these assumptions. Furthermore, wavelets provide a complete decomposition of the original series, which is located both in time and in frequency. From a mathematical viewpoint, a wavelet is a function, which enables to split a given signal into several components, each reflecting the evolution trough time of the signal at a particular frequency. Wavelet analysis has originally been used in signal processing (e.g., image processing and data compression). Its applications to economics and finance are relatively recent. Nevertheless, the range of application of wavelets is potentially wide: denoising and seasonality filtering, decorrelation and estimation of fractionally integrated models, identification of regime shift and jumps, robust estimation of the covariance and correlation between two variables at different time scales, etc.

From a physicist perspective, but with application to time series analysis, Percival and Walden (2000) and Struzik (2001) provide a mathematically rigorous and exhaustive introduction to wavelets. Struzik (2001) particularly emphasizes the unique ability of nonparametric methods (like wavelets) to let the data speak by themselves. Thus, such methods avoid making misleading interpretations of the coefficients obtained from the calibration of misspecified models. Gençay et al. (2002) discuss the use of wavelets for specific purposes in economics and finance and adopt a more intuitive approach (with many illustrations and examples), while Ramsey (2002) surveys the most important properties of wavelets and discusses their fields of application in both economics and finance. Crowley (2007) proposes a genuine guide to wavelets for economists. His article can be considered as a complete and easily understandable toolkit, precisely explaining in which circumstances to use wavelets and how to proceed. Schleicher (2002) is a complementary reference to those already named; Schleicher focuses on some mathematical concepts underlying the use of wavelets and discusses them in details using examples.

This short literature review focuses only on textbook-style references. There are however quite a large amount of economic and financial articles that have employed wavelets for empirical purposes. Ramsey[6] and Gençay[7] and their respective coauthors can be considered as the pioneers of the use of wavelets in economics and finance. Other recent contributions include Nielsen and Frederiksen (2005), Vuorenmaa (2005), Oswiecimka et al. (2006), Elder and Jin (2007), Fan et al. (2007), Fernandez and Lucey (2007), Rua and Nunes (2009), Manchaldore et al. (2010), Curci and Corsi (2012), and Hafner (2012).

19.3.1 Theoretical Background

19.3.1.1 What Is a Wavelet?

As its name suggests, a wavelet is a small wave. In the present context, the term "small" essentially means that the wave grows and decays in a limited time frame. Figure 19.9 illustrates this notion by contrasting the values taken by a simple wavelet function (the Morlet function)[8] and the values of the sin function, which can be considered as a sort of "large" wave. In order to clarify the notion of small wave, we start by introducing a function, which is called the *mother wavelet* and is denoted by $\psi(t)$. This function is defined on the real axis and must satisfy two conditions:

$$\int_{-\infty}^{\infty} \psi(t)dt = 0. \tag{19.10}$$

$$\int_{-\infty}^{\infty} |\psi(t)|^2 dt = 1. \tag{19.11}$$

Taken together, these conditions imply (i) that at least some coefficients of the wavelet function must be different from zero and (ii) that these departures from zero must cancel out. Clearly the sin function does not meet these two requirements. A vast variety of functions meets conditions (19.10) and (19.11). Nevertheless, these conditions are very general and not sufficient for many practical purposes. Therefore, one has to impose additional conditions in order to run a specific analysis with wavelets. One of these conditions is the so-called *admissibility condition*, which states that a wavelet function is admissible if its Fourier transform

$$\Psi(f) = \int_{-\infty}^{\infty} \psi(t)e^{-i2\pi ft}dt, \tag{19.12}$$

is such that

$$C_\Psi = \int_0^{\infty} \frac{|\Psi(f)|^2}{f} df \text{ satisfies } 0 < C_\Psi < \infty. \tag{19.13}$$

These conditions allow reconstructing a function from its continuous wavelet transform (see Percival and Walden (2000) for more details).

[6]See Ramsey et al. (1995), Ramsey and Zhang (1997), and Ramsey (1999).

[7]See Gençay et al. (2003), Gençay et al. (2010), Gençay and Fan (2010), and Gençay and Gradojevic (2011).

[8]The Morlet wavelet is actually similar to a sin curve modulated by a Gaussian envelope.

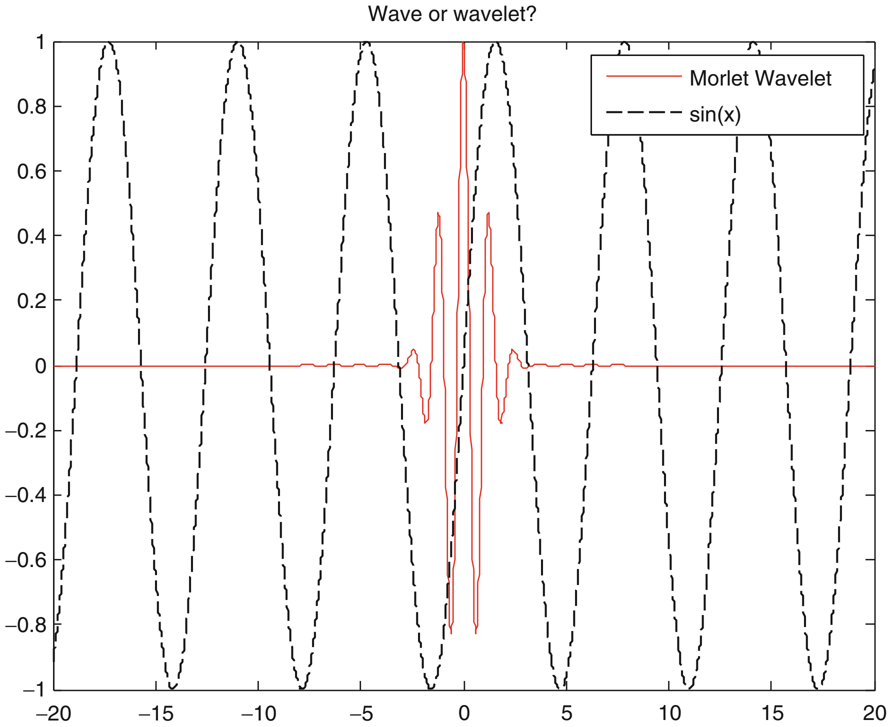

Fig. 19.9 The Morlet wavelet and the sin function

19.3.1.2 The Continuous Wavelet Transform (CWT)

As a starting point, we discuss the CWT. The CWT primarily aims at quantifying the change in a function at a particular frequency and at a particular point in time. In order to be able to achieve this, the mother wavelet $\psi(t)$ is dilated and translated:

$$\psi_{u,s}(t) = \frac{1}{\sqrt{s}}\psi\left(\frac{t-u}{s}\right), \tag{19.14}$$

where u and s are the location and scale parameters. The term $\frac{1}{\sqrt{s}}$ ensures that the norm of $\psi_{u,s}(t)$ is equal to one. The CWT, $W(u, s)$, which is a function of the two parameters u and s, is then obtained by projecting the original function $x(t)$ onto the mother wavelet $\psi_{u,s}(t)$:

$$W(u,s)=\int_{-\infty}^{\infty} x(t)\psi_{u,s}(t)dt. \tag{19.15}$$

To assess the variations of the function on a large scale (i.e., at a low frequency), a large value for s will be chosen and vice versa. By applying the CWT for a continuum of location and scale parameters to a function, one is able to decompose the function under study into elementary components. This is particularly interesting for studying a function with a complicated structure, because this procedure allows extracting a set of "basic" components that have a simpler structure than the original function. By "synthesizing" $W(u, s)$, it is also possible to reconstruct the original function $x(t)$ (see Gençay et al. (2002) for more details).

In empirical applications, several difficulties with the CWT occur. First, it is computationally impossible to analyze a signal using *all* wavelet coefficients. CWT is thus more suitable for studying functions than signals or (economics) time series. Second, as noted by Gençay et al. (2002), $W(u, s)$ is a function of two parameters and as such it contains a high amount of redundant information. We therefore turn to the discussion of the discrete wavelet transform (DWT).

19.3.1.3 The Discrete Wavelet Transform (DWT)

The core difference between the CWT and the DWT is that the latter does not use all translated and dilated versions of the mother wavelet to decompose the original signal (Gençay et al. 2003). The idea is to select u and s such that the information contained in the signal can be summarized in a minimum of wavelet coefficients. This objective is achieved by setting

$$s = 2^{-j} \text{ and } u = k2^{-j},$$

Where j and k are integers representing the set of discrete translations and discrete dilatations. Gençay et al. (2002) refer to this procedure as the *critical sampling* of the CWT. This implies that the wavelet transform of the original function or signal is calculated only at *dyadic* scales, i.e., at scales 2^j. A further implication is that for a time series with T observations, the largest number of scales for the DWT is equal to the integer J such that $J = \lfloor log_2(T) \rfloor = \lfloor log(T)/log(2) \rfloor$. It is not possible to directly apply the DWT if the length of the original series is not dyadic (i.e., if $J < log_2(T) < J + 1$). In such case, one has either to remove some observations or to "complete" the original series in order to have a series of dyadic length. Several methods exist to deal with this kind of boundary problems (see Sect. 19.3.2).

The DWT is based on two discrete wavelet filters, which are called the *mother wavelet* $h_l = (h_l, \ldots, h_{L-1})$ and the *father wavelet* $g_1 = (g_1, \ldots, g_{L-1})$. The mother wavelet is characterized by three basic properties:

$$\sum_{l=0}^{L-1} h_l = 0, \sum_{l=0}^{L-1} {h_l}^2 = 1, \text{and} \sum_{l=0}^{L-1} h_l h_{l+2n} = 0 \text{ for all integers } n \neq 0 \quad (19.16)$$

These three properties ensure that (i) the mother wavelet is associated with a difference operator, (ii) the wavelet transform preserve the variance of the original data, and (iii) a multiresolution analysis can be performed on a finite variance data series. The first property implies that the mother wavelet (also called "differencing function") is a high-pass filter as it measures the deviations from the smooth components. On the other hand, the father wavelet ("scaling function") aims at capturing long-scale (i.e., low-frequency) components of the series and generates the so-called scaling coefficients.[9]

The mother and father wavelets must respect the following conditions:

$$\sum_{l=0}^{L-1} h_l = 0. \tag{19.17}$$

$$\sum_{l=0}^{L-1} g_l = 1. \tag{19.18}$$

The application of both the mother and the father wavelets allows separating the low-frequency components of a time series from its high-frequency components. Furthermore, a band-pass filter can be constructed by recursively applying a succession of low-pass and high-pass filters.

Let's assume that we have observed a sample of size T of some random variable $x(t)$, $\{x(1), x(2), \ldots, x(T)\}$. The *wavelet* and *scaling coefficients* at the first level of decomposition are obtained by convolution of the data series with the mother and the father wavelets:

$$w_1(t) = \sum_{l=0}^{L-1} h_l x(t') \text{ and } v_1(t) = \sum_{l=0}^{L-1} g_l x(t') \tag{19.19}$$

where $t = 0,1, \ldots, T/2 - 1$ and t' the time subscript of x is defined as $t' = 2t + 1 - l \bmod T$. The modulus operator is employed to deal with boundary conditions.[10] It ensures that the time subscript of x stays always positive. If, for some particular values of t and l, the expression $2t + 1 - l$ becomes negative, the application of the modulus operator returns $t' = 2t + 1 - l + T$. Thus, we are implicitly assuming that x can be regarded as periodic. Alternative methods to deal with boundary conditions are discussed thereafter. $w_1(t)$ and $v_1(t)$ are, respectively, the wavelet and the scaling coefficients at the first scale. Hence, $w_1(t)$ corresponds to the vector containing the components of x recorded at the highest frequency. One may notice that the operation returns two series of coefficients that have length $T/2$. To continue the frequency-by-frequency decomposition of the original signal, one typically resorts to what is known as the pyramid algorithm.

19.3.1.4 Pyramid Algorithm

After having applied the mother and father wavelets on the original data series, one has a series of high-frequency components and a series of lower-frequency

[9]The low-pass filter can be directly obtained from the high-pass filter using the quadrature mirror relationship; see Percival and Walden (2000, p. 75).

[10]For two integer a and b, a modulus b is basically the remainder after dividing a by b, i.e., $a \bmod b = a - c \cdot b$ with $c = \lfloor a/b \rfloor$.

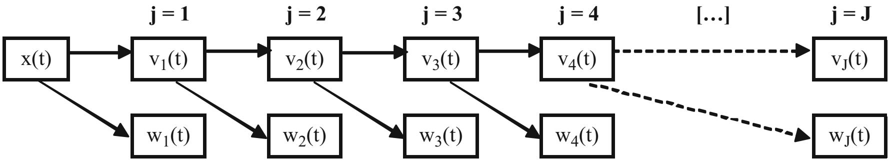

Fig. 19.10 Flowchart of the pyramid algorithm

components. The idea of the pyramid algorithm is to further decompose the (low-frequency) scaling coefficients $v_1(t)$ into high- and low-frequency components:

$$w_2(t) = \sum\nolimits_{l=0}^{L-1} h_l v_1(t') \text{ and } v_2(t) = \sum\nolimits_{l=0}^{L-1} g_l v_1(t'), \tag{19.20}$$

where $t = 0,1, \ldots,T/4 - 1$ and $t' = 2t + 1 - l \bmod T$. After two steps, the decomposition looks like $w = [w_1 \ w_2 \ v_2]$. One can then apply the pyramid algorithm again and again up to scale $J = \lfloor log_2(T) \rfloor$ to finally obtain $w = [w_1 \, w_2 \ldots w_j \, v_\text{j}]$. Figure 19.10 summarizes these steps. One may also apply the algorithm up to scale $J_p < J$ only. This is known as the *partial* DWT.

19.3.1.5 The Maximal Overlap Discrete Wavelet Transform (MODWT)

The standard DWT suffers from three drawbacks. First, it requires a series with a dyadic length. Second, DWT is not shift invariant, i.e., if one shifts the series one period to the right, the multiresolution coefficients will be different. Third, it may introduce phase shifts in the wavelet coefficients: peaks or troughs in the original series may not be correctly aligned with similar events in the multiresolution analysis. To overcome these problems, the MODWT has been proposed. This wavelet transform can handle any sample size, it has an increased resolution at coarser scales (as compared to the DWT), and it is invariant to translation. It also delivers a more asymptotically efficient wavelet variance than the DWT.[11]

The main difference between the DWT and the MODWT lies in the fact that the MODWT considers all integer translations, i.e., $u = k$. This means that the MODWT keeps at each frequency a complete resolution of the series. Whatever the scale considered, the length of the wavelet and scaling coefficient vectors will be equal to the length of the original series. The wavelet and scaling coefficients at the first level of decomposition are obtained as follows:

$$\widetilde{w}_I(t) = \sum\nolimits_{l=0}^{L-1} \widetilde{h}_l x(t') \text{ and } \widetilde{v}_1(t) = \sum\nolimits_{l=0}^{L-1} \widetilde{g}_l x(t'), \tag{19.21}$$

where $t = 0,1,\ldots T$ and $t' = t - l \bmod T$. As for the DWT, the MODWT coefficients for scales $j > 1$ can be obtained using the pyramid algorithm. For instance, $\widetilde{w}_j$ and $\widetilde{v}_j$ are calculated as

[11]See Crowley (2007) for more details about the properties of MODWT.

$$\widetilde{w}_j(t) = \sum_{l=0}^{L-1} \widetilde{h}_l \widetilde{v}_{j-1}(t') \text{ and } \widetilde{v}_j(t) = \sum_{l=0}^{L-1} \widetilde{g}_l \widetilde{v}_{j-1}(t'), \tag{19.22}$$

where $t' = 2^{j-1}\, l \bmod T$.

Using matrix notation, we can conveniently calculate the wavelet and scaling coefficients up to scale J. We first define a matrix $\widetilde{W}$ that is composed of $J + 1$ sub-matrices, each of them T x T:

$$\widetilde{W} = \begin{bmatrix} \widetilde{W}_1 \\ \widetilde{W}_2 \\ \vdots \\ \widetilde{W}_J \\ \widetilde{V}_J \end{bmatrix} \tag{19.23}$$

Each $\widetilde{W}_j$ has the following structure:

$$\widetilde{W}_j = \begin{bmatrix} \widetilde{h}_0/2^{j/2} & 0 & 0 & \cdots & 0 & \widetilde{h}_{L-1}/2^{j/2} & \cdots & \widetilde{h}_1/2^{j/2} \\ \widetilde{h}_1/2^{j/2} & \widetilde{h}_0/2^{j/2} & 0 & \cdots & 0 & 0 & \cdots & \vdots \\ \vdots & \widetilde{h}_1/2^{j/2} & \widetilde{h}_0/2^{j/2} & \cdots & 0 & 0 & \cdots & \widetilde{h}_{L-1}/2^{j/2} \\ \widetilde{h}_{L-1}/2^{j/2} & \vdots & \widetilde{h}_1/2^{j/2} & \cdots & 0 & 0 & \cdots & 0 \\ 0 & \widetilde{h}_{L-1}/2^{j/2} & \vdots & \cdots & 0 & 0 & \cdots & 0 \\ 0 & 0 & \widetilde{h}_{L-1}/2^{j/2} & \cdots & 0 & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \cdots & \vdots \\ 0 & 0 & 0 & \cdots & \widetilde{h}_0/2^{j/2} & 0 & \cdots & 0 \\ 0 & 0 & 0 & \cdots & \widetilde{h}_1/2^{j/2} & \widetilde{h}_0/2^{j/2} & \cdots & 0 \\ 0 & 0 & 0 & \cdots & \vdots & \vdots & \cdots & 0 \\ 0 & 0 & 0 & \cdots & \widetilde{h}_{L-1}/2^{j/2} & \widetilde{h}_{L-2}/2^{j/2} & \cdots & \widetilde{h}_0/2^{j/2} \end{bmatrix} \tag{19.24}$$

$\widetilde{V}_J$ has a similar structure as $\widetilde{W}_J$ but it contains the coefficients associated to the father wavelet instead of the mother wavelet.

We can now directly calculate all wavelet and scaling coefficients via

$$\widetilde{w} = \widetilde{W} x, \tag{19.25}$$

where $\widetilde{w}$ is a vector made up of $J + 1$ length T vectors of wavelet and scaling coefficients, $\widetilde{w}, \ldots, \widetilde{w}_J$ and $\widetilde{v}_j$; i.e., $\widetilde{w} = \left[\widetilde{w}_1 \widetilde{w}_2 \widetilde{w}_J \cdots \widetilde{v}_J\right]^T$.

19.3.1.6 Multiresolution Analysis (MRA)

Multiresolution analysis can be used to reconstruct the original time series x from the wavelet and scaling coefficients, $\widetilde{v}_j$ and $\widetilde{w}_j$. In order to achieve this, one has to apply the inverse MODWT on $\widetilde{v}_j$ and $\widetilde{w}_j$, $j = 1, \ldots, J$.[12]

[12]Our presentation of the multiresolution analysis is restricted to the case of the MODWT. Nevertheless, a very similar procedure exists for the DWT; see Percival and Walden (2000).

$\widetilde{W}$ is an orthonormal matrix, as such $\widetilde{W}^T\widetilde{W} = 1$. Hence, if we multiply both side of Eq. 19.25 by $\widetilde{W}^T$, we get

$$\widetilde{W}^T \widetilde{w} = \widetilde{W}^T\widetilde{W}x = x. \tag{19.26}$$

As $\widetilde{W}^T = \left[\widetilde{W}_1\ \widetilde{W}_2 \cdots \widetilde{W}_J\ \widetilde{V}_J\right]$ and $\widetilde{w} = \left[\widetilde{w}_1\ \widetilde{w}_2\ \widetilde{w}_J \cdots \widetilde{v}_J\right]^T$, we can further rearrange Eq. 19.26 and show that

$$x = \sum\nolimits_{j=1}^{J} \widetilde{W}_j{}^T \widetilde{w}_j + \widetilde{V}_J{}^T \widetilde{v}_J. \tag{19.27}$$

Setting $D_j = \widetilde{W}_j{}^T \widetilde{w}_j$ and $S_j = \widetilde{V}_j{}^T \widetilde{v}_j$, we can reconstruct the original time series as

$$x = D_1 + \ldots + D_J + S_J. \tag{19.28}$$

This "reconstruction" is known as multiresolution analysis (MRA). The elements of S_j are related to the scaling coefficients at the maximal scale and therefore represent the *smooth components* of x. The elements of D_j are the *detail* (or *rough*) *coefficients* of x at scale j.

On the basis of formula (19.28), one may also think of a way to compute an approximation or a smooth representation of the original data. This can be achieved by considering the scaling coefficients and the wavelet coefficients from scale J_s ($J_s < J$) to J only, i.e.:

$$x_S = D_S + \ldots + D_J + S_J. \tag{19.29}$$

Equation 19.29 can be used, for instance, to filter out noise or seasonalities from a time series. In image processing, Eq. 19.29 serves for data compression. Equation 19.27 has been specifically derived for the MODWT but similar results are available for the DWT (see Percival and Walden 2000).

19.3.1.7 Analysis of Variance

On the basis of the wavelet and scaling coefficients, it is also possible to decompose the variance into different frequency components. There are some slight differences between the variance decomposition for the DWT and for the MODWT. We will therefore first present the main results for the DWT and then discuss their extension to the MODWT.

Using the wavelet and scaling coefficients of the discrete wavelet transform, it is possible to decompose the energy of the original series on a scale-by-scale basis:

$$\|x\|^2 = \sum_{t=0}^{T-1} x(t)^2 = \sum_{j=1}^{J} \sum_{t=0}^{T/2^J-1} w_j(t)^2 + v_J(t)^2, \tag{19.30}$$

where $\|x\|^2$ denotes the energy of x. The wavelet coefficients capture the deviations of x from its long-run mean at the different frequency resolutions. Therefore, at scale $j = J = log_2(T)$, the last remaining scaling coefficient is equal to the sample mean of x,

$$E(x) = v_J. \tag{19.31}$$

On this basis, we can express the variance of x as

$$V(x) = E(x^2) - E(x)^2 = \sum_{j=1}^{J} E(w_j{}^2) = \sum_{j=1}^{J} V(w_j), \tag{19.32}$$

where $V(w_j)$ denotes the variance of the wavelet coefficients at scale j.

If we consider the wavelet and scaling coefficients obtained from a partial DWT, the variance of x can be expressed as

$$V(x) = \sum_{j=1}^{J_p} V(w_j) + V(v_{J_p}). \tag{19.33}$$

The variance of the scaling coefficients has to be taken into account because v_{J_p} incorporates deviations of x from its mean at scales $J_p < j < J$.[13]

An alternative way to decompose the energy of x is based on the smooth and detail coefficients of the MRA. As above, $\|x\|^2$ can be computed as the sum of the energy of the smooth and detail coefficients. This approach is, however, valid only for the DWT (See Gençay et al. 2002).

It is important to note that some of the wavelet coefficients involved in Eq. 19.32 are affected by boundary conditions. One should remove the corresponding wavelet coefficients in order to get an unbiased estimator of the wavelet variance:

$$\hat{V}(x) = \sum_{j=1}^{J} \left[\frac{1}{2\lambda_j \hat{T}_j} \sum_{t=L_j'}^{\frac{T}{2^j}-1} w_j(t)^2 \right], \tag{19.34}$$

where λ_j is the scale that is associated to the frequency interval $[1/2^{j+1}\ 1/2^j]$. $L_j' = \lceil (L-2)(1-2^{-j}) \rceil$ is the number of DWT coefficients computed using the boundaries. Hence, $\hat{T}_j = T/2^j - L_j'$ is the number of coefficients unaffected by the boundary.

[13]One may notice that the variance of the scaling coefficient at scale J is 0 as v_J is a scalar (the sample mean of x).

We now turn to the analysis of variance in the context of the MODWT. Equation 19.32 remains perfectly valid. The MODWT keeps the same number of coefficients at each stage of the wavelet transform. The way of dealing with boundary conditions must therefore be adapted. From the detail coefficients of a partial MODWT of order $J_p < log_2(T)$, the wavelet variance can be estimated as follows:

$$\hat{V}(x) = \sum_{j=1}^{J_p} \left[\frac{1}{\hat{T}_j} \sum_{t=L_j-1}^{T-1} \tilde{w}_j(t)^2 \right] \tag{19.35}$$

where $L_j = (2^j - 1)(L - 1) + 1$ is the number of scale λ_j wavelet coefficients, which are affected by boundary conditions. This number also corresponds to the length of the wavelet filter at scale λ_j. $\hat{T}_j = T - L_j + 1$ is thus the number of wavelet coefficients unaffected by the boundary.

19.3.2 Implementation and Practical Issues

19.3.2.1 Choice of a Wavelet Filter

Many different wavelet filters exist with each of them being particularly suitable for specific purposes of analysis. Wavelet filters differ in their properties and in their ability to match with the features of the time series under study. Furthermore, when it comes to implement a *discrete* wavelet transform, one also has to decide about the filter length. Because of boundary conditions, longer filters are well adapted for long time series. The simplest filter is the Haar wavelet, which is basically a difference and average filter of length two. In finance, most researchers have worked either with Daubechies (denoted as "D") or with Least-Asymmetric ("LA") filters of length 4–8. Elder and Jin (2007) and Nielsen and Frederiksen (2005) employ D(4) filters. Gençay et al. (2003, 2010) suggest that the LA (8) wavelet (i.e., a Least-Asymmetric filter of length 8) is a good choice for analyzing financial time series, while Subbotin (2008) uses a LA(4) wavelet. Crowley (2007) argues that the impact of choosing another wavelet filter has a rather limited impact on the distribution of the variance of the time series across the scales.

Depending on the purpose of the analysis, it might be appealing to select a wavelet filter which satisfies one or more of the following properties:

- Symmetry: symmetric filters are appealing as they ensure that there will be no phase shift in the output series. Unfortunately, most wavelets are not symmetric. An exception is the Haar wavelet. The requirement of a symmetric wavelet is, however, less essential if a MODWT is used as it ensures that the original series and its filter coefficients will be aligned.
- Orthogonality: this property refers to the fact that the wavelet and the scaling coefficients contain different information. This is an important feature as it allows for the wavelet decomposition to preserve the energy (variance) of the original series (Crowley 2007). Daubechies and Least-Asymmetric wavelets

meet this requirement, that is, their scaling and wavelet coefficients are orthogonal by construction.

- Smoothness: The degree of smoothness is measured by the number of continuous derivatives of the basis function. As such, the Haar wavelet is the least smooth wavelet. The choice of a more or less smooth filter depends essentially on the data series to be represented. If the original time series is very smooth, then one will opt for a smooth wavelet. For instance, the Haar wavelet is appropriate for the analysis of a pure jump process.
- Number of vanishing moments: The number of vanishing moments of the wavelet function has a direct implication on the ability of the wavelet to account for the behavior of the signal. That is, if a signal has a polynomial structure or if it can be approximated by a polynomial of order q, then the wavelet transform will be able to properly capture this polynomial structure only if it has q vanishing moments. For instance, Daubechies wavelets have a number of vanishing moments which is half the length of the filter. Thus, the Haar and D(8) have, respectively, 1 and 4 vanishing moments.

The last two properties depend not only on the wavelet filter but also on its length. In fact, the most crucial point is probably not to choose the "right" filter but to choose a filter with an appropriate length. Increasing filter length allows better fitting the data. Unfortunately, this also renders the influence of boundary conditions more severe. Hence, a trade-off has to be found.

Problems due to boundary conditions arise in two situations. The first case concerns the DWT. To use the DWT, one requires a time series with a dyadic length. If the series does not meet this requirement, i.e., if its length N is such that $2^j < N < 2^{j+1}$, one has the choice between removing observations until $N = 2^j$ and completing the series such that $N = 2^{j+1}$. Removing data might be the best alternative but it leads to a loss of information.

The second case concerns both the DWT and the MODWT. The wavelet filter has to be applied on all observations, including observations recorded at the beginning ($t = 1$). A problem arises because the convolution operator requires that $L - 1$ observations are available before t. In this case, removing data is useless. Therefore, one has to complete the data series. One solution is to pad each end of the series with zeros; this technique is known as "zero padding." An alternative is to use the fit from a polynomial model to replace nonexisting data at each end of the series ("polynomial approximation"). One may also complete each end of the series either by mirroring the last observations ("mirror" or "reflection") or by taking the values observed at the beginning of the other end of the series ("circular"). The choice depends on the data considered. For instance, if working on stock returns, the use of a "mirror" seems to be the most suitable approach as it accounts for the presence of volatility clustering. Moreover, after the multiresolution decomposition of the original signal, one may obviously discard the coefficients that are affected due to their proximity to the boundaries of the series.

Instead of selecting a priori specific wavelet function, one may also use the so-called optimal transforms. The idea is to choose the wavelet function that minimizes a loss function (e.g., the entropy cost function; see Crowley 2007).

19.3.2.2 Examples of Wavelet Filters and Their Gain Functions

Figure 19.11 shows the coefficients of the Haar, D(4), D(8), and LA(8) wavelets for level $j = 4$. One may observe the very simple structure of the Haar wavelet. When comparing the latter with the D(4) and D(8) filters, it becomes clear that the longer the filter, the smoother it is. The LA(8) looks less asymmetric than the D(8). Nevertheless it is still far from being symmetric.

Studying the frequency response of these filters permits to assess their ability to capture the different frequency components. Figure 19.12 displays the gain function for each wavelet filter at scales 1–4. It is evident from the figure that the longer filters (D(8) and LA(8)) have better frequency localization. The gain functions of the D(8) and LA(8) are similar. In order to make this statement clearer, we contrast the gain functions of the Haar, D(4) and D(8) wavelets at scale $j = 5$ in Fig. 19.13. The D(8) captures much better the components corresponding to frequencies between $1/2^j$ and $1/2^{j+1}$.

19.3.2.3 Example

Let's consider a variable x, whose dynamics is primarily driven by an AR(1) process and three cyclical components:

$$y(t) = 0.90y(t-1) + \sum\nolimits_{s=3}^{5} 5\cos\left(\frac{2\pi t}{s}\right) + \varepsilon(t), \tag{19.36}$$

$\varepsilon(t)$ is an i.i.d. Gaussian process with mean zero and unit variance and $t = 1, \ldots, 10{,}000$. In the absence of seasonalities and noise, the autocorrelation function of y should take value 0.90^k at lag k. Wavelets can be used to remove the impact of both noise and seasonalities. From Eq. 19.36, one may notice that the cyclical components have a period length of 3–5 periods. Hence, they have an impact on frequencies between 1/5 and 1/3.

At scale j, the wavelet detail D_j captures frequencies $1/2^{j+1} \leq f \leq 1/2^j$ and the wavelet smooth S_j captures frequencies $f < 1/2^{j+1}$. If we use a level 2 multiresolution analysis, the wavelet smooth S_2 will thus capture the components of the time series, which have a frequency $f < 1/8$. This means that S_2 will take into account changes in y that are associated with a period length of at least 8 units of time. Therefore, S_2 should keep the AR(1) dynamics of y, while removing its cyclical behavior and noise.

Figure 19.14 reports the autocorrelation coefficients for the original time series y, for the theoretical AR(1) process, and for the wavelet smooth S_2. In order to assess the impact of choosing a different wavelet filter, we use both the Haar and the LA (8) wavelets. The results are very similar even if for short lags the LA(8) seems to provide some improvements over the Haar. All in one, this example demonstrates the ability of a wavelet filter to deal with a complex cyclical structure and with noise.

19.3.3 Illustration: Home Price Indices for Different US Cities

19.3.3.1 Descriptive Statistics

In this section, we study the evolution of home prices in 12 US cities from January 1987 to February 2012 (302 months).[14] We employ the Case-Shiller home price indices. The data has been gathered from the Standard & Poors website. $P_j(t)$ denotes the price index level for the jth city in period t which has been standardized so that it has a value of 100 in the first month of the sample, i.e., $P_j(t = 0) = (\forall_j)$. We compute the index returns as

$$r_j(t) = \log\left[P_j(t)\right] - \log\left[P_j(t-1)\right].$$

Table 19.1 reports some descriptive statistics for the returns on each of the 12 home price indices. There are huge disparities in performance. The largest price increases are to be found in Portland (+216 % since 1987 but −31 % since the

[14] Los Angeles (LA), San Francisco (SF), Denver (De), Washington (Wa), Miami (Mi), Chicago (Chi), Boston (Bos), Las Vegas (LV), New York (NY), Portland (Po), Charlotte (Cha), and Cleveland (Cl).

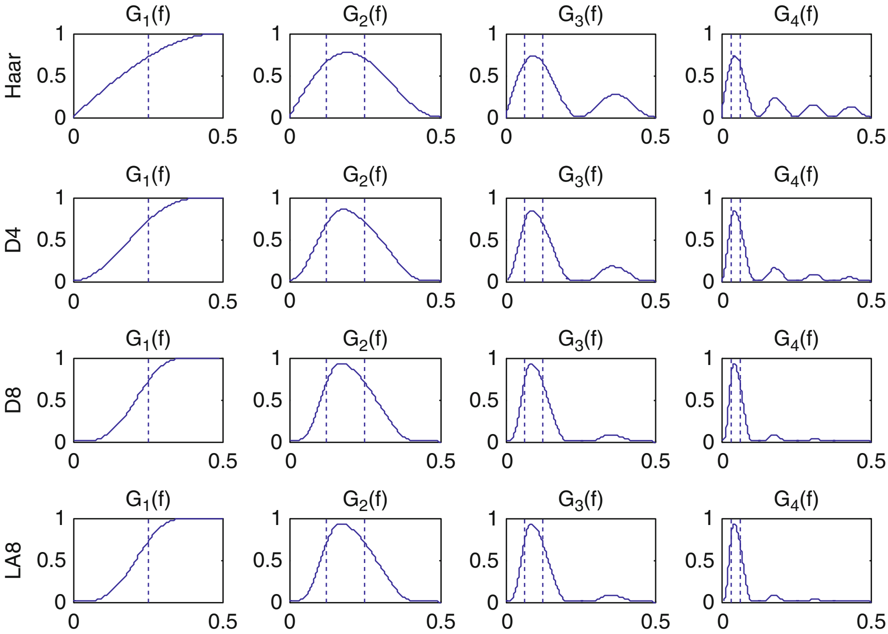

Fig. 19.12 Gain function for the Haar, D(4), D(8), and LA(8) wavelets

beginning of the subprime/financial crisis), Washington (+174 % and −34 % respectively), and Los Angeles (+169 % and −42 %). Las Vegas (+35 % and −62 %), Charlotte (+71 % and −20 %), and Cleveland (+76 % and −24 %) are the worst performers. The volatility of home price changes has been much larger in cities like San Francisco, Los Angeles, Las Vegas, and Miami than in northeast cities (plus Portland and Denver). This higher volatility is, to a large extent, the result from the severe price downturn in these four cities during the last 6 years of the sample. It is worth mentioning that some cities have been less affected by the home price crash than others (e.g., Denver and Boston). The skewness is always negative and the kurtosis is generally smaller than three.

19.3.3.2 Autocorrelations

Figure 19.15 shows the autocorrelations (up to 24 lags, i.e., 2 years) of the index returns. The full lines are for the original series, while the dotted lines show the autocorrelations computed from the smooth coefficients obtained using the MRA from a partial MODWT. We employ a LA(8) filter with $J_p = 3$. Hence, the wavelet smooth (S_3) should capture the frequency components that are associated with a period length of at least 16 months and should therefore be free of seasonal effects. In order to deal with the boundary conditions, we use the reflection method.

Some indices are very affected by seasonal effects (Portland, Boston, Denver, Charlotte, and Cleveland) while other indices are much less affected

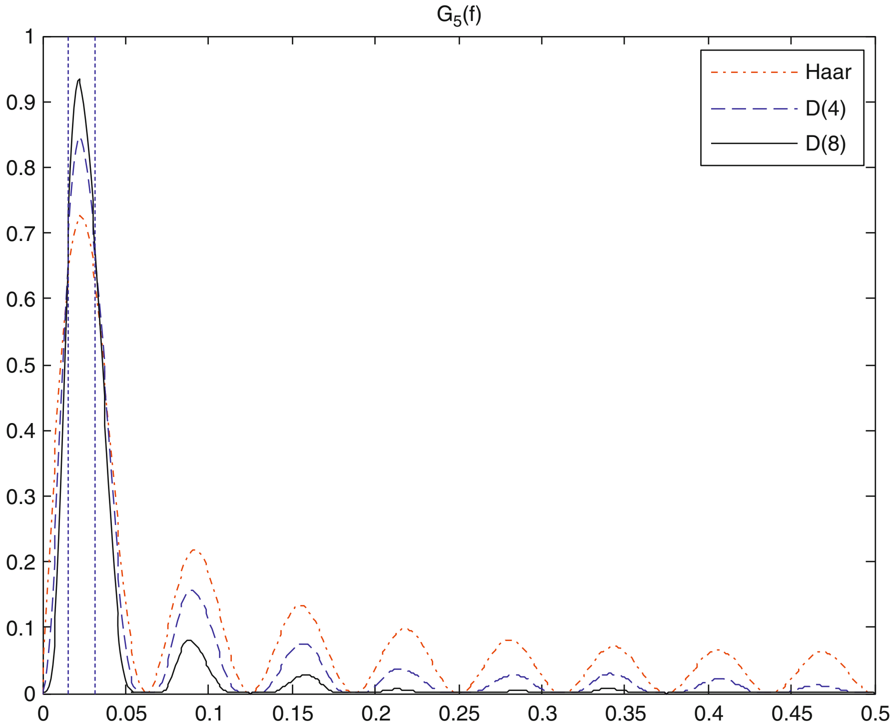

Fig. 19.13 Gain function for the Haar, D(4), and D(8) at scale $j = 5$

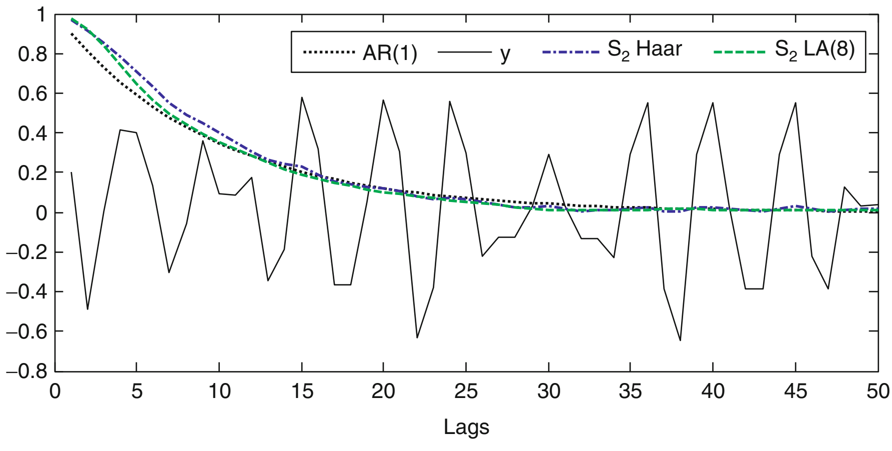

Fig. 19.14 Autocorrelations estimated before and after having removed some specific frequency components of the original time series

Table 19.1 Descriptive statistics for the 12 home price indices

	LA	SF	De	Wa	Mi	Chi	Bos	LV	NY	Po	Cha	Cl
Averag	3.9 %	3.9 %	3.5 %	4.0 %	2.8 %	2.7 %	2.9 %	1.2 %	3.0 %	4.6 %	2.1 %	2.3 %
Std.	4.4 %	4.9 %	2.6 %	3.5 %	4.0 %	3.6 %	3.2 %	4.8 %	2.8 %	3.1 %	2.1 %	3.1 %
Skew.	(0.4)	(0.7)	(0.6)	(0.2)	(1.2)	(1.1)	(0.1)	(0.3)	(0.2)	(0.8)	(0.7)	(0.8)
Kurt.	1.0	1.8	1.1	0.7	2.9	3.1	(0.0)	4.9	(0.1)	2.0	2.1	6.9
Last	159.5	124.6	121.8	175.7	139.5	105.4	146.2	89.9	159.6	129.6	108.1	94.1
High	273.9	218.4	140.3	251.1	280.9	168.6	182.5	234.8	215.8	186.5	135.9	123.5
Bottom	159.2	117.7	120.2	165.9	137.0	105.4	145.8	89.9	159.6	129.6	108.1	94.1

We report the average return, the standard deviation (both annualized and in %), the skewness, and the kurtosis of home price index returns. We also report the index level in the last month of the sample as well as the highest level reached before the crisis and the lowest level reached during the crisis

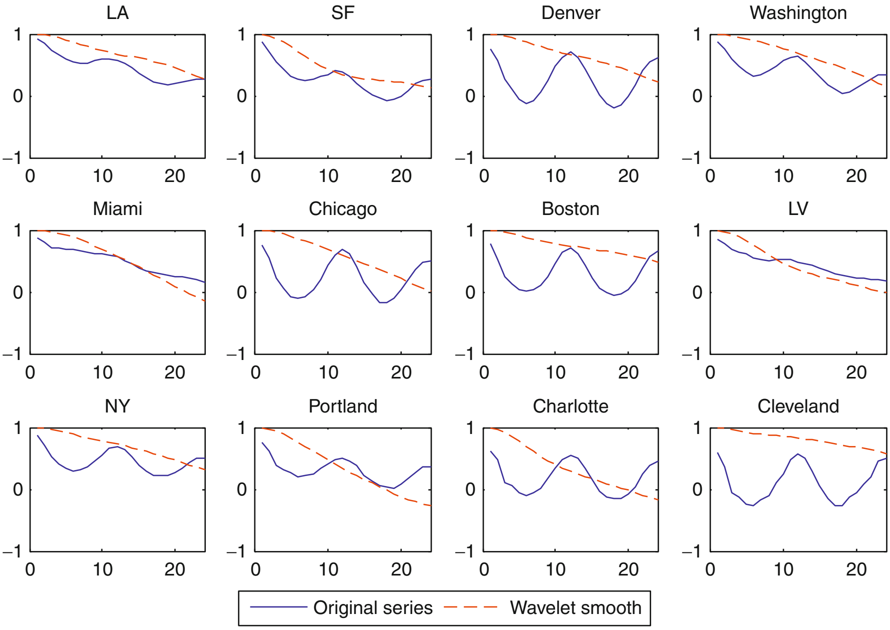

Fig. 19.15 Autocorrelations of $r_j(t)$. This figure shows the autocorrelations for both the original returns series and the wavelet smooth series for each home price index

(Miami, Las Vegas, and Los Angeles). In general the indices that display the least significant seasonal patterns are also those that have been the most affected by the recent crisis. This observation may suggest that the (quasi) absence of these patterns is the result of the predominant role of speculation on price changes in these cities.

One may again observe the ability of wavelets to remove seasonal patterns. The autocorrelations estimated from the wavelet smooth show the long-run temporal dynamics of home prices. In contrast to financial markets, whose evolution is almost unpredictable, home prices are strongly autocorrelated. The autocorrelation remains positive even after 2 years.

19.3.3.3 Variance and Cross-Correlations

Next, we analyze the variance of each index returns series and the correlations between the different indices at a variety of frequencies. We employ a partial MODWT with $J_p = 5$. Hence, at the largest scale, the wavelet coefficients contain information regarding price changes over horizon of 32–64 months. Similarly, the scaling coefficients capture the evolution for periods longer than 64 months. Figure 19.16 shows the distribution of variance across the different frequencies.

From Fig. 19.16, one may notice that most of the variance is due to frequency components associated with scales 3 and 6. On the other hand, variance at scales 1 and 2 is low and may be due to noise. Scales 4–5 are not related to important frequency components, neither to seasonal patterns (scale $j = 3$ nor to business

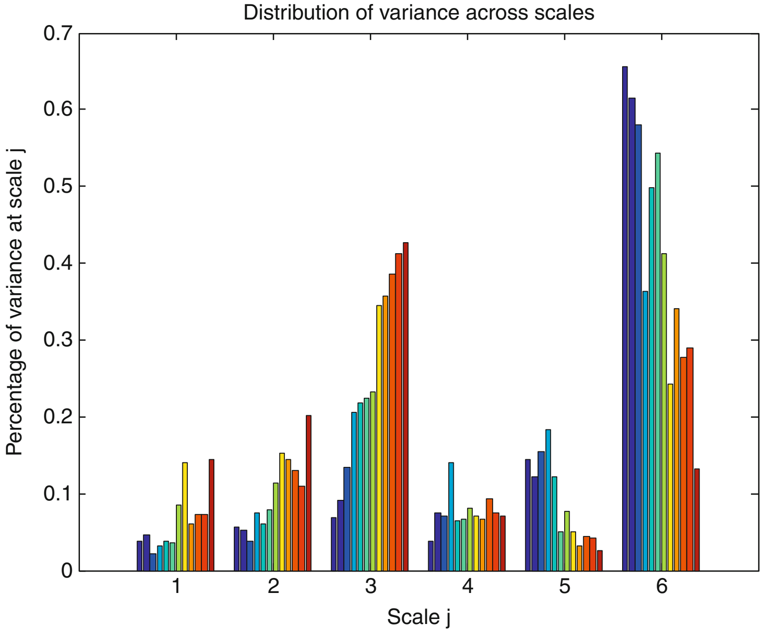

Fig. 19.16 Distribution of the wavelet variance across scales. Each bar corresponds to the variance recorded at a specific scale *j* and for a particular city. Cities are ordered as follows (from *left* to *right*): Miami, Las Vegas, Los Angeles, Washington, New York, San Francisco, Chicago, Portland, Boston, Denver, Charlotte, Cleveland

cycle components (scales $j > 5$). Thus, it comes as no surprise that they do not have much information content.

Scale 3 corresponds to periods of 8–16 months, and as such the variance observed at this scale reflects the importance of seasonal patterns in the dynamics of the various home price indices. As before, we observe that seasonal effects have a very limited impact on prices in Miami; they are also much less important in cities like Las Vegas, Los Angeles, Washington, and New York than in Boston, Denver, Charlotte, and Cleveland. Interestingly the ordering is reversed when considering the variance at scale 6. That is, the index returns series on which seasonalities have a weak impact exhibit the largest percentage of long-term volatility.

Figure 19.17 reports the correlation between the various city indices at different scales. The largest correlations are observed at scales larger than 2. In particular at scale 3, the correlations are very significant. This is because seasonalities affect most indices simultaneously. One may notice that indices 5 and 8 (Miami and Las Vegas) show less correlation with the other indices. At scales 4 and 5, the correlations become highly significant. This demonstrates that the series tend to behave very similarly in the long run.

An extension to this correlation analysis is to study how many (economic) factors are important to explain the structure of the correlation matrix at each

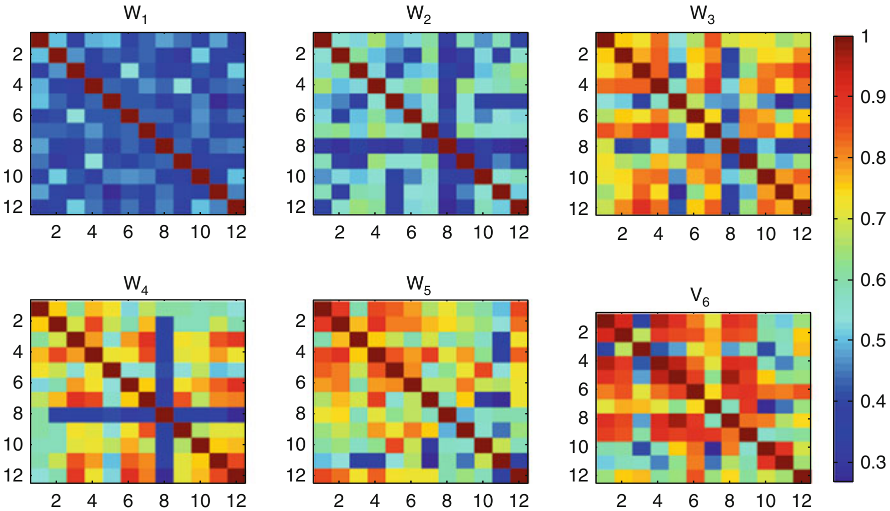

Fig. 19.17 Correlations between home price indices at different frequencies. Panels denoted by W_1 to W_5 show the correlations between the wavelet coefficients at scales $j = 1, \ldots, 5$, while panel denoted V_5 show the correlations between the scaling coefficients at scale $j = 5$. The 12 cities are order as follows: Los Angeles, San Francisco, Denver, Washington, Miami, Chicago, Boston, Las Vegas, New York, Portland, Charlotte, Cleveland

scale. In order to address this question, one may resort to random matrix theory (RMT). A good introduction is provided by Bouchaud and Potters (2004) (See also Sharifi et al. (2004) for a literature review). Here, we concentrate on the main premises of RMT. That is, this approach should help to (i) assess if the correlation coefficients have a genuine information content or if they are merely due to the noise inherent in the data and (ii) estimate the number of factors that are necessary to "explain" the correlation matrix. This is done by comparing the eigenvalues of the empirical correlation matrix with those from a theoretical distribution.

Let's consider a dataset with N time series of length T. We assume that the theoretical random matrix belongs to the ensemble of Wishart matrices. On this basis, we can derive the theoretical distribution of the eigenvalues of the correlation matrix. Under the null of pure randomness, the eigenvalues must be confined within the bounds[15]:

$$\lambda_{\min} = \left(1 + \frac{1}{q} - 2\sqrt{\frac{1}{q}}\right) \quad \text{and} \quad \lambda_{\max} = \left(1 + \frac{1}{q} + 2\sqrt{\frac{1}{q}}\right), \tag{19.37}$$

where $q = \frac{T}{N}$. If the correlation matrix is random, then the probability that any of its eigenvalues lies outside the bounds defined by $[\lambda_{\min}, \lambda_{\max}]$ is zero. Hence, the

[15]See Sharifi et al. (2004) and Kwapien et al. (2007).

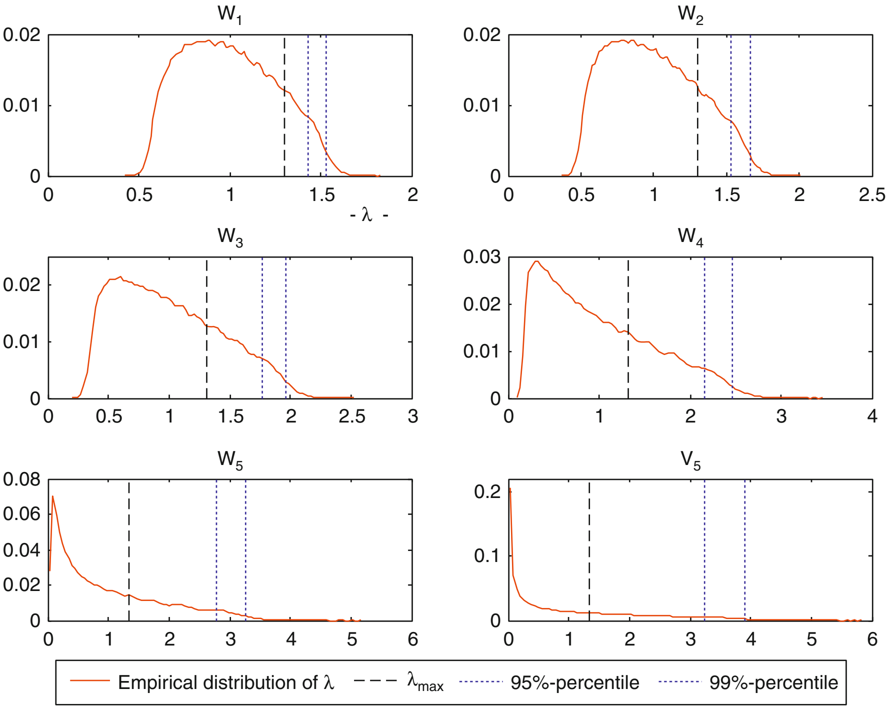

Fig. 19.18 Distribution of the empirical eigenvalues of the correlation matrix

presence of eigenvalues larger than the upper bound can be taken as an evidence that the structure of the correlation matrix is not due to chance, i.e., that there are deviations from RMT. Furthermore, the number of such eigenvalues can be interpreted as corresponding to the number of factors underlying the evolution of the N time series. A potential problem with the RMT approach is that it requires $N \to \infty$ and $T \to \infty$. In our case, these conditions are evidently not fulfilled as $T = 302$ and $N = 12$. To account for this, we also estimate λ_{max} from the empirical distribution of the correlation matrix eigenvalues. To this aim, we resample (without replacement) the original time series of returns and then apply the MODWT on the resampled data and calculate the correlation matrix and its eigenvalues at each scale of the MODWT. This procedure is done 100,000 times. In Fig. 19.18, we report λ_{max} as computed on the basis of Eq. 19.37 and the empirical values of λ_{max} obtained from our simulations. In the latter case, we consider two different values for λ_{max}, which correspond to the 5 %- and, respectively, 1 %-percentile of the empirical cumulative distribution of λ. The theoretical (RMT) maximum eigenvalue is always much lower than its empirical counterparts. This is probably due to the small sample size.

In Table 19.2, we report the eigenvalues of the correlation matrix for each scale of the MODWT. Comparing the eigenvalues λ_k, $k = 1,\ldots,12$ with $\hat{\lambda}_{max}$ demonstrates that there is a single factor underlying the evolution of home

Table 19.2 Eigenvalues of the correlation matrix at each scale of the MODWT

	w_1	w_2	w_3	w_4	w_5	v_5
λ_1	0.54	0.29	0.04	0.04	0.01	0.00
λ_2	0.60	0.30	0.07	0.07	0.02	0.00
λ_3	0.69	0.33	0.08	0.13	0.08	0.00
λ_4	0.78	0.46	0.12	0.15	0.13	0.01
λ_5	0.84	0.48	0.14	0.20	0.16	0.01
λ_6	0.86	0.61	0.18	0.23	0.18	0.05
λ_7	0.99	0.70	0.22	0.25	0.34	0.15
λ_8	1.02	0.77	0.29	0.44	0.50	0.16
λ_9	1.16	0.92	0.38	0.62	0.66	0.37
λ_{10}	1.38	1.06	0.77	0.82	0.69	1.10
λ_{11}	1.49	1.37	1.11	1.33	1.38	1.18
λ_{12}	1.64[a]	4.70[a]	8.60[a]	7.72[a]	7.84[a]	8.98[a]
λ_{max}	1.30	1.31	1.31	1.32	1.34	1.34
$\hat{\lambda}_{max}$ (95 %)	1.43	1.53	1.77	2.16	2.79	3.25
$\hat{\lambda}_{max}$ (99 %)	1.53	1.66	1.96	2.47	3.25	3.89

We report the 12 eigenvalues of the correlation matrix at each scale j as well as the theoretical (RMT) maximum eigenvalue (λ_{max} in the table) and the empirical 95 %- and 99 %-percentiles of the empirical (bootstrapped) cumulative distribution of eigenvalues at scale j ($\hat{\lambda}_{max}(95\%)$ and $\hat{\lambda}_{max}(99\%)$). [a] denotes significance at the 95 %-level

prices. At each scale, the eigenvalue that is attached to this factor is significant at the 99 % level. This unique factor can be interpreted as a sort of national-wide home price index.

19.4 Conclusion

This chapter discusses spectral and wavelet methods. It aims at being an easy-to-follow introduction and it is structured around conceptual and practical explanations. It also offers many supporting examples and illustrations. In particular, the last section provides a detailed case study, which analyzes the evolution of home prices in the USA over the last 20 years using wavelet methodology.

Abstract

In many financial models, such as those addressing value at risk and ruin probabilities, the accuracy of the fitted loss distribution in the upper tail of the loss data is crucial. In such situations, it is important to test the fitted loss distribution for the goodness of fit in the upper quantiles, while giving lesser importance to the fit in the low quantiles and the center of the distribution of the data. Additionally, in many loss models the recorded data are left truncated with the number of missing data unknown. We address this gap in literature by proposing appropriate goodness-of-fit tests.

We derive the exact formulae for several goodness-of-fit statistics that should be applied to loss models with left-truncated data where the fit of a distribution in the right tail of the distribution is of central importance. We apply the proposed tests to real financial losses, using a variety of distributions fitted to operational loss and the natural catastrophe insurance claims data, which are subject to the recording thresholds of $1 and $25 million, respectively.

Keywords

Goodness-of-fit tests • Left-truncated data • Minimum recording threshold • Loss distribution • Heavy-tailed data • Operational risk • Insurance • Ruin probability • Value at risk • Anderson-Darling statistic • Kolmogorov-Smirnov statistic

20.1 Introduction

In most loss models, the central attention is devoted to studying the distributional properties of the loss data. The shape of the dispersion of the data determines the vital statistics such as the expected loss, variance, and ruin probability, value at risk, or conditional value at risk where the shape in the right tail is crucial. Parametric procedures for testing the goodness of fit (GOF) include the likelihood ratio test and chi-squared test. A standard semi-parametric procedure to test how well a hypothesized distribution fits the data involves applying the in-sample GOF tests that provide a comparison of the fitted distribution to the empirical distribution. These tests, referred to as empirical distribution function (EDF) tests, include the Kolmogorov-Smirnov test, Anderson-Darling test, and the Cramér-von Mises tests. Related works on the discussion of these widely used tests include Anderson and Darling (1952, 1954), D'Agostino and Stephens (1986), and Shorack and Wellner (1986).

In many applications, the data set analyzed is incomplete, in the sense that the observations are present in the loss database only if they exceed a predetermined threshold level. This problem is usually absent in risk models involving market risk and credit risk. However, it is a common problem in operational risk or insurance claims models. In operational risk, banks' internal databases are subject to a minimum recording threshold of roughly \$6,000–\$10,000, and external databases usually collect operational losses starting from \$1 million, BCBS (2003). Similarly, in non-life insurance models, the thresholds are set at \$5 million, \$25 million, or other levels. Consequently, in the analysis of operational losses, recorded loss data are left truncated, and, as a result, it is inappropriate to employ standard GOF tests.

GOF tests for truncated and censored data have been studied by Dufour and Maag (1978), Gastaldi (1993), and Guilbaud (1998), among others. In this paper, we derive the exact formulae for several GOF test statistics that should be applied where there exist incomplete samples with an unknown number of missing data in low quantiles and propose two new statistics to determine the goodness of fit in the upper tail that can be used for loss models where the accuracy of the upper tail estimate is of central concern.

The paper is organized as follows. In Sect. 20.2 we describe the problem of left-truncated samples and explain the necessary adjustments that are required to the GOF tests to make them applicable for the truncated samples. In Sect. 20.3 we review the widely used test statistics for complete samples and derive the exact formulae for the statistics to be used for left-truncated samples. We propose in Sect. 20.4 two new EDF statistics to be used for the situations when the fit in the upper tail is of the central concern. Application of the modified EDF tests to operational loss data, obtained from Zurich IC2 FIRST Database, and the USA natural catastrophe insurance claims data, obtained from Insurance Services Office Inc. Property Claim Services, is presented in Sect. 20.5, with final remarks in Sect. 20.6. Necessary derivations are provided in the Appendix.

20.2 Problem Setup

Suppose we have a left-truncated sample, with the data below a prespecified threshold level H not recorded (not observable). The observable data sample $\mathbf{x} = \{x_1, x_2, \ldots, x_n\}$ has each data point at least as great as H and includes a total of n observations. Let $\{X_{(j)}\}_{1 \le j \le n}$ be a vector of the order statistics, such that $X_{(1)} \le X_{(2)} \le \ldots \le X_{(n)}$. The empirical distribution function of the sample is defined as

$$F_n(x) := \frac{\#\,observations \le x_{(j)}}{n} = \begin{cases} 0 & x < x_{(1)} \\ \dfrac{j}{n} & x_{(j)} \le x < x_{(j+1)}, \quad j = 1, 2, \ldots, n-1 \cdot \\ 1 & x \ge x_n, \end{cases} \tag{20.1}$$

Graphically, the empirical distribution function of an observed data sample is represented as a step function with a jump of size $1/n$ occurring at each recorded sample value. On the other hand, with left-truncated data which is a part of a larger complete data set, the true size of jumps of the EDF at each value of the *complete* data sample would be of size $1/n^c$, $n^c = n + m$ rather than $1/n$, where n^c is the total number of points of the complete data set and m is the unknown number of missing points. In the GOF tests the null hypothesis states that the observed loss sample belongs to a family of truncated distributions, with the parameter specified (simple test) or unspecified (composite test).

We fit a continuous *truncated* distribution F to the data, given that the data exceed or equal to H, and estimate the conditional parameters θ with the maximum likelihood (or an alternative method) by

$$\hat{\theta}_{\mathrm{MLE}} = \arg\max_{\theta} \log\left(\prod_{k=1}^{n} \frac{f_\theta(x_k)}{1 - F_\theta(H)}\right). \tag{20.2}$$

Assuming that F is the true distribution, the estimated number of missing points $\hat{m}$ and the number of observed points n are related as[1]

$$\frac{\hat{m}}{n} = \frac{z_{\mathrm{H}}}{(1 - z_{\mathrm{H}})} \tag{20.3}$$

resulting in

$$\hat{n}^c = n\frac{z_{\mathrm{H}}}{(1 - z_{\mathrm{H}})} + n = \frac{n}{(1 - z_{\mathrm{H}})} \tag{20.4}$$

where $z_{\mathrm{H}} := \hat{F}_\theta(H)$ is the estimated distribution evaluated at the truncation point.

Then, the estimated empirical distribution function $\hat{F}_{n^c}(x)$ of complete data sample is

$$\hat{F}_{n^c}(x) := \frac{\textit{estimated \# observations} \le x_{(j)}}{\hat{n}^c}, \tag{20.5}$$

where the numerator refers to the total number of observations of the complete data sample, not exceeding in magnitude the jth-order statistic of the incomplete (observed) data sample such that $X_{(1)} \le X_{(2)} \le \ldots \le X_{(n)}$. By Eqs. 20.3 and 20.4, Eq. 20.5 becomes

$$\hat{F}_{n^c}(x) = \frac{\hat{m} + j}{n/(1 - z_{\mathrm{H}})} = \frac{n z_{\mathrm{H}} + j(1 - z_{\mathrm{H}})}{n} = z_{\mathrm{H}} + \frac{j}{n}(1 - z_{\mathrm{H}}), \quad j = 1, 2, \ldots, n.$$

[1]More accurately, $\hat{m}$ should be estimated as $\hat{m} = \left\lceil n\frac{z_{\mathrm{H}}}{(1 - z_{\mathrm{H}})}\right\rceil$, but this detail can be ignored for all practical purposes.

Rearranging terms leads to the fitted distribution function of the observed sample of the following form:

$$\hat{F}^*_\theta(x) = \begin{cases} \dfrac{\hat{F}_\theta(x) - \hat{F}_\theta(H)}{1 - \hat{F}_\theta(H)} & x \geq H \\ 0 & x < H, \end{cases} \tag{20.6}$$

so that $F_\theta(X) \sim U[F_\theta(H), 1]$ and $F^*_\theta(X) \sim \mathcal{U}[0, 1]$ under the null hypothesis that the fitted distribution function is true. Therefore, the estimated empirical distribution function of the observed part of the data, using Eq. 20.1, is represented by

$$F_n(x)\left(1 - \hat{F}_\theta(H)\right) + \hat{F}_\theta(H) = \begin{cases} \hat{F}_\theta(H) & x < x_{(1)} \\ \dfrac{j}{n}\left(1 - \hat{F}_\theta(H)\right) + \hat{F}_\theta(H) & x_{(j)} \leq x < x_{(j+1)},\ j = 1, 2, \ldots, n-1 \cdot \\ 1 & x \geq x_n, \end{cases} \tag{20.7}$$

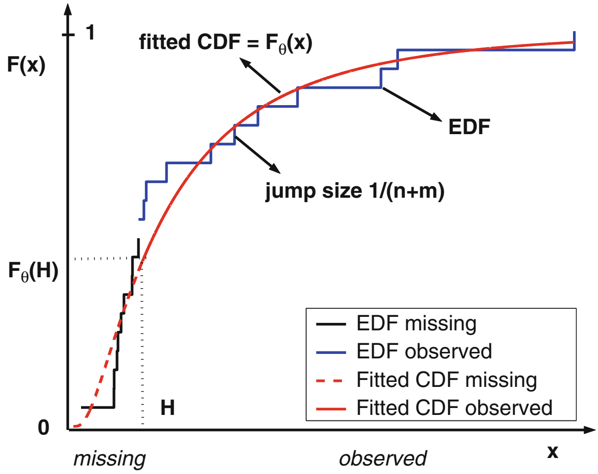
Figure 20.1 gives a visual illustration of the idea we just described. With these modifications, the in-sample GOF tests can be applied to the left-truncated samples.

In this paper we consider tests of a composite hypothesis that the empirical distribution function of an observed incomplete left-truncated loss data sample belongs to a family of hypothesized distributions (with parameters not specified), i.e.,

$$\mathbf{H_0} : F_n(x) \in F^*_\theta(x) \qquad \text{vs.} \qquad \mathbf{H_A} : F_n(x) \notin F^*_\theta(x). \tag{20.8}$$

Under the null Eq. 20.8, $F^*_\theta(X) \sim \mathcal{U}[0, 1]$, and the null is rejected if the p-value is lower than the level α, such as α from 5 % to 10 %. Letting D be the observed value of a GOF statistic (such as Kolmogorov-Smirnov or Anderson-Darling) and d the critical value for a given level α, the p-value is computed as p-value $= P(D \geq d)$. Since the distribution of the statistic is not parameter-free, one way to compute the p-values and the critical values is by means of Monte Carlo simulation, for each hypothesized fitted distribution (Ross 2001). Under the procedure, the observed value D is computed. Then, for a given level α, the following algorithm is applied:

1. Generate a large number of samples I (such as I = 1,000) from the fitted truncated distribution of size n (the number of observed data points), such that these random variates are above or equal to H.
2. Fit a *truncated* distribution and estimate conditional parameters $\hat{\theta}$ for each sample $i = 1, 2, \ldots I$.
3. Estimate the GOF statistic value D_i for each sample $i = 1, 2, \ldots I$.
4. Calculate p-value as the proportion of times the sample statistic values exceed the observed value d of the original sample.
5. Reject $\mathbf{H}_0$ if the p-value is smaller than α.



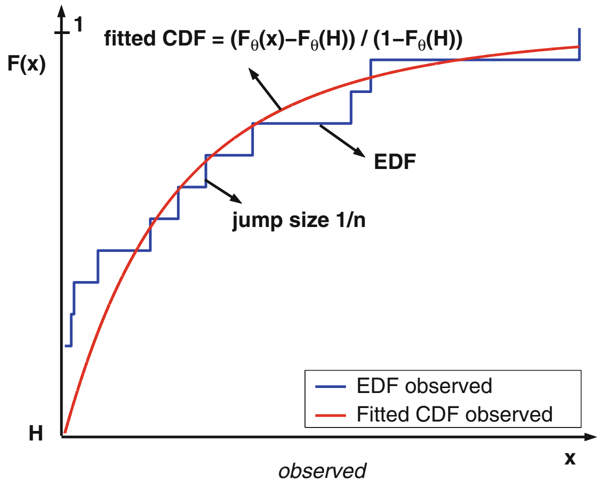


Fig. 20.1 Illustration of the empirical distribution function for data with missing observations below the threshold H and the fitted cumulative distribution function

A p-value of, for example, 0.3, would mean that in 30 % of samples of the same size simulated from the same distribution with the same parameter estimation procedure applied, the test statistic value was higher than the one observed in the original sample.

20.3 EDF Statistics for Left-Truncated Loss Samples

The EDF statistics are based on the vertical differences between the empirical and fitted (truncated) distribution function. They are divided into two classes: (1) the supremum class (such as Kolmogorov-Smirnov and Kuiper statistics) and

(2) the quadratic class (such as Anderson-Darling and Cramér-von Mises statistics). In this section, we derive the exact computing formulae for a number of EDF test statistics, modified so that they can be applied to left-truncated loss samples. For the left-truncated samples, $F^*_\theta(X)$ denotes the null distribution function for left-truncated sample values. The variable $F^*_\theta(X)$ is distributed uniformly over the [0, 1] interval. The variable $F_\theta(X)$ is distributed uniformly over the $[F_\theta(H), 1]$ interval. We reserve some other notations: $z_{\mathrm{H}} := \hat{F}_\theta(H)$ that was defined earlier and $z_j := \hat{F}_\theta\left(x_{(j)}\right)$ for truncated samples. In this section we discuss the Kolmogorov-Smirnov, Kuiper, Anderson-Darling, and the Cramér-von Mises statistics and use an asterisk (*) to denote their left-truncated sample analog.

20.3.1 Supremum Class Statistics

20.3.1.1 Kolmogorov-Smirnov Statistic

A widely used supremum class statistic, the Kolmogorov-Smirnov (*KS*) statistic, measures the absolute value of the maximum distance between the empirical and fitted distribution function and puts equal weight on each observation. Let $\{X_{(j)}\}_{1<j<n}$ be the vector of the order statistics and $X_{(1)} < X_{(2)} < \ldots < X_{(n)}$, such that strict inequalities hold. Usually, such distance is the greatest around the median of the sample. For the left-truncated data samples, the *KS* statistic is expressed as

$$KS^* = \sqrt{n}\sup_x \left|F_n(x) - \hat{F}^*_\theta(x)\right|. \tag{20.9}$$

The *KS** statistic can be computed from

$$KS^{+*} = \sqrt{n}\sup_j\left\{F_n\left(x_{(j)}\right) - \hat{F}^*_\theta\left(x_{(j)}\right)\right\} = \frac{\sqrt{n}}{1-z_{\mathrm{H}}}\sup_j\left\{z_{\mathrm{H}} + \frac{j}{n}(1-z_{\mathrm{H}}) - z_j\right\},$$
$$KS^{-*} = \sqrt{n}\sup_j\left\{\hat{F}^*_\theta\left(x_{(j)}\right) - F_n\left(x_{(j)}\right)\right\} = \frac{\sqrt{n}}{1-z_{\mathrm{H}}}\sup_j\left\{z_j - \left(z_{\mathrm{H}} + \frac{j-1}{n}(1-z_{\mathrm{H}})\right)\right\},$$

and becomes

$$KS^* = \max\{KS^{+*}, KS^{-*}\}. \tag{20.10}$$

20.3.1.2 Kuiper Statistic

The *KS* statistic gives no indication of whether the maximum discrepancy between $F_n(x)$ and $\hat{F}^*_\theta(x)$ occurs when $F_n(x)$ is above $\hat{F}^*_\theta(x)$ or when $\hat{F}^*_\theta(x)$ is above $F_n(x)$. The Kuiper statistic (V) is closely related to the *KS* statistic. It measures the total sum of the absolute values of the two largest vertical deviations of the fitted distribution function from $F_n(x)$, when $F_n(x)$ is above $\hat{F}^*_\theta(x)$ and when $\hat{F}^*_\theta(x)$ is above $F_n(x)$. For left-truncated data samples, it is computed as

$$V^* = KS^{+*} + KS^{-*}, \tag{20.11}$$

with KS^{+*} and KS^{-*} defined in Sect. 20.1.1.

20.3.1.3 Anderson-Darling Statistic

There are two variations of the Anderson-Darling (*AD*) statistic. Its simplest, supremum class version is a variance-weighted *KS* statistic with a weight of $\psi\left(\hat{F}^*_\theta(x)\right) = \left(\hat{F}^*_\theta(x)\left(1-\hat{F}^*_\theta(x)\right)\right)^{-1/2}$ attached to each observation in Eq. 20.9. (The second version will be discussed in the next section.) Under this specification, the observations in the lower and upper tails of the truncated sample are assigned a higher weight. Let $\{X_{(j)}\}_{1\le j\le n}$ be the vector of the order statistics, such that $X_{(1)} \le X_{(2)} \le \ldots \le X_{(n)}$. Then the *AD* statistic is defined for left-truncated samples as

$$AD^* = \sqrt{n}\sup_x \left| \frac{F_n(x) - \hat{F}^*_\theta(\mathtt{x})}{\sqrt{\hat{F}^*_\theta(x)\left(1-\hat{F}^*_\theta(x)\right)}} \right|. \tag{20.12}$$

For left-truncated samples, the computing formula is derived from

$$AD^{+*} = \sqrt{n}\sup_j \left\{ \frac{F_n\left(x_{(j)}\right) - \hat{F}^*_\theta\left(x_{(j)}\right)}{\sqrt{\hat{F}^*_\theta\left(x_{(j)}\right)\left(1-\hat{F}^*_\theta\left(x_{(j)}\right)\right)}} \right\} = \sqrt{n}\sup_j \left\{ \frac{z_H + \frac{j}{n}(1-z_{\mathrm{H}}) - z_j}{\sqrt{\left(z_j - z_{\mathrm{H}}\right)\left(1-z_j\right)}} \right\},$$

$$AD^{-*} = \sqrt{n}\sup_j \left\{ \frac{\hat{F}^*_\theta\left(x_{(j)}\right) - F_n\left(x_{(j)}\right)}{\sqrt{\hat{F}^*_\theta\left(x_{(j)}\right)\left(1-\hat{F}^*_\theta\left(x_{(j)}\right)\right)},} \right\} = \sqrt{n}\sup_j \left\{ \frac{z_j - z_{\mathrm{H}} - \frac{j-1}{n}(1-z_{\mathrm{H}})}{\sqrt{\left(z_j - z_{\mathrm{H}}\right)\left(1-z_j\right)}} \right\}$$

and becomes

$$AD^* = \max\{AD^{+*},\ AD^{-*}\}. \tag{20.13}$$

20.3.2 Quadratic Class Statistics

The quadratic statistics for complete data samples are grouped under the Cramér-von Mises family as

$$Q = n\int_{-\infty}^{\infty} \left(F_n(x) - \hat{F}_\theta(x)\right)^2 \psi\left(\hat{F}_\theta(x)\right) d\hat{F}_\theta(x), \tag{20.14}$$

in which the weight function $\psi\left(\hat{F}_\theta(x)\right)$ is assigned to give a certain weight to different observations, depending on the purpose. For left-truncated samples, we denote the Cramér-von Mises family as $Q*$ and $\hat{F}_\theta(x)$ is replaced by $\hat{F}^*_\theta(x)$:

$$Q^* = n\int_{H}^{\infty} \left(F_n(x) - \hat{F}^*_\theta(x)\right)^2 \psi\left(\hat{F}^*_\theta(x)\right) d\hat{F}^*_\theta(x). \tag{20.15}$$

Depending on the form of the weighting function, the sample observations are given a different weight. $\psi\left(\hat{F}^*_\theta(x)\right) = \left(\hat{F}^*_\theta(x)\left(1-\hat{F}^*_\theta(x)\right)\right)^{-1}$ yields the quadratic Anderson-Darling statistic and $\psi\left(\hat{F}^*_\theta(x)\right) = 1$ yields the Cramér-von Mises statistic.

Derivation of the computing formulae makes use of Eq. 20.1 and involves the Probability Integral Transformation (PIT) technique. For left-truncated samples, this leads to

$$Q^* = n\int_0^1 (F_n(z^*) - z^*)^2 \psi(z^*)dz^* = \frac{n}{1-z_{\mathrm{H}}}\int_{z_{\mathrm{H}}}^1 \left(F_n(z^*) - \frac{z-z_{\mathrm{H}}}{1-z_{\mathrm{H}}}\right)^2 \psi\left(\frac{z-z_{\mathrm{H}}}{1-z_{\mathrm{H}}}\right)dz, \tag{20.16}$$

where $Z^* = \hat{F}^*_\theta(X) = \frac{Z-z_{\mathrm{H}}}{1-z_{\mathrm{H}}}$ with $F^*_\theta(X) \sim \mathcal{U}[0,1]$ under the null, and so $Z = \hat{F}_\theta(X)$ with $F_\theta(X) \sim U[F_\theta(H), 1]$ under the null. $F_n(Z^*) = F_n(X) = F^*_\theta(F_n(X))$ is the empirical distribution function of Z*. $z_{\mathrm{H}} = \hat{F}_\theta(H) = F_\theta\left(\hat{F}_\theta(H)\right)$.

20.3.2.1 Anderson-Darling Statistic

The supremum version of the *AD* statistic was described in Sect. 20.1.3. Another, more generally used, version of this statistic belongs to the quadratic class defined by the Cramér-von Mises family (Eq. 20.15) with the weight function for left-truncated samples of $\psi\left(\hat{F}^*_\theta(x)\right) = \left(\hat{F}^*_\theta(x)\left(1-\hat{F}^*_\theta(x)\right)\right)^{-1}$. Again, with this specification, most weight is being put on the outer left and right quantiles of the distribution, proportional to the appropriate tails. Let $\{X_{(j)}\}_{1\le j\le n}$ be the vector of the order statistics, such that $X_{(1)} \le X_{(2)} \le \ldots \le X_{(n)}$. The computing formula for the *AD* statistic for left-truncated samples becomes (the derivation is given in Appendix)

$$\begin{aligned} AD^{2*} = &- n + 2n\log(1-z_{\mathrm{H}}) - \frac{1}{n}\sum_{j=1}^n (1+2(n-j))\log\left(1-z_j\right) + \ldots \\ &+ \frac{1}{n}\sum_{j=1}^n (1-2j)\log\left(z_j - z_{\mathrm{H}}\right). \end{aligned} \tag{20.17}$$

20.3.3 Cramér-von Mises Statistic

Cramér-von Mises (denoted as W^2) statistic belongs to the Cramér-von Mises family (Eq. 20.15) with the weight function $\psi\left(\hat{F}^*_\theta(x)\right) = 1$. Let $\{X_{(j)}\}_{1\le j\le n}$ be the vector of the order statistics, such that $X_{(1)} \le X_{(2)} \le \ldots \le X_{(n)}$. The computing formula for the statistic for left-truncated samples becomes (the derivation is given in Appendix)

$$W^{2*} = \frac{n}{3} + \frac{nz_{\mathrm{H}}}{1-z_{\mathrm{H}}} + \frac{1}{n(1-z_{\mathrm{H}})}\sum_{j=1}^n (1-2j)z_j + \frac{1}{(1-z_{\mathrm{H}})^2}\sum_{j=1}^n \left(z_j - z_{\mathrm{H}}\right)^2. \tag{20.18}$$

20.4 "Upper Tail" Anderson-Darling Statistic

In practice, there are often cases when it is necessary to test whether a distribution fits the data well in the upper tail and the fit in the lower tail or around the median is of little or less importance. Examples include operational risk and insurance claims modelling, in which goodness of the fit in the tails determines the value at risk, conditional value at risk, and ruin probabilities. Given the Basel II Capital Accord's recommendations, under the loss distribution approach the operational risk capital charge is derived from the value-at-risk measure, which requires an accurate estimate of the upper tail of the loss distribution. Similarly, in insurance, the upper tail of the claim size distribution is central to obtaining accurate estimates of ruin probability. For this purpose, we introduce a statistic, which we refer to as the *upper tail* Anderson-Darling statistic and denote by AD_{up}. We propose two different versions of the statistic.

20.4.1 Supremum Class "Upper Tail" Anderson-Darling Statistic

The first version of AD_{up} belongs to the supremum class EDF statistics. For complete data samples, each observation of the KS statistic is assigned a weight of $\psi\left(\hat{F}_\theta(x)\right) = \left(\left(1 - \hat{F}_\theta(x)\right)\right)^{-1}$. Under this specification, the observations in the upper tail are assigned a higher weight than those in the lower tail. Let $\{X_{(j)}\}_{1 \le j \le n}$ be the vector of the order statistics, such that $X_{(1)} \le X_{(2)} \le \ldots \le X_{(n)}$. Then we define the AD_{up} statistic for complete data samples as

$$AD_{\text{up}} = \sqrt{n} \sup_x \left| \frac{F_n(x) - \hat{F}_\theta(x)}{1 - \hat{F}_\theta(x)} \right|. \tag{20.19}$$

Denoting $z_j := \hat{F}_\theta\left(x_{(j)}\right)$, the computing formula is derived from

$$AD^{+}_{\text{up}} = \sqrt{n} \sup_j \left\{ \frac{\frac{j}{n} - z_j}{1 - z_j} \right\},$$

$$AD^{-}_{\text{up}} = \sqrt{n} \sup_j \left\{ \frac{z_j - \frac{j-1}{n}}{1 - z_j} \right\},$$

and becomes

$$AD_{\text{up}} = \max\left\{ AD^{+*}_{\text{up}},\ AD^{-*}_{\text{up}} \right\}. \tag{20.20}$$

For left-truncated samples, the counterpart of the AD_{up} statistic can be similarly computed using

$$AD_{\text{up}}^{+*} = \sqrt{n}\sup_j\left\{\frac{F_n\left(x_{(j)}\right) - \hat{F}_\theta^*\left(x_{(j)}\right)}{1 - \hat{F}_\theta^*\left(x_{(j)}\right)}\right\} = \sqrt{n}\sup_j\left\{\frac{z_{\text{H}} + \frac{j}{n}(1 - z_{\text{H}}) - z_j}{1 - z_j}\right\},$$
$$AD_{\text{up}}^{-*} = \sqrt{n}\sup_j\left\{\frac{\hat{F}_\theta^*\left(x_{(j)}\right) - F_n\left(x_{(j)}\right)}{1 - \hat{F}_\theta^*\left(x_{(j)}\right)}\right\} = \sqrt{n}\sup_j\left\{\frac{z_j - z_{\text{H}} - \frac{j-1}{n}(1 - z_{\text{H}})}{1 - z_j}\right\},$$

and becomes

$$AD_{\text{up}}^* = \max\left\{AD_{\text{up}}^{+*},\ AD_{\text{up}}^{-*}\right\}. \tag{20.21}$$

20.4.2 Quadratic Class "Upper Tail" Anderson-Darling Statistic

Another way to define the *upper tail* Anderson-Darling statistic is by an integral of the Cramér-von Mises family (Eq. 20.14) with the weighting function[2] of the form $\psi\left(\hat{F}_\theta(x)\right) = \left(1 - \hat{F}_\theta(x)\right)^{-2}$ for complete samples and $\psi\left(\hat{F}_\theta^*(x)\right) = \left(1 - \hat{F}_\theta^*(x)\right)^{-2}$ for left-truncated samples. Such weighting function gives a higher weight to the upper tail and a lower weight to the lower tail. We define this statistic as AD_{up}^2.

Let $\{X_{(j)}\}_{1\le j\le n}$ be the vector of the order statistics, such that $X_{(1)} \le X_{(2)} \le \ldots \le X_{(n)}$. The AD_{up}^2 statistic's general form for complete samples can be expressed as

$$AD_{\text{up}}^2 = n\int_H^\infty \frac{\left(F_n(x) - \hat{F}_\theta(x)\right)^2}{\left(1 - \hat{F}_\theta(x)\right)^2} d\hat{F}_\theta(x). \tag{20.22}$$

For complete data samples $F_\theta(X) \sim U[0, 1]$ under the null hypothesis. If we denote $z_j := \hat{F}_\theta\left(x_{(j)}\right)$, straightforward calculations lead to the following computing formula:

$$AD_{\text{up}}^2 = 2\sum_{j=1}^n \log\left(1 - z_j\right) + \frac{1}{n}\sum_{j=1}^n (1 + 2(n-j))\frac{1}{1 - z_j}.$$

For incomplete left-truncated samples, $F_\theta^*(X)$ is distributed $U[F_\theta(H),\ 1]$ under the null. Applying the PIT technique leads to the computing formula of the

[2]It has been shown that the weighting function $\psi(t) = (1-t)^{-\beta}$ possesses nice asymptotic properties only for β=[0,2) (Deheuvels and Martynov 2003). For β=2, which is the case considered in this chapter, the asymptotic distribution of the test statistic has infinite mean. This is indeed a concern for very large samples (i.e., the asymptotic case n→∞). Yet, because firms' operational loss data samples are typically relatively small, the asymptotic distribution of the test statistic should not generate large concerns. Nevertheless, the results of the proposed quadratic class upper-tail Anderson-Darling test should be treated with caution and with consideration of the properties described above.

Table 20.1 Description of EDF statistics for complete data samples

$\mathbf{H_0}: F_n(x) \in F(x)$ vs. $\mathbf{H_A}: F_n(x) \notin F_\theta(x)$	
Notations: $z_j := \hat{F}_\theta(x_{(j)}),\ j = 1, 2, \ldots, n$	
Statistic	Description and computing formula

Table 20.2 (continued)

$\mathbf{H_0}: F_n(x) \in F_\theta^*(x)$ vs. $\mathbf{H_A}: F_n(x) \notin F_\theta^*(x)$, $F_\theta^*(x) := \frac{F_\theta(x)-F_\theta(H)}{1-F_\theta(H)}$	
Notations: $z_j := \hat{F}_\theta\left(x_{(j)}\right)$, $z_{\mathrm{H}} = \hat{F}_\theta(H), j = 1, 2, \ldots, n$	
Statistic	Description and computing formula
$AD_{\mathrm{up}}^{2\,*}$	$AD_{\mathrm{up}}^{2*} = n\int_H^\infty \frac{\left(F_n(x) - \hat{F}_\theta^*(x)\right)^2}{\left(1-\hat{F}_\theta^*(x)\right)^2} d\hat{F}_\theta^*(x)$
	Computing formula: $AD_{\mathrm{up}}^{2*} = -2n\log(1-z_{\mathrm{H}}) + 2\sum_{j=1}^n \log\left(1-z_j\right) + \frac{1-z_{\mathrm{H}}}{n}\sum_{j=1}^n (1+2(n-j))\frac{1}{1-z_j}$

AD_{up}^{2*} statistic for left-truncated samples of the following form (the derivation is given in Appendix):

$$AD_{\mathrm{up}}^{2*} = -2n\log(1-z_{\mathrm{H}}) + 2\sum_{j=1}^n \log\left(1-z_j\right) + \frac{1-z_{\mathrm{H}}}{n}\sum_{j=1}^n (1+2(n-j))\frac{1}{1-z_j}.$$

Tables 20.1 and 20.2 summarize the EDF statistics and their computing formulae for complete and left-truncated samples.

20.5 Application to Loss Data

In this section we apply the GOF testing procedure to (1) operational loss data, extracted from an external database, and (2) catastrophe insurance claims data. The operational loss data set was obtained from Zurich IC Squared (IC^2) FIRST Database of Zurich IC Squared (IC^2), an independent consulting subsidiary of Zurich Financial Services Group. The external database is comprised of operational loss events throughout the world. The original loss data cover losses in the period 1950–2002. A few recorded data points were below \$1 million in nominal value, so we excluded them from the analysis, to make it more consistent with the conventional threshold for external databases of \$1 million. Furthermore, we excluded the observations before 1980 because of relatively few data points available (which is most likely due to poor data recording practices). The final data set for the analysis covered losses for the time period between 1980 and 2002. It consists of five types of losses: “relationship” (such as events related to legal issues, negligence, and sales-related fraud), “human” (such as events related to employee errors, physical injury, and internal fraud), “processes” (such as events related to business errors, supervision, security, and transactions), “technology” (such as events related to technology and computer failure and telecommunications), and “external” (such as events related to natural and man-made disasters and external fraud). The loss amounts have been adjusted for inflation using the Consumer Price Index from the U.S. Department of Labor. The numbers of data points of each type are $n = 849, 813, 325, 67$, and 233, respectively.

This table reports goodness-of-fit test statistic values for operational loss data of various risk types. p-values are reported in square brackets and were obtained via 1,000 Monte Carlo simulations

The insurance claims data set covers claims resulting from natural catastrophe events occurred in the United States over the time period from 1990 to 1996. It was obtained from Insurance Services Office Inc. Property Claim Services (PCS). The data set includes 222 losses. The observations are greater than \$25 million in nominal value.

Left-truncated distributions of four types were fitted to each of the data set: exponential, lognormal, Weibull, and Pareto (GPD). Table 20.3 presents the observed statistic values and the p-values for the six data sets (five operational losses and insurance claims), obtained with the testing procedure described in Sect. 20.2.

The results reported in Table 20.3 suggest that fitting heavier-tailed distributions, such as Pareto and Weibull, results in lower values of the GOF statistics, which leads to acceptance of the null for practically all loss types and all criteria of the goodness of fit, viewed from the high p-values. Since the analysis of operational losses deals with estimating the operational value at risk (VaR), it is reasonable to determine the ultimate best fit on the basis of the AD_{up} and AD^2_{up} statistics, introduced in this paper. As can be seen from Table 20.3, these proposed measures suggest a much better fit of the heavier-tailed distributions. Moreover, for the Pareto distribution, while the statistics that focus on the center of the data (Kolmogorov-Smirnov, Kuiper, Cramér-von Mises) do not show a good fit, the AD_{up} and AD^2_{up} statistics indicate that the fit in the upper tail is very good. It should be noted that the Pareto and Weibull distributions very often suggest a superior fit in the upper tail to the lognormal distribution. Yet it is the lognormal distribution that was suggested in 2001 by the Basel Committee (BCBS (2001)).

20.6 Conclusions

In this paper we present a technique for modifying the existing goodness-of-fit test statistics so that they can be applied to loss models in which the available data set is incomplete and is truncated from below. Such left truncation is often present in loss data when the data are being recorded starting from a fixed amount and the data below are not recorded at all. Exact computing formulae for the Kolmogorov-Smirnov, Kuiper, Anderson-Darling, and Cramér-von Mises for the left-truncated samples are presented.

In risk management, it is often vital to have a good fit of a hypothesized distribution in the upper tail of the loss data. It is important in loss models that deal with value at risk, conditional value at risk, and ruin probability. We suggest using two other versions of the Anderson-Darling statistic (which we refer to as the *upper tail* Anderson-Darling statistic) in which the weighting function is proportional to the weight of only the upper tail of the distribution. Supremum and quadratic versions of the statistic are proposed. Such statistic is convenient to use when it is necessary to examine the goodness of fit of a distribution in the right tail of the data, while the fit in the left tail is unimportant.

The technique is applied to check the goodness of fit of a number of distributions using operational loss data and catastrophe insurance claims data sets. From the empirical analysis we conclude that heavier-tailed distributions better fit the data than Lognormal or thinner-tailed distributions in many instances. In particular, the conclusion is strongly supported by the *upper tail* Anderson-Darling tests.

Appendix

Derivation of AD^{2*} Computing Formula

By the PIT technique

$$AD^{2*} = n \int_H^{+\infty} \frac{\left(F_n(x) - \hat{F}^*_\theta(x)\right)^2}{\hat{F}^*_\theta(x)\left(1 - \hat{F}^*_\theta(x)\right)} d\hat{F}^*_\theta(x)$$

$$\underline{\underline{PIT}} \;\; \hat{n}^c \int_{z_{\mathrm{H}}}^{1} \frac{(F_n(z^*)(1 - z_{\mathrm{H}}) + z_{\mathrm{H}} - z)^2}{(z - z_{\mathrm{H}})(1 - z)} dz,$$

where in the original integral $F_n(Z^*) = F^*_\theta(F_n(X)) = F_n(X)$ is the empirical distribution function of $Z^* := \hat{F}^*_\theta(X) = F^*_\theta\left(\hat{F}^*_\theta(X)\right)$ so that $F^*_\theta(\cdot) \sim \mathcal{U}[0, 1]$. Changing variable and using Eq. 20.7, the integral becomes expressed in terms of $z_{\mathrm{H}} := \hat{F}_\theta(H) = F_\theta\left(\hat{F}_\theta(H)\right)$ and $Z := \hat{F}_\theta(X) = F_\theta\left(\hat{F}_\theta(X)\right)$ so that $F_\theta(\cdot) \sim U[z_H,1]$. We estimate $\hat{n}^c$ as $\frac{n}{1-z_{\mathrm{H}}}$.

Using Eq. 20.7, the computing formula is expressed in terms of $z_j := \hat{F}_\theta\left(x_{(j)}\right) = F_\theta\left(\hat{F}_\theta\left(x_{(j)}\right)\right), j = 1, 2, \ldots, n$, as

$$\frac{1}{\hat{n}^c}AD^{2*} = \underbrace{\int_{z_{\mathrm{H}}}^{z_1} \frac{(z-z_{\mathrm{H}})^2}{(z-z_{\mathrm{H}})(1-z)}dz}_{\mathrm{A}} + \underbrace{\sum_{j=1}^{n-1}\int_{z_j}^{z_{j+1}} \frac{\left(\frac{j}{n}(1-z_{\mathrm{H}})+z_{\mathrm{H}}-z\right)^2}{(z-z_{\mathrm{H}})(1-z)}dz}_{\mathrm{B}} + \underbrace{\int_{z_n}^{1} \frac{(1-z)^2}{(z-z_{\mathrm{H}})(1-z)}dz}_{\mathrm{C}}.$$

Separately solving for A, B, and C, we obtain

$$\mathrm{A} = z_{\mathrm{H}} - z_1 + (1-z_{\mathrm{H}})(\log(1-z_{\mathrm{H}}) - \log(1-z_1));$$

$$\begin{aligned}
\mathrm{B} = {} & z_1 - z_n + \frac{1-z_{\mathrm{H}}}{n^2}\sum_{j=1}^{n-1}(n-j)^2\left(\log\left(1-z_j\right) - \log\left(1-z_{j+1}\right)\right) - \ldots \\
& - 2\frac{1-z_{\mathrm{H}}}{n^2}\sum_{j=1}^{n-1} j^2\left(\log\left(z_j - z_{\mathrm{H}}\right) - \log\left(z_{j+1} - z_{\mathrm{H}}\right)\right) \\
= {} & z_1 - z_n + (1-z_{\mathrm{H}})\log(1-z_1) - \frac{1-z_{\mathrm{H}}}{n^2}\sum_{j=1}^{n}(1+2(n-j))\log\left(1-z_j\right) + \ldots \\
& + (1-z_{\mathrm{H}})\log(z_n - z_{\mathrm{H}}) + \frac{1-z_{\mathrm{H}}}{n^2}\sum_{j=1}^{n}(1-2j)\log\left(z_j - z_{\mathrm{H}}\right);
\end{aligned}$$

$$\mathrm{C} = z_n - 1 + (1-z_{\mathrm{H}})(\log(1-z_{\mathrm{H}}) - \log(z_n - z_{\mathrm{H}})).$$

Summing the terms A, B, and C, multiplying by $\hat{n}^c$, and simplifying yields the final computing formula:

$$\begin{aligned}
AD^{2*} = {} & -n + 2n\log(1-z_{\mathrm{H}}) - \frac{1}{n}\sum_{j=1}^{n}(1+2(n-j))\log\left(1-z_j\right) + \ldots \\
& + \frac{1}{n}\sum_{j=1}^{n}(1-2j)\log\left(z_j - z_{\mathrm{H}}\right).
\end{aligned}$$

Derivation of W^{2*} Computing Formula

By the PIT technique

$$\begin{aligned}
W^{2*} &= n\int_{H}^{+\infty}\left(F_n(x) - \hat{F}_\theta^*(x)\right)^2 d\hat{F}_\theta^*(x) \\
&\underline{\underline{PIT}}\ \ \hat{n}^c\int_{z_{\mathrm{H}}}^{1}\frac{(F_n(z^*)(1-z_{\mathrm{H}}) + z_{\mathrm{H}} - z)^2}{(1-z_{\mathrm{H}})^2}dz,
\end{aligned}$$

where in the original integral $F_n(Z^*) = F^*_\theta(F_n(X)) = F_n(X)$ is the empirical distribution function of $Z^* := \hat{F}^*_\theta(X) = F^*_\theta\left(\hat{F}^*_\theta(X)\right)$ so that $F^*_\theta(\cdot) \sim \mathcal{U}[0,1]$. Changing variable and using Eq. 20.7, the integral becomes expressed in terms of $z_{\mathrm{H}} := \hat{F}_\theta(H) = F_\theta\left(\hat{F}_\theta(H)\right)$ and $Z := \hat{F}_\theta(X) = F_\theta\left(\hat{F}_\theta(X)\right)$ so that $F_\theta(\cdot) \sim U[F_\theta(H), 1]$. We estimate $\hat{n}^c$ as $\frac{n}{1-z_{\mathrm{H}}}$.

Using Eq. 20.7, the computing formula is expressed in terms of $z_j := \hat{F}_\theta\left(x_{(j)}\right) = {}_{F\theta}\left(\hat{F}_\theta\left(x_{(j)}\right)\right)$, $j = 1, 2, \ldots, n$, as

$$\frac{(1-z_{\mathrm{H}})^2}{\hat{n}^c} W^{2*} = \underbrace{\int_{z_{\mathrm{H}}}^{z_1} (z_{\mathrm{H}} - z)^2 dz}_{\mathrm{A}} + \underbrace{\sum_{j=1}^{n-1} \int_{z_j}^{z_{j+1}} \left(\frac{j}{n}(1-z_{\mathrm{H}}) + z_{\mathrm{H}} - z\right)^2 dz}_{\mathrm{B}} + \underbrace{\int_{z_n}^{1} (1-z)^2 dz}_{\mathrm{C}}.$$

Separately solving for A, B, and C, we obtain

$$\mathrm{A} = -\frac{z_{\mathrm{H}}{}^3}{3} + z_{\mathrm{H}}{}^2 z_1 - z_{\mathrm{H}} z_1{}^2 + \frac{z_1{}^3}{3};$$

$$\begin{aligned}
\mathrm{B} = {} & \frac{z_n{}^3}{3} - \frac{z_1{}^3}{3} + z_{\mathrm{H}} z_1{}^2 - z_{\mathrm{H}} z_n{}^2 + z_{\mathrm{H}}{}^2 z_1 + z_{\mathrm{H}}{}^2 z_n + \ldots \\
& + \frac{(1-z_H)^2}{n^2} \sum_{j=1}^{n-1} j^2 \left(z_{j+1} - z_j\right) + \frac{1-z_{\mathrm{H}}}{n} \sum_{j=1}^{n-1} j\left(z_j{}^2 - z_{j+1}{}^2\right) + 2 z_{\mathrm{H}} \frac{1-z_{\mathrm{H}}}{n} \sum_{j=1}^{n-1} j\left(z_{j+1} - z_j\right) \\
= {} & \frac{z_n{}^3}{3} - \frac{z_1{}^3}{3} + z_{\mathrm{H}} z_1{}^2 - z_{\mathrm{H}} z_n{}^2 - z_{\mathrm{H}}{}^2 z_1 + z_{\mathrm{H}}{}^2 z_n + \frac{(1-z_{\mathrm{H}})^2}{n^2} \left(n^2 z_n + \sum_{j=1}^{n} (1-2j) z_j\right) + \ldots \\
& + \frac{1-z_{\mathrm{H}}}{n} \left(\sum_{j=1}^{n} z_j{}^2 - n z_n{}^2\right) + 2 z_{\mathrm{H}} \frac{1-z_{\mathrm{H}}}{n} \left(n z_n - \sum_{j=1}^{n} z_j\right) \\
= {} & (1-z_{\mathrm{H}}) z_n + z_{\mathrm{H}}(1-z_{\mathrm{H}}) z_n - (1-z_{\mathrm{H}}) z_n{}^2 + \frac{(1-z_{\mathrm{H}})^2}{n^2} \sum_{j=1}^{n} (1-2j) z_j + \ldots \\
& + \frac{1-z_{\mathrm{H}}}{n} \sum_{j=1}^{n} z_j{}^2 - 2 z_{\mathrm{H}} \frac{1-z_{\mathrm{H}}}{n} \sum_{j=1}^{n} z_j;
\end{aligned}$$

$$\mathrm{C} = \frac{1}{3} + z_n{}^2 - z_n - \frac{z_n{}^3}{3}.$$

Summing the terms A, B, and C, multiplying by $\frac{\hat{n}^c}{(1-z_{\mathrm{H}})^2}$, and simplifying yields the final computing formula:

$$W^{2*} = \frac{n}{3} + \frac{n z_{\mathrm{H}}}{1-z_{\mathrm{H}}} + \frac{1}{n(1-z_{\mathrm{H}})} \sum_{j=1}^{n} (1-2j) z_j + \frac{1}{(1-z_{\mathrm{H}})^2} \sum_{j=1}^{n} \left(z_j - z_{\mathrm{H}}\right)^2.$$

Derivation of AD^2_{up} Computing Formula

By the PIT technique

$$AD^2_{\text{up}} = n\int_{-\infty}^{+\infty} \frac{\left(F_n(x) - \hat{F}_\theta(x)\right)^2}{\left(1 - \hat{F}_\theta(x)\right)^2} d\hat{F}_\theta(x) \underset{=}{\underline{PIT}} \; n\int_0^1 \frac{\left(F_n(z) - z\right)^2}{(1-z)^2} dz,$$

where $F_n(Z) = F_\theta(F_n(X)) = F_n(X)$ is the empirical distribution function of $Z = \hat{F}_\theta(X) = F\left(\hat{F}_\theta(X)\right)$ so that $F_\theta(\cdot) \sim U[0,1]$.

Using Eq. 20.1, the computing formula is expressed in terms of $z_j := \hat{F}_\theta\left(x_{(j)}\right) = F\left(\hat{F}_\theta\left(x_{(j)}\right)\right), j = 1, 2, \ldots, n$, as

$$\frac{1}{n}AD^2_{\text{up}} = \underbrace{\int_0^{z_1} \frac{z^2}{(1-z)^2} dz}_{\text{A}} + \underbrace{\sum_{j=1}^{n-1} \int_{z_j}^{z_{j+1}} \frac{\left(\frac{j}{n} - z\right)^2}{(1-z)^2} dz}_{\text{B}} + \underbrace{\int_{z_n}^{1} \frac{(1-z)^2}{(1-z)^2} dz}_{\text{C}}.$$

Separately solving for A, B, and C, we obtain

$$\text{A} = z_1 - 1 + \frac{1}{1-z_1} + 2\log(1-z_1);$$

$$\text{B} = z_n - z_1 - \frac{1}{n^2}\sum_{j=1}^{n-1}(n-j)^2\left(\frac{1}{1-z_j} - \frac{1}{1-z_{j+1}}\right) - \ldots$$

$$-2\frac{1}{n}\sum_{j=1}^{n-1}(n-j)\left(\log\left(1-z_j\right) - \log\left(1-z_{j+1}\right)\right)$$

$$= z_n - z_1 - \frac{1}{1-z_1} + \frac{1}{n^2}\sum_{j=1}^{n}(1+2(n-j))\frac{1}{1-z_j} - 2\log(1-z_1) + 2\frac{1}{n}\sum_{j=1}^{n}\log\left(1-z_j\right);$$

$$\text{C} = 1 - z_n.$$

Summing the terms A, B, and C, multiplying by n, and simplifying yields the final computing formula:

$$AD^2_{\text{up}} = 2\sum_{j=1}^{n}\log\left(1-z_j\right) + \frac{1}{n}\sum_{j=1}^{n}(1+2(n-j))\frac{1}{1-z_j}.$$

Derivation of AD^{2*}_{up} Computing Formula

By the PIT technique

$$AD^{2*}_{\text{up}} = n\int\limits_{H}^{+\infty} \frac{\left(F_n(x) - \hat{F}^*_\theta(x)\right)^2}{\left(1-\hat{F}^*_\theta(x)\right)^2} d\hat{F}^*_\theta(x) \underline{\underline{PIT}}\ \hat{n}^c \int\limits_{z_{\text{H}}}^{1} \frac{(F_n(z^*)(1-z_{\text{H}})+z_{\text{H}}-z)^2}{(1-z)^2} dz,$$

where in the original integral $F_n(Z^*) = F^*_\theta(F_n(X)) = F_n(X)$ is the empirical distribution function of $Z^* := \hat{F}^*_\theta(X) = F^*\left(\hat{F}^*_\theta(X)\right)$ so that $F^*_\theta(\cdot) \sim \mathcal{U}[0,1]$. Changing variable and using Eq. 20.7, the integral becomes expressed in terms of $z_{\text{H}} := \hat{F}_\theta(H) = F\big(\hat{F}_\theta(H)\big)$ and $Z := \hat{F}_\theta(X) = F_\theta\big(\hat{F}_\theta(X)\big)$ so that $F_\theta(\cdot) \sim U[z_{\text{H}},1]$. We estimate $\hat{n}^c$ as $\frac{n}{1-z_{\text{H}}}$.

Using Eq. 20.7, the computing formula is expressed in terms of $z_j := \hat{F}_\theta\left(x_{(j)}\right) = F\left(\hat{F}_\theta\left(x_{(j)}\right)\right), j = 1, 2, \ldots, n$ as

$$\frac{1}{\hat{n}^c} AD^{2*}_{\text{up}} = \underbrace{\int_{z_{\text{H}}}^{z_1} \frac{(z-z_{\text{H}})^2}{(1-z)^2} dz}_{\text{A}} + \underbrace{\sum_{j=1}^{n-1} \int_{z_j}^{z_{j+1}} \frac{\left(\frac{j}{n}(1-z_{\text{H}})+z_{\text{H}}-z\right)^2}{(1-z)^2} dz}_{\text{B}} + \underbrace{\int_{z_n}^{1} \frac{(1-z)^2}{(1-z)^2} dz}_{\text{C}}.$$

Separately solving for A, B and C, we obtain

$$\begin{aligned} \text{A} = {} & z_1 - z_{\text{H}} - (1-z_{\text{H}}) + (1-z_{\text{H}})^2 \frac{1}{1-z_1} - 2(1-z_{\text{H}})\log(1-z_{\text{H}}) \\ & + 2(1-z_{\text{H}})\log(1-z_1); \end{aligned}$$

$$\begin{aligned} \text{B} = {} & z_n - z_1 - \frac{(1-z_{\text{H}})^2}{n^2} \sum_{j=1}^{n-1} (n-j)^2 \left(\frac{1}{1-z_j} - \frac{1}{1-z_{j+1}}\right) - \ldots \\ & - 2\frac{1-z_{\text{H}}}{n} \sum_{j=1}^{n-1} (n-j)\big(\log\big(1-z_j\big) - \log\big(1-z_{j+1}\big)\big) \\ = {} & z_n - z_1 - (1-z_{\text{H}})^2 \frac{1}{1-z_1} + \frac{(1-z_{\text{H}})^2}{n^2} \sum_{j=1}^{n} (1+2(n-j)) \frac{1}{1-z_j} - \ldots \\ & - 2(1-z_{\text{H}})\log(1-z_1) + 2\frac{1-z_{\text{H}}}{n} \sum_{j=1}^{n} \log\big(1-z_j\big); \end{aligned}$$

$$\text{C} = 1 - z_n.$$

Summing the terms A, B, and C, multiplying by $\hat{n}^c$, and simplifying yields the final computing formula:

$$AD_{\mathrm{up}}^{2*} = -2n\log(1 - z_{\mathrm{H}}) + 2\sum_{j=1}^{n} \log\left(1 - z_j\right) + \frac{1 - z_{\mathrm{H}}}{n}\sum_{j=1}^{n} \left(1 + 2(n - j)\right)\frac{1}{1 - z_j}.$$

Abstract

The effect of a merger on credit rating is investigated by testing the significance of change in a firm's rank based on comprehensive performance score and synergistic gains. We extract principle component factors from a set of financial ratios. Percentage of variability explained and factor loadings are adjusted to get a modified average weight for each financial ratio. This weight is multiplied by the standardized Z value of the variable, and summed a set of variables to get a firm's performance score. Performance scores are used to rank the firm. Statistical significance of difference in pre- and post-merger rank is tested using the Wilcoxon sign rank (double end).

We studied the merger of financial firms after the enactment of Taiwan's Merger Law for Financial Institution in November 2000 to examine synergies produced by merger. Synergistic gains affect corporate credit ratings. After taking into account the large Taiwan market decline from 1999 to 2000, test results show there is no significant operating, market, and financial synergy produced by the merger firms. Most likely explanations for the insignificant rank changes are short observation period and the lack of an adequate sample in this investigation.

We identify and define variables for merger synergy analysis followed by principal component factor analysis, variability percentage adjustment, and performance score calculation. Finally, Wilcoxon sign rank test is used for hypothesis testing. Reader is well referred to the appendix for details.

21.1 Introduction

Corporate credit rating helps in determining the soundness of a financial system. It gives lenders and venture capitalists confidence in making direct investment in domestic and foreign countries. Credit rating determines the probability that the corporation will be able to meet its obligations. There are a number of credit rating agencies worldwide.[1] The top three agencies that deal in credit ratings are Moody's, Standard & Poor's, and Fitch IBCA. Independent objective assessments of the credit worthiness of companies help investors decide the riskiness of the security issued by the firm. Credit rating institutions base their subjective

[1]World leading credit rating agencies are Moody's Investors Service, Standard & Poor's Corp, Fitch Investors Service, Duff & Phelps, Japan Bond Research Institution, Nippon Investors Service, Japan Credit Rating Agency, China Credit Rating Agency, and Taiwan New Economy Newspaper (Weston and Mansinghka 1971; Williamson 1981).

rating judgments by the experiences and expertise of their analyst teams. Their public confidences come from their reputation. Yet different analysts or different credit rating institutions may give different meanings or powers to the likelihood of the same incident. Credit rating agencies often revise their ratings after a corporate event. This research deals with the event of corporate mergers.

A merger is the quickest method of corporate growth. At the end of the twentieth century, there was an upsurge of mergers in Europe, the USA, and Asia. The same was true for Taiwan. Mergers occurred in various industries of Taiwan, with financial industry the most dominant. For example, the merger of Bank of Taiwan, Local Bank, and the Central Credit Bureau was the first large merger initiated by the government. The institution resulting from the merger ranked in the top 70 in the world. Yuan Dao, the number one corporation in the security industry, captured 10 % of the Taiwanese brokerage business after its acquisition of Jing Hua. The Merger Law for Financial Institutions passed in November 2000 and permitted the merger of domestic financial institutions, such as banks, insurance companies, and security companies, and allowed for the establishment of assets Management Corporation. After a merger, operating income, market share, revenues, and total asset increase. But does a merger help to improve corporate quality and competence? When does merger synergy manifest? What are its merits? There are a number of questions that need discussion and analysis. The scope of this paper is limited. We study the effect of mergers on credit rating by testing the significance of change in firm's rank based on comprehensive performance score and synergistic gains.

21.2 Merger Literature

Firms merge with the stated intent of shareholders' wealth maximization. Value maximization is achieved by increased profit, reduced risk, or both. Theories that posit wealth maximization are efficiency theory (synergy), information and signaling theory, and tax advantage.[2] Non-value maximization concerns with agency theory. In this research we focus primarily on efficiency theory, also called synergy theory. Synergy theory implies three components: operation synergy, market synergy, and financial synergy. Operation synergy is produced due to economies of scale, operating reduction, and sharing of management expertise. Under market synergy, a merger reduces market competitors and increases market concentration leading to a monopolization or increased market share. The increased market share produces superior profits via pricing strategy or corporate collusion. The merging corporation increases its market share so as to influence product price

[2]Theory of merger is discussed in Brigham and Daves (2007), Copeland and Weston (1979), Gardner (1996), and Rhodes (1983). Tax incentive is discussed in Weston and Chung (1983).

and quantity and to achieve market synergy. However, corporations in pursuit of market synergy must abide by the fair trade law. Seth (1990) said it was easy to achieve market synergy via horizontal merger instead of pricing strategy or corporate collusion. Financial synergy reduces the systematic risk and lowers the capital cost. There is extensive literature of merger-related studies. The following is a selected sample.

Ansoff et al. (1971) used a questionnaire to collect 12 financial variables: sales, retained earnings, total asset, return on capital, etc. Their research showed that sales management, technology, and R&D produced operating synergy. Weston and Mansinghka (1971) estimated management energy with corporate growth using variables: total asset, sales, net profit, retained earnings, and stock price. Their research indicates that a conglomerate merger gives the corporation a higher growth rate than the growth of other corporations within the same industry. Beattie (1980) used nonsystem risk and stock return to estimate merger synergy. His finding is that after a merger, nonsystem risk declines, yet corporate stock returns do not increase. Hoshino (1982) estimated corporate synergy with seven financial data: the ratio of net worth and total liabilities, ratio between net worth and total assets, liquidity ratio, ratio of interest rate to debt, turnover ratio, ratio of net profit and total liabilities, and ratio of net profit to total assets. His finding is that a merged corporation has increased liquidity, but lower profitability and stability. Muller (1985) used market share percentage to estimate the effect of merger. His finding is that there is no significant change in market share; some companies even lose market share after merger. Sigh and Montgomery (1987) used stock returns to discuss related and non-related merger synergy. Their finding is that a related merger has a higher return. Healy et al. (1992) used the ratio between before-tax capital flow and total assets to estimate merger synergy. Their finding is that the return on operating cash flow improves significantly. Williamson (1981) stated that vertical merger could reduce the communication cost between upper and lower stream corporations, cost of product quality check, storage cost, and delivery cost. Yet Scherer (1980) thought a different market configuration could impact the gains due to economies of scale. The more complete the market competition is, the less is the gain due to economies of scale. On the other hand, Rhodes (1983) thought that the resources configuration within a corporation is complicated and bureaucratic. Hence, the internal capital market is less efficient than the external capital market. In support of financial synergy, Fluck and Lynch (1999) pointed out that after a merger, a corporation could have greater investment opportunities at lower cost than before. Lewellen (1971) suggested the merger could reduce the capital cost. Levy and Sarnat (1970) thought stockholders could achieve risk reduction via portfolio diversification at a lower cost than that of the merger. Higgins and Schall (1975) pointed out the coinsurance effect and hence a reduced cost of bankruptcy. Hence, there is a transfer of wealth from creditors to stockholders from creditors, as stockholders could reissue bonds with a lower interest rate.

Table 21.1 Merged security firms

Merged security firms	Survived corporation	Date of announcement	Date of merger
YuanDa, JinHua, Dafa	YuanDaJinHua	Nov. 29, 1999	July 01, 2000
YuanFu, JiaHe, YongSheng	YuanFu	Jan. 28, 1999	July 24, 2000
JianHong, WanSheng	JianHong	Feb. 11, 2000	Aug. 28, 2000
BaoLai, DaShun, ShiTai, HuaYu	BaoLai	Feb. 19, 2000	Sep. 9, 2000
FuBang, HuangQiu, ZhongRi, JinShan, HuaXin, ShiLing, KuaiLe	FuBang	Feb. 21, 2000	Sep. 9, 2000

13 non-merger firms used to test the model are as follows: TaiYu, DaHua, QunYi, ZhongXin, YongChang, TaiZhen, JinDing, RiShen, DaXin, KangHe, YaZhou, XinBao, and TongYi

21.3 Empirical Analysis

The effect of a merger on credit rating is investigated by (1) testing the significance of change in a firm's rank based on a comprehensive performance score and (2) examining post-merger synergy. Synergistic gains from a merger could be in the form of operating (management) synergy, market synergy, and/or financial synergy. Data for this research cover January 1999 to December 2000. Premerger analysis covers year 1999, and post-merger analysis covers year 2000.[3] Definitions of financial ratios are presented in Appendix 1. The methodology of factor extraction and weight assignment is discussed in Appendix 2. Since the analyses are based on ranks, the usual "*t*-test" method is unsuitable to examine the significance of change in operating, financial, or market performance pre- and post-merger. Hence, we use the Wilcoxon Sign Rank Test that checks whether two sets of ranks, pre- and post-merger, come from the same sample or two samples (Appendix 3).[4] In Table 21.1, we list five acquiring financial institutions and the acquired institutions. The footnote of Table 21.1 lists 13 non-merger firms. These 13 firms are included in the analysis for comparison.

21.3.1 Comprehensive Performance Score

Principle component factor analysis was used to extract common factors with factor loading greater than 1. Using 12-month financial ratio covering 1999, we produced five factors (Table 21.2, Panel A). The variability explained by five extracted factors is 24.458 %, 23.764 %, 13.268 %, 12 %, and 11.031 %.

[3]3-month and 6-month analyses were performed but are omitted as these did not add additional foresight.

[4]References for Statistical and Econometric issues are Johnson and Wichern (2007) and Woolridge (2009).

Table 21.2 Extracted factors and explained variability

		Explained variability		
Factor	Factor loading	Percentage	Cumulative percentage	Adjusted percentage
Panel A: December 1999				
1	4.647	24.458	24.458	28.937
2	4.515	23.764	48.222	28.116
3	2.521	13.268	61.49	15.698
4	2.28	12	73.49	14.198
5	2.096	11.031	84.521	13.051
Total	16.059	84.521	84.521	100
Panel B: December 2000				
1	4.245	22.34	22.34	24.746
2	3.844	20.229	42.569	22.407
3	2.991	15.74	58.309	17.435
4	2.377	12.51	70.819	13.857
5	2.011	10.584	81.403	11.724
6	1.686	8.876	90.279	9.832
Total	17.154	90.279	90.279	100.000

Principle component factors. See Appendix 2

The percentage of variability explained was adjusted to make the total variability explained equal to 100. The adjusted percentage of variability explained by five extracted factors is 28.937 %, 28.116 %, 15.698 %, 14.198 %, and 13.051 %. Using 12-month financial ratio covering 2000, six extracted common factors with factor loading greater than 1 are presented in Table 21.2 (Panel B). The adjusted percentage of variability explained by six extracted factors is 24.746 %, 22.407 %, 17.435 %, 13.857 %, 11.724 %, and 9.832 %. The adjusted variability percentage is multiplied by factor loading and summed over all variables to get the total loading for a variable. Then factor loadings are adjusted such that total factor loadings add to 100 (Eq. 21.2). Initial and adjusted weights for each variable are presented in Table 21.3. Finally, the values of adjusted weights for 1999 and 2000 are averaged and sign modified to reflect a positive or negative variable. It is presented in the last column of Table 21.3 and used to calculate comprehensive performance score. The modified average weight for each variable is multiplied by the standardized Z value of the variable and summed over all the variables to get a firm's performance score and comprehensive rank (Table 21.4). The premerger comprehensive ranks of the five merger firms and 13 non-merger firms are listed in Table 21.4, Panel A. Panel B of Table 21.4 presents comprehensive post-merger comprehensive ranks. Rank changes in Table 21.4 can be summarized as JianHong dropped from rank 1 to 6, YuanDaJinHua rose from rank 3 to 2, YuanFu rose from rank 7 to 1, FuBang dropped from rank 2 to 4, and BaoLai rose from rank 16 to 8. The test of significance of the comprehensive rank differences, for

merger and non-merger firms, was conducted using the Wilcoxon sign rank (double end) test discussed in Appendix 3. Panel A of Table 21.5 indicates that the merger firm's comprehensive rank difference is statistically insignificant. Panel B of Table 21.5 indicates that the non-merger firm's comprehensive rank difference is also statistically insignificant. Plausible explanations for the insignificant rank changes are a short observation period, the lack of adequate samples, and the sharp decline in JianHong's performance score. Another plausible reason may be that some security firms (such as YuanDaJinHua and YuanFu) have already achieved high premerger comprehensive performance scores, and any improvement in post-merger performance did not make a significant difference.

21.3.2 Test of Merger Synergy

We use 12-month data to examine operating synergy, market synergy, and financial synergy. If operating synergy exists, then operating cost ratio will be reduced

Table 21.4 Security firm's comprehensive performance score and rank

[a]means Wilcoxon sign rank test for performance score difference between before after merger is statistically significant

significantly; if market synergy exists, then two other ratios (ratio of operating income to total assets and market share change rate) will increase significantly; and existence of financial synergy is indicated by the decline in variability of operating (business) risk.

Some financial variables of security firms are greatly influenced by market conditions. The operating income, in particular, is greatly influenced by a bull or bear market. In years 1999 and 2000, the Taiwan stock market fell from over 10,000 points to over 5,000 points. In order to reduce the market impact on variables, we adjust the operating cost to operating income ratio and the operating income to total asset ratio. The operating cost ratio and the operating return on assets are normalized by the industry average of the ratio.

Table 21.6 presents a test of significance of operating synergy for merger and non-merger firms. The test result shows there are no significant changes of operating costs ratio for merger firms. But for non-merger firms, there are significant increases of operating cost ratio. Then operating income is adjusted for market drop in 2000, and the significance of operating synergy is tested again. The test result is presented in Table 21.7.

Table 21.5 Test of significance of merger and non-merger firms' comprehensive rating

Firm	December 1999 ranks	December 2000 ranks	Difference	D_i	Class	W
Panel A: merger firms

TongYi	4	9	−5	5	10	

Wilcoxonsign rank (double end) test indicates that rank difference is statistically *insignificant*, Eq. 21.6

The test of significance of merger synergy is performed by examining two financial ratios: ratio of operating income to total assets (operating return ratio) and market share. Table 21.8 presents the first test of significance of market synergy using operating return ratio. Result shows there are *significant* increases in the ratio of operating income to total assets for both merger and non-merger security firms. This indicates a positive market synergy. We repeat the test of significance after adjusting the operating income to account for the market decline. Results presented in Table 21.9 show there are insignificant differences in the ratio of operating income to total assets for both merger and non-merger security firms. The second test of significance of market synergy using market share change is presented in Table 21.10. Results in Table 21.10 show there are significant increases of market share for merger security firms. This means positive market synergy. For the non-merger firms, there are *significant* declines of market share. Taking the two variables into consideration, we state that positive market synergy is produced by the merger of security firms. We use the variability of operating risk to assess financial synergy. The test results in Table 21.11 show there is insignificant financial synergy for merger firms. However, there is significant change in the variability of operating risk for non-merger security firms.

[a]Operating cost/operating income
Wilcoxon sign rank (double end) test indicates that rank difference is statistically *insignificant*, Eq. 21.6

21.4 Conclusion

The effect of a merger on credit rating was examined by testing the significance of change in firm's rank based on a comprehensive performance score and examining post-merger synergy. Synergistic gains from a merger could be in the form of operating synergy, market synergy, and/or financial synergy. Our test showed that merger and non-merger firms' comprehensive performance rank difference was statistically insignificant. Plausible explanations for the insignificant rank changes are a short observation period and the lack of adequate samples. Other plausible explanation may be that some security firms have already achieved high premerger comprehensive performance scores, and any improvement in post-merger performance did not make a significant difference.

We used a standardized score of operating cost ratio to rank firms for their operating synergy. Test results show there is no significant operating synergy for merger and non-merger security firms. We used standardized scores of ratio of operating income to total assets and market share change to rank firms for their market synergy. Test result shows there are *significant* increases in the ratio of

Wilcoxon sign rank (double end) test indicates that rank difference is statistically *insignificant*, Eq. 21.6

operating income to total assets for both merger and non-merger security firms, indicating a positive market synergy. However, after adjusting the operating income market decline, the results indicate insignificant differences in the ratio of operating income to total assets for both merger and non-merger security firms. We used standardized score of variability of operating risk to rank firms for their financial synergy. The test results show there is insignificant financial synergy for merger firms; however, there is significant change in the variability of operating risk for non-merger security firms.

Appendix 1: Variables for Merger Synergy Analysis

Post-merger credit rating of the firm depends on the extent of synergy produced by the merger. Components of merger synergy are operating synergy, market synergy, and financial synergy.

Each synergy component is determined by firm characteristics: financial structure, solvency, asset utilization, profitability, cash flow, growth, scale, and industry-specific ratio. In this study a number of financial ratios are used to assess

operating performance of the firm before and after the merger. The following section outlines firm characteristics and variables to measure operating performance.

Merger Synergy

Operating synergy – it refers to the improvement of operating efficiency achieved via scale economy, transaction cost economy, and differential efficiency caused by merger. *Market synergy* – increase in market share due to enhanced negotiating power and dominant pricing strategy.

Financial synergy – diversification of financial risk and cost of capital reduction.

Operating Synergy

A. – Financial structure
X_{i1} – Debt ratio
X_{i2} – Ratio of long-term capital to fixed assets

Principal Component Factor Analysis of Merger Synergies

Principal component factor analysis is used to examine merger synergies. It is a multivariable statistic method focusing on the relationship between groups of variables. Its purpose is to express the original data structure with fewer factors while keeping most of the information provided by the original data structure.

Factor analysis is composed of two parts: one is common factor, and the other is specific factor. Factor analysis intends to group the variables with same common factors. In other words, it discusses how to break down every variable X_i of P variables $X_1 \sim X_P$ into the linear combination of q common factors fj(q, and $q \leq p$), $j = 1, 2 \ldots q$ and specific factor ε_i. The model is as follows:

$$\begin{aligned} X_1 &= \mu_1 + L_{11}F_1 + L_{12}F_2 + \cdots + L_{1q}F_q + \varepsilon_1 \\ X_2 &= \mu_2 + L_{21}F_1 + L_{22}F_2 + \cdots + L_{2q}F_q + \varepsilon_2 \\ &\vdots \\ X_p &= \mu_p + L_{p1}F_1 + L_{p2}F_2 + \cdots + L_{pq}F_q + \varepsilon_p \end{aligned} \tag{21.1}$$

where $F_1 \ldots, F_q$ are common factors, ε_i is specific factor for variable X_i, and L_{ij} is the factor loading of variable X_i and common factor $F_{j.}$ Factors extracted are independent and also analysis preserves the information in the original variables. There is no overlap of information among principle components. The model should be parsimonious, in the sense that a few principle components should be able to replace the original set of variables.

Variability Percentage Adjustment

All principle components with factor loading greater than 1 are selected. Then weights are assigned to different variables based on percentage of variability explained. The variability percentage adjustment is adjusted as follows:

$$V_j^{adj} = \mathrm{V_j}/\Sigma_j V_j \tag{21.2}$$

where V_j ($j = 1,2\ldots q$) is the percentage of variability explained by factor F_j.

Factor Loading Adjustment

The adjusted variability percentage V_j^{adj} is multiplied by factor loading L_{ij} and summed over all variables ($j = 1,2\ldots q$) to get the total loading fo variable X_i. Then adjust L_i such that total factor loadings add to 100.

$$\begin{aligned} L_i &= \sum V_j^{adj} L_{ij} \\ L_i^{adj} &= 100^* \left(\mathrm{L_i} / \sum \mathrm{L_i}\right) \end{aligned} \tag{21.3}$$

Every variable has a weight, L_i^{adj} before and after the estimation period; we average it to obtain weight W_i. For some variables, X_i, the greater the value of the variable, the better it is for the operating, financial, or merger synergy. Those variables are classified as positive variables. If opposite is true, then those variables are classified as negative variable. Hence adjusted variable weights are redesigned to correctly reflect operating synergy score: $W_i^* = \{W_i \text{ or } -W_i\}$ for positive and negative variables, respectively.

Performance Scores

All variables are not measured in the same unit, so they are standardized as $X_i^* = \{X_i - \mathrm{Ave}(X_i)\}/\sigma$, where $\mathrm{Ave}(X_i)$ is the average and σ is the standard deviation of variable X_i ($i = 1,2\ldots p$). The adjusted variable weight W_i^* multiplied by standardized variable Z_i gives the performance score of variable X_i. Appropriate standardized performance score of the variable is used to rank the firm for its operating or financial or market synergy. The sum of the standardized performance scores over the set of variables gives the comprehensive performance score:

$$S = \sum W_i{}^{*} \cdot Z_i \tag{21.4}$$

where the summation is over the first 19 variables listed in Appendix 1. Then firms are ranked in terms of their respective comprehensive performance score. The greater the total score is, the better is the comprehensive performance rating. On the other hand, the smaller the total score, the worse is the performance rating and lower is its rank.

Appendix 3

Wilcoxon Sign Rank Test

Usual "*t*-test" method is unsuitable to examine the significance of change in operating, financial, or market performance before and after merger as we deal with ranks. We use the Wilcoxon sign rank test which checks whether two sets of ranks, pre- and post-merger, come from the same sample or two samples. Let D be the difference between observed value from the sample and reference value. Then we delete those observations whose value of D is zero and rank incrementally the rest of observations in terms of the absolute value of D. If two or more absolute values are the same, we give each value an appropriate rank, then average those ranks, and use the averaged rank as the rank of the same absolute values.

The statistic analysis method of test is as follows:

The differences between the post-merger synergy ranks (X_i) and corresponding premerger synergy ranks (Y_i), D_i is ranked in descending order. Let R_i be the serial number of D_i (if they have the same rank, then take their average value).

$$\begin{gathered}
\boldsymbol{D_i = X_i - Y_i \qquad i = 1, 2, \cdots n} \\
\boldsymbol{R_i = rank(|D_i|) \quad i = 1, 2, \cdots n} \\
\boldsymbol{W(+) = \sum R_i \quad X_i - Y_i > 0} \\
\boldsymbol{W(-) = \sum R_i \quad X_i - Y_i < 0} \\
\boldsymbol{W = \min(W+, W-)}
\end{gathered} \tag{21.5}$$

where W(+) is the total of absolute value of serial numbers of positive rank changes and W(−) is the total of absolute value serial numbers of negative rank changes. W is the test statistic.

Test Hypotheses

For comprehensive performance ranks:

$H_{0:}$ *Performance rating after merger* = *performance rating before merger* ($\eta_1 = \eta_2$).

$H_{1:}$ *Performance rating after merger* $\neq$ *performance rating before merger* ($\eta_1 \neq \eta_2$).

For operating, market, and financial synergy:

H_0 = *No synergy occurred after merger* ($\eta_1 = \eta_2$).

H_1 = *Synergy occurred after merger* ($\eta_1 \neq \eta_2$).

We undertake a double end test. Under the significant level of α, we find the critical value $W(\alpha)$ from the appropriate statistical table. The null hypothesis is rejected if

$$\begin{aligned} &W \leq (-W(\alpha/2)) \text{ or} \\ &W \geq (W(\alpha/2)) \end{aligned} \tag{21.6}$$

This means that merger has produced significant synergy and performance (and credit) rating has affected. The appropriate variables for operating, market, and financial variables are operating cost ratio, ratio of operating income to total assets and market share, and variability of operating risk, respectively.

On-/Off-the-Run Yield Spread Puzzle: Evidence from Chinese Treasury Markets 22

Rong Chen, Hai Lin, and Qianni Yuan

Contents

Abstract

In this chapter, we document a negative on-/off-the-run yield spread in Chinese Treasury markets. This is in contrast with a positive on-/off-the-run yield spread in most other countries and could be called an "on-/off-the-run yield spread puzzle." To explain this puzzle, we introduce a latent factor in the pricing of Chinese off-the-run government bonds and use this factor to model the yield

We thank the National Natural Science Foundation of China (Grant No. 71101121 and No. 70971114) for financial support.

difference between Chinese on-the-run and off-the-run issues. We use the nonlinear Kalman filter approach to estimate the model. Regressions results suggest that liquidity difference, market-wide liquidity condition, and disposition effect (unwillingness to sell old bonds) could help explain the dynamics of a latent factor in Chinese Treasury markets. The empirical results of this chapter show evidence of phenomena that are quite specific in emerging markets such as China.

The Kalman filter is a mathematical method named after Rudolf E. Kalman. It is a set of mathematical equations that provides an efficient computational (recursive) means to estimate the state of a process, in a way that minimizes the mean of the squared error. The nonlinear Kalman filter is the nonlinear version of the Kalman filter which linearizes about the current mean and covariance. The filter is very powerful in several aspects: it supports estimations of past, present, and even future states, and it can do so even when the precise nature of the modeled system is unknown.

On-/off-the-run yield spread • Liquidity • Disposition effect • CIR model • Nonlinear Kalman filter • Quasi-maximum likelihood

22.1 Introduction

It is well known that there exists an on-the-run phenomenon in worldwide Treasury markets. This phenomenon refers to the fact that just-issued (on-the-run or new) government bonds of a certain maturity are generally traded at a higher price or lower yield than previously issued (off-the-run or old) government bonds maturing on similar dates. For example, Amihud and Mendelson (1991), Warga (1992), Kamara (1994), Furfine and Remolona (2002), Goldreich et al. (2005), and Pasquariello and Vega (2009) report the existence of positive on-/off-the-run yield spread in the US Treasury market with different frequency data. Mason (1987) and Boudoukh and Whitelaw (1991, 1993) provide similar evidence in Japan. In spite of different opinions on the information content of the yield spread, there is no disagreement in the literature that the on-/off-the-run yield spread in Treasury markets is significantly positive.

Academics have proposed many theories to explain the positive on-/off-the-run yield spread. Early studies directly attribute this spread to the liquidity difference between new bonds and old bonds (Amihud and Mendelson 1991; Warga 1992; Kamara 1994). More recent work provides some other possible explanations, such as different tax treatment (Strebulaev 2002), specialness in the repo market[1] (Krishnamurthy 2002), the value of future liquidity (Goldreich et al. 2005), search

[1]Specialness refers to the phenomenon that loans collateralized by on-the-run bonds offer lower interest rates than their off-the-run counterparts in repo markets.

costs (Vayanos and Weill 2008), and market frictions of information heterogeneity and imperfect competition among informed traders (Pasquariello and Vega 2009). No matter what arguments are proposed, however, the important role that liquidity plays in the positive on-/off-the-run yield spread and the liquidity premium hypothesis (Amihud and Mendelson 1986) has never been denied. It is widely accepted, by both practitioners and academics, that off-the-run bonds with a lower liquidity level tend to have a higher yield than otherwise similar, yet more liquid, on-the-run bonds.

In this chapter, we document a negative on-/off-the-run yield spread in Chinese Treasury markets, which is contrary to the usual on-the-run phenomenon in other countries and could be called the on-/off-the-run yield spread puzzle in China. Guo and Wu (2006) and Li and He (2008) report that on-/off-the-run yield spread in Chinese Treasury markets is significantly positive, but they did not match the on-the-run and off-the-run bonds correctly. For example, they compare the yield of a just-issued 7-year government bond with that of a previously issued 7-year government bond that has a different maturity. This is not consistent with the calculation of the usual on-/off-the-run yield spread. In order to calculate the spread correctly, we need to match the bonds in terms of maturity date. For example, we compare a just-issued 1-year government bond and a previously issued government bond maturing on similar dates. The maturities are both about 1 year and the durations are close to each other.

To explain on-/off-the-run yield spread puzzle, we introduce a latent factor in the pricing of Chinese off-the-run bonds. This latent factor is used to model the yield difference between on-the-run bonds and off-the-run bonds. We employ a nonlinear Kalman filter to estimate the model and examine the temporal properties of the latent factor. We find that the liquidity premium hypothesis still holds in Chinese Treasury markets. In particular, the change of the latent factor is positively related to the liquidity difference between off-the-run and on-the-run bonds and positively related to the market-wide liquidity condition. Both findings are consistent with the liquidity premium hypothesis. On the other hand, disposition effect (unwillingness to sell old bonds in bear markets) dramatically changes the sign of the yield spread and causes the puzzle. The change of latent factor in Chinese Treasury markets is negatively related to 7-day repo rates. When interest rates go up and the returns of the bond markets are negative, the holders of off-the-run bonds are reluctant to realize loss and will not sell their bonds, which consequently leads to a relatively low yield level of off-the-run bonds and a negative on-/off-the-run yield spread.

Our article makes several contributions to the literature. We document a negative on-/off-the-run yield spread in China. We introduce a latent factor to explain the yield difference between on-the-run bonds and off-the-run bonds and employ the nonlinear Kalman filter in estimation. Our basic ideas are in line with Longstaff et al. (2005) and Lin et al. (2011). We also provide evidence of irrational investor behavior that is quite specific in emerging Treasury markets such as China. In China, the liquidity premium hypothesis still holds, whereas the existence of disposition effect causes the puzzle.

The chapter is organized as follows. In Sect. 22.2, we present a pricing model of government bonds that introduces a latent factor for the off-the-run bonds.

In Sect. 22.3, we describe the data, report the estimation results, and perform a variety of regression analyses. We present our conclusions in Sect. 22.4.

22.2 Bond Pricing Models

22.2.1 On-the-Run Bond Pricing Model

We use the Cox et al. (1985, CIR) model to price the Chinese on-the-run government bonds. The CIR model has been a benchmark interest rate model because of its analytical tractability and other good properties. In this model, the risk-free short rate, r_t, is assumed to follow a square-root process as

$$dr_t = \kappa(\theta - r_t)dt + \sigma_r\sqrt{r_t}dW_{r,t}, \tag{22.1}$$

under the risk-neutral measure Q. κ is the speed of mean reversion, θ is the long-term mean value, σ_r is the volatility parameter of r_t, and W_r denotes a standard Brownian motion under Q. Such specification allows for both mean reversion and conditional heteroskedasticity and guarantees that interest rates are nonnegative.

At time t, the price of an on-the-run government bond maturing at t_M could be written as

$$P_t^{on} = E_t^Q\left[\sum_{m=1}^{M} C_m \exp\left(-\int_t^{t_m} r_s ds\right)\right], \tag{22.2}$$

where P_t^{on} is the on-the-run bond price, C_m is the cash flow payments at time t_m, and M is the total number of cash flow payments. That is, the price of a government bond is the expected present value of the cash flow payments under the risk-neutral measure.

Solving Eq. 22.2 gives

$$P_t^{on} = \sum_{m=1}^{M} C_m A_{m,t} \exp(-B_{m,t} r_t), \tag{22.3}$$

where

$$A_{m,t} = \left[\frac{2h\exp\{(\kappa+h)(t_m-t)/2\}}{2h+(\kappa+h)(\exp\{(t_m-t)h\}-1)}\right]^{2\kappa\theta/\sigma_r^2},$$

$$B_{m,t} = \frac{2(\exp\{(t_m-t)h\}-1)}{2h+(\kappa+h)(\exp\{(t_m-t)h\}-1)},$$

and

$$h = \sqrt{\kappa^2 + 2\sigma_r^2}.$$

22.2.2 Off-the-Run Bond Pricing Model

In order to model the on-/off-the-run yield spread in Chinese Treasury markets, we next incorporate a latent component, l, into the pricing model of Chinese off-the-run government bonds and extend (22.2) to

$$P_t^{off} = E_t^Q\left[\sum_{m=1}^{M} C_m \exp\left(-\int_t^{t_m} (r_s + l_s)ds\right)\right], \tag{22.4}$$

where P_t^{off} is the off-the-run bond price. Similar to Longstaff et al. (2005) and Lin et al. (2011), we assume that under the risk-neutral measure Q,

$$dl_t = \sigma_l dW_{l,t}, \tag{22.5}$$

where W_l is a standard Brownian motion independent of W_r under Q and σ_l is the volatility parameter.

Given the stochastic processes in (22.1) and (22.5), we can obtain the analytical solution for the pricing formula of (22.4),

$$P_t^{off} = \sum_{m=1}^{M} C_m A_{m,t} \exp\left(D_{m,t} - B_{m,t} r_t - (t_m - t)l_t\right), \tag{22.6}$$

where $D_{m,t} = \frac{\sigma_l^2 (t_m - t)}{6}$ and other notations are the same as in (22.3).

22.3 Data and Empirical Estimation

22.3.1 Data Summary

We use the price of Chinese government bonds in the interbank market to estimate the pricing model. The data are from the RESSET dataset. There are two main bond markets in China. One is the interbank bond market, while the other is the exchange bond market. The interbank bond market is a quote-driven over-the-counter market, and the participants are mainly institutional investors. Its outstanding value and trading volume account for over 90 % of Chinese bond markets. The number of bonds traded in the interbank market is at least three times that traded in the exchange market. This is very important for our empirical study, since we need enough bonds to match new and old ones.

Table 22.1 Summary statistics

	Off-the-run		On-the-run		
	Mean	Std	Mean	Std	Difference
One year					
Yield (%)	2.24	0.92	2.31	0.72	−0.07
Modified duration (years)	0.68	0.25	0.73	0.22	−0.05
Age (years)	4.3	2.92	0.26	0.22	4.04[a]
Coupon (%)	2.95	2.73	1.39	1.46	1.63[a]
Three years					
Yield (%)	2.72	0.78	2.83	0.79	−0.11[b]
Modified duration (years)	2.47	0.33	2.48	0.31	−0.01
Age (years)	3.05	1.45	0.38	0.32	2.67[a]
Coupon (%)	3.39	2.32	2.89	0.62	0.50

This table reports the summary statistics of the Chinese 1-year and 3-year on-the-run and off-the-run government bonds between December 2003 and February 2009. The coupon rate and yield are in percentages, while age and modified duration are in years. This table also reports the difference between the off-the-run bonds and the on-the-run bonds

[a]and[b] indicate statistical significance at the 5 % and 1 % level, respectively

Our sample period is from December 2003 to February 2009. We use monthly data and choose the actively traded government bonds with 1 year and 3 years to maturity. Thus, for each month in our sample period, a most recently issued 1-year and 3-year government bonds are selected as the on-the-run bonds, and we get another old bond maturing on similar dates to match each on-the-run bond.[2] Altogether, 63 matched pairs of 1-year government bonds and 63 matched pairs of 3-year government bonds are included in the final sample.

Table 22.1 reports the summary statistics for the sample bonds. As expected, the modified durations of off-the-run and on-the-run bonds are quite close to each other. This means if interest rate risk is the only risk factor, these bonds should be traded at similar yields. To examine whether the same on-the-run phenomenon exists in Chinese Treasury markets, we compute the on-/off-the-run yield spread as

$$\Delta y_{M,t} = y_{M,t}^{off} - y_{M,t}^{on}, \tag{22.7}$$

where $y_{M,t}^{off}$ and $y_{M,t}^{on}$ are the time t yield of the off-the-run bond and the on-the-run bond maturing at t_M, respectively. In our sample, $t_M - t$ is equal to 1 year or 3 years. Figure 22.1 plots the time series of $\Delta y_{M,t}$ of the 1-year bond and 3-year bond.

Table 22.1 also reports the means of on-/off-the-run yield spreads and their statistical significance. Both the 1-year on-/off-the-run yield spread and the 3-year on-/off-the-run yield spread are negative, which is inconsistent with the findings in other markets. Moreover, the 3-year on-/off-the-run yield spread is significantly

[2]The main reason for the data selection comes from the concern of trading activity. Trading in Chinese Treasury markets is not active, especially in the earlier period.

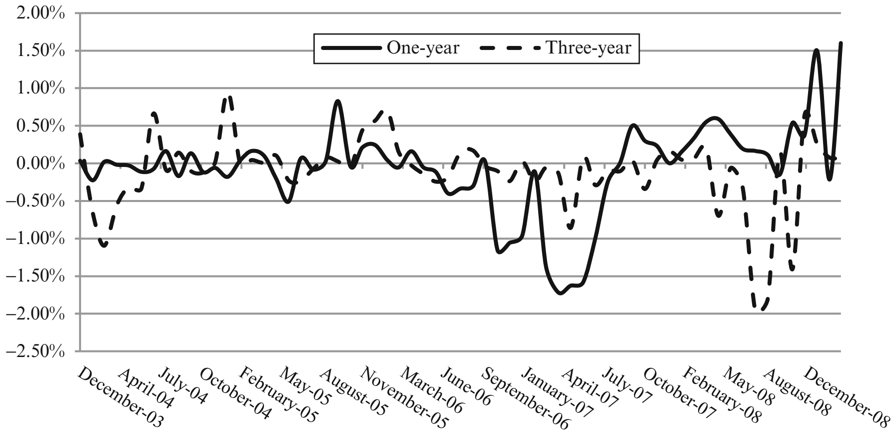

Fig. 22.1 Time series of Chinese on-/off-the-run yield spread. This figure plots the yield difference between the off-the-run and on-the-run Chinese government bonds between December 2003 and February 2009

negative at the 10 % level, which suggests the existence of a significantly negative on-/off-the-run yield spread and remains a puzzle. The 1-year on-/off-the-run yield spread is negative but not significant. However, this spread has some noise, since the difference of coupon rate between the on-the-run issues and off-the-run issues is 1.63 % and significant at the 1 % level. This difference could affect the significance of the on-/off-the-run spread at the 1-year level. Generally speaking, we find evidence of a negative on-/off-the-run spread, which is contrary to the established fact of a positive on-/off-the-run yield spread in most other countries and could be called the on-/off-the-run yield spread puzzle in China.

22.3.2 Empirical Methodology

To explain the on-/off-the-run yield spread puzzle in China, we use the CIR model to price the on-the-run issues and the CIR model with the latent factor to price the off-the-run issues. We first estimate the parameters of the CIR model using all on-the-run bonds. Given the parameters of the CIR process, we further estimate the parameters of the latent factor using off-the-run bonds. Thus, the latent factor represents the yield difference between on-the-run and off-the-run bonds.

In our empirical study, we employ the Kalman filter to estimate the parameters.[3] The standard Kalman filter is not appropriate here because it requires linear state functions and the measurement functions, while Eqs. 22.3 and 22.6 are nonlinear.

[3] See Hamilton (1994) for an explanation of Kalman filter.

Table 22.2 Estimates of pricing models

	On-the-run issues $dr_t = \kappa(\theta - r_t)dt + \sigma_r\sqrt{r_t}dW_{r,t}$		Off-the-run issues $dr_t = \kappa(\theta - r_t)dt + \sigma_r\sqrt{r_t}dW_{r,t}$ $dl_t = \sigma_l dW_{l,t}$	
The state function	$r_t = \gamma + \phi r_{t-1} + \varepsilon_t$		$r_t = \gamma + \phi r_{t-1} + \varepsilon_t l_t = l_{t-1} + \sigma_l(\eta_t - \eta_{t-1})$	
The measurement function	$\mathbf{y}_t^{on} = \boldsymbol{\alpha}_t^{on} + \boldsymbol{\beta}_t^{on} r_t + \boldsymbol{\omega}_t^{on}$		$\mathbf{y}_t^{off} = \boldsymbol{\alpha}_t^{off} + \boldsymbol{\beta}_t^{off} r_t + \boldsymbol{\xi}_t^{off} l_t + \boldsymbol{\omega}_t^{off}$	
κ	0.089(6.403)[a]			
θ	0.023(6.486)[a]			
σ_r	0.063(247.921)[a]			
σ_l			0.009(8.530)[a]	
var(ε_t)	0.000008			
var(η_t)			0.000007	
	One year	Three years	One year	Three years
var($\boldsymbol{\omega}_t^{on}$)	0.000035	0.000020		
var($\boldsymbol{\omega}_t^{off}$)			0.000011	0.0000006
RMSE	0.0045	0.0038	0.0062	0.0058
MAD	0.0596	0.0517	0.0705	0.0672

This table reports the estimate results of pricing models for on-the-run and off-the-run Chinese government bonds. The parameters of the CIR model are estimated from monthly on-the-run bond data. These parameters are then used to estimate the latent factor in the monthly off-the-run bond data. We use a nonlinear Kalman filter approach to estimate the parameters. $\mathbf{y}_t^{on} = \begin{bmatrix} y_{1,t}^{on} \\ y_{3,t}^{on} \end{bmatrix}$, $\mathbf{y}_t^{off} = \begin{bmatrix} y_{1,t}^{off} \\ y_{3,t}^{off} \end{bmatrix}$, $\boldsymbol{\omega}_t^{on} = \begin{bmatrix} \omega_{1,t}^{on} \\ \omega_{3,t}^{on} \end{bmatrix}$, and $\boldsymbol{\omega}_t^{off} = \begin{bmatrix} \omega_{1,t}^{off} \\ \omega_{3,t}^{off} \end{bmatrix}$, where subscript *1* and *3* denote 1-year and 3-year bonds and superscript *on* and *off* denote on-the-run and off-the-run bonds, respectively. The numbers in parentheses are *t* values

[a]indicates statistical significance at the 1 % level respectively. RMSE and MAD are root mean square error and mean absolute deviation, respectively

We therefore use the nonlinear Kalman filter for estimation. The details of the nonlinear Kalman filter with its Matlab codes are reported in the Appendix.

After we estimate the parameters, we then study the dynamic of the latent component and examine its temporal properties to explore the explanations of the on-/off-the-run yield spread puzzle in China.

22.3.3 Estimation Results

22.3.3.1 Estimation Results of On-the-Run Issue

The left-hand column of Table 22.2 reports the estimation results of the CIR model using on-the-run bonds. As shown, all the parameters are significant at the 1 % level. The long-term mean value, the speed of mean reversion, and the volatility parameter of r are 0.023, 0.089, and 0.063, respectively. These results are reasonable and close to the results of other research on dynamic models in the Chinese interest rate (Hong et al. 2010).

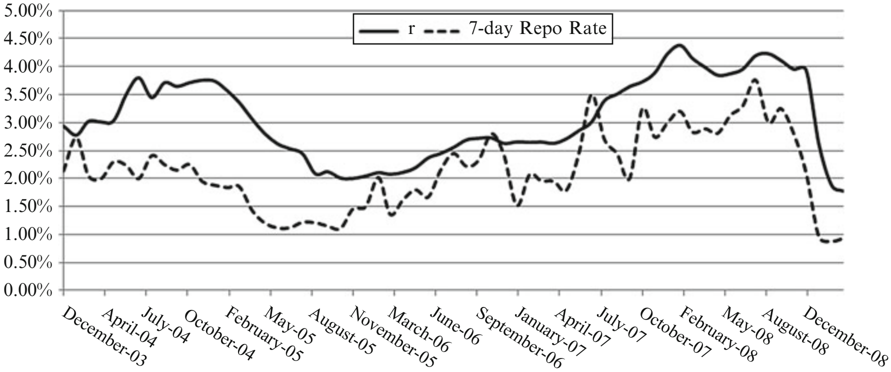

Fig. 22.2 Time series of implied risk-free interest rate and 7-day repo rate in Chinese interbank market. This figure plots the time series of implied risk-free interest rate estimated from the CIR model using Chinese on-the-run government bonds, and the time series of 7-day repo rate in Chinese interbank market

Figure 22.2 plots the time series of r estimated from the model. Most of the time, the value of r is in the interval between 2 % and 4 %. We also plot the time series of the 7-day repo rate in the Chinese interbank market. Similar trends in these two curves suggest that r does capture the change of the market interest rate.

22.3.3.2 Estimation Results of Off-the-Run Issue

With all the parameters obtained for r, we next estimate the parameters of l using the data of off-the-run bonds.[4] The right-hand column of Table 22.2 reports the estimation results. The parameter of σ_l is significant at the 1 % level.

Figure 22.3 plots the time series of l estimated from the data. As we can see from the figure, most of l are negative. We conduct the t-test and find the average of l is significantly negative at the 5 % level (the t-statistic is -017). Since l represents the yield difference between off-the-run bonds and on-the-run bonds, negative l provides further, strong evidence of the on-/off-the-run yield spread puzzle in Chinese Treasury markets.

22.3.4 Regression Analysis

The analysis so far reveals that on average, the off-the-run bonds are traded at a higher price or lower yield than the on-the-run bonds in Chinese Treasury markets, which is hard to explain rationally. We next explore the information contained in this negative yield spread by examining the temporal properties of the latent component, l.

[4]We also estimate the parameters of r and l jointly using the on-the-run and off-the-run data together and find the results are quite similar.

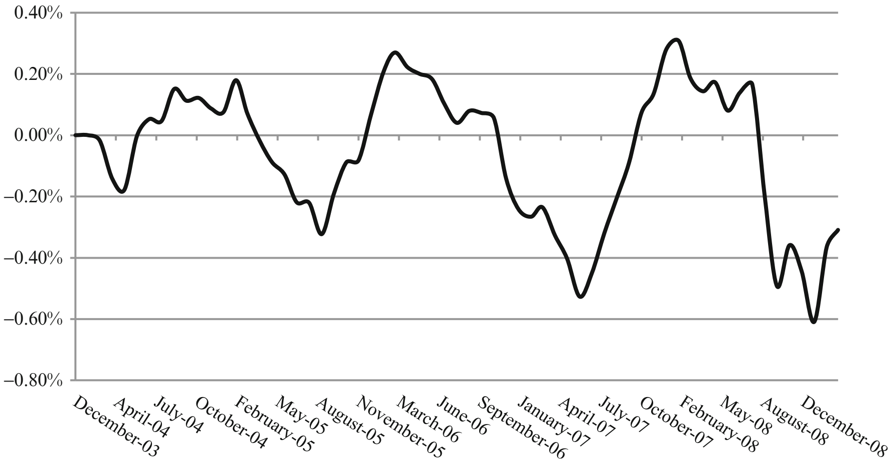

Fig. 22.3 Time series of latent factor. This figure plots the time series of latent factor estimated from the Chinese off-the-run government bonds

In order to explain the temporal properties of the latent component, we introduce several variables. One is the turnover ratio difference between on-the-run issues and off-the-run issues as a measure of liquidity difference, and it is used to examine whether an on-/off-the-run yield spread in Chinese Treasury markets is related to the difference in liquidity conditions. The turnover ratio difference between on-the-run issues and off-the-run issues is defined as

$$TR_t = \frac{\left(TR_{1,t}^{off} - TR_{1,t}^{on}\right) + \left(TR_{3,t}^{off} - TR_{3,t}^{on}\right)}{2} \times 10^{-5},$$

where TR is the turnover ratio, the subscript *1* and *3* denote 1-year bonds and 3-year bonds, and the superscript *on* and *off* denote on-the-run bonds and off-the-run bonds.

Pasquariello and Vega (2007, 2009) find that the release of macroeconomic news changes liquidity, and hence the on-/off-the-run yield spread, in the US Treasury market. For example, when macroeconomic news brings more funds into the bond market, market-wide liquidity conditions will be better, investors might trade old bonds more actively, and the yield difference between off-the-run bonds and on-the-run bonds might decrease, and vice versa. Similarly, we introduce the percentage change of a broad money supply measure, ΔM2, as a proxy of market-wide liquidity conditions to examine whether there is covariation of the latent component with changes in market-wide liquidity conditions. We use one lagged ΔM2 to examine the impact of macroeconomic conditions on Δl_t.

The last factor we investigate is investors' behavior. It is observed that in Chinese bond markets, there exists a "disposition effect." Bond holders are reluctant to realize loss and will not sell old bonds if they have a loss from the investment. Consequently, old bonds might be traded at a lower yield than new bonds. In China, the 7-day repo market is one of the most active bond markets, and

Table 22.3 Time regression results

	(1)	(2)	(3)	(4)
	$\Delta l_t = \beta_0 + \beta_1 TR_t + \varepsilon_t$	$\Delta l_t = \beta_0 + \beta_1 \Delta M2_{t-1} + \varepsilon_t$	$\Delta l_t = \beta_0 + \beta_1 R_{t-1} + \varepsilon_t$	$\Delta l_t = \beta_0 + \beta_1 TR_t + \beta_2 \Delta M2_{t-1} + \beta_3 R_{t-1} + \varepsilon_t$

$\Delta M2_{t-1}$		0.037(2.263)[a]		0.027(1.663)[b]
R_{t-1}			−0.057(−2.703)[c]	−0.045(−1.930)[a]
Adj. R^2	0.043	0.084	0.114	0.163

This table reports the results of regressing the change of latent component, Δl_t, on the on-/off-the-run turnover ratio difference (TR_t), the lagged percentage change of M2 ($\Delta M2_{t-1}$), and the lagged 7-day repo rate (R_{t-1}). The numbers in parentheses are t values

[a],[b], and [c] indicate statistical significance at the 10 %, 5 %, and 1 % level, respectively

Univariate regression of Δl_t on the turnover ratio difference

$\Delta l_t = \beta_0 + \beta_1 TR_t + \varepsilon_t$.

Univariate regression of Δl_t on the lagged percentage change of the money supply:

$\Delta l_t = \beta_0 + \beta_1 \Delta M2_{t-1} + \varepsilon_t$.

Univariate regression of Δl_t on the lagged 7-day repo rate:

$\Delta l_t = \beta_0 + \beta_1 R_{t-1} + \varepsilon_t$.

Multivariate regression of Δl_t on the turnover ratio difference, lagged percentage change of the money supply, and lagged 7-day repo rate:

$\Delta l_t = \beta_0 + \beta_1 TR_t + \beta_2 \Delta M2_{t-1} + \beta_3 R_{t-1} + \varepsilon_t$

the change of the 7-day repo rate is a good measure of market conditions. When the 7-day repo rate goes up, the bond investment will generate a loss for the investors and the disposition effect might occur. We use the interbank 7-day repo rates as the proxy of the market interest rate to investigate whether the on-/off-the-run yield spread puzzle in China is related to this irrational behavior. If the investors are rational and the liquidity premium hypothesis holds, the liquidity of the whole market will decrease in the bear market, and the old bonds will be traded at a higher yield. Thus, detecting the response of the on-/off-the-run yield spread to the change of the 7-day repo rate could help us distinguish whether the disposition effect or the liquidity factor dominates. Similarly, we use one lagged 7-day repo rate in the time series regression.

In what follows, we first run univariate time series regressions of Δl_t against each variable and then conduct multivariate regression analysis against all the three factors. The regression models are specified as follows:

Univariate regression of Δl_t on the turnover ratio difference, TR_t:

$$\Delta l_t = \beta_0 + \beta_1 TR_t + \varepsilon_t.$$

Univariate regression of Δl_t on the lagged percentage change of the money supply, $\Delta M2_{t-1}$:

$$\Delta l_t = \beta_0 + \beta_1 \Delta M2_{t-1} + \varepsilon_t.$$

Univariate regression of Δl_t on the lagged 7-day repo rate, R_{t-1}:

$$\Delta l_t = \beta_0 + \beta_1 R_{t-1} + \varepsilon_t.$$

Multivariate regression of Δl_t on the turnover ratio difference, lagged percentage change of money supply, and lagged 7-day repo rate:

$$\Delta l_t = \beta_0 + \beta_1 TR_t + \beta_2 \Delta M2_{t-1} + \beta_3 R_{t-1} + \varepsilon_t.$$

22.3.4.1 Univariate Regression Analysis

Columns (1), (2), and (3) of Table 22.3 report the results of univariate time series regressions of Δl_t against the turnover ratio difference, the lagged percentage change of the money supply, and the lagged 7-day repo rate, respectively. As shown, all coefficients are significant, indicating that all these factors are useful to explain the change of the on-/off-the-run yield spread in China. It is an interesting finding that is worth further exploring.

The coefficients for TR and the lagged ΔM2 are significantly positive at the 10 % level and the 5 % level, respectively. That means the latent component contains information about liquidity conditions. In particular, since l_t is negative most of the time, the positive sign of coefficients implies that when the explanatory variable increases, the on-/off-the-run yield spread will increase and move close to zero. In other words, there will be less difference between off-the-run bond yields and on-the-run bond yields. The significantly positive coefficient of TR suggests that if the on-/off-the-run turnover ratio difference increases, that is, the liquidity of old bonds becomes better, the yield difference between off-the-run bonds and on-the-run bonds declines, and vice versa. This is consistent with the liquidity premium hypothesis. Similarly, the significantly positive coefficient of lagged ΔM2 reveals that if the money supply increases and market-wide liquidity improves, the yield difference between old bonds and new bonds declines, and vice versa. Both results provide evidence of a liquidity premium in Chinese government bond yields. The liquidity premium hypothesis still holds in Chinese Treasury markets despite the existence of the on-/off-the-run yield spread puzzle.

The lagged 7-day repo rate is significantly negatively related to Δl_t. That is, when the market interest rate goes up and the bond investors have a loss, the yield difference between old bonds and new bonds increases and the on-/off the run spread becomes more negative. This indicates the disposition effect dominates the effect of liquidity. When investors have a loss, the unwillingness to sell old bonds leads to a lower yield for old bonds and a negative on-/off-the-run yield spread. The regression against the lagged 7-day repo rate has the largest adjusted R square, which implies the disposition effect could better explain the change in the on-/off-the-run yield spread in China than the liquidity condition.

22.3.4.2 Multivariate Regression Analysis

Column (4) of Table 22.3 reports the results of multivariate regression. The coefficient of TR is not significant any more, indicating that after controlling for market-wide liquidity conditions and the disposition effect, the liquidity difference has no influence on the on-/off-the-run yield spread. On the other hand, market-wide liquidity and the disposition effect are still significant at the 10 % level.

The adjusted R square of the multivariate is about 16 %. This suggests that the on-/off-the-run spread could be partly explained by the change in market-wide liquidity conditions and the disposition effect.

22.4 Conclusion

In this chapter, we document a negative on-/off-the-run yield spread in Chinese Treasury markets. This is contrary to the positive on-/off-the-run yield spread found in most other countries and could be called the "on-/off-the-run yield spread puzzle." We introduce a latent factor into the pricing formula of off-the-run bonds to capture the yield spread and estimate this factor by the nonlinear Kalman filter. The result confirms the existence of the puzzle.

To reveal the information content of the negative on-/off-the-run yield spread, we perform univariate and multivariate time series regressions of the change of the latent factor against the turnover ratio difference between off-the-run issues and on-the-run issues (a measure of the liquidity difference between off-the-run issues and on-the-run issues), the lagged percentage change of M2 (a measure of market-wide liquidity conditions), and the lagged 7-day repo rates (a measure of disposition effect). We find that the liquidity premium hypothesis still holds in Chinese Treasury markets. The yield spread, however, is dominated by the irrational disposition effect. When the investors have a loss from the bond investment, they are more reluctant to sell old bonds, which leads to a higher price and a lower yield for old bonds and hence causes the puzzle.

Our study is an attempt to explore the coexistence of a standard theoretical hypothesis and irrational behavior in emerging Treasury markets such as China. These markets have been a topic of interest increasingly, as the role of the emerging markets in the global economy becomes more and more important.

Appendix 1: Nonlinear Kalman Filter

Let $y_{M,t}^{on}$ represent the time t yield of an on-the-run government bond maturing at t_M. Equation 22.3 could be written as

$$P_t^{on} = \sum_{m=1}^{M} C_m A_{m,t} \exp\left(-B_{m,t} r_t\right) = \sum_{m=1}^{M} C_m \exp\left(-y_{M,t}^{on}(t_m - t)\right). \tag{22.8}$$

As shown, $y_{M,t}^{on}$ is a nonlinear function of r_t, which is inconsistent with the requirements of the standard Kalman filter that state functions and measurement functions should be linear. So we use the extended (nonlinear) Kalman filter to linearize nonlinear functions. The idea is to employ the Taylor expansions around the estimate at each step. That is, we express $y_{M,t}^{on}$ as

$$y_{M,t}^{on}(r_t) \approx y_{M,t}^{on}\left(\hat{r}_{t|t-1}\right) + \frac{\partial y_{M,t}^{on}}{\partial r_t}\Big|_{r_t=\hat{r}_{t|t-1}} \cdot \left(r_t - \hat{r}_{t|t-1}\right), \tag{22.9}$$

where $\hat{r}_{t|t-1}$ is the estimate of r_t at time t–1.

To get $\frac{\partial y_{M,t}^{on}}{\partial r_t}$, we calculate the first-order derivative of P_t^{on} with respect to r_t,

$$\frac{\partial P_t^{on}}{\partial r_t} = -\sum_{m=1}^{M} C_m A_{m,t} B_{m,t} \exp\left(-B_{m,t} r_t\right) = \frac{\partial P_t^{on}}{\partial y_{M,t}^{on}} \frac{\partial y_{M,t}^{on}}{\partial r_t}. \tag{22.10}$$

Thus, we have

$$\frac{\partial y_{M,t}^{on}}{\partial r_t} = \frac{\sum_{m=1}^{M} C_m A_{m,t} B_{m,t} \exp\left(-B_{m,t} r_t\right)}{\sum_{m=1}^{M} C_m (t_m - t) \exp\left(-y_{M,t}^{on} \cdot (t_m - t)\right)}. \tag{22.11}$$

Given $\hat{r}_{t|t-1}$, we can use Eq. 22.8 to calculate $y_{M,t}^{on}\left(\hat{r}_{t|t-1}\right)$ and then use Eq. 22.11 to get $\frac{\partial y_{M,t}^{on}}{\partial r_t}$

Finally, the linearized measurement model for the on-the-run issues at time t is

$$\mathbf{y_t^{on}} = \boldsymbol{\alpha}_\mathbf{t}^\mathbf{on} + \boldsymbol{\beta}_\mathbf{t}^\mathbf{on} r_t + \boldsymbol{\omega}_\mathbf{t}^\mathbf{on} \tag{22.12}$$

where

$$\mathbf{y_t^{on}} = \begin{bmatrix} y_{1,t}^{on} \\ y_{3,t}^{on} \end{bmatrix},$$

$$\boldsymbol{\alpha}_\mathbf{t}^\mathbf{on} = \begin{bmatrix} y_{1,t}^{on}\left(\hat{r}_{t|t-1}\right) - \hat{r}_{t|t-1} \cdot \frac{\partial y_{1,t}^{on}}{\partial r_t}\Big|_{r_t = \hat{r}_{t|t-1}} \\ y_{3,t}^{on}\left(\hat{r}_{t|t-1}\right) - \hat{r}_{t|t-1} \cdot \frac{\partial y_{3,t}^{on}}{\partial r}\Big|_{r_t = \hat{r}_{t|t-1}} \end{bmatrix},$$

$$\boldsymbol{\beta}_\mathbf{t}^\mathbf{on} = \begin{bmatrix} \frac{\partial y_{1,t}^{on}}{\partial r_t}\Big|_{r_t = \hat{r}_{t|t-1}} \\ \frac{\partial y_{3,t}^{on}}{\partial r_t}\Big|_{r_t = \hat{r}_{t|t-1}} \end{bmatrix},$$

and $\boldsymbol{\omega}_\mathrm{t}^\mathrm{on}$ is the error term,

$$\boldsymbol{\omega}_\mathbf{t}^\mathbf{on} = \begin{bmatrix} \omega_{1,t}^{on} \\ \omega_{3,t}^{on} \end{bmatrix},$$

where the subscript of *1* and *3* represent the 1-year bonds and 3-year bonds, while the superscript *on* refers to on-the-run bonds.

After we get the measurement function, the third step is to rewrite (22.1) as a discrete state function,

$$r_t = \gamma + \phi r_{t-1} + \varepsilon_t, \tag{22.13}$$

where

$$\gamma = \theta(1 - \exp(-\kappa \cdot \Delta t)),$$
$$\phi = \exp(-\kappa \cdot \Delta t),$$

and ε_t is the error term of r_t and Δt is the size of the time interval in the discrete sample. In our study, $\Delta t = 0.0833$. The conditional mean and conditional variance of r_t are

$$\begin{aligned} \hat{r}_{t|t-1} &= \theta(1 - \exp(-k\Delta t)) + \exp(-k\Delta t) \cdot r_{t-1} \\ Var\left(r_{t|t-1}\right) &= \sigma_r^2\left(\frac{1 - \exp(-k\Delta t)}{k}\right)\left(\frac{1}{2}\theta(1 - \exp(-k\Delta t) + \exp(-k\Delta t) \cdot r_{t-1})\right). \end{aligned} \tag{22.14}$$

Similarly, the state functions of the off-the-run issues are

$$\begin{aligned} r_t &= \gamma + \phi r_{t-1} + \varepsilon_t \\ l_t &= l_{t-1} + \sigma_l e_t. \end{aligned} \tag{22.15}$$

The conditional mean and conditional variance of l_t are l_{t-1} and $\sigma_l^2\Delta t$, respectively.

The corresponding measurement function is

$$\mathbf{y_t^{off}} = \boldsymbol{\alpha}_\mathbf{t}^\mathbf{off} + \boldsymbol{\beta}_\mathbf{t}^\mathbf{off} r_t + \boldsymbol{\xi}_\mathbf{t}^\mathbf{off} l_t + \boldsymbol{\omega}_\mathbf{t}^\mathbf{off}, \tag{22.16}$$

where *off* refers to off-the-run bonds,

$$\mathbf{y_t^{off}} = \begin{bmatrix} y_{1,t}^{off} \\ y_{3,t}^{off} \end{bmatrix},$$

$$\boldsymbol{\alpha}_\mathbf{t}^\mathbf{off} = \begin{bmatrix} y_{1,t}^{off}\left(\hat{r}_{t|t-1}, \hat{l}_{t|t-1}\right) - \hat{r}_{t|t-1} \cdot \dfrac{\partial y_{1,t}^{off}}{\partial r_t}\Big|_{r_t=\hat{r}_{t|t-1}} - \hat{l}_{t|t-1} \cdot \dfrac{\partial y_{1,t}^{off}}{\partial l_t}\Big|_{l_t=\hat{l}_{t|t-1}} \\ y_{3,t}^{off}\left(\hat{r}_{t|t-1}, \hat{l}_{t|t-1}\right) - \hat{r}_{t|t-1} \cdot \dfrac{\partial y_{3,t}^{off}}{\partial r_t}\Big|_{r_t=\hat{r}_{t|t-1}} - \hat{l}_{t|t-1} \cdot \dfrac{\partial y_{3,t}^{off}}{\partial l_t}\Big|_{l_t=\hat{l}_{t|t-1}} \end{bmatrix},$$

$$\boldsymbol{\beta}_\mathbf{t}^\mathbf{off} = \begin{bmatrix} \dfrac{\partial y_{1,t}^{off}}{\partial r_t}\Big|_{r_t=\hat{r}_{t|t-1}} \\ \dfrac{\partial y_{3,t}^{off}}{\partial r_t}\Big|_{r_t=\hat{r}_{t|t-1}} \end{bmatrix},$$

$$\boldsymbol{\xi}_\mathbf{t}^\mathbf{off} = \begin{bmatrix} \dfrac{\partial y_{1,t}^{off}}{\partial l_t}\Big|_{l_t=\hat{l}_{t|t-1}} \\ \dfrac{\partial y_{3,t}^{off}}{\partial \mathrm{l}_t}\Big|_{l_t=\hat{l}_{t|t-1}} \end{bmatrix},$$

$$\boldsymbol{\omega}_{\mathbf{t}}^{\mathbf{off}} = \begin{bmatrix} \omega_{1,t}^{off} \\ \omega_{3,t}^{off} \end{bmatrix},$$

$$\frac{\partial y_{M,t}^{off}}{\partial r_t} = \frac{\sum_{m=1}^{M} C_m A_{m,t} B_{m,t} \exp\left(D_{m,t} - B_{m,t} r_t - (t_m - t) l_t\right)}{\sum_{m=1}^{M} C_m (t_m - t) \exp\left(-y_{M,t}^{off} \cdot (t_m - t)\right)},$$

$$\frac{\partial y_{M,t}^{off}}{\partial l_t} = \frac{\sum_{m=1}^{M} C_m A_m (t_m - t) \exp\left(D_{m,t} - B_{m,t} r_t - (t_m - t) l_t\right)}{\sum_{m=1}^{M} C_m (t_m - t) \exp\left(-y_{M,t}^{off} \cdot (t_m - t)\right)},$$

and $\hat{l}_{t|t-1}$ is the estimate of l_t at time t–1.

Once we get the state functions and the measurement functions, we employ the regular iterative prediction-update procedure and the method of quasi-maximum likelihood to estimate the parameters. When estimating the parameters of the off-the-run issues, we use just the parameters γ and ϕ estimated from the on-the-run issues to identify σ_l.

numbers by using the Cholesky decomposition, and then the correlated default times can be decided by these random numbers and the reduced-form model. Finally, the fair BCLN coupon rate is obtained by the Monte Carlo simulation. We also discuss the effect of issuer default risk on BCLN. We show that the effect of issuer default risk cannot be accounted for thoroughly by considering the issuer as a new reference entity in the widely used one-factor copula model, in which constant default correlation is often assumed. A different default correlation between the issuer and the reference entities affects the coupon rate greatly and must be taken into account in the pricing model.

Keywords

Factor copula • Issuer default • Default correlation • Reduced-form model • Basket credit derivatives • Cholesky decomposition • Monte Carlo simulation

23.1 Introduction

Structural and reduced-form models are the two main approaches for modeling default risk. The structural model (Merton 1974) defines default as occurring when a firm's asset value falls below its debt. The reduced-form model (Jarrow and Turnbull 1995), also known as the intensity model, views the default event as an unexpected exogenous stochastic event. It estimates the intensity of the default occurrence by using market data.

However, whether by the structural or reduced-form model, obtaining the joint distribution of default times among a set of assets will be very complicated. Li (1999, 2000) first introduces the copula function (Sklar 1959) to simplify the estimation of the joint distribution. Li assumes that the default events of reference entities follow a Poisson process and sets the dependence structure as a Gaussian copula function. Finally, he performs Monte Carlo simulation to obtain the default times. The copula approach is the main approach for multi-name credit derivatives pricing in the last decade. Mashal and Naldi (2003) use the copula approach to analyze how the default probabilities of the protection sellers and buyers affect basket default swap (BDS) spreads. While pricing the single-name credit default swap (CDS) with counterparty risk based on the continuous-time Markov model, Walker (2006) indicates that using a time-dependent correlation coefficient can improve the market-standard Gaussian copula approach. By connecting defaults through a copula function, Brigo and Chourdakis (2009) find that when the counterparty risk is involved, both the default correlation and credit spread volatility impact the contingent CDS value.

In the implementation of the Gaussian copula using Monte Carlo simulation, the computational complexity increases with the number of reference entities. Thus the factor copula method, which makes the default event conditional on independent state variables, is introduced to deal with these problems. Andersen et al. (2003) find that one or two factors provide sufficient accuracy for the empirical correlation matrices one encounters in credit basket applications. Hull and White (2004) employ a multifactor copula model to price the *k*th-to-default swap and collateralized debt obligation (CDO). Moreover, Laurent and Gregory (2005) use one-factor Gaussian copula to simplify the dependence structure of reference entities and apply this approach to price BDS and CDO. Wu (2010) develops three alternative approaches to price the basket credit linked note (BCLN) with issuer default risk using only one correlation parameter. Wu et al. (2011) analyze how issuer default risk impacts the BCLN coupon rate by an implied default correlation between the issuer and the reference entities.

On the other hand, acceleration techniques such as the importance sampling method and others are used to improve the simulation efficiency. Chiang et al. (2007) and Chen and Glasserman (2008) apply the Joshi-Kainth algorithm (Joshi and Kainth 2004), and Bastide et al. (2007) use the Stein method (Stein 1972) for the multi-name credit derivative pricing to reduce variance of the simulation results.

This article constructs a factor copula framework to evaluate defaultable basket credit derivatives. The effect of the default correlation between the issuer and the reference entities is considered in the proposed model. Its application in BCLN with issuer default risk is also demonstrated. This study shows that the default correlation between the issuer and the reference entities plays an important role in the decision of fair BCLN coupon rate.

The remainder of this article is organized as follows. Section 23.2 reviews the factor copula model and shows the proposed basket credit derivative pricing model with issuer default event. Subsequently, Section 23.3 introduces the BCLN and demonstrates how to price it when issuer default risk exists. Section 23.4 presents the results of numerical analysis. Conclusions are finally drawn in Section 23.5.

23.2 Factor Copula with Issuer Default Risk

The most widely used copula function is the Gaussian copula and its definition is as follows:

$$C^{Ga}(u_1,\ u_2,\ \ldots,u_N) = \Phi_R\left(\phi^{-1}(u_1),\ \phi^{-1}(u_2),\ \ldots,\phi^{-1}(u_N)\right) \tag{23.1}$$

where Φ_R denotes a multivariate cumulative normal (Gaussian) distribution, R represents the correlation coefficient matrix, and ϕ^{-1} is the inverse function of one dimensional cumulative Gaussian distribution.

Consider a credit portfolio which contains N reference entities, the default times of each reference entity are $\tau_1,\tau_2,\ldots,\tau_N$, respectively. According to the reduced-form model, each reference entity default follows a Poisson process. The cumulative default probability before time t is

$$F_i(t) = P(\tau_i \le t) = 1 - e^{-\lambda_i t},\ i = 1, 2,\ \ldots, N \tag{23.2}$$

where λ_i is the hazard rate of the reference entity i. Because $F_i(t) \sim U(0,1)$, applying the Gaussian copula obtains the multivariate joint distribution of default times, as follows:

$$F(\tau_1, \tau_2, \ldots, \tau_N) = \Phi_R\left(\phi^{-1}(F_1(\tau_1)),\ \phi^{-1}(F_2(\tau_2)),\ \ldots,\ \phi^{-1}(F_N(\tau_N))\right) \tag{23.3}$$

Let X_i represent the Gaussian random variable corresponding to the default time of the reference entity i. In the one-factor copula model, the default time of reference entity i depends on a common factor ε_Y and a firm specific risk factor ε_{xi}. Both ε_Y and ε_{Xi} are independent standard Gaussian variables. The details of one-factor copula model are given in Appendix 1. Thus X_i can be created via Cholesky decomposition, as follows:

$$X_i = \rho_{X_iY}\varepsilon_Y + \sqrt{1 - \rho_{X_iY}{}^2}\varepsilon_{X_i}, \qquad i = 1, 2, \ldots, N \tag{23.4}$$

where ρ_{XiY} denotes the correlation coefficient between the reference entity X_i and the common factor ε_Y. How to apply the Cholesky decomposition for generating correlated random variables is shown in Appendix 2.

One-factor Gaussian copula model with constant pairwise correlations has become the standard market model. In the standard market model, all ρ_{X_iY} in Eq. 23.4 are equal to ρ, then the constant pairwise correlation $\rho_{X_iX_j}\,(i \neq j)$ will be ρ^2. Let $X_1 = \phi^{-1}(F_1(\tau_1)), X_2 = \phi^{-1}(F_2(\tau_2)), \ldots, X_N = \phi^{-1}(F_N(\tau_N))$, by mapping τ_i and X_i, we can simulate the default time of the reference entity i using the following equation:

$$\tau_i = F_i^{-1}(\phi(X_i)) = \frac{-\ln(1 - \phi(X_i))}{\lambda_i}, \qquad i = 1, 2, \ldots, N \tag{23.5}$$

When issuer default risk is involved in the basket credit derivative, a natural way is to view it as one reference entity of the derivative holder's credit portfolio, as discussed in Wu (2010). Wu (2010) assumes the issuer default time is determined by a Gaussian random variable Z. Like the reference entity variable X_i, Z is decided by the common factor ε_Y and the issuer's specific risk factor ε_Z. Both ε_Y and ε_Z are independent standard Gaussian variables. Because the issuer is viewed as one additional reference name in the portfolio, the correlation coefficient between Z and ε_Y is also ρ. In this approach, Z and X_i are formulated as follows:

$$Z = \rho\varepsilon_Y + \sqrt{1 - \rho^2}\varepsilon_Z \tag{23.6}$$

$$X_i = \rho\varepsilon_Y + \sqrt{1 - \rho^2}\varepsilon_{X_i}, \qquad i = 1, 2, \ldots, N \tag{23.7}$$

In the above approach, the default correlation between the issuer and the reference entities will be fixed to ρ^2, which is always positive. Thus, it is not flexible enough to deal with the default correlation. The default correlation between the issuer and

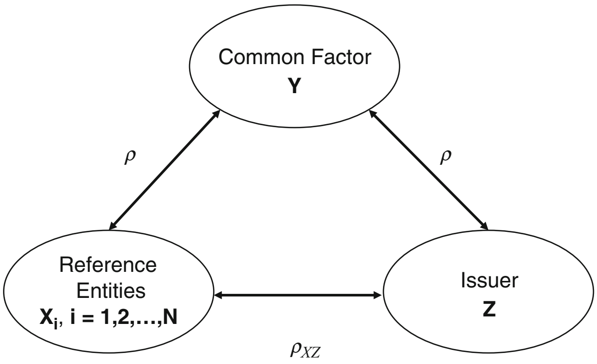

Fig. 23.1 The default correlations between the issuer, reference entities, and the common factor in the proposed model

the reference entities has a different impact on the fair coupon rate, and this needs to be considered in credit derivative pricing.

Suppose that the default correlation between the issuer and the reference entities is ρ_{XZ}. The relationship between the issuer, reference entities, and the common factor in the proposed model is shown in Fig. 23.1. Given that the three random variables ε_Y, ε_Z, and ε_{Xi} are independent of each other, X_i, which is the Gaussian random variable corresponding to the default time of the reference entity i, can be obtained by the Cholesky decomposition. Thus, when the default correlation between the issuer and the reference entities is incorporated into the pricing model, Z and X_i should be formulated as follows:

$$Z = \rho\varepsilon_Y + \sqrt{1-\rho^2}\varepsilon_Z \tag{23.8}$$

$$X_i = \rho\varepsilon_Y + \frac{\rho_{XZ}-\rho^2}{\sqrt{1-\rho^2}}\varepsilon_Z + \sqrt{1-\rho^2-\left(\frac{\rho_{XZ}-\rho^2}{\sqrt{1-\rho^2}}\right)^2}\varepsilon_{X_i} \tag{23.9}$$

To obtain a real number value of X_i, the following criteria must be satisfied.

$$\rho^2 + \left(\frac{\rho_{XZ}-\rho^2}{\sqrt{1-\rho^2}}\right)^2 \leq 1 \tag{23.10}$$

By rearranging the above equation, the criteria can be written as follows:

$$2\rho^2 + \rho_{XZ}^2 - 2\rho^2\rho_{XZ} \leq 1 \tag{23.11}$$

According to the above settings, the correlation coefficient between the reference entity X_i and X_j will be

$$
\begin{aligned}
\rho_{X_i X_j} &= \frac{\mathrm{Cov}\left(X_i, X_j\right)}{\sigma_{X_i}\sigma_{X_j}} \\
&= \mathrm{Cov}\left(\begin{array}{l}
\rho\varepsilon_Y + \dfrac{\rho_{XZ}-\rho^2}{\sqrt{1-\rho^2}}\varepsilon_Z \\
+\sqrt{1-\rho^2-\left(\dfrac{\rho_{XZ}-\rho^2}{\sqrt{1-\rho^2}}\right)^2}\,\varepsilon_{X_i}, \\
\rho\varepsilon_Y + \dfrac{\rho_{XZ}-\rho^2}{\sqrt{1-\rho^2}}\varepsilon_Z \\
+\sqrt{1-\rho^2-\left(\dfrac{\rho_{XZ}-\rho^2}{\sqrt{1-\rho^2}}\right)^2}\,\varepsilon_{X_j}
\end{array}\right) \\
&= \rho^2 + \frac{\left(\rho_{XZ}-\rho^2\right)^2}{1-\rho^2} \\
&= \frac{\rho^2+\rho_{XZ}^2-2\rho_{XZ}\rho^2}{1-\rho^2}
\end{aligned}
\tag{23.12}
$$

23.3 Pricing a Defaultable Basket Credit Linked Note

Basket credit linked note (BCLN) is a kind of basket credit derivative product. It is a note with a price or coupon linked to credit events of reference entities (obligations). The conventional form of BCLN is the *k*th-to-default BCLN. The BCLN holder (the protection seller) pays the notional principal to the BCLN issuer (the protection buyer) at the start of the contract and receives the coupon payments until either the *k*th default or the contract maturity, whichever occurs earlier. If the *k*th default occurs before contract maturity, the BCLN holder receives the recovered value of the reference entity from the BCLN issuer. Otherwise, the BCLN holder receives the notional principal back on contract maturity. In derivative markets, the issuer default risk is attracting considerable attention because of the recent financial turmoil and collapses of large financial institutions. If the BCLN issuer defaults, the BCLN holder will not receive the recovered value of the reference entity as the credit event happens nor the notional amount at the contract maturity. The coupon payments also cease due to the issuer default. Thus the issuer default results in a large loss. Therefore, it is important to incorporate issuer default risk in BCLN pricing to obtain a reasonable coupon rate.

If the issuer default risk is not considered, the value of a *k*th-to-default BCLN with N reference entities, of which the notional principal is one dollar, can be written as follows:

$$BCLN = E^Q \begin{bmatrix} c \times \sum_{i=1}^{T} e^{-rt_i} I(t_i < \tau_k) \\ + \delta_k \times e^{-r\tau_k} \times I(\tau_k \le t_T) \\ + e^{-rt_T} \times I(\tau_k > t_T) \end{bmatrix} \tag{23.13}$$

where the coupon rate is c and is paid annually. The coupon payment dates are $t_i, i = 1, 2, \cdots, T$. The maturity date is t_T. Furthermore, τ_k is the kth default time, and $\tau_1 < \tau_2 < \cdots < \tau_N$. δ_k is the recovery rate of the kth default reference entity. Thus δ_k denotes the recovery value, which the issuer pays to the BCLN holder on the kth default. The discount rate is $r\%$. Finally, Q denotes the risk-neutral probability measure, and $I(.)$ is an indicator function.

Let the above equation equals one, the equation can be rewritten as:

$$\begin{aligned} & c \times E^Q \left[\sum_{i=1}^{T} e^{-rt_i} I(t_i < \tau_k) \right] \\ & = E^Q \begin{bmatrix} 1 - \delta_k \times e^{-r\tau_k} \times I(\tau_k \le t_T) \\ - e^{-rt_T} \times I(\tau_k > t_T) \end{bmatrix} \end{aligned} \tag{23.14}$$

Here we employ the Monte Carlo simulation, which is described in Appendix 3, to obtain the initial fair BCLN coupon rate c as follows:

$$c = \frac{\sum_{s=1}^{W} \begin{bmatrix} 1 - \delta_k^s \times e^{-r\tau_k^s} \times I\left(\tau_k^s \le t_T\right) \\ - e^{-rt_T} \times I\left(\tau_k^s > t_T\right) \end{bmatrix}}{\sum_{s=1}^{W} \left[\sum_{i=1}^{T} e^{-rt_i} I\left(t_i < \tau_k^s\right) \right]} \tag{23.15}$$

where W represents the number of simulation runs. τ_k^s represents the kth default time, and δ_k^s denotes the recovery rate of the kth default reference entity at the sth simulation, respectively.

When the issuer default risk is involved, whether the issuer default occurs before or after the kth default must be taken into account. This article defines $\hat{\tau}$ as the issuer default time and $\hat{\delta}$ as the issuer recovery rate. The BCLN holder gets back the recovered value of the reference obligation if the kth default occurs before both the issuer default time $\hat{\tau}$ and maturity date t_T. If the issuer default occurs before the kth default and maturity date, the issuer will not provide the BCLN holder with the redemption proceeds and stop the coupon payments. In this situation, the notional principal multiplied by the issuer recovery rate is returned to the BCLN holder. To obtain all of the notional principal back, both the kth default time and the issuer default time must be later than the contract maturity date. Thus, the value of a kth-to-default BCLN with issuer default risk is modified as follows:

$$BCLN = E^{Q}\begin{bmatrix} c \times \sum_{i=1}^{T} e^{-rt_i} I(t_i < \min(\tau_k, \hat{\tau})) \\ + \delta_k \times e^{-r\tau_k} \times I(\tau_k < \min(\hat{\tau}, t_T)) \\ + \hat{\delta} \times e^{-r\hat{\tau}} \times I(\hat{\tau} < \min(\tau_k, t_T)) \\ + e^{-rt_T} \times I(t_T < \min(\tau_k, \hat{\tau})) \end{bmatrix} \tag{23.16}$$

Therefore, the fair value of the coupon rate c with issuer default risk is

$$c = \frac{\sum_{s=1}^{W} \begin{bmatrix} 1 - \delta_k^s \times e^{-r\tau_k^s} \times I\left(\tau_k^s < \min(\hat{\tau}^s, t_T)\right) \\ -\hat{\delta} \times e^{-r\hat{\tau}^s} \times I\left(\hat{\tau}^s < \min\left(\tau_k^s, t_T\right)\right) \\ -e^{-rt_T} \times I\left(t_T < \min\left(\tau_k^s, \hat{\tau}^s\right)\right) \end{bmatrix}}{\sum_{s=1}^{W} \left[\sum_{i=1}^{T} e^{-rt_i} I\left(t_i < \min\left(\tau_k^s, \hat{\tau}^s\right)\right)\right]} \tag{23.17}$$

where $\hat{\tau}^s$ represents the issuer default time at the sth simulation.

23.4 Numerical Analysis

The numerical example presented here is a 5-year BCLN with three reference entities; all of which are with notional principal one dollar, hazard rate 5 %, and recovery rate 30 %. Furthermore, the coupon is paid annually; the hazard rate and recovery rate of the issuer are 1 % and 30 %, respectively. Sixty thousand runs of Monte Carlo simulation are executed to calculate the coupon rates, and the results are shown in Tables 23.1, 23.2 and 23.3.

As we can see in Tables 23.1, 23.2 and 23.3, when issuer default risk is considered by viewing it as one reference entity of the credit portfolio (column II), the BCLN coupon rate increases compared to those without issuer default risk (column I) for $k = 1$–3. This is reasonable because the existence of issuer default risk increases the risk of holding a BCLN; thus, the holder will demand a higher coupon rate.

When the default correlations between the issuer and the reference entities are considered as in the proposed model, the BCLN coupon rates with issuer default risk (column III) are greater than those without issuer default risk (column I) for $k = 2$ and 3 in Tables 23.2 and 23.3. However, when $k = 1$ in Table 23.1, most of the BCLN coupon rates with issuer default risk are lower than those without issuer default risk, especially when the issuer and the reference entities are highly negatively or positively correlated. This result shows that the BCLN coupon rates with issuer default risk are not necessarily greater than those without issuer default risk. Moreover, from Figs. 23.2,

Table 23.1 First-to-default BCLN coupon rates without and with issuer default risk. (I) Default free: Issuer default risk is not included in the pricing model. (II) In credit portfolio: The issuer is viewed as one reference entity of the credit portfolio. The default correlations between the issuer and the reference entities are fixed to ρ^2, which is always positive. (III) The proposed model: The default correlation between the issuer and the reference entities is ρ_{XZ}, which may be positive or negative

	(I)	(II)	(III) The proposed model

23.3 and 23.4, we find that when the correlation between the issuer and the reference entities approaches a strongly positive correlation ($\rho_{XZ} = 0.9$), the BCLN coupon rate curve becomes flatter and less sensitive to the common factor.

23.5 Conclusion

This article applies a factor copula approach for evaluating basket credit derivatives with issuer default risk. The proposed model considers the different effects of

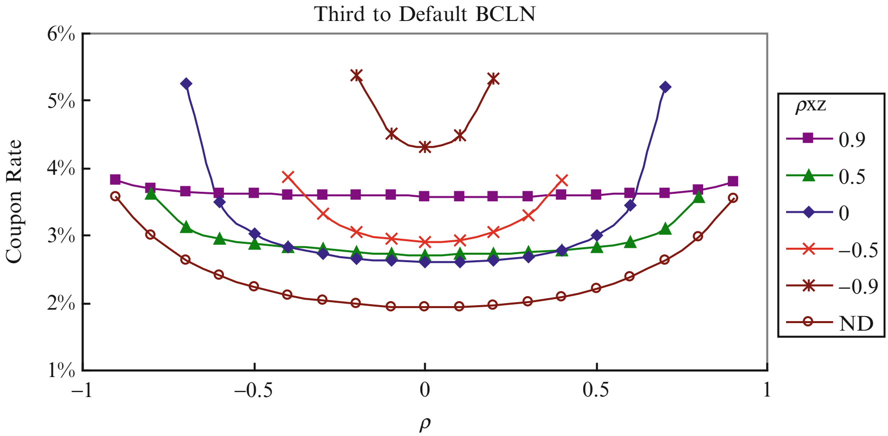

Fig. 23.4 Third-to-default BCLN coupon rates under various default correlations between the common factor and reference entities/issuer (ρ)

the default correlation between the issuer and the reference entities. A numerical example of the proposed model on BCLN is demonstrated and discussed in the article. The example shows that viewing the issuer default as a new reference entity cannot reflect the effect of issuer default risk thoroughly. The different default correlation between the issuer and the reference entities affects the coupon rate greatly and must be taken into account in credit derivative pricing.

Appendix 1: Factor Copula

In a factor copula model, we assume that different variables depend on some common factors. The most widely used model in finance is the one-factor Gaussian copula model.

One-Factor Gaussian Copula Model

Let $S_i(t) = P(\tau_i > t)$ and $F_i(t) = P(\tau_i \le t)$ be the marginal survival and marginal default distributions, respectively. Let Y be the common factor and f its density function. Assume the default times are conditionally independent, given the common factor Y. $q_t^{i|Y} = P(\tau_i > t \mid Y)$ and $p_t^{i|Y} = P(\tau_i \le t \mid Y)$ are the conditional survival and conditional default distributions, respectively. According to the law of iterated expectations, the joint survival and default distribution functions are as follows:

$$\begin{aligned} &S(t_1, t_2, \ldots, t_n) \\ &\quad = P(\tau_i > t_1, \tau_2 > t_2, \ldots, \tau_n > t_n) \\ &\quad = \int \prod_{i=1}^{n} q_t^{i|y} f(y) dy \end{aligned} \tag{23.18}$$

$$\begin{aligned} &F(t_1, t_2, \ldots, t_n) \\ &\quad = P(\tau_i \le t_1, \tau_2 \le t_2, \ldots, \tau_n \le t_n) \\ &\quad = \int \prod_{i=1}^{n} p_t^{i|y} f(y) dy \end{aligned} \tag{23.19}$$

In the one-factor Gaussian copula, the credit variable X_i is Gaussian distributed. X_i depends on the common factor Y and an individual factor ε_{Xi} as follows:

$$X_i = \rho_{X_i Y} Y + \sqrt{1 - \rho_{X_i Y}{}^2} \varepsilon_{X_i}, \quad i = 1,\ 2,\ \ \ldots,\ N \tag{23.20}$$

where Y and ε_{Xi} are two independent standard Gaussian random variables.

We can get the default time $\tau_i = F_i^{-1}(\phi(X_i))$, where $\phi(\cdot)$ is the cumulative density function of a standard Gaussian variable. Then the conditional distribution of τ_i, given the common factor Y, is

$$p_t^{i|Y} = \phi\left(\frac{\phi^{-1}(F_i(t)) - \rho_{X_i Y} Y}{\sqrt{1 - \rho_{X_i Y}^2}}\right), \tag{23.21}$$

and the joint distribution function of $\tau_1, \tau_2, \cdots, \tau_n$ is as follows:

$$\begin{aligned} F(t_1, t_2, \ldots, t_n) &= \int \prod_{i=1}^{n} p_t^{i|y} f(y) dy \\ &= \int \left[\prod_{i=1}^{n} \phi\left(\frac{\phi^{-1}(F_i(t)) - \rho_{X_i Y} Y}{\sqrt{1 - \rho_{X_i Y}^2}}\right)\right] f(y) dy \end{aligned} \tag{23.22}$$

where $f(y)$ is the standard Gaussian density. The copula of default times is a Gaussian copula.

Law of Iterated Expectations

The law of iterated expectations states that $E(Y) = E(E(Y|X))$. The proof is as follows:

$$
\begin{aligned}
E(E(Y|X)) &= \int E(Y|X) f_X(x)\, dx \\
&= \int \left(\int y \ f_{X|Y}(y|x) \ \ dy \right) f_X(x)\, dx \\
&= \int \int y \ f_{X,Y}(x,y)\, dxdy \\
&= \int y \left(\int f_{X,Y}(x,y) \ \ dx \right) dy \\
&= \int y \ f(y)\, dy = E(Y)
\end{aligned}
\tag{23.23}
$$

Appendix 2: Cholesky Decomposition and Correlated Gaussian Random Numbers

Cholesky Decomposition

A symmetric positive defined real number matrix A can be decomposed as follows:

$$A = LL^T \tag{23.24}$$

where L is a lower triangular matrix with strictly positive diagonal entries and L^T is the transpose of L. This format is the Cholesky decomposition and it is unique. The entries of L are as follows:

$$L_{j,j} = \sqrt{A_{j,j} - \sum_{k=1}^{j-1} L_{j,k}^2} \tag{23.25}$$

$$L_{i,j} = \frac{1}{L_{j,j}} \left(A_{i,j} - \sum_{k=1}^{j-1} L_{i,k} L_{j,k} \right), \quad \text{for} \quad i > j \tag{23.26}$$

Correlated Gaussian Random Numbers

In financial applications, the Cholesky decomposition is usually used to create correlated Gaussian random variables. Suppose we need to generate n correlated random Gaussian numbers, X_1, X_2, $\cdots$, X_n, given a positive defined correlation coefficient matrix R. We first generate iid standard Gaussian random variables Z_1, Z_2,$\cdots$, Z_n and let

$$X = \begin{bmatrix} X_1 \\ X_2 \\ \vdots \\ X_n \end{bmatrix}, \quad Z = \begin{bmatrix} Z_1 \\ Z_2 \\ \vdots \\ Z_n \end{bmatrix}.$$

Let $X = CZ$, where C is an $n \times n$ matrix; then $R = \mathrm{Var}(X) = E(XX^T) = CC^T$ and C is the lower triangular matrix of the Cholesky decomposition of R. Therefore, we can obtain the correlated Gaussian random variables $X_1, X_2, \cdots, X_n$ by letting $X = CZ$.

Appendix 3: Monte Carlo Simulation

Monte Carlo simulation is a computational algorithm based on random number sampling. It generates n iid random samples $X_1, X_2, \cdots, X_n$ of the random variable X and estimates $E[X]$ by $\overline{X} = \frac{X_1 + X_2 + \cdots + X_n}{n}$. $\overline{X}$ converges to $E[X]$ as $n \to \infty$, according to the law of large numbers.

Weak Law of Large Numbers (WLLN)

Let $X_1, X_2, \cdots, X_n$ be an iid sequence of random variables for which $E[X] < \infty$. Then $\frac{X_1+X_2+\cdots+X_n}{n} \xrightarrow{P} E[X]$ as $n \to \infty$. The WLLN implies that the Monte Carlo method converges to $E[X]$.

Strong Law of Large Numbers (SLLN)

Let $X_1, X_2, \cdots, X_n$ be an iid sequence of random variables for which $E[X] < \infty$. Then $\frac{X_1+X_2+\cdots+X_n}{n} \xrightarrow{a.s.} E[X]$ as $n \to \infty$. The SLLN implies that the Monte Carlo method almost surely converges to $E[X]$.

Uniform and Nonuniform Random Numbers

Usually, the computer has a uniform random number generator, which can generate a sequence of iid uniform random numbers $U_1, U_2, \cdots$ on [0,1]. Then, how do we get the nonuniform random numbers? Usually, these can be achieved by inversion. Given a distribution function $F(\cdot)$, there is a one-to-one mapping from $U(\cdot)$ to $F(\cdot)$. Since $F(\cdot)$ is nondecreasing, $F^{-1}(x) = \inf\{y : F(y) \geq x\}$. If F is continuous and strictly increasing, the inverse of the function is $F(F^{-1}(x)) = F^{-1}(F(x)) = x$. Thus, the nonuniform random numbers with distribution F can be obtained by $x = F^{-1}(u)$, where u is a uniform random number on [0,1].

Panel Data Analysis and Bootstrapping: Application to China Mutual Funds

Abstract

Thompson (*Journal of Financial Economics 99*, 1–10, 2011) argues that double clustering the standard errors of parameter estimators matters the most when the number of firms and time periods are not too different. Using panel data of similar number in firms and time periods on China's mutual funds, we estimate double- and single-clustered standard errors by wild-cluster bootstrap procedure. To obtain the wild bootstrap samples in each cluster, we reuse the regressors (X) but modify the residuals by transforming the OLS residuals with weights which follow the popular two-point distribution suggested by Mammen (*Annals of Statistics 21*, 255–285, 1993) and others. We then compare them with other

estimates in a set of asset pricing regressions. The comparison indicates that bootstrapped standard errors from double clustering outperform those from single clustering. Our findings support Thompson's argument. They also suggest that bootstrapped critical values are preferred to standard asymptotic *t*-test critical values to avoid misleading test results.

Asset-pricing regression • Bootstrapped critical values • Cluster standard errors • Double clustering • Firm and time effects • Finance panel data • Single clustering • Wild-cluster bootstrap

24.1 Introduction

Researchers using finance panel data have increasingly realized the need to account for the residual correlation across both firms and/or time in estimating standard errors of regression parameter estimates. Ignoring such clustering can result in biased OLS standard errors. Two forms of residual dependence that are common in finance applications are time-series dependence and cross-sectional dependence. The former is called a firm effect, whereas the latter a time effect. The usual solution to account for the residual dependence is to compute clustered standard errors. The notable examples are Petersen (2009) and Thompson (2011).

Using the Monte Carlo-simulated panel data, Petersen (2009) compares the performance of many different standard error estimation methods surveyed in the literature. These methods include White's heteroskedasticity-robust standard errors, single clustering (by firm or by time), and double clustering (by both firm and time). His findings suggest that the performance of different methods depends on the forms of residual dependence. For example, in the presence of a firm effect, the clustered standard errors are unbiased and can produce correctly sized confidence intervals while those estimated by OLS, White, or Fama-MacBeth method are biased.

Much of the analysis in Petersen (2009) is based on the simulated panel data set whose data structure is certain. With the simulated panel data set, it is easier to choose among the estimation methods. This paper chooses an alternative method, namely, bootstrapping, to investigate the performance of standard errors estimated by White's OLS and single- and double-clustering methods with actually observed data. The use of the bootstrap method is motivated by Kayhan and Titman (2007) who show that bootstrapped standard errors are robust to heteroskedasticity, and serial correlation problems in panel finance data applications. Moreover, despite the wide use of the bootstrap in statistical and econometric applications, the survey finding of Petersen (2009) found that the bootstrap applications are relatively scarce in the finance literature. Hence, it may be of some interest to investigate the bootstrapping application to a set of panel finance data on Chinese mutual funds.

Variable	Mean	Std. deviation	Skewness	Kurtosis	Normality test stat. W-sq.	A-sq.
Mutual funds returns	0.0006	0.0580	0.1313	0.1489	0.1809***	0.2062***
Market excess returns	0.0025	0.0465	0.1554	−0.7801	2.4993***	18.3650***

Notes: Sample size $N = 2{,}592$. Individual mutual funds return is the dependent variable, while the market excess return is the independent variable. W-sq or W^2 = Cramer-von Mises test statistic, and A-sq or A^2 = Anderson-Darling test statistic. Both test statistics are empirical distribution function (EDF) statistics. The computing formulas for W^2 and A^2 statistics are available in Stephens (1974), p. 731
*** denotes statistical significance at the 1 % level

The bootstrap method is applied to a panel data set on the monthly returns for 54 Chinese mutual funds over the period of September 2002–August 2006. The data set is applied to a set of asset pricing regressions. Table 24.1 contains summary statistics such as sample skewness, sample excess kurtosis, and two test statistics for normality for the variables used in the asset pricing regressions. They suggest that normality does not characterize the variables. Additionally, since the time-series and/or cross-sectional independence assumption is most likely to be violated in panel data sets, ignoring these dependence could result in biased estimates of the standard errors. As evidenced in Kayhan and Titman (2007), bootstrapping is a possible alternative to handle this dependence issue.

In this paper, we are particularly interested in the performance of the bootstrapped double-clustered standard error estimates, because Thompson (2011) has argued that double clustering matters most when the number of firms and time periods are not too different. Given the panel data set we have collected which consists of 54 China mutual fund returns for 48 months with data exhibiting firm and time effects, double clustering is likely to show a significant difference. Our findings show that the bootstrapped standard errors from double clustering leads to more significant test results. We also demonstrate the importance of using bootstrapped critical values in hypothesis testing.

A number of bootstrap procedures are available in the literature. The bootstrap procedure we consider in this paper is the wild-cluster bootstrap procedure, which is an extended version of the wild bootstrap proposed by Cameron et al. (2008) in a cluster setting. This procedure has been shown by Cameron et al. (2008) to perform very well in practice, despite the fact that the pairs cluster bootstrap works well in principle. In this paper, our comparison of the finite-sample size of the bootstrapped t-statistics resulting from the pairs cluster bootstrap and wild-cluster bootstrap also indicates that the wild-cluster bootstrap performs better.

The rest of the paper is organized as follows. Section 24.2 presents the wild-cluster bootstrap procedure. Section 24.3 discusses the empirical results and the last section gives conclusions.

24.2 Wild-Cluster Bootstrap

The bootstrap we use in this paper is known as the "wild-cluster bootstrap" which is based on the nonclustered wild bootstrap proposed by Wu (1986). Proofs of the ability of the wild bootstrap to provide refinements in the linear regression model for linear regression models with heteroskedastic errors can be found in Liu (1988) and Mammen (1993). Cameron et al. (2008) extended Wu's (1986) wild bootstrap to the clustered setting.

The wild-cluster bootstrap procedure involves two stages. In the first stage, we consider the asset pricing model with G clusters (subscripted by g), and with N_g observations within each cluster, namely, $y_g = X_g'\beta + e_g$, $g = 1, \ldots, G$, β is $k \times 1$, X_g is $N_g \times k$, and y_g and e_g are $N_g \times 1$ vectors. We fit the model to the actually observed panel data set by OLS and estimate White's heteroskedasticity-robust standard errors, as well as standard errors, clustered by firm, by time, and by both. We then save residuals and denote them as $\hat{e}_g$.

The second stage is the resampling procedure which creates bootstrap samples for each cluster, $\left\{\left(\hat{y}_1^*, X_1\right), \ldots, \left(\hat{y}_G^*, X_g\right)\right\}$ where $\hat{y}_g^* = X_g'\hat{\beta} + e_g^*$. For each bootstrap sample in a cluster, the explanatory variables are reused and unchanged. The residuals e_g^* are constructed according to $e_g^* = a_g\hat{e}_g$, where the weight a_g serves as a transformation of the OLS residuals $\hat{e}_g$. A variety of constructions of weights a_g have proposed in the literature[1]. We use the two-point distribution of the weight variable a_g suggested in Mammen (1993), Brownstone and Valletta (2001), and Davidson and Flachaire (2008), namely, a_g which takes on one of the following values: (i) $\left(1-\sqrt{5}\right)/2 \approx -0.6180$ with probability $\left(1+\sqrt{5}\right)/\left(2\sqrt{5}\right) \approx 0.7236$ or (ii) $\left(1+\sqrt{5}\right)/2 \approx 1.6180$ with probability $1-\left(1+\sqrt{5}\right)/\left(2\sqrt{5}\right) \approx 0.2764$. Note that this random variable a_g has a mean zero with variance equal to one and the constraint $E(a_g^3) = 1$. We perform 1,000 replications. On each replication, a new set of e_g^* is generated and a new set of bootstrap-data is created based on $\hat{y}_G^* = X_g'\hat{\beta} + e_g^*$, and therefore a new set of parameter estimates, denoted as $\hat{\beta}^*$, is obtained.

For the 1,000 starred estimates (e_g^*), we calculate their bootstrapped standard errors using different estimation methods. The bootstrapped test statistics are calculated by dividing the 1,000 parameter estimates by the corresponding bootstrapped standard errors. The bootstrapped critical values can be obtained from the bootstrapped distribution of these test statistics. A detailed explanation of the procedure we follow is documented in Appendix 1.

[1]For example, in Cameron et al. (2008), a_g takes the value +1 with probability 0.5, or the value -1 with probability 1–0.5.

24.3 Empirical Results

24.3.1 Data and Definitions of the Variables

The Data. The sample consists of the returns on 54 publicly traded closed-end mutual funds that are gathered for 48 months from September 2002 to August 2006, a total of 2,592 observations. The mutual fund data set is purchased from the GTA Information Technology Company, Shenzhen, China. For simplicity, we divide the mutual funds investment objectives into equity growth and nongrowth funds. Our sample consists of 37 (68.5 %) growth funds and 17 (31.5 %) nongrowth funds. Although the first closed-end fund in China was sold to the public in April 1998[2], complete data for all 54 mutual funds are collected from September 2002.

The summary statistics for the variables used in China's mutual fund return regressions are displayed in Table 24.1, and the test statistics for normality for these variables suggest that the variables are non-normal.

Definitions of the variables. The following are the definitions of the variables used in the estimation procedures: $R_{i,\,t}$ = the return of a mutual fund i in excess of the risk-free rate in month t. Savings deposit rate of the People's Bank of China[3] is used as the proxy for the risk-free rate. $R_{m,\,t}$ = is the market return in excess of the risk-free rate in month t and is calculated[4] as follows:

$$R_{m,t} = 0.4 \times R_{1,t} + 0.4 \times R_{2,t} + 0.2 \times 0.0006, \tag{24.1}$$

where R_1 is the monthly return on Shanghai Stock Exchange index, R_2 the monthly return on Shenzhen Stock Exchange index, and 0.06 % is the monthly return on savings deposits.

24.3.2 Results

Table 24.2 presents the results from a set of asset pricing regressions of China mutual fund returns on its market returns. The firm and time effect in OLS residuals and data can be seen graphically in Fig. 24.1. Figure 24.1, Panel A, shows the within-firm autocorrelations in OLS residuals and independent variable, respectively, for lags 1–12. Panel B of Fig. 24.1 displays the within-month autocorrelations for residuals for lags 1–12. As the independent variable is a monthly series without cross-sectional units, we cannot calculate its within-month autocorrelations, thus no within-month plot is available for the independent variable. Figure 24.1 suggests that the residuals exhibit both firm and time effects, whereas

Notes: The dependent variable is the monthly mutual fund return in excess of risk-free rate, denoted as $R_{i,t}$, and the independent variable $R_{m,t}$ is the market returns in excess of risk-free rate. Both variables are monthly observations from September 2002 to August 2006
***, and ** denote statistical significance at the 1 %, and 5 % levels, respectively

independent variable shows firm effects. Given Thompson's (2011) argument that double clustering matters most when the number of firms and time periods are not too different, our data set which has the number of mutual funds (54) similar to the number of months (48) is expected to imply that double clustering is important in our analysis.

In Table 24.2, the second column presents the OLS parameter estimates, whereas the remaining columns report their corresponding t-statistics by dividing each parameter estimate by its corresponding standard error. These t-statistics indicate all beta coefficients are statistically significant at the 1 % level, whereas the intercept is only significant in one case (under column II) when the standard error computed by single clustering by firm is used. More importantly, the *t*-statistics in Table 24.2 enable us to compare the clustered standard errors constructed from double and single clustering with the OLS White estimate. Notice that the t-statistic for beta coefficient obtained from double clustering ($\hat{SE}_{both}$) is 9.10 (column IV) which is much smaller than 46.9 calculated using the White method (column I), indicating the presence of firm and time effects. It also means that the double-clustering standard errors are much larger. A comparison of t-statistics in columns III and IV implies the $\hat{SE}_{both}$ of the beta coefficient (9.10) is similar to the standard error clustered by time which is 9.01. This means that the firm effects do not matter much. The comparison reveals that OLS White standard errors are underestimated when residuals exhibit both firm and time effects.

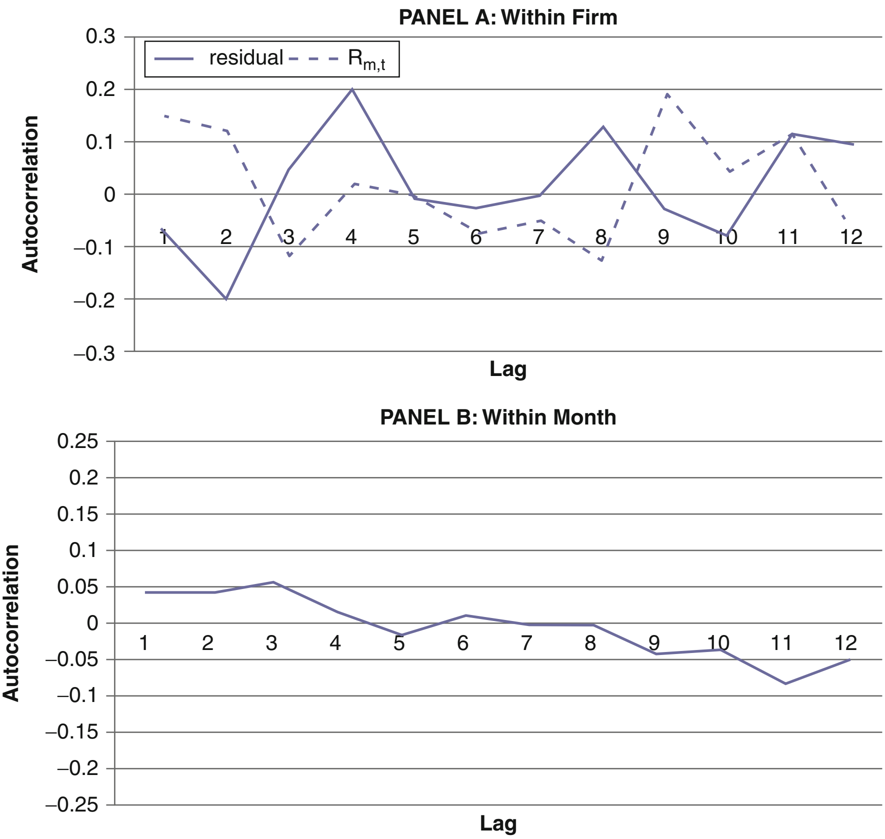

Fig. 24.1 The autocorrelations of residuals and the independent variable are plotted for 1–12 lags. The *solid lines* in *Panel A* and *B* show, respectively, within-firm and within-month autocorrelations in residuals, whereas the dashed line in *Panel A* shows the within-firm autocorrelations in the independent variable

Turning to the results obtained by the wild-cluster bootstrapping, the story changes. The bootstrapped t-statistics of the beta coefficient estimates displayed in columns V–VIII of Table 24.2 differ quite significantly from those in columns I–IV. The t-statistic is 47.2 when the bootstrapped White standard error is used and 66.8 if the bootstrapped standard error clustered by the firm is used. This means the firm effect is significant in the data. By a similar comparison, the bootstrapped t-statistic is 73.7 when the double-clustered standard error is used, meaning both the time and firm effects are strong in the residuals. The bootstrapped t-statistic is 50.9 when the bootstrapped standard error clustered by time is used implying the time effect exists in the data. These comparisons suggest both the firm and time effects matter in the computation of the bootstrapped standard errors using double as well as single clustering. Their implication is that we might follow what Kayhan and Titman (2007) have done in their study to simply compute the bootstrapped standard errors with our panel data set.

Table 24.3 Bootstrapped critical values

Percentiles	0.005	0.025	0.05	0.95	0.975	0.995

Note: Critical values are obtained by implementing the bootstrap procedure presented in the Appendix 1

Table 24.4 Rejection rates using wild-cluster bootstrapped critical values

	OLS White	Clustered by firm	Clustered by time	Clustered by firm and time
$R_{m,t}$	0.050	0.067	0.053	0.052
Intercept	0.042	0.034	0.037	0.036

Note: The number of replications is 1,000

The statistical significance of the bootstrapped t-statistics of the beta coefficient estimates is determined by using the bootstrapped critical values reported in Table 24.3. Compared with the bootstrapped critical values presented in Table 24.3, we notice that all bootstrapped t-statistics constructed from bootstrapped standard errors are statistically significant at the 1 % level. The intercept is now significant in three cases (columns V–VII) when the standard errors were computed by White and by single clustering. It is noteworthy that in Table 24.3 the bootstrapped critical values on beta coefficient estimates when double clustering is used are numerically larger than the corresponding asymptotic *t*-test critical values of 2.58 (1 %), 1.96 (5 %), and 1.65 (10 %), indicating that the use of the large-sample (normal approximation) critical values can lead to misleading test results when both firm and time effects exist in the residuals. On the other hand, intercept coefficient in column VIII was not significant when bootstrapped double clustering is used. Interestingly, we observe from Table 24.3 that bootstrapped critical values differ considerably depending on different standard error estimation methods.

We now examine the finite-sample size of the bootstrapped t-statistics assuming the beta coefficient takes the OLS estimate under the null hypothesis. Table 24.4 shows that for the bootstrapped t-statistics, no serious size distortion is found as

Table 24.5 Rejection rates using conventional critical values

	OLS White	Clustered by firm	Clustered by time	Clustered by firm and time
$R_{m,t}$	0.004	0.069	0.037	0.206
Intercept	0.012	0.046	0.036	0.203

Note: The number of replications is 1,000

reflected by the close to 5 % size values. However, for the tests based on the standard asymptotic *t*-test critical values, all tests suffer from serious size distortion. For example, those based on the OLS White and clustered by time are undersized, while others oversized (see Table 24.5).

24.4 Conclusion

In this paper, we examine the performance of single- and double-clustered standard errors using the wild-cluster bootstrap method. The panel data set on the Chinese mutual funds used in the analysis has similar number of firms (54) and time periods (48); we are particularly interested in the performance of the bootstrapped double-clustered standard errors. This is mainly due to the conclusion made in Thompson (2011) that double clustering the standard errors matters the most when the number of firms and time periods are not too different.

In the presence of firm and time effects, the standard OLS White standard errors are found to be underestimated when compared to standard errors computed from double clustering (columns I–IV, Table 24.2). Further, the wild-cluster bootstrapped standard errors are found to account for the firm and time effects in residuals, as evidenced in column VIII of Table 24.2. The bootstrapped t-statistic computed by OLS White method is found to be much smaller than that calculated from the double clustering, suggesting that the firm and time effects in residuals are strong.

The size values for the test statistics of the beta coefficient estimates in Table 24.4 suggest that the bootstrapped double clustering outperforms the single clustering either by firm or by time. They support Thompson's (2011) argument that double clustering the standard errors of parameter estimators matters the most when the number of firms and time periods are not too different. Size distortions reported in Table 24.5 imply that it may not be appropriate to compare the bootstrapped t-statistics with standard *t*-test critical values. These findings also suggest that to avoid obtaining misleading test results with the presence of either firm or time effects or both, the bootstrapped critical values are preferred to conventional critical values. Additionally, a comparison of the sizes displayed in Table 24.4 with those calculated using the pairs cluster bootstrap method shown in Table 24.6 also suggests the wild-cluster bootstrap approach performs better.

Table 24.6 Rejection rates using pairs cluster bootstrapped critical values

	OLS White	Clustered by firm	Clustered by time	Clustered by firm and time
$R_{m,t}$	0.043	0.040	0.040	0.040
Intercept	0.062	0.048	0.059	0.060

Note: The number of replications is 1,000

Appendix 1: Wild-Cluster Bootstrap Procedure

The following steps are used to obtain the wild-clustered bootstrapped standard errors and critical values:[5]

(i) *Define firm effects, and time effects*. The asset pricing model using individual variables $R_{i,t}$ and $R_{m,t}$ is specified as

$$R_{it} = \beta_0 + R_{m,t}\beta_1 + e_{it},\ \ i = 1, \ldots, N,\ \ t = 1, \ldots, T \tag{24.2}$$

where the variables $R_{i,t}$ and $R_{m,t}$ are, respectively, the return of mutual fund i and the market return in excess of risk-free rate in month t. β_0 and β_1 are unknown parameters. The construction of the variables is detailed in Sect. 24.3.1. e_{it} is the error term. It may be heteroskedastic but is assumed to be independent of the explanatory variable $E(e_{it} \mid R_{m,t}) = 0$.

Following Thompson (2011), we make the following assumptions on the correlations between errors, e_{it}:

(a) *Firm effects*: The errors may be correlated across time for a particular firm, that is, $E(e_{it}, e_{ik} \mid R_{m,t}, R_{m,k}) \neq 0$ for all $t \neq k$.

(b) *Time effects*: The errors may be correlated across firms within the same time period, that is,

$$E\left(e_{it}, e_{jt} \middle| R_{m,t}\right) \neq 0 \quad \text{for all} \ \ i \neq j.$$

Let G be the number of clusters, and let N_g be the number of observations within each cluster. The errors are assumed to be independent across clusters but correlated within clusters. The asset pricing model can be written as

$$\begin{aligned} R_{ig} &= \beta_0 + R_m\beta_1 + e_{ig}, \qquad & i = 1, \ldots, N_g \qquad g = 1, \ldots, G, \\ \mathbf{R}_g &= \delta\beta_0 + \mathbf{R}_{mg}\beta_1 + \mathbf{e}_g, \qquad & g = 1, \ldots, G, \end{aligned} \tag{24.3}$$

where R_{ig}, R_m, and e_{ig} are scalars; $\mathbf{R}_g$, $\mathbf{R}_{mg}$, and $\mathbf{e}_g$ are $N_g \times 1$ vectors; and δ is $N_g \times 1$ vector with all elements equal to 1.

(ii) *Fit data to model*. We fit model (Eq. 24.3) to the observed data using OLS and obtain the parameter estimates $\hat{\beta}_0$ and $\hat{\beta}_1$ together with the OLS residuals $\hat{\mathbf{e}}_g$, g = 1,. . ., G

[5]See also Cameron et al. (2008) for details

(iii) *Construct 1,000 bootstrap samples*. The bootstrap-residuals are obtained according to the following transformation relation: $e_g^* = a_g \hat{e}_g$, where a_g takes on one of the following values: (i) $\left(1-\sqrt{5}\right)/2 \approx -0.6180$ with probability $\left(1+\sqrt{5}\right)/\left(2\sqrt{5}\right) \approx 0.7236$ or (ii) $\left(1+\sqrt{5}\right)/2 \approx 1.6180$ with probability $1-\left(1+\sqrt{5}\right)/\left(2\sqrt{5}\right) \approx 0.2764$.

Hence,

(a) For each cluster $g = 1, \ldots, G$, set $\mathbf{e}_\mathbf{g}^* = 1.618^* \hat{\mathbf{e}}_\mathbf{g}$ with probability 0.2764 or $\mathbf{e}_\mathbf{g}^* = -0.618^* \hat{\mathbf{e}}_\mathbf{g}$ with probability 0.7236.

(b) Repeat (a) 1,000 times to obtain $\mathbf{e}_g^*$ and then construct the bootstrap samples $\mathbf{R}_g^*$ as follows:

$$\mathbf{R}_g^* = \delta\hat{\beta}_0 + \mathbf{R}_{\mathrm{mg}}\hat{\beta}_1 + e_g^*. \tag{24.4}$$

(iv) With each pseudo sample generated in step (iii), we estimate the parameters $\hat{\beta}_0^*$ and $\hat{\beta}_1^*$ by OLS, White standard errors ($\hat{SE}_{\mathrm{white}}$)which are OLS standard errors robust to heteroskedasticity, as well as standard errors clustered by firm ($\hat{SE}_{\mathrm{firm}}$), by time ($\hat{SE}_{\mathrm{time}}$), and by both firm and time ($\hat{SE}_{\mathrm{both}}$). The simulations are performed using GAUSS 9.0. The standard error formulas can be found in Thompson (2011).

(v) Construct bootstrapped test statistics by taking ratios of $\hat{\beta}_i^* \, (i = 0, 1)$ obtained by OLS to its corresponding $\hat{SE}_{\mathrm{white}}$, $\hat{SE}_{\mathrm{firm}}$, $\hat{SE}_{\mathrm{time}}$, and $\hat{SE}_{\mathrm{both}}$ obtained in step (iv). More specifically, the bootstrapped test statistics are expressed as follows:

$$w_i^* = \frac{\hat{\beta}_i^* - \hat{\beta}_i}{\hat{SE}\left(\hat{\beta}_i^*\right)}, i = 0, 1, \tag{24.5}$$

where $\hat{SE}\left(\hat{\beta}_i^*\right)$ can either be $\hat{SE}_{\mathrm{white}}$, $\hat{SE}_{\mathrm{firm}}$, $\hat{SE}_{\mathrm{time}}$, or $\hat{SE}_{\mathrm{both}}$.

(vi) Obtain the empirical distribution of the individual test statistics by sorting the 1,000 test statistics computed in step (v) in an ascending order. Bootstrapped critical values are then obtained from this empirical distribution at the following quantiles: 0.5 %, 2.5 %, 5 %, 95 %, 97.5 %, and 99.5 %, respectively.

Market Segmentation and Pricing of Closed-End Country Funds: An Empirical Analysis

25

Dilip K. Patro

Contents

Abstract

This paper finds that for closed-end country funds, the international CAPM can be rejected for the underlying securities (NAVs) but not for the share prices. This finding indicates that country fund share prices are determined globally where as the NAVs reflect both global and local prices of risk. Cross-sectional variations in the discounts or premiums for country funds are explained by the differences

The views expressed in this paper are strictly that of the author and not of the OCC or the US department of Treasury.

in the risk exposures of the share prices and the NAVs. Finally, this paper shows that the share price and NAV returns exhibit predictable variation and country fund premiums vary over time due to time-varying risk premiums. The paper employs **generalized method of moments** (**GMM**) to estimate stochastic discount factors and examines if the price of risk of closed-end country fund shares and NAVs is identical. GMM is an econometric method that was a generalization of the method of moments developed by Hansen (*Econometrica 50*, 1029–1054, 1982). Essentially GMM finds the values of the parameters so that the sample moment conditions are satisfied as closely as possible.

25.1 Introduction

The purpose of this paper is to provide an empirical analysis of pricing of closed-end country equity funds in the context of rational asset-pricing models which account for the role of market segmentation and time-varying risk premiums. Specifically, the paper addresses the following issues. How are country fund share prices and net asset values (NAVs) determined? What are the implications of differential pricing of closed-end fund shares and NAVs for cross-sectional and time-series variations in the premiums of the funds? The answers to these questions contribute to the burgeoning literature on country funds.

Closed-end country equity funds are a relatively recent innovation in international capital markets. Whereas only four closed-end country equity funds traded in New York at the end of 1984, currently there are 94 closed-end country equity funds targeting over 31 countries. Past researchers have examined issues related to the benefits of diversification from holding these funds (Bailey and Lim 1992; Chang et al. 1995; Bekaert and Urias 1996) and how they should be designed and priced (Hardouvelis et al. 1993; Diwan et al. 1995; Bodurtha et al. 1995). Relatively unexplored is how the expected returns of the country fund share prices and NAVs are determined, in a framework of market segmentation and time-varying risk premiums.

Country fund share prices are determined in the USA, but their NAVs are determined in the country of origin of the fund. Models of international asset pricing (e.g., Errunza and Losq 1985) and models of country fund pricing (e.g., Errunza et al. 1998) suggest that the expected returns on country fund share prices should be determined by their covariances with the world market portfolio. However, if there are barriers to investment, such as limits on ownership, the capital markets may be segmented. In such a segmented market, the expected returns of the NAVs will be determined by their covariances with the world market portfolio as well as the home market portfolio, to the extent that the home market is not spanned by the world market.

The foundation of this paper is in such a framework of market segmentation and its implications for international capital market equilibrium. In such a market structure where the local investors have complete access to the world market but the foreign investors (e.g., the US investors) have only partial access to the local equity market in terms of the percentage of equity of a firm they can own, the prices paid by foreigners relative to local investors can be higher due to the limited supply of the local securities. To preclude arbitrage, it is assumed that the local investors cannot buy the securities at a lower price and sell it to the foreign investor at a higher price. Thus, foreign investors are willing to pay a premium due to the diversification benefits from adding that security to their purely domestic portfolio. The premium arises only if the cash flows of the local security are not spanned by the purely domestic portfolio for the foreign investor. Since closed-end country fund's share prices and NAVs are determined in two separate markets, the expected returns on the prices and NAVs can be different, leading to premiums, both positive and negative. Thus, barriers to investments may be sufficient to generate premiums.[1]

Even in the absence of institutional restrictions on foreign equity ownership or even in a purely domestic context (see, e.g., Pontiff 1997), it is still possible for observed price returns to be much more volatile than NAV returns. As shown in the academic literature, closed-end country fund share prices and NAVs are not perfect substitutes. The sources of these differences may be attributable to differences in numeraires, information, and possibly noise trading causing excess volatility in the share price returns (see Lee et al. 1991). Apart from investment restrictions, these imperfections alone may be sufficient to generate premiums. However, Bonser-Neal et al. (1990) document that relaxation of investment restrictions leads to a decrease in the share price-NAV ratio for a sample of country equity funds. Further, Bodurtha et al. (1995) document that the correlation of changes in country fund premiums and domestic fund premiums is low and insignificant, indicating that the structure of international capital markets is an important contributor in determining premiums.

Thus, the objective of this paper is to provide an analysis of what explains the expected returns on closed-end country fund share prices and NAVs in a segmented market framework. The paper utilizes both unconditional and conditional tests on mean-variance efficiency of the world market index (as proxied by the Morgan Stanley Capital International world index) and provides results on the cross-sectional and time-series variations of premiums across closed-end country equity funds. In addition, the paper employs generalized method of moments (GMM) as discussed in Appendix 1 to estimate stochastic discount factors and examines if the price of risk of closed-end country fund shares and NAVs is identical.

[1]Hence forth both premiums and discounts are referred to as premiums. Therefore, a discount is treated as a negative premium.

The sample consists of 40 closed-end country equity funds. Twenty of the funds are from developed markets and 20 funds are from emerging markets.[2] The main empirical findings of the paper are as follows. For country fund share prices, the hypothesis that the unconditional international CAPM is a valid model cannot be rejected. However, for the NAVs the international CAPM can be rejected. This finding suggests that country fund share prices and NAVs are not priced identically. The share prices reflect the global price of risk only, but the NAVs reflect both the global and the local prices of risk. It is shown that the differences in risk exposure to the world market index of share prices and NAVs can explain up to 18.7 % of the cross-sectional variations in premiums for developed market funds, but only 1.9 % of the variation for emerging market funds.

When conditioning on information is allowed, the international CAPM explains country fund share returns and NAV returns for both developed and emerging markets. However, the hypothesis that the price of risk is identical between closed-end fund shares and NAVs can be rejected for alternate stochastic discount factors for majority of the markets. This finding is consistent with market segmentation. Therefore, differential pricing of the fund shares and the underlying portfolio causes expected returns to be different and explains the existence of premiums and their variation over time. Finally, it is shown that the country fund premiums vary over time due to differential conditional risk exposures of the share prices and NAVs.

The principal contributions of this paper are as follows. Existence of premiums on closed-end funds has been a long-standing anomaly. In the domestic setting, negative premiums have been the norm, which has been attributed to taxes, management fees, illiquid stocks, or irrational factors (e.g., noise trading). Although these factors may also be important in explaining country fund premiums, unlike domestic closed-end funds, country fund share prices and NAVs are determined in two different market segments. This paper provides a rational explanation for the premiums on country funds based on differential risk exposures of the share prices and NAVs and market segmentation. Unlike the noise trading hypothesis which assumes the presence of "sentiment" or an additional factor for the share prices but not the NAVs, this paper shows that the same factor may be priced for the share prices and the NAVs, but priced differently. The differential risk exposures are shown to be among the significant determinants of cross-sectional variations in the premiums. Further, this paper examines the role of time variations in expected returns for country fund returns and attributes the time-varying country fund premiums to time-varying country fund returns.

The paper is organized as follows. Section 25.2 presents the theoretical motivation and the hypotheses. Section 25.3 presents the data and the descriptive statistics. Section 25.4 provides the empirical results for pricing of country funds. Concluding remarks are presented in the last section.

---

[2]In 1993, the World Bank defined an emerging market as a stock market in a developing country with a GNP per capita of $8,625 or less. This is the definition of an emerging market in this paper.

25.2 Theoretical Motivation

This section first focuses on the theoretical motivation for the empirical testing of the unconditional mean-variance efficiency of the world market index in the context of country funds. The following subsections present tests for cross-sectional variations in country fund premiums and the methodology for pricing country funds using stochastic discount factors. Finally, this section outlines the methodology for explaining the time variations in country fund premiums attributable to time-varying risk premium.

25.2.1 Pricing of Country Funds in the Context of International CAPM

In a global pricing environment, the world market portfolio surrogates the market portfolio. If purchasing power parity is not violated and there are no barriers to investment, the world market portfolio is mean-variance efficient (see, e.g., Solnik 1996; Stulz 1995) and expected returns are determined by the international CAPM. The international CAPM implies that the expected return on an asset is proportional to the expected return on the world market portfolio:

$$E[r]_i = \beta_i E[r_w] \tag{25.1}$$

where, for any asset i, $E[r_i]$ is the expected excess return on the asset and $E[r_w]$ is the expected excess return on the world market portfolio. The excess returns are computed in excess of the return on a risk-free asset. Following a standard practice (see Roll 1977), mean-variance efficiency of a benchmark portfolio can be ascertained by estimating a regression of the form

$$r_{i,t} = \alpha_i + \beta_{i,w} r_{w,t} + e_{i,t} \tag{25.2}$$

where $r_{i,t}$ is the excess return on a test asset and $r_{w,t}$ is the return on a benchmark portfolio.

The GMM-based methodology as outlined in Mackinlay and Richardson (1991) is employed to test mean-variance efficiency of the world market index in the context of country funds, using just a constant and the excess return on the world market index as the instruments.[3] The hypothesis that $\alpha_i = 0$, for all $i = 1, \ldots, N$, where N is the number of assets, is tested. This is the restriction implied by the international CAPM. The joint hypothesis is tested by a Wald test for country fund share prices and NAVs returns. Since country fund's share prices are determined with complete access to their markets of origin, their expected returns are expected to be determined via the

[3]Although the evidence in favor of the domestic CAPM is ambiguous, many studies such as Cumby and Glen (1990) and Chang et al. (1995) do not reject the mean-variance efficiency of the world market index. Interestingly, although Cumby and Glen (1990) do not reject mean-variance efficiency of the world market index, they reject mean-variance efficiency of the US market index.

international CAPM (see, e.g., Errunza and Losq 1985). However, if the country from which the fund originates has restrictions on foreign equity investments, the expected returns of the NAVs will be determined via their covariances with both the world market portfolio and the part of the corresponding local market portfolio which is not spanned by the world market portfolio (see Errunza et al. 1998).

$$\text{Letting } e_{i,t} = r_{i,t} - \alpha_i - \beta_{i,w} r_{w,t} \tag{25.3}$$

for the N assets, the residuals from the above equation can be stacked into a vector e_{t+1}. The model implies that $E[e_{i,t+1}|Z_t] = 0$, for $\forall$ i and $\forall$ t. Therefore, $E[e_{t+1} \otimes Z_t] = 0$ for $\forall$ t, where Z_t is a set of predetermined instruments. GMM estimation is based on minimizing the quadratic form $f'\Omega f$, where the sample counterpart of $E[e_{t+1} \otimes Z_t]$ is given by $f = \{1/T[\sum E[e_{t+1} \otimes Z_t]\}$ and Ω is an optimal weighting matrix in the sense of Hansen (1982).

25.2.2 Cross-Sectional Variations in Country Fund Premiums

If the mean-variance efficiency of the world market portfolio is not rejected, then expected returns of the test assets are proportional to their "betas" with respect to the world market portfolio. Therefore,

$$E(r_a) = \lambda_w \beta_{a,w} \text{ where } a = p \text{ or } n \tag{25.4}$$

where $E(r_p)$ and $E(r_n)$ are the expected excess returns on the share prices and NAVs, respectively, and λ_w is the risk premium on the world market index. Stulz and Wasserfallen (1995) demonstrate that the logarithm of two share prices can be written as a linear function of the differences in their expected returns.[4] Therefore,

$$\text{Prem} = \log(P/NAV) = E(r_n) - E(r_p) \tag{25.5}$$

where Prem is the premium on a fund calculated as the logarithm of the price-NAV ratio. Combining Eqs. 25.4 and 25.5 leads to the testable implication

$$\text{Prem} = \lambda_w \left(\beta_{n,w} - \beta_{p,w}\right) \tag{25.6}$$

The above equation assumes that the international CAPM is valid and world capital markets are integrated. In reality, the world markets may be segmented. Therefore, the effect of market segmentation is captured by introducing additional

[4]Stulz and Wasserfallen (1995) use the log-linear approximation of Campbell and Ammer to write the logarithm of the price of a stock as $\ln(P) = E\Sigma\eta^i[(1 - \eta)d^{t+j+1} - r^{t+j+1}] + \theta$, where η is a log-linear approximation parameter and r^{t+j+1} is the return from t+j to t+j+1. Assuming that η is the same for prices and NAVs, and the relation holds period by period, the premium can be written as above.

variables based on prior research of Errunza et al. (1998) who document that measures of access, spanning, and substitutability of the prices and NAVs have explanatory power for the cross-sectional variation of premiums. The spanning measure (SPN) is the conditional variance of the NAV return of a fund, unspanned by the US market return and the fund's share price returns, with specification as follows:

$$r_{n,t} = \alpha_i + \beta_i r_{US,t} + \beta_i r_{p,t} + e_{i,t} \tag{25.7}$$

where $e_{i,t}$ has a GARCH (1, 1) specification. The conditional volatility of $e_{i,t}$ is the measure of spanning. The measure of substitution (SUB) is the ratio of conditional volatilities of the share price and NAV returns of a fund not spanned by the US market. The specifications for the expected return equations are

$$r_{n,t} = \alpha_i + \beta_i r_{US,t} + e_{n,t} \tag{25.8}$$

$$r_{p,t} = \alpha_i + \beta_i r_{US,t} + e_{p,t} \tag{25.9}$$

where the error terms $e_{n,t}$ and $e_{p,t}$ have GARCH (1, 1) specifications.[5] The ratio of the conditional volatilities of the residuals in Eqs. 25.8 and 25.9 is used as the measure of substitutability of the share prices and NAVs.

Since it is difficult to systematically classify countries in terms of degree of access, a dummy variable is used to differentiate developed and emerging markets. The dummy variable takes value of one for developed markets. Another measure of access, which is the total purchase of securities from a country by US residents as a proportion of total global purchase, is also used as a measure of access to a particular market. It is expected that the premiums are lower for countries with easy access to their capital markets. Therefore, the coefficient on the access variable is expected to be negative. The measure of spanning is interpreted as the degree of ease with which investors could obtain substitute assets for the NAVs. As noted earlier, even if there are barriers to foreign equity ownership, availability of substitute assets can overcome the barriers. Since the spanning variable is the volatility of the residual as specified in Eq. 25.7, it is expected to be positive. The measure of imperfect substitutability of the share prices and NAVs is the ratio of the variances of the share price and NAV returns. It is expected that the premium is inversely related to this measure. Therefore, the extended cross-sectional equation is

$$\text{Prem}_i = \delta_0 + \delta_1 \text{DIF}_i + \delta_2 \text{SPN}_i + \delta_3 \text{SUB}_i + \delta_4 \text{ACC}_i + e_i \tag{25.10}$$

where:

DIF_i = the difference of the betas on the world market index for the NAVs and the share prices.

SPN_i = the conditional residual volatility from Eq. 25.7 used as measures of spanning.

---

[5]Note that unlike here, Errunza et al. (1998) use returns on industry portfolios to proxy for the US market.

SUB_i = the imperfect substitutability of the share prices and the NAVs proxied by the ratio of conditional volatilities in Eqs. 25.8 and 25.9.

ACC = a measure of access to a market proxied by a dummy variable which is 1 for developed markets [ACC(d)] or the total purchase of securities from the US residents from that country as a fraction of global security purchases [ACC(cf)].

The empirical specification in Eq. 25.10 or its variations is used in the empirical analysis for explaining cross-sectional variations in premiums. The higher the difference of risk exposures, the higher is the premium. Therefore, the sign of δ_1 is expected to be positive. However, as the level of unspanned component is higher, the level of premiums should be higher. Therefore the sign of δ_2 is expected to be positive. Also, the higher the substitutability of the share prices and the NAVs, the lower should be the premium. Therefore, δ_3 is expected to be negative. Since higher access is associated with lower premiums, δ_4 is also expected to be negative.

25.2.3 Conditional Expected Returns and Pricing of Country Funds

If investors use information to determine expected returns, expected returns could vary over time because of rational variations in risk premium. In such a scenario, the premium on a country fund can be time varying as a result of the differential pricing of the share prices and the NAVs.

Let $R_{t+1} = \frac{P_{t+1}+D_{t+1}}{P_t}$, where P_{t+1} is the price at time t+1 and D_{t+1} is the dividend at time t+1. Asset-pricing models imply that $E[M_{t+1}R_{t+1}|Z_t] = 1$, where Z_t is a subset of the investor's information set at time t (see, e.g., Ferson 1995). M is interpreted as a stochastic discount factor (SDF). The existence of the above equation derives from the law of one price. Given a particular form of an SDF, it is estimated by using GMM as outlined earlier.[6]

The SDFs examined in this paper are the SDFs implied by the international CAPM and its extension under market segmentation. The international CAPM is obtained by assuming that the SDF is a linear function of the return on the world market index ($R_{w,\,t+1}$). Specifically, the SDF is:

$$\text{International CAPM: } M = \lambda_0 + \lambda_1 R_{w,t+1} \tag{25.11}$$

A two-factor SDF, where the second factor is the return on a regional index (specifically for Asia or Latin America), is also estimated. Such a model is implied by the models of Errunza and Losq (1985).[7] Specifically, the SDFs is:

$$\text{Two-factor model: } M = \lambda_0 + \lambda_1 R_{w,t+1} + \lambda_2 R_{h,t+1} \tag{25.12}$$

[6]Ferson and Foerster (1994) show that an iterated GMM approach has superior finite sample properties. Therefore the iterated GMM approach is used in the estimations.

[7]For such conditional representation, see, for example, Ferson and Schadt (1996).

Once an SDF is estimated for a group of share prices and NAVs, the coefficients of the estimated SDFs are compared to test the hypothesis that for a given SDF, the share price and NAV are priced identically.[8]

25.2.4 Conditional Expected Returns and Time-Varying Country Fund Premiums

To examine the role of time-varying risk premiums in explaining the time variation in country fund premiums, the following procedure is used. Similar to Ferson and Schadt (1996), a conditional international CAPM in which the betas vary over time as a linear function of the lagged instrumental variables is used. The following equations are estimated via GMM:

$$r_{p,t+1} = \alpha_p + \beta_{p,w}(Z_t) r_{w,t+1} + e_{p,t+1} \tag{25.13}$$

$$r_{n,t+1} = \alpha_n + \beta_{n,w}(Z_t) r_{w,t+1} + e_{n,t+1} \tag{25.14}$$

where the excess return on the world market index is scaled by a set of instrumental variables. Using Eq. 25.6 and the above time-varying betas, the premium can be written as

$$\mathrm{Prem}_{t+1} = \gamma_0 + \gamma_1 \left[\beta_{n,w}(Z_t) - \beta_{p,w}(Z_t)\right] + e_{\mathrm{prem},t+1} \tag{25.15}$$

The empirical specification in Eq. 25.15 is used for explaining the time-varying premiums. If the time-varying betas are significantly different and their difference can explain the time variation of country fund premiums, the coefficient γ_1 is expected to be positive and significant.

25.3 Data and Descriptive Statistics

The sample includes all single-country closed-end country equity funds publicly trading in New York as of 31 August 1995. The test sample is limited to country funds with at least 100 weeks of weekly NAV observations.[9] An overview of the sample is presented in Table 25.1. The funds are classified as developed market or

[8]See Cochrane (1996) for such specifications. Cochrane (1996) calls such models as "scaled factor models." See Bansal et al. (1993) for a nonlinear specification of stochastic discount factors.

[9]Unlike industrial initial public offerings (IPOs), closed-end fund IPOs are "overpriced" (Weiss 1989). Peavy (1990) finds that new funds show significant negative returns in the aftermarket. Hanley et al. (1996) argue that closed-end funds are marketed to a poorly informed public and document the presence of flippers – who sell them in the immediate aftermarket. They also document evidence in support of price stabilization in the first few days of trading. Therefore, the first 6 months (24 weeks) of data for each fund is excluded in the empirical analysis.

Table 25.1 Closed-end country funds: sample overview

Fund name	IPO date	Symbol	No of shares (millions)	Net assets ($ millions)	Listing

This table presents the sample of closed-end country funds. The funds are classified as from developed markets or emerging markets using the World Bank's definition of emerging markets. The China funds are classified as developed market funds because the majority of their investments are in Hong Kong. The net assets reported is as of 31 December 1994. The listing of the funds is denoted as NYSE, New York Stock Exchange and AMEX, American Stock Exchange. The Germany fund, Korea fund, and the Thai capital fund also trade on the Osaka Stock Exchange. The future Germany fund is now called Central European equity fund

emerging market funds using the World Bank's definition of an emerging market. The three China funds are classified as developed market funds because the majority of their assets are in Hong Kong. The weekly (Friday closing) prices, NAVs, and corresponding dividends for each fund are obtained from *Barrons* and *Bloomberg*. [10] The returns are adjusted for stock splits and dividends. The 7-day Eurodollar deposit rate, provided by the Federal Reserve, is used as the risk-free benchmark.

[10]For some of the funds, such as the India growth fund, the prices and net asset values are as of Wednesday closing. This may lead to nonsynchronous prices and NAVs. However, as Bodurtha et al. (1995) and Hardouvelis et al. (1993) show, the effects of nonsynchronous trading are not pervasive and do not affect the analysis.

This table presents the descriptive statistics of the sample of closed-end country funds. The sample covers the period January 1991–August 1995 (244 weekly observations). All the returns are weekly returns in US dollars. The premium on a fund is calculated as the logarithm of the price-net asset value ratio. The "volatility ratio" is the ratio of variance of price returns over the variance of NAV returns for that fund. An asterisk (*) denotes that the variance of price returns is significantly higher than the variance of NAV returns, from an F-test at the 5 % level of significance

Table 25.2 reports the descriptive statistics for the sample of funds. The IFC global indices are available weekly from December 1988. Therefore, for emerging market funds which were launched before December 1988, the analysis begins in December 1988. To enable comparison across funds, a common time frame of January 1991–August 1995 is chosen. Since, the data for the first 6 months are not used in the analysis, only 30 funds listed on or before July 1990 are considered. The mean premium on the index of developed market funds is −8.31 %, whereas the mean premium on the emerging market funds is 0.44 %. A *t*-test of the difference of means indicates that the mean premium of the index of the emerging market funds is significantly higher than the mean premiums on the index of developed market funds at the 1 % level of significance.

Figure 25.1 plots the time series of the premiums for the index of developed and emerging market funds. The figure clearly indicates that the premiums on emerging market funds are usually positive and higher than the premiums on developed market funds, highlighting the effects of market segmentation. Table 25.2 also presents the ratio of the variance of the excess price returns over the variance of the excess NAV returns. For 27 funds out of the 30 funds, the ratios are significantly higher than one.[11]

A set of predetermined instrumental variables similar to instruments used in studies of predictability of equity returns for developed markets (Fama and French 1989; Ferson and Harvey 1993) and emerging markets (Bekaert 1995) are used in the empirical analysis when testing conditional asset-pricing models. The instruments are the dividend yield on the Standard and Poor's 500 Index, calculated as the last quarter's dividend annualized and divided by the current market price (DIVY); the spread between 90-day Eurodollar deposit rate and the yield on 90-day US treasury bill (TED); and the premium on an index of equally weighted country funds (FFD). Only three instruments are used in order to be parsimonious representation of the conditional asset-pricing models.

TED is calculated using data from the Federal Reserve of Chicago and DIVY is obtained from *Barrons*. FFD is constructed using the sample of 30 funds listed in Table 25.2. Table 25.3 reports the sample characteristics of these instruments. As Fama and French (1989) show, the dividend yields and interest rates track the business cycle, and expected returns vary as a function of these instruments. Table 25.4 reports the descriptive statistics for the returns on the market indices and the correlations of returns on the market indices of various countries with the returns on the US index. The developed market indices are from Morgan Stanley Capital International and the emerging market indices are from the International Finance Corporation. All the developed market indices have significantly higher correlations with the US market index, compared to the emerging markets, which implies that there are potential diversification benefits from investing in emerging markets.

[11]Assuming that the price returns and NAV returns are from two normal populations, the test statistic which is the ratio of the variances has an F distribution (if the two variances are estimated using the same sample size). The null hypothesis that the variance of price returns is greater than the variance of NAV returns is tested using this statistic at the 5 % level of significance.

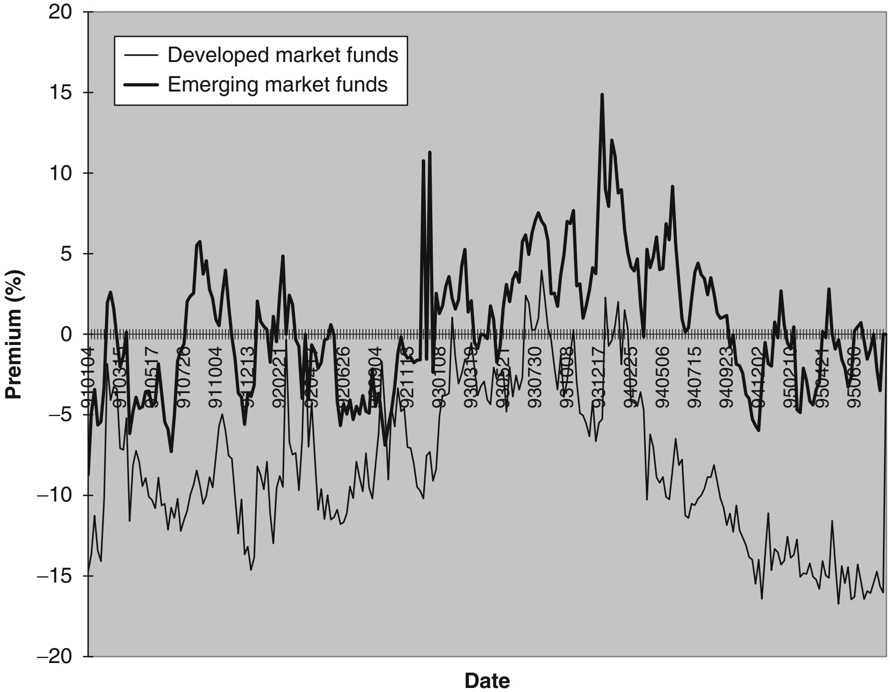

Fig. 25.1 Country fund premiums

Table 25.3 Summary statistics for the instrumental variables

Panel A: Means and standard deviations (%)			
	Mean		Std. dev
TED	0.34		0.18
DIVY	2.91		0.23
FFD	−3.87		3.93
Panel B: Correlations of the instrumental variables			
	TED	DIVY	FFD
TED	1.00		
DIVY	0.50	1.00	
FFD	−0.55	−0.25	1.00

The statistics is based on weekly data from January 1991–August 1995 (244 weekly observations). The spread between 90-day Eurodollar deposits and 90-day US treasury yields (TED), the dividend yield on the Standard and Poor's 500 index (DIVY), and an equally weighted index of the premiums for the sample of funds in Table 25.2 (FFD)

This table presents the descriptive statistics for the returns on market indices of developed and emerging markets for the time period January 1991–August 1995. The table also presents the correlation of the returns, with the returns on the US market. All the developed market indices are weekly indices from Morgan Stanley Capital International. The emerging market indices are from the International Finance Corporation

25.4 Empirical Results: Pricing of Country Funds

This section presents the empirical results for pricing of country funds. The results from the unconditional tests indicate that, in general, developed market closed-end fund returns have significant risk exposures to the world market index, while emerging market closed-end fund returns have significant risk exposures to both the world market index and the corresponding local market index. Second, the hypothesis of unconditional mean-variance efficiency of the world market index cannot be rejected using the share price returns of either developed or emerging market funds and NAV returns of some of the developed market funds. However, the hypothesis of unconditional mean variance of the world market index can be rejected for emerging market NAVs and some developed market NAVs. This finding indicates that while the share prices reflect the global price of risk, the NAVs may reflect both the global and the respective local prices of risk. Tests of predictability using global instruments indicate that country fund share price and NAVs exhibit significant predictable variation. When conditional asset-pricing restrictions are examined using alternate stochastic discount factors, the results indicate that the share prices and NAVs of the closed-end country funds are not priced identically for some developed and all the Asian market funds. This finding is consistent with market segmentation. Finally, it is shown that the time-varying premiums for country funds are attributable to time-varying risk premiums. The detailed results are discussed below.

25.4.1 Unconditional Risk Exposures of Country Funds

To ascertain the risk exposures of the share price and NAV returns of the sample of country funds, the following econometric specification is employed:

$$r_{p,t} = \alpha_p + \beta_{p,w} r_{w,t} + \beta_{p,h} r_{h,t} + e_{p,t} \tag{25.16}$$

$$r_{n,t} = \alpha_n + \beta_{n,w} r_{w,t} + \beta_{n,h} r_{h,t} + e_{n,t} \tag{25.17}$$

where, for any country fund "i" (the subscript "i" has been dropped for convenience):

$r_{p,t}$ = the excess total return on the share price (including dividends) of a country fund between t−1 and t.

$r_{n,t}$ = the excess return on the NAV of a country fund between t−1 and t.

$r_{w,t}$ = the excess return on the Morgan Stanley Capital International (MSCI) world market index.

$r_{h,t}$ = the excess return on the MSCI or International Finance Corporation (IFC) global index, corresponding to the country of origin of the fund.

The coefficients $\beta_{p,w}$, $\beta_{p,h}$ are the risk exposures on the world and home market portfolios for the price returns, and $\beta_{n,w}$,$\beta_{n,h}$ are the risk exposures on the world and home market portfolios for the NAV returns. Two hypotheses are tested. The hypotheses are share price returns have significant risk exposures to the world market index and the NAV returns have significant risk exposures to both the world market index and the corresponding local market index. These hypotheses are implied by the international CAPM and its extension under market segmentation (see Errunza and Losq 1985 and Diwan et al. 1995). If assets are priced in a global environment, the country fund share price as well as NAV returns should have significant risk exposure to the world market index only. However, when there are barriers to investment, the local market factor may be a source of systematic risk for the NAVs.

The risk exposures on the prices and NAVs could be different when the prices and NAVs are imperfect substitutes. By jointly estimating Eqs. 25.16 and 25.17, the hypothesis that the risk exposures on the world market and the home market indices are identical for the price and NAV returns is tested via a Wald test which is χ^2 distributed, with degrees of freedom equal to the number of restrictions.[12] Since the local indices are significantly correlated with the world index, for ease of interpretation, they are made orthogonal to each other by regressing the local index returns on a constant and the world index return and using the residuals as the local index return. Therefore, the risk exposure on the local or regional index is the marginal exposure in the presence of the world market index.

The results from the regressions to estimate risk exposures are reported in Table 25.5. Panel A of Table 25.5 presents the results for developed market funds and panel B presents the results for the emerging market funds. The results presented in Table 25.5 indicate that 15 of the 15 developed market funds and 12 of the 15 emerging market funds price returns have significant exposure to the world index at the 5 % level of significance. Also, 12 of the developed market funds and 14 of the emerging market funds price returns have significant exposure to their corresponding local market index, in the presence of the orthogonal world market index. For the NAVs, all 15 of the developed funds and ten of the emerging market funds returns have significant exposure to the world market index. Moreover, 14 of the developed and 13 of the emerging market NAV returns have significant exposure to their local market index, in the presence of the world market index. The adjusted R-squares across all the regressions vary from a low of zero to a high of 92 %.[13]

[12]For a set of linear restrictions, the Wald test statistic is given by $W = [R\beta\text{-}r]'[R\,\mathrm{Var}(\beta)\,R'][R\beta\text{-}r]$, where β is the vector of estimated parameters and $R\beta = r$ is the set of linear restrictions.

[13]Risk exposures of the price and NAV returns were also estimated using regional indices in place of the local market indices for the funds from Europe, Latin America, and Asia. These results indicate that, out of the 12 European funds, only two funds' price returns have significant risk exposure to the MSCI Europe index in the presence of the MSCI world index. Also, out of the seven Latin American funds, all seven price returns and six NAV returns have significant exposure to the Latin American index. Also, out of the 11 Asian funds, nine price returns and eight NAV returns have significant risk exposures to the Asian index.

This table presents the results from GMM estimation of risk exposures of the price ($r_{p,\ t}$) and the NAV ($r_{n.t}$) returns of country fund share and NAV excess returns on the MSCI world index ($r_{w,\ t}$)and the excess return on the corresponding local market index ($r_{h,\ t}$). For developed market funds, the time series covers the time from January 1991–August 1995. The price and the NAV risk exposures are estimated simultaneously using an exactly identified system of equations. The t-stats robust to heteroskedasticity and serial correlation (six Newey-West lags) are presented below the coefficients. An asterisk (*) denotes significance at the 5 % level of significance. The last two columns present the Chi-squares from a Wald test for the equality of the coefficients on the world market and local market indices for the price and NAV returns. The models estimated are of the form

$r_{a,t} = \alpha_a + \beta_{a,h} r_{h,.t} + \beta_{a,w} r_{w,t} + e_{a,t}$ where a = p and n

These results confirm the hypothesis that returns on prices and NAVs are generated as a linear function of the returns on the world market and possibly the corresponding local market index. The fact that 27 out of the 30 funds have significant risk exposure to the world market index indicates that the share prices may be determined via the global price of risk. The higher adjusted R-squares for the NAVs indicate that the world market index and the corresponding local market index have higher explanatory power for the time-series variations of the returns. The intercepts in the univariate regressions are not significantly different from zero, which suggests that the return on the world market index and an orthogonal return on the local market index are mean-variance efficient for the price and NAV returns.

When Wald tests are performed to test the hypothesis that the risk exposures on the prices and NAVs are identical, the results presented in the last two columns of Table 25.5 indicate that for 21 (14 from developed) out of the 30 funds, the null hypothesis of the same betas on the world index is rejected at the 10 % level of significance. Similarly, for eight funds the null hypothesis of the same betas on the local index is rejected at the 5 % level. This is a very important finding since it indicates that the systematic risks of the shares and NAVs are different. The fact that closed-end funds may have different risk exposures for the share and NAVs has been documented for domestic funds by Gruber (1996). Also different risk exposures for restricted and unrestricted securities have been documented by Bailey and Jagtiani (1994) for Thai securities and by Hietala (1989) for Finnish securities.

These results indicate that country fund share prices and NAVs may have differential risk exposures. The different risk exposures will result in different expected returns for the share prices and NAVs, which is one of the sources of the premiums. This section clearly shows that country fund share price and NAV returns have significant risk exposure to the world market index. The different risk exposures will result in different expected returns for the share prices and NAVs, which is one of the sources of the premiums. The issue of whether the country funds are priced in equilibrium via the international CAPM is the focus of next section.

25.4.2 Pricing of Country Funds in the Context of International CAPM

The results of the mean-variance efficiency of the MSCI world index, using Eq. 25.2, are presented in Table 25.6. The table reports the χ^2 and the p-values from a Wald test for the hypothesis that a set of intercepts are jointly zero.[14] This hypothesis is the restriction implied by unconditional international CAPM. Failure to reject this hypothesis would imply that the world market index is mean-variance efficient and expected returns are proportional to the expected returns on the world

[14]Other studies such as Cumby and Glen (1990) fail to reject the mean-variance efficiency of the MSCI world market portfolio for national indices of developed markets. Also, Chang et al. (1995) fail to reject the mean-variance efficiency of the MSCI world market index for a sample of developed as well as emerging market indices.

market index. The hypothesis is tested using GMM for an exactly identified system as shown in section IA. To ensure a longer time series, the tests are conducted using funds listed before December 1990.

The null hypothesis that the intercepts are jointly zero cannot be rejected for the share prices of the 15 developed market funds as well as the 15 emerging market funds. But, the null hypothesis is rejected at the 5 % level for the NAVs of both developed and emerging market funds. The tests are also conducted on subsets of funds to check the robustness of the results. Since the classification of developed and emerging markets is based on national output, it may not always capture whether a country's capital market is well developed. The subset consists of funds with zero intercepts for the NAV returns, on an individual basis. For this subset of the developed market funds consisting of 11 funds, though not reported here, the mean-variance efficiency of the world index cannot be rejected for both the share prices and NAVs. For emerging market funds NAVs, even for subsets of funds, the MSCI world market index is not mean-variance efficient. These results indicate that the world market index is an appropriate benchmark for the share prices but not necessarily for the NAVs.

These results have important implications for capital market integration. Since for the NAVs, the mean-variance efficiency of the world market index is rejected, it implies that the share prices and NAVs are priced differently. This differential pricing is sufficient to generate premiums on the share prices. Also, the fact that mean-variance efficiency of the world market index cannot be rejected for share prices of both developed and emerging markets is consistent with the theoretical prediction of Diwan et al. (1995). Since the country fund share prices are priced with complete access to that market, in equilibrium, their expected returns should be proportional to their covariances with the world market portfolio. If the NAVs are priced with incomplete access, the world market portfolio is not mean-variance efficient with respect to those returns. The results in this section are consistent with this notion. As the earlier section shows, the risk exposures of the share prices and NAVs may differ. If the international CAPM is a valid model for the share prices and NAVs, as outlined in section IB, this differential risk exposure can explain cross-sectional variations in premiums. The next section analyzes the effect of the differential risk exposures of the share prices and NAVs on the country fund premiums.

25.4.3 Cross-Sectional Variations in Country Fund Premiums

This section presents the results for tests of the hypothesis that cross-sectional variation in country fund premiums is positively related to the differences in the risk exposures of the share prices and NAVs. The theoretical motivation for this was presented in section IC. Equation 25.10 is estimated for each week during the last 75 weeks of the sample and the parameter estimates are averaged. The results indicate that cross-sectional variation in country fund premiums is explained by the

Table 25.6 Pricing of country funds in the context of international CAPM

Test assets	Chi-squares for price returns [p-value]	Chi-squares for NAV returns [p-value]
Developed market country funds (15 funds)	15.71 [0.40]	44.48 [0.00]
Emerging market country funds (15 funds)	10.64 [0.77]	25.47 [0.04]

This table presents the Chi-squares for the null hypothesis that the intercepts are jointly zero for a set of assets when their excess returns are regressed on the excess return on the MSCI world index. The regression estimated is

$r_{i,t} = \alpha_i + \beta_i r_{w,t} + e_{i,t},\ i = 1.... N$

The null hypothesis H_o: $\alpha_i = 0$ for all $i = 1...N$ is tested by a Wald test using GMM estimates from an exactly identified system. The p-values are based on standard errors robust to heteroskedasticity and serial correlation (13 Newey-West lags). The sample covers January 1991–August 1995. The test assets are excess price/NAV returns of country funds

The composition of the test assets are as follows – the developed market funds are AUT, AUS, FRA, GER, GERE, GERF, GERN, GSPN, IRL, ITA, JPNO, SGP, SPN, SHEL, and GBR. The emerging market funds are BRA, CHL, FPHI, INDG, INDO, JAKG, KOR, MYS, MEX, PRT, RTWN, TWN, THAC, THA, and TUR

differential risk exposures of a closed-end country fund share price and NAV returns. The estimation proceeds are as follows: after the betas are estimated using 75 weeks of data prior to the last 75 weeks of the sample, the difference in the betas on the world index is used as an explanatory variable in regressions with the premiums as the dependent variable.

The results are reported in Table 25.7. The results indicate that, for the full sample, the difference in risk exposure is significant and the adjusted R-square is 9.5 %. For the developed market funds, the results in panel B indicate that the differences in the betas on the world index have significant explanatory power for the cross-section of premiums for the developed market funds, with an adjusted R-square of 18.7 %. For the emerging market funds, however, as reported in panel C, the differences in risk exposures are not significant, and the adjusted R-square is only 1.9 %. This result is not surprising, given the result of the previous section that the world market index is not mean-variance efficient for the emerging market NAVs. When a dummy variable which takes value of one for the developed markets is added, it is highly negatively significant, indicating that the premiums for developed market funds are significantly lower than the emerging market fund premiums. The differential risk exposure is however significant only at the 10 % level, when the dummy variable is added.

As an extended specification, measures of spanning, integration, and substitution (based on prior research of Errunza et al. 1998) are used as additional explanatory variables. When measures of spanning, substitution, and access are used as additional explanatory variables, the adjusted R-squares go up to 39.5 % for the full sample. The measure of spanning has a positive sign as expected. The measure of spanning is also significant across the developed market funds. However, contrary

Results from an OLS regression of premiums on country funds on DIF (the difference between the betas on the world market index, for the price returns and NAV returns). The coefficient ACC (CF) is a measure of access proxied by the total purchase of securities by US residents (divided by the global purchase) from the country of origin of the fund. The coefficient ACC(d) is a dummy variable that takes value one for developed markets and zero for emerging markets. The coefficients below are the averages from the regression of the premiums on the independent variables for each week for the last 75 weeks of the sample (Mar 94–Aug 95). The t-statistics are presented in the parenthesis * and ** denote significance at the 5 % and 10 % levels of significance, respectively. The spanning measure (SPN) is the conditional variance of the NAV return of a fund, unspanned by the US market return and the fund's share price returns, with specification as follows:

$r_{n,t} = \alpha_i + \beta_i r_{US,t} + + \beta_i r_{p,t} + e_{i,t}$

where $e_{i,t}$ has a GARCH(1, 1) specification. The measure of substitution (SUB) is the ratio of conditional volatilities of the share price and NAV returns of a fund not spanned by the US market. The specification are

$r_{n,t} = \alpha_i + \beta_i r_{US,t} + e_{n,t}, \ r_{p,t} = \alpha_i + \beta_i r_{US,t} + e_{p,t}$

The error terms $e_{n,t}$ and $e_{p,t}$ have GARCH (1, 1) specifications as follows (h_t is variance of the error term):

$h_t = \theta_0 + \theta_1 e^2_{i,t-1} + \theta_2 h_{t-1}$

The equation for the cross-sectional regressions is

$Prem_i = \delta_0 + \delta_1 DIF_i + \delta_2 SPN_i + \delta_3 SUB_i + \delta_4 ACC_i + e_i$

to expectation, the measure of spanning is not significant across emerging market funds. This could be due to very low variability of the variables within emerging markets. The measure of substitutability, which is the ratio of conditional variances of the price returns and NAV returns, is not significant. The measure of substitutability persists to be insignificant for the subsets of emerging market funds. The measure of access proxied by purchase of securities by US residents from that market is not significant.

These results indicate that differential risk exposures and measures of access and spanning are significant determinants of cross-sectional variation in closed-end country fund premiums. Also, the measures of segmentation explain premiums better across developed and emerging markets compared to only within emerging markets. The phenomenon that differential risk exposures can explain cross-sectional variations in premiums on unrestricted securities relative to securities restricted to only local investors has been previously documented for Thai equities by Bailey and Jagtiani (1994) and for Swiss equities by Stulz and Wasserfallen (1995). Therefore, both market segmentation and other factors which make the closed-end country fund shares and the underlying securities imperfect substitutes – which is the source of the differences in the risk exposures and the excess volatility of the share prices – account for the cross-sectional variations in the premiums. The significance of the difference in risk exposures indicates that the greater the difference in risk exposures across a sample of country funds, the higher the premium. Second, the premium is higher for country funds originating from countries whose capital markets are less integrated with the US capital market.

Although an important finding, the differential risk exposures cannot explain the time variation in premiums. The academic literature has documented that the country fund premiums vary over time. Figure 25.1 illustrates the time variation of country fund premiums. Section IIIB reported the results for pricing of country funds in the context of the unconditional international CAPM which indicated that country fund share prices are priced consistent with the international CAPM, whereas the NAVs may or may not be priced via the international CAPM. Unconditional mean-variance efficiency of a benchmark portfolio implies conditional mean-variance efficiency, but not vice versa (Ferson 1995). If expected returns conditional on an information set are also different for the share prices and the NAVs, it could explain not only the premiums but also their variation over time, which is further explored in section IIIF. To analyze the time variability of expected returns, the predictability of the funds share price and NAV returns is examined in the next section.

25.4.4 Predictability of Closed-End Country Fund Returns

To assess the predictability of price and NAV returns, 4-week cumulative returns (the sum of returns over a 4-week period beginning the next week) are used, since most studies of predictability have used a monthly horizon. Predictability of the returns would imply that expected returns vary over time due to rational variation in risk premiums. To test the hypothesis of predictability, the returns for both share prices and NAVs are regressed on a set of global and fund-specific instruments, to ascertain the predictive power of these instruments. The global instruments are TED and DIVY. The fund-specific instrument is the lagged premium on an equally weighted index of all the funds in the sample (FFD). The lagged premium was found to have predictive power for price returns by Bodurtha et al. (1995). Also, Errunza et al. (1998) find that when time series of premiums is regressed on a global fund premium, it is highly significant. However, unlike Errunza et al. (1998) here the lagged premium is used. Significance of this variable would indicate that investors use information about past premiums to form expectations about future prices. The regression is of the form

$$\sum_{t=t+1}^{t=t+4} r_{a,t} = \eta_0 + \eta_1 FFD_t + \eta_2 TED_t + \eta_3 DIVY_t + e_{a,t} \tag{25.18}$$

where $r_{a,t}$ is the excess return on the price or NAV of an equally weighted portfolio of developed or emerging market funds.

The results from the regressions are presented in Table 25.8. Wald tests of no predictability, which test the hypothesis that a set of coefficients are jointly zero, indicate that the fund factor predicts price returns for 4 funds only and it also predicts 15 funds' NAV returns. The predictive power of the lagged premiums for price returns has been attributed to noise trading (see Bodurtha et al. 1995). The fact that it predicts NAV returns may indicate that noise trading is not an important determinant of expected returns of share prices of closed-end funds. When global instruments are used, the Wald test of no predictability can be rejected at the 5 % level for only five funds' price returns and 15 funds' NAV returns. Overall, using all the instruments, the null hypothesis of no predictability can be rejected for six share prices and 20 NAVs. The poor predictability of the share prices is puzzling, since the share prices are determined in the USA and the instruments used have been shown to predict returns in the USA.

In summary, closed-end country fund price and NAV returns exhibit considerable predictability. The existence of predictable variation in returns is interpreted as evidence of time-varying expected returns. The differences between the predictability of prices and NAVs also imply that they are not priced identically, which is further examined in the next section using time-varying expected returns.

25.4.5 Conditional Expected Returns and Pricing of Country Funds

Table 25.9 reports the results of estimating the SDFs specified in Eqs. 25.11 and 25.12. The models in panels A and B correspond to the international CAPM and a two-factor model, with the world market return and the regional returns for Latin America or Asia as the factors. For both the models,

Table presents the Chi-squares from a Wald test to ascertain importance of the fund factor and global instruments in predicting the 4-week ahead cumulative returns of the prices and NAVs. The fund factor FFD is the lagged premium on an equally weighted index of all country funds in the sample. The global instruments include the lagged spread on 90-day Eurodollar deposits and 90-day US treasury yields (TED) and the lagged dividend yield on the S&P 500 index (DIVY). The estimates are obtained via GMM using an exactly identified set of moment conditions. The table below reports Chi-squares for a Wald test that a set of one or more instruments is zero. The p-values are robust to heteroskedasticity. The model estimated is as follows, where

$$\sum_{t=t+1}^{t=t+4} r_{a,t} = \eta_0 + \eta_1 FFD_t + \eta_2 TED_t + \eta_3 DIVY_t + e_{a,t}$$

the conditional restrictions are tested. As noted earlier, if expected returns vary over time due to rational variation in risk premiums, conditional expected returns should be used. The conditional restrictions are tested by using a set of lagged instrumental variables TED and DIVY as predictors of excess returns. The tests use sets of assets – two sets of four developed market funds, a set of three Latin American funds, and two sets of three Asian funds. To ensure an adequate time series, the funds selected are the ones listed prior to December 1989. Also, using too many assets would result in too many moment conditions.[15]

The funds selected are listed in Table 25.9. After estimating a model using GMM, its goodness-of-fit is ascertained by the J-statistic. The J-statistic is a test of the overidentifying restrictions of the model. The p-values given below the J-statistic indicate that none of the models are rejected for any test assets, at conventional significance levels. This finding is consistent with the idea that for a group of assets, there may be a number of SDFs that satisfy the pricing relation. Also, failure to reject the conditional international CAPM even for the NAVs indicates that while the unconditional international CAPM is not a valid model for emerging market funds and some developed market funds, the conditional international CAPM may be a valid model. This finding is consistent with the finding of Buckberg (1995) who fails to reject the conditional international CAPM for a set of emerging market indices. It must be noted that, unlike traditional conditional models, using stochastic discount factors implies a nonlinear relation between asset returns and the returns on the market index. Failure to reject such specifications may indicate that nonlinear specifications perform better in explaining equity returns.

Table 25.9 also reports the results for tests of hypothesis that the coefficients of the SDFs of the price returns and the NAV returns are identical. The p-values for the Wald tests indicate that the null hypothesis can be rejected at all conventional levels for a subset of the developed market funds and all the Asian funds. This is a striking result, since it indicates that, although the same factors may be priced for the share prices and NAVs, the factors are priced differently. In traditional asset-pricing framework, it is equivalent to saying that the risk premiums are different. This result is consistent with the previous finding of Harvey (1991) who reports that for a sample of industrial markets, although the conditional international CAPM cannot be rejected, the price of risk varies across countries. Also, De Santis (1995) finds that stochastic discount factors that can price developed market indices cannot price emerging market indices. The difference in the price of risk is one of the sources of the premiums for the country funds. When the two-factor model is used, again the tests reject the hypothesis that the coefficients are identical for the Asian funds. However, the hypothesis of identical coefficients for the price and NAV returns cannot be rejected for a set of developed market funds and the Latin American funds.

The above results imply that a subset of the developed markets and the Asian market are segmented from the US market. However, a subset of the developed markets and the Latin American markets are integrated with the US market. The results for Latin America are not affected, when tests are conducted excluding the time period surrounding the Mexican currency crisis. Therefore, differential risk exposures are more important in explaining the premiums for the Latin American markets and the developed markets that are integrated with the world market. The results in this section clearly show that while some markets may be integrated

[15]Cochrane (1996) shows that iterated GMM estimates behave badly when there are too many moment conditions (37 in his case).

Estimation of stochastic discount factors, based on the equation $E[M(t,1)\ R(t,1)|Z_t] = 1$ via GMM. The sample covers January 1990–August 1995. The instrument set Z_t includes a constant, the lagged spread on 90-day Eurodollar deposits and 90-day US Treasury yields (LTED), and the dividend yield on Standard and Poor's 500 index (LDIVY). The estimations with the returns on regional indices (R_h) also use the lagged regional return (for Asia or Latin America) as an instrument

The stochastic discount factors estimated are

ICAPM: $M = \lambda_0 + \lambda_1 R_w$

Two-factor: $M = \lambda_0 + \lambda_1 R_w + \lambda_2 R_h$

DF is the degrees of freedom for Hansen's test of the overidentifying restrictions (the J-statistic), which has an χ^2 distribution. The t-stats for the coefficients are given in parenthesis (an asterisk indicates significance at the 5 % level) and the p-values for the J-stat is given in brackets. The last two columns report Chi-squares and p-values for tests of hypotheses that the coefficients of the price returns and NAV returns are identical. J1 is for a joint test for all the coefficients and J2 is a test for the coefficients on the world market index with the world capital market, others are not. If capital markets are segmented, that is sufficient to generate the premiums on the share prices. However, if markets are integrated, differential risk exposures may explain the premiums. This finding is different from the existing literature on country fund pricing, which has attributed the existence of premiums on irrational factors such as noise trading. The preceding analysis clearly shows that differential pricing of the same factors or differential risk exposures on the same factor may lead to premiums on the share prices. The next section provides an analysis of the effect of time-varying expected returns on country fund premiums.

25.4.6 Conditional Expected Returns and Time-Varying Country Fund Premiums

Table 25.9 reports the results of regressing the premiums on the country funds on the differences in conditional risk exposures of share price returns and NAV returns estimated using Eqs. 25.13, 25.14, and 25.15. The conditional risk exposures are estimated as a linear function of lagged dividend yields and the term premium. The null hypothesis is that the coefficient of the difference in the conditional betas is significant. The results indicate that the difference in conditional betas is highly significant in explaining the time-varying premiums on country funds. For 24 out of the 30 funds, the coefficient is significant. Also, the adjusted R-squares are high, especially for the developed market funds. For many of the funds, however, the coefficient is negative, implying that using the world market index alone is not sufficient to explain the return-generating process and the returns on the NAVs may reflect the local price of risk.

The adjusted R^2 values are higher for the developed market funds. This result is consistent with earlier results which show that the world market index is not an appropriate benchmark for emerging market NAVs. Also, majority of the emerging market funds are from Asia. The results in Table 25.9 indicated that these markets are segmented from the world market. Therefore, different risk exposures to the world market index do not explain much of the variation in the premiums for the emerging markets.

This is an important finding since the existing literature on closed-end funds has attributed the existence of premiums to irrational factors, such as noise trading. The preceding analysis shows clearly that segmented capital markets in which risk premiums vary over time are sufficient to generate two different prices for the same set of cash flows. Also, the differences in prices may vary over time as expected returns vary over time due to rational variations in expected returns. If the price of risk is different across markets, the same security will have different expected returns. The difference in these expected returns results in the premium on the share price. If the expected returns vary over time because of rational variation in risk premiums, the premiums will also vary over time as a function of the differential expected returns (Table 25.10).

25.5 Conclusions

Closed-end country funds are becoming an increasingly attractive source of capital in international equity markets. This paper provides an empirical analysis of the pricing of these funds in the context of rational asset-pricing models. The paper finds that differential risk exposures, market segmentation, and time-varying risk premiums play important roles in the differential pricing of the share prices and NAVs. Based on the unconditional international CAPM, the existence of premiums can be attributed to different risk exposures, as is the case with developed market funds and differential pricing of the shares and NAVs, as is the case with emerging market funds and some developed market funds.

The paper also analyzes the pricing of country funds when conditioning information is allowed. The results indicate that, for alternate stochastic discount factors, for majority of the funds, the pricing of country fund shares and NAVs is consistent with the conditional international CAPM. However, tests of the estimated stochastic discount factors indicate that, for a subset of the developed market funds and all the Asian funds, closed-end country fund share prices and NAVs are priced differently. This result indicates that the international capital markets are not fully integrated. Finally, this paper shows that the premiums on country funds vary over time because of time variation in expected returns.

The findings in this paper have several possible extensions. The focus of the paper has been on rational explanations for country fund premiums based on differential risk exposures and market segmentation effects. It will be interesting to extend this analysis and examine the effect of other factors such as taxes, numeraires, liquidity, and bid-ask spreads.

Appendix 1: Generalized Method of Moments (GMM)

GMM is an econometric method that was a generalization of the method of moments developed by Hansen (1982). The moment conditions are derived from the model. Suppose Y_t is a multivariate independently and identically distributed (i.i.d) random variable. The econometric model specifies the relationship between Z_t and the true parameters of the model (θ_0). To use GMM there must exist a function $g(Z_t, \theta_0)$ so that

$$m(\theta_0) \equiv E[g(Z_t, \theta_0)] = 0 \tag{25.19}$$

In GMM, the theoretical expectations are replaced by sample analogs:

$$f(\theta, Z_t) = 1/T \sum g(Z_t, \theta). \tag{25.20}$$

The law of large numbers ensures that the RHS of above equation is the same as

$$E[f(Z_t, \theta_0)]. \tag{25.21}$$

Results from an OLS regression of premiums on country funds on the difference between the time-varying betas on the world market index. The t-statistics robust to heteroskedasticity are presented in the parenthesis. An asterisk (*) denotes significance at the 5 % level of significance. The regression estimated is of the form

$$\mathrm{Prem}_{t+1} = \gamma_0 + \gamma_1[\beta_{n,w}(Z_t) - \beta_{p,w}(Z_t)] + e_{prem,t+1}$$

The time-varying betas are estimated using the conditional international CAPM for an index of developed and emerging market funds price and NAV returns, using the equations

$$r_{a,t+1} = \alpha_a + \beta_{a,w} r_{w,t+1} + \sum_i \gamma_{a,i}\left(r_{w,t+1} * z_t\right) + e_{a,t+1} \quad a = p \text{ and } n$$

where $r_{p,t+1}$ is the excess return on the share price and $r_{n,t+1}$ is the excess NAV return and Prem $_{t+1}$ is the premium for the time period January 1991–August 1995. $r_{w,t+1}$ is the excess return on the world market index and Z_t is a set of instrumental variables DIVY and TED

The sample GMM estimator of the parameters may be written as (see Hansen 1982)

$$\Theta = \arg\min \left[1/T \sum g(Z_t, \theta)\right]' W_T 1/T \sum g(Z_t, \theta)\Big] \tag{25.22}$$

So essentially GMM finds the values of the parameters so that the sample moment conditions are satisfied as closely as possible. In our case for the regression model,

$$y_t = X_t{}'\beta + \varepsilon_t \tag{25.23}$$

The moment conditions include

$$E[(y_t - X_t{}'\beta)x_t] = E[\varepsilon_t x_t] = 0 \text{ for all t} \tag{25.24}$$

So the sample moment condition is

$$1/T \sum (y_t - X_t{}'\beta)x_t$$

and we want to select β so that this is as close to zero as possible. If we select β as $(X'X)^{-1}(X'y)$, which is the OLS estimator, the moment condition is exactly satisfied. Thus, the GMM estimator reduces to the OLS estimator and this is what we estimate. For our case the instruments used are the same as the independent variables. If, however, there are more moment conditions than the parameters, the GMM estimator above weighs them. These are discussed in detail in Greene (2008, Chap. 15). The GMM estimator has the asymptotic variance

$$\left(X'Z\,(Z'\Omega Z)^{-1}Z'X\right)^{-1} \tag{25.25}$$

The White robust covariance matrix may be used for Ω as discussed in appendix C when heteroskedasticity is present. Using this approach, we estimate GMM with White heteroskedasticity consistent t-stats.

A Comparison of Portfolios Using Different Risk Measurements

26

Jing Rung Yu, Yu Chuan Hsu, and Si Rou Lim

Contents

Abstract

In order to find out which risk measurement is the best indicator of efficiency in a portfolio, this study considers three different risk measurements: the mean-variance model, the mean absolute deviation model, and the downside risk model. Meanwhile short selling is also taken into account since it is an important

strategy that can bring a portfolio much closer to the efficient frontier by improving a portfolio's risk-return trade-off. Therefore, six portfolio rebalancing models, including the MV model, MAD model, and the downside risk model, with/without short selling, are compared to determine which is the most efficient. All models simultaneously consider the criteria of return and risk measurement. Meanwhile, when short selling is allowed, models also consider minimizing the proportion of short selling. Therefore, multiple objective programming is employed to transform multiple objectives into a single objective in order to obtain a compromising solution. An example is used to perform simulation, and the results indicate that the MAD model, incorporated with a short selling model, has the highest market value and lowest risk.

Keywords

Portfolio selection • Risk measurement • Short selling • MV model • MAD model • Downside risk model • Multiple objective programming • Rebalancing model • Value-at-risk • Conditional value-at-risk

26.1 Introduction

Determining how to maximize the profit and minimize the risk of a portfolio is an important issue in portfolio selection. The mean-variance (MV) model of portfolio selection is based on the assumptions that investors are risk averse and the return of assets is normally distributed (Markowitz 1952). This model is regarded as the basis of modern portfolio theory (Deng et al. 2005).

However, the MV model is limited in that it only leads to optimal decisions if the investor's utility functions are quadratic or if investment returns are jointly elliptically distributed (Grootveld and Hallerbach 1999; Papahristoulou and Dotzauer 2004). Thus, numerous researches have focused on risk, return, and diversification in the development of investment strategies. Also, a large number of researches have been proposed to improve the performance of investment portfolios (Deng et al. 2000; Yu and Lee 2011).

Konno and Yamazaki (1991) proposed a linear mean absolute deviation (MAD) portfolio optimization model. The MAD model replaces the variance of objective function in the MV model with the mean absolute deviation. The major advantage of the MAD model is that the estimation of the covariance matrix of asset returns is not needed. Also, it is much easier to solve large-scale problems with linear programming than with quadratic approaches (Simaan 1997).

Portfolio selection under shortfall constraints originated from Roy's (1952) safety-first theory. Economists have found that investors care about downside losses more than they care about upside gains. Therefore, Markowitz (1959) suggested using semi-variance as a measure of risk, instead of variance, because semi-variance measures downside losses rather than upside gains. The use of downside risk (DSR) measures is proposed due to the problems encountered in using a conventional mean-variance analysis approach in the presence of non-normality in the emerging market data. Unlike the mean-variance framework, the downside risk measure does not assume that the return distributions of assets are normal. In addition, the increasing emphasis of investors on limiting losses might make the downside risk measure more intuitively appealing (Stevenson 2001; Ang et al. 2006). The downside risk measure can help investors make proper decisions when returns are non-normally distributed, especially for emerging market data or for an international portfolio selection (Vercher et al. 2007).

Another type of shortfall constraint is value-at-risk (VaR), which is a percentile-based metric system for risk measurement purposes (Jorion 1996). It is defined as the maximum loss that a portfolio can suffer at a given level of confidence and at a given horizon (Fusai and Luciano 2001). However, VaR is too weak to handle the situation when losses are not "normally" distributed, as loss distribution tends to exhibit "fat tail" or empirical discreteness. Conditional value-at-risk (CVaR) is an alternative measure that quantifies losses that might be encountered in the tail of loss distribution (Rockafellar and Uryasev 2002; Topaloglou et al. 2002). A confidence level is required when employing the measurements of VaR and CVaR. The allocation of a portfolio varies with the varying confidence level. Therefore, neither measure is included for comparison in this chapter.

Generally, short selling has good potential to improve a portfolio's risk-return trade-off (White 1990; Kwan 1997) and is considered by most investors to obtain interest arbitrage; however, it comes with high risk (Angel et al. 2003). Since high risks should be avoided, the role of short selling is minimized in this chapter. Instead, three kinds of portfolio models with and without short selling are compared.

Section 26.2 introduces the mean-variance, mean absolute, and downside risk models. In Sect. 26.3, the rebalancing models with/without short selling are proposed. In Sect. 26.4, the performances of three different risk measurements with/without short selling are compared by using the historical data of 45 stocks listed in the TSE50 index. Finally, Sect. 26.5 presents the conclusions along with suggestions for future research.

26.2 Portfolio Selection Models

In this section, the mean-variance, the mean absolute deviation, and the downside risk models are introduced separately. First, the notations are defined as follows:
n is the number of available securities.
w_i is the investment portion in securities i for $i = 1, \ldots, n$.
r_i is the return on securities i.
μ is the expected portfolio return.
${\sigma_i}^2$ is the variance of the return on securities i.
${\sigma_{ij}}^2$ is the covariance between the returns of securities i and j.
r_{it} is the return on securities i in period t for $t = 1, \ldots, T$, which is assumed to be available through historical data.
R_i is equal to $\frac{1}{T}\sum_{t=1}^{T} r_{it}$.
d_t is the deviation between the return and the average return.

26.2.1 The Mean-Variance Model (MV)

The MV model uses the variance of the return as the measure of risk and formulates the portfolio optimization problem as the following quadratic programming problem (Markowitz 1952):

$$\begin{aligned} &\text{Min } \sigma_p = \sum_{i=1}^{n} w_i^2 \sigma_i^2 + \sum_{i=1}^{n} \sum_{j=1(i \neq j)}^{n} \sigma_{ij} w_i w_j \\ &\text{s.t. } \sum_{i=1}^{n} r_i w_i \geq \mu, \end{aligned} \tag{26.1}$$

$$\sum_{i=1}^{n} w_i = 1, \tag{26.2}$$

$$w_i \geq 0, \tag{26.3}$$

for $i = 1, \ldots, n$.

Constraint (26.1) expresses the requirements μ of a portfolio return, and constraint (26.2) is the budget constraint. The model is known to be valid if an investor is risk averse in the sense that he prefers less standard deviation of the portfolio rather than more. Since $w_i \geq 0$, a short sale is not allowed here.

26.2.2 The Mean Absolute Deviation Model (MAD)

The mean-variance model is weak in constructing a large-scale portfolio due to the computational difficulty associated with solving a large-scale quadratic programming problem with a dense covariance matrix. The MAD model (Konno and Yamazaki 1991) replaces the variance in the objective function of the MV model with the mean absolute deviation as follows:

$$\text{Min } \frac{1}{T} \sum_{t=1}^{T} \left| \sum_{i=1}^{n} (r_{it} - R_i) w_i \right|$$

s.t. Constraints (26.1) $\sim$ (26.3).

Because of the absolute deviation, the MAD model can be linearized as following (Chang 2005):

$$\text{Min } \frac{1}{T} \sum_{t=1}^{T} d_t$$

s.t. Constraints (26.1) $\sim$ (26.3),

$$d_t + \sum_{i=1}^{n} (r_{it} - R_i)w_i \geq 0,\ t = 1, \ldots, \mathrm{T}, \tag{26.4}$$

$$d_t - \sum_{i=1}^{n} (r_{it} - R_i)w_i \geq 0,\ \ t = 1, \ldots, \mathrm{T}. \tag{26.5}$$

If the return is lower than the average return, constraint (26.4) is a binding constraint which means $d_t = -\sum_{i=1}^{n} (r_{it} - R_i)w_i$ for $t = 1, \ldots, T$. Otherwise, constraint (26.5) is a binding constraint which means $d_t = \sum_{i=1}^{n} (r_{it} - R_i)w_i$ for $t = 1, \ldots, T$. For more details on the reformulation, please refer to Appendix 1.

Apparently, the MAD model does not require the covariance matrix of asset returns, and consequently its estimation is not needed. Large-scale problems can be solved faster and more efficiently because the MAD model has a linear rather than quadratic nature.

26.2.3 The Downside Risk Model

Vercher et al. (2007) consider the equivalent formulation of the portfolio selection problem (Speranza 1993) and reformulate the following linear optimization model by considering downside risk measurement:

$$\mathrm{Min}\ \frac{1}{T}\sum_{t=1}^{T} d_t^-$$

s.t. Constraints (26.1) $\sim$ (26.3),

$$d_t^- + \sum_{i=1}^{n} (r_{it} - R_i)w_i \geq 0,\ t = 1, \ldots, T \tag{26.6}$$

where $d_t = d_t^+ + d_t^-,\ d_t^+,\ d_t^- \geq 0$.

Downside risk measurement focuses on returns falling below some critical level (Grootveld and Hallerbach 1999). Differing from the MAD model, the downside risk model ignores constraint (26.5). If the return is lower than the average return, constraint (26.6) is a binding constraint. Please refer to Appendix 2 for more details.

26.3 The Proposed Model

Multiple period portfolio selection models with rebalancing mechanisms have become attractive in the financial field in order to get desired returns in situations that are subject to future changes (Yu et al. 2010). To reflect a changing situation in the models, the rebalancing mechanism is adopted for multiple periods (Yu and Lee 2011).

Six rebalancing models are introduced. These are MV, MAD, DSR, MV_S, MAD_S, and DSR_S. The first three models lack short selling, and the other three have short selling. The model notations are denoted as follows: $w_{i,0}^{+}$ is the weight of security i held in the previous period, $w_{i,0}^{-}$ is the weight of securities i sold short in the previous period, w_i^{+} is the total weight of securities i bought after rebalancing, and w_i^{-} is the total weight of securities i sold short after rebalancing.

With each rebalancing, l_i^{+} is the weight of securities i bought in this period, l_i^{-} is the weight of securities i sold in this period, s_i^{+} is the weight of securities i sold short in this period, s_i^{-} is the weight of securities i repurchased in this period, u_i is the binary variable that indicates whether the securities i are selected for buying, v_i is the binary variable that indicates whether the securities i are selected for selling short, and k is the initial margin requirement for short selling.

26.3.1 The MV Model

The conventional MV model can be regarded as a bi-objective model without short selling, whose objective functions are the maximization of portfolio return and minimization of portfolio risk, as measured by the portfolio variance:

$$\text{Max} \sum_{i=1}^{n} R_i w_i$$

$$\text{Min}\, \sigma_p$$

s.t. Constraint (26.2),

$$w_i = w_{i,0}^{+} + \ell_i^{+} - \ell_i^{-}, \tag{26.7}$$

$$0.05u_i \le w_i \le 0.2u_i, \tag{26.8}$$

for $i = 1, 2, \ldots, n$.

Constraint (26.7) is the rebalancing constraint; it shows the current weight for the ith security according to the previous period. Constraint (26.8) is the required range of weights for each security in buying. For simplexity, the upper and lower bounds of each weight are set 0.2 and 0.05, respectively.

26.3.2 The MAD Model

The objectives of the MAD model include the maximization of return and minimization of the mean absolute deviation, which is transformed into a linear deviation as follows:

$$\text{Max} \sum_{i=1}^{n} R_i w_i$$

$$\text{Min}\ \frac{1}{T}\sum_{t=1}^{T} d_t$$

s.t. Constraints (26.2) ~ (26.5), (26.7), (26.8).

26.3.3 The DSR Model

The DSR model considers the objectives of maximizing the return and minimizing the downside risk, which is transformed into a linear risk as follows:

$$\text{Max}\sum_{i=1}^{n} R_i w_i$$

$$\text{Min}\frac{1}{T}\sum_{t=1}^{T} d_t^-$$

s.t. Constraints (26.2), (26.3), (26.6), (26.7), (26.8).

When short selling is allowed, the above three models are reformulated as follows (Yu and Lee 2011):

26.3.4 The MV_S Model

$$\text{Max}\sum_{i=1}^{n} R_i\left(w_i^+ - w_i^-\right)$$

$$\text{Min}\,\sigma_p$$

$$\text{Min}\sum_{i=1}^{n} w_i^-$$

$$\text{s.t.}\ \sum_{i=1}^{n}\left(w_i^+ + k w_i^-\right) = 1, \tag{26.9}$$

$$w_i^+ = w_{i,0}^+ + \ell_i^+ - \ell_i^-, \tag{26.10}$$

$$w_i^- = w_{i,0}^- + s_i^+ - s_i^-, \tag{26.11}$$

$$0.05u_i \le w_i^+ \le 0.2u_i, \tag{26.12}$$

$$0.05v_i \leq w_i^- \leq 0.2v_i, \tag{26.13}$$

$$u_i + v_i = y_i, \tag{26.14}$$

for $i = 1, 2, \ldots, n$.

Unlike the MV model, the MV_S model has an extra objective, namely, minimizing the short selling proportion. The total budget is including the cost of buying and short selling as shown in constraint (26.9). k is the initial margin requirement for short selling. Constraint (26.10) indicates the current weight for the ith securities based on the previous period. Constraint (26.11) indicates the current short selling proportion of the ith security adjusted by the previous period. Constraints (26.12) and (26.13) limit the upper and lower bounds, respectively, of the long and short selling proportion for the ith security.

26.3.5 The MAD_S Model

Based on the MAD model (Konno and Yamazaki 1991), the MAD_S model replaces the objective function of minimizing the variance in the MV_S model (Yu and Lee 2011) with the objective of minimizing the absolute deviation of average return, as follows:

$$\text{Min} \sum_{i=1}^{n} \left(\left| \left(w_i^+ - w_i^-\right) r_{it} - \left(w_i^+ - w_i^-\right) R_i \right| \right)$$

The objective of the mean absolute deviation can be transformed into a linear problem:

$$\text{Min} \frac{1}{T} \sum_{t=1}^{T} d_t$$

$$\text{s.t. } d_t + \sum_{i=1}^{n} \left(w_i^+ - w_i^-\right) r_{it} - \left(w_i^+ - w_i^-\right) R_i \geq 0, \tag{26.15}$$

$$d_t - \sum_{i=1}^{n} \left(w_i^+ - w_i^-\right) r_{it} - \left(w_i^+ - w_i^-\right) R_i \geq 0, \tag{26.16}$$

for $t = 1, \ldots, T$.

The following is the MAD_S model:

$$\text{Max} \sum_{i=1}^{n} R_i \left(w_i^+ - w_i^-\right)$$

$$\text{Min}\ \frac{1}{T}\sum_{t=1}^{T} d_t$$

$$\text{Min}\sum_{i=1}^{n} w_i^-$$

s.t. Constraints (26.9) $\sim$ (26.16).

26.3.6 The DSR_S Model

The DSR_S model focuses on the deviation when the return falls below the average return, as follows:

$$\text{Max}\sum_{i=1}^{n} R_i\left(w_i^+ - w_i^-\right)$$

$$\text{Min}\ \frac{1}{T}\sum_{t=1}^{T} d_t^-$$

$$\text{Min}\sum_{i=1}^{n} w_i^-$$

s.t. Constraints (26.9) $\sim$ (26.14),

$$d_t^- + \sum_{i=1}^{n}\left(w_i^+ - w_i^-\right)r_{it} - \left(w_i^+ - w_i^-\right)R_i \geq 0, \tag{26.17}$$

for $t = 1, \ldots, T$.

Apparently, all six models have multiple objectives. Therefore, multiple objective programming (Zimmermann 1978, and Lee and Li 1993) is adopted to transform the multiple objectives into a single objective. For more details, please refer to Appendix 3. Taking the MAD_S model as an example, we can reformulate the multiple objectives as follows:

$$\begin{aligned}&\text{Max}\ \lambda\\ &\text{s.t.}\ \ \lambda \leq \frac{(r^* - r_l)}{\left(r_g - r_l\right)},\end{aligned} \tag{26.18}$$

$$\lambda \leq \frac{(\sigma^* - \sigma_l)}{\left(\sigma_g - \sigma_l\right)}, \tag{26.19}$$

$$\lambda \leq \frac{\left(w^{*} - w_{l}^{-}\right)}{\left(w_{g}^{-} - w_{l}^{-}\right)}, \tag{26.20}$$

$$r^{*} = \sum_{i=1}^{n} R_{i}\left(w_{i}^{+} - w_{i}^{-}\right), \tag{26.21}$$

$$\sigma^{*} = \frac{1}{T}\sum_{t=1}^{T} d_{t}^{-}, \tag{26.22}$$

$$w^{-*} = \sum_{i=1}^{n} w_{i}^{-}, \tag{26.23}$$

Constraints (26.9) $\sim$ (26.16).

For multiple objective programming (Lee and Li 1993), r^* is the return of the portfolio, r_l is the anti-ideal return of the portfolio, r_g is the ideal return of the portfolio that maximizes the objective, σ^* is the inherent risk of the portfolio, σ_l is the anti-ideal risk of the portfolio, σ_g is the ideal risk of the portfolio, w^{-*} is the short selling proportion of the portfolio, w_l is the anti-ideal short selling proportion of the portfolio, and w_g^- is the ideal short selling proportion of the portfolio. The constraints (26.18–26.20) are the achievements for maximizing the return, minimizing the absolute deviation and objectives minimizing the short selling problem of the corresponding portfolio, which are less than or equal to the whole achievement (λ). The whole achievement (λ) should be maximized.

In the same way, the other five multiple objective models can be reformulated in turn as a single-objective model. The details of the transformation are introduced in Appendix 3.

26.4 Experimental Results

Forty-five stocks listed on the Taiwan Stock Exchange were adopted and used to compare the six models discussed above in order to determine which one is the best. The benchmark is the Taiwan 50 Index (TSE50).

The exchange codes of the 45 stocks are listed in Table 26.1. The duration of the analyzed data is from November 1, 2006, to November 24, 2009. The historical data of the first 60 transaction days are used to build the initial models. For the monthly updates, 20 transaction days are set as a sliding window. This study assumes a budget of \$1 million NTD is invested in the Taiwan Stock Market. For investments based on the weights generated by the initial models, the first transaction day is January 25, 2007, and there are 34 rebalancing times in total. The models are executed on an Intel Pentium Dual CPU E2200 2.20GHz and 2G RAM computer, with Lingo11.0, an optimizing software.

From Table 26.2, it is apparent that the MAD and DSR models are more efficient than the MV model because they both use linear transformation for problem solving. This is much faster and more efficient when handling a large-scale

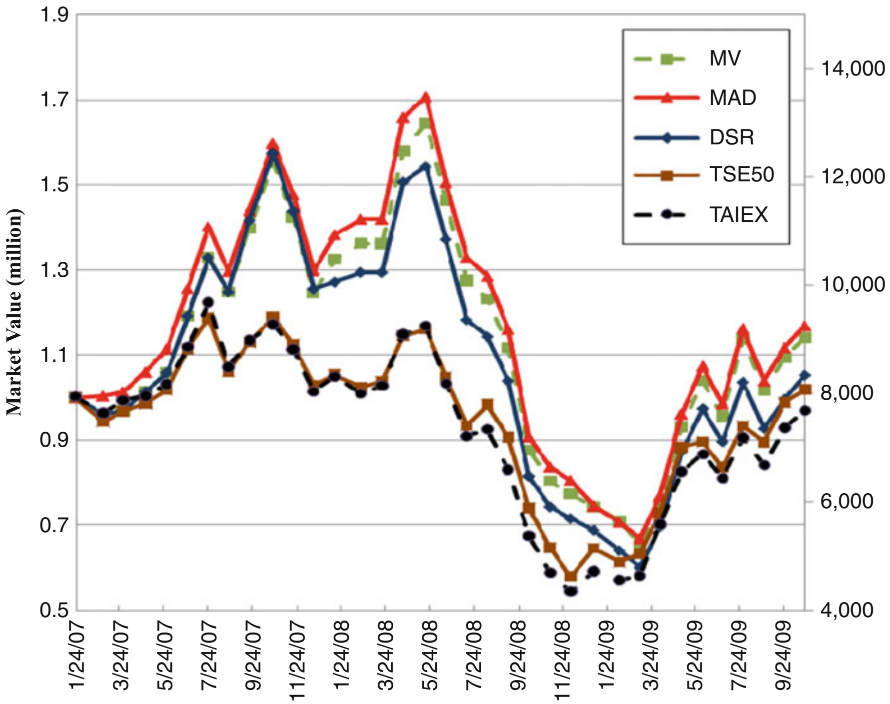

Fig. 26.1 The market value of three risk measurements without short selling, the TSE50, and TAIEX

problem. As one can see in Table 26.2, the MV model takes 9 min and 6 sec to compute the result. However, the MAD and DSR models only take 1 min or slightly more to solve the same data. Moreover, it is not necessary to calculate the covariance matrix to set up the MAD and DSR models; this makes it very easy to update the models when new data are added (Konno and Yamazaki 1991).

Figures 26.1, 26.2 and 26.3 show the comparisons of the MV, MAD, and DSR models, respectively. These are the models without short selling. Figures 26.4, 26.5 and 26.6 show the comparisons of the MV_S, MAD_S, and DSR_S models, respectively. These are the models with short selling. The TSE50 is used as the benchmark to these models. As shown in Fig. 26.1, the market value of the MAD

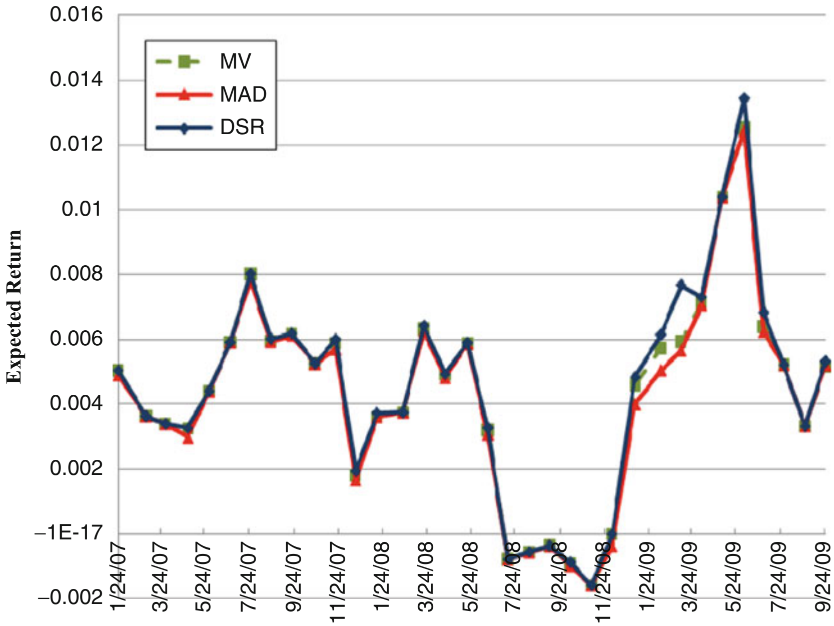

Fig. 26.2 The expected return of three risk measurements without short selling

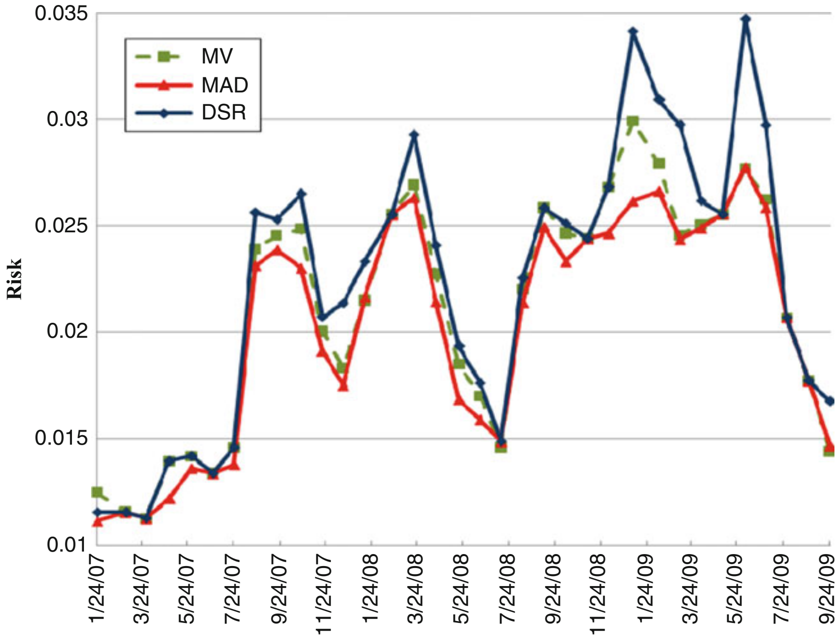

Fig. 26.3 The risk of three risk measurements without short selling

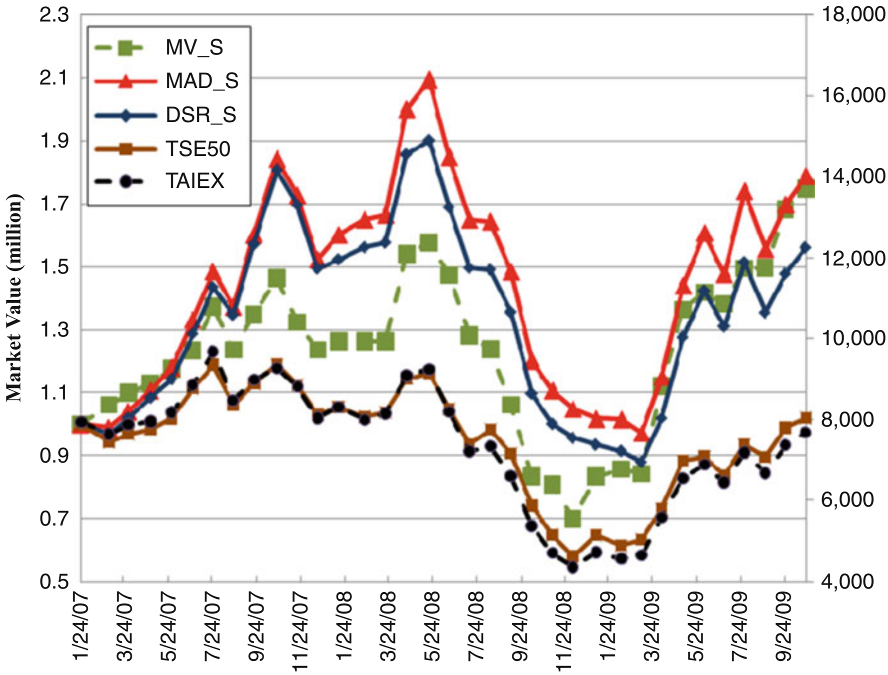

Fig. 26.4 The market value of three risk measurements with short selling, the TSE50, and TAIEX

model is always greater than that of the other models and the benchmark. Figures 26.2 and 26.3 display the expected return and risk of the portfolios constructed with three risk measurements without short selling. Figure 26.2 shows that the expected returns of these three portfolios are almost the same. However, Fig. 26.3 shows that the MAD model has the lowest risk under a similar expected return to that of the others. Especially, in January 24, 2009, the risk in the MAD model was much lower than in the other two models.

Downside risk measurement is applied when investors only take the negative return into consideration and focus on the loss of investment. In other words, their concern is with the real loss, not with the positive deviation of the average return in portfolios. Therefore, in Fig. 26.3, the risk generated by the DSR model is always higher than other measurements.

In Fig. 26.4, the market value of the MV_S, MAD_S, and DSR_S models is compared. Since these models take short selling into consideration, the portfolio selection is more flexible, and the risk is much lower, as Fig. 26.6 shows. Under the same expected return, the MAD_S model has the lowest risk among the three models, using the mean absolute deviation risk measure. Figure 26.4 shows that it also has the highest market value. Even though the market value of each model is increased after short selling is allowed, the market value of the MAD_S model is always higher than the other models and the benchmark. Evidently, the MAD model is suggested for use as the best risk measurement tool with or without short sell.

26.5 Conclusion

This chapter compares six different rebalancing models, with/without short selling, in order to determine which is more flexible for portfolio selection. One of the advantages of the MAD and DSR models is that they can be linearized; thus, they are faster and more efficient than the MV model, especially with large-scale problems.

The experimental results indicate that the MAD and MAD_S models are efficient in handling data and show higher market value than the other models; moreover, they have lower risks in situations with/without short selling.

However, there remain important risk measurements, such as VaR and CVaR, for future research to investigate. Thus, future studies may focus on developing rebalancing models with the measures of VaR and CVaR. Since the rebalancing period is fixed, the dynamic rebalancing mechanism is required for the first change environment. In addition, a portfolio selection model able to predict future returns is required.

Appendix 1

The Linearization of the MAD Model

Konno and Yamazaki (1991) assume that r_{it} is the realization of random variable r_i during period t ($t = 1, \ldots, T$), and $R_i = \frac{1}{T}\sum_{i=1}^{n} r_{it}$.

The MAD model is as follows:

$$\begin{aligned} &\text{Max } \frac{1}{T}\sum_{t=1}^{T}\left|\sum_{i=1}^{n}(r_{it}-R_i)w_i\right| \\ &\text{s.t.} \sum_{i=1}^{n} R_i x_i \geq \mu, \\ &\sum_{i=1}^{n} w_i = 1, \\ &w_i \geq 0, \end{aligned}$$

for $i = 1, \ldots, n$.

$$\text{Let}\left|\sum_{i=1}^{n}(r_{it}-R_i)w_i\right| = d_t = {d_t}^{+} + {d_t}^{-},$$

$${d_t}^{+}\text{and } {d_t}^{-} \geq 0,$$

$$\text{then}\sum_{i=1}^{n}(r_{it}-R_i)w_i = {d_t}^{+} - {d_t}^{-},$$

$$d_t - d_t^- = \sum_{i=1}^{n} (r_{it} - R_i) w_i + d_t^-,$$

$$d_t^- = \frac{1}{2}\left(d_t - \sum_{i=1}^{n} (r_{it} - R_i) w_i\right) \geq 0.$$

$$2d_t^- = d_t - \sum_{i=1}^{n} (r_{it} - R_i) w_i.$$

Similarity, perform the same process,

$$d_t^+ = \sum_{i=1}^{n} (r_{it} - R_i) w_i + d_t^-,$$

$$d_t - d_t^+ = -\sum_{i=1}^{n} (r_{it} - R_i) w_i + d_t^+,$$

$$2d_t^+ = -\sum_{i=1}^{n} (r_{it} - R_i) w_i + d_t,$$

$$d_t^+ = \frac{1}{2}\left(\sum_{i=1}^{n} (r_{it} - R_i) w_i + d_t\right) \geq 0,$$

$$d_t^+, d_t^- \geq 0.$$

Two constraints are added because d_t^+, $d_t^- \geq 0$.
Then the model can be transformed into a linear model as follows:

$$\text{Min}\ \frac{1}{T}\sum_{t=1}^{T}\left|\sum_{i=1}^{n} (r_{it} - R_i) w_i\right| = \frac{1}{T}\sum_{t=1}^{T} d_t^+ + d_t^-$$

$$d_t^+ = \frac{1}{2}\left(\sum_{i=1}^{n} (r_{it} - R_i) w_i + d_t\right) \geq 0,$$

$$\Rightarrow \sum_{i=1}^{n} (r_{it} - R_i) w_i + d_t \geq 0.$$

$$d_t^{-} = \frac{1}{2}\left(-\sum_{i=1}^{n}(r_{it} - R_i)w_i + d_t\right) \geq 0,$$

$$\Rightarrow -\sum_{i=1}^{n}(r_{it} - R_i)w_i + d_t \geq 0.$$

where $d_t = d_t^{+} + d_t^{-}$.

Therefore, the MAD model can be linearized as the following linear model:

$$\begin{aligned}
&\text{Min } \frac{1}{T}\sum_{t=1}^{T} d_t \\
&\text{s.t. } d_t + \sum_{i=1}^{n}(r_{it} - R_i)w_i \geq 0, t = 1, \ldots, T, \\
&d_t - \sum_{i=1}^{n}(r_{it} - R_i)w_i \geq 0, t = 1, \ldots, T, \\
&\sum_{i=1}^{n} R_i x_i \geq \mu, \\
&\sum_{i=1}^{n} w_i = 1, \\
&w_i \geq 0,
\end{aligned}$$

for $i = 1, \ldots, n$.

Appendix 2

The Linearization of the DSR Model

The use of variance as a measure of risk makes no distinction between gains and losses. The following mean semi-absolute deviation risk measurement proposed by Speranza (1993) is used to find the portfolios with minimum semi-variance:

$$\text{Min } \frac{\frac{1}{T}\sum_{t=1}^{T}\left|\sum_{i=1}^{n}(r_{it} - R_i)w_i\right| - \sum_{i=1}^{n}(r_{it} - R_i)w_i}{2}$$

$$\text{s.t.} \sum_{i=1}^{n} R_i x_i \geq \mu,$$

$$\sum_{i=1}^{n} w_i = 1,$$

$$w_i \geq 0,$$

for $i = 1, \ldots n$.

Because of the absolute deviation, $\left|\sum_{i=1}^{n} (r_{it} - R_i) w_i\right|$ of the DSR model can be linearized in the same manner as the MAD model:

$$\sum_{i=1}^{n} (r_{it} - R_i) w_i = d_t{}^{+} - d_t{}^{-}$$

$$\frac{\left|\sum_{i=1}^{n} (r_{it} - R_i) w_i\right| - \sum_{i=1}^{n} (r_{it} - R_i) w_i}{2} = \frac{d_t{}^{+} + d_t{}^{-} - d_t{}^{+} + d_t{}^{-}}{2} = d_t{}^{-}$$

$$d_t{}^{+} = \frac{1}{2}\left(\sum_{i=1}^{n} (r_{it} - R_i) w_i + d_t\right) \geq 0,$$

$$d_t{}^{-} \geq 0.$$

Then the DSR model is reformulated as follows:

$$\text{Min} \frac{1}{T} \sum_{t=1}^{T} d_t^{-}$$

$$\text{s.t.} \sum_{i=1}^{n} R_i x_i \geq \mu,$$

$$\sum_{i=1}^{n} w_i = 1,$$

$$w_i \geq 0,$$

$$d_t^{-} + \sum_{i=1}^{n} (r_{it} - R_i) w_i \geq 0, t = 1, \ldots, T,$$

$$d_t{}^{-} \geq 0, t = 1, \ldots, T,$$

for $i = 1, \ldots, n$.

Appendix 3

Multiple Objective Programming

The aforementioned multiple objective models in Sect. 26.3 are solved by fuzzy multiple objective programming (Zimmermann 1978; Lee and Li 1993) in order to transform the multiple objective model into a single-objective model. Fuzzy multiple objective programming based on the concept of fuzzy set uses a min operator to calculate the membership function value of the aspiration level, λ, for all of the objectives.

The following is a multiple objective programming problem (Lee and Li 1993):

$$\mathrm{Max}\, Z = [Z_1, Z_2, \ldots, Z_l]^T = [c_1 x, c_2 x, \ldots, c_l x]^T$$

$$\mathrm{Min}\, W = [W_1, W_2, \ldots, W_l]^T = [q_1 x, q_2 x, \ldots, q_l x]^T$$

$$\text{s.t. } Ax^* b,$$

$$x \geq 0,$$

where C_k, $k = 1, 2, \ldots, l$, c_s, $s = 1, 2, \ldots, r$, and x are n-dimensional vectors; b is an m-dimensional vector; A is an $m \times n$ matrix; and * denotes the operators $\leq$, $=$, or $\geq$ The program aimed to achieve its maximization of the achievement level for each objective while also considering a trade-off among the conflicting objectives or criteria. The ideal and anti-ideal solutions must be obtained in advance. This ideal solution and anti- ideal solutions are given by the decision maker, respectively, as follows:

$$I^+ = \left(Z_1^*, Z_2^*, \ldots, Z_l^*; W_1^*, W_2^*, \ldots, W_l^*\right),$$

$$I^- = \left(Z_1^-, Z_2^-, \ldots, Z_r^-; W_1^-, W_2^-, \ldots, W_r^-\right).$$

The membership (achievement) functions for the objectives are defined as follows:

$$\mu_k(Z_K) = \frac{Z_K(x) - Z_k^-}{Z_k^* - Z_k^-}, k = 1, 2, \ldots, l,$$

$$\mu_s(Z_s) = \frac{W_s^- - W_s(x)}{W_s^- - W_s^*}, s = 1, 2, \ldots, r.$$

Then the "min" operator is used; the multiple objective programming is formulated as follows:

$$
\begin{aligned}
&\text{Max } \lambda \\
&\text{s.t. } \lambda \leq \left(Z_K(x) - Z_k^-\right)/\left(Z_k^* - Z_k^-\right), k = 1, 2, \ldots, l, \\
&\qquad \lambda \leq \left(W_s^- - W_s(x)\right)/\left(W_s^- - W_s^*\right), s = 1, 2, \ldots, r, \\
&\qquad x \in X,
\end{aligned}
$$

where λ is defined as $\lambda = \min_i \mu(x) = \min_{k,s} \left(\mu_k(Z), \mu_s(W_s)\right)$.

in Taiwan have requested the banks to estimate the default probability of the loan based on its credit classification. A proper forecasting procedure for credit rating of the loan is crucially important in abiding the rule.

Credit rating is an ordinal scale from which the credit category of a firm can be ranked from high to low, but the scale of the difference between them is unknown. To model the ordinal outcomes, this study first constitutes an attempt utilizing the ordered logit and the ordered probit models, respectively. Then, we use ordered logit combining method to weigh different techniques' probability measures as described in Kamstra and Kennedy (*International Journal of Forecasting 14*, 83–93, 1998) to form the combining model.

The samples consist of firms in the TSE and the OTC market and are divided into three industries for analysis. We consider financial variables, *market* variables, as well as macroeconomic variables and estimate their parameters for out-of-sample tests. By means of cumulative accuracy profile, the receiver operating characteristics, and McFadden R^2, we measure the goodness-of-fit and the accuracy of each prediction model. The performance evaluations are conducted to compare the forecasting results, and we find that combining technique does improve the predictive power.

Bankruptcy prediction • Combining forecast • Credit rating • Credit risk • Credit risk index • Forecasting models • Logit regression • Ordered logit • Ordered probit • Probability density function

27.1 Introduction

This study explores the credit rating forecasting techniques for firms in Taiwan. We employ the ordered logit and the ordered probit models for rating classification and then a combining procedure to integrate both. We then examine empirically the performance of these alternative methods, in particular, whether the combining forecasting performs better than any individual method.

Credit rating forecasting has long time been very important for bond classification and loan analysis. In particular, under the Basel II environment, regulators in Taiwan have requested the banks to estimate the default probability of the loan based on its credit classification. A proper forecasting procedure for credit rating of the loan is crucially important in abiding the rule.

Different forecasting models and estimation procedures have various underlying assumptions and computational complexities. They have been used extensively by researchers in the literature. Review papers like Hand and Henley (1997), Altman and Sounders (1997), and Crouhy et al. (2000) have traced the developments of the credit classification and bankruptcy prediction models over the last two decades.

Since Beaver's (1966) pioneered work, there have been considerable researches on the subject of the credit risk. Many of them (Altman 1968; Pinches and Mingo 1973; Altman and Katz 1976; Altman et al. 1977; Pompe and Bilderbeek 2005) use the multivariate discriminant analysis (MDA) which assumes normality for the explanatory variables of the default class. Zmijewski (1984) utilizes the probit model, and Ohlson (1980) applies the logit model in which discrete or continuous data can be fitted.

Kaplan and Urwitz (1979), Ederington (1985), Lawrence and Arshadi (1995), and Blume et al. (1998) show that it is a consistent structure considering credit rating as ordinal scale instead of interval scale. That is, the different values of the dependent variables as different classes represent an ordinal, but not necessarily a linear scale. For instance, higher ratings are less risky than lower ratings, but we don't have a quantitative measure indicating how much less risky they are.

Kaplan and Urwitz (1979) conduct an extensive examination of alternative prediction models including N-chotomous probit analysis which can explain the ordinal nature of bond ratings. To test the prediction accuracy of various statistical models, Ederington (1985) compares the linear regression, discriminant analysis, ordered probit, and unordered logit under the same condition. He concludes that the ordered probit can have the best prediction ability and the linear regression is the worst.

In a survey paper on forecasting methods, Mahmoud (1984) concludes that combining forecasts can improve accuracy. Granger (1989) summarizes the usefulness of combining forecasts. Clemen (1989) observes that combining forecasts increase accuracy, whether the forecasts are subjective, statistical, econometric, or by extrapolation. Kamstra and Kennedy (1998) integrate two approaches with logit-based forecast-combining method which is applicable to dichotomous, polychotomous, or ordered-polychotomous contexts.

In this paper, we apply the ordered logit and the ordered probit models in credit rating classification for listed firms in Taiwan and then combine two rating models with a logit regression technique. The performance of each model is then evaluated and we find that combining technique does improve the predictive power.

27.2 Methodology

27.2.1 Ordered Probit Model

Credit rating is an ordinal scale from which the credit category of a firm can be ranked from high to low, but the scale of the difference between them is unknown. To model the ordinal outcomes, let the underlying response function be

$$Y^* = X\beta + \varepsilon \tag{27.1}$$

where Y^* is the latent variable, X is a set of explanatory variables, and ε is the residual. Y^* is not observed, but from which we can classify the category j:

$$Y_i = j \qquad \text{if } \tau_{j-1} < Y_i^* \leq \tau_j \; (i = 1, 2, \ldots, n; \quad j = 1, 2, \ldots, J). \tag{27.2}$$

Maximum likelihood estimation can be used to estimate the parameters given a specific form of the residual distribution.

For the ordered probit model, ε is normally distributed with mean 0 and variance 1. The probability density function is

$$\phi(\varepsilon) = \frac{1}{\sqrt{2\pi}} \exp\left(-\frac{\varepsilon^2}{2}\right) \tag{27.3}$$

and the cumulative density function is

$$\Phi(\varepsilon) = \int_{-\infty}^{\varepsilon} \frac{1}{\sqrt{2\pi}} \exp\left(-\frac{t^2}{2}\right) dt. \tag{27.4}$$

27.2.2 Ordered Logit Model

For the ordered logit model, ε has a logistic distribution with mean 0 and variance $\pi^2/3$. The probability density function is

$$\lambda(\varepsilon) = \frac{\exp(\varepsilon)}{[1 + \exp(\varepsilon)]^2} \tag{27.5}$$

and the cumulative density function is

$$\Lambda(\varepsilon) = \frac{\exp(\varepsilon)}{1 + \exp(\varepsilon)}. \tag{27.6}$$

27.2.3 Combining Method

To combine the ordered logit and the ordered probit models for credit forecasting, the logit regression method as described in Kamstra and Kennedy (1998) is applied. We first assume that firm's credit classification is determined by an index θ. Suppose there are J rating classes, ordered from 1 to J. If θ exceeds the threshold value τ_j, $j = 1, \ldots, j - 1$, credit classification changes from j rating to $j + 1$ rating. The probability of company i being in rating j is given by the integral of a standard logit from $\tau_{j-1} - \theta_i$ to $\tau_j - \theta_i$.

Each forecasting method is considered as producing $J - 1$ measures $\omega_{ji} = \tau_j - \theta_i$, $j = 1, \ldots, j - 1$ for each firm. These measures can be estimated as

$$\omega_{ji} = \ln\left[\frac{P_{1i} + \cdots + P_{ji}}{1 - P_{1i} - \cdots - P_{ji}}\right] \tag{27.7}$$

Table 27.1 Sample numbers across the industry

Industry	Non-bankruptcy observations	Bankruptcy observations	Total
Panel A: *In-sample (2000.Q1 ~ 2004.Q4)*			
Traditional	3,993	509	4,502
Manufacturing	2,450	411	2,861
Electronics	8,854	191	9,045
Panel B: *Out-of-sample (2005.Q1 ~ 2005.Q3)*			
Traditional	629	63	692
Manufacturing	432	38	470
Electronics	1,990	72	2,062

where P_{ji} is a probability estimate for firm i in rating j. The combining method proposed by Kamstra and Kennedy (1998) consists of finding, via MLE, an appropriate weighted average of ω's in ordered logit and ordered probit techniques.[1]

To validate the model, we use cumulative accuracy profile (CAP) and its summary statistics, the accuracy ratio (AR). A concept similar to the CAP is the receiver operating characteristic (ROC) and its summary statistics, the area under the ROC curve (AUC). In addition, we also employ the McFadden's R^2 (pseudo R^2) to evaluate the performance of the credit rating model. McFadden's R^2 is defined as $1-$(unrestricted log-likelihood function/restricted log-likelihood function).

27.3 Empirical Results

Data are collected from the Taiwan Economic Journal (TEJ) database for the period between the first quarter in 2000 and the third quarter in 2005, with the last three quarters used for out-of-sample tests. The sample consists of firms traded in the Taiwan Security Exchange (TSE) and the OTC market.

The credit rating of the sample firms is determined by the Taiwan Corporate Credit Risk Index (the TCRI). Among ten credit ratings, 1–4 represent the investment grade levels, 5–6 represent the low-risk levels, and 7–9 represent the high-risk or speculative grade levels. The final rating, 10, represents the bankruptcy level.

Table 27.1 exhibits the descriptive statistics for the samples which are divided into three industry categories. Panel A contains the in-sample observations, while panel B shows the out-of-sample observations. There are 509 bankruptcy cases in the traditional industry, 411 in the manufacturing sector, and 191 in the electronics industry for in-sample data. For out-of-sample data, there are 63 in the traditional, 38 in the manufacturing, and 72 in the electronics industries, respectively. Table 27.2 displays the frequency distributions of the credit ratings for in-samples in these three industries.

[1]See Kamstra and Kennedy (1998) for the detail description.

Table 27.2 Frequency distributions of the credit ratings

Ratings	Traditional	Manufacturing	Electronics
1	10	3	156
2	47	71	259
3	151	62	252
4	380	294	1,066
5	921	321	2,343
6	1,044	559	2,736
7	645	465	1,272
8	459	338	490
9	336	337	280
10	509	411	191
Subtotal	4,502	2,861	9,045

Note: Level 10 represents the bankruptcy class

Bonfim (2009) finds that not only the firms' financial situation has a central role in explaining default probabilities, but also macroeconomic conditions are very important when assessing default probabilities over time. Based on previous studies in the literature, 62 explanatory variables including financial ratios, market conditions, and macroeconomic factors are considered. We use the hybrid stepwise method to find the best predictors in the ordered probit and ordered logit models. The combining technique using logit regression is then applied.

27.3.1 Model Estimates

27.3.1.1 Ordered Logit Model

Table 27.3 illustrates the in-sample estimation results under the ordered logit model for each industry. From the likelihood ratio, score ratio, and Wald ratio, with significant level at 1 %, we can determine the goodness-of-fit for each model.

For the traditional industry, the coefficients of Fixed Asset to Long Term Funds Ratio (Fixed Asset to Equity and Long Term Liability Ratio), Interest Expense to Sales Ratio, and Debt Ratio are positive. It shows that firms with higher ratios will get worse credit ratings as well as higher default probabilities. On the other hand, the coefficients of Accounts Receivable Turnover Ratio, Net Operating Profit Margin, Return on Total Assets (Ex-Tax, Interest Expense), Depreciation to Sales Ratio, Free Cash Flow to Total Debt Ratio, Capital Spending to Gross Fixed Assets Ratio, Retained Earning to Total Assets Ratio, and Ln (Total Assets/GNP price-level index) are negative so that firms tend to have good credit qualities as well as lower default probabilities when these ratios become higher. All these signs meet our expectation.

For the manufacturing industry, the coefficient of the dummy variable for the Negative Net Income for the last 2 years is positive, so the losses worsen the credit rating. On the other hand, the coefficients of Equity to Total Asset Ratio, Total Assets Turnover Ratio, Return on Total Assets (Ex-Tax, Interest Expense),

Table 27.3 Regression results estimated by the ordered logit. This table represents the regression results estimated by the ordered logit model. Panel A shows the 11 explanatory variables fitted in the traditional industry. Panel B shows the nine explanatory variables fitted in the manufacturing industry. X47	Retained Earning to Total Assets Ratio	−3.210***	(0.174)
X49	Market Value of Equity/Total Liability	−0.048***	(0.004)
X50	Ln (Total Assets/GNP price-level index)	−8.797***	(0.704)

***Represents significantly different from zero at 1 % level
**Represents significantly different from zero at 5 % level
*Represents significantly different from zero at 10 % level

Accumulative Depreciation to Gross Fixed Assets, Retained Earning to Total Assets Ratio, Ln (Total Assets/GNP price-level index), Ln (Age of the firm), and Ln (Net Sales) are all negative. The ratios improve the credit standings.

For the electronics industry, the coefficient of Interest Expense to Sales Ratio is positive, and the coefficients of Equity to Total Asset Ratio, Return on Total Assets (Ex-Tax, Interest Expense), Free Cash Flow to Total Debt Ratio, Accumulative Depreciation to Gross Fixed Assets, Cash Reinvestment Ratio, Working Capital to Total Assets Ratio, Retained Earning to Total Assets Ratio, Market Value of Equity/Total Liability, and Ln (Total Assets/GNP price-level index) are negative.

In general, the matured companies like those in the traditional and the manufacturing industries should focus mainly on their capabilities in operation and in liquidity. Also, the market factors are important for the manufacturing firms. For high-growth industry like the electronics, we should pay more attention to their market factors and the liquidity ratios. The common explanatory variables among three industries seem related to the operating returns, the retained earnings, and the asset size.

27.3.1.2 Ordered Probit Model

Table 27.4 shows the in-sample estimation results using the ordered probit model for each industry.

For the traditional industry, the coefficients of Fixed Asset to Long Term Funds Ratio, Interest Expense to Sales Ratio, and Debt Ratio are positive in the ordered probit model, which are similar to the results from the ordered logit model. On the other hand, the coefficients of Accounts Receivable Turnover Ratio, Net Operating Profit Margin, Return on Total Assets (Ex-Tax, Interest Expense), Depreciation to Sales Ratio, Operating Cash Flow to Total Liability Ratio, Capital Spending to Gross Fixed Assets Ratio, and Retained Earning to Total Assets Ratio are negative, also showing no big difference with the results from the ordered logit model.

For the manufacturing industry, the coefficients of Accounts Payable Turnover Ratio and the dummy variable for the negative Net Income for the last 2 years are positive. On the other hand, the coefficients of Equity to Total Asset Ratio, Quick Ratio, Total Assets Turnover Ratio, Return on Total Assets (Ex-Tax, Interest Expense), Accumulative Depreciation to Gross Fixed Assets, Cash Flow Ratio, Retained Earning to Total Assets Ratio, and Ln (Age of the firm) are negative. The results are also similar to those of the ordered logit model, only that the ordered logit seems focusing more on the size factors (sales, asset), while the ordered probit concerns more on the liquidity (quick ratio, cash flow ratio, and payables) of the firm.

For the electronics industry, the coefficients of Interest Expense to Sales Ratio is positive and the coefficients of Free Cash Flow to Total Debt Ratio, Working Capital to Total Assets Ratio, Retained Earning to Total Assets Ratio, Market Value of Equity/Total Liability, LN (Total Assets/GNP price-level index), and LN (Age) are negative.

Table 27.5 shows the threshold values estimated by the two models. Threshold values represent the cutting points for neighboring ratings.

Table 27.4 Regression results estimated by the ordered probit. This table represents the regression results estimated by the ordered probit model. Panel A shows the ten explanatory variables fitted in the traditional industry. Panel B shows the ten explanatory variables fitted in the manufacturing industry. 27.3.2 Credit Rating Forecasting

Tables 27.6 and 27.7 illustrate the prediction results of the ordered logit and the ordered probit models. Following Blume et al. (1998), we define the most probable rating as the actual rating or its immediate adjacent ratings. The ratio of the number of the predicted ratings as the most probable ratings to the total number of the ratings being predicted can assess the goodness-of-fit for the model. For out-of-sample firms, the predictive power of the ordered logit model for each industry is 86.85 %, 81.06 %, and 86.37 %, respectively; and the predictive power of the ordered probit model for each industry is 86.42 %, 80.21 %, and 84.87 %, respectively. The results from two models are quite similar.

27.3.3 Estimation Results Using the Combining Method

Table 27.8 depicts the regression results using the Kamstra-Kennedy combining forecasting technique. The coefficients are the logit estimates on ω's. These ω values are all positive and strongly significant for each industry.

Table 27.9 shows the prediction results of the combining forecasting model. For out-of-sample test, the predictive power of the combining model for each industry is 89.88 %, 82.77 %, and 88.02 %, respectively, which are higher than those of the ordered logit or ordered probit models by 2–4 %.

27.3.4 Performance Evaluation

To evaluate the performance of each model, Fig. 27.1 illustrates the ROC curves estimated by the three models, respectively.

From these ROC curves we can distinguish the performance of each rating model. Furthermore, we can compare the AUC and AR calculated from the ROC and CAP (See Table 27.10).

For the traditional industry, the AUCs from the ordered logit, the ordered probit, and the combining model are 95.32 %, 95.15 %, and 95.32 %, respectively. For the manufacturing industry, they are 94.73 %, 93.66 %, and 95.51 %, respectively. And for the electronics industry, they are 92.43 %, 92.30 %, and 94.07 %, respectively. These results apparently show that the combining forecasting model performs better than any individual one.

27.4 Conclusion

This study constitutes an attempt to explore the credit rating forecasting techniques. The samples consist of firms in the TSE and the OTC market and

AR	90.63 %	91.03 %	88.15 %
McFadden's R-square	42.34 %	43.16 %	46.28 %

CAP represents the cumulative accuracy profile, *AR* represents accuracy ratio. McFadden's R^2 is defined as 1−(unrestricted log-likelihood function/restricted log-likelihood function) are divided into three industries, i.e., traditional, manufacturing, and electronics, for analysis. Sixty-two explanatory variables consisting of financial, market, and macroeconomics factors are considered. We utilize the ordered logit, the ordered probit, and the combining forecasting model to estimate the parameters and conduct the out-of-sample tests. The main result is that the combining forecasting method leads to a more accurate rating prediction than that of any single use of the ordered logit or ordered probit analysis. By means of cumulative accuracy profile, the receiver operating characteristics, and McFadden R^2, we can measure the goodness-of-fit and the accuracy of each prediction model. These performance evaluations depict consistent results that the combining forecast performs better.

Appendix 1: Ordered Probit Procedure for Credit Rating Forecasting[2]

Credit rating is an ordinal scale from which the credit category of a firm can be ranked from high to low, but the scale of the difference between them is unknown. To model the ordinal outcomes, we follow Zavoina and McKelvey (1975) to begin with a latent regression

$$Y^* = X\beta + \varepsilon \tag{27.8}$$

where

$$Y^* = \begin{bmatrix} Y_1^* \\ \vdots \\ Y_N^* \end{bmatrix}, X = \begin{bmatrix} 1 & X_{11} & \cdots & X_{K1} \\ \vdots & \vdots & & \vdots \\ 1 & X_{1N} & \cdots & X_{KN} \end{bmatrix}$$

$$\beta = \begin{bmatrix} \beta_0 \\ \vdots \\ \beta_K \end{bmatrix}, \varepsilon = \begin{bmatrix} \varepsilon_0 \\ \vdots \\ \varepsilon_N \end{bmatrix}.$$

Here, β is a vector of unknown parameters, X is a set of explanatory variables, and ε is a random disturbance term assumed to follow the multivariate normal distribution with mean 0 and variance-covariance matrix $\sigma^2 I$, that is,

$$\varepsilon \sim N\left(0, \sigma^2 I\right). \tag{27.9}$$

Y^*, the dependent variable of theoretical interests, is unobserved, but from which we can classify the category j:[3]

[2]There are detailed discussion about ordered data in Ananth and Kleinbaum (1997), McCullagh (1980), Wooldridge (2010), and Greene (2011).

[3]In our case, $J = 10$ and $K = 62$.

$$Y_i = j \text{ if } \tau_{j-1} < Y_i^* \leq \tau_j \ (i = 1, 2, \ldots, N; j = 1, 2, \ldots, J) \tag{27.10}$$

where Y is the one we do observe, an ordinal version of Y^*, and the τ's are unknown parameters to be estimated with β. We assume that $-\infty = \tau_0 \leq \tau_1 \leq \cdots \leq \tau_J = +\infty$.

From Eqs. 27.8 and 27.10, we have

$$\begin{aligned} \tau_{j-1} < Y_i^* \leq \tau_j &\Leftrightarrow \tau_{j-1} < X_i\beta + \varepsilon_i \leq \tau_j \\ &\Leftrightarrow \frac{\tau_{j-1} - X_i\beta}{\sigma} < \frac{\varepsilon_i}{\sigma} \leq \frac{\tau_j - X_i\beta}{\sigma} \end{aligned} \tag{27.11}$$

where X_i is the i_{th} row of X.

From Eqs. 27.9 and 27.11, the probability of $Y_i = j$ can be written as

$$\Pr(Y_i = j) = \Phi\left(\frac{\tau_j - X_i\beta}{\sigma}\right) - \Phi\left(\frac{\tau_{j-1} - X_i\beta}{\sigma}\right) \tag{27.12}$$

where $\Phi(.)$ represents the cumulative density function of standard normal distribution. The model (27.12) is under-identified since any linear transformation of the underlying scale variable Y^*, if applied to the parameters and $\tau_0, \ldots, \tau_J$ as well, would lead to the same model. We will assume without loss of generality that, $\tau_1 = 0$ and $\sigma = 1$ in order to identify the model. The model we will estimate turns out to be

$$\Pr(Y_i = j) = \Phi\big(\tau_j - X_i\beta\big) - \Phi\big(\tau_{j-1} - X_i\beta\big). \tag{27.13}$$

Maximum likelihood estimation can be used to estimate the $J + K - 1$ parameters, $\tau_2, \ldots, \tau_{J-1}$ and $\beta_0, \beta_1, \ldots, \beta_K$, in Eq. 27.13. To form the likelihood function, first, define a dummy variable $Y_{i,j}$:

$$Y_{i,j} = \begin{cases} 1 \text{ if } Y_i = j \\ 0 \text{ otherwise} \end{cases}.$$

Then, for simple notation, we set $Z_{i,j} = \tau_j - X_i\beta$ and $\Phi_{i,j} = \Phi(Z_{i,j})$. The likelihood function, L, is

$$L = L(\beta_0, \ldots, \beta_K, \tau_2, \ldots, \tau_{J-1} | Y) = \prod_{i=1}^{n} \prod_{j=1}^{J} \big(\Phi_{i,j} - \Phi_{i,j-1}\big)^{Y_{i,j}}. \tag{27.14}$$

So, the log-likelihood function, ln L, is

$$\ln L = \sum_{i=1}^{n} \sum_{j=1}^{J} Y_{i,j} \ln\big(\Phi_{i,j} - \Phi_{i,j-1}\big). \tag{27.15}$$

Now, we want to maximize ln L subject to $\tau_1 \le \tau_2 \le \ldots \le \tau_{J-1}$.
Let $N_{i,j} = \frac{1}{\sqrt{2\pi}} e^{-\frac{z_{i,j}^2}{2}}$ for $1 \le j \le J$ and $1 \le i \le N$, and let $\delta_{l,j} = \begin{cases} 1 \text{ if } l = j \\ 0 \text{ if } l \ne j \end{cases}$, it follows that

$$\begin{aligned} \frac{\partial \Phi_{i,j}}{\partial \beta_u} &= N_{i,j} \frac{\partial Z_{i,j}}{\partial \beta_u} = -N_{i,j} X_{u,i} \text{ for } 0 \le u \le K \\ \frac{\partial \Phi_{i,j}}{\partial \tau_l} &= N_{i,j} \frac{\partial Z_{i,j}}{\partial \tau_l} = N_{i,j} \delta_{l,j} \text{ for } 2 \le l \le J-1 \end{aligned} \tag{27.16}$$

and

$$\begin{aligned} \frac{\partial N_{i,j}}{\partial \beta_u} &= Z_{i,j} N_{i,j} X_{u,i} \quad \text{for } 0 \le u \le K \\ \frac{\partial N_{i,j}}{\partial \tau_l} &= -Z_{i,j} N_{i,j} \delta_{l,j} \text{ for } 2 \le l \le J-1 \end{aligned} \tag{27.17}$$

By using Eqs. 27.16 and 27.17, we can calculate the $J + K - 1$ partial derivatives of Eq. 27.15 with respect to the unknown parameters, β and τ, respectively:

$$\begin{aligned} \frac{\partial \ln L}{\partial \beta_u} &= \sum_{i=1}^{n} \sum_{j=1}^{J} Y_{i,j} \frac{(N_{i,j-1} - N_{i,j}) X_{u,i}}{\Phi_{i,j} - \Phi_{i,j-1}} \qquad \text{for } 0 \le u \le K \\ \frac{\partial \ln L}{\partial \tau_l} &= \sum_{i=1}^{n} \sum_{j=1}^{J} Y_{i,j} \frac{(N_{i,j}\delta_{l,j} - N_{i,j-1}\delta_{l,j-1}) X_{u,i}}{\Phi_{i,j} - \Phi_{i,j-1}} \quad \text{for } 2 \le l \le J-1. \end{aligned} \tag{27.18}$$

And the elements in the $(J + K - 1) \times (J + K - 1)$ matrix of second partials are

$$\frac{\partial^2 \ln L}{\partial \beta_u \partial \beta_V} = \sum_{i=1}^{n} \sum_{j=1}^{J} Y_{i,j} \frac{(\Phi_{i,j} - \Phi_{i,j-1})(Z_{i,j-1} N_{i,j-1} - Z_{i,j} N_{i,j}) - (N_{i,j-1} - N_{i,j})^2 X_{u,i} X_{v,i}}{(\Phi_{i,j} - \Phi_{i,j-1})^2},$$

$$\frac{\partial^2 \ln L}{\partial \beta_u \partial \tau_l} = \frac{\partial^2 \ln L}{\partial \tau_l \partial \beta_u} = \sum_{i=1}^{n} \sum_{j=1}^{J} Y_{i,j} \left[\frac{(\Phi_{i,j} - \Phi_{i,j-1})(Z_{i,j} N_{i,j} \delta_{l,j} - Z_{i,j-1} N_{i,j-1} \delta_{l,j-1})}{(\Phi_{i,j} - \Phi_{i,j-1})^2} - \frac{(N_{i,j-1} - N_{i,j})(N_{i,j}\delta_{l,j} - N_{i,j-1}\delta_{l,j-1})}{(\Phi_{i,j} - \Phi_{i,j-1})^2} \right] X_{u,i},$$

$$\frac{\partial^2 \ln\ L}{\partial \tau_l \partial \tau_m} = \sum_{i=1}^{n}\sum_{j=1}^{J} Y_{i,j}\left[\frac{\left(\Phi_{i,j}-\Phi_{i,j-1}\right)\left(Z_{i,j-1}N_{i,j-1}\delta_{m,j-1}\delta_{l,j-1}-Z_{i,j}N_{i,j}\delta_{m,j}\delta_{l,j}\right)}{\left(\Phi_{i,j}-\Phi_{i,j-1}\right)^2} - \frac{\left(N_{i,j}\delta_{l,j}-N_{i,j-1}\delta_{l,j-1}\right)\left(N_{i,j}\delta_{m,j}-N_{i,j-1}\delta_{m,j-1}\right)}{\left(\Phi_{i,j}-\Phi_{i,j-1}\right)^2}\right]. \tag{27.19}$$

We then set the $J + K - 1$ equations in Eq. 27.18 to zero to get the MLE of the unknown parameters. The matrix of second partials should be negative definite to insure that the solution is a maximum. The computer program NPROBIT, which uses the Newton-Raphson method, can solve the nonlinear equations in Eq. 27.18.

Appendix 2: Ordered Logit Procedure for Credit Rating Forecasting

Consider a latent variable model where Y^* is the unobserved dependent variable, X a set of explanatory variables, β an unknown parameter vector, and ε a random disturbance term:

$$Y^* = X\beta + \varepsilon \tag{27.20}$$

ε is assumed to follow a standard logistic distribution, so the probability density function of ε is

$$\lambda(\varepsilon) = \frac{\exp(\varepsilon)}{[1+\exp(\varepsilon)]^2} \tag{27.21}$$

and the cumulative density function is

$$\Lambda(\varepsilon) = \frac{\exp(\varepsilon)}{1+\exp(\varepsilon)}. \tag{27.22}$$

Y^*, the dependent variable of theoretical interests, is unobserved, but from which we can classify the category j:

$$Y_i = j \ \text{ if } \ \tau_{j-1} < Y_i^* \le \tau_j \ \ (i = 1, 2, \ldots, N; j = 1, 2, \ldots, J) \tag{27.23}$$

where Y is the one we do observe, an ordinal version of Y^*, and the τ's are unknown parameters satisfying $\tau_1 \le \ldots \le \tau_J$ and to be estimated with β.

From Eqs. 27.20 and 27.22, we form the proportional odds model:

$$\Pr(Y_i \leq j|X) = \frac{\exp\left(\tau_j - X_i\beta\right)}{1 + \exp\left(\tau_j - X_i\beta\right)} \tag{27.24}$$

or equivalently

$$\begin{aligned} \log \mathrm{it}\left(\Pi_{ij}\right) &= \log\left[\frac{\Pi_{ij}}{1 - \Pi_{ij}}\right] \\ \log\left[\frac{\Pr(Y_i \leq j|X_i)}{\Pr(Y_i > j|X_i)}\right] &= \tau_j - X_i\beta \end{aligned} \tag{27.25}$$

where $\Pi_{ij} = \Pr(Y_i \leq j)$. Notice that in the proportional odds model, β is assumed to be constant and not depend on j. The validity of this assumption can be checked based on a χ^2 score test. The model that relaxes the proportional odds assumption can be represented as

$$\log \mathrm{it}\left(\Pi_{ij}\right) = \tau_j - X_i\beta_j, \tag{27.26}$$

where the regression parameter vector β is allowed to vary with j. Both models can be fit through the procedure of maximum likelihood estimation.

Appendix 3: Procedure for Combining Probability Forecasts

To combine the ordered logit and the ordered probit models for credit forecasting, the logit regression method as described in Kamstra and Kennedy (1998) is applied. We first assume that firm's credit classification is determined by an index θ. Suppose there are J rating classes, ordered from 1 to J. If θ exceeds the threshold value τ_j, $j = 1,\ldots J - 1$, credit classification changes from j rating to $j + 1$ rating. The probability of company i being in rating j is given by the integral of a standard logit from $\tau_{j-1} - \theta_i$ to $\tau_j - \theta_i$.

Each forecasting method is considered as producing $J - 1$ measures, $\omega_{ji} = \tau_j - \theta$, $j = 1, \ldots, J - 1$ for each firm. These measures can be estimated as

$$\omega_{ji} = \ln\left[\frac{P_{1i} + \cdots + P_{ji}}{1 - P_{1i} - \cdots - P_{ji}}\right] \tag{27.27}$$

where P_{ji} is a probability estimate for firm i in rating j. For firm i we have

$$P_{ji} = \begin{cases} \dfrac{e^{\omega_{ji}}}{1 + e^{\omega_{ji}}} & \text{for } j = 1 \\ \dfrac{e^{\omega_{ji}}}{1 + e^{\omega_{ji}}} - \dfrac{e^{\omega_{j-1i}}}{1 + e^{\omega_{j-1i}}} & \text{for } j = 2\cdots J - 1\,. \\ \dfrac{1}{1 + e^{\omega_{j-1i}}} & \text{for } j = J \end{cases} \tag{27.28}$$

In our case, there are two forecasting techniques A and B. For firm i, the combining probability estimate is

$$P_{ji} = \begin{cases} \dfrac{e^{\pi_j+\pi_A\omega_{jiA}+\pi_B\omega_{jiB}}}{1+e^{\pi_j+\pi_A\omega_{jiA}+\pi_B\omega_{jiB}}} & \text{for } j=1 \\ \dfrac{e^{\pi_j+\pi_A\omega_{jiA}+\pi_B\omega_{jiB}}}{1+e^{\pi_j+\pi_A\omega_{jiA}+\pi_B\omega_{jiB}}} - \dfrac{e^{\pi_{j-1}+\pi_A\omega_{j-1iA}+\pi_B\omega_{j-1iB}}}{1+e^{\pi_{j-1}+\pi_A\omega_{j-1iA}+\pi_B\omega_{j-1iB}}} & \text{for } j=2\cdots J-1\cdot \\ \dfrac{1}{1+e^{\pi_{j-1}+\pi_A\omega_{j-1iA}+\pi_B\omega_{j-1iB}}} & \text{for } j=J \end{cases} \tag{27.29}$$

This can be estimated using an ordered logit software package with the ω_A and ω_B values as explanatory variables and the τ_1 and π_2 parameters playing the role of the unknown threshold values.

Can We Use the CAPM as an Investment Strategy?: An Intuitive CAPM and Efficiency Test

28

Fernando Gómez-Bezares, Luis Ferruz, and Maria Vargas

Contents

Abstract

The aim of this chapter is to check whether certain playing rules, based on the undervaluation concept arising from the CAPM, could be useful as investment strategies, and can therefore be used to beat the Market. If such strategies work, we will be provided with a useful tool for investors, and, otherwise, we will

The authors wish to thank Professor José Vicente Ugarte for his assistance in the statistical analysis of the data presented in this chapter.

obtain a test whose results will be connected with the Efficient Market Hypothesis (EMH) and with the CAPM.

The basic strategies were set out in Gómez-Bezares, Madariaga, and Santibáñez (Análisis Financiero 68:72–96, 1996). Our purpose now is to reconsider them, to improve the statistical analysis, and to examine a more recent period for our study.

The methodology used is both intuitive and rigorous: analyzing how many times we beat the Market with different strategies, in order to check whether beating the Market happens by chance. Furthermore, we set out to study, statistically, when and by how much we beat it, and to analyze whether this is significant.

28.1 Introduction

Finance, as it is currently taught in business schools and brought together in the most prestigious text books, places great importance on the Capital Asset Pricing Model (CAPM)[1] and on the Efficient Market Hypothesis (EMH)[2]. For example, Brealey, Myers, and Allen (2008) conclude their famous book by saying that within what we know about Finance, there are seven key ideas: the first of which is Net Present Value (NPV), the second CAPM, and the third EMH[3]; leaving aside for the moment NPV,[4] we have as the two clearly outstanding concepts the CAPM and the EMH. In our opinion, asset pricing models (above all the CAPM) and the efficiency of the Markets are among the foundations of the current paradigm which has been in vogue since the 1970s.[5] And this is perfectly logical; the financial objective of a company is to maximize its Market value[6]; to this end it must make investments with a positive NPV, and to calculate the NPV financiers require an asset pricing model such as the CAPM; ultimately the Markets need to be efficient so that they can notice increases in value provided by investments. We can thus see by this simple reasoning how the three concepts highlighted by Brealey, Myers, and Allen are interrelated.

[1]Sharpe (1964), Lintner (1965).

[2]One of its main defenders has been Fama (1970, 1991, 1998).

[3]There are also other four key ideas.

[4]A fundamental concept, predating the other two and clearly related to the CAPM and the EMH.

[5]See Gómez-Bezares and Gómez-Bezares (2006). Also of interest could be Dimson and Mussavian (1998, 1999).

[6]The interesting work by Danielson, Heck and Shaffer (2008) is also worth looking at.

An alternative way of viewing this is to say that Finance, as it is currently understood, is the science of pricing; we have to valuate so that we can know which decisions will result in the greatest added value, and to valuate we need asset pricing models (like the CAPM). Finally, the result of our labor will be recognized by the Market, if the Market is efficient and values more highly those stocks with a higher intrinsic value.

The Golden Age of these two principles was the decade of the 1970s, appearing in works such as Fama (1970), Black, Jensen, and Scholes (1972) and Fama and MacBeth (1973): the Market correctly values the assets (the EMH) and we have a good model of asset pricing (the CAPM). However, since then there have been many critiques of both of these principles: the efficient Market principle has been criticized by psychologists and behavioral economists, who question the rationality of human beings, as well as by econometricians, who claim that prices are susceptible to prediction (Malkiel 2003). There is ample criticism in the literature, but the EMH also has important apologists; among the classic defenders are the works of Fama (1991, 1998) as well as the very noteworthy and recent study by Fama and French (2010), in which they show that portfolio managers, on average, do not beat the Market, thereby proving that the Market is indeed efficient.

The detractors of the efficient Market hypothesis (currently, above all, psychologists and behavioral economists) underline again and again the inefficiencies they observe. These problems with the model, when they are seen to occur repeatedly, are termed "anomalies" (for a summary, see Malkiel 2003). Fama and French (2008) studied different anomalies, concluding that some are more significant than others. However, they concluded that we cannot be sure whether to attribute abnormal returns to inefficiencies of the Market or to rewards for risk-taking.

This brings us back to the debate regarding asset pricing models. According to the CAPM, the expected return on an asset should be a positive linear function of its systematic risk measured by beta, which is the sole measurement of risk. This statement has been questioned in many ways; one very important contribution in this respect is that of Fama and French (1992) in which they comment that the beta can contribute little to an explanation of expected returns and, in fact, that there are other variables that can explain a lot more. Their work gave rise to the famous Fama and French three-factor model. The existence of variables other than the beta which can help to explain mean returns is not in itself an argument against the efficiency of the Market if we consider them to be risk factors: as risk is our enemy we demand higher returns for higher risk, and we can measure this risk in terms of a range of factors. This approach may be compatible with Arbitrage Pricing Theory (APT), but it conflicts with the CAPM.

But we could also consider that the problem is that the Markets are inefficient, and hence expected returns respond to variables that are not risk factors, variables to which they should not react. Let us take as example momentum, which tells us that recent past high (or low) returns can help to predict high (or low) returns in the near future. Some may think that this could be used as a risk factor to explain returns whereas others would say that it is an inefficiency of the Market. The truth is that the asset pricing model and efficiency are tested jointly (Fama 1970, 1991, 1998), in such a way that, when they work, they both work,[7] but when they fail we cannot know which of them has failed.[8]

The CAPM tests fall far short of giving definitive results. Although some have given it up for dead and buried because it cannot fit the data or because of theoretical problems, one recent magnificent study by Levy (2010) rejects the theoretical problems posed by psychologists and behavioral economists and, based on ex ante data, says that there is experimental support for the CAPM.

Brav, Lehavy, and Michaely (2005), in an approach related to the above, set out to test the model, not by looking at past returns (as a *proxy* of expected returns) but instead at the expectations of Market analysts, on the basis that these may be assumed to be unbiased estimates of the Market expectations. From their analysis, they found a positive relationship between expected returns and betas.

Asset pricing models (such as the CAPM) look at the relationship between return and risk. Recently, there has been more focus on liquidity. Liu (2006) builds an enhanced CAPM based on two factors: the Market and liquidity – he obtains their corresponding factorial weighting which he uses to explain the expected returns. The model works correctly and allows him to account several anomalies; according to Liu, his enhanced CAPM lends new support to the risk-return paradigm.

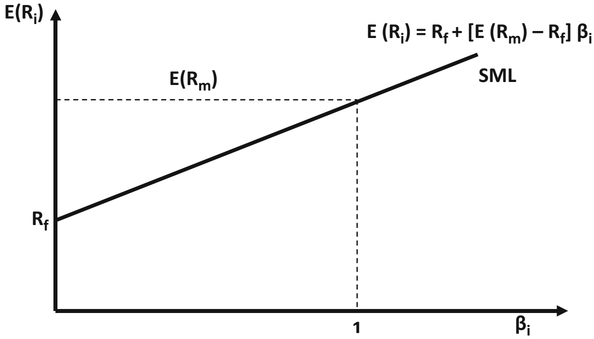
The methods most commonly used to contrast the CAPM are time-series and cross-sectional studies, which each present different statistical problems. What we set out to achieve in this chapter is to replicate a simple and intuitive but also rigorous methodology that we believe is much less problematic from a statistical point of view. The procedure was first proposed by Gómez-Bezares, Madariaga, and Santibáñez (1996), and in this chapter we attempt to replicate it with a more updated sample and greater statistical rigor. The basic idea is simple: an individual who knows the CAPM calculates at the beginning of each month the return that each stock has rendered in the past and compares it with the return it ought to have given according to the CAPM. The stocks which gave higher returns than they ought to have are cheap (undervalued) while those which gave lower return are expensive (overvalued). If we assume that return levels are going to persist, the investor should buy the cheap stocks and sell off the expensive ones in order to beat the Market. We illustrate this line of reasoning in Fig. 28.1.

In Fig. 28.1, the betas appear on the horizontal axis and the expected return on the vertical axis (R_f is the riskless rate; R_m is the Market return). We also show the Security Market Line (SML), with its formula above it, which is the formula for the CAPM. Our investor decides to buy the stocks which are cheap and refrain from selling short the expensive stocks (due to the limitations on short selling). Based on the data at his disposal, the stocks which have gained a value more than that the SML indicates are undervalued, that is to say, they are above

[7]We refer to the situation we have described previously which occurred at the beginning of the 1970s.

[8]See also Copeland, Weston, and Shastri (2005, p. 244).

Fig. 28.1 shows the Security Market Line (SML). The betas appear on the horizontal axis, and the expected return on the vertical axis



the SML. Believing that this situation will continue, he will buy all of these stocks, trusting that he will obtain an adjusted return higher than the Market return. If this happens (which he can find out by using Jensen's alpha), and this strategy consistently proves to result in abnormal returns (positive Jensen alphas, or to put it another way, the stocks stay above the SML in the next period), he will have found a way to beat the Market; therefore it is not efficient. Moreover, he shall be able to predict which stocks will, in the future, outperform the SML and therefore do not comply with the CAPM, which goes against the CAPM. There would then be one way left to save the EMH: risk should not be measured using the beta (i.e., the CAPM is mistaken) and therefore a positive value for alpha is not synonymous with beating the Market (which could not be done consistently in an efficient Market); we could also save the CAPM as follows: risk must be measured with the beta; however, the Market fails to value stocks accurately and hence it can be beaten; what we cannot do is to save both the EMH and the CAPM simultaneously.

On the other hand, if our investor cannot consistently beat the Market with his strategy but can only achieve about a 50 % success rate, more or less, we must conclude that the portfolio assembled with the previously undervalued stocks sometimes performs better than the SML and other times not as well, purely by chance, and then settles down to the value it ought to have according to the CAPM. We will not have a Market-beating strategy, and the results are compatible with the EMH; likewise, we will see that on a random basis the portfolios perform better than the SML at times and other times worse, which is compatible with the CAPM (every month there may be random oscillations around the SML); therefore two key elements of the aforementioned paradigm would be rescued.

In our research, we use Jensen's (1968, 1969) and Treynor's (1965) indices, since they consider systematic risk. These indices have been very widely used in the literature.[9]

[9]Recent studies that use these indices are, for example, Samarakoon and Hasan (2005), Abdel-Kader and Qing (2007), Pasaribu (2009), Mazumder and Varela (2010), and Ferruz, Gómez-Bezares, and Vargas (2010).

One of the virtues of this method is that it is perfectly replicable, as we have hypothesized an investor who makes decisions based on information in the public domain whenever he makes them. Meanwhile, we feel, reasonably enough, that the beta values and the risk premium may vary over time. We also use the most liquid stocks (to avoid problems with lack of liquidity) and portfolios (which reduces the measuring problems).

The results of our analysis clearly indicate that our strategy is not capable of beating the Market consistently, and therefore it is compatible with both the CAPM and the EMH. The result, to which we have come via different routes, which supports the strategy's robustness, supports the results reported by Fama and French (2010) and Levy (2010) although they used very different methods. Doubtless, both the CAPM and the EMH are simplifications of reality, but they help us to explain that reality.

The rest of our chapter is organized as follows: in Sect. 28.2, we describe the sample analyzed with information about the assets that it comprises, and we comment on the method used to calculate the returns and betas; in Sect. 28.3, we comment on the method employed, with reference to the proposed strategies and how these were formulated, we then go on to analyze the scenarios in which the strategies succeed in beating the Market and we describe the statistical tests used for the analyses; in Sect. 28.4, we show the results obtained by the different strategies and we analyze the number of occasions on which we were able to beat the Market and whether these results occur by chance. Furthermore, we analyze when and in what magnitude we beat the Market; in Sect. 28.5, we summarize the main conclusions drawn, highlighting the implications of our results in relation to the possibilities of using strategies to beat the Market according to the CAPM, and, therefore, we set out our conclusions as to the efficiency of the Market and the validity of the CAPM. In addition, there is a list of the references on which our research is based and an Appendix which contains, in greater detail, the statistical evidence gathered during our study.

28.2 Data

Our analysis is based on the 35 securities that comprise the IBEX 35 (the official index of the Spanish Stock Exchange Market) in each month from practically the beginning of trading in Continuous Market in Spain (1989) up to March 2007.[10] We chose this index because it includes the 35 most liquid companies in the Spanish Market and, taking into account that the CAPM in Sharpe-Lintner's version is valid for liquid companies, it would have been difficult to find such companies in Spain outside the IBEX 35.

[10]We have not extended our analysis beyond March 2007 in order to exclude the period of the global financial crisis which had a very damaging effect on major companies listed on the IBEX 35, such as banks, as this could have distorted our results.

The IBEX 35 is a capitalization-weighted index comprising the 35 most liquid companies which quote in the Continuous Market in Spain. It fulfills all of the criteria required of an indicator which aspires to be a benchmark for trading: it is representative (almost 90 % of the trading volume in the Continuous Market and approximately 80 % of the Market capitalization is held by the 35 firms listed on the IBEX 35), it can be replicated (ease of replication), its computation is guaranteed, it is widely publicized and impartial (supervised by independent experts).

The selection criteria for securities listed on the IBEX 35 are as follows:

- Securities must be included in the SIBE trading system.
- Stocks must be representative with a big Market capitalization and trading volume.
- There must be a number of "floating" stocks which is sufficient to ensure that the index's Market capitalization is sufficiently widespread and allows for hedge and arbitrage strategies in the Market for derivatives on the IBEX 35.
- The average Market capitalization of a stock measurable on the index[11] must be greater than 0.30 % of the average capitalization of the index during the monitoring period.[12]
- The stock must have been traded in at least 1/3 of the sessions during the monitoring period or be among the top 15 stocks measured in terms of Market capitalization.

The IBEX 35 is revised on a half-yearly basis in terms of its composition and the number of stocks considered of each firm; nevertheless, if financial operations are carried out which affect significantly any of the listed stocks, it can be adjusted accordingly. In general, the index is adjusted when there are increases in capital with preemptive rights, extraordinary dividend distributions, stocks integration as a result of increases in capital excluding preemptive rights, reductions in capital due to stocks redemption, capital reductions against own funds with distribution of the value to the shareholders (this is not the payment of an ordinary dividend), as well as mergers, takeovers, and demergers. Special adjustments of the index are often carried out.

In the 6-monthly selection of the 35 most liquid stocks, there is no minimum or maximum number of adjustments made with regard to the previous period. No changes at all may be required, or as many adjustments as necessary may be made, based on the results obtained when measuring the liquidity.

Having described the context in which we intend to carry out our study, we will propose a series of strategies that will enable us to test the validity of the CAPM and the degree to which the Market is efficient. For this we will take a hypothetical investor who, each month, examines the 35 stocks of the IBEX 35 listed at that moment and for which there are at least 36 monthly data available prior to that moment.

[11]The average Market capitalization of a stock in the Index is the arithmetic average of the result we obtain when multiplying the stocks allowed to be traded in each session during the monitoring period by the closing price of the stock in each of those sessions.

[12]The monitoring period is the 6-month period ending prior to each ordinary meeting of the Commission.

The data on returns for all the stocks were obtained from *Bloomberg*.

In Table 28.1, we show the annual descriptive statistics from our database.

There are two panels in Table 28.1: in panel A we show the descriptive statistics for the monthly returns of the previous period (December 1989 to November 1992). In this period, the index did not exist as such, so we have looked at the return of those stocks which, being included in the IBEX 35 at the beginning of the contrasting period, provide data in the corresponding month as they then were quoted in the Continuous Market. In panel B, we bring together the descriptive

Table 28.1 reports the annual descriptive statistics for our database. In Panel A, we show the figures for the monthly returns for the previous period and in Panel B the figures for monthly returns for the contrasting period

For Panel B, we consider only the returns on stocks which we have included in our study, that is to say, those stocks which were part of the IBEX 35 at a given time and which had a track record of monthly returns of at least 36 months. For panel A, as the index as such did not yet exist, we include those stocks listed on the IBEX 35 at the beginning of the contrasting period, for which there is data in the corresponding previous month; for example, the stocks we included for the month of December 1989 are those which were quoted on the IBEX 35 in December 1992 but which also were quoted in the Continuous Market back in December 1989. For the subsequent months the number of stocks considered in the study rises consistently since the number of stocks quoted continued to grow data for the monthly returns during the contrasting period, that is, it includes the returns on the stocks which are included in our study (namely, the stocks which comprised the IBEX 35 at each moment and for which there were at least 36 prior quotations).

We built the Market portfolio,[13] and as a risk-free asset we took the monthly return on the 1-month Treasury Bills.

28.3 Methods

The aim of our study is to check whether it is possible to obtain abnormal returns using the CAPM, that is to say, whether the returns derived from the use of the model are greater than those which could be expected according to the degree of systematic risk undertaken.

To this end, we analyzed the period December 1989 to March 2007. The study focuses on the 35 securities comprising the IBEX 35 at any given moment during the said period.

From this starting point, we propose two possible strategies for testing the efficient Market hypothesis and the validity of the CAPM: the first strategy assumes an individual who adjusts his portfolio at the end of each month, selling those stocks he bought at the end of the previous month and buying those he considers to be undervalued according to the CAPM; the second strategy is similar to the first, but with the distinction that in this case the investor does not buy all of the undervalued stocks but just 75 % of them, namely, those which are furthest removed from the SML. We use two methods to calculate which securities are the most undervalued: Jensen's ratio and Treynor's ratio. The reason for using a second method is in response to the critique by Modigliani (1997) of Jensen's alpha, in which she argues that differences in return cannot be compared when the risks are significantly different.

To conduct our analysis, we begin by dividing the overall period analyzed in our study (December 1989 to March 2007) into two subperiods: the first (December 1989 to November 1992) allows us to calculate the betas of the model at the beginning of the following (we carried out this calculation with the 36 previous month data). The second subperiod (December 1992[14] to March 2007) allows us to carry out the contrast.

[13]This has been constructed as a simple average of returns for the stocks comprising the IBEX 35 each month, corrected for dividend distributions, splits, etc. Of course, in this case, it is not necessary that there be at least 36 months of prior quotations for the stocks to be included in the portfolio.

[14]Initially, we intended to let the beginning of the second subperiod be the launch date of the IBEX 35 (January 1992), however, given the requirement that we set ourselves of a prior 36-month period to compute the betas of the model, we had to move this forward to December. Likewise, it was originally our intention that the beginning of the first subperiod be the launch date of the Continuous Market (April 1989) but most of the securities included in our study were listed for the first time in December 1989, so data could only be obtained from that date onward.

So our hypothetical investor will firstly, at the end of each month, observe the stocks that comprise the IBEX 35[15] and will buy those which are undervalued (in our second analysis method he will buy just 75 % of the stocks which are the most undervalued). A stock is undervalued if its return is higher than what is ought to be based on the CAPM.

To obtain this we compute the monthly betas for each stock (β_i) during the contrasting period by regressing the monthly returns on each stock[16] on the returns on the Market portfolio[17] in the 36 months immediately prior to this. Then, we calculate the mean monthly returns on stock i ($\overline{\Re_i}$), on the Market portfolio ($\overline{R_M}$) and on the risk-free asset ($\overline{R_F}$) during the same period as a simple average of the corresponding 36 monthly returns. From all of the foregoing we can compute the mean monthly return ($\overline{R_i}$), which, according to the CAPM, the stock ought to have gained during this 36-month period,

$$\overline{R_i} = \overline{R_F} + \left[\overline{R_M} - \overline{R_F}\right]\beta_i \tag{28.1}$$

We then compare it with the actual return gained ($\overline{\Re_i}$) to determine whether the stock is undervalued.

Once we have determined which stocks are undervalued, according to our first strategy the investor buys all of the undervalued stocks each month,[18] while with the second strategy, he disregards the first quartile and just buys 75 % of the most undervalued stocks. The quartiles are assembled based on either Jensen's alphas or Treynor's ratio.[19]

The next step consists in evaluating how well the CAPM functions; if the undervalued stocks continue to be undervalued indefinitely, we would expect any

[15]And for which there is a minimum of 36-monthly data prior to the month analyzed so that the beta can be calculated. In the case of companies which have recently merged, the beta is calculated by looking at the weighted average monthly returns on the companies prior to the merger. The weighting is proportional to the relative importance of each company involved in the merger.

[16]We look at the return obtained by our investor from capital gains, dividends, and the sale of preemptive rights. The returns are also adjusted to take splits into account.

[17]The return on the Market portfolio is calculated based on a simple average of the returns gained by the stocks which comprise the IBEX 35 in each month. The reason we decided to build our own portfolio rather than relying on a stock Market index such as the IBEX 35 itself is that we wanted to obtain an index corrected by capital gains, dividends, splits, and preemptive rights. Moreover, an equally weighted portfolio is theoretically superior.

[18]Overvalued stocks are not included in our analysis as we decided to exclude short selling.

[19]In this second variant, although the quartiles are built based on Treynor's ratio, we continue to use Jensen's index to work out whether or not a stock is undervalued. This is because of the problems we have encountered when determining which stocks are undervalued using Treynor's ratio. These are related to the return premiums and the negative betas which appear in some cases in our database. Naturally, we take on board the problems of using Treynor's ratio to construct the quartiles, as there could be stocks with positive alphas and low Treynor ratios which would exclude such stocks from the analysis. This is due to the form of Treynor's ratio as a quotient.

portfolio assembled with them to beat the Market in a given month, but this will not occur if in that month the CAPM operates perfectly.

Jensen's index allows us to determine whether we have been able to beat the Market, in which case it must yield a positive result:

$$\alpha_p = \left(R_p - R_F\right) - \beta_p(R_M - R_F) \tag{28.2}$$

where,

β_p is the beta for the portfolio, calculated as a simple average of the individual betas[20] of the stocks included in the portfolio (all of the undervalued stocks, or alternatively the top 75 % thereof as we have outlined above).

R_p is the return on the portfolio and is calculated as the simple average of the individual returns obtained each month for the stocks that comprise it.

R_M and R_F are the monthly returns on the Market portfolio and the risk-free asset respectively, for the month in question.

α_p is Jensen's alpha for the portfolio p.

The Z-statistic, which follows an approximately normal distribution, (0.1), allows us to determine whether the number of months in which our investor beats the Market is due to chance:

$$Z = (Y - np)/\sqrt{np(1-p)} \tag{28.3}$$

Y indicates the number of periods in which the portfolio comprising undervalued stocks beats the Market, n represents the number of months analyzed and to p we give a value of 0.5 as this is the probability of beating the Market if the CAPM and the efficient Market hypothesis are fulfilled,[21] and we want to find out if the difference (Y – np) is due to chance.

A value of $|Z| > 1.96$ would lead us to reject the null hypothesis of a difference due to chance, with a significance level of 5 %.

Moreover, in order to make our results more robust, we developed a series of statistical tests which are presented in Appendix. We carried out a mean test for each of the proposed strategies to ascertain whether we beat the Market or not, both parametric – which means normality – as well as nonparametric (Wilcoxon's test); in addition we tested the hypothesis that we could beat the Market 50 % of the time, and for this we used a binomial test. We also analyzed, on a monthly and on a yearly basis, whether or not there were differences between the performance means achieved in each month/year, using the ANOVA, a nonparametric test (Kruskal and Wallis), and also the technique of contingency tables and the chi-square

[20]Which have been calculated with the 36 previous months' data.

[21]If the CAPM and the efficient Market hypothesis are fulfilled exactly, the results of any portfolio (adjusted for risk) should match, as an average, with those of the Market. Here we suppose that, by pure chance, for any given month, they will end up 50 % above and 50 % below the Market average.

Pearson test together with the likelihood ratio. Finally, we conducted regression analysis of the performance measurement as a dependent variable and the time dimension (months) as an independent variable to see whether the performance improved or worsened over time. These tests allow us to confirm our results, which we shall see in the next section.

28.4 Results

28.4.1 Strategy 1: The Investor Buys All the Undervalued Stocks

In this first strategy, the investor observes, in a given month, the track record (for the previous 36 months) of the 35 stocks which comprise the IBEX 35 at the moment in question,[22] and buys all those that are undervalued according to Jensen's index. The next step is to check whether he has managed to beat the Market with the portfolio of undervalued stocks.

Table 28.2 shows the results of this strategy. We show for each of the 14 years in our study and for the other 4 months the number of months (and the percentage) in which the investor's portfolio has beaten the Market. In addition, we show this result for the whole period. Furthermore, and also with respect to the whole period, we show the result for the Z-statistic.

As we can see in Table 28.2, only in 92 of the 172 months analyzed in our study is the Market beaten, which is equal to 53.49 %[23]; moreover, the figure for Z-statistic (which is below 1.96) confirms that the CAPM does not offer a significantly better strategy than investing in the Market portfolio. In other words, we could say that the success of the investor (in the months in which he succeeds in beating the Market) could be due to chance. This conclusion is further confirmed in Appendix by the mean tests which allow us to accept that the mean of Jensen's alphas is zero and by the binomial test which allows accepting a success probability rate of 50 %.

If we now focus on the analysis of each year in our time frame, we can see that in only two of the 14 years covered in our study, to be precise from December 2004 to November 2006, the CAPM proves to be a useful tool for the investor allowing him to use a strategy to beat the Market; in fact, in 75 % and 83.33 % of the months of each of those 2 years our investor beats the Market, thus confirming the poor performance of the model, or the inefficiency of the Market.

[22]Which have a track record of at least 36 months in the Market. If, in a given month, there is a stock which is listed on the IBEX35 but does not have at least 36 months of prior data, this will be included in our study in the month in which it reaches this figure, unless by that stage it has already been deleted from the IBEX35.

[23]We have not included the transaction costs, which undoubtedly would be higher for the managed portfolio and, therefore, would make that strategy less attractive.

Table 28.2 Results of the Strategy 1 (buying all of the undervalued stocks)

YEAR	No. of successful months	% success	
DEC 1992/NOV 1993	4	33.33%	
DEC 1993/NOV 1994	4	33.33%	
DEC 1994/NOV 1995	5	41.67%	
DEC 1995/NOV 1996	7	58.33%	
DEC 1996/NOV 1997	7	58.33%	
DEC 1997/NOV 1998	6	50%	
DEC 1998/NOV 1999	7	58.33%	
DEC 1999/NOV 2000	6	50%	
DEC 2000/NOV 2001	6	50%	
DEC 2001/NOV 2002	5	41.67%	
DEC 2002/NOV 2003	7	58.33%	
DEC 2003/NOV 2004	7	58.33%	
DEC 2004/NOV 2005	9	75%	
DEC 2005/NOV 2006	10	83.33%	
DEC 2006/MAR 2007	2	50%	Z-statistic
DEC 1992/MAR 2007	**92**	**53.49%**	0.91

In Table 28.2, we bring together the results of a strategy in which our hypothetical investor buys all the undervalued stocks on the Index. To be specific, we provide for each of the 14 years in our study as well as for the other 4 months, the number of months (and the percentage) in which the portfolio beats the Market. We also show this result for the period as a whole. Moreover, for the period as a whole, we show the result for the Z-statistic

In the first 2 years (from December 1992 to November 1994), the opposite happens: in just 33.33 % of the months the investor's strategy beats the Market. In those months it seems, therefore, that he could use the opposite strategy to beat it.

The statistical tests carried out and included in the Appendix do not provide us with clear conclusions as to the basis for the differences in performance of the investor's strategy between the different months and years, because the different tests used gave us different results. However, the regression analysis does confirm that the performance of the portfolio improves over time, as we obtain a positive and significant beta.

28.4.2 Strategy 2: The Investor Buys the Three Stock-Quartiles with the Highest Degree of Undervaluation

With this strategy, which has two variants, what lets us find out whether a stock is or is not undervalued is, just as with the previous strategy, the difference between the mean monthly return actually achieved by the stock in a given month (using information on the previous 36 months) and that which it ought to have achieved according to the CAPM. However, with this second strategy, the investor disregards the first quartile of undervalued stocks and buys the other 75 %, those that are the most undervalued.

In the 1st variant of this second strategy, the ranking of the stocks (in each month) by quartiles is done using Jensen's index and in the 2nd variant it is done using Treynor's ratio.

28.4.2.1 Strategy 2, 1st Variant: The Quartiles Are Built Based on Jensen's Index

In Table 28.3, we show the results of this strategy:

The results, although slightly better, are not very different from those achieved by the previous strategy, as once again the CAPM proves not to be a useful tool for beating the Market. In only 94 of the 172 months in our study (54.65 %) does the strategy manage to beat the Market. The value for Z-statistic again confirms this result. And again, the mean tests show that the mean for the alphas for the investor's portfolio can be zero; while the binomial test shows that the probability of success in beating the Market can be 50 % (see Appendix).

There is also a slight improvement in the results by years in comparison with the results achieved by the previous strategy; the CAPM proves to be a useful Market-beating tool in 5 of the 14 years analyzed (December 1995 to November 1996, December 1998 to November 1999, December 2002 to November 2003, December 2004 to November 2005, and December 2005 to November 2006), which implies that the model either works badly or that the Market is inefficient since it is possible to beat it in most months.

Table 28.3 Results of Strategy 2, 1st Variant (buying the top three quartiles of the most undervalued stocks, constructed based on Jensen's Index)

YEAR	No. of successful months	% success	
DEC 1992/NOV 1993	3	25%	
DEC 1993/NOV 1994	4	33.33%	
DEC 1994/NOV 1995	5	41.67%	
DEC 1995/NOV 1996	8	66.67%	
DEC 1996/NOV 1997	6	50%	
DEC 1997/NOV 1998	7	58.33%	
DEC 1998/NOV 1999	8	66.67%	
DEC 1999/NOV 2000	6	50%	
DEC 2000/NOV 2001	5	41.67%	
DEC 2001/NOV 2002	5	41.67%	
DEC 2002/NOV 2003	9	75%	
DEC 2003/NOV 2004	6	50%	
DEC 2004/NOV 2005	10	83.33%	
DEC 2005/NOV 2006	10	83.33%	
DEC 2006/MAR 2007	2	50%	Z-statistic
DEC 1992/MAR 2007	**94**	**54.65%**	1.22

Table 28.3 shows the results of the strategy in which the investor disregards the first quartile of undervalued stocks and buys the remaining 75 %, which are the stocks that are most undervalued. The quartiles are built using Jensen's Index

The opposite results are obtained for the first 2 years (from December 1992 to November 1994), in which the percentages of success (25 % and 33.33 %, respectively) are the lowest.

The ANOVA, the Kruskal–Wallis test, and the contingency table with Pearson's chi-square-statistic and the likelihood ratio all lead us to the conclusion[24] that there are no differences between the performance means achieved by the portfolio in the months in our analysis, so the small differences could be due to mere chance. However, these tests do not allow us to offer conclusions when we look at the years that comprise our sample, as different conclusions can be drawn from the different tests used.

Moreover, the regression analysis once again allows us to confirm that, as with the previous strategy, the performance of the portfolio improves over time.

28.4.2.2 Strategy 2, 2nd Variant: The Quartiles Are Constructed Based on Treynor's Ratio

In Table 28.4, we show the results of this strategy.

The conclusions are very similar to those which the two previous strategies lead us to, thus we can see, for the whole period, a scant success rate for the strategy.

Table 28.4 Results of Strategy 2, 2nd Variant (buying the top three quartiles of the most undervalued stocks, constructed based on Treynor's Ratio)

YEAR	No. of successful months	% success	
DEC 1992/NOV 1993	3	25%	
DEC 1993/NOV 1994	4	33.33%	
DEC 1994/NOV 1995	7	58.33%	
DEC 1995/NOV 1996	7	58.33%	
DEC 1996/NOV 1997	6	50%	
DEC 1997/NOV 1998	7	58.33%	
DEC 1998/NOV 1999	7	58.33%	
DEC 1999/NOV 2000	7	58.33%	
DEC 2000/NOV 2001	4	33.33%	
DEC 2001/NOV 2002	5	41.67%	
DEC 2002/NOV 2003	8	66.67%	
DEC 2003/NOV 2004	6	50%	
DEC 2004/NOV 2005	10	83.33%	
DEC 2005/NOV 2006	10	83.33%	
DEC 2006/MAR 2007	2	50%	Z-statistic
DEC 1992/MAR 2007	**93**	**54.07%**	1.07

Table 28.4 shows the results of the strategy in which the investor disregards the first quartile of undervalued stocks and buys the remaining 75 %, which are the stocks that are most undervalued. The quartiles are built using Treynor's Ratio

[24] See Appendix.

Moreover, the value for Z-statistic once again leads us to accept the hypothesis that any possible success or failure is due to chance. Meanwhile, the tests we include in Appendix confirm the previous results: the mean tests support the interpretation that the mean performance of the portfolios is zero, therefore we do not beat the Market, and the binomial test suggests that the strategy's success rate is 50 %.

Focusing now on the analysis by years, there are 3 years (December 2002 to November 2003 and December 2004 to November 2006) in which we can confirm that the Market is not efficient or the model does not work well, since in those years the CAPM seems to be a useful Market-beating tool. However, in the first 2 years of our study as well as in the ninth year, the lowest success rates are delivered, which does not allow us to confirm the efficient Market hypothesis, as by using the opposite strategy we could have beaten it.

With regard to the statistical tests to analyze the robustness of the above-mentioned results for the various years and months in our database and those shown in Appendix, we find that there are no significant differences between the performance means achieved by the portfolio in the different months, so any difference can be due to chance. Nonetheless, we cannot draw conclusions on a yearly basis as the tests produce different results.

Finally, once again the result of the previous strategies is confirmed: the performance of the investor's portfolio improves over time. Overall, simply looking at the graphics for the three strategies where we can see the Jensen alphas achieved by our investor over time, if the reader disregards the initial data, he will see that the adjusted line is flat.

28.5 Conclusion

The aim of our study was to analyze whether the design of strategies based on the CAPM can enable an investor to obtain abnormal returns. We also set out to explore this using a methodology that was both intuitive and scientifically rigorous.

We also set out to determine whether the efficient Market hypothesis was fulfilled and whether we could accept the validity of the CAPM, since if strategies that can beat the Market with a degree of ease exist, we cannot confirm either the efficiency of the Market or the workability of the CAPM, as this defends that the only way to obtain extra returns is to accept a higher degree of systematic risk. Conversely, we would then be in possession of a tool enabling the investor to achieve higher returns than the Market for a given level of systematic risk.

Analyzing the behavior of an investor who can buy the stocks comprising the IBEX 35 at any given moment, that is, the benchmark for the Spanish stock

Market, and who reconfigures his portfolio on a monthly basis, we find that, regardless of the strategy used (buying all of the undervalued stocks or buying the 75 % most undervalued stocks, either measured with Jensen's alpha or with Treynor's ratio), the investor manages to beat the Market about 50 % of the time. We opted to exclude from our calculations the transaction costs, so we in fact overvalued the investor's results. Therefore, we can conclude that the CAPM is not an attractive tool for an investor who wishes to achieve abnormal returns. It seems that undervalued stocks rapidly fit the SML, and so from another perspective, we can confirm the efficient Market hypothesis and the workability of the CAPM. These conclusions are backed up by a series of statistical tests included in Appendix.

A positive aspect of our study from the point of view of its applicability is that the behavior we have envisaged for our virtual investor is perfectly replicable as he acts only with the information available in any given month. Meanwhile, by focusing on the stocks that make up the IBEX 35, our study's conclusions are applicable to the most representative and consolidated stocks on the Spanish Market.

Furthermore, our system possesses interesting statistical advantages: it allows for variation of the beta and of the risk premium over time, it avoids the risk of illiquidity, and it reduces errors in measurement. We have also considered its robustness.

Finally, it is important to point out that at all times we have accepted implicitly the logic of the CAPM, when measuring performance with Jensen's index (which implies basing ourselves on the CAPM). For this reason our results enable us to confirm that it is the efficiency of the Market which prevents abnormally high returns compared to those the Market itself is able to achieve, and that the CAPM is a model that works reasonably well; hence it cannot be used as a Market-beating tool.

Appendix

In this section, we report a series of statistical tests done using the "Stata" program, which support the results obtained in our study, thereby, we believe, making it more robust.[25] These statistics are drawn up for each of the strategies we tried out: buying all of the undervalued stocks, buying the top 75 % most undervalued stocks using Jensen's Index to select them, and buying the 75 % most undervalued stocks according to Treynor's Ratio.

[25] See Agresti (2007), Anderson et al. (2011), Conover (1999) and Newbold et al. (2009) for a widening of the statistical processing used in this Appendix.

Strategy 1: Investor Buys All Undervalued Stocks

1. *Summary statistics*

We work here, as for all of the strategies, with the Jensen values recorded for each of the portfolios (172).

	Percentiles	Smallest		
1%	−0.1064671	−0.1087249		
5%	−0.0279054	−0.1064671		
10%	−0.0180511	−0.0708467	Obs.	172
25%	−0.0077398	−0.0540319	Sum of Wgt.	172
50%	0.0012046		Mean	0.001246
		Largest	Std. Dev.	0.0213603
75%	0.0123422	0.0389192		
90%	0.0237416	0.0444089	Variance	0.0004563
95%	0.0309298	0.0509601	Skewness	−1.397642
99%	0.0509601	0.0773151	Kurtosis	10.85719

We would point out that in this table the Jensen values are far from normality, as can be seen in the readings for asymmetry and kurtosis.

2. *Mean test*

Variable	Obs.	Mean	Std. Err.	Std. Dev.	[95% Conf. Interval]
jensen	172	0.001246	0.0016287	0.0213603	−0.001969 0.004461

mean = mean (jensen) t = 0.7650
Ho: mean = 0 degrees of freedom = 171

Ha: mean < 0 Ha: mean != 0 Ha: mean > 0
Pr(T < t) = 0.7773 Pr(|T| > |t|) = 0.4453 Pr(T > t) = 0.2227

From this mean test, we can accept that the mean for the Jensen alphas is zero; in fact, if we focus on the two-sided test we obtain a probability of 0.4453, higher than 5 %. This allows us to conclude that we are not able to beat the Market with this strategy.

3. *Nonparametric mean test*

sign	Obs.	sum ranks	expected
positive	92	8451	7439
negative	80	6427	7439
zero	0	0	0
all	172	14878	14878

unadjusted variance 427742.50
adjustment for ties 0.00
adjustment for zeros 0.00
----
adjusted variance 427742.50

Ho: jensen = 0
z = 1.547
Prob > |z| = 0.1218

We can see again that Wilcoxon's nonparametric test leads to the same conclusion: we cannot beat the Market with this strategy.

4. *Frequencies*

BEAT	BEAT		
	NO	YES	Total
NO	80 46.51	0 0	80 46.51
YES	0 0	92 53.49	92 53.49
Total	80 46.51	92 53.49	172 100

From this contingency table, we see that the proportion of months in which we beat the Market is very similar to the proportion in which we fail to do so.

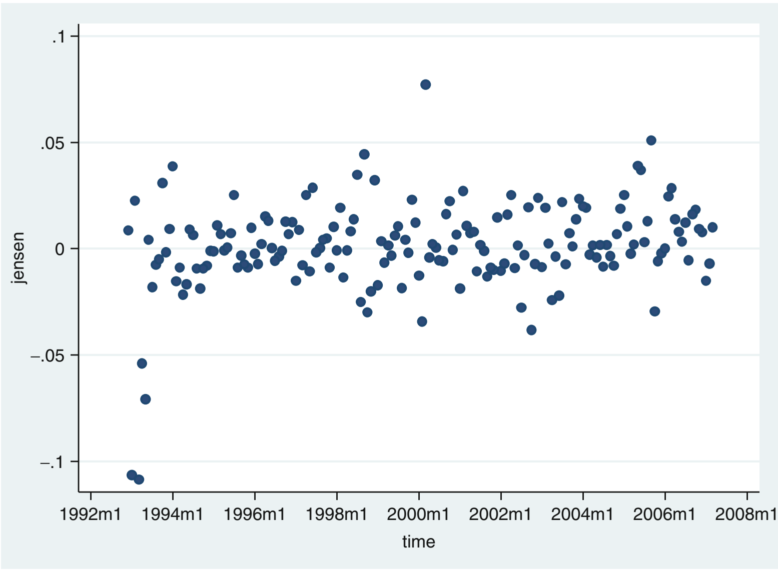
5. *Probabilities test*

Variable	N	Observed K	Expected K	Assumed p	Observed p
Jensen	172	92	86	0.50000	0.53488

Pr(k >= 92) = 0.200842 (one-sided test)
Pr(k <= 92) = 0.839213 (one-sided test)
Pr(k <= 80 or k >= 92) = 0.401684 (two-sided test)

We use this binomial test to determine whether the probability of beating the Market is similar to the probability of failing to beat it (50–50). If we look at the two-sided test, we obtain a probability of 0.401684, above 5 %, and so we accept the success rate is around 50 %, which supports the results obtained with the contingency table.

6. *Fit of Jensen by month*



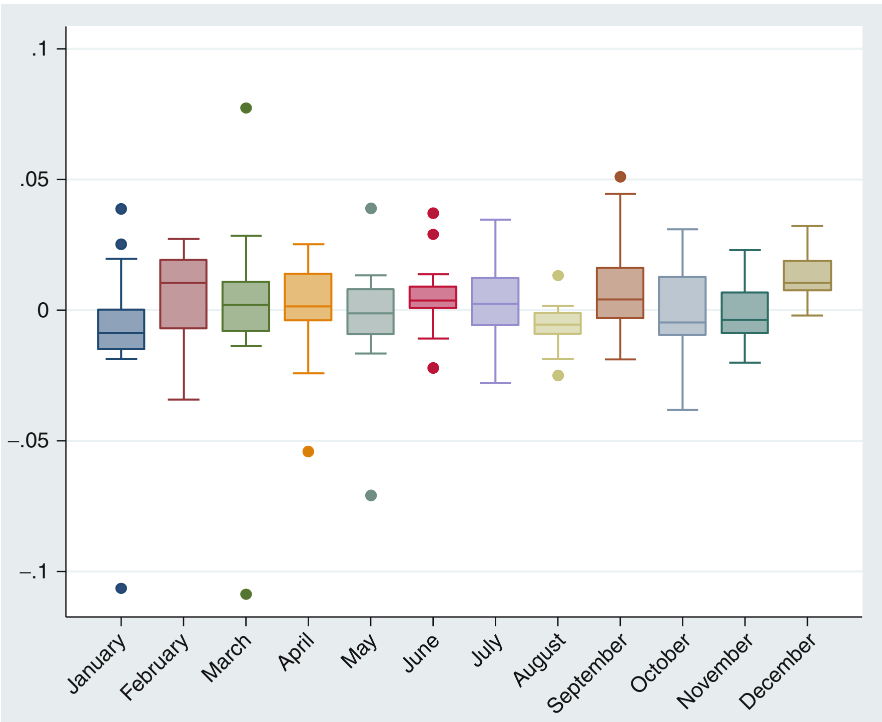
7. *Linear fit*

Source	SS	df	MS	Number of obs.	172
Model	0.00459285	1	0.00459285	F(1, 170)	10.63
Residual	0.07342831	170	0.00043193	Prob > F	0.0013
Total	0.07802116	171	0.00045626	R-squared	0.0589
				Adj. R-squared	0.0533
				Root MSE	0.02078

jensen	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]
time	0.0001041	0.0000319	3.26	0.001	0.0000411	0.0001671
_cons	–0.048762	0.0154174	–3.16	0.002	–0.0791963	–0.0183277

From the above table we can observe that the regression slope which connects Jensen's index (the dependent variable) and time measured in months (the independent variable) gives a positive and significant coefficient for beta which allows us to conclude that this strategy gives results that improve over time.

8. *One-way analysis of Jensen by month*



9. *One-way ANOVA (by month)*

Source	SS	df	MS		
Model	0.00607108	11	0.00055192	Number of obs	172

5	−0.0167755	0.0078803	−2.13	0.035	−0.0323384	−0.0012126
6	−0.0049838	0.0080151	−0.62	0.535	−0.0208128	0.0108451
7	−0.0026922	0.0080151	−0.34	0.737	−0.0185211	0.0131368
8	−0.0082308	0.0078803	−1.04	0.298	−0.0237937	0.0073321
9	−0.0112643	0.0080151	−1.41	0.162	−0.0270932	0.0045647
10	−0.0092672	0.0080151	−1.16	0.249	−0.0250961	0.0065618
11	−0.0115344	0.0080151	−1.44	0.152	−0.0273633	0.0042946
12	(dropped)					

We carry out an ANOVA to determine whether the means for Jensen's indices obtained in the different months are uniform. We can see that F has a value of 1.23 and a related probability of 0.2729, above 5 %, which leads us to accept that the means for Jensen's indices are uniform throughout the months included in our study.

10. *Kruskal-Wallis tests (Rank sums), by month*

Month	Obs.	Rank Sum
January	15	949
February	15	1551
March	15	1310
April	14	1217
May	14	1093
June	14	1386
July	14	1270
August	14	798
September	14	1382
October	14	1025
November	14	1032
December	15	1865

chi-squared = 22.716 with 11 d.f.
probability = 0.0194

We use the Kruskal–Wallis nonparametric test to measure the same phenomenon as with the ANOVA, and we see that for a significance level of 1 % we would come to the same conclusion as we did with the ANOVA, while for a significance level of 5 %, we can rule out uniformity from month to month.

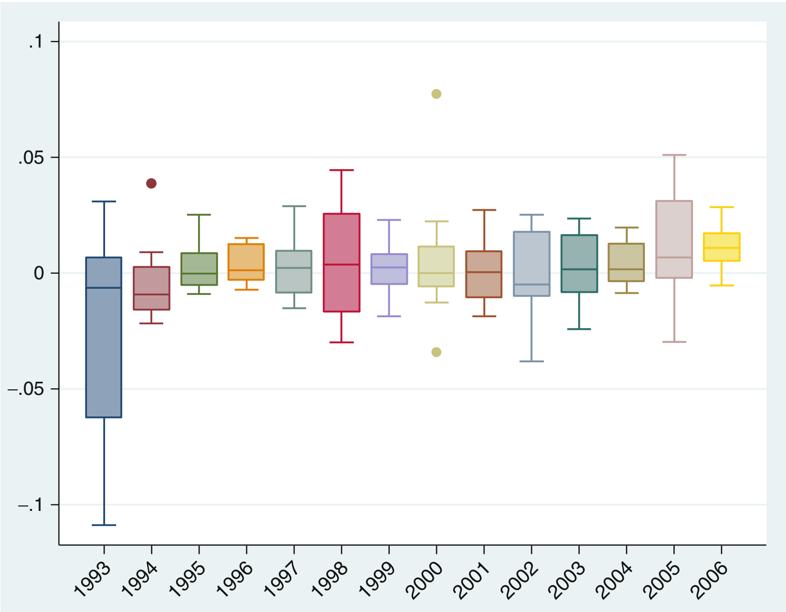
11. *Contingency table (by month)*

Month	BEAT		
	NO	YES	Total
January	11	4	15
February	5	10	15
March	7	8	15
April	6	8	14
May	7	7	14
June	2	12	14
July	6	8	14
August	11	3	14
September	6	8	14
October	8	6	14
November	9	5	14
December	2	13	15
Total	80	92	172

Pearson chi2(11) = 26.3578 Pr = 0.006
likelihood-ratio chi2(11) = 28.4294 Pr = 0.003

We use this contingency table to test the same point as with the ANOVA and the Kruskal–Wallis test above, to determine whether there are any differences between the months, and we find that both with Pearson's chi-square test and with the likelihood ratio the probability is less than 1 %, which leads us to conclude that the chances of beating the Market are not the same month on month, so that there will be some months in which it is easier to do so than others.

12. *One-way analysis of Jensen by year*



13. *One-way ANOVA (by year)*

Source	SS	df	MS		
Model	0.01216506	13	0.00093577	Number of obs	168
Residual	0.06538048	154	0.00042455	F(13, 154)	2.2
Total	0.07754554	167	0.00046435	Prob > F	0.0117
				R-squared	0.1569
				Adj R-squared	0.0857
				Root MSE	0.0206

jensen	Coef.	Std. Err.	t	P>|t|	[95% Conf. Interval]	
_cons	0.0113553	0.005948	1.91	0.058	−0.000395	0.0231055

9	−0.0108019	0.0084118	−1.28	0.201	−0.0274192	0.0058155
10	−0.0127709	0.0084118	−1.52	0.131	−0.0293883	0.0038465
11	−0.009494	0.0084118	−1.13	0.261	−0.0261114	0.0071234
12	−0.0078177	0.0084118	−0.93	0.354	−0.0244351	0.0087997
13	0.0003579	0.0084118	0.04	0.966	−0.0162595	0.0169752
14	(dropped)					

We performed an ANOVA based on years, to see whether the strategy gives similar Jensen values from year to year for those years included in our study (we excluded 1992 and 2007 because they could provide only 1 and 3 months of data, respectively. These years are also excluded from the other tests done based on years). We obtained a figure F of 2.20 with a related probability of 0.0117, thus for a significance level of 1 % we would accept that the means are uniform from one year to another, however, for a significance level of 5 % we must rule out this hypothesis and conclude that the Jensen values differ from one year to another.

14. *Kruskal-Wallis tests (Rank sums), by year*

Year	Obs.	Rank Sum
1993	12	722
1994	12	661
1995	12	1017
1996	12	1092
1997	12	1024
1998	12	1083
1999	12	993
2000	12	1002
2001	12	931
2002	12	906
2003	12	1019
2004	12	1058
2005	12	1275
2006	12	1413

chi-squared = 16.527 with 13 d.f.
probability = 0.2218

We now use the Kruskal–Wallis test to find out the same point as we did with the ANOVA. We see that we obtain a probability greater than 5 % which means we can accept that the mean Jensen values are uniform from one year to another.

15. *Contingency table (by year)*

Year	BEAT		
	NO	YES	Total
1993	8	4	12
1994	9	3	12
1995	6	6	12
1996	5	7	12
1997	5	7	12
1998	6	6	12
1999	5	7	12
2000	6	6	12
2001	6	6	12
2002	7	5	12
2003	5	7	12
2004	5	7	12
2005	4	8	12
2006	1	11	12
Total	78	90	168

Pearson chi2(13) = 15.2205 Pr = 0.294
likelihood-ratio chi2(13) = 16.7608 Pr = 0.210

The contingency table confirms the result of the previous test, namely, that there are no differences between the Jensen values for the different years so that any small difference can be due to chance.

Strategy 2: The Investor Buys the Most Undervalued Stocks

Strategy 2, 1st Variant: Quartiles Constructed Using Jensen's Index

1. *Summary statistics*

	Percentiles	Smallest		
1%	−0.1414719	−0.1486773		
5%	−0.0391241	−0.1414719		
10%	−0.0192669	−0.1117398	Obs.	172
25%	−0.0103728	−0.0683232	Sum of Wgt.	172
50%	0.0017188		Mean	0.0011871
		Largest	Std. Dev.	0.0280576
75%	0.0154674	0.0545513		
90%	0.0294085	0.0690987	Variance	0.0007872
95%	0.0390722	0.0696097	Skewness	−1.842765
99%	0.0696097	0.0745625	Kurtosis	11.929

We would point out that in this table the Jensen values are far from normality, as can be seen in the readings for asymmetry and kurtosis.

2. *Mean test*

Variable	Obs.	Mean	Std. Err.	Std. Dev.	[95% Conf. Interval]	
jensen (Q)	172	0.001187	0.0021394	0.0280576	–0.0030359	0.0054101

mean = mean (jensen) t = 0.5549
Ho: mean = 0 degrees of freedom = 171

Ha: mean < 0	Ha: mean != 0	Ha: mean > 0
Pr(T < t) = 0.7101	Pr(|T| > |t|) = 0.5797	Pr(T > t) = 0.2899

From this mean test we assume that the mean for Jensen's alphas is zero, in fact, if we focus on the two-sided test we can detect a probability of 0.5797, higher than 5 %. This allows us to conclude that we are not able to beat the Market with this strategy.

3. *Nonparametric mean test*

sign	Obs.	sum ranks	expected
positive	94	8567	7439
negative	78	6311	7439
zero	0	0	0
all	172	14878	14878

unadjusted variance 427742.50
adjustment for ties 0.00
adjustment for zeros 0.00
----
adjusted variance 427742.50
Ho: jensen = 0
z = 1.725
Prob > |z| = 0.0846

We can see again, that Wilcoxon's nonparametric test leads to the same conclusion: we cannot beat the Market with this strategy.

4. *Frequencies*

BEAT	BEAT		
	NO	YES	Total
NO	78 45.35	0 0	78 45.35
YES	0 0	94 54.65	94 54.65
Total	78 45.35	94 54.65	172 100

From this contingency table, we see that the proportion of months in which we beat the Market is very similar to the proportion of months in which we do not, with a slightly higher probability of beating the Market.

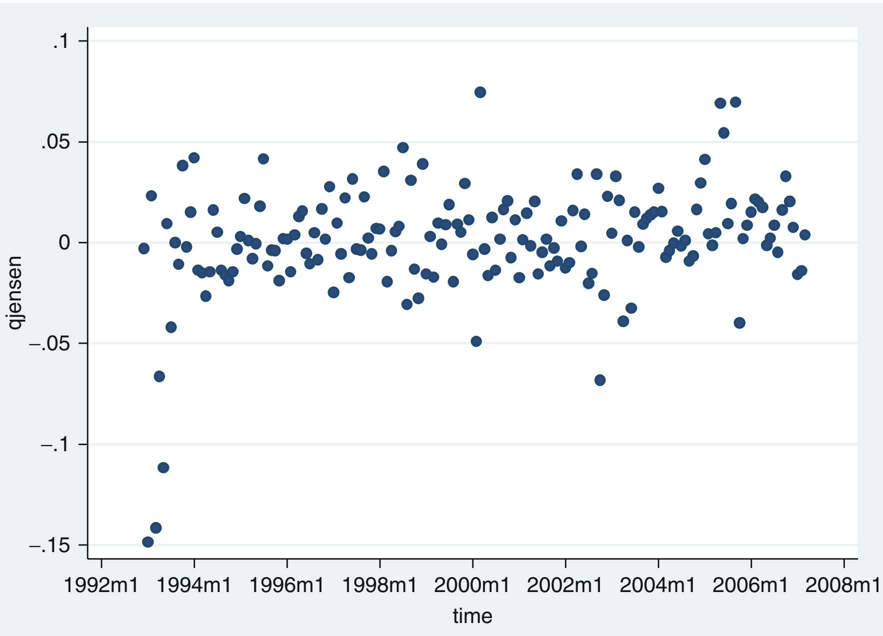
5. *Probabilities test*

Variable	N	Observed K	Expected K	Assumed p	Observed p
Jensen (Q)	172	94	86	0.50000	0.54651

Pr(k >= 94) = 0.126331 (one-sided test)
Pr(k <= 94) = 0.902626 (one-sided test)
Pr(k <= 78 or k >= 94) = 0.252662 (two-sided test)

With this binomial test we set out to find whether the probability of beating the Market is the same as the probability of not beating it; (50–50). If we look at the two-sided test, we get a probability of 0.252662, above 5 %, hence we can accept that the success rate is 50 %, which backs up the results obtained with the contingency table.

6. *Fit of Jensen (quartiles) by month*



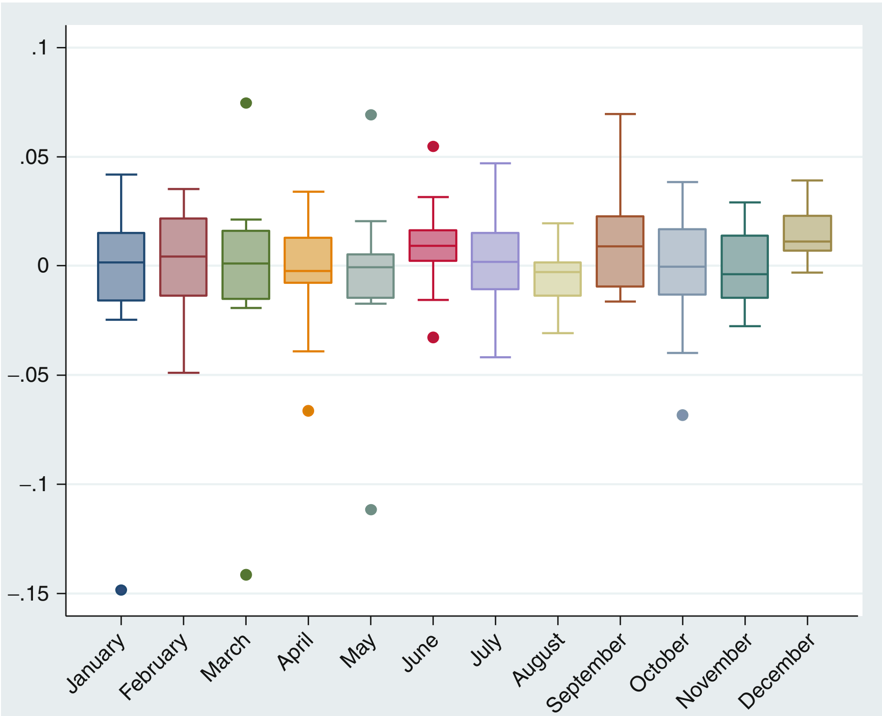
7. *Linear fit*

Source	SS	df	MS	Number of obs	172
Model	0.00979599	1	0.00979599	F(1, 170)	13.34
Residual	0.1248204	170	0.00073424	Prob > F	0.0003
Total	0.13461639	171	0.00078723	R-squared	0.0728
				Adj R-squared	0.0673
				Root MSE	0.0271

jensen (Q)	Coef.	Std. Err.	t	P>|t|	[95% Conf. Interval]	
time	0.000152	0.0000416	3.65	0	0.0000699	0.0002341
_cons	−0.0718465	0.0201013	−3.57	0	−0.1115268	−0.0321663

From the above table we can observe that the regression slope, which connects Jensen's index (the dependent variable) and time measured in months (the independent variable), gives a positive and significant coefficient for beta which allows us to conclude that this strategy gives results that improve over time.

8. *One-way analysis of Jensen (quartiles) by month*



9. *One-way ANOVA (by month)*

Source	SS	df	MS	Number of Obs.	172
Model	0.00735542	11	0.00066868	F(11, 160)	0.84

4	–0.0060897	0.0104804	–0.58	0.562	–0.0267874	0.0146081
5	–0.0172233	0.0104804	–1.64	0.102	–0.037921	0.0034744
6	–0.0069927	0.0106595	–0.66	0.513	–0.0280443	0.0140588
7	–0.0014246	0.0106595	–0.13	0.894	–0.0224761	0.019627
8	–0.014007	0.0104804	–1.34	0.183	–0.0347047	0.0066907
9	–0.0143055	0.0106595	–1.34	0.181	–0.035357	0.0067461
10	–0.0125205	0.0106595	–1.17	0.242	–0.0335721	0.008531
11	–0.0123631	0.0106595	–1.16	0.248	–0.0334147	0.0086884
12	(dropped)					

We perform an ANOVA to see whether the means for Jensen values obtained for the different months are uniform. We find that F-statistic has a value of 0.84 with a related probability of 0.5997, above 5 %, which leads us to accept that the means for Jensen values are uniform among the months included in our sample.

10. *Kruskal-Wallis tests (Rank sums), by month*

Month	Obs.	Rank Sum
January	15	1167
February	15	1428
March	15	1228
April	14	1105
May	14	1077
June	14	1451
July	14	1216
August	14	885
September	14	1385
October	14	1156
November	14	1020
December	15	1760

chi-squared = 14.369 with 11 d.f.
probability = 0.2133

We now use the Kruskal–Wallis test to find out the same point as we did with the ANOVA. We come to the same conclusion as we did with the ANOVA.

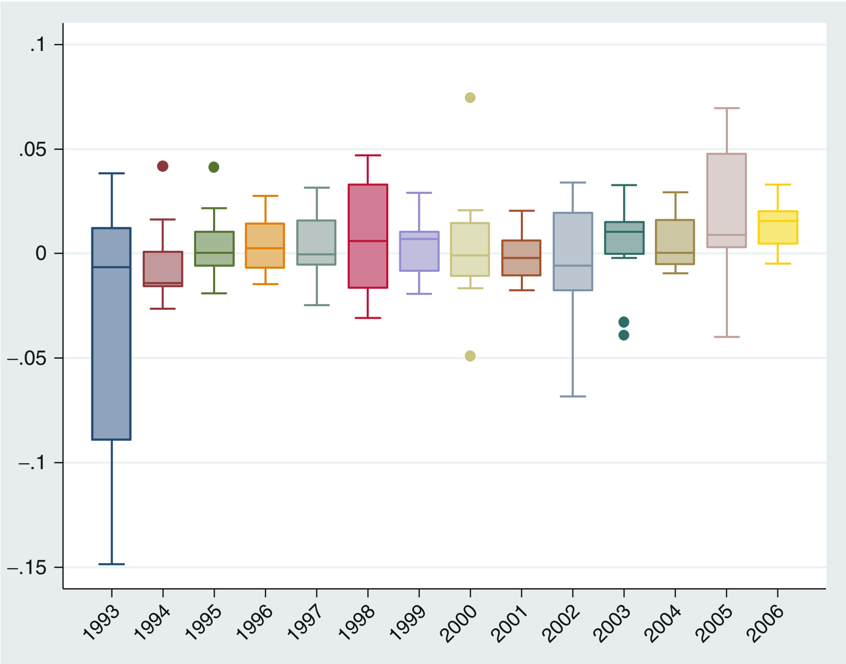
11. *Contingency table (by month)*

Month	BEAT		
	NO	YES	Total
January	7	8	15
February	5	10	15
March	7	8	15
April	8	6	14
May	9	5	14
June	3	11	14
July	7	7	14
August	9	5	14
September	6	8	14
October	7	7	14
November	8	6	14
December	2	13	15
Total	78	94	172

Pearson chi2(11) = 16.2331 Pr = 0.133
likelihood-ratio chi2(11) = 17.3939 Pr = 0.097

The contingency table allows us to test the same point as above with the ANOVA and the Kruskal–Wallis test, and leads to the same conclusions; hence, we can accept that all months show a similar tendency in terms of beating the Market.

12. *One-way analysis of Jensen (quartiles) by year*



13. *One-way ANOVA (by year)*

Source	SS	df	MS		
Model	0.02482403	13	0.00190954	Number of obs.	168

11	−0.0087823	0.010873	−0.81	0.421	−0.0302617	0.0126972
12	−0.0075224	0.010873	−0.69	0.49	−0.0290019	0.013957
13	0.0071267	0.010873	0.66	0.513	−0.0143528	0.0286061
14	(dropped)					

We now perform an ANOVA by years to see whether the strategy gives similar Jensen values among the years in our sample. We obtain a value for F-statistic of 2.69 with a related probability of 0.0019; hence we conclude that the means for Jensen values are not uniform from one year to another.

14. *Kruskal-Wallis tests (Rank sums), by year*

Year	Obs.	Rank Sum
1993	12	735
1994	12	665
1995	12	980
1996	12	1042
1997	12	1002
1998	12	1064
1999	12	1045
2000	12	972
2001	12	846
2002	12	913
2003	12	1136
2004	12	1070
2005	12	1353
2006	12	1373

chi-squared = 17.864 with 13 d.f.
probability = 0.1627

We now use the Kruskal–Wallis nonparametric test to find out the same point as we did with the ANOVA. We see that we obtain a probability greater than 5 % which means we can accept that the mean Jensen values are uniform from one year to another.
15. *Contingency table (by year)*

Year	BEAT		
	NO	YES	Total
1993	8	4	12
1994	9	3	12
1995	6	6	12
1996	4	8	12
1997	6	6	12
1998	5	7	12
1999	4	8	12
2000	6	6	12
2001	7	5	12
2002	7	5	12
2003	3	9	12
2004	6	6	12
2005	2	10	12
2006	2	10	12
Total	75	93	168

Pearson chi2(13) = 19.9673 Pr = 0.096
likelihood-ratio chi2(13) = 21.0731 Pr = 0.071

The contingency table confirms the result of the previous test, namely, that there are no differences between the Jensen values for the different years so that any small difference can be due to chance.

Strategy 2, 2nd Variant: Quartiles Built Using Treynor's Ratio

1. *Summary statistics*

	Percentiles	Smallest		
1%	–0.0968895	–0.104714		
5%	–0.0382262	–0.0968895		
10%	–0.0231222	–0.0940315	Obs.	172
25%	–0.0106754	–0.0702515	Sum of Wgt.	172
50%	0.0023977		Mean	0.0014829
		Largest	Std. Dev.	0.0256145
75%	0.0157561	0.0484799		
90%	0.0285186	0.0629996	Variance	0.0006561
95%	0.04065	0.0648316	Skewness	–0.9274022
99%	0.0648316	0.0745625	Kurtosis	6.503481

We note that in this table the Jensen values are far from normality, as can be seen in the readings for asymmetry and kurtosis, although this is less obvious than for the previous strategies.

2. *Mean test*

Variable	Obs.	Mean	Std. Err.	Std. Dev.	[95% Conf. Interval]
Jensen (Q)	172	0.001483	0.0019531	0.0256145	−0.0023724 0.0053381

mean = mean (jensen) t = 0.7592

Ho: mean = 0 degrees of freedom = 171

Ha: mean < 0	Ha: mean != 0	Ha: mean > 0
Pr(T < t) = 0.7756	Pr(|T| > |t|) = 0.4487	Pr(T > t) = 0.2244

From this mean test, we can accept that the mean for the Jensen alphas is zero; in fact, if we focus on the two-sided test, we obtain a probability of 0.4487, which is higher than 5 %. This allows us to conclude that we cannot beat the Market with this strategy.

3. *Nonparametric mean test*

sign	Obs.	sum ranks	expected
positive	93	8460	7439
negative	79	6418	7439
zero	0	0	0
all	172	14878	14878

unadjusted variance 427742.50
adjustment for ties 0.00
adjustment for zeros 0.00
----
adjusted variance 427742.50
Ho: jensen = 0
z = 1.561
Prob > |z| = 0.1185

We can see again that Wilcoxon's nonparametric test leads to the same conclusion: we cannot beat the Market with this strategy.

4. *Frequencies*

BEAT	BEAT		
	NO	YES	Total
NO	79 45.93	0 0	79 45.93
YES	0 0	93 54.07	93 54.07
Total	79 45.93	93 54.07	172 100

From this contingency table, we see that the proportion of months in which we beat the Market is very similar to the proportion in which we do not, with a slightly higher figure for those months in which we do beat the Market.

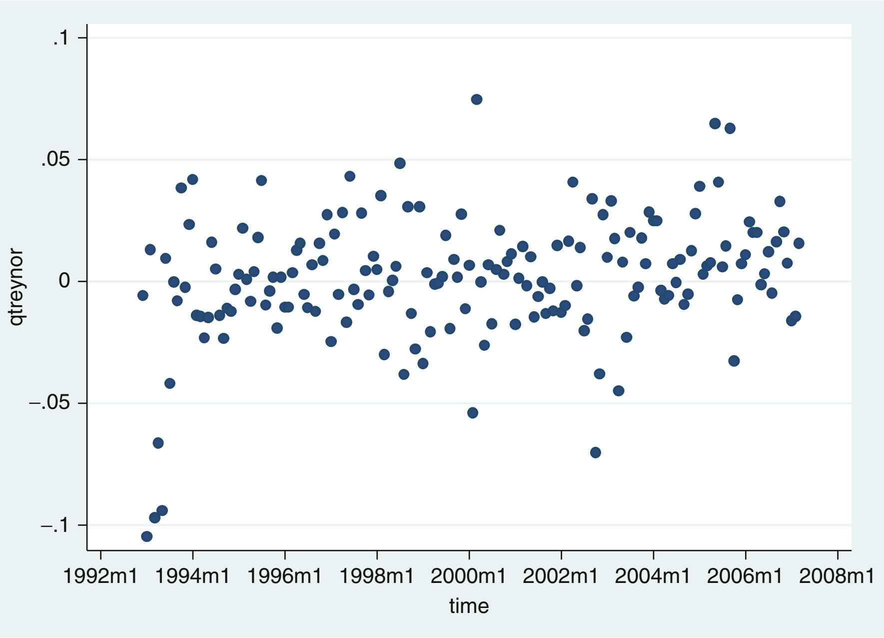
5. *Probabilities test*

Variable	N	Observed K	Expected K	Assumed p	Observed p
Jensen (Q)	172	93	86	0.50000	0.5407

Pr(k >= 93) = 0.160787 (one-sided test)
Pr(k <= 93) = 0.873669 (one-sided test)
Pr(k <= 79 or k >= 93) = 0.321574 (two-sided test)

We use this binomial test to determine whether the probability of beating the Market is similar to the probability of failing to beat it (50–50). If we look at the two-sided test, we obtain a probability of 0.321574, above 5 %, and so we accept the success rate is around 50 %, which supports the results obtained with the contingency table.

6. *Fit of Jensen (quartiles) by month*



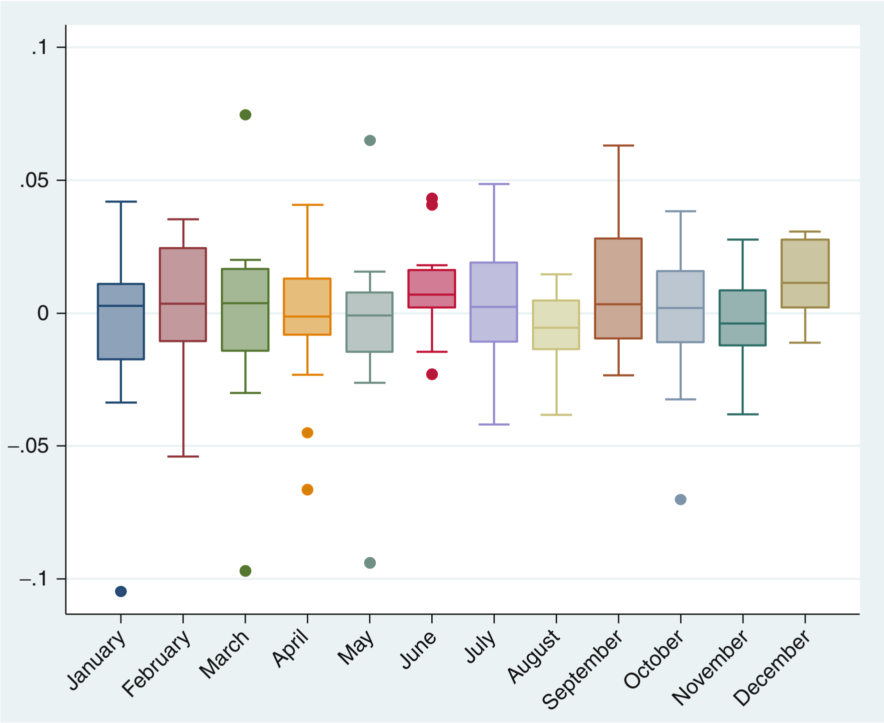
7. *Linear fit*

Source	SS	df	MS	Number of obs.	172
Model	0.00721202	1	0.00721202	F(1, 170)	11.68
Residual	0.1049811	170	0.00061754	Prob > F	0.0008
Total	0.11219312	171	0.0006561	R-squared	0.0643
				Adj R-squared	0.0588
				Root MSE	0.02485

jensen (Q)	Coef.	Std. Err.	t	P>|t|	[95% Conf. Interval]	
time	0.0001304	0.0000382	3.42	0.001	0.0000551	0.0002058
_cons	−0.0611824	0.0184347	−3.32	0.001	−0.0975728	−0.024792

From the above table we can observe that the regression slope which connects Jensen's index (the dependent variable) and time measured in months (the independent variable) gives a positive and significant coefficient for beta which allows us to conclude that this strategy gives results that improve over time.

8. *One-way analysis of Jensen (quartiles) by month*



9. *One-way ANOVA (by month)*

Source	SS	df	MS		
Model	0.00656026	11	0.00059639	Number of Obs.	172
Residual	0.10563286	160	0.00066021	F(11, 160)	0.9
Total	0.11219312	171	0.0006561	Prob > F	0.5387
				R-squared	0.0585
				Adj. R-squared	–0.0063
				Root MSE	0.02569

jensen (Q)	Coef.	Std. Err.	t	P>|t|	[95% Conf.	Interval]
_cons	0.0092267	0.0068671	1.34	0.181	–0.0043352	0.0227886
1	–0.0125889	0.0097116	–1.3	0.197	–0.0317683	0.0065906
2	–0.0150679	0.0097116	–1.55	0.123	–0.0342474	0.0041115
3	0.003986	0.0095484	0.42	0.677	–0.0148711	0.0228431
4	–0.0040562	0.0095484	–0.42	0.672	–0.0229133	0.0148009
5	–0.0145235	0.0095484	–1.52	0.13	–0.0333805	0.0043336
6	–0.0055123	0.0097116	–0.57	0.571	–0.0246917	0.0136671
7	–0.0003726	0.0097116	–0.04	0.969	–0.0195521	0.0188068
8	–0.0092886	0.0095484	–0.97	0.332	–0.0281457	0.0095684
9	–0.013379	0.0097116	–1.38	0.17	–0.0325584	0.0058005
10	–0.0120712	0.0097116	–1.24	0.216	–0.0312506	0.0071083
11	–0.0105584	0.0097116	–1.09	0.279	–0.0297378	0.008621
12	(dropped)					

We perform an ANOVA to see whether the means for the Jensen values obtained for the different months are uniform. We find that F-statistic has a value of 0.90 with a related probability of 0.5387, above 5 %, which leads us to accept that the means for the Jensen values are uniform among the months included in our sample.

10. *Kruskal-Wallis tests (Rank sums), by month*

Month	Obs.	Rank Sum
January	15	1153
February	15	1442
March	15	1297
April	14	1107
May	14	1046
June	14	1430
July	14	1220
August	14	899
September	14	1352
October	14	1160
November	14	1044
December	15	1728

chi-squared = 12.840 with 11 d.f.
probability = 0.3039

We now use the Kruskal–Wallis nonparametric test to find out the same point as we did with the ANOVA. We come to the same conclusion as we did with the ANOVA.

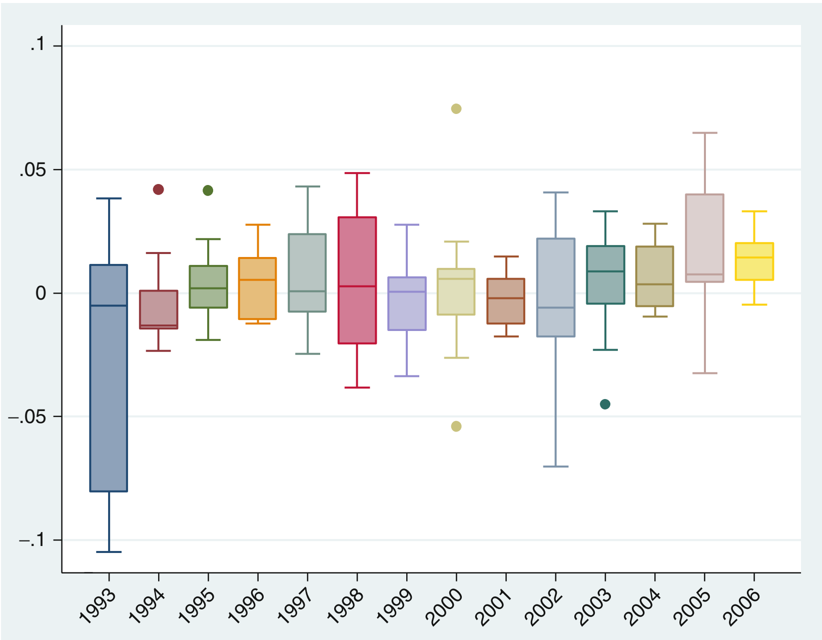
11. *Contingency table (by month)*

Month	BEAT		
	NO	YES	Total
January	7	8	15
February	5	10	15
March	6	9	15
April	9	5	14
May	8	6	14
June	3	11	14
July	7	7	14
August	10	4	14
September	7	7	14
October	6	8	14
November	8	6	14
December	3	12	15
Total	79	93	172

Pearson chi2 (11) = 15.8416 Pr=0.147
likelihood-ratio chi2(11) = 16.5468 Pr = 0.122

The contingency table allows us to test the same point as above with the ANOVA and the Kruskal–Wallis test, and leads to the same conclusions; hence we can accept that all months show a similar tendency in terms of beating the Market.

12. *One-way analysis of Jensen (quartiles) by year*



13. *One-way ANOVA (by year)*

Source	SS	df	MS		
Model	0.0170417	13	0.0013109	Number of obs.	168
Residual	0.09434205	154	0.00061261	F(13, 154)	2.14
Total	0.11138374	167	0.00066697	Prob > F	0.0147
				R-squared	0.153
				Adj. R-squared	0.0815
				Root MSE	0.02475

jensen	Coef.	Std. Err.	t	P>|t|	[95% Conf. Interval]	
_cons	0.0135106	0.007145	1.89	0.061	−0.0006043	0.0276254
1	−0.041029	0.0101045	−4.06	0	−0.0609904	−0.0210676
2	−0.0190657	0.0101045	−1.89	0.061	−0.0390271	0.0008957
3	−0.0091611	0.0101045	−0.91	0.366	−0.0291225	0.0108003
4	−0.0100757	0.0101045	−1	0.32	−0.0300372	0.0098857
5	−0.0077821	0.0101045	−0.77	0.442	−0.0277435	0.0121793
6	−0.0098938	0.0101045	−0.98	0.329	−0.0298552	0.0100676
7	−0.0154658	0.0101045	−1.53	0.128	−0.0354272	0.0044956
8	−0.0103002	0.0101045	−1.02	0.31	−0.0302616	0.0096612
9	−0.0158053	0.0101045	−1.56	0.12	−0.0357667	0.0041561
10	−0.0165104	0.0101045	−1.63	0.104	−0.0364718	0.003451
11	−0.0080536	0.0101045	−0.8	0.427	−0.028015	0.0119078
12	−0.0072511	0.0101045	−0.72	0.474	−0.0272125	0.0127103
13	0.004184	0.0101045	0.41	0.679	−0.0157774	0.0241454
14	(dropped)					

We now perform an ANOVA by years to see whether the strategy gives similar Jensen values among the years in our sample. We obtain a value for F-statistic of 2.14 with a related probability of 0.0147; hence we conclude that for a significance level of 1 % we can accept that the means for the Jensen values are the same from one year to another, however for a significance level of 5 % we must reject this hypothesis and we would conclude that there are differences between the Jensen values of different years.

14. *Kruskal-Wallis tests (Rank sums), by year*

Year	Obs.	Rank Sum
1993	12	740
1994	12	679
1995	12	1025
1996	12	1033
1997	12	1065
1998	12	1022
1999	12	877
2000	12	1026
2001	12	824
2002	12	920
2003	12	1166
2004	12	1110
2005	12	1322
2006	12	1387

chi-squared = 18.336 with 13 d.f.
probability = 0.1452

We now use the Kruskal–Wallis test to find out the same point as we did with the ANOVA. We see that we obtain a probability greater than 5 % which means we can accept that the means for the Jensen values are uniform from one year to another.

15. *Contingency table (by year)*

Year	BEAT		
	NO	YES	Total
1993	8	4	12
1994	9	3	12
1995	4	8	12
1996	5	7	12
1997	6	6	12
1998	5	7	12
1999	6	6	12
2000	4	8	12
2001	8	4	12
2002	7	5	12
2003	4	8	12
2004	6	6	12
2005	2	10	12
2006	2	10	12
Total	76	92	168

Pearson chi2 (13) = 19.9908 Pr = 0.095
likelihood-ratio chi2(13) = 21.0581 Pr = 0.072

The contingency table confirms the result of the previous test, namely, that there are no differences between the Jensen values for the different years and that any small difference can be due to chance.

Abstract

To deal with today's uncertain and dynamic business environments with different background of decision makers in computing trade-offs among multiple organizational goals, our series of papers adopts an analytic hierarchy process (AHP) approach to solve various accounting or finance problems such as developing a business performance evaluation system and developing a banking performance evaluation system. AHP uses hierarchical schema to incorporate nonfinancial and external performance measures. Our model has a broader set of measures that can examine external and nonfinancial performance as well as internal and financial performance. While AHP is one of the most popular multiple goals decision-making tools, multiple-criteria and multiple-constraint (MC^2) linear programming approach also can be used to solve group decision-making problems such as transfer pricing and capital budgeting problems. This model is rooted by two facts. First, from the linear system structure's point of view, the criteria and constraints may be "interchangeable." Thus, like multiple criteria, multiple-constraint (resource availability) levels can be considered. Second, from the application's point of view, it is more realistic to consider multiple resource availability levels (discrete right-hand sides) than a single resource availability level in isolation. The philosophy behind this perspective is that the availability of resources can fluctuate depending on the decision situation forces, such as the desirability levels believed by the different managers. A solution procedure is provided to show step-by-step procedure to get possible solutions that can reach the best compromise value for the multiple goals and multiple-constraint levels.

29.1 Introduction

In this chapter, we provide an up-to-date review on our past works in AHP and MC^2 linear programming models to solve real-world problems faced by managers in accounting and finance. These applications include developing a business performance evaluation system using an analytic hierarchical model, a banking performance evaluation system, capital budgeting, and transfer pricing problems. A good performance measurement system should incorporate strategic success factors, especially to be successful in today's competitive environment. Balanced scorecard is a hot topic, but it lacks linkages among different basic units of financial and nonfinancial measures or across different levels of managers. The model proposed in this study uses a three-level hierarchical schema to combine financial and nonfinancial performance measures systematically. Its emphasis is on an external as well as an internal business performance measures such as the balanced scorecard method. This method is more likely to cover a broader set of measures that include operational control as well as strategic control.

The purpose of this chapter is to provide additional insight for managers who face group decision-making problems in accounting and finance and want to find practical solutions.

29.2 Designing a Comprehensive Performance Evaluation System: Using the Analytic Hierarchy Process

AHP is one of the most popular multiple goals decision-making tools (Ishizaka et al. 2011). Designing a comprehensive performance measurement system has frustrated many managers (Eccles 1991). The traditional performance measures enterprises have used may not well fit in for the new business environment and competitive realities. The figures that enterprises have traditionally used are not very useful for the information-based society we are becoming. We suspect that firms are much more productive than these out-of-date measures.

A broad range of firms is deeply engaged in redefining how to evaluate the performance of their businesses. New measurements for quantification are needed to perform business evaluation. Drucker (1993) put the ever-increasing measurement dilemma this way:

> Quantification has been the rage in business and economics these past 50 years. Accountants have proliferated as fast as lawyers. Yet we do not have the measurements we need. Neither our concepts nor our tools are adequate for the control of operations, or for managerial control. And, so far, there are neither the concepts nor the tools for business control, i.e., for economic decision making. In the past few years, however, we have become increasingly aware of the need for such measurements.

Drucker's message is clear: a traditional measure is not adequate for business evaluation. A primary reason why traditional measures fail to meet new business needs is that most measures are lagging indicators (Eccles and Pyburn 1992).

The emphasis of accounting measures has been on historical statements of financial performance. They are the result of management performance, not the cause of it; i.e., they are better at measuring the consequence of yesterday's decisions but unlikely to provide useful indicators for future success. As a result, they easily conflict with new strategies and current competitive business realities.

To ameliorate this accounting lag situation, researchers have frequently attempted to provide new measuring procedures (Kaplan 1986; Wu et al. 2011). Yet most measuring guidelines may not be well represented analytically. Managers keep asking: What are the most important measures of performance? What are the associations among those measures? Unfortunately, we know little about how measures are integrated into a performance measurement system regarding a particular business. For example, is the customer service perceived as a more important measure than cost of quality? Another question often raised is: What is the association between the customer service and on-time delivery or manufacturing cycle time?

The current wave of dissatisfaction with traditional accounting systems has been intensified partly because most measures have internal and financial focus. The new measure should broaden the basis of nonfinancial performance measurement. Measures must truly predict long-term strategic success. External performance relative to competitors such as market share is as of importance as internal measures. In addition, the recent rise of global competitiveness reemphasizes the primacy of operational, i.e., nonfinancial, performance over financially oriented performance. Nonfinancial measures reflect the actionable steps needed for surviving in today's competitive environment (Fisher 1992).

When a company uses an activity-based costing system (Campi 1992; Ayvaz and Pehlivanli 2011) or just-in-time manufacturing system, using nonfinancial measures is inevitable. Nonfinancial measures reduce communication gap between workers and managers; i.e., workers can better understand what they are measured by, and managers can get timely feedback and link them to strategic decision making.

The answer proposed in this study is to use hierarchical schema to incorporate nonfinancial and external performance measures. The model has a broader set of measures that can examine external and nonfinancial performance as well as internal and financial performance. On the basis of the schema, this chapter demonstrates how Saaty's analytic hierarchy process (e.g., see Saaty (1980) and Harker and Vargas (1987)) can be merged with the performance measurement. The analytic hierarchy process is a theory of measurement that has been widely applied in modeling human judgment process. In this sense, the performance measuring method proposed in this study is referred to as the Analytic Hierarchical Performance Model (AHPM).

While the AHP has been applied in a number of cases of capital budgeting, auditing, preference analysis, and balanced scorecard to product planning, enterprise risk management, and internal control structure study (see Arrington et al. 1984; Boucher and MacStravic 1991; Liberatore et al. 1992; Hardy and Reeve 2000; Huang et al. 2011; Li et al. 2011), little attention is devoted to the problem of an analytical and comprehensive business performance model to cover a broader base of measures in the currently changing environment in accounting information systems. Although Chan and Lynn (1991) originally investigated the application of the AHP in business performance evaluation, the problem of structuring the decision hierarchy in an appropriate manner is yet to be explored. The methodology proposed in this chapter will resolve this issue.

29.2.1 Hierarchical Schema for Performance Measurement

The AHP is a theory of measurement that has been extensively applied in modeling the human judgment process (e.g., Lee 1993; Muralidhar et al. 1990). It decomposes a complex decision operation into a multilevel hierarchical structure. The primary advantage of the AHP is its simplicity and the availability of the software.

Several desirable features of the AHP can help resolve issues in performance evaluation. For example, nonfinancial and external effects can be identified and integrated with financial and internal aspects of business performance through the AHP. Furthermore, the AHP is a participation-oriented methodology that can aid coordination and synthesis of multiple evaluators in the organizational hierarchy. Participation makes a positive contribution to the quality of the performance evaluation process. This point is further explored within the context of hierarchical schema of performance evaluation as follows.

Performance measures have the relationship with management levels. They need to be filtered at each superior/subordinate level in an organization; i.e., measures do not need to be the same across management levels. Performance measures at each level, however, should be linked to performance measures at the next level up. Performance measurement information is tailored to match the responsibility of each management level. For example, at the highest level, the CEO has responsibility for performance of the total business. In contrast, the production manager's main interest may be in cost control because he or she is responsible for this. Taking this idea into account leads to the notion that the performance measuring process consists of different levels according to management levels.

Depending on organizational levels, therefore, a three management level model will be suggested: top, middle, and operational. To recognize the ever-increasing importance of nonfinancial measures, at the top management level, the hierarchy consists of two criteria: nonfinancial and financial performance. One level lower (middle-level management) includes performance criteria such as market share, customer satisfaction, productivity, ROI, and profitability.

The lowest level (operational management level) includes measures that lead to simplifications in the manufacturing process as related to high-level performance measures. Examples are quality, delivery, cycle time, inventory turnover, asset turnover, and cost. Typically, the criteria at the lowest level may have several sub-criteria. For example, quality measures may have four sub-criteria: voluntary, (appraisal and prevention,) and failure, (internal and external,) costs. With relation to these criteria, accounting information is controlled typically with respect to each product (or service) or division (or department). As a result, product and division levels are added. One should keep in mind that the above three-level hierarchical schema is dynamic over time. As a company evolves, the hierarchy must be accordingly adjusted.

Another interesting aspect is that the hierarchy is not company invariant. The hierarchy must be adjusted depending on unique situation faced by each individual company or division. Basically, the hierarchal schema is designed to accommodate any number of levels and alternatives. New level or alternative can be easily added or deleted to the hierarchy once introduced. For example, another level regarding products may be added at the bottom in order to evaluate performance of different products.

29.2.2 Analytic Hierarchical Performance Model

Based on the hierarchical structure, the performance indices at each level of the AHPM are derived by the analytic hierarchy process. The AHPM collects input judgment in the form of matrix by pairwise comparisons of criteria. An eigenvalue method is then used to scale weights of criteria at each level; i.e., the relative importance of each criterion at each level is obtained. The relative importance is defined as a performance index with respect to each alternative (i.e., criterion, product, or division).

From now on, each step of the AHPM in obtaining the weights is explored. First, a set of useful strategic criteria must be identified. Let n_t be the total number of criteria under consideration at the top management level. Typically, $n_t = 2$ (nonfinancial and financial measures). The relative weight of each criteria may be evaluated by pairwise comparison; i.e., two criteria are compared at one time until all combinations of comparison are considered (only one pairwise comparison is needed if $n_t = 2$). The experience of many users of this method and the experiments reported (Saaty 1980) are likely to support that the 1–9 scale for pairwise comparisons captures human judgment fairly well while the scale can be altered to suit each application. The result from all of pairwise comparisons is stored in an input matrix:

$$A_t = \left(\alpha_{tij}\right) \text{ (an } n_t \text{ by } n_t \text{ matrix).}$$

The element α_{tij} states the importance of alternative i compared to alternative j. For instance, if at $\alpha_{t12} = 2$, then criterion 1 is twice as important as criterion 2. Applying an eigenvalue method to A_t results in a vector $W_t = (w_{ti})$ that has n_t elements.

In addition to the vector, the inconsistency ratio (γ) is obtained to estimate the degree of inconsistency in pairwise comparisons. The common guideline is that if the ratio surpasses 0.1, a new input matrix must be generated. Generally speaking, each element of the vector resulting from an eigenvalue method is the estimated relative weight of the corresponding criterion of one level with respect to one level higher; i.e., the element w_{ti} is the relative weight of the ith criteria at this level.

At the second level of hierarchy, consider the ith criterion of the top management level. Then, we have one input matrix of pairwise comparisons of criteria (at middle management level) that corresponds to the ith criterion of the top management level. The result is stored in an n_m by n_m matrix A^i_m. Here, n_m is the total number of criteria at this level. Applying an eigenvalue method to A^i_m results in the relative weight for each criterion with relation to the i^{th} criteria at one level higher. This "local relative weight" is stored in a local weighing vector W^i_m. We need n_t local weighing vectors at this level. The "global relative weight" at this level is computed and then stored in a vector $W_m = (w_{mi})$ that has the n_m elements as

$$W_m = W_t \times \left[W_m^1 \ldots W_m^{nt}\right].$$

The similar computing process continues at the operational management level until we have all global relative weights as W_o.

A prototype for the AHPM with three-level hierarchies was built via commercial software for the analytic hierarchy process, called *Expert Choice* (Forman et al. 1985).

Above relative weights can be utilized in a number of ways for performance measurement. Clearly, it implies the relative importance among criteria at each level. For example, consider an automobile company where market share and ROI are two important criteria in performance evaluation. If the AHPM generates their weights as 0.75 and 0.25, respectively, it is reasonable to conclude that market share affects the company's performance three times higher than ROI. The weights can be used as a measure for allocating future resources in products or divisions. Assume the automobile company produces two types of autos, sedan and minivan. If the AHPM generates global relative weights as 0.8 and 0.2, respectively, i.e., the performance of sedans is four times higher than minivans, then this may provide a good reason for the CEO to invest in sedans four times higher than minivans.

One important performance control measure is the rate of performance change that can be computed at any level. The change of performance can be measured. This measure is useful in estimating the elasticity of the performance of any alternative. This elasticity can aid in resource allocation decisions; i.e., further resources may be assigned to more elastic products of divisions.

For the example of computing this elasticity, at the middle management level, the rate is then

$$\varepsilon_m = \sum\nolimits_{i=1}^{nm} W_{mi} \Delta C_{mi} / C_{mi}.$$

Here, ΔC_{mi} is the amount of change of the ith criteria. For example, if the ROI is increased from 5 % to 7 % and the market share is changed from 20 % to 25 % in the automobile company discussed above,

$$\varepsilon_m = 0.25 \times \frac{2}{5} + 0.75 \times \frac{5}{20} = 0.2875.$$

We may conclude that the overall business performance has been increased by \$28.75 % with respect to middle management level. Similarly, the performance change rates at any level can be obtained. Typically, they vary depending on levels of the AHPM; i.e., they have different implications.

29.2.3 An Example

The suitability of the AHPM is illustrated with a study on a hypothetical automobile company. Nonfinancial criteria include market share, customer satisfaction, and productivity. Financial criteria include ROI and profitability. At the operational level, six criteria such as quality, delivery, cycle time, inventory turnover, asset turnover, and cost are considered.

First, nonfinancial and financial criteria are compared and stored in a vector:

$$\mathrm{W_t} = (0.4, 0.6).$$

Next, the middle management level is considered. The relative weights of middle-level performance criteria with relation to each top-level criterion are to be computed. First, the local relative weights were computed.

For the nonfinancial criteria,

$$\mathrm{A_m^1} = \begin{bmatrix} 1 & 2 & 4 \\ 1/2 & 1 & 3 \\ 1/4 & 1/3 & 1 \end{bmatrix}$$

For the sake of convenience, ROI and profitability are not listed in this comparison matrix.

The lower triangle is not listed because, in the eigenvalue method, the lower triangle is simply the reciprocity of the upper triangle. As a result,

$$W_m^1 = (0.558,\ \ 0.320,\ \ 0.122).$$

For each weighing computing, an inconsistency ratio was computed and checked for acceptance; i.e., in this case, the ratio ($\gamma = 0.017$) was accepted because $\gamma \leq 0.1$.

For the financial criteria, ROI is estimated to be twice more important than profitability, i.e.,

$$W_m^2 = (0.667,\ \ 0.333).$$

Accordingly, the global relative weights of the managerial criteria (in the order of market share, customer satisfaction, productivity, ROI, and profitability) are then

$$\begin{aligned} \mathrm{W_m} &= (0.4,\ \ 0.6) \times \begin{bmatrix} 0.558 & 0.320 & 0.122 & 0 & 0 \\ 0 & 0 & 0 & 0.667 & 0.333 \end{bmatrix} \\ &= (0.223,\ \ 0.128,\ \ 0.049,\ \ 0.400,\ \ 0.200). \end{aligned}$$

Here, the global relative weights of market share, customer satisfaction, productivity, ROI, and profitability are 22.3 %, 12.8 %, 4.9 %, 40 %, and 20 %, respectively. Note that these percentages are elements of the above $\mathrm{W_m}$.

Let us move down to the operational level. The following are local relative weights of operational level criteria (in the order of quality, delivery, cycle time, cost, inventory turnover, and asset turnover).

For the market share,

$$\mathrm{A}_0^1 = \begin{bmatrix} 1 & 2 & 3 & 3 & 5 & 7 \\ 1/2 & 1 & 2 & 3 & 4 & 5 \\ 1/3 & 1/2 & 1 & 2 & 4 & 5 \\ 1/3 & 1/3 & 1/2 & 1 & 2 & 3 \\ 1/5 & 1/4 & 1/4 & 1/2 & 1 & 2 \\ 1/7 & 1/5 & 1/5 & 1/3 & 1/2 & 1 \end{bmatrix}$$

For convenience, the local weights are arranged in the order of quality, cycle time, delivery, cost, inventory turnover, and asset turnover:

$$W_o^1 = (0.372,\ 0.104,\ 0.061,\ 0.250,\ 0.174,\ 0.039).$$

Similarly,

$$W_o^2 = (0.423,\ 0.038,\ 0.270,\ 0.185,\ 0.055,\ 0.029);$$

$$W_o^3 = (0.370,\ 0.164,\ 0.106,\ 0.260,\ 0.064,\ 0.037);$$

$$W_o^4 = (0.220,\ 0.060,\ 0.030,\ 0.4150,\ 0.175,\ 0.101);$$

$$W_o^5 = (0.246,\ 0.072,\ 0.065,\ 0.334,\ 0.160,\ 0.122).$$

Consequently, we get the global relative weights of operational criteria as

$$\begin{aligned} \mathrm{W}_o &= (0.223, 0.128, 0.049, 0.400, 0.200) \\ &\quad \times \begin{bmatrix} 0.372 & 0.104 & 0.061 & 0.250 & 0.174 & 0.039 \\ 0.423 & 0.038 & 0.270 & 0.185 & 0.055 & 0.029 \\ 0.370 & 0.164 & 0.106 & 0.260 & 0.064 & 0.037 \\ 0.220 & 0.060 & 0.030 & 0.414 & 0.175 & 0.101 \\ 0.246 & 0.072 & 0.065 & 0.334 & 0.160 & 0.122 \end{bmatrix} \\ &= (0.292, 0.074, 0.078, 0.324, 0.151, 0.079). \end{aligned}$$

Finally, the relative importance of operational level performance measures are 29.2 %, 7.4 %, 7.8 %, 32.4 %, 15.1 %, and 7.9 %, respectively. One should note that nonfinancial measures are integrated with financial measures in the scaling process.

Our automobile company can adopt these performance measures for further analysis. The measures serve as the basis for the rate of performance change. In addition, they can be further used for evaluating the performance of each product if the product level is connected to the operational management level in the AHPM.

29.2.4 Discussions

It is too optimistic to argue that there can be one right way of measuring performance. There are two factors to be considered. First, each business organization requires its own unique set of measures depending on its environment. What is most effective for a company depends upon its history, culture, and management style (Eccles 1991). To be used for any business performance measurement, a well-designed model must be flexible enough to incorporate a variety of measures while retaining major aspects. Second, managers should change measures over time. In the current competitive business environment, change is not incidental. It is essential. Change must be managed. The AHPM is highly flexible so that managers may adjust its structure to evolving business environments. This flexibility will allow a company to improve its performance measurement system continuously.

Generally, a performance measurement system exists to monitor the implementation of planning of an organization and aid to motivate desirable individual performance through a realistic communication of performance information in related goals of business. This premise of performance measurement requires a significant number of feedbacks and corrective actions in the practice of accounting information systems (Nanni et al. 1990), i.e., feedbacks between levels and also within level. In the implementation of AHPM, these activities are common procedures. A clean separation of levels in the hierarchy of the AHPM is an idealization for simplifying the presentation. The flexibility of the AHPM, however, accommodates as many feedbacks and corrective actions as possible.

Performance is monitored by group rather than by an individual because of its ever-increasing importance of teamwork in the success of businesses. The integrated structure of the AHPM facilitates group decision and thus increases the chance that managers put trust in the resulting measures. This structure will enhance more involvement of lower-level managers as well as workers when a firm implements the AHPM. Furthermore, the hierarchy of the AHPM corresponds to that of business organization. As a result, group decision at each level is facilitated. For example, middle-level managers will be responsible for determining weights for middle-level criteria while lower-level managers will be responsible for operational level criteria.

The iterative process of weighing goals among managers, as the implementation of AHPM progresses, will help them to understand which strategic factors are important and how these factors are linked to other goals to be a successful company as a group.

Information technology plays a critical role in designing a performance measurement system to provide timely information to management. A computer-based decision support system can be used to utilize this conceptual foundation in a real-world situation. The AHPM can be easily stored in an enterprise database because of the commercial software, *Expert Choice*. As a result, the AHPM can be readily available to each management level via the network system of an enterprise. The AHPM fits any corporate information architecture to pursue the company's long-term strategy.

29.2.5 Conclusions

A well-designed performance model is a must for an enterprise to gain competitive edges. The performance measurement model proposed in this study is the first kind of analytical model to cover a wide variety of measures while providing operational control as well as strategic control. With comparison to previous evaluation methods, the model shows advantages such as flexibility, feedbacks, group evaluation, and computing simplicity. A prototype was built via a personal computer so that the model can be applied to any business situations.

The possible real-time control is of importance for the competitive business environment we are facing today. In sum, the contribution of this study is of both conceptual and practical importance.

29.3 Developing a Comprehensive Performance Measurement System in the Banking Industry: An Analytic Hierarchy Approach

The objective of this study is to design a practical model for a comprehensive performance measurement system that incorporates strategic success factors in the banking industry. A performance measurement system proposed in this study can be used to evaluate top managers of a main bank or managers of a branch office.

Performance measurement should be closely tied to goal setting of an organization because it feeds back information to the system on how well strategies are being implemented (Chan and Lynn 1991; Eddie et al. 2001). A balanced scorecard approach (Kaplan and Norton 1992; Tapinos et al. 2011) is a hot topic currently in this area, but it does not provide systematic aggregation of each level as well as different levels of managers' performance for the overall company. In other words, there is no systematic linkage between financial and nonfinancial measures across different levels of management hierarchy. A traditional performance measurement system, which focuses on financial measures such as return on assets (ROA), however, may not serve this purpose well for middle- or lower-level managers in the new competitive business environment either.

The model proposed in this study will have a broader set of measures that incorporate traditional financial performance measures such as return on assets and debt to equity ratio as well as nonfinancial performance measures such as the quality of customer service and productivity. Using Saaty's analytic hierarchy process (AHP) (Saaty 1980; Harker and Vargas 1987), the model will demonstrate how multiple performance criteria can be systematically incorporated into a comprehensive performance measurement system. The AHP enables decision makers to structure a problem in the form of a hierarchy of its elements according to an organization's structure or ranks of management levels and to capture managerial decision preferences through a series of comparisons of relevant factors or criteria. The AHP has been applied recently to several business problems (e.g., divisional performance evaluation (Chan and Lynn 1991), capital budgeting

(Liberatore et al. 1992), and real estate investment (Kamath and Khaksari 1991), marketing applications (Dyer and Forman 1991), information system project selection (Schniederjans and Wilson 1991), activity-based costing cost driver selection (Schniederjans and Garvin 1997), developing lean performance measures (DeWayne 2009), and customer's choice analysis in retail banking (Natarajan et al. 2010)). The AHP is relatively easy to use and its commercial software is available. This study will be an analytical and comprehensive performance evaluation model to cover a broader base of measures in the rapidly changing environment of today's banking industry. The following section presents background. The third section discusses methodology. The fourth section presents a numerical example. The last section summarizes and concludes this chapter.

29.3.1 Background

Recent research topic guide from Institute of Management Accountants lists "performance measurement" as one of top priority research issues. Therefore, this project will be interesting to bank administrators as well as managerial accountants.

With unprecedented competitive pressure from nonbanking institutions, deregulation, and the rapid acquisition of smaller banks by large national or regional banks, the most successful banks in the new millennium will be the ones that adapt strategically to a changing environment (Calvert 1990). Management accounting and finance literature have emphasized using both financial and nonfinancial measures as performance guidelines in the new environment (e.g., Chan and Lynn 1991; Rotch 1990). However, most studies do not propose specifically how we should incorporate these financial and nonfinancial factors into a formal model.

The performance measurement system proposed in this study is the formal model applied using the AHP in the banking industry to cover a wide variety of measures while providing operational control as well as strategic control. The AHP can incorporate multiple-subjective goals into a formal model (Dyer and Forman 1991). Unless we design a systematic performance measurement system that includes financial as well as nonfinancial control factors, there may be incorrect behavior by employees because they misunderstand the organization's goals and how they relate to their individual performance.

Compared with previous evaluation methods, the model proposed in this study will have advantages such as flexibility, continuous feedback, teamwork in goal setting, and computational simplicity. To be used for any business performance measurement, a well-designed model must be flexible enough to incorporate a variety of measures while retaining major success factors. The AHP model is flexible enough for managers to adjust its structure to a changing business environment through an iterative process of weighing goals. This flexibility will allow a company to improve its performance measurement system continuously. Through the iterative process of goal comparisons, management could get continuous feedback for the priority of goals and work as a team. The possible real-time control is of importance in the competitive business environment we are facing today.

29.3.2 Methodology

The analytic hierarchy process (AHP) collects input judgments in the form of a matrix by pairwise comparisons; i.e., two criteria are compared at one time. The experience of many users of this method supports use of a 1–9 scale for pairwise comparisons to capture human judgment while the scale can be altered to fit each application (Saaty 1980).

A simple example will be provided to explain how AHP operates. Consider the situation where a senior executive has to decide on which of three managers to promote to a senior position in the firm. The candidate's profiles have been studied and rated on three criteria: leadership, human relations skills, and financial management ability. First, the decision maker compares each of the criteria in pairs to develop a ranking of the criteria. In this case, the comparisons would be:

1. Is leadership more important than human relations skills for this job?
2. Is leadership more important than financial management ability for this job?
3. Are human relations skills more important than financial management ability for this job?

The response to these questions would provide an ordinal ranking of the three criteria. By adding a ratio scale of 1–9 for rating the relative importance of one criterion over another, a decision maker could make statements such as "leadership is four times as important as human relations skills for this job," "financial management ability is three times as important as leadership," and "financial management ability is seven times as important as human relations skills." These statements of pairwise comparisons can be summarized in a square matrix. The preference vectors are then computed to determine the relative rankings of the three criteria in selecting the best candidate. For example, the preference vectors of the three criteria are 0.658 for financial management ability, 0.263 for leadership, and 0.079 for human relations skills.

Once the preference vector of the criteria is determined, each of the candidates can be compared on the basis of the criteria in the following manner:

1. Is candidate A superior to candidate B in leadership skills?
2. Is candidate A superior to candidate C in leadership skills?
3. Is candidate B superior to candidate C in leadership skills?

Again, rather than using an ordinal ranking, the degree of superiority of one candidate over another can be assessed. The same procedures can be applied to human relations skills and financial management ability. The responses to these questions can be summarized in matrices where the preference vectors are again computed to determine the relative ranking of the three candidates for each criterion. Accordingly, the best candidate should be the one who ranks "high" on the "more important" criteria. The matrix multiplication of preference vectors of candidates on evaluation criteria and the preference vector of evaluation criteria will provide the final ranking of the candidates. In this example, the candidates are ranked A, B, and C. This example provides the usefulness of the AHP for setting priorities for both qualitative and quantitative measures (Chan and Lynn 1991).

We could apply the same procedures to a bank. Based on the hierarchical structure of a banking institution, the relative weights of criteria at each level of managers are derived by AHP. Here the relative importance of performance measures can be defined as a performance index with respect to each alternative (i.e., criterion, service, or branch office). For example, derive the relative weights of financial and nonfinancial criteria at the highest management level through the pairwise comparisons of criteria. Next, the relative weights of middle-level performance criteria with relation to each top-level criterion are to be computed then enter these relative weights into an *n* x *n* matrix format. Finally, this matrix is multiplied by the relative weights of criteria of the top management level. The same procedures can be applied to the next lower-level management. This AHP approach could link systematically the hierarchical structure of business performance measurement between different levels of organizational structures.

Consider a local bank where market share and return on assets are two important criteria in performance evaluation. If the AHP generates their weights as 0.4 and 0.6, respectively, it is reasonable to conclude that return on assets affects the bank's performance one and a half times higher than market share. The weights can be used as a measure for allocating future resources in products or branch offices. Assume the bank has two types of services, commercial loans and residential mortgage loans. If the AHP generates relative weights as 0.8 and 0.2 (i.e., the performance of commercial loans is four times higher than mortgage loans), then this may provide a good reason for top management to invest resources in the commercial loan market four times higher than the residential loan market.

The use of the AHP for multiple-criteria situation is superior to ad hoc weighing because it has the advantage of forcing the decision maker to focus exclusively on the criteria at one time and the way in which they are related to each other (Saaty 1980).

A model could be built using a microcomputer program called *Expert Choice* so that the model can be applied to any bank easily.

29.3.3 A Numerical Example

This section presents a numerical example for a commercial bank. The Commercial Omaha Bank (COB) is a local bank that specializes in commercial loans. Their headquarters are located in Omaha, Nebraska, and they have several branch offices throughout rural areas of Nebraska. The top management of COB realized that the current measurement system is not adequate for their strategic performance management and identified the following measures based on the hierarchy of the organization for their new performance measurement using AHP. These measures are shown in Table 29.1.

The OCB uses financial criteria such as return on assets and debt to equity and nonfinancial criteria such as market share, productivity, and quality of service. At the lowest management level, income to interest expense, service charges, interest revenue, growth of deposits, default ratio, and customer satisfaction can be used. Each computing step of the AHP is discussed as follows.

First, nonfinancial and financial criteria are computed and the result is entered in a vector:

$$W_t = (0.5, 0.5).$$

Table 29.1 New performance measures

Level of organization	High	Middle	Low
	Financial measures	Return on assets	Income to interest expenses
		Debt to equity	Service charges
			Interest revenue
	Nonfinancial measures	Market share	Growth of deposits
		Productivity	Default ratio
		Quality	Customer satisfaction

Next, the mid-level management is considered. The relative weight of mid-level performance criteria with relation to each top-level criterion is to be computed. Here, the local relative weights are computed.

For the nonfinancial criteria,

$$A_m^1 \begin{bmatrix} 1 & 3 & 4 \\ 1/3 & 1 & 3 \\ 1/4 & 1/3 & 1 \end{bmatrix}.$$

Here, the market share is estimated to be three times more important than productivity and four times more important than the quality of service. Productivity is estimated to be three times more important than the quality of service. From this result,

$$W_m^1 = (0.608, 0.272, 0.120).$$

For each weight computation, an inconsistency ratio (γ) was computed and checked for the acceptance level. If $\gamma \leq 0.1$, it is acceptable. For this example, it is acceptable since $\gamma = 0.065$. If it is not acceptable, the input matrix should be adjusted or recomputed.

For the financial criteria, ROA is estimated to be three times more important than debt to equity ratio. Therefore,

$$W_m^2 = (0.75, 0.25).$$

The global relative weights of the criteria are

$$\begin{aligned} \mathrm{W_m} &= (0.5, 0.5) \times \begin{pmatrix} 0.608, 0.272, 0.120, 0, 0 \\ 0, 0, 0, 0.75, 0.25 \end{pmatrix} \\ &= (0.304, 0.136, 0.060, 0.375, 0.125). \end{aligned}$$

Here the global relative weights of market share, productivity, quality of service, ROA, and debt to equity ratio are 30.4 %, 13.6 %, 6 %, 37.5 %, and 12.5 %, respectively.

Let us move to the lower-level managers. Income to interest expense, service charges, interest revenue, growth of deposits, default ratio, and customer satisfaction are criteria at this level.

For market share,

$$A_0^1 = \begin{bmatrix} 1 & 2 & 3 & 4 & 5 & 6 \\ 1/2 & 1 & 2 & 3 & 4 & 5 \\ 1/3 & 1/2 & 1 & 3 & 4 & 5 \\ 1/4 & 1/3 & 1/3 & 1 & 3 & 4 \\ 1/5 & 1/4 & 1/4 & 1/3 & 1 & 3 \\ 1/6 & 1/5 & 1/5 & 1/4 & 1/3 & 1 \end{bmatrix}$$

For simplicity of presentation, the local weights are arranged in the order of income to interest expense, service charges, interest revenue, growth of deposits, default ratio, and customer satisfaction:

$$W_o^1 = (0.367, 0.238, 0.183, 0.109, 0.065, 0.038).$$

Here the local weights with relation to market share are 36.7 %, 23.8 %, 18.3 %, 10.9 %, 6.5 %, and 3.8 %, respectively.

For other criteria at one level higher, the local weights can be calculated in the same way. These are

$$W_o^2 = (0.206, 0.163, 0.179, 0.162, 0.143, 0.146);$$

$$W_o^3 = (0.155, 0.231, 0.220, 0.103, 0.169, 0.122);$$

$$W_o^4 = (0.307, 0.197, 0.167, 0.117, 0.117, 0.094);$$

$$W_o^5 = (0.266, 0.133, 0.164, 0.159, 0.154, 0.124).$$

For the next step, the global relative weights of lower-level management criteria are

0.367 0.238 0.183 0.109 0.065 0.038

$$\mathrm{W}_0 = (0.304, 0.136, 0.060, 0.375, 0.125) \times \begin{bmatrix} 0.206 & 0.163 & 0.179 & 0.162 & 0.143 & 0.146 \\ 0.155 & 0.231 & 0.220 & 0.103 & 0.169 & 0.122 \\ 0.307 & 0.197 & 0.167 & 0.117 & 0.117 & 0.094 \\ 0.266 & 0.133 & 0.164 & 0.159 & 0.159 & 0.124 \end{bmatrix}$$
$$= (0.297, 0.199, 0.176, 0.125, 0.112, 0.089).$$

Finally, the relative importance of lower-level performance measures are 29.7 %, 19.9 %, 17.6 %, 12.54 %, 11.2 %, and 8.9 %, respectively. Note that financial measures are integrated with nonfinancial measures in the scaling process. The OCB can extend these performance measures into the next lower level of each product using the same method.

29.3.4 Summary and Conclusions

A performance measurement system should incorporate nonfinancial as well as financial measures to foster strategic success factors for a bank in the new environment. Generally, a good performance measurement system should monitor employees' behavior in a positive way and be flexible enough to adapt to the changing environment. To motivate employees, a bank should communicate performance information of an individual employee in relation to overall business goals. This characteristic of performance measurement requires a significant amount of feedback both between and within levels and corrective actions in the practice of accounting information (Nanni et al. 1990).

The AHP model proposed in this study is flexible enough to incorporate the "continuous improvement" philosophy of today's business environment by changing weighting values of measures. In addition, the integrated structure of AHP allows group performance evaluation, which is a buzzword for "teamwork" in today's business world. The iterative process of getting input data in the AHP procedure also helps each manager as well as employee to be aware of the importance of strategic factors of each performance measure of the bank.

29.4 Optimal Trade-offs of Multiple Factors in International Transfer Pricing Problems

Ever since DuPont and General Motors Corporation of the USA initiated transfer pricing systems for the interdivisional transfer of resources among their divisions, many large organizations, with the creation of profit centers, have used a transfer pricing system in one way or the other. Recently, transfer pricing problems have become more important because most corporations increase transfer of goods or services dramatically among their divisions as a result of restructuring or downsizing their organizations (Tang 1992). Therefore, designing a good transfer pricing strategy should be a major concern for both top management and divisional managers (Curtis 2010).

Transfer pricing problems have been extensively studied by a number of scholars. Many of them have recognized that a successful transfer pricing strategy should consider multiple criteria (objectives), such as overall profit, total market share, divisional autonomy, performance evaluation, and utilized production capacity (Abdel-khalik and Lusk 1974; Bailey and Boe 1976; Merville and Petty 1978; Yunker 1983; Lecraw 1985; Lin et al. 1993). However, few developed methods have a capability of dealing with all possible optimal trade-offs of multiple criteria in optimal solutions of the models with involvement of multiple decision makers.

In this chapter, we propose a multiple factor model to provide managers from different background, who are involved in transfer price decision making of a multidivisional corporation, with a systematic and comprehensive scenario about all possible optimal transfer prices depending on both multiple-criteria and multiple-constraint levels (in short, multiple factors). The trade-offs of the optimal transfer prices, which have rarely been considered in the literature, can be used as a basis for managers of corporations to make a high-quality decision in selecting their transfer pricing systems for business competition.

This chapter proceeds as follows. First, existing transfer pricing models will be reviewed. Then, the methodology of formulating and solving a transfer pricing model with multiple factors will be described. A prototype of a transfer pricing problem in a corporation will be illustrated to explain the implications of the multiple factor transfer pricing model. Finally, conclusions and remaining research problems will be presented.

29.4.1 Existing Transfer Pricing Models

In the literature of transfer pricing problems, the various approaches can be categorized into four groups: (i) market-based pricing, (ii) accounting-based pricing, (iii) marginal cost pricing (or opportunity cost pricing), and (iv) negotiation-based pricing. Market-based prices are ideal for transfer prices when external market prices are available. Even though empirical research has found that some corporations prefer cost-based prices to market-based prices, market-based pricing method is recommended when the emphasis is on the motivation of divisional managers (Borkowski 1990). Pricing intermediate goods based on the market price will motivate the supplying division to reduce its costs to achieve efficiency and to allow divisional autonomy for both the supplying division and the purchasing division. Statistics show that almost a third of corporations actually use market-based transfer pricing (Tang 1992).

However, if there is no outside market for intermediate goods or services, then accounting-based pricing, marginal cost pricing (economic models and mathematical programming techniques), or negotiation-based pricing (behavioral approach) is commonly recommended for finding a transfer pricing system.

In the accounting-based pricing approach, the divisional managers simply use accounting measurements of the divisions, such as full costs or variable costs, as their transfer prices. Thus, the transfer price of one division may differ from that of another division. These transfer prices may not be globally optimal for the corporation as a whole (Abdel-khalik and Lusk 1974; Eccles 1983).

In marginal cost pricing approaches, Hirshleifer (1956) recommended use of an economic model to set transfer pricing at a manufacturing division's marginal cost to achieve the global optimal output. A problem of this economic model is that it can destroy the divisional manager's autonomy, and the supplying division may not get the benefit of efficiencies. Moreover, the manufacturing division manager in this case should be evaluated based on cost, not on profit. Similarly, Gould (1964) and Naert (1973) recommended economic models based on current entry and current exit prices. Their models also focus on global profit maximization and have the same problems as Hirshleifer's. Note that when the transfer price is set based on marginal costs, the division should be either controlled as a standard cost center or merged into a larger profit center with a division that processes the bulk of its output.

Ronen and McKinney (1970) suggested dual prices in which a subsidy is given to the manufacturing division by the central office in addition to marginal costs. This subsidy would not be added to the price charged to the purchasing division. They believed that autonomy is enhanced because the corporate office is only a transmitter of information, not a price setter, and that the supplying division has the same autonomy as an independent supplier. However, there might be a gaming chance where all divisions are winners but the central office is a loser. There is also a "marginal cost plus" approach that charges variable manufacturing costs (usually standard variable costs) and is supplemented by periodic lump-sum charges to the transferees to cover the transferor's fixed costs, or their fixed costs plus profit, or some kind of subsidy. It is difficult, however, to set a fixed fee that will satisfy both the supplying division and the purchasing division. This method enables the purchasing division to absorb all the uncertainties caused by fluctuations in the marketplace. Moreover, the system begins to break down if the supplying division is operating at or above the normal capacity since variable costs no longer represent the opportunity costs of additional transfers of goods and services (Onsi 1970).

As an alternative method to identify marginal costs as the transfer prices, a mathematical programming approach becomes more attractive for the transfer pricing problem because it handles complex situations in a trade setting (Dopuch and Drake 1964; Bapna et al. 2005). The application of linear programming to the transfer pricing problem is based on the relationship between the primal and dual solutions in the linear programming problem. Shadow prices, which reflect the input values of scarce resources (or opportunity cost) implied in the primal problem, can be used as the basis for a transfer price system. However, these transfer prices have the following limitations for decision making: (i) those transfer prices based on dual values of a solution tend to reward divisions with scarce resources, (ii) the linear formulation requires a great deal of local information, and (iii) transfer prices based on shadow prices do not provide a guide for performance evaluation of divisional managers.

Based on the mathematical decomposition algorithm developed by Dantzig and Wolfe (1960), Baumol and Fabian (1964) demonstrated how to reduce complex optimization problems into sets of smaller problems solvable by divisions and the central office (corporation). Although the final analysis of output decisions is made by the central manager, the calculation process is sufficiently localized that central management does not have to know anything about the internal technological arrangements of the divisions. However, this approach does not permit divisional autonomy.

Ruefli (1971) proposed a generalized goal decomposition model for incorporating multiple criteria (objectives) and some behavioral aspects within a three-level hierarchical organization into the mathematical formulation of transfer pricing problems. Bailey and Boe (1976) suggested another goal programming model as a supplement of Ruefli's model. Both models overcome the shortcoming of linear programming in dealing with multiple criteria and the organizational hierarchy. Merville and Petty (1978) used a dual formulation of goal programming to directly find the shadow price as the optimal transfer price for multinational corporations. However, the optimal solution of these models that results in the transfer prices is determined by a particular distance (norm) function because of the mathematical structure of goal programming. Thus, the optimal solution represents only a single optimal trade-off of the multiple criteria, not all possible optimal trade-offs.

Watson and Bulmer (1975) and Thomas (1980) criticized the lack of behavioral considerations in the mathematical programming approaches. They suggested a negotiated transfer pricing to further the integration of differentiation within the organization. The differentiation of the organization exists because, for example, different managers can interpret the same organizational problem differently. Generally, the negotiated transfer pricing will be successful under conditions such as the existence of some form of outside markets for the intermediate product, freedom to buy or sell outside, and sharing all market information among the negotiators. Negotiated prices may require iterative exchanges of information with the central office as a part of a mathematical programming algorithm.

29.4.2 Methodology

29.4.2.1 MC^2 Linear Programming

Practically speaking, since linear programming has only a single criterion (objective) and a single resource availability level (right-hand side), it has limitations in handling real-world transfer pricing problems. For instance, linear programming cannot be used to solve the problem in which a corporation tries to maximize overall profit and the total market share simultaneously. This dilemma is overcome by a technique called multiple-criteria (MC) linear programming (Zeleny 1974; Goicoechea et al. 1982; Steuer 1986; Yu 1985). To extend the framework of MC linear programming, Seiford and Yu (1979) and Yu (1985) formulated a model of multiple-criteria and multiple-constraint level (MC^2) linear programming. This model is rooted by two facts. First, from the linear system structure's point of view, the criteria and constraints may be "interchangeable." Thus, like multiple criteria, multiple-constraint (resource availability) levels can be considered. Second, from the application's point of view, it is more realistic to consider multiple resource availability levels (discrete right-hand sides) than a single resource availability level in isolation. The philosophy behind this perspective is that the availability of resources can fluctuate depending on the decision situation forces, such as the desirability levels believed by the different managers. For example, if the differentiation of budget among managers in transfer pricing problems (Watson and Baumler 1975) is represented by different levels of budget, then this differentiation can be resolved by identifying some best compromise of budget levels as the consensus budget.

The theoretical connections between MC linear programming and MC^2 linear programming can be found in Gyetvan and Shi (1992). Decision problems related to MC^2 linear programming have been extensively studied in Lee et al. (1990), Shi (1991), and Shi and Yu (1992). Key ideas of MC^2 linear programming, a primary theoretical foundation of this chapter, are outlined as follows.

An MC^2 linear programming problem can be formulated as

$$\begin{aligned} &\text{Max}\, \lambda^t \text{Cx} \\ &\text{s.t.}\;\; \text{Ax} \leq \text{D}\gamma \\ &\text{x} \geq 0, \end{aligned}$$

where $C \in \mathbf{R}^{\mathbf{qxn}}$, $A \in \mathbf{R}^{\mathbf{mxn}}$, and $D \in \mathbf{R}^{\mathbf{mxp}}$ are matrices of qxn, mxn, and mxp dimensions, respectively; $x \in \mathbf{R}^{\mathbf{n}}$ are decision variables; $\lambda \in \mathbf{R}^{\mathbf{q}}$ is called the *criteria parameter*; and $\gamma \in \mathbf{R}^{\mathbf{p}}$ is called the *constraint level parameter*. Both (γ,λ) are assumed unknown.

The above MC^2 problem has q criteria (objectives) and p constraint levels. If the constraint level parameter γ is known, then the MC^2 problem reduces to an MC linear programming problem (e.g., Yu and Zeleny 1975). In addition, if the criteria parameter λ is known, it reduces to a linear programming problem (e.g., Charnes and Cooper 1961; Dantzig 1963).

Denote the index set of the basic variables $\{x_{ji}, \ldots, x_{jm}\}$ for the MC^2 problem by $J = \{j_1, \ldots, j_m\}$. Note that the basic variables may contain some slack variables. Without confusion, J is also called a basis for the MC^2 problem. Since a basic solution J depends on parameters (γ, λ), define that (i) a basic solution J is *feasible* for the MC^2 problem if and only if there exists a $\gamma^0 > 0$ such that J is a feasible solution for the MC^2 problem with respect to γ^0 and (ii) J is *potentially optimal* for the MC^2 problem if and only if there exist a $\gamma^0 > 0$ and a $\lambda^0 > 0$ such that J is an optimal solution for the MC^2 problem with respect to (γ^0, λ^0). Let $\Gamma(J)$ be the *constraint level parameter set* of all γ such that the basis J is feasible and $\Lambda(J)$ be the *criteria parameter set* of all λ that the basis J is dual feasible. Then, for a given basis J of the MC^2 problem, (i) J is a feasible solution if and only if the set $\Gamma(J)$ is not empty and (ii) J is potentially optimal if and only if both sets $\Gamma(J)$ and $\Lambda(J)$ are not empty. For an MC^2 problem, there may exist a number of potentially optimal solutions {J} as parameters (γ, λ) vary depending on decision situations.

Seiford and Yu (1979) derived a simplex method to systematically locate the set of all potentially optimal solutions {J}. The computer software of the simplex method (called MC^2 software) was developed by Chien et al. (1989). This software consists of five subroutines in each iteration: (i) pivoting, (ii) determining primal potential bases, (iii) determining dual potential bases, (iv) determining the effective constraints for the primal weight set, and (v) determining the effective constraints for the dual weight set (Chap. 8 of Yu 1985). It is written in PASCAL and operates in a man-machine interactive fashion. The user cannot only view the tableau of each iteration but also trace the past iterations. In the next section, the framework of the MC^2 problem, as well as its software, will be used to formulate and solve the multiple factor transfer pricing problems.

29.4.2.2 Multiple Factor Transfer Pricing Model

The review of existing transfer pricing models shows that two major shortcomings, from a management point of view, need to be overcome in the previous mathematical models of transfer pricing problems. First, neither the linear programming approach nor the goal programming approach can provide a comprehensive scenario of all possible optimal trade-offs between multiple objectives under consideration for a given transfer pricing problem, such as maximizing the overall profits for a corporation and minimizing the underutilization of production capacity (Tang 1992). Transfer pricing scheme by linear programming only reflects a single objective of a corporation. As a result, the linear programming approach cannot help the corporation seek to simultaneously achieve several objectives, some in conflict, in business competition. The transfer price determined by the goal programming approach is an optimal compromise (i.e., trade-off) among several objectives of the corporation. However, it misses other possible optimal compromises of the objectives that result from some linear combinations of objective weights. These compromises lead to different optimal transfer prices for different decision situations that the corporation may face. Second, none of the past mathematical models can deal with the organizational differentiation problems, as Watson and Baumler (1975) pointed out. In real-life cases, when a corporation designs its transfer prices for the divisions, the involved decision makers (executives or the members of the task force) can give different opinions on the same issue, such as production capacity and customer's demand. In mathematical models, these different interpretations can be represented by different "constraint levels." Because both linear programming and goal programming presume a fixed single constraint level, they fail to mathematically describe such an organizational differentiation problem.

The MC^2 linear programming framework can resolve the above shortcomings inherent in the previous transfer pricing models. Based on Yunker (1983) and Tang (1992), the four important objectives of transfer pricing problems in most corporations are considered: (i) maximizing the overall profit, (ii) maximizing the total market share, (iii) maximizing the subsidiary profit (note that the subsidiary profit maximization is used to reflect the degree of the subsidiary autonomy in decision making. It may differ from the overall profit), and (iv) maximizing the utilized production capacity. Even though the following model contains only these four specific objectives, the generality of the modeling process fits in all transfer pricing problems with multiple-criteria and multiple-constraint levels.

Let k be the number of divisions in a corporation under consideration and t be the index number of the products that each division of the corporation produces.

Define x_{ij} as the units of the jth product made by the ith division, $i = 1, \ldots, k$; $j = 1, \ldots, t$. For the coefficients of the objectives, let p_{ij} be the unit overall profit generated from the jth product made by the ith division, m_{ij} be the market share value for the jth product made by the ith division in the market, s_{ij} be the unit subsidiary profit generated from the jth product made by the ith division, and c_{ij} be the unit utilized production capacity of the ith division to produce the jth product. For the coefficients of the constraints, let b_{ij} be the budget allocation rate for producing the jth product by the ith division. For the coefficients of the constraint levels, let b_{ij}^{s}

be the budget availability level believed by the sth manager (or executive) for producing the jth product by the ith division, s = 1, . . . , h; d_i^s be the production capacity level believed by the sth manager for the ith division; d_{ij}^s be the production capacity level believed by the sth manager for the ith division to produce the jth product; and e_{ij}^s be the initial inventory level believed by the sth manager for the ith division to hold the jth product. Then, the multiple factor transfer pricing model is

$$\begin{aligned}
&\text{Max } \Sigma_{i=1}^{k} \quad \Sigma_{j=1}^{l} \quad \mathrm{p_{ij}x_{ij}}\\
&\text{Max } \Sigma_{i=1}^{k} \quad \Sigma_{j=1}^{l} \quad \mathrm{m_{ij}x_{ij}}\\
&\text{Max } \Sigma_{i=1}^{k} \quad \Sigma_{j=1}^{l} \quad s_{\mathrm{ij}}\mathrm{x_{ij}}\\
&\text{Max } \Sigma_{i=1}^{k} \quad \Sigma_{j=1}^{l} \quad c_{\mathrm{ij}}\mathrm{x_{ij}}\\
&\text{Subject to } \Sigma_{i=1}^{k} \quad \Sigma_{j=1}^{l} \quad \mathrm{bijxij} \leq \left(\mathrm{b^1{}_{ij}}, \ldots, \mathrm{b^h{}_{ij}}\right) \qquad (29.1)\\
&\Sigma_{j=1}^{k} \quad \mathrm{xij} \leq \left(\mathrm{d^1{}_{ij}}, \ldots \mathrm{d^h{}_i}\right)\\
&\mathrm{x_{ij}} \leq \left(\mathrm{d^1{}_{ij}}, \ldots, \mathrm{d^h{}_{ij}}\right)\\
&-\mathrm{x_{ij}} + \mathrm{x}_{\mathrm{i}+1,j} \leq \left(\mathrm{e^1{}_{ij}}, \ldots, \mathrm{e^h{}_{ij}}\right)\\
&\mathrm{X_{ij}} \geq 0, i = 1, \ldots, k, j = 1, \ldots, t.
\end{aligned}$$

In the next section, a prototype of the transfer pricing model in a corporation will be illustrated to demonstrate the implications for decision makers.

29.4.3 Model Implications

29.4.3.1 Numerical Example

As an illustration of the multiple factor transfer pricing model, the United Chemical Corporation has two divisions that process raw materials into intermediate or final products. Division 1, which is located in Kansas City, manufactures two kinds of chemicals, called Products 1 and 2. Product 1 in Division 1 is intermediate product and cannot be sold externally. It can, however, be processed further by Division 2 into a final product. Division 2, which is located in Atlanta, manufactures Product 2 and finalizes Product 1 in Division 1. The executives (president, vice president for production, and vice president for finance) and all divisional managers agree on the following multiple objectives:

(i) Maximize the overall company's profit.
(ii) Maximize the market share goal of Product 2 in Division 1 and Products 1 and 2 in Division 2.
(iii) Maximize the utilized production capacity of the company so that each division manager can avoid any underutilization of normal production capacity.

The data related to these objectives is given in Table 29.2.

In Table 29.2, Product 1 of Division 1 is a by-product that has no sale value in Division 1 at all. The unit profit −$4 of this product means its production cost.

Table 29.2 Data of the objectives in the United Chemical Corporation

Division 1	Product 1	Product 2	Division 2	Product 1	Product 2
Unit profit ($)	−4	8		13	5
Market price	0	40		46.2	38
Unit utilizing production capacity (h)	4	4		3	2

All other products generate profits. We use a market price of each product to maximize the market share goal. Note that the market prices of three products in Table 29.2 are different.

In the company, besides the president, the vice presidents for production and for finance are the main decision makers and may have different interpretations of the same resource availability across the divisions. The vice president for production views the constraint level based on the material, manpower, and equipment under control, while the vice president for finance views the constraint level based on the available cash flow. The president will make the final decision for the company's transfer price setting on the basis of the compromises of both vice presidents. All divisional managers will carry out the president's decision, although they have their autonomy to provide the information about the divisional profits and costs for the executives. The interpretations of the vice presidents for the resource constraint levels are summarized in Table 29.3.

All executives and divisional managers agree on the units of resources consumed to produce the products. The data is given in Table 29.4.

Let x_{ij} be the units of the jth product produced by the ith division, i = 1, 2; j = 1, 2. Using the information in Tables 29.2, 29.3, and 29.4, the multiple factor transfer pricing model is formulated as

$$\begin{array}{l} \text{Max} \quad -4x_{11} + 8x_{12} + 13x_{21} + 5x_{22} \\ \text{Max} \quad 40x_{12} + 46.2x_{21} + 38x_{22} \\ \text{Max} \quad 4x_{11} + 4x_{12} + 3x_{21} + 2x_{22} \\ \text{Subject to} \quad -x_{11} + x_{21} \le (0, 100) \\ \quad 0.4x_{12} + 0.4x_{21} + 0.4x_{22} \le (45{,}000, 40{,}000) \\ X_{12} \le (38{,}000, 12{,}000) \\ X_{21} \le (45{,}000, 50{,}000) \\ X_{22} \le (36{,}000, 10{,}000) \\ x_{ij} \le 0, i = 1, 2; j = 1, 2. \end{array} \tag{29.2}$$

Since this multiple factor transfer pricing problem is a typical MC^2 problem, the MC^2 software of Chien et al. (1989) can be used to solve the problem. Let $\lambda = (\lambda_1, \lambda_2, \lambda_3)$ be the weight parameter for the objectives, where $\lambda_1 + \lambda_2 + \lambda_3 = 1$ and $\lambda_1, \lambda_2, \lambda_3 \ge 0$. Let $\gamma = (\gamma_1, \gamma_2)$ be the weight parameter for the constraint levels, where $\gamma_1 + \gamma_2 = 1$ and $\gamma_1, \gamma_2 \ge 0$. Because both weight parameters (γ, λ) are unknown before design time, the solution procedure of MC^2 linear programming must be used to locate all possible potentially optimal solutions as (γ, λ) vary. The implications of the potentially optimal solutions for accounting decision makers will be explained in the next subsection. After putting (γ, λ) into the above model, it becomes

Table 29.3 The constraint levels of the vice presidents

	Vice president for production	Vice president for finance
Transfer product constraint	0	100
Budget constraint ($)	45,000	40,000
Production capacity of Product 2 in Division 1	38,000	12,000
Production capacity of Product 1 in Division 2	45,000	50,000
Production capacity of Product 2 in Division 2	36,000	10,000

Table 29.4 The unit consumptions of resources

Division 1	Product 1	Product 2	Division 2	Product 1	Product 2
Transfer product constraint	−1.0	0		1.0	0
Budget constraint ($)	0	0.4		0.4	0.4
Production capacity of Product 2 in Division 1		1.0			
Production capacity of Product 1 in Division 2				1.0	
Production capacity of Product 2 in Division 2					1.0

$$\begin{aligned}
\text{Max}\quad & \lambda_1(-4x_{11} + 8x_{12} + 13x_{21} + 5x_{22}) \\
& + \lambda_2(40x_{12} + 46.2x_{21} + 38x_{22}) \\
& + \lambda_3(4x_{11} + 4x_{12} + 3x_{21} + 2x_{22}) \\
\text{Subject to} & \\
& -x_{11} + x_{21} \le 100\gamma_2 \\
& 0.4x_{12} + 0.4x_{21} + 0.4x_{22} \le 45,000\gamma_1 + 40,000\gamma_2 \\
& x_{12} \le 38,000\gamma_1 + 12,000\gamma_2 \\
& x_{21} \le 45,000\gamma_1 + 50,000\gamma_2 \\
& x_{22} \le 36,000\gamma_1 + 10,000\gamma_2 \\
& x_{ij} \ge 0, i = 1,2; j = 1,2.
\end{aligned} \tag{29.3}$$

Let s_q, q = 1, . . . , 5, be the slack variables corresponding to the constraints. The MC^2 software yields two potentially optimal solutions $\{J_1, J_2\}$ and their associated values of (γ, λ) as shown in Table 29.5. Here, $V(J_i)$ denotes the objective value of potentially optimal solution J_i, which is a function of (γ, λ). When (γ, λ) are specified, $V(J_i)$ is the payoff of using J_i.

Table 29.5 means that if the γ takes the value from $\Gamma(J_1)$ and the λ takes the value from $\Lambda(J_1)$, J_1 is the optimal solution for the transfer pricing problem. In this case, products $\{x_{11}, x_{12}, x_{21}, x_{22}\}$ will be produced to achieve the objective payoff $V(J_1)$ and the resource of x_{22} has the amount of s5 unused. Similarly, the potentially optimal solution J_2 can be interpreted. However, J_2 is different from J_1

Table 29.5 All potentially optimal solutions

J_i	$\Gamma(J_i)$	$\Lambda(J_i)$	$V(J_i)$		
$J_1 = (x_{11}, x_{12}, x_{21}, x_{22}, s_5)$	$\gamma_1 + \gamma_2 = 1,$	$\lambda_1 + \lambda_2 + \lambda_3 = 1,$	856,500	736,400	γ
	$65\gamma_1 - 280\gamma_2 - 0,$	$\lambda_1 - \lambda_3,$	4,720,000	4,234,000	
	$\gamma_1, \gamma_2 - 0$	$\lambda_1, \lambda_2, \lambda_3 - 0$	526,000	47,444,000	
$J_2 = (x_{11}, x_{12}, x_{21}, x_{22}, s_2)$	$\gamma_1 + \gamma_2 = 1,$	$\lambda_1 + \lambda_2 + \lambda_3 = 1,$	889,000	596,400	γ
	$65\gamma_1 - 280\gamma_2 - 0,$	$\lambda_1 - \lambda_3,$	4,967,000	3,170,000	
	$\gamma_1, \gamma_2 - 0$	$\lambda_1, \lambda_2, \lambda_3 - 0$	539,000	41,184,000	

Table 29.6 All optimal transfer prices

J_i	$p_q(J_i)$
$J_1 = (x_{11}, x_{12}, x_{21}, x_{22}, s_5)$	$p_1(J_1) = 4\lambda_1 - 4\lambda_3,$
	$p_2(J_1) = 12.5\lambda_1 + 95\lambda_2 + 5\lambda_3,$
	$p_3(J_1) = 3\lambda_1 + 2\lambda_2 + 2\lambda_3$
	$p_4(J_1) = 4\lambda_1 + 8.2\lambda_2 + 5\lambda_3$
	$p_5(J_1) = 0$
$J_2 = (x_{11}, x_{12}, x_{21}, x_{22}, s_2)$	$p_1(J_2) = 4\lambda_1 - 4\lambda_3,$
	$p_2(J_2) = 0,$
	$p_3(J_2) = 8\lambda_1 + 40\lambda_2 + 4\lambda_3$
	$p_4(J_2) = 9\lambda_1 + 46.2\lambda_2 + 7\lambda_3$
	$p_5(J_2) = 5\lambda_1 + 38\lambda_2 + 2\lambda_3$

because there is the unused budget s_2 for J_2 and the parameter set $\Gamma(J_1)$ _ $\Gamma(J_2)$. Because Product 1 in Division 1 is a by-product and its unit profit is $-\$4$, whenever $\lambda_1 < \lambda_3$, both J_1 and J_2 are not optimal.

Let $p_q(J_i)$, $q = 1, \ldots, 5$; $i = 1, 2$, be the shadow price of J_i for the qth constraint. According to the marginal cost pricing approach, the optimal transfer prices of $\{J_1, J_2\}$ are designated as the shadow prices of $\{J_1, J_2\}$. These optimal transfer prices are found in Table 29.6. Table 29.6 shows that (i) the relative transfer price between x_{11} and x_{21} is $p_1(J_1) = 4\,\lambda_1 - 4\,\lambda_3$; (ii) the transfer price for budget across the divisions is $p_2(J_1) = 12.5\,\lambda_1 + 95\,\lambda_2 + 5\,\lambda_3$; (iii) the transfer price for x_{12} is $p_3(J_1) = 3\,\lambda_1 + 2\,\lambda_2 + 2\,\lambda_3$; (iv) the transfer price for x_{21} is $p_4(J_1) = 4\,\lambda_1 + 8.2\,\lambda_2 + 5\,\lambda_3$; and (v) the transfer price for x_{22} is $p_5(J_1) = 0$.

29.4.4 Optimal Trade-offs and Their Accounting Implications

Optimal trade-offs related to transfer prices of the multiple factor model consist of three components: (i) trade-offs among multiple objectives, (ii) trade-offs among multiple-constraint levels, and (iii) trade-offs between multiple objectives and multiple-constraint levels. The trade-offs among multiple objectives imply that all possible optimal compromises of the multiple objectives are determined by locating all possible weights of importance of these objectives. Similarly,

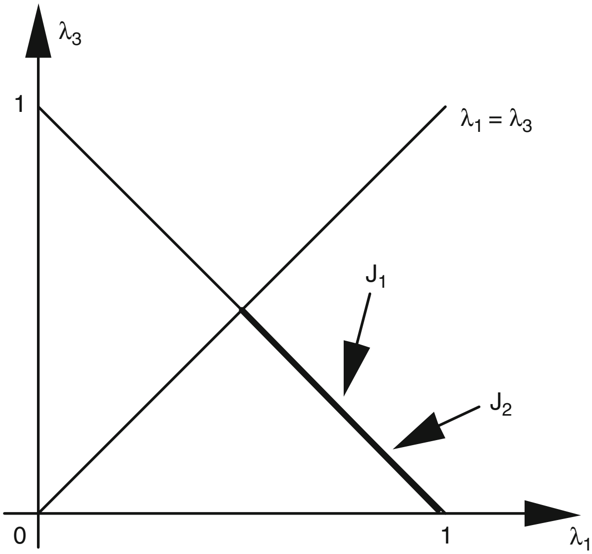

Fig. 29.1 Optimal trade-offs between profit (λ_1) and production capacity (λ_3)

the trade-offs among multiple-constraint levels imply that all possible optimal compromises of the multiple-constraint levels that represent the executives' different opinions are determined by locating all possible weights of importance of these opinions. The trade-offs between multiple objectives and multiple-constraint levels measure the effects on the transfer pricing problem by the interaction of the objectives and constraint levels. These three cases of the optimal trade-offs can be analyzed through the potentially optimal solutions of the multiple factor model. The optimal transfer prices also result from those solutions. In the following, three trade-off cases and accounting implications of the corresponding optimal transfer prices are explored in detail by using the above numerical example.

Because there are two potentially optimal solutions $\{J_1, J_2\}$ in the example, the optimal trade-offs should be studied in terms of both J_1 and J_2. For the trade-offs among three objectives that are the overall company's profit, the market share of the company, and the utilized production capacity of the company:

(i) If the overall company's profit is not considered (this implies $\lambda_1 = 0$ and $\lambda_3 \neq 0$), then either J_1 or J_2 is not optimal since $\lambda_3 < 0$ (see Table 29.5).

(ii) If the market share of the company is not considered (i.e., $\lambda_2 = 0$), then both J_1 and J_2 are optimal for which $\lambda_1 + \lambda_3 = 1$, $\lambda_1 \geq \lambda_3$, and λ_1, $\lambda 3 \geq 0$. The graphical representation is shown in Fig. 29.1. From Fig. 29.1, any weighting values of λ_1 and λ_3 taken from the feasible (dark) segment guarantee that the utility values of both the overall company's profit and the utilized production capacity of the company are maximized. The resulting optimal transfer prices associated with J_1 are $p_1(J_1) = 4\lambda_1 - 4\lambda_3$, $p_2(J_1) = 12.5\lambda_1 + 5\lambda 3$, $p_3(J_1) = 3\lambda_1 + 2\lambda_3$, $p_4(J_1) = 4\lambda_1 + 5\lambda_3$, and $p_5(J_1) = 0$, respectively. The resulting optimal transfer

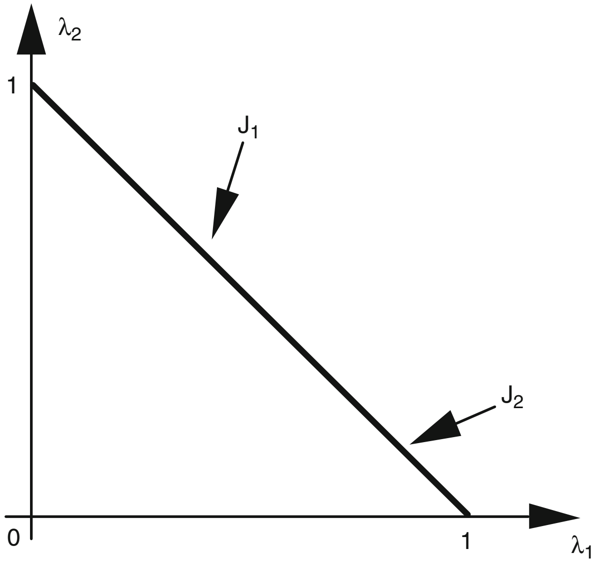

Fig. 29.2 Optimal trade-offs between profit (λ_1) and market share (λ_2)

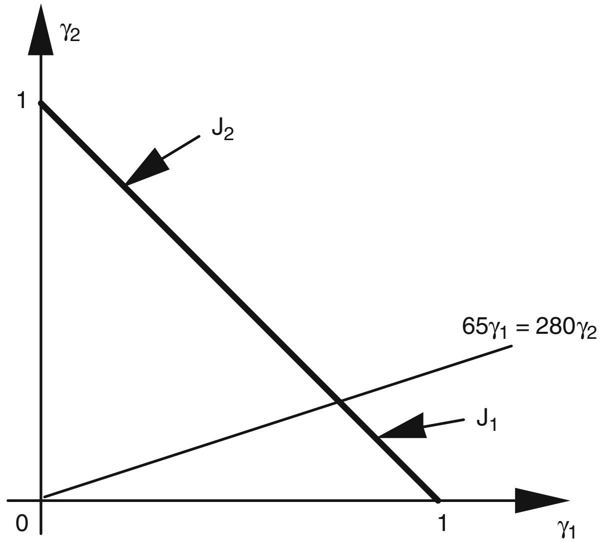
prices associated with J_2 are $p_1(J_2) = 4\lambda_1 - 4\lambda_3$, $p_2(J_2) = 0$, $p_3(J_2) = 8\lambda_1 + 4\lambda_3$, $p_4(J_2) = 9\lambda_1 + 7\lambda 3$, and $p_5(J_2) = 5\lambda 1 + 2\lambda 3$, respectively. The weighting values of λ_1 and λ_3 in the transfer prices for J_1 and J_2 are given in Fig. 29.1, because $\Lambda(J_1) = \Lambda(J_2)$.

(iii) If the utilized production capacity of the company is not considered (i.e., $\lambda_3 = 0$), then both J_1 and J_2 are optimal for which $\lambda_1 + \lambda_2 = 1$ and λ_1, λ_2 _ 0, where the graphical representation is shown in Fig. 29.2. Figure 29.2 implies that any weighted combination of λ_1 and λ_2 taken from the indicated feasible segment maximizes the utility values of both the overall company's profit and the market share of the company. The resulting optimal transfer prices of J_1 are $p_1(J_1) = 4\lambda_1$, $p_2(J_1) = 12.5\lambda_1 + 95\lambda_2$, $p_3(J_1) = 3\lambda_1 + 2\lambda_2$, $p_4(J_1) = 4\lambda_1 + 8.2\lambda_2$, and $p_5(J_1) = 0$, while the resulting optimal transfer prices of J_2 are $p_1(J_2) = 4\lambda_1$, $p_2(J_2) = 0$, $p_3(J_2) = 8\lambda_1 + 40\lambda_2$, $p_4(J_2) = 9\lambda_1 + 46.2\lambda_2$, and $p_5(J_2) = 5\lambda_1 + 38\lambda_2$, respectively.

For the trade-offs among two constraint levels (the different opinions of two vice presidents), the weight of the vice president for production is γ_1 while that of the vice president for finance is γ_2 such that $\gamma_1 + \gamma_2 = 1$, $\gamma_1, \gamma_2 \geq 0$. The range of γ_1 and γ_2 are decomposed into two subsets: $\Gamma(J_1) = \{\gamma_1, \gamma_2 \geq 0 \mid 65\gamma_1 - 280\gamma_2 \geq 0 \text{ and } \gamma_1 + \gamma_2 = 1\}$ and $\Gamma(J_2) = \{\gamma_1, \gamma_2 \geq 0 \mid -65\gamma_1 + 280\gamma_2 \geq 0 \text{ and } \gamma_1 + \gamma_2 = 1\}$ (see Table 29.5). The graphical representation of $\Gamma(J_1)$ and $\Gamma(J_2)$ is shown in Fig. 29.3. Whenever the weighting values of γ_1 and γ_2 are taken from $\Gamma(J_1)$, the corresponding compromise of two vice presidents will result in the optimal transfer prices of J_1 in Table 29.6. Similarly, the decision situation of constraint levels for J_2 can be explained.

Finally, there are many optimal trade-off situations between three objectives and two constraint levels involved with the transfer pricing problem. For example, two cases are illustrated as follows:

Fig. 29.3 Optimal trade-offs between V.P. for production (γ_1) and V.P. for finance (γ_2)



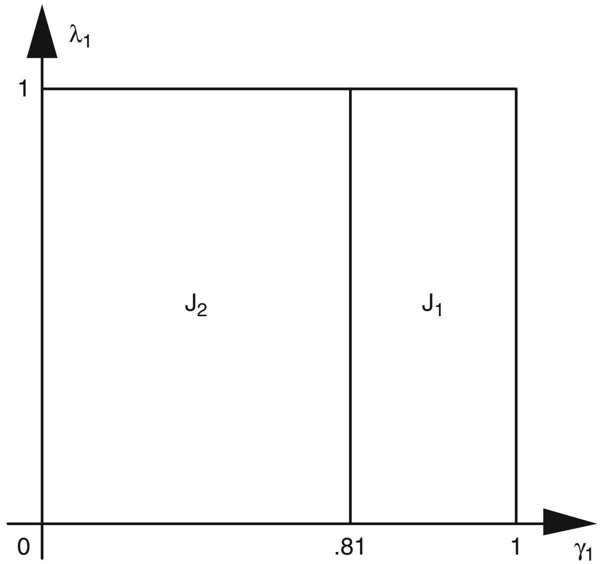


Fig. 29.4 Optimal trade-offs V.P. for production (γ_1) and total profit (λ_1)

(i) In the case that the utilized production capacity of the company is not considered (i.e., $\lambda_3 = 0$) in contrast to the weighting value of the market share and that of the vice president for finance (i.e., $0 \leq \lambda_2 \leq 1$ and $0 \leq \gamma_2 \leq 1$), the optimal trade-offs between the overall company's profit and the constraint level believed by the vice president for production for J_1 and J_2 are shown in Fig. 29.4. Here, if the values of (γ_1, λ_1) are taken from $0 \leq \lambda_1 \leq 1$ to $.81 \leq \gamma_1 \leq 1$, then the optimal transfer prices

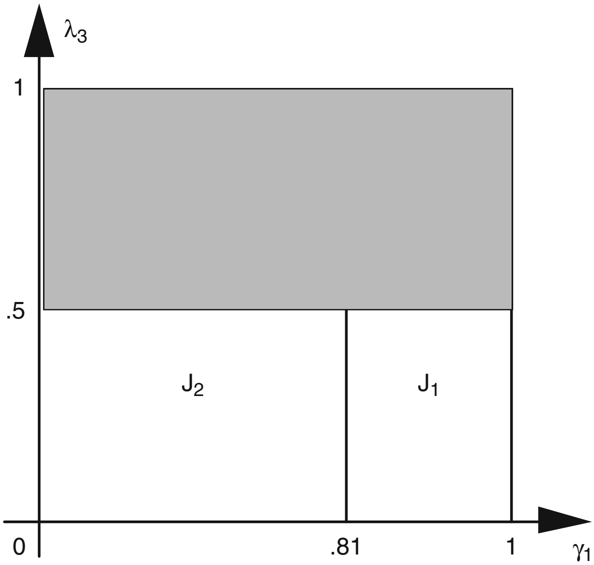

Fig. 29.5 Optimal trade-offs between V.P. for production (γ_1) and production capacity (λ_3)

associated with J_1 will be chosen. They are $p_1(J_1) = 4\lambda_1$, $p_2(J_1) = 12.5\lambda_1 + 95\lambda_2$, $p_3(J_1) = 3\lambda_1 + 2\lambda_2$, $p_4(J_1) = 4\lambda_1 + 8.2\lambda_2$, and $p_5(J_1) = 0$. Otherwise, the values of (γ_1, λ_1) are taken from $0 \le \lambda_1 \le 1$ to $0 \le \gamma_1 \le .81$, and the optimal transfer prices associated with J_2, $p_1(J_2) = 4\lambda_1$, $p_2(J_2) = 0$, $p_3(J_2) = 8\lambda_1 + 40\lambda_2$, $p_4(J_2) = 9\lambda_1 + 46.2\lambda_2$, and $p_5(J_2) = 5\lambda_1 + 38\lambda_2$ will be chosen.

(ii) In the case that the weighting value of the overall company's profit is fixed at .5 (i.e., $\lambda_1 = .5$) and the weighting value of the market share and that of the vice president for finance are any of $0 \le \lambda_2 \le 1$ and $0 \le \gamma_2 \le 1$, respectively, Fig. 29.5 shows the optimal trade-offs between the utilized production capacity of the company and the constraint level believed by the vice president for production for J_1 and J_2. In Fig. 29.5, if the values of (γ_1, λ_3) are taken from $0 \le \lambda_3 \le .5$ to $.81 \le \gamma_1 \le 1$, then the optimal transfer prices associated with J_1 are $p_1(J_1) = 2 - 4\lambda_3$, $p_2(J_1) = 6.25 + 95\lambda_2 + 5\lambda_3$, $p_3(J_1) = 1.5 + 2\lambda_2 + 2\lambda_3$, $p_4(J_1) = 2 + 8.2\lambda_2 + 5\lambda_3$, and $p_5(J_1) = 0$, respectively. If the values of (γ_1, λ_3) are taken from $0 \le \lambda_3 \le .5$ to $0 \le \gamma_1 \le .81$, then the optimal transfer prices associated with J_2 are $p_1(J_2) = 2 - 4\lambda_3$, $p_2(J_2) = 0$, $p_3(J_2) = 4 + 40\lambda_2 + 4\lambda_3$, $p_4(J_2) = 4.5 + 46.2\lambda_2 + 7\lambda_3$, and $p_5(J_2) = 2.5 + 38\lambda_2 + 2\lambda_3$, respectively. Note that when the weighting values fall in the range of $.5 \le \lambda_3 \le 1$ and $0 \le \gamma_1 \le 1$, there is not any optimal trade-off because both J_1 and J_2 are not optimal solutions (recall that this is caused by the by-product 1 in Division 1 that has -\$4 as the unit profit).

It is worth noting some important implications for accounting decision makers from the above trade-off analysis. First, the multiple factor transfer pricing model has a capability of systematically locating all possible optimal transfer prices through the optimal trade-offs of multiple objectives and multiple-constraint levels. Since the set of all possible optimal transfer prices found by this model describes every possible decision situation within the model framework, the optimal transfer price obtained from either linear programming or goal programming models is included in the subset as a special case.

Second, the multiple factor transfer pricing model can be applied to solve transfer pricing problems not only with complex structure but also with some organizational behavior contents, such as the organizational differentiation (see Table 29.3 for different constraint levels). Consequently, this model can foster more autonomous flexibility than any other mathematical programming model by allowing central management or local managers to express their own preference structures and weights.

Third, the proposed method facilitates decision makers' participation that may make a positive management achievement of organizational goals (Locke et al. 1981). The model can aid coordination and synthesis of multiple conflicting views. This may be quite effective in a transfer pricing situation in which many objectives are contradictory to each other and these objectives are measured differently by a number of decision participants.

Fourth, in most multiple-criteria solution techniques, including the goal programming approach, if the decision makers are not satisfied with the optimal solution obtained by using their preferred weights of importance for the multiple objectives, then an iterative process has to be conducted for incorporating the decision makers' new preference on the weights and finding new solutions until decision makers are satisfied. However, the proposed model eliminates such a time- and cost-consuming iterative process since it already considers all possible optimal solutions with respect to the changes of parameter (γ, λ). Whenever decision makers want to change their preference on the weights, the corresponding optimal transfer prices can be immediately identified from the results like in Table 29.6. This model, in turn, allows the performance evaluation of optimal transfer prices.

Finally, the optimal transfer prices obtained by the multiple factor model have a twofold significance in terms of decision characteristics. If the problem is viewed as a deterministic decision problem, whenever the preferred weighting values of objectives and constraint levels are known, the resulting optimal solutions can be identified from the potentially optimal solutions of the model. Then, the corresponding optimal transfer prices can be adopted to handle the business situation (recall the above trade-off analysis). If the problem is viewed as a probabilistic decision problem, it involves the assessment of the likelihood of (γ, λ) to occur at the various points of the range. With proper assumptions, the uncertainty may be represented by random variables with some known probability distribution. A number of known criteria such as maximizing expected payoff, minimizing the variance of the payoff, maximin payoff, maximizing the probability of achieving a targeted payoff, stochastic dominance, probability dominance, and mean-variance dominance can be used to choose the optimal transfer prices (see Shi 1991). In summary, the multiple factor transfer pricing model fosters flexibility in designing the optimal transfer prices for the corporation to cope with all possible changes of business competition. This model is more likely to be a better aid for executives or managers to understand and deal with their current or future transfer pricing problems.

29.4.5 Conclusions

A multiple factor transfer pricing model has been developed to solve the transfer pricing problems in a multidivisional corporation. This model can provide a systematic and comprehensive scenario about all possible optimal transfer prices depending on multiple-criteria and multiple-constraint levels. The trade-offs of optimal transfer prices offer a broad basis for managers of a corporation to flexibly implement the optimal transfer pricing strategy and cope with various business situations. Furthermore, this method also aids global optimization, division autonomy, and performance evaluation.

There are some research problems remaining to be explored. From a practical point of view, the framework of this model can be applied to other accounting areas such as capital budgeting, cost allocation, audit sampling objectives, and personnel planning for an audit corporation if the decision variables and formulation are expressed appropriately. From a theoretical point of view, the decomposition algorithm of linear programming (Dantzig and Wolfe 1960) can be incorporated into the MC^2-simplex method (Seiford and Yu 1979) to sharpen the multiple factor transfer pricing model's capability of solving the large-scale transfer pricing problem. Thus, this incorporation may result in the development of more effective solution procedures. How to incorporate other trade-off techniques, such as the satisficing trade-off method (Nakayama 1994), into the MC^2 framework for designing optimal transfer pricing strategies is another interesting research problem.

29.5 Capital Budgeting with Multiple Criteria and Multiple Decision Makers

Capital budgeting is not a trivial task if a firm is to maintain competitive advantages by adopting new information or manufacturing systems. A firm may implement innovative accounting systems such as activity-based costing (ABC) or balanced scorecard to generate more useful information for better economic decision making in the ever-changing business environment. ABC can provide value-adding and non-value-adding activity information about new capital investments. Investment justification in the new manufacturing environment, however, requires a comprehensive decision-making process that involves competitive analysis, overall firm strategy, and evaluation of uncertain cash flows (Howell and Schwartz 1994). The challenge here is to measure cash flows as well as intangible benefits that these new systems will bring. Furthermore, conflicts of goals, limited resources, and uncertain risk factors may complicate the capital budgeting problem (see Hillier (1963), Lee (1993), Karanovic et al. (2010) for details). These problems of conflicts of goals among decision makers and limited resources in a typical organization support the use of multiple-criteria and multiple-constraint levels (MC^2) linear programming (Seiford and Yu 1979).

While traditional techniques such as payback or accounting rate of return are used as a secondary method, discounted cash flow (DCF) methods, including net present value (NPV) and internal rate of return (IRR), are the primary quantitative methods in capital budgeting (Kim and Farragher 1981). The payback method estimates how long it will take to recover the original investment. However, this method incorporates neither the cash flows after the payback period nor the variability of those cash flows (Boardman et al. 1982). The accounting rate of return method measures a return on the original cost of the investment. Both of the above methods ignore the time value of money. DCF methods may not be adequate to evaluate new manufacturing or information systems, because of a bias in favor of short-term investments with quantifiable benefits (Mensah and Miranti 1989).

A current trend in capital budgeting methods utilizes mathematical programming and higher discount rates to incorporate higher risk factors (Pike 1983; Palliam 2005). Hillier (1963) and Huang (2008) suggested useful ways to evaluate risky investments by estimating expected values and standard deviations of net cash flows for each alternative investment. They showed that the standard deviation of cash flows is easily obtainable. With this information, a complete description of the risky investment is possible via probability distribution of the IRR, NPV, or annual cost of the proposed investment under the assumption of the net cash flows from the investment, which are normally distributed. Similarly, Turney (1990) suggested a stochastic dynamic adjustment model to incorporate greater risk premiums when significant additional funds are required in multiple time periods. Lin (1993) also proposed a multiple-criteria capital budgeting model under risk. His model used chance constraints of uncertain cash flows and accounting earnings as risk factors. Pike (1988) empirically tested the correlation between sophisticated capital budgeting techniques and decision-making effectiveness and found that management believed that sophisticated investment techniques improve effectiveness in the evaluation and control of large capital projects. Weingartner (1963) introduced a mathematical programming approach in the capital budgeting problem. Other researchers have extended Weingartner's work with different directions (e.g., Baumol and Quandt 1965; Bernard 1969; Howe and Patterson 1985). The development of chance-constrained programming (CCP) by Charnes and Cooper (1961) also enriched with applications of mathematical programming models in the capital budgeting problem. They also developed an approximation solution method to the CCP with zero-one variables using a linear constraint.

A typical mathematical capital budgeting approach maximizes DCFs that measure a project's desirability on the basis of its expected net present value as a primary goal. DCF analysis, however, ignores strategic factors such as future growth opportunities (Cheng 1993). Furthermore, management can change their plans if operating conditions change. For example, they can change input and output mixes or abandon the project in a multi-period situation. The increasing involvement of stakeholders, other than shareholders, in a business organization supports a multiple-objective approach (Bhaskar 1979). Other empirical studies also found that firms used multiple criteria in their capital budgeting problems (e.g., Bhaskar and McNamee 1983; Thanassoulis 1985). The goal programming approach has been used to handle multiple-objective problems. It emphasizes weights of importance of the multiple objectives with respect to the decision maker's (DM) preference (Bhaskar 1979; Deckro et al. 1985). Within the framework of hierarchical goal optimization, several goal programming models have been suggested to unravel multiple-objective capital budgeting problems (e.g., Ignizio 1976; Lee and Lerro 1974). Similarly, Santhanam et al. (1989) used a zero-one goal programming approach for information system project selection, but their article lacks a multiple time horizon (learning curve) effect. Choi and Levary (1989) investigated the use of a chance-constrained goal programming approach to reflect multiple goals for a multinational capital budgeting problem. Reeves and Hedin (1993) suggested interactive goal programming (IGP) which allows more flexibility for DMs in considering trade-offs and adjusting goal target levels. However, because of the difficulties of measuring the preferences and priorities of decision makers, Reeves and Franz (1985) developed a simplified interactive multiple-objective linear programming (SIMOLP) method which uses an interactive procedure for a DM to identify a preferred solution and Gonzalez et al. (1987) applied this procedure in a capital budgeting problem (see Corner et al. (1993) and Reeves et al. (1988) for other examples). Interactive multiple-objective techniques such as SIMOLP or IGP can reduce the difficulty of the solution process. Such studies suggest that most capital budgeting problems require the analysis of multiple criteria that better reflect a real-world situation. Thanassoulis (1985) addressed multiple objectives such as the maximization of shareholder wealth, maximization of firm growth, minimization of financial risk, maximization of the firm liquidity, and minimization of environmental pollution.

However, these existing multiple-criteria approaches, including goal programming, implicitly assume that there is only one decision maker setting up the constraint (budget availability) level of a capital budgeting problem. This assumption is not realistic because in most real-world capital budgeting problems, such as constructing a major highway or shopping mall, multiple decision makers must involve the decision of the constraint levels (see Sect. 29.5.2 for detailed discussion). To remove this assumption of a single decision maker from models of capital budgeting with multiple criteria, this article attempts to incorporate multiple decision makers' preferences using (1) the analytic hierarchy process (AHP) approach and (2) MC^2 linear programming in a capital budgeting situation. Our approach shows its strength in quantifying strategic and nonfinancial factors that are important in the current competitive business environment. The problem of incommensurable units in the selection criteria, because of nonfinancial and qualitative measures, can be resolved by using the AHP approach. The MC^2 approach fosters modeling flexibility by incorporating decision makers' preferences as multiple-constraint levels.

The rest of the article is organized as follows. Sect. 29.2 introduces the AHP and MC^2 framework. Sect. 29.3 demonstrates the managerial significance and implications of capital budgeting problems by illustrating an example. Sect. 29.4 concludes the article with several future research avenues.

29.5.1 AHP and MC^2 Framework

In general, an organization has limited resources. Furthermore, each manager's risk assessments and preferences about a new project may be different. For example, a financial manager may think that his or her company has only 50 million dollars available for a new project and he will not approve this project unless he is sure about substantial financial benefits. In contrast, a production manager may think his company should have at least 60 million dollars to implement just-in-time (TIT) manufacturing. The production manager strongly believes that this new system will produce high-quality products with lower costs to maintain competitive advantages against competitors. It is clear that there is a conflict of interests between managers. Even top management's goal may be different from other managers'. To increase other managers' involvement and motivation, top management should induce other managers' inputs. There must be trade-offs between goals of different managers in this group decision-making process. AHP and MC^2 linear programming can be used to resolve this type of group dilemma.

29.5.1.1 Analytical Hierarchy Process (AHP)

AHP is a practical measurement technique that has been widely applied in modeling the human judgment process (Saaty 1980). AHP enables decision makers to structure a complex problem in the form of a hierarchy of its elements according to an organization's structure or ranks of management levels. It captures managerial decision preferences through a series of comparisons of relevant criteria. This feature of the AHP minimizes the risk of inconsistent decisions due to incommensurable units in the selection criteria. Recently, AHP has been applied to several accounting problems (e.g., capital budgeting (Liberatore et al. 1992), real estate investment (Kamath and Khaksari 1991), and municipal government capital investment (Chan 2004)).

The preference of each manager may be analyzed through the use of AHP or multiple attribute utility technique (MAUT). Both AHP and MAUT have their own strengths and weaknesses. For a recent debate regarding the two methods, readers are referred to Dyer and Forman (1991). In this article, the AHP is employed mainly due to its capability of reducing computational complexity and availability of software.

29.5.1.2 MC^2 Linear Programming
