taken in this chapter and presented for a long period by estimating series two times; the first treats the case before the adoption of inflation targeting by Turkish monetary policy authorities. The second allows us to examine real sphere during the adoption of inflation-targeting policy.

59.5 Interest Rate Shock and Real Sphere

Appendixes 3 and 4 show the responses of the real exchange rate, the shares prices, the industrial production, and the consumer prices to a monetary policy shock during the pre-IT and the post-IT policy, respectively. The confidence bounds were bootstrapped, since this gives more accurate confidence coverage compared to the asymptotic ones. Results are reported in Tables 59.6 and 59.7 in Appendix 5.

It is worth noting that for each figure presented in Appendixes 3 and 4, the horizontal axis of graphs shows the number of periods after a monetary policy shock has been initialized. The vertical axis measures the response of the relevant variables.

The simulation analysis covers 20 periods. The solid lines for each graph denote impulse responses. The dotted lines are approximately 95 error bands (with 95 % confidence intervals) that are derived from a bootstrap routine with 100 replications. Bootstrap confidence bands are computed by percentile method advanced by Hall (1992) and Lütkepohl et al. (2001).

59.5.1 Pre-IT (Before IT Adoption)

Figure 59.3 presented in Appendix 3 reveals the responses of our series after an unexpected increase of the short-term interest rate which normally leads to an exchange rate appreciation (Mishkin 2001). This cannot be seen in the response of real exchange rate due to nonsignificant response in the short and long run.

Table 59.7 Kenneth S, Rogoff and Carmen M. Reinhart (2010)

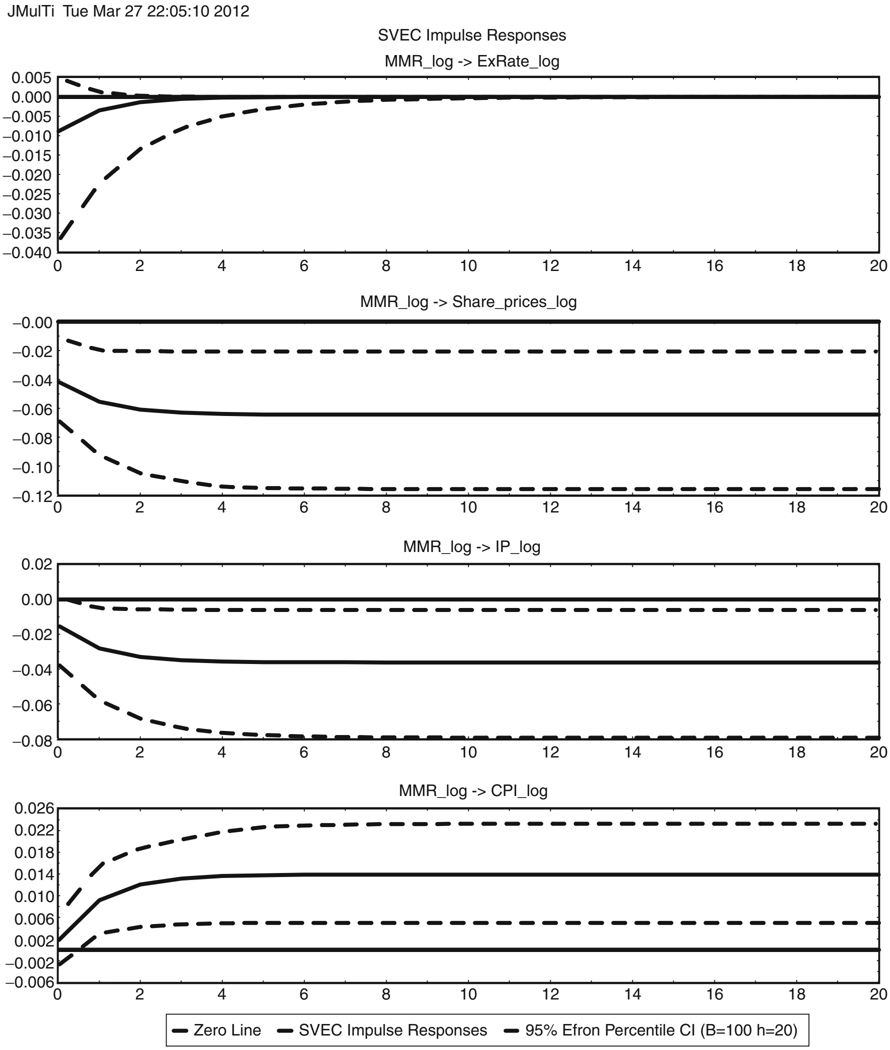

Fig. 59.3 Responses of the main macro variables to a monetary policy shock before IT

Despite the trial by Turkish authorities to implement a new stabilization and structural adjustment program, the banking sector was in turbulence in May 2001. According to Table 59.7, this result could be explained by the predominance of many preponderant banking crisis dates especially in 1991 and 2000 which were accompanied by a considerable output collapse in 2001 (Rogoff and Reinhart 2010).

59.5.2 Post-IT (After IT Adoption)

Figure 59.4 presented in Appendix 4 reveals the responses of our series after an unexpected increase of the short-term interest rate. Seeking to reduce the size of the money supply, normally, a contractionary monetary policy shock in the very

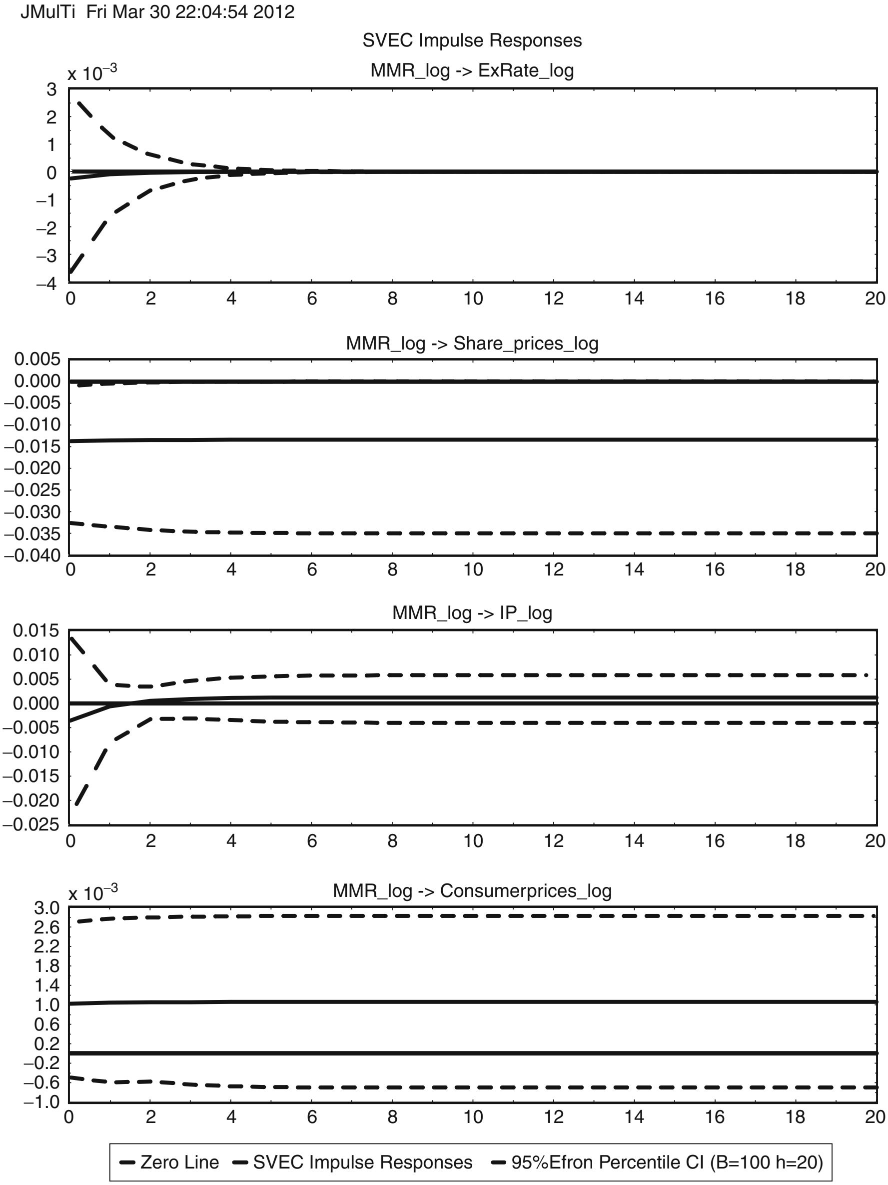

Fig. 59.4 Responses of the main macro variables to a monetary policy shock after IT adoption

short run depresses exchange rate which in turn reduces share prices, and it also appreciates consumer prices which in turn reduces the output. The other important result obtained from this study is that a contractionary policy has a nonsignificant effect on price level in only non-inflation-targeting period. This may be interpreted as a particular case of monetary policy effectiveness in inflation-targeting period. But, this does not mean that monetary policy in inflation-targeting period is more effective than monetary policy in non-inflation-targeting period. This result contradicts the findings of Akyurek and Kutan (2008) who advance that the performances of Turkey after inflation-targeting regime are better than its pre-inflation-targeting regime, at least in terms of containing inflation.

However, the findings reveal that monetary policy affects the price level, share prices, real exchange rate, and output level in the very short run before inflation-targeting policy. These results are similar to those advanced by Fair (2007) and Ball and Sheridan (2005) who show no evidence that inflation targeting improves a country's performance.

To conclude, our results are similar to those of the IMF World Economic Outlook (2005) which offers evidence of either "no increase or a decrease in the volatility of output" due to inflation-targeting policy.

59.6 Conclusion

In this chapter, we based our analysis on two SVEC models with long- and short-run restrictions to detect the impact and dynamic effects of a contractionary monetary policy shock on the output, inflation rate, share prices, and exchange rate. The overall responses of the macroeconomic variables in our SVEC models are consistent with most common theoretical expectations that we discussed in this chapter: an expansionary interest policy shock leads to a decrease in price level, a fall in output, an appreciation in the exchange rate, an improvement in the share prices in the very short run for the most of non-inflation-targeting period. For this pre-IT period, we did not find any evidence of empirical anomalies advanced in empirical literature, i.e., the price puzzle and the exchange rate puzzle.

Our approach in this chapter overcomes such empirical anomalies only for the pre-IT policy. The exchange rate puzzle and the price puzzle were observed for the whole inflation-targeting period.

One of the most important results of this study is that the impact effect of a monetary policy shock on the real sphere is negative and generally statistically significant only in pre-IT period.

Appendix 1: Joint Forecast Error Covariance Matrix, Pre-IT, and Post-IT Forecasting Results

The forecast errors have zero mean and, hence, the forecasts are unbiased. The joint forecast error covariance matrix for all forecasts up to horizon h is

$$Cov\begin{pmatrix} y_{T+1}-y_{T+1/T} \\ \ddot{} \\ . \\ \\ y_{T+h}-y_{T+h/T} \end{pmatrix} = \begin{pmatrix} I & 0 & . & . & 0 \\ \Phi_1 & I & . & . & 0 \\ . & . & . & . & . \\ . & . & . & . & . \\ \Phi_{h-1} & Q_{h-2} & . & . & I \end{pmatrix} \left(\sum\nolimits_u \otimes I_h\right) \begin{pmatrix} I & 0 & . & . & 0 \\ \Phi_1 & I & . & . & 0 \\ . & . & . & . & . \\ . & . & . & . & . \\ \Phi_{h-1} & \Phi_{h-2} & . & . & I \end{pmatrix}' \tag{59.9}$$

where $y_{T+1/T} = y_{T+j}$ for $j \leq 0$.

Assuming normally distributed disturbances, these results can be used for setting up forecast intervals for any linear combination of these forecasts.

Determination of Capital Structure: A LISREL Model Approach

60

Cheng-Few Lee and Tzu Tai

Contents

Abstract

Most previous studies investigate theoretical variables which affect the capital structure of a firm; however, these latent variables are unobservable and generally estimated by accounting items with measurement errors. The use of these observed accounting variables as theoretical explanatory latent variables will cause error-in-variable problems during the analysis of the factors of capital structure.

Since Titman and Wessels (*Journal of Finance 43*, 1–19, 1988) first utilize LISREL system to analyze the determinants of capital structure choice based on a structural equation modeling (SEM) framework, Chang et al. (*The Quarterly Review of Economic and Finance 49*, 197–213, 2009) and Yang et al. (*The Quarterly Review of Economics and Finance 50*, 222–233, 2010) extend the empirical work on capital structure research and obtain more convincing results by using multiple indicators and multiple causes (MIMIC) model and structural equation modeling (SEM) with confirmatory factor analysis (CFA) approach, respectively.

In this chapter, we employ structural equation modeling (SEM) in LISREL system to solve the measurement errors problems in the analysis of the determinants of capital structure and find the important factors consistent with capital structure theory by using date from 2002 to 2010. The purpose of this chapter is to investigate whether the influences of accounting factors on capital structure change and whether the important factors are consistent with the previous literature.

Keywords

Capital structure • Structural equation modeling (SEM) • Multiple indicators and multiple causes (MIMIC) model • LISREL system • Simultaneous equations • Latent variable • Determinants of capital structure • Error in variable problem

60.1 Introduction

In previous research in capital structure, many models are derived based on theoretical variables; however, these variables are often unobservable in the real world. Therefore, many studies use the accounting items from the financial statements as proxies to substitute for the theoretically derived variables. In the regression analysis, the estimated parameters from accounting items as proxies for unobservable theoretical attributes would cause some problems. First, there are measurement errors between the observable proxies and latent variables. According to the previous theoretical literature in corporate finance, a theoretical variable can be formed with either one or several observed variables as a proxy. But there is no clear rule to allocate the unique weights of observable variables as the perfect proxy of a latent variable. Second, because of unobservable attributes to capital structure choice, researchers can choose different accounting items to measure the same attribute in accordance with the various capital structure theory and the their bias economic interpretation. The use of these observed variables as theoretical explanatory latent variables in both cases will cause error-in-variable problems. Joreskog (1977) Joreskog and Sorbom (1981, 1989) and Jorekog and Goldberger (1975) first develop the structure equation modeling (hereafter called SEM) to analyze the relationship between the observed variables as the indicators and the latent variables as the attributes of the capital structure choice.

Since Titman and Wessels (1988) (hereafter called TW) first utilize LISREL system to analyze the determinants of capital structure choice based on a structural equation modeling (SEM) framework, Chang et al. (2009) and Yang et al. (2010) extend the empirical work on capital structure choice and obtain more convincing results. These papers employ structural equation modeling (SEM) in LISREL system to solve the measurement errors problems in the analysis of the determinants of capital structure and to find the important factors consistent with capital structure theories. Although TW initially apply SEM to analyze the factors of capital structure choice, their results are insignificant and poor to explain capital structure theories. Maddala and Nimalendran (1996) point out the problematic model specification as the reason for TW's poor finding and propose a multiple indicators and multiple causes (hereafter called MIMIC) model to improve the results. Chang et al. (2009) reproduce TW's research on determinants of capital structure choice but use MIMIC model to compare the results with TW's. They state that the results show the significant effects on capital structure in a simultaneous cause-effect framework rather than in SEM framework. Later, Yang et al. (2010) incorporate the stock returns with the research on capital structure choice and utilize structural equation modeling (SEM) with confirmatory factor analysis (CFA) approach to solve the simultaneous equations with latent determinants of capital structure. They assert that a firm's capital structure and its stock return are correlated and should be decided simultaneously. Their results are mainly same as TW's finding; moreover, they also find that the stock returns as a main factors of capital structure choice.

In this chapter, we compare the results of the determinants of capital structure from the period 2002–2010 with the results in previous chapter by using LISREL system. The purpose of this chapter is to investigate whether the influences of accounting factors on capital structure are of difference from TW's results and whether the important factors are consistent with the theories in previous literature. During the financial crisis, the influences of accounting factors on the firm's capital structure may have some difference due to the extremely decline of the equity market in the economic recession. Also, the method of reducing measurement error via the average of 3-year data may be invalid because the samples will have different time series pattern after significant event such as current financial crisis. Therefore, this chapter aims at whether the parameters used in TW paper are still significant or not during the financial crisis.

This chapter is organized as follows. In Sect. 60.2, we review the accounting items as proxies for latent variables in TW paper and describe the sample data used in LISREL system. Then, in Sect. 60.3, we introduce SEM to investigate the determinants of capital structure choice and illustrate the SEM approach for TW work in LISREL program. The results of empirical work and the analysis of the comparison with TW's finding are shown in Sect. 60.4. Finally, Sect. 60.5 represents the conclusions of this study.

Table 60.1 Attributes and indicators

Attributes	Indicators
Asset structure	Intangible asset/total assets (INT_TA)
	Inventory plus gross plant and equipment/total assets (IGP_TA)
Non-debt tax shield	Investment tax credits/total asset (ITC_TA)
	Depreciation/total asset (D_TA)
	Non-debt tax shields/total asset (NDT_TA)
Growth	Capital expenditures/total asset (CE_TA)
	The growth of total asset (GTA)
	Research and development/sales (RD_S)
Uniqueness	Research and development/sales (RD_S)
	Selling expense/sales (SE_S)
Industry classification	SIC code (IDUM)
Size	Natural logarithm of sales (LnS)
Volatility	The standard deviation of the percentage change in operating income (SIGOI)
Profitability	Operating income/sales (OI_S)
	Operating income/total assets (OI_TA)
Capital structure (dependent variables)	Long-term debt/market value of equity (LT_MVE)
	Short-term debt/market value of equity (ST_MVE)
	Convertible debt/market value of equity (C_MVE)
	Long-term debt/book value of equity (LT_BVE)
	Short-term debt/book value of equity (ST_BVE)
	Convertible debt/book value of equity (C_BVE)

60.2 Determinants of Capital Structure and Data

Before we utilize SEM approach to analyze the determinants of capital structure, the observable indicators are first briefly described in this section and then the data used in this chapter is subsequently introduced.

60.2.1 Determinants of Capital Structure

TW provide eight characteristics to determine the capital structure: asset structure, non-debt tax shields, growth, uniqueness, industry classification, size, volatility, and profitability. These attributes are unobservable; therefore, some useful and observable accounting items are classified into these eight characteristics in accordance with the previous literature on capital structure. The attributes as latent variables, their indicators as independent variables, and the indicators of capital structure as dependent variables are shown in Table 60.1. The parentheses in indicators are the notations used in LISREL system. Moreover, TW adopt the long-term debt, the short-term debt, and the convertible debt over either market value of equity or book value of equity as the indicators of capital structure as shown in the bottom of Table 60.1.

Based on the trade-off theory and agency theory, firms with larger tangible and collateral assets may have less bankruptcy, asymmetry information, and agency costs. Myers and Majluf (1984) indicate that companies with larger collateral assets attempt to issue more secured debt to reduce the cost arising from information asymmetry. Moreover, Jensen and Meckling (1976) and Myers (1977) state that there are agency costs related to underinvestment problem in the leveraged firm. Therefore, the collateral assets are positive correlated to debt ratios. According to TW paper, the ratio of intangible assets to total assets (INT_TA) and the ratio of inventory plus gross plant and equipment to total assets (IGP_TA) are viewed as the indicators to evaluate the asset structure attribute.

DeAngelo and Masulis (1980) extend Miller's (1977) model to analyze the effect of non-debt tax shields increasing the costs of debt for firms. Bowen et al. (1982) find their empirical work on the influence of non-debt tax shields on capital structure consistent with DeAngelo and Masulis's (1980) optimal debt model. Following Fama and French (2002) and TW paper, the indicators of non-debt tax shields are investment tax credits over total asset (ITC_TA), depreciation over total asset (D_TA), and non-debt tax shields over total asset (NDT_TA) which NDT is defined as in TW paper with the corporate tax rate 34 %.

According to TW paper, we use capital expenditures over total asset (CE_TA), the growth of total asset (GTA), and research and development over sales (RD_S) as the indicators of growth attribute. TW argue the negative relationship between growth opportunities and debt because growth opportunities only add firm's value but cannot collateralize or generate taxable income. Furthermore, the indicators of uniqueness include development over sales (RD_S) and selling expense over sales (SE_S). Titman (1984) indicates that uniqueness negatively correlates to debt because the firms with high-level uniqueness will cause customers, suppliers, and workers to suffer relatively high costs of finding alternative products, buyers, and jobs when firms liquidate. SIC code (IDUM) as proxy of industry classification attribute followed Titman's (1984) and TW's suggestions that firms manufacturing machines and equipment have high liquidation cost and thus more likely to issue less debt.

The indicator of size attribute is measured by natural logarithm of sales (LnS). The financing cost of firms may relate to firm size since small firms have higher cost of nonbank debt financing (see Bevan and Danbolt 2002). Therefore size is supposed to be positive associated with debt level. Besides, volatility attribute is estimated by the standard deviation of the percentage change in operating income (SIGOI). The large variance in earnings means higher possibility of financial distress; therefore, to avoid bankruptcy to happen, firms with larger volatility of earnings will have less debt. Finally, the pecking order theory developed in Myers (1977) paper indicates that firms prefer to use internal finance rather than external finance when raising capital. The profitable firms are likely to have less debt and

Table 60.2 The Compustat code of observable data

Accounting	Code	Accounting	Code
Total asset	AT	Net income	NI
Intangible asset	INTAN	R&D expense	RDIP
Inventory	INVT	Sales	SALE
Gross plant and equipment	PPEGT	Selling expense	XSGA
Investment tax credits	ITCB	SIC code	SIC
Depreciation	DPACT	Short-term debt	DLC
Income tax	TXT	Long-term debt	DLTT
Operating income	EBIT	Convertible debt	DCVT
Interest payment	XINT	Book value of equity	SEQ
Capital expenditures	CAPX	Market value of equity	MKVALT

profitability and hence are negatively related to debt level. Following TW paper, the indicators of profitability are operating income over sales (OI_S) and operating income over total assets (OI_TA).

60.2.2 Data

The sample period from 2002 to 2010 is the same as the duration of variables used in TW paper. The sources of data are from Compustat and CRSP in WRDS. The codes of the accounting items used to calculate the observed variables in Compustat are shown in Table 60.2.

The process of dealing with data is same as TW. The firms with incomplete record on variables and with negative values of total asset and operating income are deleted from the samples. After combination of all data from Compustat and CRSP, one indicator of non-debt tax shields is also excluded because almost all samples are zero or insignificant. For indicator of industry classification, we use dummy variable which equal to one for firms with SIC codes between 3400 and 4000 and equal to zero otherwise.

According to the problem of measurement errors, TW suggested that the sampling period should be divided into three subperiods. In each subperiod, the variables are the average of 3-year data due to random year-to-year fluctuations in variables. The dependent variables and independent variables used to measure uniqueness, non-debt tax shields, asset structure, and the industry classification are measured during the period 2005–2007. The indicators of size and profitability are measured during the period 2002–2004. Two independent variables, capital expenditures/total asset (CE_TA) and the growth of total asset (GTA), are measured during 2008–2010. Finally, the standard deviation of the percentage change in operating income (SIGOI) is estimated during the whole sample period 2002–2010 in order to obtain as the same measure as in TW paper.

60.3 Methodology and LISREL System

In this section, we first introduce the SEM approach and present an example of path diagram to show the structure of structural model and measurement model in SEM framework. Then, the specified structure in SEM approach is given in accordance with the constraints in TW paper and the code is illustrated in Appendix.

60.3.1 SEM Approach

The SEM incorporates three equations as follows:

$$\textit{Structural model: } \eta = \beta\eta + \Phi\xi + \varsigma \tag{60.1}$$

$$\textit{Measurement model for } y\text{: } y = \Lambda_{\mathrm{y}}\eta + \upsilon \tag{60.2}$$

$$\textit{Measurement model for } x\text{: } x = \Lambda\xi + \delta \tag{60.3}$$

where x is the matrix of observed independent variables as the indicators of attributes, y is the matrix of observed dependent variables as the indicators of capital structure, ξ is the matrix of latent variables as attributes, and η is the latent variables that link determinants of capital structure (a linear function of attributes) to capital structure(y).

Figure 60.1 shows an example of the path diagram of SEM approach where the observed independent variables $\mathrm{x} = (\mathrm{x}_1, \mathrm{x}_2, \mathrm{x}_3)'$ are located in rectangular, the observed dependent variables $\mathrm{y} = (\mathrm{y}_1, \mathrm{y}_2)'$ are set in hexagons, variables $\eta = (\eta_1, \eta_2)'$, $\xi = (\xi_1, \xi_2)'$ in ovals denote the latent variables, and the corresponding sets of disturbance are $\varsigma = (\varsigma_1, \varsigma_2)'$, $\upsilon = (\upsilon_1, \upsilon_2)'$, and $\delta = (\delta_1, \delta_2, \delta_3)'$.

The structural model can be specified as the system of equations which combines (60.1) and (60.2), and then we can obtain the structural model in TW paper as follows:

$$y = \Gamma\xi + \varepsilon \tag{60.4}$$

In this chapter, the accounting items can be viewed as the observable independent variables (x) which are the causes of attributes as the latent variables (ξ), and the debt-equity ratios represented the indicators of capital structure are the observable dependent variables (y).

The fitting function for maximum likelihood estimation method for SEM approach is the following:

$$F = \log|\Sigma| + tr\left(S\Sigma^{-1}\right) - \log|S| - (p+q) \tag{60.5}$$

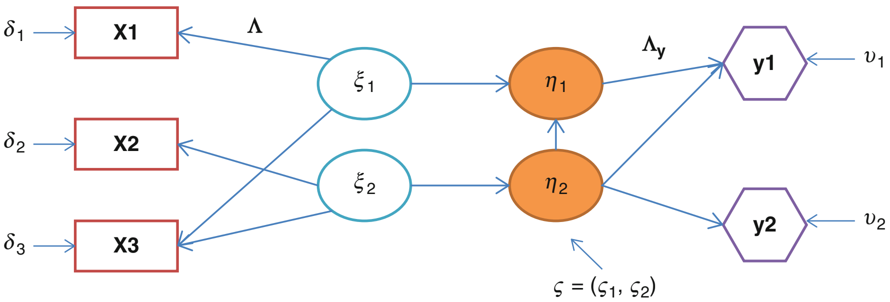

Fig. 60.1 Path diagram of SEM approach
In this path diagram, the SEM formulas (60.1), (60.2), and (60.3) are specified as follows: $\beta = \begin{bmatrix} 0 & \beta_1 \\ 0 & 0 \end{bmatrix}, \Phi = \begin{bmatrix} \Phi_1 & 0 \\ 0 & \Phi_2 \end{bmatrix}, \Lambda_y = \begin{bmatrix} \Lambda_{y1} & \Lambda_{y2} \\ 0 & \Lambda_{y3} \end{bmatrix}, \Lambda = \begin{bmatrix} \Lambda_1 & 0 \\ 0 & \Lambda_2 \\ \Lambda_3 & \Lambda_4 \end{bmatrix}$ where Λ_{y1}, Λ_{y2}, Λ_{y3}, Λ_1, Λ_2, Λ_3, and Λ_4 denote unknown factor loadings; β_1, Φ_1, and Φ_2 denote unknown regression weights; υ_1, υ_2, δ_1, δ_2, and δ_3 denote measurement errors; and ς_1, and ς_2 denote error terms

where S is the observed covariance matrix, Σ is the model-implied covariance matrix, p is the number of independent variables (x), and q is the number of dependent variables (y).

60.3.2 Illustration of SEM Approach in LISREL System

In general, SEM consists of two parts, the measurement model and structural model. The measurement model analyzes the presumed relations between the latent variables viewed as the attributes and observable variables viewed as the indicators. For example, in TW paper, capital expenditures over total assets (CE_TA) and research and development over sales (RD_S) are the indicators of the growth attributes (Growth). In the measurement model, each indicator is assumed to have measurement error associated with it. On the other hand, the structure model presents the relationship between unobserved variables and outcome. For instance, the relationship between attributes and the capital structure is represented by the structure model. Moreover, the relationship between the capital structure and its indicators estimated by debt-equity ratios is modeled by the measurement model.

TW also specific settings include zero measurement error of variables, the standard deviation of the percentage change in operating income (SIGOI) and SIC code (IDUM), measurement errors uncorrelated with each other indicator, with the latent variables, and with the errors in the structural equations. The attributes of volatility and industry classification equal to their indicators, respectively. Based on eight attributes as latent variables, thirteen indicators for determinants of capital structure choice, and six indicators of capital structure in TW paper, the SEM measurement model formula (60.3) and structural model formula (60.4) are specified as follows:

$$x = \begin{bmatrix} GTA \\ CE\_TA \\ RD\_S \\ SE\_S \\ D\_TA \\ NDT\_TA \\ INT\_TA \\ IGP\_TA \\ LnS \\ OI\_TA \\ OI\_S \\ SIGOI \\ IDUM \end{bmatrix}, \xi = \begin{bmatrix} Growth \\ Uniqueness \\ Non\_Debt\_Tax\_Shields \\ Asset\_Structure \\ Size \\ Profitability \\ Volatility \\ Industry\_Dummy \end{bmatrix},$$

$$\Lambda = \begin{bmatrix} \Lambda_1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ \Lambda_2 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ \Lambda_3 & \Lambda_4 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & \Lambda_5 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \Lambda_6 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \Lambda_7 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & \Lambda_8 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & \Lambda_9 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & \Lambda_{10} & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & \Lambda_{11} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & \Lambda_{12} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}, \delta = \begin{bmatrix} \delta_1 \\ \delta_2 \\ \delta_3 \\ \delta_4 \\ \delta_5 \\ \delta_6 \\ \delta_7 \\ \delta_8 \\ \delta_9 \\ \delta_{10} \\ \delta_{11} \\ 0 \\ 0 \end{bmatrix},$$

$$y = \begin{bmatrix} LT\_MVE \\ ST\_MVE \\ C\_MVE \\ LT\_BVE \\ ST\_BVE \\ C\_BVE \end{bmatrix}, \Gamma = \begin{bmatrix} \Gamma_{1,1} & \cdots & \Gamma_{1,8} \\ \vdots & \ddots & \vdots \\ \Gamma_{6,1} & \cdots & \Gamma_{6,8} \end{bmatrix}, \varepsilon = \begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \varepsilon_3 \\ \varepsilon_4 \\ \varepsilon_5 \\ \varepsilon_6 \end{bmatrix}$$

where the variables for x, y, and ξ are defined as in Table 60.1. The codes of SEM in LISREL system are illustrated in Appendix.

60.4 Empirical Results and Analysis

In our empirical research, the estimates of the parameters of measurement model are presented in Tables 60.3 and 60.4. The regression coefficients of

The *bold numbers* are significant at 5 % level matrix Λ in (60.3) are illustrated in Table 60.3, and most coefficients of independent variables except operating income over sales (OI_S) and intangible asset over total assets (INT_TA) are the same direction as TW paper. However, only five of them are significant. Table 60.4 shows the relationship between the attributes (the latent variables). Compared with TW results, only four relations are significantly the same: the relation between profitability and uniqueness, the relation between non-debt tax shields and size, the relation between profitability and non-debt tax shields, and the relation between asset structure and industry dummy. Even though the results of attributes' relations are different from TW paper, the estimated correlations between attributes in TW do not show the t-statistic value. Thus we cannot conclude which results represent correct and convincing relationships between the latent variables.

Moreover, there are only two significant estimates of structural coefficients (uniqueness and asset structure) in Table 60.5. The results inconsistent with TW paper may result from the several reasons as below. First, insignificant and incorrect latent variables may cause the wrong outcome of structural model. Besides, too many latent variables and the lack of using indicators with unique weights corresponding to their attributes may also cause the week results (Maddala and Nimalendran 1996). The other conjecture of inconsistent results is that the sampling fluctuation during financial crisis may aggravate the problem of measurement error.

Although the results of estimates of structural coefficients seem very week, the evidence of negative relationship between debt ratio and uniqueness is consistent the statement of Titman (1984) that the high costs of liquidation are imposed on the customers, workers, and suppliers of firms with high uniqueness products. Besides, the evidence of the attribute of asset structure negatively related to debt ratios corresponds to the supposition of Grossman and Hart (1982). They indicate that in order to avoid the threat of bankruptcy and closely monitor, managers in firms with higher debt are less likely to consume excessive perquisites.

60.5 Conclusion

This chapter utilizes the structure equation modeling (SEM) approach to estimate the impact of unobservable attributes on the capital structure. We use the sample period from 2002 to 2010 as same as the duration in TW paper to investigate whether the influences of accounting factors on capital structure are consistent with TW's results and whether the important factors are associated with the previous literature. In SEM framework, the debt ratios as indicators of capital structure choice to present the dependent variables and the observable accounting data from the financial statements used to calculate the indicators of attributes to form the latent variables.

Compared with the results of TW, our empirical work still cannot support the influence of most attributes on the decision of capital structure. The main reason of weak finding in our chapter and TW paper is too many latent variables as indicated in Maddala and Nimalendran (1996). And, another possible reason is the problem of sampling fluctuation during financial crisis which may cause serious measurement error in SEM approach. However, our empirical results show the significantly negative relationship between debt ratio and uniqueness which is consistent with the statement of Titman (1984) and TW results. Finally, in contrast with the unclear and insignificant relationship between the attribute of asset structure and debt ratios in TW paper, our finding of the significant negative relationship supports the argument of Grossman and Hart (1982) that firms with less collateral assets may choose higher debt levels to limit managers' consumption of perquisites.

Abstract

The objective of this chapter is to demonstrate specific test methodology for detection of earnings management in the oil and gas industry. This study utilized several parametric and nonparametric statistical methods to test for such earnings management. The oil and gas industry was used given the earlier evidence where such firms manage earnings in order to ease the public view of the significant price swings that occur in oil and gas prices. In this chapter, our

focus is on total accruals as the primary means of earnings management. The prevailing view is that total accruals account for a greater amount of earnings management and should be more readily detected. The model to be considered is the Jones model (*Journal of Accounting Research 29*, 193–228, 1991) which projects the expected level of discretionary accruals. By comparing actuals vs. projected accruals, we are able to compute the total unexpected accruals. Next, we correlate unexpected total accruals with several difficult to manipulate indicators that reflect company's level of activities. The significant positive correlations between unexpected total accruals and these variables are an indication that oil and gas firms do not manage income before extraordinary items and discontinued operations. A second test is conducted by focusing on the possible use of special items to reduce reported net income by comparing mean levels of several special items pre-2008 and 2008. The test results indicate significant difference between 2008 means and the pre-2008 period.

Keywords

Earnings management • Jones model (1991) • Discretionary accruals • Income from operations • Nonrecurring items • Special items • Research and development expense • Write-downs • Political cost • Impression management • Oil and gas industry

61.1 Introduction

Repeated oil crises have often resulted in above normal profits for integrated oil and gas companies. Such above normal profits typically attract attention in the news media and consequently in the political environment. In this circumstance, the political environment in North America typically provides a short-lived threat of higher taxes and/or regulations. In the latest crude oil price hike in 2008 that reached \$140 per barrel, oil and gas companies reported unusually high profits. This was true even though, by the end of 2008, prices were about 50 % of their peak. Reporting high income numbers represent a short-term threat that focuses public attention on these companies for a period of time until consumers adapt to new and higher prices (i.e., \$2.89 per gallon in 2010 is way above \$1.90 per gallon in 2006–2007, but it is significantly lower than a near \$5.00 per gallon in 2008–2009).

The agency model predicts that faced with higher taxes and stricter regulations, management tends to use accounting accruals and/or special items to decrease reported income. Because of the possibility of reversals of all or of these accruals in future years, management has to time their responses to such crises to make its point to influence public opinion. Thus, the purpose of earnings management by management of these companies is to buy time until the public attitudes adjust to the new pricing and profitability levels. Earnings management is by no means a tool that can be used over a long period (i.e., multiple years) given the nature of the financial accounting accruals (i.e., firms cannot decrease sales by delaying revenue recognition over several years or keep reporting higher depreciation expense year after year). It is an important issue however for both regulators and those in the accounting profession, particularly auditors.

61.2 Literature Review

The earnings management literature can be broadly divided into two categories: (i) accrual management and (ii) operating decisions (real activity manipulation or economic earnings management). Accruals management is primarily the accounting choices available to management under generally accepted accounting practices (GAAP) that obscure true economic performance (Dechow and Skinner 2000). On the contrary, real earnings management takes place when managers intentionally change the timing or structuring of an operation, investment, or financing transaction to influence the output of an accounting system (Gunny 2010). Accruals management does not have any direct cash flow consequences as it is the manipulation of accounting numbers by using different accounting procedures and/or revising some specific accounting items to obtain desired reported earnings. In real earnings management, managers tend to take actions that affect cash flows and eventually earnings (Gupta et al. 2010). Over production by firms building up inventories when demand is falling allows management to report increased earnings because GAAP mandated the use of absorption or full costing for reporting purposes.

Much has been written in the area of earnings management. Earnings management may arise in several contextual settings where it can be identified that there exist conditions in which managers' incentive to manage earning is large (Healy and Wahlen 1999; Marquardt and Weidman 2004a among others). The empirical research has investigated many different incentives and settings conducive for earnings management. Some of settings investigated in Marquardt and Weidman (2004a) include the following: (1) equity offerings, where the motivation to manage earnings around equity offerings is viewed as increasing the stock price to benefit the firm; (2) management buyouts which is an opposite goal to reduce the stock price; and (3) firms attempting to avoid earning decreases. In general, as indicated above, earnings management could be either income increasing or income decreasing.

The incentives as per Healy and Whalen (1999) include the following: (1) Capital market expectations and valuation. Here the argument made is that the widespread use of accounting information by investors and financial analysts to help value stock can create an incentive for managers to manipulate earning. (2) Contracts written in terms of accounting numbers. Compensation contracts which are based on accounting numbers are used to align the incentives of management with that of external stakeholders. Watts and Zimmerman (1979) argue that contacts create incentives for earnings management, because it is costly for compensation committees and creditors to "undo" earnings management. (3) Antitrust or other government regulation. The idea is that accounting discretion is used to manage industry-specific regulatory constraints.

In a more recent study, Ang (2011) examines the effect of the Sarbanes-Oxley Act (SOX), specifically Section 404, on earnings management among large firms as defined by the Fortune 500. Ang's findings are that firms tend to filter information that investors receive as well as disguise the true earnings of the firm. Overall, Ang concludes that earnings management activity was diminished with the enactment of Sarbanes-Oxley. In another recent study, Ota (2011) examines earnings forecast in a global setting, more specifically for Japanese firms. This study considers earnings management and its determinants with the conclusion that issues related to distress, growth, size, as well as prior forecasting errors are all related to earnings management in Japan. A further part of this study concludes that analysts are indeed knowledgeable of earnings management practice and take such practices into consideration when preparing their own independent forecasts of earnings.

Habib and Hansen (2008) provide an updated literature review regarding earnings management. Their work essentially extends and updates the earlier work of Healey and Wahlen. In an earlier work, Burgstahler and Dichev (1997) consider the distribution of earnings changes and find a lower frequency of decreases in earnings but higher frequencies of increases. The implication is of course that management seeks to avoid such decreases in reported earnings.

Earnings management has potential costs which may be high or low depending on the situation which can be grouped into (1) costs of detected earnings management and (2) the cost of undetected earnings management (Marquardt and Wiedman 2004b). If a firm's use of earnings management becomes publicly known through the release of SEC enforcement actions, earnings restatements, shareholder litigation, qualified audit opinion, and negative business coverage by press, then it is termed detected earnings management. In undetected earnings management, there is no obvious event of public announcement of its occurrence. In terms of the research methodologies employed in earnings management studies, work by McNichols (2000) critically reviews several approaches from an empirical standpoint. In summary, McNichols considers three approaches typically seen in such analyses. Her work contends that further research should consider alternative specifications as opposed to the more traditional aggregate accrual models.

61.3 Empirical Methodology and Data

61.3.1 Integrated Companies

Integrated oil and gas companies are in the public spotlight whenever there is a spike in consumer prices. Other companies within the industry (e.g., refineries, transportation including pipelines, equipment, and service companies) may or may not report higher profits but are not subject to the same degree of media scrutiny and criticism (i.e., price gouging). In addition, large integrated companies have the resources needed to manage their earnings. Smaller oil and gas producers, with limited resources and limited operations, may find it more difficult to be involved in earnings management. At the time this study has been conducted, we consider 2008 to be a target year for earnings management. Our contention is based on the fact that crude oil prices reached a record price of $140 per barrel in 2008.

61.3.2 Tools of Earnings Management and Associated Costs

Tools of earnings management may include total accruals (A/R, inventory, accounts payable, and depreciation). They may also use special items including write-downs, restructuring charges, and discontinued operations. Companies involved in earnings management are always subject to scrutiny by regulatory agencies (i.e., SEC), external auditors, financial analysts, as well as media attention. Management of such firms has to judge each situation to determine whether it is wise to get involved in this type of activities. According to Marquardt and Wiedman (2004b), the use of special items carries a small cost if discovered, while managing of revenue (A/R) carries a very high cost if discovered. In the current study, we do not presume that management is biased for/against any tool. The argument we use is that a significant reduction of an extremely high profitability situation may prove appropriate. Also, the nature of the industry and the diversity of these companies' businesses (i.e., search, exploration, development, production, transportation, and marketing of oil and gas products) would allow a very wide range of possibilities for management of these companies to influence reported income. For instance, assessing goodwill for impairment provides an excellent opportunity to drive reported profits down because of the conservative nature of impairment losses. Likewise, accelerating the process of expensing research and development costs is another conservative accounting tool that would not raise auditor's concern but yet could affect reported profit. Also, the use of special items such as an upward revision of the provision for site restoration and environmental protection is a very strong tool in management's hands to drive down reported profits.

61.3.3 Measures of Earnings Management

Complete discussion of the empirical methodology is included in the Appendix. In general, the detection of earnings management is based on a variety of measures including (for more details, please see Ronen and Yaari 2008) serial correlation of income streams, the standard deviation of earnings relative to the standard deviation of cash flows, and the correlation between discretionary accruals and change in operating cash flows. In this chapter, our focus is on total accruals as the primary means of earnings management. The prevailing view is that total accruals account for a greater amount of earnings management and should be more readily detected. The model to be considered is the Jones model (1991) which projects the expected level of discretionary accruals.

61.3.4 Data

The sample is drawn from the North America COMPUSTAT – Fundamentals Annual through the Wharton Research Database and consists of international integrated oil and gas companies that carry a GSUBIND code 10102010. The initial sample consists of 1,428 annual observations covering the period 1950–2010. Companies included in the final sample of 836 annual observations met the following conditions: (1) information is available for the 2008 event year, (2) there is a minimum number of 6 annual consecutive observations per company, and (3) all data needed for analysis is available. After excluding out-of-range unusable observations, the final sample consists of 28 integrated oil and gas companies from Argentina, Austria, Brazil, Canada, China, France, Italy, Kazakhstan, the Netherlands, Norway, Russia, South Africa, Spain, the UK, and the USA.

61.3.5 Data Items

The following data items (COMPUSTAT – Fundamentals Annual) were collected for all firms with the GSUBIND code 10102010 and used in the empirical part of this study. The following mnemonics are collected:

AT	Total assets for
GDWLIP	Goodwill impairment (pretax)
IB	Income before extraordinary items
OANCF	Cash flow from operations – net
PPEGT	Property, plant, and equipment – gross
SALE	Sales – net
SPIOP	Special items – pretax
XIDO	Extraordinary items and discontinued operations
XRD	Research and development expense
WDP	Write-downs – pretax

61.4 Empirical Findings

61.4.1 Does Management Employ Total Accruals to Manage Earnings?

The presence of earnings management can be detected by observing a negative correlation between unexpected total accruals ($UTACC_{2008}$) and a change in operating cash flows for the same year ($\Delta OANCF_{2008}$) (see Leuz et al. 2003). Table 61.1 provides parametric and nonparametric correlation coefficients for $UTACC_{2008}$ and several variables including $\Delta OANCF_{2008}$. The statistics are presented for all companies, North American companies and the non-North American companies. The results that are presented indicate no evidence of

Table 61.1 Correlation coefficients for $UTACC_{2008}$

Sample	$\Delta OANCF_{2008}$	$OANCF_{2007}$	$OANCF_{2008}$	$SALES_{2008}$
All Observations (28)				
Pearson corr.	−0.020	0.120	0.097	0.102

Table 61.2 T-test results – special items (2008 versus pre-2008)

Item	Observations 2008	Observations pre-2008	Mean 2008	Mean pre-2008	T-value	One-tail significance
SPI	24	660	1,492.30	48.96	5.419	0.000
WDP	4	32	1,862.47	410.39	1.994	0.027
GDWLIP	5	7	5,507.40	328.10	1.250	0.120
XRD	13	415	535.33	200.20	5.075	0.000

earnings management. In fact, the significant positive correlation coefficients between UTACC2008 and $\Delta OANCF_{2008}$ suggest that North American integrated oil and gas companies actually do not use total accruals to manage earnings.

61.4.2 Does Management Employ Special Items to Manage Earnings?

Using special items to manage earnings is (1) less costly, i.e., unlike the case with manipulating revenues and/or operating expenses which are closely monitored by auditors, and (2) has no reversal problem, i.e., the timing of write-downs and/or spending is under management control. The results presented in Table 61.2 indicate that special items SPI which include goodwill impairment (GDWLIP), in-progress research and development (RDIP), restructuring costs (RCP), and other write-downs before taxes were significantly higher in 2008 ($1,492.30 million) versus an average of $48.96 million for the pre-2008 fiscal year. The t-test value of 5.419 is significant at the 0.000 level. The results in Table 61.2 also provide t-test statistics on some individual components of SPI. For example, the 2008 mean write-down before taxes of $1,862.47 million is significantly higher than the pre-2008 mean write-down of $410.39. The t-test statistic here shows a t-value of 1.994 which is significant at the

0.027 level. The component GDWLIP does not reveal a significant increase in recognizing goodwill impairment though these companies reported on average $5,507.40 million impairment losses in 2008 compared to only $328.10 mean losses in the pre-2008 period. One should notice that individual means do not add up to the total SPI because of the different number of observations used in computing individual components' means. Other components of SPI are missing either because they are not available in the data base or because they do not display significant t-values.

Research and development expenditures represent another discretionary item that management is able to control (see Shehata, October 1991). As the results reported in Table 61.2 reveal, average spending on research and development (XRD) is approximately $535.33 million in 2008 compared to a pre-2008 average of $200.20 million. The t-test statistic indicates a t-value of 5.075 at the 0.000 level.

Given the results reported in Table 61.2, one may conclude that management of integrated oil and gas companies does indeed employ special items as a tool to manage earnings.

61.5 Conclusion

Earnings management, which is an extensively researched topic in accounting, could be either income increasing or income decreasing. While there are several motivations for managing earnings and the associated costs depending whether earnings management is detected through public announcements or not, there are implications for incentive design and standard setting in a firm. In this chapter we explore the income decreasing earnings management by integrated oil and gas companies. Our findings provide evidence that integrated oil and gas companies do indeed use special items to manage earnings downwards. While there could be several reasons, one main reason is impression management. Although we selected earnings management as our topic, our primarily objective in this chapter is to demonstrate the important application of standard statistical analysis to the issue of detecting earnings management practices.

Appendix: Methodology

Detecting Earnings Management

The paper uses the Jones model (1991) as the basis for projecting the expected level of discretionary accruals. The steps are as follows:

Step 1: Define total accruals ($TACC$) for as the difference between income (NI) before extra ordinary items and discontinued operations (EOI) and cash flows from operations (OCF). Compute the $TACC_{it} = NI_{it} - EOI_{it} - OCF_{it}$ for each year (t) for firm (i).

Step 2: Divide the data available into two periods, namely, the estimation period $t = 1, \ldots, T_i$ and the prediction period $p = 1, \ldots, P$.

Step 3: Use ordinary least squares to obtain the coefficient estimates a_i, b_i, and c_i of α_i, β_i, and γ_i, respectively. The linear regression expectation model (Jones 1991) for total accruals after controlling for changes in the economic circumstances of the firm is

$$\frac{TACC_{it}}{TA_{it-1}} = \alpha_i \left[\frac{1}{TA_{it-1}}\right] + \beta_i \left[\frac{\Delta REV_{it}}{TA_{it-1}}\right] + \gamma_i \left[\frac{PPE_{it}}{TA_{it-1}}\right] + \varepsilon_{it} \tag{61.1}$$

where

$TACC_{it}$	is the total accruals in year (t) for firm (i)
ΔREV_{it}	is the revenues in year (t) less revenues in year ($t-1$) for firm (i)
PPE_{it}	is the gross property, plant, and equipment in year (t) for firm (i)
TA_{it-1}	is the total assets in year ($t-1$) for firm (i)
ε_{it}	is the error term in year (t) for firm (i)
$i = 1, \ldots, N$	is the firm index ($N = XX$)
$t = 1, \ldots, T_i$	is year index for the years included in the estimation period for firm (i), where T_i ranges between 6 and 22 years.

The gross property, plant, and equipment and change in revenue are included to control for changes in nondiscretionary accruals due to changing conditions. All variables in the accruals expectation model are scaled by lagged assets to reduce heteroscedasticity. The lagged assets are assumed to be positively associated with the variance of the disturbance term.

Model (1) was used to calculate the coefficients α_i, β_i, and γ_i for the estimation period ending in 2007. This procedure is conducted on a company-by-company basis and produced 28 individual models that fit the *TACC* history of each of the sample companies. Each of these models is used in step 4 below to estimate *TACC* for the event year 2008 for each of the 28 firms.

Step 4: Compute the discretionary accruals for the event year (2008) for firm (i) as follows.

The coefficients α_i, β_i, and γ_i obtained from running model (1) are used to predict $TACC_{2008}$ for each of the 28 sample firms. This procedure produced an estimated $ETACC_{2008}$ which is compared to the actual $ATACC_{2008}$. This comparison produced the unexpected total accruals ($UTACC_{2008}$) for the event year.

$$UTACC_{2008} = ETACC_{2008} - ATACC_{2008} \tag{61.2}$$

where

$UTACC_{2008}$	is the unexpected total accruals for the event year 2008
$ETACC_{2008}$	is the estimated expected total accruals for the event year 2008
$ATACC_{2008}$	is the actual total accruals for the event year 2008.

Step 5: Test for earnings management. This study ran several parametric and nonparametric statistics to test for earnings management as follows:

1. Correlations: We measured correlation coefficients (Pearson, Kendall's tau, and Spearman's Rho) to test for significant correlation between $UTACC_{2008}$ and $\Delta ONACF$ (a change in operating cash flows). A significant negative correlation between the two variables would represent a good sign of earnings management, i.e., a higher level of a change in operating cash flows negatively correlates with higher $UTACC_{2008}$ (Leuz et al., September 2003).
2. T-test: We compared means $UTACC_{2008}$ for North American companies against all other international companies included in the sample.
3. Regression analysis: We ran the following regression model

$$UTACC_{2008} = \beta_i \text{ Country} + \xi \tag{61.3}$$

where

$UTACC_{2008}$	is the unexpected total accruals for 2008
Country	is a partition variable coded 1 for North American companies, 0 otherwise
ξ	is an error term.

Step 6: Testing for use of special items to manage earnings.

This study assumes that integrated oil and gas companies will find it easier and less costly to manage earnings using special items such as *SPI*, *WDP*, *GDWLIP*, and *XRD*. T-test is used to compare means of each of these items for 2008 fiscal year and pre-2008 means. Unlike total accruals which require a fitting period and an event period, special items' expected level is always zero (Marquardt and Wiedman 2004a). Consequently, the unexpected amount of any of the above items is

$$\begin{aligned} USPI_{2008} &= SPI - 0, \\ UWDP_{2008} &= UWDP - 0, \\ UGDWLIP_{2008} &= GDWLIP - 0, \\ UXRD_{2008} &= XRD - 0 \end{aligned}$$

where

$USPI_{2008}$	is unexpected special items for fiscal year 2008
$UWDP_{2008}$	is unexpected write-downs for fiscal year 2008
$UGDWLIP_{2008}$	is unexpected goodwill impairment loss for fiscal year 2008
$UXRD_{2008}$	is unexpected research and development for fiscal year 2008.

Abstract

This paper examines two asymmetric stochastic volatility models used to describe the volatility dependencies found in most financial returns. The first is the autoregressive stochastic volatility model with Student's t-distribution (ARSV-t), and the second is the basic Svol of JPR (*Journal of Business and Economic Statistics 12*(4), 371–417, 1994). In order to estimate these models, our analysis is based on the Markov Chain Monte Carlo (MCMC) method. Therefore, the technique used is a Metropolis-Hastings (Hastings, *Biometrika 57*, 97–109, 1970), and the Gibbs sampler (Casella and George *The American Statistician 46*(3) 167–174, 1992; Gelfand and Smith, *Journal of the American Statistical Association 85*, 398–409, 1990; Gilks et al. 1993). The empirical results concerned on the Standard and Poor's 500 Composite Index (S&P), CAC 40, Nasdaq, Nikkei, and Dow Jones stock price indexes reveal that the ARSV-t model provides a better performance than the Svol model on the mean squared error (MSE) and the maximum likelihood function.

Keywords

Autoregression • Asymmetric stochastic volatility • MCMC • Metropolis-Hastings • Gibbs sampler • Volatility dependencies • Student's t-distribution • SVOL • MSE • Financial returns • Stock price indexes

62.1 Introduction

Stochastic volatility (SV) models are workhorses for the modelling and prediction of time-varying volatility on financial markets and are essential tools in risk management, asset pricing, and asset allocation. In financial mathematics and financial economics, stochastic volatility is typically modelled in a continuous time setting which is advantageous for derivative pricing and portfolio optimization. Nevertheless, since data is typically only observable at discrete points in time, in empirical applications, discrete-time formulations of SV models are equally important.

Volatility plays an important role in determining the overall risk of a portfolio and identifying hedging strategies that make the portfolio neutral with respect to market moves. Moreover, volatility forecasting is also crucial in derivatives trading.

Recently, SV models allowing the mean level of volatility to "jump" have been used in the literature; see Chang et al. (2007), Chib et al. (2002), and Eraker et al. (2002). The volatility of financial markets is a subject of constant analysis movements in the price of financial assets which directly affects the wealth of individual, companies, charities, and other corporate bodies. Determining whether there are any patterns in the size and frequency of such movements, or in their cause and effect, is critical in devising strategies for investments at the micro level and monetary stability at the macro level. Shephard and Pitt (1997) used improved and efficient Markov Chain Monte Carlo (MCMC) methods to estimate the volatility process "in block" rather than one point of time such as highlighted by Jacquier et al. (1994), for a simple SV model. Furthermore, Hsu and Chiao (2011) analyze the time patterns of individual analyst's relative accuracy ranking in earnings forecasts using a Markov chain model by treating two levels of stochastic persistence.

Least squares and maximum likelihood techniques have long been used in parameter estimation problems.

However, those techniques provide only point estimates with unknown or approximate uncertainty information. Bayesian inference coupled with the Gibbs sampler is an approach to parameter estimation that exploits modern computing technology. The estimation results are complete with exact uncertainty information. Section 62.2 presents the Bayesian approach and the MCMC algorithms. The SV model is introduced in Sect. 62.3, whereas empirical illustrations are given in Sect. 62.4.

62.2 The Bayesian Approach and the MCMC Algorithm

The Bayesian approach is a classical methodology where we assume that there is a set of unknown parameters. Alternatively, in the Bayesian approach the parameters are considered as random variables with given prior distributions. We then use observations (the likelihood) to update these distributions and obtain the posterior distributions.

Formally, let X = ($X_1, \ldots, X_T$) denote the observed data and θ a parameter vector:

$$P\left(\frac{\theta}{X}\right) \propto P\left(\frac{X}{\theta}\right) * P(\theta)$$

The posterior distribution $P(\theta/X)$ of a parameter $\theta/$ given the observed data X, where $P(X/\theta)$ denotes the likelihood distribution of X and $P(\theta)$ denotes the prior distribution of θ.

It would seem that in order to be as subjective as possible and to use the observations as much as possible, one should use priors that are non-informative. However, this can sometimes create degeneracy issues and one should choose a different prior for this reason. Markov Chain Monte Carlo (MCMC) includes the Gibbs sampler as well as the Metropolis-Hastings (M-H) algorithm.

62.2.1 The Metropolis-Hastings

The Metropolis-Hastings is the baseline for MCMC schemes that simulate a Markov chain $\theta^{(t)}$ with $P(\theta/Y)$ as the stationary distribution of a parameter θ given a stock price index X. For example, we can define θ_1, θ_2, and θ_3 such that $\theta = (\theta_1, \theta_2, \theta_3)$ where each θ_1 can be scalar, vectors, or matrices. MCMC algorithms are iterative, and so at iteration t we will sample in turn from the three conditional distributions. Firstly, we update θ_1 by drawing a value ${\theta_1}^{(t)}$ from $p(\theta_1/Y, \theta_2^{(t-1)}, \theta_3^{(t-1)})$. Secondly, we draw a value for ${\theta_2}^{(t)}$ from $p(\theta_2/Y, \theta_1^{(t)}, \theta_3^{(t-1)})$, and finally, we draw ${\theta_3}^{(t)}$ from $p(\theta_3/Y, \theta_1^{(t)}, \theta_2^{(t)})$.

We start the algorithm by selecting initial values, ${\theta_i}^{(0)}$, for the three parameters. Then sampling from the three conditional distributions in turn will produce a set of Markov chains whose equilibrium distributions can be shown to be the joint posterior distributions that we require.

Following Hastings (1970), a generic step from a M-H algorithm to update parameter θ_i at iteration t is as follows:

1. Sample θ_i^* from the proposal distribution $p_t(\theta_i/\theta_i^{(t-1)})$.
2. Calculate $f = p_t(\theta_i^{(t-1)}/\theta_i^*)/p_t(\theta_i^*/\theta_i^{(t-1)})$ which is known as the Hastings ratio and which equals 1 for symmetric proposals as used in pure Metropolis sampling.
3. Calculate $s_t = fp(\theta_i^*/Y, \phi_i)/p(\theta_i^{(t-1)}/Y, \phi_i)$, where ϕ_i is the acceptance ratio and gives the probability of accepting the proposed value.
4. Let $\theta_i^{(t)} = \theta_i^*$ with probability min(1, s_t); otherwise let $\theta_i^{(t)} = \theta_i^{(t-1)}$.

A popular and more efficient method is the acceptance-rejection (A-R) M-H sampling method which is available. Whenever the target densities are bounded by a density from which it is easy to sample.

62.2.2 The Gibbs Sampler

The Gibbs sampler (Casella and Edward 1992; Gelfand and Smith 1990; Gilks et al. 1992) is the special M-H algorithm whereby the proposal density for updating θ_j equals the full conditional $p(\theta_j^*/\theta_j)$ so that proposals are acceptance with probability 1.

The Gibbs sampler involves parameter-by-parameter or block-by-block updating, which when completed from the transaction from $\theta^{(t)}$ to $\theta^{(t+1)}$:

1. $\theta_1^{(t+1)} \approx f_1(\theta_1/\theta_2^t, \theta_3^{(t)}, \ldots \theta_D^{(t)})$
2. $\theta_2^{(t+1)} \approx f_2(\theta_2/\theta_1^{t+1}, \theta_3^{(t)}, \ldots \theta_D^{(t)})$

.

.

.

.

D. $\theta_D^{(t+1)} \approx f_D(\theta_D/\theta_1^{t+1}, \theta_2^{(t+1)}, \ldots \theta_{D-1}^{(t+1)})$

Repeated sampling from M-H samplers such as the Gibbs samplers generates an autocorrelated sequence of numbers that, subject to regularity condition (ergodicity, etc.), eventually "forgets" the starting values $\theta^0 = (\theta_1^{(0)}, \theta_2^{(0)}, \ldots\ldots, \theta_D^{(0)})$ used to initialize the chain and converges to a stationary sampling distribution $p(\theta/y)$.

In practice, Gibbs and M-H algorithms are often combined, which results in a "hybrid" MCMC procedure.

62.3 The Stochastic Volatility Model

62.3.1 Autoregressive SV Model with Student's Distribution

In this paper, we will consider the pth order ARSV-t model, ARSV(p)-t, as follows:

$$\begin{cases} Y_t = \sigma\xi\exp(V_t/2) \\ V_t = \phi_1 V_{t-1} + \ldots. + \phi_p V_{t-p} + \eta_{t-1} \end{cases}$$

$$\xi_t = \frac{\varepsilon_t}{\sqrt{\kappa_t/(v-2)}}$$

$$\kappa_t \approx \chi^2(v)$$

where κ_t is independent of (ε_t, η_t), Y_t is the stock return for market indexes, and V_t is the log-volatility which is assumed to follow a stationarity AR(p) process with a persistent parameter $|\phi| \prec 1$. By this specification, the conditional distribution, ξ_t, follows the standardized t-distribution with mean zero and variance one. Since κ_t is independent of (ε_t, η_t), the correlation coefficient between ξ_t and η_t is also ρ.

If $\phi \approx N(0, 1)$, then

$$\phi_1 = \frac{\left(\sum_{t=1}^{T} V_t V_{t-1}\right) - \phi_2 \left(\sum_{t=1}^{T} V_{t-1} V_{t-2}\right) + \overline{\phi_1}}{\left(\sum_{t=1}^{t} V_{t-1}^2\right) - 1}$$

and

$$\phi_2 = \frac{\left(\sum_{t=2}^{T} V_t V_{t-2}\right) - \phi_1 \left(\sum_{t=2}^{T} V_{t-1} V_{t-2}\right) + \overline{\phi_2}}{\left(\sum_{t=2}^{T} V_{t-2}^2\right) - 1}$$

The conditional posterior distribution of the volatility is given by

$$p(V/\Theta, Y) \propto e^{\left(\frac{1}{2*\sigma^2}\left(\sum_{t=1}^{T} Y_t^2 e^{-V_t}\right) - \frac{1}{2}\sum_{t=1}^{T} (V_t - \phi_1 V_{t-1} - \phi_2 V_{t-2})^2 - \frac{1}{2}\sum_{t=1}^{T} (V_{t+1} - \phi_1 V_t - \phi_2 V_{t-2})^2\right)}$$

The representation of the SV-t model in terms of a scale mixture is particularity useful in a MCMC context since it allows for sampling a non-log-concave sampling problem into a log-concave one. This allows for sampling algorithms which guarantee convergence in finite time (see Frieze et al. 1994). Allowing log returns to be student-t-distributed naturally changes the behavior of the stochastic volatility process; in the standard SV model, large value of $|Y_t|$ induces large value of the V_t.

62.3.2 Basic Svol Model

Jacquier, Polson, and Rossi (1994), hereafter JPR, introduced Markov chain technique (MCMC) for the estimation of the basic Svol model with normally distributed conditional errors:

$$\begin{cases} Y_t = \sqrt{V_t}\,\varepsilon_t^s \\ \log(V_t) = \alpha + \delta \log(V_{t-1}) + \sigma_v\,\varepsilon_t^v \end{cases}$$
$$\left(\varepsilon_t^s, \varepsilon_t^v\right) \approx N(0, I_2)$$

Let $\Theta = (\alpha, \delta, \sigma_v)$ be the vector of parameters of the basic SVOL, and $V = (V_t)_{t=1}^{T}$, where α is the intercept. The parameter vector consists of a location α, a volatility persistence δ, and a volatility of volatility σ_v.

The basic Svol specifies zero correlation, the errors of the mean, and variance equations.

Briefly, the Hammersley-Clifford theorem states that having a parameter-set Θ, a state V_t, and an observation Y_t, we can obtain the joint distribution $p(\Theta, V/Y)$ from p(Θ, V/Y) and $p(V/\Theta, Y)$, under some mild regularity conditions. Therefore by applying the theorem iteratively, we can break a complicated multidimensional estimation problem into many sample one-dimensional problems.

Creating a Markov chain $\Theta^{(t)}$ via a Monte Carlo process, the ergodic averaging theorem states that the time average of a parameter will converge towards its posterior mean.

The formula of Bayes factorizes the posterior distribution likelihood function with prior hypotheses:

$$P(\Theta, V/Y)\alpha P(Y/V, \Theta)P(V/\Theta)P(\Theta)$$

where α is the intercept, δ the volatility persistence, and σ_v is the standard deviation of the shock to log V_t.

We use a normal-gamma prior, so, the parameters α, $\delta \approx N$, and $\sigma_v^2 \approx IG$, (Appendix 1)

Then

$$P(\alpha, \delta/\sigma_v, V, Y) \approx \prod P(V_t/V_{t-1}, \alpha, \delta, \sigma_v)P(\alpha, \delta)\alpha N$$

And for σ_v, we obtain

$$P\left(\sigma^2/\alpha, \sigma_v, V, Y\right)\alpha \prod P(V_t/V_{t-1}, \alpha, \delta, \sigma_v)P\left(\sigma_v^2\right)\alpha IG$$

62.4 Empirical Illustration

62.4.1 The Data

Our empirical analysis focuses on the study of five international financial indexes: the Dow Jones Industrial, the Nikkei, the CAC 40, the S&P500, and the Nasdaq. The indexes are compiled and provided by Morgan Stanley Capital International. The returns are defined as $y_t = 100 * (\log S_t - \log S_{t-1})$. We used the last 2,252 observations for all indexes except the Nikkei, when we have only used 2,201 observations due to lack of data. The daily stock market indexes are for five different countries over the period 1 January 2000 to 31 December 2008.

Table 62.1 reports the mean, standard deviation, median, and the empirical skewness as well as kurtosis of the five series. All series reveal negative skewness and overkurtosis which is a common finding of financial returns.

62.4.2 Estimation of SV Models

The standard SV model is estimated by running the Gibbs and A-R M-H algorithm based on 15,000 MCMC iterations, where 5,000 iterations are used as burn-in period.

Tables 62.2 and 62.3 show the estimation results in the basic Svol model and the SV-t model of the daily indexes. α and δ are independent priors.

The prior in δ is essentially flat over [0, 1]. We impose stationarity for $\log(V_t)$ by truncating the prior of δ. Other priors for δ are possible.

Geweke (1994a, b) proposes alternative priors to allow the formulation of odds ratios for non-stationarity. Whereas Kim et al. (1998) center an informative Beta prior around 0.9.

Table 62.1 Summary statistics for daily returns

	Mean	SD	Median	Skewness	Kurtosis
CAC 40	3.7E-04	0.013	5.0e-4	−0.295	5.455
Dow Jones	2.8e-04	0.015	4.0e-4	−0.368	4.522

S&P	2.8e-04	0.008	4.5e-4	−0.523	5.659

Table 62.2 Estimation results for the Svol model

	CAC 40	Dow Jones	Nasdaq	Nikkei	S&P
σ	0.4317(0.0312)	0.4561(0.0421)	0.5103(0.0393)	0.5386(0.0523)	0.4435(0.0623)
α	−0.1270(0.0421)	0.0059(0.0534)	0.1596(0.0332)	0.1966(0.0493)	−0.1285(0.0593)
δ	−0.7821(0.0621)	0.0673(0.0317)	0.6112(0.0429)	0.8535(0.0645)	0.7224(0.0423)

Table 62.3 Estimation results for the SV-t model

	CAC 40	Dow Jones	Nasdaq	Nikkei	S&P
Φ_1	0.4548(0.0037)	0.40839(0.0021)	0.5225(0.0065)	0.4348(0.0059)	0.2890(0.0046)
Φ_2	0.5544(0.1524)	0.6437(0.1789)	0.4473(0.1326)	0.4865(0.1628)	0.6133(0.1856)
σ	0.0154(0.0294)	0.0205(0.0367)	0.0131(0.0524)	0.0148(0.0689)	0.0135(0.0312)
ρ	−0.02191(0.0625)	−0.0306(0.0346)	−0.0489(0.0498)	−0.0751(0.0255)	−0.0235(0.0568)

Table 62.2 shows the results for the daily indexes. The posterior of δ are higher for the daily series. The highest means are 0.782, 0.067, 0.611, 0.85, and 0.722, for the full sample Nikkei.

This result is not a priori curious because the model of Jacquier et al. (1994) can lead to biased volatility forecast.

Well, as the basic SVOL, there is no apparent evidence of unit of volatility. There are other factors that can deflect this rate such exchange rate (O'Brien and Dolde 2000).

Deduced from this model, against the empirical evidence, positive and negative shocks have the same effect in volatility.

Table 62.3 shows the Metropolis-Hastings estimates of the autoregressive SV model.

The estimates of ϕ are between 0.554 and 0.643, while those of σ are between 0.15 and 0.205.

Against, the posterior of ϕ for the SV-t model are located higher.[1] This is consistent with temporal aggregation (as suggested by Meddahi and Renault 2000). This result confirms the typical persistence reported in the GARCH literature. After the result, the first volatility factors have higher persistence, while the small values of Φ_2 indicate the low persistence of the second volatility factors.

The second factor Φ_2 plays an important role in the sense that it captures extreme values, which may produce the leverage effect, and then it can be considered conceivable.

The estimates of ρ are negative in most cases. Another thing to note is that these estimates are relatively higher than that observed by Asai et al. (2006) and Manabu Asai (2008). The estimated of ρ for index S&P using Monte Carlo simulation is −0.3117, then it is −0.0235 using Metropolis-Hasting. This implies that for each data set, the innovations in the mean and volatility are negatively correlated.

Negative correlations between mean and variance errors can produce a "leverage" effect in which negative (positive) shocks to the mean are associated with increases (decreases) in volatility.

The return of different indexes not only is affected by market structure (Sharma 2011) but also is deeply influenced by different crises observed in international market, i.e., the Asian crises detected in 1987 and the Russian one in 2002.

[1] We choose $p = 2$ because if $p = 1$ and $v \rightarrow \infty$, the ARSV-t model declined to the asymmetric SV model of Harvey and Shephard (1996).

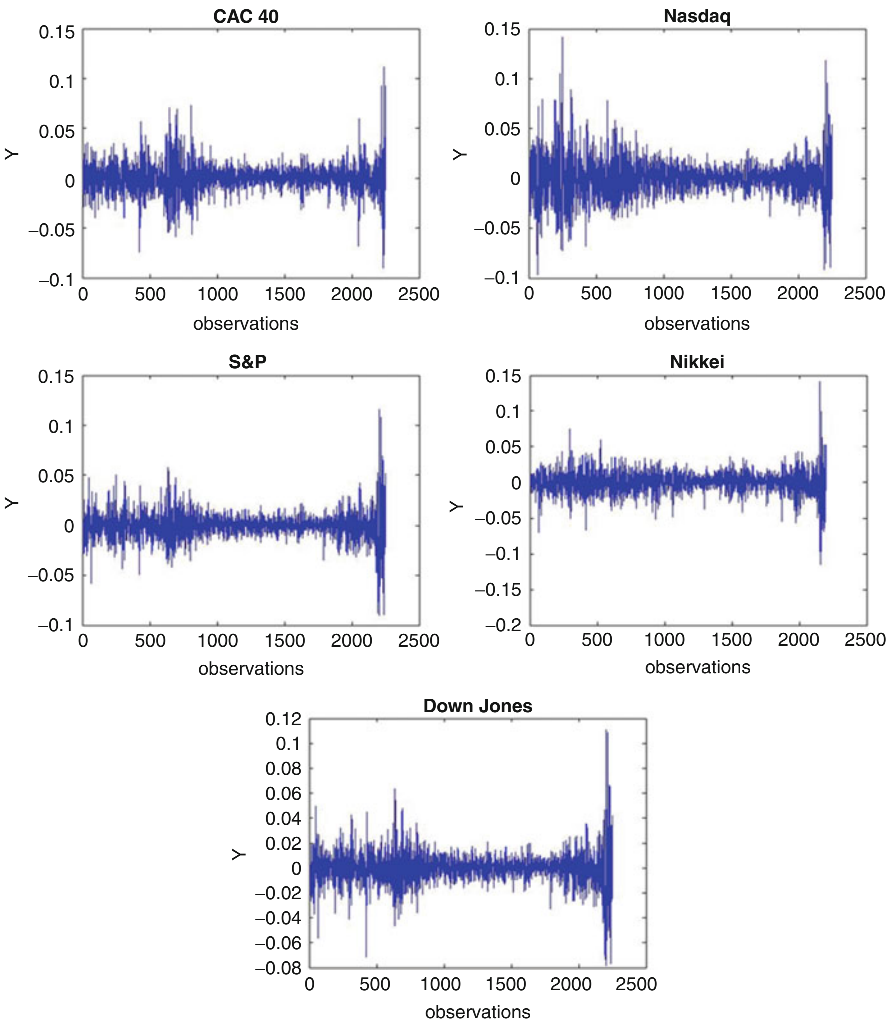

Fig. 62.1 Return for indexes

The markets in our sample are subject to several crises that directly affect the evolution of the return indexes. The event of 11 September 2002 the Russian crisis and especially the beginning of the subprime crisis in the United States in July 2007 justify our results. These results explored in Fig. 62.1 suggest that periods of market crisis or stress increase the volatility. Then the volatility at time (t) depends on the volatility at $(t-1)$ (Engle 1982).

When the new information comes in the market, it can be disrupted and this affects the anticipation of shareholders for the evolution of the return.

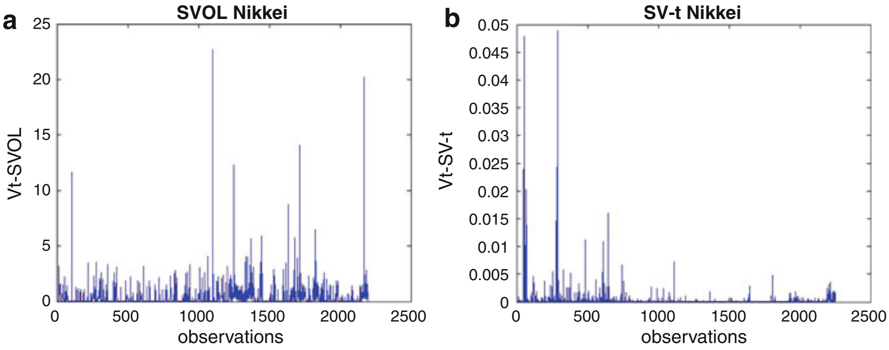

Fig. 62.2 Smoothed estimates of Vt, basic SVOL, and SV-t model

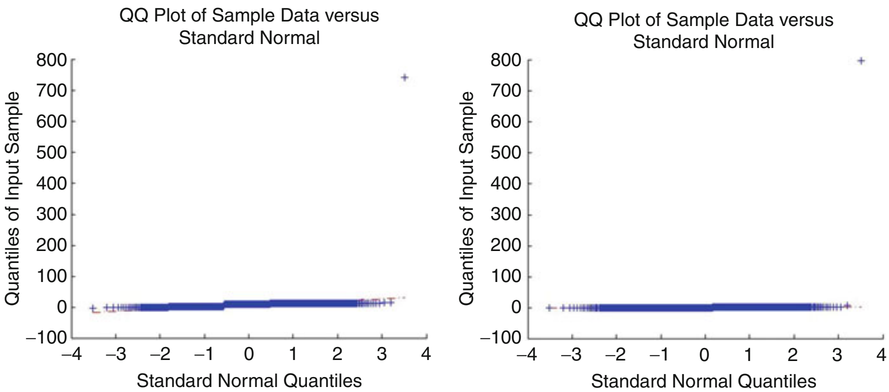

Fig. 62.3 QQ plot of normalized innovation based on the basic Svol model (*left*) and the SV-t model (*right*)

The resulting plots of the smoothed volatilities are shown in Fig. 62.2. We take our analysis in the Nikkei indexes, but the others are reported in Appendix 2.

The convergence is very remarkable for the Nikkei, like Dow Jones, Nasdaq, and the CAC 40 indexes. This enhances the idea that the algorithm used for estimated volatility is a good choice.

The basic Svol model mis-specified can induce substantial parameter bias and error in inference about V_t; Geweke (1994a, b) showed that the basic Svol has the same problem with the largest outlier, October 1987 "Asiatique crisis." The V_t for the model Svol reveal a big outlier on period crises.

The corresponding plots of innovation are given by Fig. 62.3 for two models basic Svol and SV-t for Nikkei indexes. Appendix 3 shows the QQ plot for the other indexes, respectively, for the Nasdaq, S&P, Dow Jones, and CAC 40 for the two models. The standardized innovation reveals a big outlier when the market in stress (Hwang and Salmon 2004).

Table 62.4 MSE and likelihood for two models

	CAC 40		Dow Jones		Nasdaq		Nikkei		S&P	
	SVOL	SV-t	SVOL	SV-t	SVOL	SV-t	SVOL	SV-t	SVOL	SV-t
MSE	0.0.210	0.0296	0.1277	0.0040	0.2035	0.0229	0.0241	0.0168	0.0248	0.0395
Likelihood	$-2.595.10^{-4}$	−0.0046	−0.0374	−0.0012	−0.2257	−0.0158	$-0.2257.10^{-4}$	−0.0094	−0.0054	0.02016

The advantages of asymmetric basic SV is able to capture some aspects of financial market and the main properties of their volatility behavior (Danielsson 1994; Chaos 1991; Eraker et al. 2000).

It is shown that the inclusion of student-t errors improves the distributional properties of the model only slightly. Actually, we observe that basic Svol model is not able to capture extreme observation in the tail of the distribution. In contrast, the SV-t model turns out to be more appropriate to accommodate outliers. The corresponding plot of innovation for the basic model is unable to capture the distribution properties of the returns. This is confirmed by the Jarque-Bera normality test and the QQ plot revealing departures from normality, mainly stemming from extreme innovation.

Finally, in order to detect which of the two models is better, we opt for two indicators of performance, such as the likelihood and the MSE. Likelihood is a function of the parameters of the statistical model that plays a preponderant role in statistical inference. MSE is called squared error loss, and it measures the average of the square of "error." Table 62.4 reveals the results for this measure and indicates that the SV-t model is much more efficient than the other. Indeed, in terms of comparison, we are interested in the convergence of two models. We find that convergence to the SV-t model is fast.

Table 62.4 shows the performance of the algorithm and the consequence of using the wrong model on the estimates of volatility. The efficiency is at 60 %.

The MCMC is more efficient for all parameters used in these two models. In a certain threshold, all parameters are stable and converge to a certain level. Appendices 4 and 5 show that the α, δ, σ, ϕ converge and stabilize; this shows the power for MCMC.

The results for both simulated show that the algorithm of SV-t model is fast and converges rapidly with acceptable levels of numerical efficiency. Then, our sampling provides strong evidence of convergence of the chain.

62.5 Conclusion

We have applied these MCMC methods to the study of various indexes. The ARSV-t models were compared with Svol models of Jacquier et al. (1994) models using the S&P, Dow Jones, Nasdaq, Nikkei, and CAC 40.

The empirical results show that SV-t model can describe extreme values to a certain extent, but it is more appropriate to accommodate outliers. Surprisingly, we have frequently observed that the best model is the Student's t-distribution (ARSV-t) with their forecast performance. Our result confirms the finding from Manabu Asai (2008), who indicates, first, that the ARSV-t model provides a better fit than the MFSV model and, second, the positive and negative shocks do not have the same effect in volatility. Our result proves the efficiency of Markov chain for our sample and the convergence and stability for all parameters to a certain level. This paper has made certain contributions, but several extensions are still possible. To find the best results, opt for extensions of SVOL.

Appendix 1

The posterior volatility is

$$P(V/\Theta, V) \propto P(Y/\Theta, V)P(V/\Theta) \propto \prod_{t=1}^{T} P(V_t/V_{t-1}, V_{t+1}, \Theta, Y_t)$$

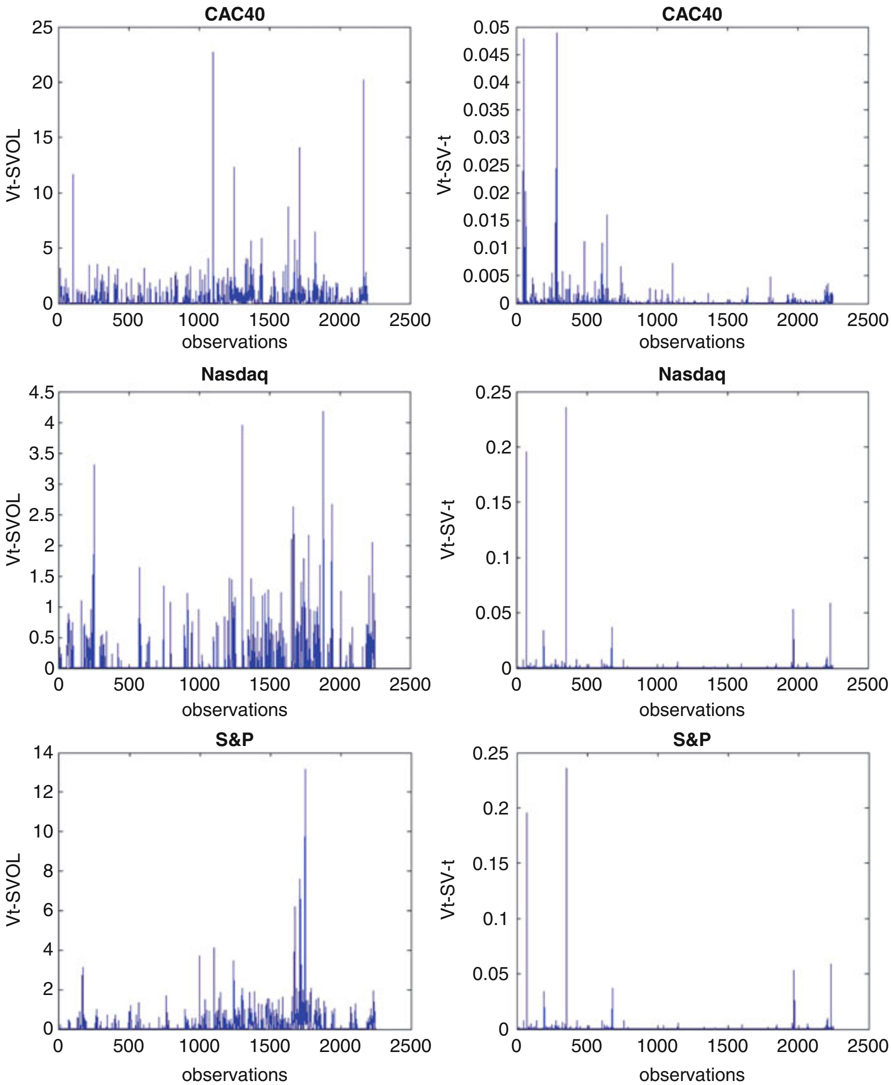

Fig. 62.4 (continued)

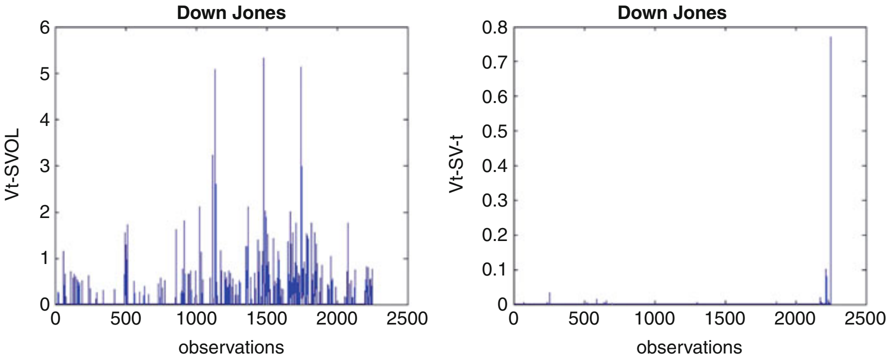

Fig. 62.4 Smoothed estimates of Vt, basic SVOL, and SV-t model

with

$$P(V/V_{t-1}, V_{t+1}, \Theta, Y_t) \propto P(Y_t/V_t, \Theta)P(V_t/V_{t-1}, \Theta)P(V_{t+1}/V_t, \Theta)$$

A simple calculation shows that

$$\prod(V_t) = P(V_t/V_{t-1}, V_{t+1}, \Theta, Y_t) \propto \frac{1}{V_t^{0.5}} \exp\left(\frac{-Y_t^2}{2V_t}\right) \frac{1}{V_t} \exp\left(-\frac{(\log V_t - \mu_t)^2}{2\sigma^2}\right)$$

with

$$\mu_t = \frac{\alpha(1-\beta) + \beta(\log V_{t+1} + \log V_{t-1})}{1+\beta^2}$$

and

$$\sigma^2 = \frac{\sigma_v^2}{1+\beta^2}$$

The MCMC algorithm consists of the following steps:

$$P(\alpha, \delta/\sigma_v, V, Y) \approx N$$

$$P\left(\sigma_v^2/\alpha, \delta, V, Y\right) \approx IG$$

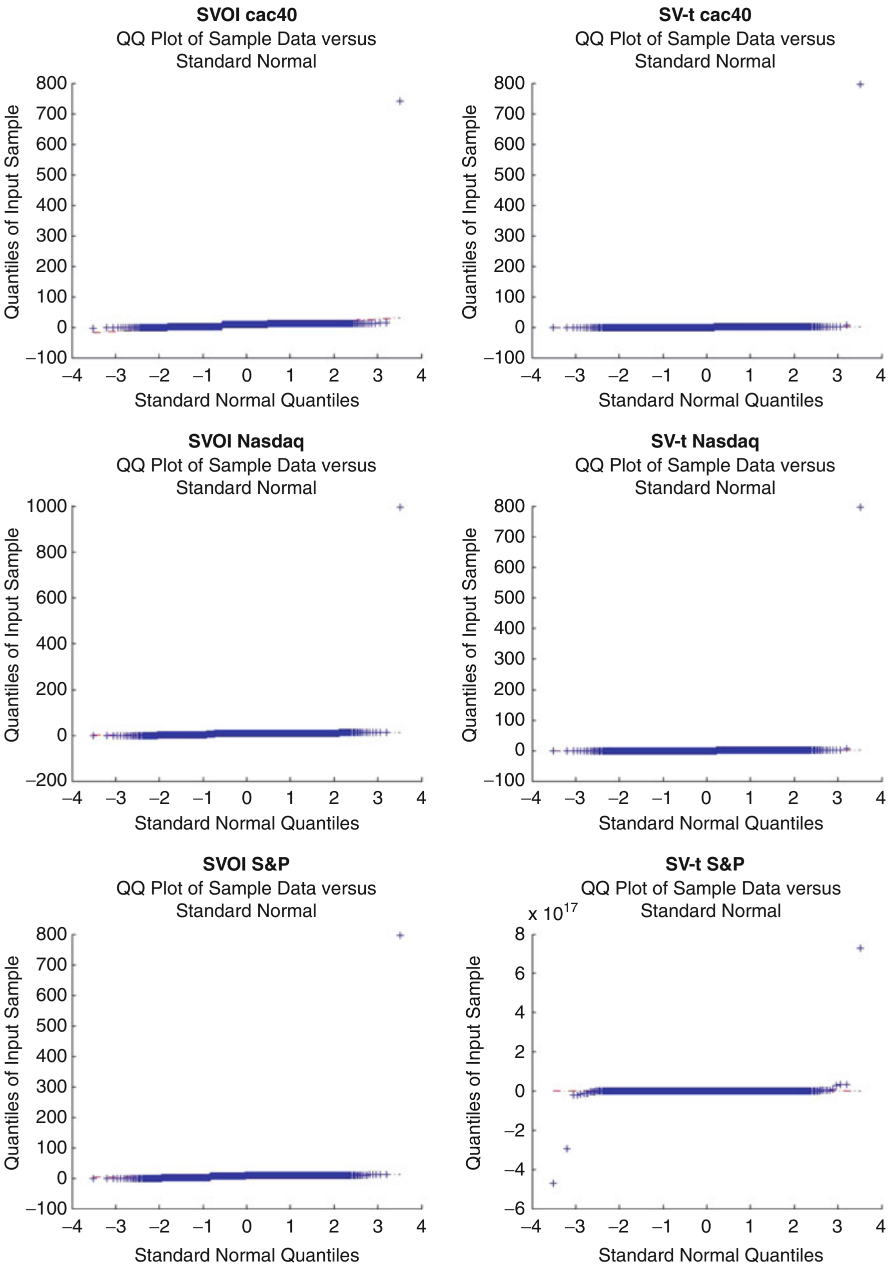

Fig. 62.5 (continued)

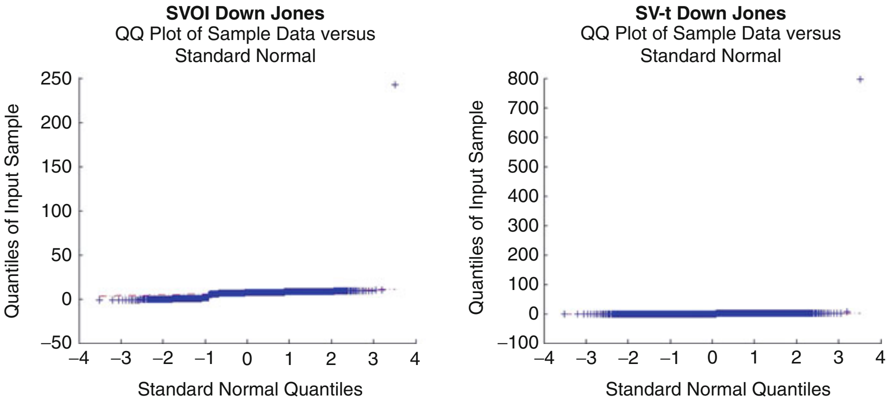

Fig. 62.5 Smoothed estimates of Vt, basic SVOL, and SV-t model

$$P(V_t/V_{t-1}, V_{t+1}, \Theta, Y_t) : \text{Metropolis-Hastings}$$

An iteration (j),

$$\alpha^{(j)} = \frac{\sum_{t=1}^{T} \log V_t^{(j-1)} - \beta^{(j-1)} \sum_{t=1}^{T} \log V_{t-1}^{(j-1)}}{\left(\sigma_v^2\right)^{(j-1)} + T}$$

By following the same approach, the estimator δ at step (j) is given by

$$\delta^{(j)} = \frac{\sum_{t=1}^{T} \left[\log V_{t-1}^{(j-1)} \left(\log V_t^{(j-1)} - \alpha^{(j)}\right)\right]}{\left(\sigma_v^2\right)^{(j-1)} + \sum_{t=1}^{T} \left(\log V_{t-1}^{(j-1)}\right)^2}$$

For parameter σ_v^2, the prior density is an inverse gamma (IG (a, b)). The expression of the estimator parameter σ_v^2 at step (j) is given by

$$\left(\sigma_v^2\right)^{(j)} = \frac{\frac{1}{2} \sum_{t=1}^{T} \left(\log V_t^{(j-1)} - \alpha^{(j)} - \delta^{(j)} \log V_{t-1}^{(j-1)}\right)^2 + b}{T/2 + a - 1}$$

Abstract

We examine the impact of internal control material weaknesses (ICMW hereafter) on sell-side analysts. Using matched firms, we find that ICMW reporting firms have less accurate analyst forecasts relative to non-reporting firms when the reported ICMWs belong to the Pervasive type. ICMW reporting firms have more optimistically biased analyst forecasts compared to non-reporting firms. The optimistic bias exists only in the forecasts issued by the analysts affiliated with less highly reputable brokerage houses. The differences in accuracy and bias between ICMW and non-ICMW firms disappear when ICMW disclosing firms stop disclosing ICMWs. Collectively, our results suggest that the weaknesses in internal control increase forecasting errors and upward bias for financial analysts. However, a good brokerage reputation can curb the optimistic bias.

We use the Ordinary Least Squares (OLS) methodology in the main tests to examine the impact of internal control material weaknesses (ICMW hereafter) on sell-side analysts. We match our ICMW firms with non-ICMWs based on industry, sales, and assets. We reestimate the models using rank regression technique to assess the sensitivity of the results to the underlying functional form assumption made by OLS. We use Cook's distance to test the outliers.

Keywords

Internal control material weakness • Analyst forecast accuracy • Analyst forecast bias • Brokerage reputation • Sarbanes-Oxley act • Ordinary least squares regressions • Rank regressions • Fixed effects • Matching procedure • Cook's distance

63.1 Introduction

As part of the Sarbanes-Oxley Act of 2002 (SOX), SEC registrants' executives are now required to certify that they have evaluated the effectiveness of their internal controls over financial reporting (Section 302, effective in August 2002) and to provide an annual report to assess the effectiveness of the internal control structure and procedures (Section 404, effective in November 2004).[1,2] These assessments of internal control requirements have arguably been the most controversial aspect of SOX. On the one hand, many firms complain that internal control problems are inconsequential for financial statement users, and hence the high compliance costs of assessing internal control are not justified (Solomon 2005). On the other hand, a growing chorus of investors claims that good internal controls result in much more reliable corporate financial statements, which benefit financial statement users by reducing their information collection and interpretation costs.[3]

In this paper we test whether internal control problems are inconsequential for financial statement users by examining the impact of internal control material weaknesses (ICMWs hereafter) on one group of the most important financial statement users – sell-side analysts. We examine the association between the analyst forecast accuracy and bias and the disclosed ICMWs under SOX Sections 302 and 404 and how the brokerage reputation will influence this association. Additionally, we investigate the impact of the types and severity of ICMWs on forecast accuracy.

Based on a sample of 727 firms that have disclosed ICMWs since August of 2002, we find that the analysts' forecasts are less accurate among ICMW reporting firms relative to matched non-reporting firms. When we classify ICMW reporting firms into Pervasive or Contained ICMW reporting firms, the accuracy is significantly lower among Pervasive ICMW reporting firms. Our findings suggest that Pervasive ICMWs significantly increase the complexity of the forecasting task for analysts. In contrast, Contained ICMWs *alone* do not significantly increase the complexity of the forecasting task for analysts. When we investigate the association between analyst forecast bias and ICMWs,

[1]Key points of Section 302 include the following: (1) The signing officers must certify that they are responsible for establishing and maintaining internal control and have designed such internal controls to ensure that material information relating to the registrants and its consolidated subsidiaries is made known to such officers by others within those entities, particularly during the period in which the periodic reports are being prepared. (2) The officers must query "have evaluated the effectiveness of the registrant's internal controls" as of a date within 90 days prior to the report and have presented in the report their conclusions about the effectiveness of their internal controls based on their evaluation as of that date.

[2]Key points of Section 404 include the following: (1) Management is required to produce an internal control report as part of each annual Exchange Act report. (2) The report must affirm the responsibility of management for establishing and maintaining an adequate internal control structure and procedures for financial reporting. (3) The report must also contain an assessment, as of the end of the most recent fiscal year of the registrant, of the effectiveness of the internal control structure and procedures of the issuer for financial reporting. (4) External auditors are required to issue an opinion on whether effective internal control over financial reporting was maintained in all material respects by management. This is in addition to the financial statement opinion regarding the accuracy of the financial statements.

[3]For example, Donald J. Peters, a portfolio manager at T. Rowe Price Group, says: "The accounting reforms [of SOX] have been a win. It is [now] much easier for financial statement users to have a view of the true economics" of a company (Wall Street Journal, January 29, 2007).

we find that the analysts' forecasts are more optimistically biased toward ICMW reporting firms compared to matched non-reporting firms. Taken together, our overall findings on accuracy and bias suggest that ICMWs add a unique dimension to forecasting complexity.

In addition, we separate the analysts' brokerage houses into two groups: highly reputable and less highly reputable brokerage houses. Highly reputable brokerage houses value analysts' reports more than less highly reputable brokerage houses. Hence, analysts are likely to feel constrained from adding an arbitrarily high optimistic bias to their private estimates for fear of hurting the brokerage house's reputation. In addition, more reputable brokerage firms tend to spend significant resources in collecting information, and thus the access to firms' private information is relatively less important for analysts from highly reputable brokerage houses (compared to those from less highly reputable brokerage houses). We predict and find that analysts from less highly reputable brokerage houses are more likely to issue optimistic forecasts for ICMW reporting firms.

We also examine the association between ICMW and forecast accuracy (and bias) in the post-reporting periods. We find that the differences in accuracy and bias between ICMW reporting firms and control firms disappear when firms stop reporting material weaknesses.

This paper makes four major contributions to the accounting literature. First, sell-side analysts are among the most important users of financial reports. Researchers have long been interested in learning about analysts' use of accounting information (Schipper 1991). While prior studies provide evidence of the link between earnings quality and weaknesses in internal control, exactly how weakness in internal control affects the users of earnings reports directly has been largely ignored.[4] This study adds to this research by *directly* documenting a relation between ICMW and accuracy along with bias of analyst forecasts. The evidence presented in this paper shows that internal control deficiencies can influence the quality of analysts' forecasts.

Secondly, this study finds that not all ICMWs are created equal. The association between ICMW and forecast accuracy depends upon the severity of the reported ICMWs. When we separate material weaknesses into Contained or Pervasive types of weaknesses (based on the severity of the weaknesses), we find that firms identified with Pervasive ICMWs are more likely to be associated with forecast errors. In contrast, the relation between ICMW and accuracy is insignificant among firms identified with Contained ICMWs.

Thirdly, we are able to link brokerage reputation to the analysts' optimistic bias. Conceptually, it makes sense that the optimistic bias should be related to the reputation of the brokerage houses since highly reputable brokerage houses

[4]A recent working paper by Kim et al. (2009) confirms our results. They find that internal control quality is inversely; associated with analysts' error and forecast dispersion.

are more concerned with the analysts' forecasts. In addition, highly reputable houses have the resources to conduct more sophisticated analyses. This study presents the evidence to demonstrate that a good brokerage reputation can curb the optimistic bias.

Finally, the study also shows that the differences in accuracy and bias between ICMW reporting firms and control firms disappear when firms stop reporting material weaknesses. We provide evidence that ICMWs indeed contribute to lower forecast accuracy and more positive forecast bias.

The chapter is organized as follows. Section 63.2 develops hypotheses, and Sect. 63.3 describes sample selection process and forecast properties measurement. Sections 63.4 and 63.5 present the empirical tests and additional analysis, respectively. Conclusions are presented in Sect. 63.6.

63.2 Hypothesis Development

63.2.1 Internal Control Material Weakness and Forecast Accuracy

The extant literature on the relation between ICMW, accruals quality, and management's earnings guidance implies that ICMWs could affect analysts' forecast accuracy.

Doyle et al. (2007a) and Ashbaugh et al. (2008) find that ICMW reporting firms have lower accruals quality. Lobo et al. (2012) link accruals quality with analysts' forecast accuracy by documenting that firms with lower accruals quality tend to have larger forecast errors. They conclude that analysts are unable to fully resolve the uncertainty in firms with lower accruals quality.

Extant literature also suggests that ICMWs could affect management's earnings guidance. In a recent study, Feng et al. (2009) discover that ICMW reporting firms have less accurate management earnings guidance. Management's earnings guidance has been shown to be directly related to forecast accuracy, since the earnings guidance provides valuable information for analysts (Chen et al. 2011). Thus, we conjecture that ICMW disclosing firms are associated with less accurate analysts' earnings forecast. This leads to our first hypothesis in the alternative form as the following:

H1 Analysts' earnings forecast for ICMW reporting firms will be less accurate relative to non-reporting firms (in alternative form).

Internal control material weaknesses vary widely with respect to severity and underlying reasons. (See page 196 of Doyle et al. 2007b). Doyle et al. (2007b) find that the type of internal control problem is an important factor when examining determinants of ICMWs. They recommend that the type and severity of ICMWs should be considered by future research on internal control.

If a firm's management lacks the abilities or resources to exercise efficient internal control within the firm, the firm tends to have ICMWs about the overall control environment (defined as Pervasive ICMWs).[5] Alternatively, even if management has sufficient capabilities and resources to prepare accurate and adequate financial statements, a firm may still have internal control deficiencies over financial reporting. Such internal control deficiencies may be related to controls over specific account balances or transaction-level processes (defined as Contained ICMWs).[6,7] Doyle et al. (2007a) find that among all ICMW reporting firms, the earnings quality is significantly lower for firms reporting Pervasive ICMWs. In contrast, Contained ICMWs have no impact on earnings quality.

In making their forecasts, analysts can use earnings-related information, disaggregated segmental information, and information provided by management (Previts and Bricker 1994; Bouwman and Frishkoff 1995; Rogers and Grant 1997). If analysts use firms' earnings-related and segmental information to make forecasts, they might have more difficulty in predicting earnings for firms with Pervasive ICMWs. This is because earnings quality of Pervasive type ICMW firms is low (Doyle et al. 2007a). On the contrary, analysts should have no difficulty in predicting earnings for firms with Contained ICMWs, because auditors would be able to mitigate the errors in reported earnings associated with Contained ICMWs. Consistent with this argument, Doyle et al. (2007a) find that account-specific material weaknesses are not associated with lower earnings quality. If analysts use the guidance provided by management or other unaudited reports to make forecasts, it is possible that Contained ICMWs might still introduce errors into the reports since these reports are unaudited. In this case, both Pervasive and Contained ICMWs may increase the forecasting difficulties for analysts. Taken together, the forecast errors are expected to be larger for firms with Pervasive ICMWs than for firms with Contained ICMWs.

To compare the forecast accuracy between Pervasive and Contained ICMWs, we classify firms into two groups based on the company's stated reasons for material weaknesses. The first group of firms discloses *only* Contained ICMWs

---

[5]For example, DynTek Inc. disclosed the following deficiencies in their 2004, 10-K: "The material weaknesses that we have identified relate to the fact that our overall financial reporting structure and current staffing levels are not sufficient to support the complexity of our financial reporting requirements. We have experienced employee turnover in our accounting department including the position of Chief Financial Officer. As a result, we have experienced difficulty with respect to our ability to record, process and summarize all of the information that we need to close our books and records on a timely basis and deliver our reports to the Securities and Exchange Commission within the time frames required under the Commission's rules."

[6]For example, Westmoreland Coal Inc. disclosed the following deficiencies in their 2005, 10-K: "The company's policies and procedures regarding coal sales contracts with its customers did not provide for a sufficiently detailed, periodic management review of the accounting for payments received. This material weakness resulted in a material overstatement of coal revenues and an overstatement of amortization of capitalized asset retirement costs." Moody suggests that these types of material weaknesses are "auditable" and thus do not represent as serious a concern regarding the reliability of the financial statements.

[7]The detailed classification of Pervasive and Contained ICMWs is provided in Appendix 1.

(defined as G1 firms), which are related to controls over specific accounting choices. The second group of firms discloses Pervasive ICMWs (with or without Contained ICMWs) (defined as G2 firms). Note that unlike G1 firms that disclose only one type of ICMWs (i.e., Contained ICMWs). G2 firms may disclose two types of ICMWs (i.e., Pervasive as well as Contained ICMWs).[8] We have the following hypothesis based on the types of ICMWs:

H2 The analysts' forecast errors are more pronounced for forecasts issued for G2 firms (compared to those issued for G1 firms) (in alternative form).

63.2.2 Internal Control Material Weaknesses and Optimistic Forecast Bias

Extant literature suggests that sell-side analysts have an inclination to issue optimistic forecasts for several reasons. First, the compensation of analysts is tied to the amount of trade they generate for their brokerage firms. Given widespread unwillingness or inability to sell short, more trades will result from more optimistic forecasts. Moreover, mutual funds, the client group with resources to generate large trades, are precluded by regulation from selling short. Hence, without reputation concerns, analysts will prefer to issue more optimistic forecasts.

Secondly, a positive outlook improves the chances of analysts' brokerage houses winning investment banking deals. A number of prior studies have suggested that initial public offering (IPO) activities may compromise the quality of analysts' research. For example, Womack (1996) argues that analysts are reluctant to issue unfavorable forecasts if there is an IPO underwriting relationship.

Thirdly, prior studies show that analyst forecasts contain private information in addition to a statistical model based only on public information. Hence, access to management is crucial for analysts, as evidenced by the reports from Institutional Investor (a firm that compiles annual analyst rankings) showing that analysts rank the access to management as the sixth most valuable attribute out of 13 attributes (ahead of accuracy of earnings estimates, written reports, stock selection, and financial modeling). As evidenced by Huang et al. (2005), being optimistic has historically helped analysts maintain good relations with management.[9]

---

[8]The conclusions of this paper remain the same if we classify G2 firms as firms disclosing only Pervasive ICMWs.

[9]Our sample period starts after the introduction of Regulation Fair Disclosure (Reg. FD). The goal of Reg. FD is to prohibit management from selectively disclosing private information to analysts. However, as pointed out by recent research (see, e.g., Ke and Yu 2006; Kanagaretnam et al. 2012), there is no empirical evidence of management relations incentive weakening after Reg. FD. In the post-Reg. FD period, there are other incentives for analysts to please management, such as to gain favored participation in conference calls (Libby et al. 2008; Mayew 2008). Anecdotal evidence also shows that Reg. FD does not prevent a company from more subtle forms of retaliations against analysts who issue negative research reports (Solomon and Frank 2003).

The optimistic bias in analyst forecasts is more pronounced when earnings are less predictable (e.g., Lim 2001; Das et al. 1998). Feeling less accountable in uncertain environments, analysts are inclined to issue more optimistic forecasts. Consistently, Zhang (2006) concludes that greater information uncertainty predicts more positive forecast bias.

Since both less predictable earnings (Doyle et al. 2007a) and an uncertain information environment (Beneish et al. 2008) are more prevalent among ICMW firms, we expect that analysts will issue positively biased forecasts when firms have ICMWs.[10] We, therefore, offer our next hypothesis regarding the relation between forecast bias and ICMWs:

H3 Analysts' earnings forecasts are more positively biased among ICMW reporting firms relative to non-reporting firms (in alternative form).

63.2.3 The Impact of the Reputation of Brokerage Houses

As we discussed before, the magnitude of the bias is held in check by reputational concerns. We hypothesize that highly reputable brokerage houses value analysts' reports more than less highly reputable brokerage houses. Hence, their analysts are likely to feel constrained from adding an arbitrarily high optimistic bias to their private estimates by the fear of hurting the brokerage houses' reputations. In addition, highly reputable brokerage firms tend to have significant resources to collect information, and thus the access to firms' private information is relatively less important for analysts from highly reputable brokerage houses.[11]

Alternatively, analysts from less highly reputable brokerage houses tend to have limited resources in research and thus have more incentives to issue more biased forecasts. If ICMWs indeed increase the cost of information collection and research, these extra costs will exacerbate the need of analysts from less highly reputable brokerage houses to access firms' private information. Hence, we expect that analysts from less highly reputable brokerage houses will issue more upwardly biased forecasts for ICMW firms (compared to analysts from highly reputable brokerage houses). We, therefore, offer our last hypothesis:

H4 The analysts' optimistic biases associated with ICMW firms are more pronounced for forecasts issued by analysts from less highly reputable brokerage houses (compared to analysts from highly reputable brokerage houses) (in alternative form).

---

[10]Note that our hypothesis is still valid if the forecasts have been made before the disclosure of ICMWs. Doyle et al. (2007a) argue that Sarbanes-Oxley has led to the disclosure of ICMWs that might have existed for some time. Indeed, they find that accrual quality has been lower for ICMW firms relative to non-ICMW firms even in the periods prior to the disclosure of ICMWs.

[11]Brown et al. (2009) document stock market response to an analyst's recommendation change and the difference between the analyst's recommendation and the consensus recommendation. The market's reaction is strongly influenced by the analyst's reputation.

63.3 Sample Selection and Descriptive Statistics

63.3.1 The Sample Selection and Matching Procedure

We first use the key words "internal control" and "material weakness" to search the 8-K, 10-Q, and 10-K filings in Lexis/Nexis during the period of August 2002 to December 2006 and obtain 1,275 firms which disclose at least one material weakness (ICMW firms).[12] We then cross-check our 1,275 firms against Doyle et al.'s (2007a) 1,210 sample firms, which are obtained by Doyle et al. through searching 10Kwizard.com (10-Ks, 10-Qs, and 8-Ks) from August 1, 2002, to October 31, 2005.[13] We find that there are 181 firms in Doyle et al.'s (2007a) sample but not in ours. We subsequently add these 181 firms into our sample to create an initial sample of 1,456 firms. Out of the 1,456 initial sample firms, 952 firms have the required firm characteristics variables (for regressions) in the Compustat and CRSP annual database. Among these 952 firms, 745 firms have analyst forecast data in IBES database.

Next we identify a sample of matched firms that do not disclose internal control material weaknesses (non-ICMW firms) with similar IBES, CRSP, and Compustat requirements as the ICMW firms. We match ICMW firms with non-ICMW firms by industry, firm size, and sales performance, as measured during the fiscal year in which the ICMW is disclosed. Industry is defined by using the 48 industry codes identified by Fama and French (1997), firm size is measured as total assets (Compustat #6), and sales performance is measured as total sales (Compustat #12).

The matching algorithm is similar to that used by Francis et al. (2006). In particular, matches are identified by an algorithm that calculates the distance between each ICMW firm k and its matched non-ICMW counterpart j. Specifically, for each non-ICMW firm j in the same Fama-French industry as ICMW firm k, we calculate the percentage difference in assets, $\text{AssetsDIS} = \left|\frac{\text{Assets}_j - \text{Assets}_k}{\text{Assets}_k}\right|$, and the percentage difference in sales, $\text{SalesDIS} = \left|\frac{\text{Sales}_j - \text{Sales}_k}{\text{Sales}_k}\right|$. The sum of the two distance measures yields a matching score for each non-ICMW firm j that is in the same industry as ICMW firm k. From the set of matching scores that are less than two, we choose the non-ICMW firm with the smallest matching score for each ICMW firm; we then remove the matched pair (the ICMW and its non-ICMW counterpart) from the lists of ICMW and non-ICMW firms. In some cases, a single non-ICMW firm is the best match for several ICMW firms. In this case, we control for the order in which we match a non-ICMW firm to an ICMW firm by first

[12]It could be argued that our sample might miss some firms which have ICMWs but choose not to disclose them. However, discovery and disclosure of material weaknesses are mandatory according to 2004 SEC FAQ #11. We, therefore, use the disclosure of ICMW as a proxy for the existence of ICMW.

[13]We thank Sarah McVay for making the data available on her website (http://pages.stern.nyu.edu/~smcvay/research/Index.html).

calculating all possible matching scores and then assigning the non-ICMW firm j to the ICMW firm k whose matching score is the smallest among the candidate ICMWs. For the remaining candidate non-ICMWs, we repeat the above steps using the remaining ICMW firms. In total, the application of these procedures produces a final sample of 727 pairs of ICMW and non-ICMW firm-year observations.[14]

63.3.2 Descriptive Statistics

Panels A and B in Table 63.1 show the number and percentage of sample firms by industry and by stock exchange, respectively. Industry groups with the largest representations in the sample include durable manufacturers (20.4 %), computers (19.1 %), retail (12.9 %), and financial (12.5 %). Our sample distribution is similar to that of Ghosh and Lubberink (2006) and Beneish et al. (2008). As a comparison, in the last two columns of Table 63.1 we also present the number and percentage of 2003 Compustat population by industry. The industry distributions of our sample firms and 2003 Compustat firms are similar. The industry groups with the largest representations in 2003 Compustat population are also durable manufacturers, computers, and financial. The retail industry has a larger weight in our sample relative to the 2003 Compustat population. In terms of stock exchange, the majority of ICMW firms are listed on NASDAQ (436 firm-years) and NYSE (245 firm-years).

Table 63.2 Panel A presents the descriptive statistics for sample firms and matched firms. The median number of analysts following sample firms is smaller than that of analysts following matched firms. The firm size is measured as the natural logarithm of the market value of equity. The median firm size suggests that sample firms are smaller than matched firms (significant at the 0.1 significance level). There are no significant mean and median differences in leverage between sample firms and matched firms. The mean and median profitability of sample firms, measured by return on assets (ROA), are significantly lower than those of matched firms at the 0.01 significance level.

The mean and median of book to market ratios (BM) of sample firms are significantly larger than those of matched firms at the 0.01 significance level. The mean and median of percentage change in earnings of sample firms are significantly smaller than those of matched firms at the 0.01 significance level, which suggests a systematic downward shift in reported earnings for firms disclosing ICMWs. Also, the median number of negative earnings of sample firms is significantly greater than that of matched firms at the 0.01 significance level. Taken together, the statistics imply that sample firms are followed by fewer analysts and have smaller market capitalization, higher book to market ratio, and lower profitability than their matched firms.

[14]If a firm in our final sample reports internal material weaknesses in multiple years, the firm will show up in our sample multiple times. We have 599 distinct firms showing up once in our final sample and 64 firms showing up twice in our sample. The conclusions of this paper remain the same if we exclude these 64 firms from our analyses.

Table 63.1 Industry and exchange distributions of firms reporting internal control material weakness (ICMW)

Panel A: by industry

Industry name	SIC codes	Sample *N*	Sample %	2003 Compustat *N*	2003 Compustat %
Mining and construction	1000–1999 excluding 1300–1399	13	1.79	158	2.56

NASDAQ	436	59.97
AMEX	29	3.99
OTC	16	2.20
Other	1	0.14
Total	727	100.00

A total of 727 firm-year observations have reported ICMW and have data available from Compustat and IBES. SIC codes and stock exchanges are from the Compustat
The sample period is from 2003 to 2006. All data are from CRSP, Compustat, and IBES databases

63.3.3 The Sample Firms by Types of ICMW

As we discussed in Sect. 63.2, we classify firms disclosing ICMWs into two groups: one group of firms discloses only Contained ICMWs, and the other group of firms discloses Pervasive ICMWs (with or without Contained ICMWs).

The classification of Contained or Pervasive ICMWs is similar to that of Moody's. Contained ICMWs are defined as internal control issues related to controls over specific account balances, or transaction-level processes, or accounting policy interpretations. Pervasive ICMWs are defined as internal control issues related to controls over the control environment or the overall financial reporting process.

Table 63.2 Descriptive statistics for selected variables

Panel A: descriptive statistics for the ICMW sample and the matched sample firms				
	ICMW sample ($N = 727$)		Matched sample ($N = 727$)

ECHG	−0.261	−0.101	−0.183	−0.129

Matched firms consist of firms in the same industry based on the 48 industry codes identified by Fama and French (1997) with the closest market value and sales at the end of fiscal year

*, **, *** denote two-tailed significance levels of 10 %, 5 %, and 1 %, respectively, for the differences between the ICMW sample and the matched sample. *T*-test is used to test the difference between the mean of the ICMW sample and the matched sample, and median test is used to test the difference between the median of the ICMW sample and the matched sample

We match ICMW firms with non-ICMW firms by industry, firm size, and sales performance, as measured in the fiscal year in which the ICMW is disclosed. Industry is defined using the 48 industry codes identified by Fama and French (1997), firm size is measured as total assets (Compustat #6), and sales performance is measured as total sales (Compustat #12). The matching algorithm is similar to that used by Francis et al. (2006)

All the variables are defined in Appendix 2. N is the number of firm-year observations

*, **, *** denote two-tailed significance levels of 10 %, 5 %, and 1 %, respectively, for the differences between G1 firms and G2 firms. *T*-test is used to test the difference between the mean of G1 sample and G2 sample, and median test is used to test the difference between the median of G1 sample and G2 sample

G1 firms are firms that disclose *only* Contained ICMW, and G2 firms are firms that disclose *at least* Pervasive ICMW. The Contained and Pervasive internal control material weaknesses are similar to Moody's classification scheme. The Contained internal control material weakness is defined as the internal control issues related to controls over specific account balances, or transaction-level processes, or special accounting policy interpretation; the Pervasive internal control material weakness is defined as the internal control issues related to controls over the control environment or the overall financial reporting process

The detailed classification procedures are as follows: we first provide a breakdown of the firms based on firms' stated reasons for material weaknesses as in Ge and McVay (2005). Firms usually disclose internal control issues in nine areas: Account-Specific, Training and Personnel, Period-End Reporting/Accounting Policies, Revenue Recognition, Segregation of Duties, Account Reconciliation, Subsidiary-Specific, Senior Management, and Technology Issues. We then classify

Contained internal control issues as (1) Account-Specific, (2) Period-End Reporting/Accounting Policies, (3) Revenue Recognition, and (4) Account Reconciliation issues. The rationale for this classification is that these internal control issues are all related to controls over specific account balances, or transaction-level processes, or accounting policy interpretation. We next classify Pervasive internal controls issues as (1) Training and Personnel, (2) Segregation of Duties, (3) Subsidiary-Specific, (4) Senior Management, and (5) Technology Issues. All of these control issues are related to controls over the control environment or the overall financial reporting process.

We record 1,372 distinct deficiencies for our 727 firm-year observations since some firms disclose more than one ICMW. Among these 1,372 deficiencies, 431 are Account-Specific deficiencies; 243 are Period-End Reporting/Accounting Policies deficiencies; 138 are Revenue Recognition deficiencies; 90 are Account Reconciliation issues deficiencies; 165 are Training and Personnel deficiencies; 53 are Segregation of Duties deficiencies; 89 are Subsidiary-Specific deficiencies; 56 are Senior Management deficiencies; and 68 are Technology deficiencies. Examples of our material weakness classification scheme are presented in Appendix 1.

Among 727 ICMW firm-year observations, 348 firm-year observations disclose Contained ICMWs; 318 firm-year observations disclose both Contained and Pervasive ICMWs; and 61 firm-year observations disclose only Pervasive ICMWs. Hence, there are 348 G1 firm-year observations and 379 G2 firm-year observations (318 firm-year observations plus 61 firm-year observations).

We examine and compare G1 and G2 firms' profitability, business complexity, and changes in earnings. We use return on assets (ROA) and a loss indicator (LOSS) to proxy for profitability. ROA is calculated as earnings before extraordinary items (Compustat #18) scaled by average total assets (Compustat # 6); and LOSS is an indicator variable that equals one if earnings are negative and zero otherwise. As in Ge and McVay (2005), we use the existence of a foreign currency adjustment to proxy for the complexity of the business (FOREIGN) (Compustat Data Item #150). Lastly, we examine the percentage change in earnings.

The descriptive statistics provided in Table 63.2 Panel B suggest that G1 firms are, on average, more profitable than G2 firms. The average return on assets (ROA) of G1 firms is significantly higher than that of G2 firms (at the 0.01 significance level); the average loss (LOSS) of G1 firms is significantly lower than that of G2 firms (at the 0.1 significance level). By comparing our business complexity measure, the existence of a foreign currency adjustment (FOREIGN), we find that the business models of G2 firms, on average, are significantly more complex than those of G1 firms (at the 0.1 significance level). Lastly, we find no significant differences in means and medians of earnings changes (ECHG), which suggests that there are no systematic differences in the reporting earnings between G1 and G2 firms.

In summary, we find that G2 firms are less profitable and more complex compared to G1 firms. These results imply that the managements of G2 firms may have limited resources to invest in proper internal control (due to lower profitability) and have more difficulty in establishing efficient internal control (due to higher complexity) than G1 firms.

63.4 Empirical Tests

63.4.1 Variable Measurement

Based on Kanagaretnam et al. (2012), we define forecasts accuracy and bias as follows:

Forecast accuracy (ACCURACY) is calculated as $-\frac{|\text{EPS Forecasted}-\text{EPS Actual}\,|}{\text{Beginning Stock Price}}$; both forecasted and actual earnings per share are from IBES Summary Files. Because we are interested in assessing the impact of a firm's internal control on its financial statements, we try to focus on a particular announcement date: the annual earnings announcement. Forecast accuracy is computed as the absolute difference between the last median forecasted earnings before the annual earnings announcement and the actual earnings for the year in which ICMWs are disclosed.[15] We deflate forecast accuracy by beginning stock price to facilitate comparisons across firms.

Forecast bias (BIAS) is calculated as $\frac{\text{EPS Forecasted}-\text{EPS Actual}}{\text{Beginning Stock Price}}$, both forecasted and actual earnings per share are from IBES Summary Files. Forecast bias is computed as the difference between the last median forecasted earnings before the annual earnings announcement and the actual earnings for the year in which ICMWs are disclosed. We also deflate forecast bias by beginning stock price to facilitate comparisons across firms.[16]

63.4.2 Univariate Analysis

We first examine whether there are significant differences between ICMW firms and their matched firms in forecast accuracy and bias using mean and median tests. The results are reported in Table 63.3.

We find that median forecast accuracy for the ICMW sample is significantly smaller than that for matched firms at the 0.01 level, suggesting that internal control material weaknesses are related to less accurate forecasts. In addition, we find that median forecast bias for the ICMW sample is significantly larger than that for matched firms at the 0.01 level, consistent with the notion that internal control material weaknesses are related to more optimistic forecasts.

A similar pattern exists when comparing forecast accuracy and bias separately for G1 firms and their matched firms and for G2 firms and their matched firms.

[15]Note that the ACCURACY is defined so that larger errors correspond to a lower level of accuracy.

[16]As a sensitivity test, we calculate ACCURACY and BIAS using the simple average of the measures across the 6 or 12 monthly reporting periods on the IBES before the company's fiscal year end. In other words, we choose all median forecasts across the 6 or 12 monthly reporting periods on IBES before the company's fiscal year ends and then average the median forecasts to create our ACCURACY and BIAS variables. The results are similar to what we report in this paper (not tabulated). When we use forecasts from the prior year instead of the current year, we also get similar results (not tabulated).

Table 63.3 Accuracy and bias statistics for all ICMW firms, Contained ICMW (G1) and Pervasive ICMW firms (G2), and their matched firms

	ICMW firms ($N = 727$)		Matched firms ($N = 727$)	
	Mean	Median	Mean	Median
ACCURACY	−0.019	−0.003***	−0.015	−0.002
BIAS	0.007*	0.001***	−0.001	0.000
	G1 firms ($N = 348$)		Matched firms ($N = 348$)	
	Mean	Median	Mean	Median
ACCURACY	−0.017	−0.003***	−0.022	−0.002
BIAS	0.004	0.001***	0.000	0.000
	G2 firms ($N = 379$)		Matched firms ($N = 379$)	
	Mean	Median	Mean	Median
ACCURACY	−0.020***	−0.004***	−0.009	−0.002
BIAS	0.010***	0.001***	0.000	0.000

ACCURACY is forecast accuracy, calculated as the negative of the absolute difference between actual EPS and last median forecasted EPS scaled by stock price. BIAS is forecast bias, calculated as the difference between last median forecasted EPS and actual EPS scaled by stock price. *, **, *** denote two-tailed significance levels of 10 %, 5 %, and 1 %, respectively, for the differences between ICMW firms and matched firms, G1 firms and matched firms, and G2 firms and matched firms. *T*-test is used to test the difference between the mean of the ICMW sample and the matched sample, and median test is used to test the difference between the median of the ICMW sample and the matched sample

Matched firms consist of firms in the same industry based on the 48 industry codes identified by Fama and French (1997) with the closest market value and sales at the end of fiscal year

G1 firms are firms that disclose *only* Contained ICMW, and G2 firms are firms that disclose *at least* Pervasive ICMW. The Contained and Pervasive internal control material weaknesses are similar to Moody's classification scheme. The Contained internal control material weakness is defined as the internal control issues related to controls over specific account balances, or transaction-level processes, or special accounting policy interpretation; the Pervasive internal control material weakness is defined as the internal control issues related to controls over the control environment or the overall financial reporting process

The median forecast accuracy of G1 firms is smaller than that of the matched firms at the 0.01 significance level. For G2 firms, the median forecast accuracy is also smaller than that of matched firms at the 0.01 significance level. In terms of optimistic bias, we find that median forecast biases for G1 and G2 samples are larger than those for their matched firms at the 0.01 significance level.

These findings suggest that internal control material weaknesses are associated with less accurate and more optimistic forecasts for both G1 and G2 firms. In the next two subsections, we examine the association between ICMW and forecast accuracy (and bias) using multivariate regressions.

The definitions of all the independent variables are provided in Appendix 2. Since we have a large number of independent variables incorporated in our regression models, the statistical inference on the variables could be affected by multicollinearity. Multicollinearity is a high degree of correlation (linear dependency) among several independent variables. It commonly occurs when some of the independent variables measure the same concepts or phenomena.

In Table 63.4, we present the pair-wise correlations among all independent variables in the regressions and find that none of the correlations are larger than 0.50 (or smaller than −0.50) except for the correlation between SKEW and EPSVOL. To avoid the multicollinearity issue, we choose not to include these two variables in the same regression model.

63.4.3 Analysis of Forecast Accuracy

The hypotheses to be tested are that analyst accuracy and bias are a function of ICMWs. However, the results will be difficult to interpret if endogeneity is a concern. We include firm-specific fixed effects to control for the possibility that endogeneity arises from omitted unobserved factors (e.g., business models) that may be correlated with both forecast quality and ICMWs.

The model employed to test the association between forecast accuracy and ICMW is (H1 and H2):

$$\begin{aligned}\mathrm{ACCURACY}_{\mathrm{i,t}} = \alpha_0 + \alpha_1 \mathrm{ICMW}_{i,t} + \alpha_2 \mathrm{NUM}_{i,t} + \alpha_3 \mathrm{MV}_{i,t} + \alpha_4 \mathrm{LEV}_{i,t} \\ + \alpha_5 \mathrm{ROA}_{i,t} + \alpha_6 \mathrm{BM}_{i,t} + \alpha_7 \mathrm{EPSVOL}_{i,(t-5,t-1)} + \alpha_8 \mathrm{ABSECHG}_{i,t} \\ + \alpha_9 \mathrm{LOSS}_{i,t} + \alpha_{10} \mathrm{SPECIAL}_{i,t} + \alpha_{11} \mathrm{RET}_{i,(t-3,t-1)} + \alpha_{12} \mathrm{DA}_{i,t} + \varepsilon\end{aligned} \tag{63.1}$$

where ACCURACY is forecast accuracy, calculated as the negative of the absolute difference between actual EPS and last median forecasted EPS scaled by stock price. ICMW is an indicator variable that equals one if a firm discloses a material weakness in internal control and zero otherwise. The definitions of the other variables are provided in Appendix 2.

In our regression model we first control for earnings characteristics. Prior research identifies earnings volatility (EPSVOL), losses (LOSS), and special items (SPECIAL) as earnings characteristics that can negatively affect forecast accuracy. The forecasting task is more difficult for firms with historically more volatile earnings compared to firms with historically more stable earnings (e.g., Kross et al. 1990; Lim 2001), losses, and special items (Brown and Higgins 2001). In addition, we include absolute earnings changes (ABSECHG) to capture any shift in reported earnings. Prior studies show that forecast errors are larger for larger earnings surprises (e.g., Lang and Lundholm 1996; Duru and Reeb 2002). Moreover, we use absolute abnormal accruals (DA) to control for earnings quality. DA is estimated using the modified Jones model of Larcker et al. (2007). We expect a negative relation between forecast accuracy and DA.[17]

[17]Note that the differences in the earnings quality could also be the consequences of the existence of ICMWs. By controlling for absolute abnormal accruals, we may overcontrol the impact of ICMWs. But it will bias against us finding any results.

All the variables are described in Appendix 2
**, *** significant at 0.05 level and 0.01 level, respectively

We next control for other firm characteristics such as size, growth, financial leverage, profitability, and risk. Firm size is measured as the natural logarithm of market value at the end of the year (MV) and has been used in the literature as a proxy for a number of factors. To the extent that size reflects information availability about a firm (other than through annual reports), a positive relation with forecast accuracy is expected (Ho 2004). However, firm size could also proxy for a host of other factors, such as managers' incentives, for which predictions for the relation with forecast accuracy are unclear.[18]

We measure growth as the natural logarithm of the ratio of the book value of equity to the market value of equity at the end of the year (BM). Dechow and Sloan (1997) and Richardson et al. (2004) find that forecast accuracy and bias are related to measures of growth. Consistent with prior research, we expect firms with low book to market ratios (i.e., high growth firms) to have more accurate forecasts than firms with high book to market ratios (i.e., turnaround and declining firms). We also include the debt to equity ratio (LEV) to proxy for financial leverage and return on assets (ROA) to proxy for profitability. We do not have predictions for the sign of these two variables. Finally, we use the equally weighted market-adjusted cumulative return over the past 3 years (RET) to proxy for firm risk. We expect a negative relation between forecast accuracy and RET.[19]

Next, we use the natural logarithm of the number of analysts who issue the forecasts in calculating the last median earnings (NUM) to account for the effects of differences in forecast characteristics on forecast accuracy. Lys and Soo (1995) argue that the number of analysts proxies for the intensity of competition in the market. We expect a positive relation between forecast accuracy and analyst following. Finally, we include firm-specific and exchange-specific fixed effects to control for firm-specific and exchange-specific shocks.

The results of the accuracy tests are reported in Table 63.5. Column 3 shows the OLS regression results for the overall sample along with the matched sample; Column 4 shows the OLS regression results for G1 sample firms and their matched firms; and Column 5 shows the OLS regression results for G2 sample firms and their matched firms.

The results presented in Table 63.5 show that the coefficients on ICMW for the overall sample and G1 sample firms are not significantly different from zero. These findings suggest that forecast accuracy is not significantly different for all ICMW disclosing firms and for Contained ICMW disclosing firms relative to their corresponding matched firms when controlling for other independent variables. In contrast, for G2 sample firms, the coefficient of ICMW in Column 4 is significantly negative (at the 0.1 level for the two-tailed test). The negative coefficient suggests that forecast accuracy is significantly lower for Pervasive ICMW disclosing firms compared with their matched firms.

Inferences about the control variables in the regression are generally similar to previous studies. Specifically, firms with lower frequency of negative earnings,

[18]Fan and Yeh (2006) find that forecasting error is a negative function of firm size.

[19]The results are similar if we use value-weighted market-adjusted cumulative returns.

Table 63.5 OLS regression estimations relating ACCURACY to ICMW firm variables
$\mathrm{ACCURACY}_{i,t} = \alpha_0 + \alpha_1 \mathrm{ICMW}_{i,t} + \alpha_2 \mathrm{NUM}_{i,t} + \alpha_3 \mathrm{MV}_{i,t} + \alpha_4 \mathrm{LEV}_{i,t} + \alpha_5 \mathrm{ROA}_{i,t} + \alpha_6 \mathrm{BM}_{i,t} + \alpha_7 \mathrm{EPSVOL}_{i,(t-5,t-1)} + \alpha_8 \mathrm{ABSECHG}_{i,t} + \alpha_9 \mathrm{LOSS}_{i,t} + \alpha_{10} \mathrm{SPECIAL}_{i,t} + \alpha_{11} \mathrm{RET}_{i,(t-3,t-1)} + \alpha_{12} \mathrm{DA}_{i,t} + \varepsilon$

Observations include ICMW firms and matched firms that do not disclose ICMW. Matched firms consist of firms in the same industry based on the 48 industry codes identified by Fama and French (1997) with the closest market value and sales at the end of fiscal year. Regressions in the third, fourth, and fifth columns include all ICMW firms and matched firms, G1 firms and matched firms, and G2 firms and matched firms separately. Regressions control for exchange and firm fixed effects. Outliers are excluded using Cook's (1977) distance statistic. N is the number of firm-year observations. *, **, *** denote two-tailed significance levels of 10 %, 5 %, and 1 %, respectively. All the variables are defined in Appendix 2 lower book to market ratio, smaller abnormal accruals, and a larger number of analyst following have more accurate forecasts (as evidenced by significant P-value [<0.1] in Table 63.5). The results documented in this subsection are consistent with our H2 hypothesis.

One alternative explanation for our findings is that auditors may become more conservative in the year of the ICMW, leading to a systematic downward shift in reported earnings, as evidenced by the results in Table 63.2 Panel A.[20] The systematic downward shift may account for the differences in ACCURACY between ICMW firms and non-ICMW firms. This alternative explanation is unlikely since we have included ABSECHG, absolute changes in reported earnings, in the regression model to capture any systematic shift in reported earnings.

63.4.4 Analysis of Forecast Bias

We estimate the following regression model to test H3 and H4 on forecast bias:

$$\begin{aligned}\mathrm{BIAS}_{\mathrm{i,t}} = {} & \beta_0 + \beta_1\mathrm{ICMW}_{i,t} + \beta_2\mathrm{NUM}_{i,t} + \beta_3\mathrm{MV}_{i,t} + \beta_4\mathrm{LEV}_{i,t} + \beta_5\mathrm{BM}_{i,t} \\ & + \beta_6\mathrm{SKEW}_{i,(t-5,t-1)} + \beta_7\mathrm{ECHG}_{i,t} + \beta_8\mathrm{LOSS}_{i,t} + \beta_9\mathrm{SPECIAL}_{i,t} \\ & + \beta_{10}\mathrm{NECHG}_{i,t} + \beta_{11}\mathrm{RET}_{i,(t-3,t-1)} + \beta_{12}\mathrm{DA}_{i,t} + \varepsilon \end{aligned} \tag{63.2}$$

where BIAS is forecast bias, calculated as the difference between last median forecasted EPS and actual EPS scaled by stock price.[21] The definitions of Eq. 63.2's other variables are provided in Appendix 2.

As in the forecast accuracy tests, we use losses (LOSS) and special items (SPECIAL) to control for earnings characteristics.[22] Unlike the accuracy test, we use earnings changes (ECHG) instead of absolute earnings changes (ABSECHG). We expect that optimistic forecast bias is positively associated with earnings characteristics because these characteristics are positively related to the complexity of forecasting tasks. In addition, we include ECHG and NECHG to control for the anchoring behavior of analysts who tend to anchor their forecasts closely to previous period's actual results.[23] We use the difference between the mean and median of price-scaled earnings from five prior years (minimum of 4 years) to proxy for earnings skewness (SKEW). We expect that optimistic forecast bias is

[20]We thank an anonymous referee for pointing this out to us.

[21]When we use forecasts from the prior year instead of the current year, we also get similar results (not tabulated).

[22]We exclude earnings volatility (EPSVOL) variable because the variable is significantly correlated with SKEW variable. In a sensitivity test, we replace SKEW by EPSVOL; the results are similar to what we report in the paper.

[23]See Shiller (1999) on anchoring behavior of financial analysts.

negatively associated with earnings skewness primarily due to mean-median differences in skewed earnings distributions (Gu and Wu 2003).

As in the forecast accuracy test, we use size (MV), growth (BM), leverage (LEV), profitability (ROA), risk (RET), and earnings quality (DA) to control for differences in firm characteristics. We have no prediction on the signs of these variables. We also include the log of the number of analysts following the firm (NUM) to account for differences in forecasts characteristics that affect forecast bias. In addition, we include firm-specific and exchange-specific fixed effects to control for firm-specific and exchange-specific shocks.

In Table 63.6 we report the results for the bias test. The coefficient on ICMW is significantly positive for the overall sample at the 0.05 significance level, which suggests that analysts tend to be more optimistic toward ICMW disclosing firms. Inferences about the control variables suggest that firms with smaller size, higher leverage, higher frequency of negative earnings, and lower profitability have more optimistically biased forecasts (as evidenced by significant P-value [<0.1] in Table 63.6). The results presented in Table 63.6 are consistent with our H3 hypothesis. Analysts' earnings forecasts are more positively biased among ICMW reporting firms relative to non-reporting firms.

63.4.5 Analysis of Brokerage Reputation

In this subsection, we examine the impact of the brokerage reputation on the positive bias. We use Institutional Investors' ranking of brokerage houses to proxy for brokerage reputation: a brokerage is considered to be of high reputation if it is consistently (for at least three prior years) ranked among the "Leaders" by Institutional Investors during the sample period. The following 12 brokers are identified as highly reputable: Bear Stearns & Co; CS First Boston; Goldman Sachs; Lehman Brothers; Donaldson, Lufkin & Jenrette; J.P. Morgan Securities; Merrill Lynch; Morgan Stanley & Co; Paine Webber; Prudential Securities; Salomon Brothers; and Smith Barney. The other brokerages are classified as less highly reputable brokerages.

An analyst's brokerage affiliation data comes from the IBES Detailed Files. We first separate all forecasts issued for ICMW firms into two subsamples based on whether the forecasts are issued by the analysts from highly reputable brokerage houses or not. All forecasts issued by the analysts affiliated with highly reputable brokerage houses belong to the highly reputable brokerage subsample, and the remaining forecasts belong to the less highly reputable brokerage subsample.

For each analyst, we only keep the last forecast issued for each forecast period. We then calculate the median forecasted earnings for each forecast period for each sample firm in each subsample. Note that, if a firm has forecasts made by the analysts affiliated with both highly reputable and less highly reputable brokerage houses, the firm will show up in both subsamples with different values for the medians. The median forecasted earnings in the highly reputable brokerage (less highly reputable brokerage) subsample are calculated based on the forecasts made

Observations include ICMW firms and matched firms that do not disclose ICMW. Matched firms consist of firms in the same industry based on the 48 industry codes identified by Fama and French (1997) with the closest market value and sales at the end of fiscal year. Regressions control for exchange fixed effects. Outliers are excluded using Cook's (1977) distance statistic. N is the number of firm-year observations. All the variables are defined in Appendix 2

*, **, *** denote two-tailed significance levels of 10 %, 5 %, and 1 %, respectively

by the analysts affiliated with highly reputable brokerage houses (less highly reputable brokerage houses).

We next compute forecast bias (BIAS) as the difference between the last median forecasted earnings before the annual earnings announcement and the actual earnings for the year in which ICMWs are disclosed. As in the prior section, we also deflate forecast bias by beginning stock price to facilitate comparisons across firms. We reestimate Eq. 63.2 for highly reputable brokerage forecasts of the sample firms and their matched firms (638 observations) and for less highly reputable brokerage forecasts of the sample firms and their matched firms (816 observations), respectively.

The results are presented in Columns 3–4 of Table 63.7. As reported in Column 3, the analysts affiliated with highly reputable brokerage houses are less likely to issue biased forecasts for firms with ICMWs (compared to the analysts from less highly reputable brokerage houses). The significantly positive relation between ICMWs and forecast bias only exists when those forecasts are made by the analysts affiliated with less highly reputable brokerage houses as reported in Column 4 (P-value < 0.1).

There are some sample firms that have forecasts made by analysts affiliated with both highly reputable and less highly reputable brokerage houses. We repeat our tests for this subsample. We reestimate Eq. 63.2 for highly reputable brokerage forecasts of the subsample firms and their matched firms (276 observations) and for less highly reputable brokerage forecasts of the subsample firms and their matched firms (276 observations), respectively.

The results are presented in Table 63.7 Columns 5–6. Similar to what are reported for the whole sample, the significantly positive relation between ICMWs and forecast bias only exists when those forecasts are made by the analysts affiliated with less highly reputable brokerage houses as reported in Column 5 (P-value < 0.1).

Taken together, our regression results show that analysts from less highly reputable brokerage houses are likely to issue more optimistic forecasts. We interpret these findings as that highly reputable brokerage houses value the creditability of analysts' reports more than less highly reputable brokerage houses. Hence, analysts are likely to feel constrained from adding an arbitrarily high optimistic bias to their estimates by a fear of hurting the brokerage houses' reputations.

63.5 Additional Tests

63.5.1 ICMW Resolution and Forecast Accuracy and Bias

Our first additional test probes our findings of the association between ICMWs and forecast accuracy (and bias) for G2 firms. In particular, we investigate whether the association between ICMW and forecast accuracy (and bias) still exists when firms resolve the internal control deficiencies. If there is indeed an association between ICMW and forecast accuracy (and bias), we should find no difference in forecast accuracy (and bias) between G2 firms and their matched firms after ICMW firms resolve their internal control issues. To test this hypothesis, we examine whether the

Observations include ICMW firms and matched firms that do not disclose ICMW. Regressions in the third and fourth columns include estimates made by analysts affiliated with highly reputable brokers and the estimates made by analysts affiliated with less highly reputable brokers separately The regressions results in the fifth and sixth columns are for ICMW firms that are covered by both analysts affiliated with highly reputable and less highly reputable brokers. The regressions results on the estimates made by analysts affiliated with highly reputable brokers are reported in the fifth column, and the regressions results on the estimates made by analysts affiliated with less highly reputable brokers are reported in the sixth column. Regressions control for exchange and firm fixed effects. Outliers are excluded using Cook's (1977) distance statistic. *, **, *** denote two-tailed significance levels of 10 %, 5 %, and 1 %, respectively. All the variables are defined in Appendix 2. Dependent variable is BIAS forecast accuracy (and bias) for G2 sample firms is significantly different from their matched firms after the sample firms stop disclosing internal control material weaknesses.

We start by assigning a post-ICMW year to each G2 firm-year observation. The post-ICMW year is defined as the first year after the year in which ICMWs are disclosed in our sample period (i.e. the first year in which our sample firms solve their disclosed internal control issues).[24] We then reestimate Eqs. 63.1 and 63.2 for the post-ICMW firm-year observations. We have 196 post-ICMW firm-year observations for G2 sample, and 183 firm-year observations are lost due to the lack of required data. The un-tabulated results show that the ICMW coefficients in both accuracy and bias tests are no longer significant, which suggests that in the first year in which our sample firms solve their disclosed internal control issues, there are no significant differences in accuracy and bias between G2 firms and their matched firms.

63.5.2 The Differences in the Frequency of Analyst Forecasts Between Highly Reputable Houses and Less Highly Reputable Houses

For our sample period, analysts affiliated with highly reputable houses on average issue 3.49 annual earnings forecasts for each firm each year (the median number of forecasts issued is 3), while analysts affiliated with less highly reputable houses on average issue 3.07 annual earnings forecasts for each firm each year (the median number of forecasts issued is 2). Thus, it appears that analysts affiliated with highly reputable houses issue forecasts more frequently than those affiliated with less highly reputable houses. To further examine this issue, we create one variable STALE, which is calculated as the difference between the date of fiscal year end and the date of the last annual forecast issued by an analyst. In un-tabulated test, we find that the mean and median STALE values for analysts affiliated with highly reputable houses are 99.83 and 68 days, respectively. In contrast, the mean and median STALE values for analysts affiliated with the less highly reputable houses are 110.92 and 75 days. Both mean and median differences for the STALE variable between analysts affiliated with highly reputable houses and those affiliated with less highly reputable houses are statistically significant at the 0.01 levels.

To make sure that our results in Table 63.7 are not caused by the differences in the frequency of analyst forecasts made by highly reputable houses and less highly reputable houses, we include an ADJSTALE variable in Eq. 63.2. The ADJSTALE variable is the median value of the STALE variable for each forecast period for each sample firm. We then reestimate the revised Eq. 63.2 for highly reputable brokerage forecasts of the sample firms and their matched firms (638 observations) and for less highly reputable brokerage forecasts of the sample firms and their

[24] For firms that disclose ICMWs for multiple years, the last year in which ICMWs are disclosed for the firms in our sample period is used.

matched firms (816 observations), respectively. Similar to what are reported in Table 63.7, we find that the significantly positive relation between ICMWs and forecast bias only exists when those forecasts are made by the analysts affiliated with less highly reputable brokerage houses (results are not tabulated). Hence, our results in Table 63.7 are unlikely to be caused by the differences in the frequency of analyst forecasts made by highly reputable houses and less highly reputable houses.

63.5.3 Other Robustness Tests

We conduct several additional tests to probe the robustness of our main results reported in Tables 63.4 and 63.5. Eames and Glover (2003) document that there is no significant relation between forecast error and earnings predictability after controlling for the level of earnings. We, first, investigate whether the level of earnings will affect our results. Our main results remain qualitatively the same after controlling for the level of earnings (not tabulated).

Second, we reestimate the models using rank regression techniques to assess the sensitivity of the results to the underlying functional form assumption made by OLS (Cavanagh and Sherman 1998). The results using rank regressions support the reported results (not tabulated). Lastly, we classify our sample firms into 302 and 404 ICMW firms to capture any differences in ICMW disclosures between Sections 302 and 404. ICMW firms under Section 302 are those that have a market value of less than $75 million or have disclosed their material weakness prior to November 15, 2004. ICMW firms under Section 404 are those that have a market value of at least $75 million and disclose a material weakness on or after November 15, 2004. We reestimate our Eqs. 63.1 and 63.2 separately for 302 and 404 disclosures. The results for 302 and 404 firms are qualitatively similar (not tabulated).

Last, on April 28, 2003, an enforcement agreement, the Global Settlement, was reached between the SEC, NASD, NYSE, and ten of the largest investment firms in the USA to address issues of conflict of interest within their businesses. One of the goals of Global Settlement is to reduce the biases in analyst reports. To make sure that our results are not influenced by the Global Settlement, we include a set of dummy variables in all our regression models to control for year-specific shocks. Our un-tabulated results are similar to what are reported in the paper.

63.6 Conclusion

In this paper we investigate the effects of ICMWs on the accuracy and optimistic bias of financial analysts' earnings forecasts. We find that financial analysts' earnings forecasts are less accurate and more positively biased among ICMW reporting firms relative to non-reporting firms.

When separating all the ICMW reporting firms into Pervasive ICMW and Contained ICMW reporting firms, we find that accuracy is only inversely associated with Pervasive ICMWs. One possible explanation is that the managers of Pervasive ICMW reporting firms cannot effectively control firms' financial reporting process, which leads to much noisier financial statements and thus makes financial analysts' earnings forecasts less accurate.

In addition, we find that analysts from less highly reputable brokerage houses are likely to issue more optimistic forecasts. We interpret these findings as that highly reputable brokerage houses value the creditability of analysts' reports more than less highly reputable brokerage houses. Hence, analysts are likely to feel constrained from adding an arbitrarily high optimistic bias to their estimates by a fear of hurting the brokerage houses' reputations.

Our results suggest that the weaknesses in internal control increase the complexity of the forecasting tasks for financial analysts. Analysts' forecasts become less accurate if the weaknesses belong to the Pervasive type. The weaknesses in internal control are also associated with more positively biased forecasts. However, the good reputation of brokerage firms appears to curb the upward bias. We also show that when Pervasive ICMW reporting firms stop disclosing weaknesses, the documented relation between accuracy (bias) and ICMWs disappears.

Appendix 1: Material Weakness Classification Examples

G1 Contained Material Weaknesses

1. Account-Specific
   e.g., "U.S. Cellular did not maintain effective controls over the completeness, accuracy, presentation and disclosure of its accounting for income taxes." (U.S. Cellular Inc., 2004 10-K report)
2. Period-End Reporting/Accounting Policies
   e.g., "–a lack of an ongoing formal self-assessment process related to internal control over financial reporting." (Ivanhoe energy Inc., 2004 10-K report)
3. Revenue Recognition
   e.g., "The Company's policies and procedures regarding coal sales contracts with its customers did not provide for a sufficiently detailed, periodic management review of the accounting for payments received. This material weakness resulted in a material overstatement of coal revenues and an overstatement of amortization of capitalized asset retirement costs." (Westmoreland Coal Co., 2005 10-K report)
4. Account Reconciliation
   e.g., "The Company did not maintain effective controls over reconciliations of certain financial statement accounts." (SIRVA Inc., 2004 10-K report)

G2 Pervasive material weaknesses

1. Segregation of Duties
   e.g., "Inadequate segregation of duties was noted with respect to the revenue, expenditure and payroll processes as numerous incompatible tasks are performed by the same accounting personnel." (Versant Co., 2004 10-K report)

2. Subsidiary-Specific
   e.g., "We have reported to the SEC that one of our foreign subsidiaries operating in Nigeria made improper payments of approximately $2.4 million to an entity owned by a Nigerian national who held himself out as a tax consultant when in fact he was an employee of a local tax authority. The payments were made to obtain favorable tax treatment and clearly violated our Code of Business Conduct and our internal control procedures." (Halliburton Co., 2002 10-K report)
3. Senior Management
   e.g., "management did not set a culture that extended the necessary rigor and commitment to internal control over financial reporting." (SIRVA Inc, 2004 10-K report)
4. Technology Issues
   e.g., "There are weaknesses in the Company's information technology ("IT") controls which makes the Company's financial data vulnerable to error or fraud; a lack of documentation regarding the roles and responsibilities of the IT function; lack of security management and monitoring and inadequate segregation of duties involving IT functions." (Earthshell Co., 2005 10-K report)
5. Training and Personnel
   e.g., "The Company lacks personnel with adequate expertise in accounting for income taxes in accordance with U.S. GAAP." (Westmoreland Coal Co., 2005 10-K report)

Appendix 2: Variable Definitions

Variables	Definition and data source
NUMBER	The number of analysts who make the forecasts in calculating the last median earnings
NUM	Natural logarithm of the number of analysts who make the forecasts in calculating the last median earnings
SKEW	The skewness of the earnings, calculated as the mean-median difference of price-scaled *earnings* from the prior 5 years (minimum of 4 years)
SPECIAL	An indicator variable equal to one if special items (Compustat # 17) are not equal to zero, zero otherwise
RET	Is the equally weighted market-adjusted cumulative return over the past 3 years
DA	The absolute value of abnormal total accruals. The calculation of DA is estimated using the modified Jones model of Larcker et al. (2007)
LOSS	An indicator variable equal to one if earnings are negative, zero otherwise
ECHG	Is the change in earnings (Compustat #18), calculated as the change in earnings over the previous year scaled by the previous year's earnings
NECHG	Is equal to one if ECHG is negative and zero otherwise

(*continued*)

Variables	Definition and data source
ABSECHG	The absolute change in earnings (Compustat #18), calculated as the absolute value of the change in earnings over the previous year scaled by the previous year's earnings
EPSVOL	The standard deviation of earnings before extraordinary items (Compustat #18) estimated using data from the prior 5 years (minimum of 4 years)
BM	The natural logarithm of book value (Compustat # 60) to the market (Compustat # 25* Compustat #199) of the firms
ROA	The ratio of return to asset, calculated as earnings before extraordinary items (Compustat #18) scaled by average total assets (Compustat # 6)
LEV	The ratio of debt (Compustat # 34 + Compustat # 9) to averaged total assets (Compustat # 6)
MV	Natural logarithm of the market value of equity (Compustat #199*#25)
FOREIGN	An indicator variable equal to one if foreign currency translation (COMPUSTAT Data Item #150) is not zero, zero otherwise
G1	An indicator variable that equals one if a firm discloses only Contained ICMWs in year t, and zero otherwise
G2	An indicator variable equal to one if a firm discloses Pervasive ICMWs in year t, and zero otherwise
ICMW	An indicator variable equal to one if the firm has disclosed internal control material weakness in year t, and zero otherwise
STALE	The days between the date of fiscal year end and the date of the last annual forecast issued (before the fiscal year end) by an analyst
ADJSTALE	The median value of the STALE variable for a firm per fiscal year
AGE	The number of years that a firm has been the CRSP database
BROKERAGE REPUTATION	The Institutional Investors' ranking of brokerage houses is used to proxy for brokerage reputation: a brokerage is considered to be of high reputation if it is consistently (at least for three prior years) ranked among the "Leaders" by Institutional Investors during the sample period. The following 12 brokers are identified as highly reputable: Bear Stearns & Co; CS First Boston; Goldman Sachs; Lehman Brothers; Donaldson, Lufkin & Jenrette; J.P. Morgan Securities; Merrill Lynch; Morgan Stanley & Co; Paine Webber; Prudential Securities; Salomon Brothers; and Smith Barney. The other brokerages are classified as less highly reputable

Appendix 3: Matching Procedure

The matches are identified by an algorithm that calculates the distance between each ICMW firm k and its matched non-ICMW counterpart j. Specifically, for each non-ICMW firm j in the same Fama-French industry as ICMW firm k, we calculate the percentage difference in assets, $\text{AssetsDIS} = \left|\frac{\text{Assets}_j - \text{Assets}_k}{\text{Assets}_k}\right|$, and the percentage difference in sales, $\text{SalesDIS} = \left|\frac{\text{Sales}_j - \text{Sales}_k}{\text{Sales}_k}\right|$. The sum of the two distance measures yields a matching score for each non-ICMW firm j that is in the same industry as ICMW firm k. From the set of matching scores that are less than two, we choose the non-ICMW firm with the smallest matching score for each ICMW firm; we then remove the matched pair (the ICMW and its non-ICMW counterpart) from the lists of ICMW and non-ICMW firms. In some cases, a single non-ICMW firm is the best match for several ICMW firms. In this case, we control for the order in which we match a non-ICMW firm to an ICMW firm by first calculating all possible matching scores, and then assigning the non-ICMW firm j to the ICMW firm k whose matching score is the smallest among the candidate ICMWs. For the remaining candidate non-ICMWs, we repeat the above steps using the remaining ICMW firms.

Appendix 4: Ordinary Least Squares (OLS) Method

For the main tests, we use Ordinary Least Squares (OLS) or linear least squares method to estimate the ACCURACY and BIAS parameters in the following linear regression models (Greene 2011). This method minimizes the sum of squared vertical distances between the observed responses (ICMW and control variables) in the dataset and the responses predicted by the linear approximation.

$$\begin{aligned}\mathrm{ACCURACY}_{\mathrm{i,t}} = {} & \alpha_0 + \alpha_1 \mathrm{ICMW}_{i,t} + \alpha_2 \mathrm{NUM}_{i,t} + \alpha_3 \mathrm{MV}_{i,t} + \alpha_4 \mathrm{LEV}_{i,t} \\ & + \alpha_5 \mathrm{ROA}_{i,t} + \alpha_6 \mathrm{BM}_{i,t} + \alpha_7 \mathrm{EPSVOL}_{i,(t-5,t-1)} + \alpha_8 \mathrm{ABSECHG}_{i,t} \\ & + \alpha_9 \mathrm{LOSS}_{i,t} + \alpha_{10} \mathrm{SPECIAL}_{i,t} + \alpha_{11} \mathrm{RET}_{i,(t-3,t-1)} + \alpha_{12} \mathrm{DA}_{i,t} + \varepsilon\end{aligned} \tag{63.3}$$

$$\begin{aligned}\mathrm{BIAS}_{\mathrm{i,t}} = {} & \beta_0 + \beta_1 \mathrm{ICMW}_{i,t} + \beta_2 \mathrm{NUM}_{i,t} + \beta_3 \mathrm{MV}_{i,t} + \beta_4 \mathrm{LEV}_{i,t} + \beta_5 \mathrm{BM}_{i,t} \\ & + \beta_6 \mathrm{SKEW}_{i,(t-5,t-1)} + \beta_7 \mathrm{ECHG}_{i,t} + \beta_8 \mathrm{LOSS}_{i,t} + \beta_9 \mathrm{SPECIAL}_{i,t} \\ & + \beta_{10} \mathrm{NECHG}_{i,t} + \beta_{11} \mathrm{RET}_{i,(t-3,t-1)} + \beta_{12} \mathrm{DA}_{i,t} + \varepsilon\end{aligned} \tag{63.4}$$

Appendix 5: Cook's Distance

We use Cook's distance to test the influence of outliers when performing least squares regression analysis. Cook's distance is calculated using the following formula (Cook 1977):

$$D_i = \frac{\sum_{j=1}^{n} \left(\widehat{Y_j} - \widehat{Y_{j(i)}}\right)\left(\hat{Y}_j - \hat{Y}_{j(i)}\right)^2}{p \cdot MSE}$$

where $\hat{Y}_J$ is the prediction from Eqs. 63.1 and 63.2 for observation j; $\hat{Y}_{j(i)}$ is the prediction for observation j from a refitted regression model in which observation i has been omitted; *MSE* is the mean square error of Eqs. 63.1 and 63.2. *P* is the number of fitted parameters in Eqs. 63.1 and 63.2. The higher the Cook's D is, the more influential the point. We choose 4/Nas our cutoff point. N is the number of observations in the regression tests. We exclude all observations with Cook's D higher than 4/N.

Appendix 6: Rank Regression

As a robust test, we reestimate the models using rank regression techniques to assess the sensitivity of the results to the underlying functional form assumption made by OLS (Cavanagh and Sherman 1998). Rank regression is one type of nonparametric tests that are widely used for studying populations that take on a ranked order. The use of nonparametric methods may be necessary when data have a ranking but no clear numerical interpretation. We first performance rank transformation (quintile rank) on all continuous variables used in Eqs. 63.1 or 63.2 and then performing OLS test on the ranks of the data instead of the data themselves.

What Increases Banks Vulnerability to Financial Crisis: Short-Term Financing or Illiquid Assets?

64

Gang Nathan Dong and Yuna Heo

Contents

Abstract

It is not clear whether short-term financing increases banks' vulnerability to financial crisis or just reflects the weakness of banks' balance sheets. This chapter examines the role of short-term financing and assets with deteriorated quality in the financial crisis 2007–2009.

We apply logit and OLS econometric techniques to analyze the Federal Reserve Y-9C report data. We show that short-term financing is a response to the adverse economic shocks rather than a cause of the recent crisis. The likelihood of financial crisis actually stems from the illiquidity and low

creditworthiness of the investment. Our results are robust to endogeneity concerns when we use a difference-in-differences (DiD) approach with the Lehman bankruptcy in 2008 proxying for an exogenous shock.

Keywords
Financial crisis • Short-term financing • Debt maturity • Liquidity risk • Deterioration of bank asset quality

Banks will be required to hold emergency stocks of easy-to-sell assets . . . 'liquidity coverage ratio' that will require banks to hold buffers against a 30-day market crisis.
–Financial Times, January 8, 2012

64.1 Introduction

Does short-term financing increase banks' vulnerability to financial crisis? Banks have a special feature, what we called "lend long and borrow short," that the illiquid loans which typically constitute assets be financed by volatile and demandable deposits. This means that banks which want to finance illiquid investments have to borrow short-term debt; hence, the increasing illiquidity of the investment possibly causes higher exposure of liquidity risk and the susceptibility to crises. Recently, the role of short-term financing to financial crises is being debated again in depth.[1] In particular, short-term financing and its rollover risks have been recognized as a distinct characteristic of the financial crisis 2007–2009 since, during recent financial crisis, bank runs were incited by short-term creditors who were concerned about liquidity and solvency, unlike old-style bank runs instigated by uninsured depositors. This indicates that short-term financing exposes banks to rollover risk and can amplify financial crises. However, it is not clear whether the short-term financing indeed causes the vulnerability of financial crisis or just reflects the weakness of banks' balance sheets.

Why is short-term financing an important source of financing for banks? One well-known answer is that short-term financing is an equilibrium response to the agency problems.[2] Unless banks are fully equity financed, they have the wrong incentives when it comes to continuing or liquidating its project. Similar to a risk-shifting problem, banks have an incentive to continue excessively risky projects at the cost of debt holders. Therefore, banks' choice of maturity structure and the

[1]See Brunnermier (2009), Diamond and Rajan (2009), Gorton (2009), Gorton and Metrick (2012), Ivashina and Scharfstein (2009), Eisenbach (2010), Kashyap (2010), Benmelech and Dvir (2011), and Brunnermeier et al. (2011).

[2]See Diamond and Rajan (2001), Diamond (2004), Diamond and Rajan (2009), Eisenbach (2010), and Kashyap (2010).

implied exposure to rollover risk can play an important role of risk takings and bank runs in financial crisis. Banks can choose any combination of long-term and short-term debt to finance its investment.[3] While long-term debt has the same maturity as the projects' final payoff, short-term debt has to be rolled over after the additional information about the project's expected payoff and the liquidation value becomes available. Rollover risk arises since it may not be possible to satisfy all withdrawals of short-term creditors, even by liquidating all of the bank's assets.

However, the likelihood of financial crisis can stem not from short-term financing, but from the illiquidity and low creditworthiness of the investment being financed.[4] How assets with low quality and short-term financing affect the financial crisis 2007–2009? The answer can be summarized as follows: A substantial amount of mortgage-backed securities with exposure to subprime risk were kept on bank balance sheets, and banks financed these securities and other risky assets with short-term debt. As the housing market deteriorated, the perceived risk of mortgage-backed securities increased, and it became difficult to roll over short-term borrowing against those securities. The funding problems led to fire sales of assets, and these fire sales made banks obtain short-term financing even harder. These difficulties of bank funding spilled over to the entire economy, causing bank runs and financial crisis. Therefore, short-term financing could be a symptom of adverse economic shocks rather than a cause. In this setting, the investments being financed are becoming illiquid and as a result banks will increase short-term financing.[5]

Given the ambiguous causality, this chapter examines the role of short-term financing and assets with deteriorated quality in the financial crisis 2007–2009. Specifically, we try to answer two questions: (1) Does short-term financing predicts the financial crisis? (2) Do assets with deteriorated quality increase banks' vulnerability to financial crisis? Empirically we test whether short-term financing and assets with low creditworthiness are related to a bank's risk and profitability during

[3]Given the complexity of bank-risk taking, investors would have demanded a very high premium for financing the bank long term. Creditors would have been willing to hold short-term debt on the bank since that would give them the option to exit or get a higher premium if banks were appeared to be getting into trouble. So, creditors would have demanded lower premium for holding short-term secured debt in light of potential agency problems at banks. Thus, from the banker's perspective, financing with short-term debt claims is more attractive to the banks than issuing long-term claims. Clearly, banks should have been worried about the possibility that they could become illiquid and incapable of rolling over financing (Diamond and Rajan 2009).

[4]Diamond and Rajan (2001) argue that "It is no surprise that illiquid or poor quality investment when a bank or banking system is close to its debt capacity will result in a buildup of short-term debt."

[5]Eisenbach (2010) points out similar view, saying that "While short-term debt acts as an effective disciplining device when banks only face idiosyncratic risk, it is severely undermined when aggregate risk is added. The problem is that the disciplining effect is too weak in good sates and too powerful in bad states. This leads to a two-sided inefficiency: In good aggregate states the banks take excessive risks in the form of projects with negative net present value. Bad aggregate states suffer from fire sales as projects with positive net present value are liquidated."

the crisis.[6] The following results are found: (1) Short-term financing is a response, rather than a cause, of the recent financial crisis; (2) Assets that experienced asset deterioration are positively related to financial distress. The results are consistent to recent findings of banks' risk-taking behaviors and short-term financing literatures.[7] Finally, we check if the above results are driven by endogeneity concerns, namely, that significant omitted variables are correlated with both dependent and independent variables.

Section 64.2 summarizes the related literatures and hypotheses development. Section 64.3 explains the data and descriptive statistics. Section 64.4 presents the empirical results. Section 64.5 conducts robustness checks, and Sect. 64.6 concludes.

64.2 Related Literatures

What caused the financial crisis?[8] What keeps asset prices and lending depressed? According to Diamond and Rajan (2009), there are some consensus on the proximate causes of the crisis: (1) The US financial sector misallocated resources to real estate, financed through the issuance of exotic new financial instruments; (2) a significant portion of these instruments found their way, directly or indirectly, into commercial and investment bank balance sheets; (3) these investments were largely financed with short-term debt.

There are two approaches linking short-term financing to financial crisis. According to the first approach, taking on short-term debt increases banks' exposure to bank runs, and the bank is therefore more likely to fail. In the second approach, short-term financing is endogenous and is potentially the only financing available for lower-quality banks. Hence, the likelihood of failure is not necessarily driven by short-term debt itself but rather is a consequence of the bank's underlying economic conditions.

The first approach describes that short-term financing exposes banks to rollover risk and thus can cause and increase financial crisis. There is a growing agreement that an excessive buildup of short-term debt was a proximate cause of the financial crises. In the recent crisis, many studies point out the fragility embedded in

[6]Brunnermeier et al. (2011) suggest a more comprehensive measure of short-term financing. But in this paper we define short-term financing as short-term debt subtracted by long-term debt due in 1 year.

[7]Benmelech and Dvir (2011) and Bhattacharyya and Purnanandam (2011).

[8]According to Bhattacharyya and Purnanandam (2011), the analysis of the causes of the financial crisis in the USA during 2007–2009 has followed three distinct sources. One track focuses on the important role played by the shadow banking system in the securitization of mortgage loans (Gorton and Metrick 2012). A second track examines the incentives provided by the securitization process to skimp on adequate due diligence in the origination process (Keys et al. 2010). A third track focuses on the role of banks in originating unduly risky loans and also examines the incentives of bank management to originate risky loans (Fahlenbrach and Stulz 2011; Acharya and Richardson 2010).

short-term debt and rollover risk on the collapse of the housing and mortgage-backed securities market[9] as well as the increased short-term repurchase agreements (Brunnermeier and Oehmke 2013; He and Xiong 2009). As a result, some of them argue to regulate the use of short-term debt in the shadow banking system (Gotron and Metrick 2012). Borrowing with large amounts of short-term debt can lead to the threat of runs on banks, because there may be an externality across lenders (Diamond 2004). These runs on firms are very similar to the bank runs analyzed in Diamond and Dybvig (1983).[10]

In contrast to this view, some financial economists argue that short-term financing may be the optimal choice for borrowers who experience the deterioration in asset quality (Diamond and Rajan 2001; Eisenbach 2010; Benmelech and Dvir 2010). Diamond and Rajan (2001) suggest that maturity mismatch may be an optimal ex ante capital structure for banks when they cannot commit to fully repay investors once a project has been completed. In their model, if the projects being financed are seen as becoming less liquid due to an adverse shock to fundamentals, banks will find it harder to secure long-term financing from creditors and as a result will increase short-term financing. Short-term financing is hence a result of adverse fundamental economic shock rather a cause.[11]

In addition to the relation between short-term financing and financial crises, the finance literature abounds with attempts to quantify and explain risk-taking behavior of banks. Many studies have pointed out that risk-taking incentives among banks cause the financial crisis (see Bernanke 1983). However, the difficulty to accurately measure the banks' risk limits the access to information needed to evaluate the risk factors of banks.

Among recent studies, Bhattacharyya and Purnanandam (2011) document remarkable changes in the composition of risk taking by banks from 2006 to 2006.

[9]Changes in asset prices show up immediately on balance sheets and have an instant impact on the net worth of all constituents of the financial system. The net worth of financial intermediaries is especially sensitive to fluctuations in asset prices given the highly leveraged nature of such intermediaries' balance sheets. Procyclical leverage can be seen as a consequence of the active management of balance sheets by financial intermediaries who respond to changes in prices and measured risk. For financial intermediaries, their models of risk and economics capital dictate active management of their overall Value-at-Risk (VaR) through adjustments of their balance sheets (Adrian and Shin 2010).

[10]When banks do not have cash on hand to pay all depositors and must liquidate assets at a loss to pay those who withdraw first, this can lead all depositors to withdraw whenever they expect enough others to withdraw, even though this makes them collectively worse off. They all withdraw because the payments to those who withdraw impose losses on those who wait to withdraw after the bank runs out of money.

[11]Theories of imperfect capital markets (Bernanke and Gertler 1989; Kiyotaki and Moore 1997) argue that the banking sector is especially vulnerable to adverse selection and moral hazard, both caused by asymmetric information. The US financial sector is indeed becoming more vulnerable to systemic risk. Rajan (2005) argues that compensation structure at many financial firms may induce additional risk taking against underperforming their peers. This type of common exposure may increase the possibility of a severe tail event, if exacerbated by liquidity and informational frictions.

According to Bhattacharyya and Purnanandam (2011), the systematic risk doubled between 2000 and 2006, and banks with heavy involvement in residential mortgage lending and securitization have higher earnings per share. Banks heavily engaged in residential mortgage lending started exhibiting lower earnings and stock returns even prior to the crisis.

In addition, many recent studies have suggested that governance structures are related to risk-taking behavior of banks. Cheng et al. (2010) find evidence that excess compensation is correlated with risk taking and suggest that institutional investors both pushed managers towards a risky business model and rewarded them for it through higher compensation. Fahlenbrach and Stulz (2011) show that banks where the incentives of CEOs were better aligned with those of shareholders did not perform better during the crisis. Beltratti and Stulz (2011) investigate a sample of banks across the world and show that banks with more vulnerable financing with better governance performed worse during the crisis. Ellul and Yerramilli (2010) find that bank holding companies with strong and independent risk management functions tend to have lower enterprise-wide risk. However, none of these studies provide an answer to the question whether short-term financing or deteriorated assets contributed to the crisis.

64.3 Data and Summary Statistics

64.3.1 Data

This study focuses on commercial banks in the USA with SIC code 60 or 61. The sample is from 1993 to 2009, consisting of a panel database. Banks' monthly stock return from CRSP and financial statement data from Compustat and Federal Reserve from FR Y-9C are obtained.

Table 64.1 presents the variables' definition. Short-term financing is defined as short-term debt subtracted by long-term debt due in 1 year. Assets with deteriorated quality is defined as loans secured by real estate (scaled by total assets) subtracted by short-term financing. *Crisis* is an indicator variable that equals 1 for year 2007–2009 and zero otherwise. Std(ROA) is defined as a standard deviation of net income divided by total assets in a given firm and a given year. Earning per shares (EPS) is defined as net income divided by numbers of shares outstanding. Stock returns are holding period returns from CRSP monthly.

64.3.2 Descriptive Statistics

Table 64.2 provides the average and standard deviation of main variables from year 1993 to 2009. Short-term financing increased before 2007 and drastically decreased year between 2008 and 2009. Assets with deteriorated quality also increased and peaked at 2008. During the crisis period, the EPS plummeted and the standard deviation of earnings increased dramatically.

Table 64.1 Variable definitions

Variable	Calculation	Sources
Short-term financing	Short-term debt subtracted by long-term debt due in 1 year/total assets	Compustat
Assets with deteriorated quality	(Loan secured by real estate/total assets) – short-term financing	FR Y-9C report Compustat
Std(ROA)	Standard deviation of return on assets (net income/total assets)	Compustat FR Y-9C report
Crisis	An indicator variable that equals one for years 2007–2009, zero otherwise	
Ln (total assets)	Log of total assets	FR Y-9C report
Market to book equity	Market value of equity/book value of equity	CRSP indices monthly
Leverage	debt/equity	Compustat
Earning per share	Net income/numbers of outstanding shares	FR Y-9C report CRSP indices monthly
Stock return	Holding period of return	CRSP indices monthly

Table 64.2 Mean and standard deviation by year

	Short-term financing		Assets with deteriorated quality		Earnings per share	
Year	Mean	Standard deviation	Mean	Standard deviation	Mean	Standard deviation
1993	0.03	0.05	0.34	0.15	1.77	1.74
1994	0.04	0.05	0.35	0.15	1.81	1.82
1995	0.04	0.05	0.38	0.15	1.67	0.98
1996	0.05	0.20	0.37	0.24	1.85	1.57
1997	0.05	0.25	0.38	0.28	1.77	1.15
1998	0.06	0.18	0.34	0.23	1.71	1.98
1999	0.08	0.17	0.35	0.24	1.65	2.17
2000	0.06	0.13	0.39	0.20	1.52	1.38
2001	0.06	0.14	0.40	0.21	1.49	1.14
2002	0.06	0.10	0.41	0.18	1.66	1.15
2003	0.06	0.09	0.41	0.18	1.69	1.13
2004	0.06	0.09	0.44	0.19	1.55	1.09
2005	0.06	0.09	0.46	0.19	1.67	1.20
2006	0.06	0.09	0.47	0.19	1.73	1.37
2007	0.07	0.07	0.47	0.18	1.44	1.36
2008	0.06	0.06	0.49	0.17	−0.27	3.26
2009	0.04	0.05	0.48	0.17	−0.92	4.99

Table 64.3 shows the summary statistics of variables used in study. The average of short-term financing is 0.056 and the average of assets with deteriorated quality 0.412. During the sample period, the average EPS is $1.39 and the average stock return is 1.1 %. Bhattacharyya and Purnanandam (2011) report the average EPS of $1.82 and the average return of 18 % during the peak period of 2000–2006.

Table 64.3 Summary statistics

Variable	Mean	Standard deviation	Minimum	Maximum
Short-term financing	0.056	0.122	0.000	4.992
Assets with deteriorated quality	0.412	0.205	−4.452	0.907
Std(ROA)	0.015	0.014	0.000	0.251
Crisis	0.175	0.380	0.000	1.000
Ln (total asset)	14.218	1.552	11.898	21.612
Market to book equity	1.470	1.220	−4.084	14.382
Leverage	10.995	5.125	−0.400	152.340
Earnings per share	1.391	2.105	−62.572	33.760
Stock return	0.011	0.097	−0.750	1.756

The correlation matrix is reported in Table 64.4. There is no large correlation between variables, except the correlation between short-term financing and assets with deteriorated quality.

64.4 Empirical Results

Table 64.5 shows the logit analysis results of short-term financing and assets with deteriorated quality. The dependent variable is a dummy variable that equals one if a bank bankrupted, filed for bankruptcy protection, or closed and received by the FDIC during year 2007–2009 and zero otherwise. The independent variables are short-term financing (short-term debt subtracted by long-term debt due in 1 year) and assets with deteriorated quality (loans secured by real estate subtracted by short-term financing). The control variables include log of total asset, market to book equity, and leverage. The results show that there are increasing assets with deteriorated quality, in contrast to decreasing short-term financing during the financial crisis years, indicating that short-term financing may not have contributed to the crisis, but reflect the weakness of banks' balance sheets.

Table 64.6 reports the regression results of standard deviation of ROA on short-term financing and assets with deteriorated quality. The dependent variable is the standard deviation of ROA and independent variables include short-term financing and assets with deteriorated quality. The control variables include log total asset, market to book equity ratio, and leverage ratio. The results show that short-term financing is not significantly related to the bank risk as measured by the standard deviation of ROA. Instead, assets with deteriorated quality during crisis years are positively related to the bank risk. This suggests that it is the assets with quality deterioration rather than short-term financing that actually caused bank distress. However, this finding does not exclude the possibility that exposures to rollover risk by short-term financing might also cause bank distress during the crisis.

Table 64.7 reports the regression results of earnings per share on short-term financing and assets with deteriorated quality. The dependent variable is EPS and the independent variables include short-term financing and assets with deteriorated

Table 64.4 Correlation table

	Short-term financing	Assets with deteriorated quality	Std(ROA)	Crisis	Log(total asset)	Market to book equity	Leverage	Earnings per share	Stock return
Short-term financing	1								
Assets with deteriorated quality	−0.682	1							
Std(ROA)	−0.018	−0.018	1						
Crisis	−0.003	0.152	0.130	1

			(9.74)	(9.36)
Intercept	-1.549^{***}	-2.768^{***}	-8.355^{***}	-13.63^{***}
	(−51.00)	(−32.02)	(−29.11)	(−34.88)
N	9,060	9,060	9,060	9,060

The parenthesis with ***, **, and * indicates its statistical significant level of 0.1 %, 1 %, and 5 %, respectively

quality. The control variables include log total asset, market to book equity ratio, and leverage ratio. The results suggest that short-term financing is positively related to banks' profitability. During the crisis years, short-term financing's contribution to bank profitability is significantly negative, indicating that short-term financing could be a symptom of adverse economic shocks rather than a cause of financial crisis, whereas assets with quality deterioration actually reduced banks' profits.

Table 64.8 reports the regression results of stock returns on short-term financing and assets with deteriorated quality. The results suggest that short-term financing is positively related to bank performance as measured by stock returns; however, during the crisis years, the effect turns to negative. The relation between assets with deteriorated quality and stock returns is always negative, regardless of the sample period.

64.5 Robustness Checks

As a robust check, we add time fixed effects to the regressions and report the results in Table 64.9. The dependent variables are standard deviation of ROA, EPS, and stock returns. Independent variables include short-term financing and assets with deteriorated quality. Consistent with the previous results, Table 64.9 shows that short-term financing during crisis is negatively related to standard deviation of ROA, suggesting that short-term financing might not actually contribute to financial crisis. The positive relation between assets with deteriorated quality and bank

Table 64.6 Regression of standard deviation of ROA on short-term financing. This table reports the regression results of standard deviation of ROA on short-term financing and assets with deteriorated quality. The dependent variable is a standard deviation of return on assets and independent variables include short-term financing and assets with deteriorated quality. The control variables include log total asset, market to book equity, and leverage

Dependent variable: Std(ROA)	(1)	(2)	(3)	(4)	(5)	(6)

performance suggests that the low creditworthiness of the investment assets might have caused the bank distress during the crisis.

We now examine if the above results are driven by endogeneity concerns. Specifically, are significant omitted variable(s) correlated with both dependent and independent variables driving our results spuriously? In order to do so, we consider the bankruptcy filing of Lehman Brothers on September 15, 2011 (2008Q3), as an exogenous shock. We employ a difference-in-differences approach to analyze whether banks with different short-term financing and deteriorated assets react differently in terms of equity returns when they face the unexpected shock of Lehman Brothers bankruptcy. Accordingly, banks with more short-term financing and deteriorated assets are defined as the treatment group, and banks with less short-term financing and deteriorated assets are the control or non-treated group. We rank all commercial banks based on their short-term financing and deteriorated assets in the year 2007Q2 and Q3. The dummy variable of post-Lehman bankruptcy is set to one if the date is 2008Q4 and zero if the date is 2007Q4. Table 64.10 reports the DiD regression results.

In columns 1 and 2, the dummy variable of *top-quartile short-term financing* is set to one if a bank's short-term financing is in the top quartile and zero if it is in the bottom

Table 64.7 Regression of earnings per share on short-term financing. This table reports the regression results of earnings per share on short-term financing and assets with deteriorated quality. The dependent variable is earnings per share and independent variables include short-term financing and assets with deteriorated quality. The control variables include log total asset, market to book equity, and leverage

Dependent variable: EPS	(1)	(2)	(3)	(4)
Short-term financing		1.511***		
		(9.04)		
Assets with deteriorated quality				−0.929***
				(−8.94)
Short-term financing × crisis	−9.345***	−9.917***		
	(−14.58)	(−15.46)		
Assets with deteriorated quality × crisis			−3.079***	−2.765***
			(−30.18)	(−25.72)
Log(total asset)	0.244***	0.218***	0.260***	0.214***
	(17.51)	(15.33)	(19.66)	(15.17)
Market to book	0.0944***	0.0931***	0.0238	0.0326
	(5.44)	(5.39)	(1.41)	(1.93)

	(−37.32)	(−37.05)	(−33.91)	(−34.09)
Intercept	−0.532**	−0.249	−0.658***	0.336
	(−2.75)	(−1.27)	(−3.58)	(1.57)
N	9,060	9,060	9,060	9,060
Adjusted R-square	0.176	0.183	0.233	0.240

The parenthesis with ***, **, and * indicates its statistical significant level of 0.1 %, 1 %, and 5 %, respectively

quartile A third dummy variable of *top-quartile short-term financing × post-Lehman bankruptcy* is the cross product of the previous two dummy variables. In columns 3 and 4, the dummy variable of *top-quartile deteriorated assets* is set to one if a bank's deteriorated asset is in the top quartile and zero if it is in the bottom quartile. A third dummy variable of *top-quartile deteriorated assets × post-Lehman bankruptcy* is the cross product of the previous two dummy variables. The coefficient estimates of the cross-product dummy for short-term financing in DiD specifications (1) and (2) are not statistically significant, whereas the coefficient estimates of the cross-product dummy for deteriorated assets in (3) and (4) are significantly negative, suggesting that a bank with asset experiencing deterioration of quality after the Lehman shock have much lower equity returns. This suggests that our results are not driven by omitted variables(s) that happen to be correlated with both dependent and independent variables.

64.6 Conclusion

It is not clear whether short-term financing indeed caused the banks' vulnerability to financial crisis or simply reflects the weakness of banks' balance sheets. Given the ambiguous causality, in this chapter we examine the role of short-term financing

Table 64.8 Regression of stock returns on short-term financing. This table reports the regression results of stock returns on short-term financing and assets with deteriorated quality. The dependent variable is earnings per share and independent variables include short-term financing and assets with deteriorated quality. The control variables include log total asset, market to book equity, and leverage

and assets with deteriorated quality during the crisis of 2007–2009. We find that short-term financing is a response or a symptom of the adverse economic shocks rather than a cause of the recent crisis; instead, assets that experienced quality deterioration are positively related to bank distress. These results might suggest that financial crisis can stem not from short-term financing, but from the illiquidity and low creditworthiness of the investment. However, this finding does not rule out the possibility that exposures to rollover risk by short-term financing might also contribute to the distress in the banking sector during the crisis.

Appendix

We focus on all publicly traded commercial banks in the USA, namely, with SIC codes 60 and 61 and filing Federal Reserve Y-9C report in each quarter. FR Y-9C report collects basic financial data from a domestic bank holding company (BHC) on a consolidated basis in the form of a balance sheet, an income statement, and detailed supporting schedules, including a schedule of off balance-sheet items. By focusing on commercial banks, we do not include insurance companies, investment

Table 64.9 Fixed effects regression. This table presents the fixed effect regression results for robust checks. Dependent variables are standard deviation of ROA and earnings per share and stock returns. Independent variables include short-term financing and assets with deteriorated quality. The control variables include log total asset, market to book equity, and leverage

banks, investment management companies, and brokers. Our sample is from 1993 to 2009 and consisted of an unbalanced panel of 538 unique banks. We obtain a bank's monthly equity returns from CRSP and financial statement data from Compustat and FR Y-9C filed by a bank with the Federal Reserve.

Short-term financing (*STF*) is defined as short-term debt subtracted by long-term debt due in 1 year. Assets with deteriorated quality (*ADQ*) are defined as loans secured by real estates and scaled by total assets (*AT*) subtracted by short-term financing. *Crisis* is an indicator variable that equals one if a bank bankrupted, filed for bankruptcy protection, or closed and received by the FDIC during year 2007–2009 and zero otherwise. Bank risk is defined as the standard deviation of net income which is divided by total assets in a given firm and a given year. Earnings per shares are defined as net income divided by numbers of shares outstanding. Stock returns are holding period of returns from CRSP monthly.

After obtaining the data from CRSP, Compustat, and FR Y-9C, we merge them using the company identification (*PERMCO*) and calendar year. The correlation matrix reports no large correlation between the various independent variables. These low correlations suggest no evidence of multicollinearity in our following regressions, which is also confirmed by a low condition number of 2.67 (see Belsley et al. 1980). The first multivariate analysis is a logit regression:

$$\text{Crisis} = \beta_0 + \beta_1 STF + \beta_2 ADQ + \beta_3 \log(AT) + \beta_4 \text{Leverage} + \varepsilon \tag{64.1}$$

The second analysis is an OLS regression where the standard deviation of return on asset (*ROA*) serves as a proxy for bank risk:

$$\begin{aligned}\text{Std(ROA)} = \beta_0 + \beta_1 STF + \beta_2 ADQ + \beta_3 STF \times \text{Crisis} + \beta_4 ADQ \\ \times \text{Crisis} + \beta_5 \log(AT) + \beta_6 M2B + \beta_7 \text{Leverage} + \varepsilon\end{aligned} \tag{64.2}$$

To understand the effect of short-term financing on bank performance, we regress the bank's EPS on short-term financing activities and other control variables:

$$\begin{aligned}\text{EPS} = \beta_0 + \beta_1 STF + \beta_2 ADQ + \beta_3 STF \times \text{Crisis} + \beta_4 ADQ \times \text{Crisis} \\ + \beta_5 \log(AT) + \beta_6 M2B + \beta_7 \text{Leverage} + \varepsilon\end{aligned} \tag{64.3}$$

We also consider the stock returns as a measure of bank performance and conduct the following OLS regression:

$$\begin{aligned}\text{Return} = \beta_0 + \beta_1 STF + \beta_2 ADQ + \beta_3 STF \times \text{Crisis} + \beta_4 ADQ \times \text{Crisis} \\ + \beta_5 \log(AT) + \beta_6 M2B + \beta_7 \text{Leverage} + \varepsilon\end{aligned} \tag{64.4}$$

As a robustness check, we add the fixed effects to all regression models and redo our empirical analysis. Finally, we examine if the above results are driven by endogeneity concerns. Specifically, are significant omitted variable(s) correlated with both dependent and independent variables driving our results spuriously? In order to do so, we consider the bankruptcy filing of Lehman Brothers on September 15, 2011 (2008Q3) as an exogenous shock. We employ a difference-in-differences (DiD) approach (see Meyer 1995; Angrist and Krueger 1999 for detailed explanations of this methodology). We specifically analyze whether banks with different short-term financing and deteriorated assets react differently in terms of equity returns when they face the unexpected shock of Lehman Brothers bankruptcy. Accordingly, banks with more short-term financing and deteriorated assets are defined as the treatment group, and banks with less short-term financing and deteriorated assets are the control or non-treated group. We rank all commercial banks based on their short-term financing and deteriorated assets in the year 2007Q2 and Q3 (average over the two quarters). The dummy variable of post-Lehman bankruptcy is set to one if the date is 2008Q4 (the quarter after the bankruptcy filing of Lehman Brothers) and zero if the date is 2007Q4 (1 year before the bankruptcy filing of Lehman Brothers):

$$\begin{aligned}\text{Return} = \beta_0 + \beta_1\text{Post-Lehman} + \beta_2\text{Top-Quartile} + \beta_3\text{Top-Quartile} \\ \times \text{ Post-Lehman} + \beta_4\log(AT) + \beta_5 M2B + \beta_6\text{Leverage} + \varepsilon\end{aligned} \tag{64.5}$$

65 Accurate Formulas for Evaluating Barrier Options with Dividends Payout and the Application in Credit Risk Valuation

Tian-Shyr Dai and Chun-Yuan Chiu

Contents

Abstract

To price the stock options with discrete dividend payout reasonably and consistently, the stock price falls due to dividend payout must be faithfully modeled. However, this will significantly increase the mathematical difficulty since the post-dividend stock price process, the stock price process after the price falls due to dividend payout, no longer follows the lognormal diffusion process. Analytical pricing formulas are hard to be derived even for the simplest vanilla options.

This chapter approximates the discrete dividend payout by a stochastic continuous dividend yield, so the post-dividend stock price process can be approximated by another lognormally diffusive stock process with a stochastic continuous payout ratio up to the ex dividend date. Accurate approximation analytical pricing formulas for barrier options are derived by repeatedly applying the reflection principle. Besides, our formulas can be applied to extend the applicability of the first passage model — a branch of structural credit risk model. The stock price falls due to the dividend payout in the option pricing problem is analog to selling the firm's asset to finance the loan repayment or dividend payout in the first passage model. Thus, our formulas can evaluate vulnerable bonds or the equity values given that the firm's future loan/dividend payments are known.

Barrier option • Option pricing • Stock option • Dividend • Reflection principle • Lognormal • Credit risk

65.1 Introduction

Black and Scholes (1973) arrive at their groundbreaking option pricing formula for non-dividend-paying stocks. Their option pricing model is extended to evaluate the credit risk of a defaultable firm by assuming that the firm defaults when its firm value fails to meet the debt obligation at maturity. Thus, both equities and the corporate debts can be viewed as contingent claims of the firm value, and their values can be evaluated by the aforementioned Black-Scholes option pricing formula (see Merton 1974). To deal with the dividend payout problem, Merton (1973) extends Black-Scholes formula by assuming that the stock pays a fixed continuous dividend yield. This assumption is used in the credit risk evaluation problem by allowing the firm to sell a fixed ratio of its asset continuously to finance the loan repayment or dividend payout (see Kim et al. 1993; Leland 1994). However, most dividends and coupon payments are paid discretely rather than continuously. Pricing stock options with discrete dividend payout seems to be first investigated in Black (1975). This discrete payout setting is analog to the setting that allows the firm to discretely sell its asset to finance the loan repayment or dividend payout under the credit risk evaluation problem. Although much financial literature alternatively assumes that the firm is restricted from selling its asset (see Leland 1994) or is allowed to sell its asset continuously at a fixed rate (see Kim et al. 1993; Leland 1994; Leland and Toft 1996), it is not the only — or even the typical — situation in the real-world financial markets. For example, British Petroleum Plc. sold its asset to finance the spill fund demanded by the US President Obama.[1] Recent news also report that many companies, like

[1]See "http://online.wsj.com/article/SB10001424-052748704862404575350830340543798.html" for the news entitled "BP Won't Issue New Equity to Cover Spill Costs."

Anglo American Plc. and Potash Corp. of Saskatchewan Inc., sold their asset to meet the required dividend payments.[2] Although this discrete payment setting might be more realistic, it incurs significant mathematical difficulty since the stock price process (or the firm's value process) becomes much more complicated (see Lando 2004).

Pricing stock options with discrete dividend payout has drawn a lot of attention in the literature. Frishling (2002) shows that the underlying stock price processes are usually modeled in three following different ways. **Model 1** suggests that the stock price minus the present value of future dividends over the life of the option follows the lognormal diffusion process (see Roll 1977; Geske 1979). **Model 2** suggests that the stock price plus the forward values of the dividends paid from today up to option maturity follows a lognormal diffusion process (see Heath and Jarrow (1988) and Musiela and Rutkowski (1997)). **Model 3** suggests that the stock price falls with the amount of dividend paid at the ex dividend date and follows the lognormal diffusion process between two ex dividend dates. Frishling (2002) argues that these three models are incompatible with each other and generate very different prices. In addition, Frishling (2002), Bender and Vorst (2001), and Bos and Vandermark (2002) argue that only model 3 can reflect the reality and generate consistent option prices. Except the aforementioned three models, Chiras and Manaster (1978) suggest that the discrete dividends can be transformed into a fixed continuous dividend yield. The stock option can then be analytically solved by Merton's formula (see Merton 1973). But Dai and Lyuu (2009) show that the pricing results of their approach can deviate significantly from those generated by **model 3**. The aforementioned observations suggest that the credit risk evaluation problem could be significantly mispriced if the aforementioned approaches (except **model 3**) are adopted.

On the other hand, pricing under **model 3** is mathematical intractable since the post-dividend stock price process, the stock price process after the price fall due to dividend payout, is no longer lognormally distributed. Bender and Vorst (2001), Bos and Vandermark (2002), Vellekoop and Nieuwenhuis (2006), Dai and Lyuu (2009), and Dai (2009) provide approximating analytical pricing formulas or efficient numerical methods for pricing vanilla options. But no announced papers derive analytical pricing formulas for pricing barrier stock options with discrete dividend payout.

A barrier option is a popular exotic option whose payoff depends on whether the path of the underlying stock has reached a certain predetermined price level called barrier. The study of pricing barrier options is of special interesting since this problem is dual to the problem of credit risk evaluation under the first passage model — a credit risk model that models the evolution of the firm value and forces the firm to default if its value is below a certain predefined default boundary.[3]

---

[3]Note that the roles played by the stock price and the barrier in the barrier option pricing problem are analog to the roles played by the firm value and the default boundary in the first passage model.

Reiner and Rubinstein (1991) derive analytical pricing formula for the barrier option given the condition that the underlying stock pays no dividend or fixed continuous dividend yield. Thus, the process of the stock return can be expressed as a drifted Brownian motion, and the joint density of the extreme stock price over the option life and the stock price at the option maturity date can therefore be derived by taking advantages of the reflection principle and Girsanov's theorem. By using the risk-neutral variation technique, the pricing formulas can be derived with the aforementioned joint density function. Note that the Reiner and Rubinstein (1991) approach cannot be directly extended to price barrier options with discrete dividend under **model 3** or to evaluate the equity or the corporate debt values of a defaultable firm with discrete loan or dividend payout. In addition, deal with the discrete payout with the aforementioned models except **model 3** can produce unreasonable pricing results (see Frishling 2002). Besides, Gaudenzi and Zanette (2009) develop a tree model to address this pricing problem. The impact of discrete dividend is heuristically estimated by the linear interpolation method to avoid the combinatorial explosion problem due to non-recombining property of a bushy tree (see Dai 2009). However, it seems that their pricing results oscillate drastically due to nonlinearity error problem (see Figlewski and Gao 1999).

A dividend c_1 is paid at time t_1. The black solid curve denotes the stock price process prior to time t_1 (see Eq. 65.1). The stock price process after time t_1 is approximated by a stock price process that pays a continuous dividend q up to time t_1 (see Eq. 65.10). This approximation process is plotted in gray curve in time interval $[0, t_1]$ and is plotted in black dash curve after time t_1.

The major contribution of this chapter is to derive approximate analytical formulas for pricing barrier stock options with discrete dividend payout. As a by-product, our formula can be applied to evaluate the credit risk under the first passage model that allows the firm to sell its asset to finance the payout. Note that analytical pricing formula for the barrier option can be derived if the underlying stock pays no dividends (see Reiner and Rubinstein 1991). They show that the process of the stock return can be expressed as a Brownian motion with drift, so the joint density of the extreme stock price over a time interval and the stock price at the end of that time interval can be derived by taking advantages of the reflection principle for Brownian motion and Girsanov's theorem. Specifically speaking, assume that the stock price process $P(t)$ under the risk-neutral probability is given by

$$P(t) = P(0)e^{\lambda t+\sigma B(t)}, \tag{65.1}$$

where $\lambda \equiv r - 0.5\sigma^2$, r denotes the annual risk-free interest rate, σ denotes the volatility, and $B(t)$ denotes the standard Brownian motion. Then the process of the stock return can be expressed by a Brownian motion with drift: $\lambda t + \sigma B(t)$, as plotted in black solid curve in Fig. 65.1. In **model 3**, the stock price process is assumed to jump down with the dividend amount at an ex dividend date to avoid arbitrage. Specifically, assume that the i-th dividend c_i is paid at time t_i, where $t_1 < t_2 < t_3. \ldots$ In Fig. 65.1, we assume that the option maturity T is less than t_2 for simplicity. Thus, the stock price at time $t \in [t_1, t_2)$ must be expressed as

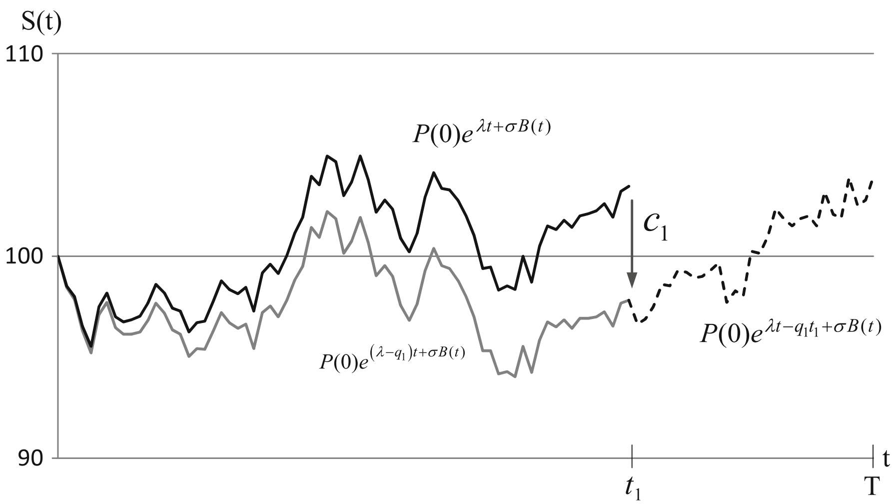

Fig. 65.1 Approximating the stock price process with discrete dividends

$$P(t) = \left(P(0)e^{\lambda t+\sigma B(t_1)} - c_1\right)e^{\lambda(t-t_1)+\sigma(B(t)-B(t_1))}, \tag{65.2}$$

which makes the stock return no longer a Brownian motion with drift. To address the problem, we extend Dai and Lyuu (2009) idea by setting a continuous dividend yield q to satisfy

$$P(0)e^{\lambda t+\sigma B(t_1)} - c_1 = P(0)e^{(\lambda-q)t+\sigma B(t_1)}.$$

q can be approximated solved by Taylor expansion to be a linear function of c_1 and $B(t_1)$. Due to the Markov property of the stock price process, the process of stock return after time t_1 can be approximated by another Brownian motion with drift: $\lambda t - qt_1 + \sigma B(t)$ as plotted in black dashed curve in Fig. 65.1. Since the processes of stock returns for the time interval $[0, t_1]$ and $[t_1, T]$ can be expressed by Brownian motions, the approximation analytical formulas can be derived by repeatedly applying the reflection principle. The numerical results suggest that our approximation pricing formulas provide accurate option pricing results. For evaluating the credit risk problem, our model can explicitly illustrate how the repayments by selling the firm asset influence the financial status of the firm and the credit qualities of other outstanding corporate debts.

The chapter is organized as follows. Section 65.2 introduces required background knowledge and preparations for formula derivation. In Sect. 65.3.1, we derive our approximation formula for the barrier option with single dividend. In Sect. 65.3.2, we extend our formulas to the multi-dividend case. Experimental results given in Sect. 65.4 verify the accuracy of our pricing formulas. Section 65.5 concludes the chapter.

65.2 Preliminaries

65.2.1 Pricing Formula for Barrier Option Without Dividend

Assume that a barrier stock option with strike K initiates at time 0 and matures at time T. The payoff of an up-and-out call option at maturity is as follows:

$$\text{payoff} = \begin{cases} (P(T)-K)^+ & \text{if } P_{\max} < B \\ 0 & \text{if } P_{\max} \geq B \end{cases},$$

where $(A)^+$ denotes max(A, 0), $P_{\max}$ denotes the maximum underlying stock price between time 0 and time T, and B denotes the barrier. Similarly, the payoff of a down-and-out call option at maturity is as follows:

$$\text{payoff} = \begin{cases} (P(T)-K)^+ & \text{if } P_{\min} < B \\ 0 & \text{if } P_{\min} \geq B \end{cases},$$

where $P_{\min}$ denotes the minimum stock price between time 0 and time T. For simplicity, our chapter will focus on up-and-out call option, and the extensions to other barrier options are straightforward.

To derive the pricing formula for up-and-out calls, we need to know whether the stock price process has ever hit the barrier. Note that the stock price process has ever hit the barrier during time interval [0, τ] if and only if the maximum stock price during time interval [0, τ] is greater than the barrier. The following theorem can be applied to derive the joint density of the stock price at time τ and the maximum stock price during the time interval [0, τ].

Theorem 65.1 *Let $\widetilde{W}(t) = \theta t + B(t)$ be a Brownian motion with a drift term θt and $\widetilde{M}(\tau) = \max_{0 \leq t \leq \tau} \widetilde{W}(t)$ be its maximum value over a certain time period* [0, τ]. *The joint density function of $\left(\widetilde{M}(\tau), \widetilde{W}(\tau)\right)$ is given by*

$$f_{\tilde{M}(\tau),\tilde{B}(\tau)}(m, w) = \begin{cases} \dfrac{2(2m-w)}{\tau\sqrt{2\pi\tau}} e^{\theta w - \frac{1}{2}\theta^2\tau - \frac{1}{2\tau}(2m-w)^2} & \text{if } m \geq w^+ \\ 0 & \text{otherwise.} \end{cases} \tag{65.3}$$

The support of this density function is illustrated in Fig . 65.2a.

This theorem can be derived by applying the reflection principle and Girsanov's theorem as discussed in Shreve (2007).

Reiner and Rubinstein (1991) derive analytical formulas for barrier options without discrete dividend payout by the aforementioned theorem. A detailed explanation of their derivation is given below since the derivation of our formula also takes advantage of their derivation. Define the stock return in Eq. 65.1 λt + $\sigma B(t)$ as $\sigma \hat{B}(t)$; that is, $\hat{B}(t)$ is a Brownian motion with drift term: $\hat{B}(t) \equiv \lambda t/\sigma + B(t)$. Define the maximum value of the Brownian motion

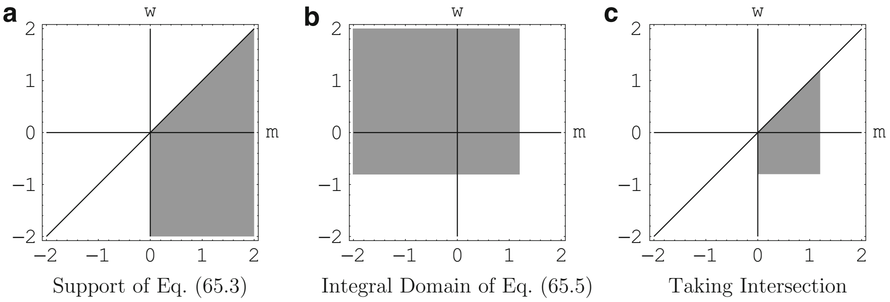

Fig. 65.2 Domain of double integral in Eq. 65.6

$\hat{M}(\tau)$ by $\hat{M}(\tau) = \max_{0\le t\le\tau}\widetilde{W}(t)$. Thus, the value of an up-and-out call option can be derived as follows:

$$C = e^{-rT}E\left\{\left(P(0)e^{\sigma\hat{W}(T)} - K\right)1_{\left\{\hat{W}(T)\ge k,\hat{M}(T)\le b\right\}}\right\}, \tag{65.4}$$

where k and b in Eq. 65.4 stand for $\frac{1}{\sigma}\log\frac{K}{P(0)}$ and $\frac{1}{\sigma}\log\frac{B}{P(0)}$, respectively. By substituting Eq. 65.3 into Eq. 65.4 with $\theta = \sigma/\lambda$, we have

$$C = \int_k^\infty\int_{-\infty}^b e^{-rT}\ \left(P(0)e^{\sigma w} - K\right)\ f_{\hat{M}}\ \ (T),\hat{W}(T)^{(m,\ \ w)dmdw} \tag{65.5}$$

$$= \int_k^b\int_{w^+}^b e^{-rT}\left(P(0)e^{\sigma w} - K\right)\frac{2(2m-w)}{T\sqrt{2\pi T}}e^{\theta w-\frac{1}{2}\theta^2T-\frac{1}{2T}(2m-w)^2}\ dmdw, \tag{65.6}$$

where the domain of integral in Eq. 65.5, i.e., $-\infty < m < b$ and $k < w < \infty$, is the support of the indicator function in Eq. 65.4 as illustrated in Fig. 65.2b. The domain of integral in Eq. 65.6 is the intersection of the support of the joint density function $f_{\hat{M}(T),\hat{W}(T)}(m,w)$ and the support of indicator function $1_{\left\{\hat{W}(T)\ge k,\hat{M}(T)\le b\right\}}$ as illustrated in Fig. 65.2c.

In the double integral formula Eq. 65.6, since only $f_{\hat{M}(T),\hat{W}(T)}(m,w)$ contains the variable m, $\int_{w^+}^b f_{\hat{M}(T),\hat{W}(T)}(m,w)\,dm$ can be evaluated first by the following lemma:

Lemma 65.2

$$\int_{v^+}^B\frac{2(2u-v)}{\beth\sqrt{2\pi\beth}}e^{\theta v-\frac{1}{2}\theta^2\beth-\frac{1}{2\beth}(2u-v)^2}du$$
$$= \frac{1}{\sqrt{2\pi\beth}}e^{\theta v-\frac{1}{2}\theta^2\beth-\frac{v^2}{2\beth}}\left(1 - e^{\frac{2B(v-B)}{\beth}}\right).$$

Panel (a) denotes the support of the density function of $f_{\tilde{M}(T),\tilde{W}(T)}$ in Eq. 65.3, i.e., a set of points $(m,\ w)$ that make $f_{\tilde{M}(T),\tilde{W}(T)}(m,w)$ nonzero.

Panel (b) denotes the domain of integral in Eq. 65.5, which is also the support of the indicator function of Eq. 65.4. Panel (c) denotes the intersection of shadow areas in Panel (a) and (b), which is the domain of integral in Eq. 65.6.

Proof

$$\begin{aligned}&\int_{v^+}^{B} \frac{2(2u-v)}{\text{ב}\sqrt{2\pi\text{ב}}} e^{\theta v - \frac{1}{2}\theta^2 \text{ב} - \frac{1}{2\text{ב}}(2u-v)^2} du\\ &= \frac{1}{\sqrt{2\pi\text{ב}}} e^{\theta v - \frac{1}{2}\theta^2\text{ב} - \frac{v^2}{2\text{ב}}}\left(1 - e^{\frac{2B(v-B)}{\text{ב}}}\right).\end{aligned}$$

By applying Lemma 65.2, Eq. 65.6 can be rewritten as

$$\begin{aligned}C = e^{-rT}\int_k^b & -\frac{K}{\sqrt{2\pi T}} e^{-\frac{w^2}{2T}+\theta w-\frac{T\theta^2}{2}} + \frac{K}{\sqrt{2\pi T}} e^{-\frac{w^2}{2T}+\theta w-\frac{T\theta^2}{2}+\frac{2b(w-b)}{T}}\\ &+ \frac{P'(0)}{\sqrt{2\pi T}} e^{-\frac{w^2}{2T}+\theta w+\sigma w-\frac{T\theta^2}{2}} - \frac{P'(0)}{\sqrt{2\pi T}} e^{-\frac{w^2}{2T}+\theta w+\sigma w-\frac{T\theta^2}{2}+\frac{2b(w-b)}{T}} dw.\end{aligned} \tag{65.7}$$

In Eq. 65.7, each term of the integrand is of the form $Le^{\phi_2 x^2+\phi_1 x+\phi_0}$, where ϕ_0, ϕ_1, ϕ_2, and L are all constants. The integral can be converted into the cumulative distribution function (CDF) of the standard normal distribution by the following identity:

$$\int_{-\infty}^{l} e^{\phi_2 x^2+\phi_1 x+\phi_0} dx = \sqrt{\frac{\pi}{-\phi_2}} e^{-\frac{\phi_1^2-4\phi_0\phi_2}{4\phi_2}} N\left(\frac{l-m}{s}\right),$$

where $\mathrm{m} = -\frac{\phi_1}{2\phi_2}$, $\mathrm{s} = \frac{1}{\sqrt{-2\phi_2}}$, and $N(\cdot)$ denotes the CDF of the standard normal distribution. Equation 65.31 in Appendix gives the derivation of this identity. Finally, we obtain the closed form pricing formula:

$$\begin{aligned}C = P(0)&\left\{N\left(\delta_+\left(T,\frac{P(0)}{K}\right)\right) - N\left(\delta_+\left(T,\frac{P(0)}{B}\right)\right)\right\}\\ &- Ke^{-rT}\left\{N\left(\delta_-\left(T,\frac{P(0)}{K}\right)\right) - N\left(\delta_-\left(T,\frac{P(0)}{B}\right)\right)\right\}\\ &- B\left(\frac{P(0)}{B}\right)^{-\frac{2r}{\sigma^2}}\left\{N\left(\delta_+\left(T,\frac{B^2}{KP(0)}\right)\right) - N\left(\delta_+\left(T,\frac{B}{P(0)}\right)\right)\right\}\\ &+ Ke^{-rT}\left(\frac{P(0)}{B}\right)^{-\frac{2r}{\sigma^2}+1}\left\{N\left(\delta-\left(T,\frac{B^2}{KP(0)}\right)\right) - N\left(\delta_-\left(T,\frac{B}{P(0)}\right)\right)\right\}\end{aligned} \tag{65.8}$$

where

$$\delta_\pm(\tau, s) \equiv \frac{1}{\sigma\sqrt{\tau}}\left[\log\ s + \left(r \pm \frac{1}{2}\sigma^2\right)\tau\right].$$

65.2.2 Approximate the Dividend-Paying Stock Price Process

Obviously, the stock price process before the first ex dividend date is as given in Eq. 65.1. Here we only focus on what happens after the first ex dividend date.

Extending the idea by Dai and Lyuu (2009), the stock price $P(t)$ between the first and second ex dividend date, defined as t_1 and t_2, respectively, can be approximated by a stock price process that pays a continuous dividend yield ζ_1 from time 0 to time t_1 as follows:

$$\begin{aligned} P(t) &= \left[P(0)e^{\lambda t_1+\sigma B(t_1)} - c_1\right] e^{\lambda(t-t_1)+\sigma(B(t)-B(t_1))} \\ &= P(0)e^{(\lambda-\zeta_1)t_1+\sigma B(t_1)+\lambda(t-t_1)+\sigma(B(t)-B(t_1))}, \end{aligned} \tag{65.9}$$

and hence,

$$P(0)e^{\lambda t_1+\sigma B(t_1)} - c_1 = P(0)e^{\lambda t_1+\sigma B(t_1)} \cdot e^{-\zeta_1 t_1}.$$

Since c_1 is usually small, ζ_1 is also small, and hence, $e^{-\zeta_1 t}$ can be approximated well by its first order Taylor expansion $1 - \zeta_1 t$. Replacing $e^{-\zeta_1 t_1}$ in the RHS of the above identity by $1 - \zeta_1 t_1$ gives

$$\begin{aligned} &P(0)e^{\lambda t_1+\sigma B(t_1)} - c_1 \approx P(0)e^{\lambda t_1+\sigma(B(t_1)-B(0))}(1-\zeta_1 t_1) \\ &\Rightarrow \zeta_1 \approx \frac{c_1 e^{-\lambda t_1}(1-\sigma(B(t_1)-B(0)))}{t_1 P(0)}, \end{aligned}$$

where $e^x \approx 1 + x$ is used again in the last approximation. By substituting $k_1 \equiv \frac{c_1 e^{-\lambda t_1}}{P(0)} + 1$, $\zeta_1 \equiv \frac{(k_1-1)(1-\sigma(B(t_1)-B(0)))}{t_1}$ into Eq. 65.9, we obtain the following approximating process for Eq. 65.9:

$$\begin{aligned} P(t) &\approx P(0)e^{\lambda t-(k_1-1)(1-\sigma(B(t_1)-B(0)))+\sigma(B(t_1)-B(0))+\sigma(B(t)-B(t_1))} \\ &= P(0)e^{(\lambda t-k_1+1)+k_1\sigma(B(t_1)-B(0))+\sigma(B(t)-B(t_1))} \end{aligned} \tag{65.10}$$

Note that the stock price after the second ex dividend date can be recursively defined by the aforementioned method. For example, the stock price $P(t)$ between the second ex dividend date t_2 and the third ex dividend date t_3 can be expressed as follows:

$$\begin{aligned} P(t) &= \left(P(t_1)e^{\lambda(t_2-t_1)+\sigma(B(t_2)-B(t_1))} - c_2\right)e^{\lambda(t-t_2)+\sigma(B(t)-B(t_2))} \\ &= P(0)e^{(\lambda-\zeta_1)t_1+\sigma(B(t_1)-B(0))}e^{(\lambda-\zeta_2)(t_2-t_1)+\sigma(B(t_2)-B(t_1))} \\ &\quad e^{\lambda(t-t_2)+\sigma(B(t)-B(t_2))} \\ &\approx P(0)e^{(\lambda t-k_1-k_2+2)+k_1k_2\sigma(B(t_1)-B(0))} \\ &\quad e^{+k_2\sigma(B(t_2)-B(t_1))+\sigma(B(t)-B(t_2))}, \end{aligned} \tag{65.11}$$

where

$$\zeta_2 \approx \frac{(k_2 - 1)[1 - k_1\sigma(B(t_1) - B(0)) - \sigma(B(t_2) - B(t_1))]}{t_2 - t_1}, \tag{65.12}$$

and

$$k_2 \equiv \frac{c_2 e^{-\lambda t_2 + k_1 + 1}}{P(0)} - 1.$$

65.3 Deriving Pricing Formulas

We will first derive the analytical approximating pricing formula in the single-discrete-dividend case in Sect. 65.3.1. Our approach used in Sect. 65.3.1 can be extended to obtain pricing formulas in general case. We will show that in Sect. 65.3.2 by the same approach as in Sect. 65.3.1 to derive the pricing formula in the multi-discrete-dividend case.

65.3.1 Single-Discrete-Dividend Case

Recall that combining Eq. 65.1 and 65.10, the stock price process can be approximated by

$$\dot{P}(t) \equiv \begin{cases} P(0)e^{\lambda t + \sigma(B(t) - B(0))} & 0 \le t < t_1 \\ P(0)e^{(\lambda t - k_1 + 1) + k_1\,\sigma(B(t_1) - B(0)) + \sigma(B(t) - B(t_1))} & t_1 \le t \le T, \end{cases} \tag{65.13}$$

where t_1 represents the only ex dividend date. Note that we denote the above approximating process for single-dividend case by $\dot{P}(t)$. Similarly, we will use $\ddot{P}(t)$ to denote the approximating process for two-dividend case later. Our goal is to compute the following expectation as an approximation to call value:

$$\dot{C} \equiv e^{-rT} E\left[\left(\dot{P}(T) - K\right) 1_{\{\Xi_1 \cap \Xi_2 \cap \Xi_3\}}\right], \tag{65.14}$$

where Ξ_1, Ξ_2 represent the events that stock price does not hit barrier B during time period $[0, t_1)$ and $[t_1, T]$, respectively, and Ξ_3 is the event that stock price is greater than strike price at maturity date. That is, the three events Ξ_1, Ξ_2, Ξ_3 are defined by

$$\begin{aligned} \Xi_1 &\equiv \{\dot{P}(t) < B| \ \ 0 \le t < t_1\}, \\ \Xi_2 &\equiv \{\dot{P}(t) < B| \ \ t_1 \le t \le T\}, \\ \Xi_3 &\equiv \{\dot{P}(T) > K\}. \end{aligned}$$

Similarly to Eq. 65.4, first we rewrite the process $\dot{P}(t)$ for $t \in [t_1, T]$ as follows:

$$\begin{aligned} \dot{P}(t) \ &= \ P(0)e^{(\lambda t - k_1 + 1) + k_1\,\sigma(B(t_1) - B(0)) + \sigma(B(t) - B(t_1))} \\ &= P'(0)e^{k_1\,\sigma\hat{B}}(t_1) + \sigma\hat{W}_1(t - t_1) \end{aligned}, \tag{65.15}$$

where we introduce a process $\hat{W}_1(t-t_1) \equiv \frac{\lambda}{\sigma}(t-t_1) + (B(t) - B(t_1))$ $\forall t \in (t_1, T)$, and $P'(0)$ stands for $P(0)e^{(1-k_1)(1+\lambda t_1)}$ for simplicity. Putting Eq. 65.13 and the above identity together, with $\hat{B}(t) \equiv \frac{\lambda t}{\sigma} + B(t)$ $\forall t \in [0, t_1]$ defined as aforementioned, we obtain

$$\dot{P}(t) = \begin{cases} P(0)e^{\sigma\hat{B}(t)} & 0 \le t < t_1 \\ P'(0)e^{k_1\sigma\hat{B}(t_1)+\sigma\hat{W}_1(t-t_1)} & t_1 \le t \le T. \end{cases} \quad (65.16)$$

Note that the two processes $\hat{B}(t)$ for $t \in [0,\ t_1]$ and $\hat{W}_1(t)$ for $t \in [t_1,\ T]$ are independent due to the Markov property of Brownian motion. Let $\hat{M}_1\eta_1 \equiv \max_{t_1 \le t \le T} \hat{W}_1(t-t_1)$ be the maximum value of $\hat{W}_1(t)$ over time period $[t_1, T]$, where η_1 denotes the abbreviation of $T - t_1$. Theorem 65.1 says that the joint density functions $f_{\hat{M}(t_1),\hat{B}(t_1)}$ and $f_{\hat{M}_1\eta_1,\hat{W}_1\eta_1}$ are given by

$$f_{\hat{M}(t_1),\hat{B}(t_1)}(m,w) = \begin{cases} \dfrac{2(2m-w)}{t_1\sqrt{2\pi t_1}}e^{\varepsilon}1 & \text{if } m \ge w^+ \\ 0 & \text{otherwise;} \end{cases} \quad (65.17)$$

$$f_{\hat{M}_1\eta_1,\hat{W}_1\eta_1}(m_1,w_1) = \begin{cases} \dfrac{2(2m_1-w_1)}{\eta_1\sqrt{2\pi\eta_1}}e^{\varepsilon}2 & \text{if } m_1 \ge w_1{}^+ \\ 0 & \text{otherwise,} \end{cases} \quad (65.18)$$

where $\varepsilon_1 = \theta w - \frac{1}{2}\theta^2 t_1 - \frac{1}{2t_1}(2m-w)^2$, $\varepsilon_2 = \theta w_1 - \frac{1}{2}\theta^2\eta_1 - \frac{1}{2\eta_1}(2m_1-w_1)^2$ and $\theta = \lambda/\sigma$. For convenience, from now on we will use the symbols f_0 and f_1 to represent $f_{\hat{M}(t_1),\hat{B}(t_1)}$ and $f_{\hat{M}_1\eta_1,\hat{W}_1\eta_1}$, respectively. Substituting Eq. 65.16 into Eq. 65.14, with the above joint density functions, we can compute · analytically. Note that Ξ_1, Ξ_2, Ξ_3 can be rewritten as

$$\begin{aligned} \Xi_1 &= \{\hat{M}(t_1) < b\}, \\ \Xi_2 &= \{\hat{M}_1\eta_1 < b' - k_1\hat{B}(t_1)\}, \\ \Xi_3 &= \{\hat{W}_1\eta_1 > k' - k_1\hat{B}(t_1)\}, \end{aligned}$$

where b, b', and k' represent $\frac{1}{\sigma}\log\frac{B}{P(0)}$, $\frac{1}{\sigma}\log\frac{B}{P'(0)}$ and $\frac{1}{\sigma}\log\frac{K}{P'(0)}$ for simplicity. Thus, the analytical pricing formula can be derived by law of iterated expectation as follows:

$$\begin{aligned} \dot{C} &= e^{-rT}E\left[E\left[\left(\dot{P}(T)-K\right)1_{\{\Xi_1\cap\Xi_2\cap\Xi_3\}}|\hat{B}(t_1),\hat{M}(t_1)\right]\right] \\ & e^{-rT}\int_{-\infty}^{b}\int_{w^+}^{b}\int_{k\prime-k_1w}^{b\prime-k_1w}\int_{w_1{}^+}^{b\prime\ -k_1w}\left(P'(0)e^{k_1\sigma w+\sigma w_1}-K\right) \\ & \cdot\frac{2(2m_1-w_1)}{\eta_1\sqrt{2\pi\eta_1}}e^{\varepsilon}2 \\ & \cdot\frac{2(2m-w)}{t_1\sqrt{2\pi t_1}}e^{\varepsilon}1_{dm_1\,dw_1\,dmdw.} \end{aligned} \quad (65.19)$$

To simplify the above multiple integral, first recall that Eq. 65.6 can be derived as Eq. 65.8 by first evaluating $\int_{w^+}^{b} f_{\hat{B}(t),\hat{M}(t)}(m,w)\,dm$ with lemma 2.2. Similarly, to simplify Eq. 65.19, first we evaluate $\int_{w^+}^{b} f_0(m,w)\,dm$ and $\int_{w_1^+}^{b\prime-k_1 w} f_1(m_1,w_1)$, and then obtain a double integral similar to Eq. 65.7. We will rewrite this double integral in terms of a bivariate normal CDF, just like the way to rewrite Eq. 65.7 in terms of the standard normal CDF. Like single-variate case, the CDF of a bivariate normal distribution can be approximated efficiently and accurately by a number of numerical schemes.[4] However, literatures only give the approximation for

$$\int_{-\infty}^{d}\int_{-\infty}^{c} f_{X,Y}(x,y)dxdy,$$

while the double integral we deal with is of the form

$$\int_{-\infty}^{d}\int_{-\infty}^{h(x)} f_{X,Y}(x,y)dxdy,$$

where $f_{X,\,Y}$ stands for the joint density function of a bivariate normal distribution, c and d are constants, and the value of h depends on x. To tackle this problem, we use a change of variable to adapt the double integral. Specifically, Eq. 65.19 can be simplified as follows:

$$\begin{aligned}\dot{C} = e^{-rT}&\int_{-\infty}^{b}\int_{k\prime-k_1 w}^{b\prime-k_1 w}\left(P'(0)e^{k_1\sigma w+\sigma w_1}-K\right)\\ &\cdot\left(\int_{w_1^+}^{b\prime-k_1 w}\frac{2(2m_1-w_1)}{\eta_1\sqrt{2\pi\eta_1}}e^{\varepsilon}2dm_1\right)\end{aligned}\qquad(65.20)$$

$$\cdot\left(\int_{w^+}^{b}\frac{2(2m-w)}{t_1\sqrt{2\pi t_1}}e^{\varepsilon}1\,dm\right)dw_1\,dw.\qquad(65.21)$$

By applying lemma 65.2 twice on Eqs. 65.20 and 65.21 and the change of variable

$$\begin{cases}x = w_1 + k_1 w\\ y = w,\end{cases}$$

[4]See, for example, Hull (2003).

Table 65.1 Coefficients of the exponential terms of $Q(i)$

$Q(1) = -\frac{K}{2\pi\sqrt{\eta_1 t_1}} e^{-\frac{y^2}{2t_1} + \theta y + \theta(x - yk_1) - \frac{1}{2}\theta^2\eta_1 - \frac{\theta^2 t_1}{2} - \frac{(x-yk_1)^2}{2\eta_1}}$,
$Q(2) = \frac{K}{2\pi\sqrt{\eta_1 t_1}} e^{-\frac{y^2}{2t_1} + \theta y + \theta(x - yk_1) - \frac{1}{2}\theta^2\eta_1 - \frac{\theta^2 t_1}{2} - \frac{(x-yk_1)^2}{2\eta_1} + \frac{2(x-b\prime)(b\prime-yk_1)}{\eta_1}}$,
$Q(3) = \frac{K}{2\pi\sqrt{\eta_1 t_1}} e^{-\frac{y^2}{2t_1} + \theta y + \theta(x - yk_1) - \frac{1}{2}\theta^2\eta_1 - \frac{\theta^2 t_1}{2} - \frac{(x-yk_1)^2}{2\eta_1} + \frac{2b(y-b)}{t_1}}$,
$Q(4) = -\frac{K}{2\pi\sqrt{\eta_1 t_1}} e^{-\frac{y^2}{2t_1} + \theta y + \theta(x - yk_1) - \frac{1}{2}\theta^2\eta 1 - \frac{\theta^2 t_1}{2} - \frac{(x-yk_1)^2}{2\eta_1} + \frac{2(x-b\prime)(b\prime-yk_1)}{\eta_1} + \frac{2b(y-b)}{t_1}}$,
$Q(5) = \frac{P'(0)}{2\pi\sqrt{\eta_1 t_1}} e^{-\frac{y^2}{2t_1} + \theta y + x\sigma + \theta(x - yk_1) - \frac{1}{2}\theta^2\eta 1 - \frac{\theta^2 t_1}{2} - \frac{(x-yk_1)^2}{2\eta_1}}$,
$Q(6) = -\frac{P'(0)}{2\pi\sqrt{\eta_1 t_1}} e^{-\frac{y^2}{2t_1} + \theta y + x\sigma + \theta(x - yk_1) - \frac{1}{2}\theta^2\eta_1 - \frac{\theta^2 t_1}{2} - \frac{(x-yk_1)^2}{2\eta_1} + \frac{2(x-b\prime)(b\prime-yk_1)}{\eta_1}}$,
$Q(7) = -\frac{P'(0)}{2\pi\sqrt{\eta_1 t_1}} e^{-\frac{y^2}{2t_1} + \theta y + x\sigma + \theta(x - yk_1) - \frac{1}{2}\theta^2\eta_1 - \frac{\theta^2 t_1}{2} - \frac{(x-yk_1)^2}{2\eta_1} + \frac{2b(y-b)}{t_1}}$,
$Q(8) = \frac{P'(0)}{2\pi\sqrt{\eta_1 t_1}} e^{-\frac{y^2}{2t_1} + \theta y + x\sigma + \theta(x - yk_1) - \frac{1}{2}\theta^2\eta_1 - \frac{\theta^2 t_1}{2} - \frac{(x-yk_1)^2}{2\eta_1} + \frac{2(x-b\prime)(b\prime-yk_1)}{\eta_1} + \frac{2b(y-b)}{t_1}}$.

we have[5]

$$
\begin{aligned}
\dot{C} = \; & e^{-rT} \int_{-\infty}^{b} \int_{k\prime}^{b\prime} \left(P'(0)e^{\sigma x} - K\right) \\
& \cdot \frac{1}{\sqrt{2\pi\eta_1}} e^{\theta\left(x - k_1 y\right) - \frac{1}{2}\theta^2 \eta_1 - \frac{(x-k_1 y)^2}{2\eta_1}} \\
& \left(1 - e^{\dfrac{2(b' - k_1 y)\left(x - k_1 y - (b' - k_1 y)\right)}{\eta_1}}\right) \\
& \cdot \frac{1}{\sqrt{2\pi t_1}} e^{\theta y - \frac{1}{2}\theta^2 t_1 - \frac{y2}{2t_1}} \left(1 - e^{\frac{2b(y-b)}{t_1}}\right) \mathrm{dxdy}. \\
= \; & e^{-rT} \int_{-\infty}^{b} \int_{k\prime}^{b\prime} \sum_{i=0}^{8} Q(i)\, dxdy,
\end{aligned}
\tag{65.22}
$$

where the integrands $Q(1)$, $Q(2)$, ···, $Q(8)$, by immediately expanding whole the integrand, are given in Table 65.1.

Since each of the integrands $Q(1)$, $Q(2)$, ···, $Q(8)$ is a quadratic form of x, y taking exponential and multiplied by a constant, we rewrite the double integral of each integrand in terms of a bivariate normal CDF. Thus, all the double integrals of $Q(1)$, $Q(2)$, ···, $Q(8)$ can be evaluated. To simplify these double integrals, we introduce the following formula:

[5]The Jacobian determinant $\frac{\partial(w_1,w)}{\partial(x,y)} = 1$.

Lemma 65.3 *Let* $F_{X_1,X_2}(a,b,\Omega)$ *be the CDF of a bivariate normal distributed random vector* (X_1, X_2). *That is,*

$$\begin{aligned} F_{X_1,X_2}(a,b,\boldsymbol{\Omega}) &\equiv \int_{-\infty}^{a}\int_{-\infty}^{b} f_{X_1,X_2}(x_1,x_2)dx_1dx_2 \\ &= \int_{-\infty}^{a}\int_{-\infty}^{b} \frac{1}{2\pi\sqrt{|\Omega|}}e^{-\frac{1}{2}\mathrm{X}^T\Omega\mathrm{X}}dx_1dx_2 \end{aligned}$$

where $\mathbf{x}$ *and* Ω *denote* $(x_1, x_2)^T$ *and the covariance matrix, respectively, and both* X_1 *and* X_2 *have mean* 0 *and variance* 1. *The following double integral can be expressed in terms of* $F_{X1,\ X2}$ *as*

$$\begin{aligned} &G(p,q,\phi_1,\phi_2,\phi_3,\phi_4,\phi_5,\phi_6) \\ &\equiv \int_{-\infty}^{q}\int_{-\infty}^{p} e^{\phi_1x^2+\phi_2xy+\phi_3y^2+\phi_4x+\phi_5y+\phi_6}dxdy \\ &= \frac{2\pi}{\sqrt{\beth}}\exp\left(\phi_6+\frac{\phi_2\phi_4\phi_5-\phi_3\phi_4^2-\phi_1\phi_5^2}{\beth}\right) \\ &\quad F_{\Upsilon_1,\Upsilon_2}\left(\frac{\sqrt{\beth}p+\dfrac{2\phi_3\phi_4-\phi_2\phi_5}{\sqrt{\beth}}}{\sqrt{-2\phi_3}},\frac{\sqrt{\beth}q+\dfrac{2\phi_1\phi_5-\phi_2\phi_4}{\sqrt{\beth}}}{\sqrt{-2\phi_1}},\Omega\right), \end{aligned}$$

where

$$\beth \equiv 4\phi_1\phi_3-\phi_2^2, \tag{65.23}$$

$$\Omega \equiv \begin{pmatrix} 1 & \dfrac{\phi_2}{2\sqrt{\phi_1\phi_3}} \\ \dfrac{\phi 2}{2\sqrt{\phi_1\phi_3}} & 1 \end{pmatrix}. \tag{65.24}$$

Proof To make $\phi_1x^2 + \phi_2xy + \phi_3y^2 + \phi_4x + \phi_5y + \phi_6$ equal $\mathbf{z}^T\vartheta\mathbf{z} + \mathbf{z}^T\beta + \delta$, we set

$$\vartheta \equiv \begin{pmatrix} \phi_1 & \dfrac{\phi_2}{2} \\ \dfrac{\phi_2}{2} & \phi_3 \end{pmatrix}, \beta \equiv \begin{pmatrix} \phi_4 \\ \phi_5 \end{pmatrix}, \delta \equiv \phi_6.$$

By Eqs. 65.38, 65.39, 65.42, and 65.43, we have

$$
\begin{aligned}
\mathrm{m} &= -\frac{1}{4\phi_1\phi_3-\phi_2^2}\begin{pmatrix}2\phi_3\phi_4-\phi_2\phi_5\\ 2\phi_1\phi_5-\phi_2\phi_4\end{pmatrix},\\
\delta' &= \phi_6+\frac{\phi_2\phi_4\phi_5-\phi_3\phi_4^2-\phi_6\phi_5^2}{4\phi_1\phi_3-\phi_2^2},\\
\Phi_{1,1} &= \sqrt{\frac{-2\phi_3}{4\phi_1\phi_3-\phi_2^2}},\\
\Phi_{2,2} &= \sqrt{\frac{-2\phi_1}{4\phi_1\phi_3-\phi_2^2}},\\
\Omega &= \begin{pmatrix}1 & \frac{\phi_2}{2\sqrt{\phi_1\phi_3}}\\ \frac{\phi_2}{2\sqrt{\phi_1\phi_3}} & 1\end{pmatrix},\\
|-\vartheta| &= \frac{4\phi_1\phi_3-\phi_2^2}{4}.
\end{aligned}
$$

By substituting all above equations into Eq. 65.45, we obtain

$$
\begin{aligned}
&\int_{-\infty}^{q}\int_{-\infty}^{p} e^{\phi_1x^2+\phi_2xy+\phi_3y^2+\phi_4x+\phi_5y+\phi_6}dxdy\\
&=\frac{2\pi}{\sqrt{\beth}}\exp\left(\phi_6+\frac{\phi_2\phi_4\phi_5-\phi_3\phi_4^2-\phi_1\phi_5^2}{\beth}\right)\\
&F_{\Upsilon_1\Upsilon_2}\left(\frac{\sqrt{\beth}p+\frac{2\phi_3\phi_4-\phi_2\phi_5}{\sqrt{\beth}}}{\sqrt{-2\phi_3}},\frac{\sqrt{\beth}q+\frac{2\phi_1\phi_5-\phi_2\phi_4}{\sqrt{\beth}}}{\sqrt{-2\phi_1}},\Omega\right)
\end{aligned}
$$

where $\beth = 4\phi_1\phi_3-\phi_2^2$. Thus, the proof is completed.

With lemma 65.3, the double integrals of $Q(1)$, $Q(2)$, ⋯, $Q(8)$ can be evaluated immediately. For example, the integral of $Q(1)$ is given by

$$
\begin{aligned}
&\int_{-\infty}^{b}\int_{k\prime}^{b\prime}Q(1)dxdy=\int_{-\infty}^{b}\int_{k\prime}^{b\prime}-\frac{K}{2\pi\sqrt{\eta_1t_1}}\\
&e^{-\frac{y^2}{2t_1}+\theta y+\theta(x-yk_1)-\frac{1}{2}\theta^2\eta_1-\frac{\theta^2t_1}{2}-\frac{(x-yk_1)^2}{2\eta 1}}dxdy\\
&=-\frac{K}{2\pi\sqrt{\eta_1t_1}}\left(\int_{-\infty}^{b}\int_{-\infty}^{b\prime}e^{\varepsilon_3}dxdy\right.\\
&\quad\left.-\int_{-\infty}^{b}\int_{-\infty}^{k\prime}e^{\varepsilon_4}dxdy\right),
\end{aligned}
\tag{65.25}
$$

where $\varepsilon_3 = -\frac{1}{2\eta_1}x^2 + \frac{k_1}{\eta_1}xy - \left(\frac{k_1^2}{2\eta_1} + \frac{1}{2t_1}\right)y^2 + \theta x + (\theta - \theta k_1)y - \frac{T\theta^2}{2}$, and $\varepsilon_4 = -\frac{1}{2\eta_1}x^2 + \frac{k_1}{\eta_1}xy - \left(\frac{k_1^2}{2\eta_1} + \frac{1}{2t_1}\right)y^2 + \theta x + (\theta - \theta k_1)y - \frac{T\theta^2}{2}$. Note that the integrand is a quadratic form of x, y taking exponential. Let $\phi_1(1)$, $\phi_2(1)$, $\phi_3(1)$, $\phi_4(1)$, $\phi_5(1)$, $\phi_6(1)$ be the coefficients of x^2, xy, y^2, x, y and the constant term of the quadratic form, respectively. That is,

$$
\begin{aligned}
\phi_1(1) &\equiv -\frac{1}{2\eta_1}, \\
\phi_2(1) &\equiv \frac{k_1}{\eta_1}, \\
\phi_3(1) &\equiv -\left(\frac{k_1^2}{2\eta_1} + \frac{1}{2t_1}\right), \\
\phi_4(1) &\equiv \theta, \\
\phi_5(1) &\equiv (\theta - \theta k_1), \\
\phi_6(1) &\equiv -\frac{T\theta^2}{2}.
\end{aligned}
$$

By Lemma 3.1, Eq. 65.25 can be rewritten in terms of bivariate normal CDF as

$$
\equiv D(1)\begin{bmatrix} G(b', b, \phi_1(1), \phi_2(1), \phi_3(1), \phi_4(1), \phi_5(1), \phi_6(1)) \\ -G(k', b, \phi_1(1), \phi_2(1), \phi_3(1), \phi_4(1)\phi_5(1), \phi_6(1)) \end{bmatrix},
$$

where $D(1) \equiv -\frac{K}{2\pi\sqrt{\eta_1 t_1}}$, and $\daleth(1)$, $\Omega(1)$ are obtained by substituting $a(1)$, $a(2)$, ⋯, $a(6)$ into Eqs. 65.23, 65.24, respectively. That is,

$$
\begin{aligned}
\daleth(1) &\equiv 4\phi_1(1)\phi_3(1) - \phi_2(1)^2, \\
\Omega(1) &\equiv \begin{pmatrix} 1 & \dfrac{\phi_2(1)}{2\sqrt{\phi_1(1)\phi_3(1)}} \\ \dfrac{\phi_2(1)}{2\sqrt{\phi_1(1)\phi_3(1)}} & 1 \end{pmatrix}.
\end{aligned}
$$

Similarly, we have

$$
\begin{aligned}
&\int_{-\infty}^{b}\int_{k\prime}^{b\prime} Q(i)dxdy \\
&\quad = D(i)[G(b', b, \phi_1(i), \phi_2(i), \phi_3(i), \phi_4(i), \phi_5(i), \phi_6(i)) \\
&\qquad - G(k', b, \phi_1(i), \phi_2(i), \phi_3(i), \phi_4(i), \phi_5(i), \phi_6(i))], \\
&\qquad \forall i = 2, 3, \ldots 8,
\end{aligned}
$$

where we define $\phi_1(i)$, $\phi_2(i)$, $\phi_3(i)$, $\phi_4(i)$, $\phi_5(i)$, $\phi_6(i)$ as the coefficients of x^2, xy, y^2, x, y and the constant term of the quadratic form in the exponential part of $Q(i)$ for $i = 2, 3, \cdots, 8$. Specifically, the parameters are given by $\phi_1(i) = \phi_1(1)$, $\phi_3(i) = \phi_3(1)$, $\phi_2(i) = (-1)^{i+1}\phi_2(1)$ $\forall i = 2, 3, \cdots, 8$, and $D(i)$, $\phi_4(i)$, $\phi_5(i)$, $\phi_6(i)$ are given by Table 65.2.

Table 65.2 Coefficients of $D(i)$, $\phi_4(i)$, $\phi_5(i)$, and $\phi_6(i)$

i	D(i)	$\phi_4(i)$	$\phi_5(i)$	$\phi_6(i)$
2	$\frac{K}{2\pi\sqrt{\eta_1 t_1}}$	$\frac{2b'}{\eta_1}+\theta$	$\theta+k_1\left(\frac{2b'}{\eta_1}-\theta\right)$	$-\frac{4b'^2+T^2\theta^2-T\theta^2 t_1}{2T-2t_1}$
3	$\frac{K}{2\pi\sqrt{\eta_1 t_1}}$	θ	$\frac{2b}{t_1}+\theta-\theta k_1$	$-\frac{2b^2}{t_1}-\frac{T\theta^2}{2}$
4	$-\frac{K}{2\pi\sqrt{\eta_1 t_1}}$	$\frac{2b'}{\eta_1}+\theta$	$\frac{2b}{t_1}+\theta+k_1\left(\frac{2b'}{\eta_1}-\theta\right)$	$-\frac{2b^2}{t_1}-\frac{T\theta^2}{2}-\frac{2b'^2}{\eta_1}$
5	$\frac{P'(0)}{2\pi\sqrt{\eta_1 t_1}}$	$\theta+\sigma$	$\theta-\theta k_1$	$-\frac{T\theta^2}{2}$
6	$-\frac{P'(0)}{2\pi\sqrt{\eta_1 t_1}}$	$\frac{2b'}{\eta_1}+\theta+\sigma$	$\theta+k_1\left(\frac{2b'}{\eta_1}-\theta\right)$	$-\frac{4b'^2+T^2\theta^2-T\theta^2 t_1}{2T-2t_1}$
7	$-\frac{P'(0)}{2\pi\sqrt{\eta_1 t_1}}$	$\theta+\sigma$	$\frac{2b}{t_1}+\theta-\theta k_1$	$-\frac{2b^2}{t_1}-\frac{T\theta^2}{2}$
8	$\frac{P'(0)}{2\pi\sqrt{\eta_1 t_1}}$	$\frac{2b'}{\eta_1}+\theta+\sigma$	$\frac{2b}{t_1}+\theta+k_1\left(\frac{2b'}{\eta_1}-\theta\right)$	$-\frac{2b^2}{t_1}-\frac{T\theta^2}{2}-\frac{2b'^2}{\eta_1}$

Thus, we obtain the pricing formula

$$\begin{aligned}\dot{C} &= e^{-rT}\int_{-\infty}^{b}\int_{k\prime}^{b\prime} Q(1)+Q(2)+\ldots+Q(8)dxdy \\ &= e^{-rT}\sum_{i=1}^{8}[D(i)[G(b',b,\phi_1(i),\phi_2(i),\phi_3(i),\phi_4(i),\phi_5(i),\phi_6(i)) \\ &\quad -G(k',b,\phi_1(i),\phi_2(i),\phi_3(i),\phi_4(i),\phi_5(i),\phi_6(i))]].\end{aligned}$$

65.3.2 Multi-Discrete-Dividend Case

The above approach can be repeatedly applied to derive approximated pricing formulas for barrier stock options with multiple-discrete-dividend payout. For simplicity, we derive the pricing formula for the two-dividend case in this section. The extensions for three or more dividends cases are straightforward. Note that $t_1 < t_2 < T < t_3$ in the two-dividend case.

To evaluate the option, we need to derive the joint density function of the maximum stock prices over the time intervals [0, t_1), [t_1, t_2), and [t_2, T] and the stock price at time T. Let $\hat{M}_1(t_2-t_1) \equiv max_{t_1\le t<t_2}\hat{W}_1(t-t_1)$ be the maximum value of $\hat{W}_1(t)$ over the time interval [t_1, t_2) and $\hat{M}_2\eta_2 \equiv max_{t_2\le t\le T}\hat{W}_2(t-t_2)$ be the maximum value of $\hat{W}_2(t)$ over the time interval [t_2, T], where η_2 denotes the abbreviation of $T-t_2$.

The joint density function of $\hat{M}_1(t_2-t_1)$ and $\hat{W}_1(t_2-t_1)$ and the density function of $\hat{M}_2\eta_2$ and $\hat{W}_2\eta_2$ can be derived by applying Theorem 65.1 as follows:

$$f_{\hat{M}_1}(t_2-t_1),\hat{W}_1(t_2-t_1)(m_1,w_1) = \begin{cases} \dfrac{2(2m_1-w_1)}{(t_2-t_1)\sqrt{2\pi(t_2-t_1)}}e^{\theta w_1-\frac{1}{2}\theta^2(t_2-t_1)-\frac{1}{2(t_2-t_1)}\left(2m_1-w_1\right)^2} & \text{if } m_1 \ge {w_1}^+, \\ 0 & \text{otherwise,} \end{cases} \tag{65.26}$$

$$f_{\hat{M}_2}\eta_2, \hat{W}_2\eta_2\,(m_2, w_2) = \begin{cases} \dfrac{2(2m_2 - w_2)}{\eta_2\sqrt{2\pi\eta_2}} e^{\theta w_2 - \frac{1}{2}\theta^2\eta_2 - \frac{1}{2\eta_2}\left(2m_2 - w_2\right)^2} & \text{if } m_2 \geq {w_2}^+, \\ 0 & \text{otherwise.} \end{cases} \tag{65.27}$$

For simplicity, we use $\ddot{f}_0$, $\ddot{f}_1$, and $\ddot{f}_2$ to represent the density functions $f_{\hat{M}}(t_1), \hat{B}(t_1)$ (see Eq. 65.17), $f_{\hat{M}_1}(t_2 - t_1), _{\hat{W}_1}(t_2 - t_1)$, and $f_{\hat{M}_2}\eta_2, \hat{W}_2\eta_2$, respectively. Note that the drifted Brownian motions $\hat{B}(t)$ for $t \in [0, t_1)$, $\hat{W}_1(t - t_1)$ for $t \in [t_1, t_2)$, and $\hat{W}_2(t - t_2)$ for $t \in [t_2, t_3]$ are independent due to the Markov property of Brownian motion; the joint density function of maximum stock prices over $[0, t_1)$, $[t_1, t_2)$, and $[t_2, T]$ and the stock prices at time t_1, t_2, and T can be calculated by directly multiplying $\ddot{f}_0$ with $\ddot{f}_1$ and $\ddot{f}_2$

The option value can be evaluated by the risk-neutral variation method as follows:

$$\ddot{C} \equiv e^{-rT} E\left[\left(\hat{P}(T) - K\right) 1_{\left\{\ddot{\Xi}_1 \cap \ddot{\Xi}_2 \cap \ddot{\Xi}_3 \cap \ddot{\Xi}_4\right\}}\right], \tag{65.28}$$

where $\ddot{\Xi}_1, \ddot{\Xi}_2, \ddot{\Xi}_3$ represent the events that the stock price process does not hit the barrier B during the time interval $[0, t_1)$, $[t_1, t_2)$, and $[t_2, T]$, respectively, and $\ddot{\Xi}_4$ denotes the event that the stock price at maturity is greater than the strike price. Specifically, $\ddot{\Xi}_1, \ddot{\Xi}_2, \ddot{\Xi}_3$, and $\ddot{\Xi}_4$ are defined as

$$\begin{aligned} &\ddot{\Xi}_1 \equiv \left\{\hat{M}(t_1) < b\right\}, \\ &\ddot{\Xi}_2 \equiv \left\{\hat{M}_1(t_2 - t_1) < b' - k_1\hat{B}(t_1)\right\}, \\ &\ddot{\Xi}_3 \equiv \left\{\hat{M}_{2\eta 2} < b'' - k_1k_2\hat{B}(t_1) - k_2\hat{W}(t_2 - t_1)\right\}, \\ &\ddot{\Xi}_4 \equiv \left\{\hat{W}_{2\eta 2} < k'' - k_1k_2\hat{B}(t_1) - k_2\hat{W}_1(t_2 - t_1)\right\}, \end{aligned}$$

where $k'' \equiv \frac{1}{\sigma}\log\frac{K}{S''(0)}$, and $b'' \equiv \frac{1}{\sigma}\log\frac{B}{S''(0)}$, respectively. Thus, we can compute the pricing formula in Eq. 65.28 by applying the law of iterated expectation as follows:

$$\begin{aligned} \ddot{C} &= e^{-rT} E\Big[E\Big[E\Big[\left(\hat{P}(T) - K\right) 1_{\left\{\ddot{\Xi}_1 \cap \ddot{\Xi}_2 \cap \ddot{\Xi}_3 \cap \ddot{\Xi}_4\right\}} \\ &\qquad \left|\hat{B}(t_1), \hat{M}(t_1), \hat{W}_1(t_2 - t_1), \hat{M}_1(t_2 - t_1)\right]\left|\hat{B}(t_1), \hat{M}(t_1)\right]\Big] \\ &= e^{-rT} \int_{-\infty}^{b} \int_{w^+}^{b} \int_{-\infty}^{b\prime - k_1 w} \int_{w_1^+}^{b\prime - k_1 w} \int_{k'' - k_1k_2w - k_2w_1}^{b'' - k_1k_2w - k_2w_1} \int_{w_2^+}^{b''| - k_1k_2w - k_2w_1} \\ &\qquad \left(S''(0) e^{k_1k_2\sigma w + k_2\sigma w_1 + \sigma w_2} - K\right) \\ &\qquad \cdot \ddot{f}_2(m_2, w_2) \cdot \ddot{f}_1(m_1, w_1) \cdot \ddot{f}_0(m, w) dm_2 dw_2 dm_1 dw_1 dm dw, \end{aligned} \tag{65.29}$$

where the domain of integral in Eq. 65.29 is obtained by taking the intersection of the supports of $\ddot{f}_2(m_2, w_2)$,$\ddot{f}_1(m_1, w_1)$,$\ddot{f}_0(m, w)$ Since only $\ddot{f}_2(m_2, w_2)$ contains m_2, $\ddot{f}_1(m_1, w_1)$ contains m_1, and $\ddot{f}_0(m, w)$ contains m in the integrand in Eq. 65.29, $\int \ddot{f}_0(m, w)dm$, $\int \ddot{f}_1(m_1, w_1)dm_1$ and $\int \ddot{f}_2(m_2, w_2)\, dm_2$ can be simplified as follows:

$$
\begin{aligned}
\ddot{C} = e^{-rT} & \int_{-\infty}^{b} \int_{-\infty}^{b\prime - k_1 w} \int_{k'' - k_1 k_2 w - k_2 w_1}^{b'' - k_1 k_2 w - k_2 w_I} \\
& \left(S''(0) e^{k_1 k_2 \sigma w + k_2 \sigma w_1 + \sigma w_2} - K \right) \\
& \cdot \left(\int_{w_2^+}^{b'' - k_1 k_2 w - k_2 w_1} \frac{2(2m_2 - w_2)}{\eta_2 \sqrt{2\pi \eta_2}} \right. \\
& \left. \times e^{\theta w_2 - \frac{1}{2}\theta^2 \eta_2 - \frac{1}{2\eta_2}(2\mathrm{m}_2 - w_2)^2} dm_2 \right) \\
& \cdot \left(\int_{w_1^+}^{b' - k_1 w} \frac{2(2m_1 - w_1)}{(t_2 - t_1)\sqrt{2\pi (t_2 - t_1)}} \right. \\
& \left. \times e^{\theta w_1 - \frac{1}{2}\theta^2 (t_2 - t_1) - \frac{1}{2(t_2 - t_1)}(2m_1 - w_1)^2} dm_1 \right) \\
& \cdot \left(\int_{w^+}^{b} \frac{2(2m - w)}{t_1 \sqrt{2\pi t_1}} e^{\theta w - \frac{1}{2}\theta^2 t_1 - \frac{1}{2t_1}(2m - w)^2} dm \right) dw_2 dw_1 dw.
\end{aligned}
$$

To eliminate the variables in the lower and the upper limits for the integrals on w_1 and w_2, we substitute

$$
\begin{cases}
x = w_2 + k_2 w_1 + k_1 k_2 w, \\
y = w_1 + k_1 w, \\
z = w
\end{cases},
$$

into the aforementioned formula to get[6]

$$
\ddot{C} = e^{-rT} \int_{-\infty}^{b} \int_{-\infty}^{b\prime} \int_{k''}^{b''} \sum_{i=1}^{16} O(i) dx dy dz, \tag{65.30}
$$

where $O(1)$, $O(2)$,⋯, $O(16)$ are defined in Table 65.3

Again, each of the integrands $O(1)$, $O(2)$,⋯, $O(16)$ is a quadratic form taking exponential. We reformulate the integrals of them in terms of the CDF of the multivariate normal distribution by the lemma shown below. Appendix gives the proof of this lemma.

[6]The Jacobian determinant $\frac{\partial(w_2, w_1, w)}{\partial(x, y, z)}$ is 1.

Table 65.3 The definitions of $O(1), \ldots, O(16)$

$$O(1) = -\frac{K}{\sqrt{8\pi^3\eta_2(t_2-t_1)t_1}}e^{-\frac{z^2}{2t_1}+\theta z+\theta(y-zk_1)+\theta(x-yk_2)-\frac{\theta^2 t_1}{2}-\frac{1}{2}\theta^2\eta_2-\frac{1}{2}\theta^2(t_2-t_1)-\frac{(x-yk_2)^2}{2\eta_2}-\frac{(y-zk_1)^2}{2(t_2-t_1)}},$$

$$O(2) = \frac{K}{\sqrt{8\pi^3\eta_2(t_2-t_1)t_1}}e^{-\frac{z^2}{2t_1}+\theta z+\theta(y-zk_1)+\theta(x-yk_2)-\frac{\theta^2 t_1}{2}-\frac{1}{2}\theta^2\eta_2-\frac{1}{2}\theta^2(t_2-t_1)+\frac{2b(z-b)}{t_1}-\frac{(x-yk_2)^2}{2\eta_2}-\frac{(y-zk_1)^2}{2(t_2-t_1)}},$$

$$O(3) = \frac{K}{\sqrt{8\pi^3\eta_2(t_2-t_1)t_1}}e^{-\frac{z^2}{2t_1}+\theta z+\theta(y-zk_1)+\theta(x-yk_2)-\frac{\theta^2 t_1}{2}-\frac{1}{2}\theta^2\eta_2-\frac{1}{2}\theta^2(t_2-t_1)-\frac{(x-yk_2)^2}{2\eta_2}+\frac{2\left(x-b''\right)\left(b''-yk_2\right)}{\eta_2}-\frac{(y-zk_1)^2}{2(t_2-t_1)}},$$

$$O(4) = -\frac{K}{\sqrt{8\pi^3\eta_2(t_2-t_1)t_1}}e^{-\frac{z^2}{2t_1}+\theta z+\theta(y-zk_1)+\theta(x-yk_2)-\frac{\theta^2 t_1}{2}-\frac{1}{2}\theta^2\eta_2-\frac{1}{2}\theta^2(t_2-t_1)+\frac{2b(z-b)}{t_1}-\frac{(x-yk_2)^2}{2\eta_2}+\frac{2\left(x-b''\right)\left(b''-yk_2\right)}{\eta_2}-\frac{(y-zk_1)^2}{2(t_2-t_1)}},$$

$$O(5) = \frac{K}{\sqrt{8\pi^3\eta_2(t_2-t_1)t_1}}e^{-\frac{z^2}{2t_1}+\theta z+\theta(y-zk_1)+\theta(x-yk_2)-\frac{\theta^2 t_1}{2}-\frac{1}{2}\theta^2\eta_2-\frac{1}{2}\theta^2(t_2-t_1)-\frac{(x-yk_2)^2}{2\eta_2}-\frac{(y-zk_1)^2}{2(t_2-t_1)}+\frac{2(y-b')(b'-zk_1)}{t_2-t_1}},$$

$$O(15) = \frac{S''(0)}{\sqrt{8\pi^3\eta_2(t_2-t_1)t_1}} e^{-\frac{z^2}{2t_1}+\theta z+x\sigma+\theta(y-zk_1)+\theta(x-yk_2)-\frac{\theta^2 t_1}{2}-\frac{1}{2}\theta^2\eta_2-\frac{1}{2}\theta^2(t_2-t_1)-\frac{(x-yk_2)^2}{2\eta_2}+\frac{2(x-b'')(b''-yk_2)}{\eta_2}-\frac{(y-zk_1)^2}{2(t_2-t_1)}+\frac{2(y-b')(b'-zk_1)}{t_2-t_1}},$$

$$O(16) = -\frac{S''(0)}{\sqrt{8\pi^3\eta_2(t_2-t_1)t_1}} e^{-\frac{z^2}{2t_1}+\theta z+x\sigma+\theta(y-zk_1)+\theta(x-yk_2)-\frac{\theta^2 t_1}{2}-\frac{1}{2}\theta^2\eta_2-\frac{1}{2}\theta^2(t_2-t_1)+\frac{2b(z-b)}{t_1}-\frac{(x-yk_2)^2}{2\eta_2}+\frac{2(x-b'')(b''-yk_2)}{\eta_2}-\frac{(y-zk_1)^2}{2(t_2-t_1)}+\frac{2(y-b')(b'-zk_1)}{t_2-t_1}}.$$

Lemma 65.4 *Let $F_{X_1,X_2,X_3}(a,b,c,\Omega)$ be the CDF of a multivariate normal distributed random vector (X_1, X_2, X_3). That is,*

$$\begin{aligned}
&F_{X_1,X_2,X_3}(a,b,c,\Omega) \\
&\equiv \int_{-\infty}^{a}\int_{-\infty}^{b}\int_{-\infty}^{c} f_{X_1,X_2,X_3}(x_1,x_2,x_3)dx_1dx_2dx_3 \\
&= \int_{-\infty}^{a}\int_{-\infty}^{b}\int_{-\infty}^{c} \frac{1}{\sqrt{8\pi^3|\Omega|}} e^{-\frac{1}{2}x^T\Omega \mathrm{x}} dx_1dx_2dx_3
\end{aligned}$$

where $\mathbf{x}$ and Ω denote $(x_1, x_2, x_3)^T$ and the covariance matrix, respectively, and each of X_1, $X_{2,}$ and X_3 has mean 0 and variance 1. The following triple integral can be expressed in terms of F_{X_1,X_2,X_3} as

$$\begin{aligned}
&H(p,q,r,A,B,C) \equiv \int_{-\infty}^{r}\int_{-\infty}^{q}\int_{-\infty}^{p} \\
&e^{\phi_1x^2+\phi_2y^2+\phi_3z^2+\phi_4xy+\phi_5yz+\phi_6xz+\phi_7x+\phi_8y+\phi_9z+\phi_{10}}dxdydz \\
&= e^{C\prime}\sqrt{\frac{\pi^3}{|-A|}F_{\Upsilon_1,\,\Upsilon_2,\,\Upsilon_3}\left(\frac{\chi_1-\mathrm{m}_1}{\Phi_{1,1}},\frac{\chi_2-\mathrm{m}_2}{\Phi_{2,2}},\frac{\chi_3-\mathrm{m}_3}{\Phi_{3,3}},\Omega\right)},
\end{aligned}$$

where

$$\begin{aligned}
A &= \begin{pmatrix} \phi_1 & \frac{\phi_4}{2} & \frac{\phi_6}{2} \\ \frac{\phi_4}{2} & \phi_2 & \frac{\phi_5}{2} \\ \frac{\phi_6}{2} & \frac{\phi_5}{2} & \phi_3 \end{pmatrix}, B = \begin{pmatrix} \phi_7 \\ \phi_8 \\ \phi_9 \end{pmatrix}, C = \phi_{10}, \\
\Phi &= \begin{pmatrix} \Phi_{1,1} & 0 & 0 \\ 0 & \Phi_{2,2} & 0 \\ 0 & 0 & \Phi_{3,3} \end{pmatrix}, \\
\Phi_{j,j} &= \sqrt{\left((-2A)^{-1}\right)_{j,j}} \forall j = 1,2,3, \\
\mathrm{m} &= -\frac{1}{2}A^{-1}B, \\
C' &= C - \frac{1}{4}B^TA^{-1}B \\
\Omega &= (-2\mathrm{S}A\Psi)^{-1}.
\end{aligned}$$

Let $A(i)$, $B(i)$, $C(i)$ be

$$A(i) = \begin{pmatrix} \phi_1(i) & \frac{\phi_4(i)}{2} & \frac{\phi_6(i)}{2} \\ \frac{\phi_4(i)}{2} & \phi_2(i) & \frac{\phi_5(i)}{2} \\ \frac{\phi_6(i)}{2} & \frac{\phi_5(i)}{2} & \phi_3(i) \end{pmatrix},$$

$$B(i) = \begin{pmatrix} \phi_7(i) \\ \phi_8(i) \\ \phi_9(i) \end{pmatrix}, C(i) = \phi_{10}(i),$$

respectively. Thus, we have

$$\begin{aligned}&\int_{-\infty}^{b}\int_{-\infty}^{b\prime}\int_{k''}^{b''} O(i)dxdydz\\&= L(i)\left[H\left(b'', b', b, A(i), B(i), C(i)\right)\right.\\&\quad \left.-H\left(k'', b', b, A(i), B(i), C(i)\right)\right], \forall i = 2, 3, \cdots, 8,\end{aligned}$$

where

$$\begin{aligned}
\phi_1(i) &= -\frac{1}{2\eta_2},\\
\phi_2(i) &= -\left(\frac{k_2^2}{2\eta_2} + \frac{1}{2(t_2 - t_1)}\right),\\
\phi_3(i) &= -\left(\frac{k_1^2}{2(t_2 - t_1)} + \frac{1}{2t_1}\right),\\
\phi_6(i) &= 0,\\
\phi_4(i) &= \begin{cases} \dfrac{k_2}{\eta_2} & \text{if}\, i = 4l + 1\,\text{or}\;\; i = 4l + 2\\ -\dfrac{k_2}{\eta_2} & \text{otherwise}\end{cases}\\
\phi 5(i) &= \begin{cases} \dfrac{k_2}{t_2 - t_1} & \text{if}\;\; i = 8l + 1, 8l + 2, 8l + 3, \text{or}\, 8l + 4\\ -\dfrac{k_2}{t_2 - t_1} & \text{otherwise}\end{cases}, \forall i = 1, 2, \cdots, 16,\\
L(i) &= \frac{K}{\sqrt{8\pi^3\eta_2(t_2 - t_1)t_1}}, \quad i = 2, 3, 5, 8,\\
L(i) &= -L(2), \quad i = 1, 4, 6, 7\\
L(i) &= \frac{S''(0)}{\sqrt{8\pi^3\eta_2(t_2 - t_1)t_1}}, \quad i = 9, 12, 14, 15,\\
L(i) &= -L(9), \quad i = 10, 11, 13, 16,
\end{aligned}$$

and the rest parameters can be easily derived.

Finally, we obtain the following pricing formula in two-dividend case:

$$\begin{aligned}\ddot{C} &= e^{-rT}\int_{-\infty}^{b}\int_{-\infty}^{b\prime}\int_{k''}^{b''}\\&\quad O(1) + O(2) + \cdots + O(16)dxdydz\\&= e^{-rT}\sum_{i=1}^{16}\left[L(i)\left[H\left(b'', b', b, A(i),\;\; B(i),\;\; C(i)\right)\right.\right.\\&\quad \left.\left.- H(k'', b', b,\;\; A(i),\;\; B(i),\;\; C(i))\right]\right].\end{aligned}$$

65.4 Numerical Results

Option values in different initial underlying stock prices with $r = 0.03$, $\sigma = 0.2$, $K = 50$, $B = 65$, $T = 1$, $t_1 = 0.5$, and $c_1 = 0$. "Ours" and "RR" stand for the pricing results by Eq. 65.8 and our closed form approximation for single-dividend case, respectively. "diff" gives their difference.

To show that our approximating formula prices accurately, in this section we give the numerical results of our formula, compared with other pricing schemes.

First we show that our pricing formula can exactly price a barrier option in zero-dividend case. Equation 65.8 given in Reiner and Rubinstein (1991) is our special case when all discrete dividend c_i are zero. Table 65.4 gives the comparison of the pricing results by our formula in single-dividend case and Eq. 65.8, with settings $r = 0.03$, $\sigma = 0.2$, $K = 50$, $B = 65$, $T = 1$, $t_1 = 0.5$, and $c_1 = 0$. As shown in this table, Eq. 65.8 and our pricing formula give almost the same result. Notice that the approximations for CDF $N(x)$ and $F_{\Upsilon_1,\Upsilon_2}(a, b, \Omega)$ could cause insignificant errors.

Option values approximated by model 1 (denoted as "M1"), 2 (denoted as "M2"), and our formula in different initial underlying stock prices with $r = 0.03$, $\sigma = 0.2$, $K = 50$, $B = 65$, $T = 1$, $t_1 = 0.5$, and $c_1 = 1$. The columns "error" list the difference between their left column and the benchmark (denoted as "B"). MAE denotes the maximum absolute error, and RSE stands for the root-mean-square error.

As mentioned in Frishling (2002), only model 3 can reflect the real-world phenomenon. Though models 1 and 2 suggested by Roll (1977) and Heath and Jarrow (1988) try to approximate model 3, Table 65.5 shows that their pricing results are less accurate than ours. Table 65.5 gives the comparison of the pricing

Table 65.6 Comparing the pricing results by different models in single-dividend case. All settings are the same with table 65.5, but now we fix $P(0) = 50$ and compare the pricing results for different dividend c_1

results by models 1 and 2 and our formula in single-dividend case, where we use the results by Monte Carlo simulation with 1,000,000 paths as a benchmark. Table 65.6 gives the same comparison as Table 65.5, while Table 65.6 compares the pricing results for several different c_1 and one fixed $P(0)$, but Table 65.5 compares the results for different $P(0)$ fixing c_1. As shown in Table 65.6, our pricing formula produces poorer results as c_1 increases, but on average, our pricing results are still more accurate than others. Furthermore, typically dividend c_1 is quite small, and hence, our pricing formula approximates option values accurately. In two-dividend case, the pricing results comparison is shown in Table 65.7. As shown in these tables, our formula also produces more accurate results the model 1 and 2. Thus, we can conclude that our formula is better in all cases.

65.5 Conclusions

There are several different ways to model the stock price process with discrete dividend. As suggested by Frishling (2002), only model 3 can reflect real-world phenomenon. However, it is hard to price a barrier option under model 3. Our chapter suggests a way to derive analytically approximating pricing formulas for a barrier option under model 3. Though the resulting analytical formulas involve multiple integral, as shown above, all of them can be reformulated in terms of the

CDF of a multivariate normal distribution. As a result, our pricing formula prices efficiently. Furthermore, numerical results show that our pricing formulas produce accurate result.

Option values in two-dividend case approximated by models 1 and 2 and our formula in different initial underlying stock prices with $r = 0.03$, $\sigma = 0.2$, $K = 50$, $B = 65$, $T = 1.5$, $t_1 = 0.5$, and $t_2 = t_1 + 0.5$.

Appendix: Solve the Integration of Exponential Functions by the CDF of Multivariate Normal Distribution

If the price of the underlying asset is assumed to follow the lognormal diffusion process, most option pricing formulas, including the pricing formulas in this chapter, can be expressed in terms of multiple integrations of an exponential function, where the exponent term is a quadratic function of integrators $z_1, z_2, \cdots$. The integration problem can be numerically solved by reexpressing the formulas in terms of CDF of multivariate normal distribution, which can be efficiently solved by accurate numerical approximation methods (see Hull 2003). These numerical methods are provided by mathematical softwares, like Matlab and Mathematica. Take the simplest case – the single integral, for example. Under the premise $\phi_2 < 0$, the integral $\int_{-\infty}^{l} e^{\phi 2x^2+\phi_1 x+\phi_0}\, dx$ can be rewritten as

$$\sqrt{\frac{\pi}{-\phi_2}} e^{-\frac{\phi_1^2-4\phi_0\phi_2}{4\phi_2}} N\left(\frac{l-m}{s}\right), \tag{65.31}$$

where

$$\mathrm{m} = -\frac{\phi_1}{2\phi_2}$$
$$\mathrm{s} = \frac{1}{\sqrt{-2\phi_2}},$$

and $N(\cdot)$ denotes the CDF of a univariate standard normal distribution. Note that the above identity is used to derive the pricing formula in no-dividend case.

However, the integration for multivariate case is not straightforward. To address this problem, we derive a general formula for the multivariate integration with n integrators: $z_1, z_2, \cdots, z_n$.

Some matrix and vector calculations are employed to simplify derivation. For simplicity, for any matrix $\beth$, we use $|\beth|$, $\beth^T$, and $\beth^{-1}$ to denote the determinant, the transpose, and the inverse matrix of $\beth$. $\beth_{i,j}$ stands for the element located at the i-th row and j-th column of $\beth$. For any vector v, we use v_i to denote the i-th element of v. We further assume that $\mathbf{z} = (z_1, z_2, \cdots, z_n)^T$ is a column vector with n variables, β is an $n \times 1$ constant vector, δ is a constant, and ϑ is an $n \times n$ symmetric invertible negative-definite constant matrix. Then the general integral formula is derived in the following theorem:

Theorem 65.5 *For any general quadratic formula* $\mathbf{z}^T\ \vartheta\mathbf{z} + \beta^T\mathbf{z} + \delta$, *the n-variate integral for* $e^{\mathrm{z}^T\vartheta\mathrm{z}+\beta^T\mathrm{z}+\delta}$

$$\int_{-\infty}^{\chi_n}\int_{-\infty}^{\chi_{n-1}}\cdots\int_{-\infty}^{\chi_1} e^{\mathrm{z}^T\vartheta\mathrm{z}+\beta^T\mathrm{z}+\delta}dz \tag{65.32}$$

can be expressed in terms of a CDF of an n-dimensional standard normal distribution

$$F_{\Upsilon_1,\Upsilon_2,\cdots,\Upsilon_n}(l_1,l_2,\cdots,l_n,\Omega)\equiv$$
$$\int_{-\infty}^{l_n}\int_{-\infty}^{l_{n-1}}\cdots\int_{-\infty}^{l_1}\frac{1}{\sqrt{|\Omega|(2\pi)^n}}e^{-\frac{1}{2}y^T\Omega^{-1}y}dy,$$

where Ω *denotes the covariance matrix of a n-variate standard normal random vector* $(\Upsilon_1, \Upsilon_2,\cdots, \Upsilon_n)$.

Proof To express the integral in Eq. 65.32 in terms of a CDF of a standard normal distribution, the exponent term $\mathbf{z}^T\ \vartheta\mathbf{z} + \beta^T\mathbf{z} + \delta$ should be expressed in terms of the exponent term of a standard normal distribution. That is,

$$\mathbf{z}^T\vartheta\mathbf{z}+\beta^T\mathbf{z}+\delta=-\frac{1}{2}\mathbf{y}^T\boldsymbol{\Omega}^{-1}\mathbf{y}+\delta' \tag{65.33}$$

for some constant δ'. This can be achieved by first deriving a proper constant vector **m** and a proper diagonal matrix **S** and then substituting

$$\mathrm{y}=\mathrm{S}^{-1}\mathrm{n} \tag{65.34}$$

into the left-hand side of Eq. 65.33, where **n** is the abbreviation of $\mathbf{z} - \mathbf{m}$. The following lemma derives a proper **m** by completing the square identity for $\mathbf{z}^T\ \vartheta\mathbf{z} + \beta^T\mathbf{z}$.

Lemma 65.6 *Under the premises that* ϑ *is a symmetric invertible* $n \times n$ *matrix, and* $\mathbf{z}$, β *are both* $n \times 1$ *vectors, we have*

$$\mathbf{z}^T\vartheta\mathbf{z}+\beta^T\mathbf{z}=\left(\mathbf{z}+\frac{1}{2}\vartheta^{-1}\beta\right)^T\vartheta\left(\mathbf{z}+\frac{1}{2}\vartheta^{-1}\beta\right)-\frac{1}{4}\beta^T\vartheta^{-1}\beta. \tag{65.35}$$

Proof By expanding the right-hand side of Eq. 65.35, we have

$$\begin{aligned}&\left(\mathbf{z}+\tfrac{1}{2}\vartheta^{-1}\beta\right)^T\vartheta\left(\mathbf{z}+\frac{1}{2}\vartheta^{-1}\beta\right)-\frac{1}{4}\beta^T\vartheta^{-1}\beta\\&=\mathbf{z}^T\vartheta\mathbf{z}+\beta^T\mathbf{z}=\text{the left-hand side of Eq.65.35.}\end{aligned} \tag{65.36}$$

With lemma 65.6, we obtain

$$\mathbf{z}^T\vartheta\mathbf{z}+\mathbf{z}^T\beta+\delta=\mathbf{n}^T\vartheta\mathbf{n}+\delta', \tag{65.37}$$

where

$$\mathbf{m} \equiv -\frac{1}{2}\vartheta^{-1}\beta, \tag{65.38}$$

$$\delta' \equiv \delta - \frac{1}{4}\beta^T\vartheta^{-1}\beta. \tag{65.39}$$

The diagonal matrix Φ can be derived by equating the right-hand sides of Eq. 65.33 and Eq. 65.37 to get

$$\mathbf{n}^T\vartheta\mathbf{n} + \delta' = -\frac{1}{2}\mathbf{y}^T\boldsymbol{\Omega}^{-1}\mathbf{y} + \delta'.$$

Subtracting δ' from both sides of above equation yields

$$\mathbf{n}^T\vartheta\mathbf{n} = -\frac{1}{2}\mathbf{y}^T\Omega^{-1}\mathbf{y} \tag{65.40}$$

$$-\frac{1}{2}\mathbf{n}^T(\Phi\Omega\Phi)^{-1}\mathrm{n}, \tag{65.41}$$

By comparing the right-hand side of Eqs. 65.40 and 65.41, we have $-\frac{1}{2}(\Phi\Omega\Phi)^{-1} = \vartheta$, which is rewritten as $\Phi\Omega\Phi = (-2\vartheta)^{-1}$. Recall that Φ is a diagonal matrix. All diagonal elements of Ω are all 1 since Ω is a covariance matrix of multivariate standard normal random variables. Thus, we have $(\Phi\Omega\Phi)i$, $i = \Phi_{i,i}^2$, which leads us to obtain

$$\Phi_{i,j} \equiv \begin{cases} \sqrt{\left((-2\vartheta)^{-1}\right)_{i,i}} & \text{if } i{=}j \\ 0 & \text{otherwise} \end{cases} \tag{65.42}$$

and

$$\Omega \equiv (-2\Phi\vartheta\Phi)^{-1}. \tag{65.43}$$

Now we can evaluate Eq. 65.32 with δ', $\mathbf{m}$, Φ, and Ω defined above. By applying the change of variable Eq. 65.34, Eq. 65.32 can be rewritten as

$$\begin{aligned} &\int_{z_n=-\infty}^{z_n=\chi_n}\int_{z_{n-1}=-\infty}^{z_{n-1}=\chi_{n-1}}\cdots\int_{z_1=-\infty}^{z_1=\chi_1} e^{\mathbf{z}^T\vartheta\mathbf{z}+\beta^T\mathbf{z}+\delta}\mathbf{dz} \\ &= \int_{z_n=-\infty}^{z_n=\chi_n}\int_{z_{n-1}=-\infty}^{z_{n-1}=\chi_{n-1}}\cdots\int_{z_1=-\infty}^{z_1=\chi_1} e^{-\frac{1}{2}\mathbf{y}^T\boldsymbol{\Omega}^{-1}\mathbf{y}+\delta\prime} \\ &\left|\left|\frac{\partial\mathbf{x}}{\partial\mathbf{y}}\right|\right|dy. \end{aligned} \tag{65.44}$$

Since the elements in vector $\mathbf{y}$ can be represented as $\left(\frac{z_1-\mathbf{m}_1}{\Phi_{1,1}}, \frac{z_2-\mathbf{m}_2}{\Phi_{2,2}}, \cdots, \frac{z_n-\mathbf{m}_n}{\Phi_{n,n}}\right)^T$, the Jacobian determinant can be straightforwardly computed to get $\left|\frac{\partial \mathrm{x}}{\partial \mathrm{y}}\right| = \prod_{i=1}^{n} \Phi_{i,i} = |\Phi|$. Thus, Eq. 65.44 can be further rewritten as the following closed form formula:

$$e^{\delta\prime}\sqrt{\frac{\pi^n}{|-\vartheta|}}F_{\Upsilon_1,\Upsilon_2,\cdots,\Upsilon_n}\left(\frac{\chi_1-\mathbf{m}_1}{\Phi_{1,1}}, \frac{\chi_2-\mathbf{m}_2}{\Phi_{2,2}}, \cdots, \frac{\chi_n-\mathbf{m}_n}{\Phi_{n,n}}, \Omega\right), \tag{65.45}$$

where $|\Phi|\sqrt{|\Omega|} = \sqrt{|\Phi\Omega\Phi|} = \sqrt{|-2\vartheta|^{-1}}$ and $\mathrm{I} - 2\vartheta| = 2^n\mathrm{I} - \vartheta|$ are substituted into Eq. 65.45. This integration formula is similar to the single integral case given. Q.E.D.

Pension Funds: Financial Econometrics on the Herding Phenomenon in Spain and the United Kingdom

66

Mercedes Alda García and Luis Ferruz

Contents

Abstract

This work reflects the impact of the Spanish and UK pension funds investment on the market efficiency; specifically, we analyze if manager's behavior enhances the existence of herding phenomena.

To implement this study, we apply a less common methodology: the estimated cross-sectional standard deviations of betas. We also estimate the betas

with an econometric technique less applied in the financial literature: state-space models and the Kalman filter. Additionally, in order to obtain a robust estimation, we apply the Huber estimator.

Finally, we apply several models and study the existence of herding towards the market, size, book-to-market, and momentum factors.

The results are similar for the two countries and style factors, revealing the existence of herding. Nonetheless, this is smaller on size, book-to-market, and momentum factors.

66.1 Introduction

For some time, Western countries have been undergoing a range of demographic and social changes: increased life expectancy, ageing population, shorter active phases, and longer retirement periods. All of these changes, together with increasing concern over the viability of public pension systems, have led to a greater role for complementary pension systems.

Together with all these factors, society has become increasingly aware of the need to save for a higher retirement income; as Sanz (1999) observes, the state pension incomes are lower than those received during working life. Thus, together with tax incentives, pension plans are one of the key financial products for saving in developed economies.

The need to find a backup to the state pension has caused more and more professional and nonprofessional investors to take out pension plans by investing in pension funds.

As a consequence, these products are beginning to take a leading role in the industry of collective investment; according to INVERCO (Spanish Association of Investment and Pension Funds), the investment in such products worldwide in 2010 exceeded 12½ billion euros, of which more than 3 billion euros came from Europe, highlighting the United Kingdom, which represents a third of the total European investment.

The origin of pension funds and pension plans can be traced to the foundation of the welfare states, when various governments began to expand public spending, in particular on social welfare: education, health, pensions, housing, and unemployment benefit.

Among the different parts of the welfare state, pensions are included under the heading of the Social Welfare Systems, and the European pension systems are organized around the *Livonia* focus which is divided into three pillars, as González and García (2002) notes:

1. The first pillar consists of the Social Security System. It is integrated by the public system, which is mandatory, defined benefit pensions, and pay-as-you-go system, which guarantees a minimum level of pension. The pay-as-you-go system means that active workers pay, with their contributions, the pensions of retirees at that time; although each worker's pension depends on the contributions made during working life.
2. The second pillar consists of private and complementary occupational plans, within the scope of companies and workers associations. This pillar may be either voluntary or compulsory and may replace or supplement the first pillar, so it may be either private or public.
3. The third pillar consists of individual savings decisions, so it is private and voluntary; an example is the personal pension plans.

Therefore, the first pillar is the Public Social Welfare System, while the second and third comprise the Complementary Social Welfare System.

The evolution of each of these pillars depends on the evolution of the state system, so if the latter has expanded, providing more generous state pensions, the other two have been developed to a lesser extent, and vice versa. For instance, Fernández (2011) notes that the third pillar is weak in Spain because public pensions are close to the final salary.

Therefore, complementary pension systems have varying characteristics across Europe depending on the private pension's development (second and third pillars), and we can divide them into three groups:

– Countries in which private pension systems have reached a high stage of development: the United Kingdom, Ireland, the Netherlands, and Sweden.
– Countries in which private pension systems have reached a considerable degree of development, but are still evolving: Spain, Portugal, Italy, and Germany.
– Countries in which private pension systems are less developed: France, Belgium, and some East European countries.

With regard to legislation in Europe on these products, it must be noted that each country has its own, so that across Europe we can observe significant differences.

Among the different European countries, we focus on Spain and the United Kingdom because they represent two different systems and their industries have different size; as a result, we want to study if these characteristics provide different results on the topic studied: the herding phenomenon.

Respect the pension systems, these two markets are the most representative of two different pension systems:

Spain belongs to the "Mediterranean model," which is characterized by generous public pensions. In contrast, the United Kingdom belongs to the "Anglo-Saxon model," with less generous public pensions, so private pensions are more developed.

Equally, the differences in size between the two markets allow us to observe whether they enhance or not the existence of herding.

With regard to the United Kingdom, according to the OECD (2010), it is the leading country in Europe (1.1 billion euros) and the second in worldwide terms, just behind the United States.

For its part, Spain occupies seventh place in Europe with 84 milliard of euros invested in 2010, and given that these products did not come on the market here until 1988, this country has experienced a significant growth over the past years; as a result, this trend could have implications for the existence of herding.

We focus on the study of herding because traditionally, most of the financial studies examine the pension funds' performance, analyzing the manager behavior; however, the market efficiency can also be affected by the pension funds' investment, for example, through the herding phenomenon, an aspect that we study in this paper.

We apply a less common methodology to detect herding, based on the state-space models, as in the work of Christie and Huang (1995). Nonetheless, this model suffers from several inadequacies: it supposes that the instability of the market means that the whole market should demonstrate negative or positive returns and it introduces dummy variables arbitrarily; therefore, we also focus on the work of Hwang and Salmon (2004), who calculate herding using a single-factor model. In particular, they base on the market return from the CAPM model, using the betas dispersion of all market stocks.

The rest of the work is organized as follows: in the second section we describe the herding phenomenon and the third section carries out a literature review on the topic. The fourth section develops the methodology. The fifth section compiles the data and presents the empirical results. Finally, we show the main conclusions.

66.2 The Herding Phenomenon

This topic is part of the behavioral finance, which is focused on the study of the rationality of investment decisions and the implications of the cognitive processes in the make decisions (Fromlet 2001).

Investors' preference, such as the avoidance of loss, may produce some irrational reactions and affect the market efficiency (Kahnemann and Tversky 1979; Tversky and Kahnemann 1986). This behavior may imply price fluctuations, not necessarily related to the arrival of new market information, but rather by the emergence of collective phenomena, like herding (Thaler 1991; Shefrin 2000), affecting the efficiency and stability of the market.

In financial literature, herding arises when investors decide to imitate the decisions of other participants in the market or market movements; that it is to say, they imitate market agents who are thought to be better informed, rather than follow their own beliefs and information.

We assume the manager as investor, given that even though individual investors make the investments in pension plans, the managers are responsible for buying and selling in the market; likewise, they also vary the composition of the pension fund portfolio. Therefore, managers are the final investors and they carry out the investment in the market, albeit according to the guidelines established by the members of the pension plans.

In financial language, the herding phenomenon is one of the most widely discussed because, in the field of the asset pricing, it helps to explain market anomalies; however, the difficulty in its measurement and calculation has limited their research.

It is generally accepted that herding can lead to a situation in which market prices cannot reflect all of the information, then the market becomes unstable and moves towards the inefficiency. For that reason, market regulators show an interest in reducing this type of phenomena.

Theoretical and empirical studies have focused on finding causes and implications related to herding. The majority agree that this may due to both rational and irrational investor behavior.

According to Devenow and Welch (1996), irrational viewpoint focuses on the psychology of the investor, where the investor follows others blindly.

On the other hand, rational herding may appear due to diverse causes:

The first of them is the existence of imperfect information, that it is to say, when it is believed that other market participants are better informed. Banerjee (1992), Bikhchandani et al. (1992), Hirshleifer et al. (1994), Calvo and Mendoza (2000), Avery and Zemsky (1998), Chari and Kehoe (2004), Gompers and Metrick (2001), Puckett and Yan (2007), and Sahut et al. (2011) show evidence of such imperfect information.

The second aspect that causes rational herding is the costs of reputation. Scharfstein and Stein (1990), Trueman (1994), Rajan (1994), or Maug and Naik (1996), focusing on agency theory, show evidence of this. These studies prove that mutual fund managers imitate others in order to obtain bonuses as set out in their compensation-reputation scheme rewarding.

Compensation schemes also cause rational herding, as an investor will be rewarded based on their performance against the others; therefore, the deviations with respect to the market consensus could lead to an undesirable cost. Studies such as those of Roll (1992), Brennan (1993), Rajan (1994), or Maug and Naik (1996) demonstrate this.

In addition to these explanations, some authors have considered other factors, like the degree of institutional participation, the spread of opinions, derivatives markets and their sophistication, or uninformed investors. Among these are Patterson and Sharma (2006), Demirer and Kutan (2006), Henker et al. (2006), and Puckett and Yan (2007).

Despite the uncertainty surrounding the causes of this behavior, the study of herding in financial markets has followed two lines of investigation. The first one analyzes the tendency of individuals (individual investors). Among them, we highlight the works of Lakonishok et al. (1992a); Grinblatt et al. (1995); Wermers (1999), and Uchida and Nakagawa (2007).

The second trend focuses on market herding as a whole, that is to say, as a collective behavior of all participants buying or selling a certain asset at the same time. The most representative studies within this line of investigation are those of Christie and Huang (1995), Chang et al. (2000), Hwang and Salmon (2004), Patterson and Sharma (2006), and Wang (2008).

In this paper we focus on this second approach; to this purpose, we use the observing deviations from the equilibrium expressed in CAPM prices, a focus less used in financial literature.

Based on the works of Christie and Huang (1995) and Hwang and Salmon (2004), we capture herding with the use of observed returns data, instead of measuring it in the same way as Lakonishok et al. (1992a), by detailed records of individual trading activities which may not be available in many cases. For this reason, in order to detect herding, we use the cross-sectional dispersion of the betas.

Nonetheless, as this model suffers from some deficiencies as it supposes that market betas are statics, we build a time-varying distribution of the cross-sectional dispersion of betas. Likewise, as its betas do not take into account outliers, we apply a robust estimation.

The estimation method applied is the state-space model, using the Kalman filter. This methodology is more innovative in financial literature, and as far as we know, it has not been applied to pensions, so we will obtain new empirical evidence.

Likewise, as this technique has not been applied to pension funds, it will allow us to detect, for the first time, if pension fund managers produce herding behavior in the markets.

66.3 Literature Review

As we mentioned, we focus on the study of herding considering the market as a whole. In this trend, we find various types of models that detect herding: models of returns' dispersion and state-space models.

In the first ones we can distinguish between linear and nonlinear models. In the linear models, the most common measurement is the cross-sectional standard deviation of returns (henceforth CSSD), while in the nonlinear ones is the cross-sectional absolute deviation of returns (henceforth CSAD).

Studies based on these models show mixed evidence of this behavior. Christie and Huang (1995) find evidence in American stocks, but not during the market crises. Chang et al. (2000) find this in Taiwan, South Korea, and Japan, but not in Hong Kong and the United States. Lin and Swanson (2003) do not find this in international securities. Gleason et al. (2004) show this for ETFs funds. Bowe and Domuta (2004) also find positive results in the Jakarta stock market. Weiner (2006) finds scarce evidence for herding in the oil market. Demirer and Kutan (2006), together with Tan et al. (2008), study the Chinese market, but they do not find evidence of herding. In the Polish market, Goodfellow et al. (2009) find evidence of individual herding in bear markets, while they do not find evidence for institutional herding. Bohl et al. (2011) observe that restrictions on short-term positions lead to adverse herding in the United States, the United Kingdom, Germany, France, Australia, and South Korea. Economou et al. (2011) detect the presence of herding in Greek, Italian, and Portuguese markets.

With respect to the Spanish market, there are different studies that detect herding: Blasco and Ferreruela (2007, 2008) Lillo et al. (2008), and Blasco et al. (2011).

On the other hand, the state-space model (used in this work) also provides mixed evidence: Gleason et al. (2003) use it on the European futures markets, but the results display absence of herding. Hwang and Salmon (2004) find it in the Korean and American markets. In addition, they clearly observe it when the markets are stable and the investors are sure of the futures markets' direction. The authors conclude that financial crises stimulate a return towards efficiency.

Wang (2008) applies this to various markets (developed and emerging) and concludes that herding in emerging markets is greater than in developed ones.

Demirer et al. (2010) apply some models to the Taiwanese market, obtaining different results depending on the method. These authors find a lack of herding with the linear method (CSSD), but with the nonlinear model (CSAD) and the state-space model, they find strong evidence.

Shapour et al. (2010) also discover such evidence in the Tehran stock market, but no evidence of herding when they study towards size and book-to-market factors.

With regard to studies of herding in collective investment instruments (mutual and pension funds), we observe different analyses:

Oehler and Goeth-Chi (2000) examine German mutual funds that invest on bond market. The results show herding, but to a lesser degree than in the stock market. Kim and Wei (2002) also get positive evidence in domestic and international Korean mutual funds. Voronkova and Bohl (2005) do not detect an influence of Polish pension funds on the stock market. Wylie (2005) examines this behavior in the portfolio holdings of UK equity mutual fund managers, revealing some modest results. Walter and Weber (2006) analyze whether the German mutual fund managers demonstrate this behavior, and their results confirm it. Lobao et al. (2007) obtain evidence in Portuguese mutual funds, detecting a stronger tendency to herd among medium-cap funds, and a decrease when the stock market corrects itself or is more volatile.

Ferruz et al. (2008a, b) notice evidence of this phenomenon in value, growth, and cash stocks in Spanish equity mutual funds. Hsieh et al. (2010) show that mutual funds on 13 emerging Asian countries influence on the existence of herding, and this phenomenon is more pronounced during and after crises; for this reason, they suggest that mutual funds' behavior may have contributed to the crises. Fong et al. (2011) document the existence of herding due to information cascades, in a sample of US equity mutual funds. Jame (2011) examines the magnitude and effects of herding on pension fund price in the United States. Jame uses the measurement proposed by Lakonishok et al. (1992b) and confirms that pension funds are involved on the development of herding.

Given the small number of studies that analyze this topic in pension funds, this paper contributes to the financial literature by studying the influence of Spanish and British pension fund managers in their respective markets.

66.4 Methodology

66.4.1 CAPM and Herding

Herding leads to mispricing so rational decisions may be disturbed through the use of biased beliefs and views of expected returns and risks. More specifically, in the CAPM model, herding produces biased betas, and they deviate from equilibrium.

In order to observe empirically how this phenomenon affects the betas, we take as a starting point the CAPM model in equilibrium:

$$E_t(r_{it}) = \beta_{imt} E_t(r_{mt}) \tag{66.1}$$

where r_{it} and r_{mt} are the excess return of fund i and the excess market return over the risk-free asset during the period t, respectively, β_{imt} is the systematic risk measure, and $E_t(\cdot)$ is the conditional expectation at time t in order to price the fund i.

The CAPM model assumes that β_{imt} does not change over time, despite considerable empirical evidence demonstrating that betas are not constant, among those, Harvey (1989), Ferson and Harvey (1991, 1993), and Ferson and Korajczyk (1995).

Nonetheless, following Hwang and Salmon (2004), the evidence shows that the betas do not change over time in equilibrium, which means that the variation of betas can be interpreted as behavioral anomalies, such as herding, rather than from fundamental changes in the beta or the equilibrium relationship between $E_t(r_{mt})$ and $E_t(r_{it})$.

In this way, the individual cross-sectional dispersion of betas is lower than in equilibrium; given that if all returns were expected to be equal to the market return, all betas would be equal to one and the cross-sectional variance would be zero.

In addition, if we assume that $E_t(r_{mt})$ represents the market as a whole and investor first forms a view of the market as a whole and then considers the value of the individual asset, subsequently the investor's behavior is conditional on $E_t(r_{mt})$ and the observed beta (β_{imt}) will be biased, at least in the short-term, given $E_t(r_{mt})$.

In this way, the biased betas appear because the beliefs of the investors change, they follow the market more than they should in equilibrium, and they ignore the equilibrium relation, trying to match the individual asset returns with the market return. In this case takes place the so-called herding towards the market.

The opposite behavior is also possible, producing adverse herding. This appears when high betas (larger than one) become higher and low betas (smaller than one) become lower. On this occasion, individual return becomes more sensitive for large beta stocks and less sensitive for low beta stocks. This leads to a reversion in the long-term equilibrium of β_{imt}. In fact, adverse herding should exist if herding exists, since there must be some systematic adjustment back to the CAPM equilibrium.

66.4.2 Measuring Herding

When there is herding in the market portfolio, the CAPM equilibrium does not occur, and both beta and expected return are biased. Therefore, instead of the equilibrium in (1), Hwang and Salmon (2004) assume that the following relation is produced in presence of herding towards the market:

$$\frac{E_t^b(r_{it})}{E_t(r_{mt})} = \beta_{imt}^b = \beta_{imt} - h_{mt}(\beta_{imt} - 1) \tag{66.2}$$

where $E_t^b(r_{it})$ is the market's biased short run conditional expectation on the excess returns of fund i, β_{imt}^b is the market beta at time t in the presence of herding, and h_{mt} is a latent herding parameter that changes over time, less than one ($h_{mt} \leq 1$) and conditional on market fundaments.

When $h_{mt} = 0$, then $\beta_{imt}^b = \beta_{imt}$, and herding does not exist, producing the CAPM equilibrium. However, when $h_{mt} = 1$, then $\beta_{imt}^b = 1$, it is perfect herding towards the market portfolio in the sense that all individual funds move in the same direction and magnitude as the market portfolio.

In general, when the herding parameter (h_{mt}) is between zero and one ($0 < h_{mt} < 1$), a certain degree of herding exists in the market, determined by the magnitude of the herding coefficient.

Considering the situation described in the previous section, the relationship between the real and biased expected excess fund returns and its beta can be explained.

Therefore, for a fund with $\beta_{imt} > 1$, then $E_r(r_{it}) > E_t(r_{mt})$, and the fund presents herding towards the market, so that $E_t^b(r_{it})$ moves towards $E_t(r_{mt})$, and $E_r(r_{it}) > E_t^b(r_{it}) > E_t(r_{mt})$. As a result, the fund seems less risky than it should be, suggesting that $\beta_{imt}^b < \beta_{imt}$.

On the other hand, for a fund with $\beta_{imt} < 1$, it gives $E_r(r_{it}) < E_t(r_{mt})$, and the fund presents herding towards the market when $E_t^b(r_{it})$ moves towards $E_t(r_{mt})$, which is why $E_r(r_{it}) < E_t^b(r_{it}) < E_t(r_{mt})$. The fund seems riskier than it should be, suggesting that $\beta_{imt}^b > \beta_{imt}$.

Finally, for a fund with a beta equal to one, $\beta_{imt} = 1$, the fund is neutral to herding.

As we have already mentioned, the existence of herding implies adverse herding, allowing $h_{mt} < 0$; therefore, for a fund with $\beta_{imt} > 1$, then $E_t^b(r_{it}) > E_r(r_{it}) > E_t(r_{mt})$, while a fund with $\beta_{imt} < 1$ will produce the following: $E_t^b(r_{it}) < E_r(r_{it}) < E_t(r_{mt})$.

66.4.3 Models for Measuring Herding

Herding of a market portfolio can be captured with the parameter h_{mt} of the expression (66.2); however, neither the beta nor the herding parameter is observed.

For this reason, we use state-space models in order to extract those parameters. As we aim to measure herding in terms of the market as a whole, we assume that the Eq. 66.2 captures all of the market assets, so we can calculate herding using all of the assets and not only one, eliminating the effects of the idiosyncratic movements of individual betas (β_{imt}^b).

Since the cross-sectional mean of the betas (β_{imt}^b or β_{imt}) is always one, Hwang and Salmon (2004) show that

$$
\begin{aligned}
Std_c\left(\beta_{imt}^b\right) &= \sqrt{E_c\left((\beta_{imt} - h_{mt}(\beta_{imt} - 1) - 1)^2\right)} \\
&= \sqrt{E_c\left((\beta_{imt} - 1)^2\right)}(1 - h_{mt}) = Std_c(\beta_{imt})(1 - h_{mt}) \qquad (66.3)
\end{aligned}
$$

where $E_c(\cdot)$ represents the cross-sectional expectation, $Std_c(\beta^b_{imt})$ is the cross-sectional standard deviation of the beta in equilibrium, and $\sqrt{E_c\left((\beta_{imt} - h_{mt}(\beta_{imt} - 1) - 1)^2\right)}$ is a direct function of the herding parameter.

In order to minimize the impact of the idiosyncratic changes in β_{imt}, a great number of assets are used in the calculation of $Std_c(\beta_{imt})$, so $Std_c(\beta_{imt})$ will be stochastic in order to observe the movements in the equilibrium beta.

Nonetheless, as it is expected that the market as a whole $Std_c(\beta_{imt})$ does not change significantly in the short term, unless the structure of companies changes suddenly, it is assumed that $Std_c(\beta_{imt})$ does not exhibit any systematic movement and that the changes in $Std_c(\beta^b_{imt})$ in the short term are due to the changes in h_{mt}, that is to say, due to the presence of herding.

66.4.4 The State-Space Models

In the previous section, we remark that the herding parameter is not observed, so we apply state-space models. Those models may be estimated by using the Kalman filter, which is an algorithm to perform filtering on the state-space model.

In order to extract herding from model (66.3), we follow the procedure used by Hwang and Salmon (2004). First, taking logarithms of (66.3)

$$\log\left[Std_c\left(\beta^b_{imt}\right)\right] = \log[Std_c(\beta_{imt})] + \log(1 - h_{mt}) \tag{66.4}$$

and considering the assumptions carried out for $Std_c(\beta_{imt})$, it is rewritten like this:

$$\log\left[Std_c\left(\beta^b_{imt}\right)\right] = \mu_m + \upsilon_{mt} \tag{66.5}$$

where $\mu_m = E[\log[Std_c(\beta_{imt})]]$ and $\upsilon_{mt} \sim iid(0, \sigma^2_{m\upsilon})$, then

$$\log\left[Std_c\left(\beta^b_{imt}\right)\right] = \mu_m + H_{mt} + \upsilon_{mt} \tag{66.6}$$

where $H_{mt} = \log(1 - h_{mt})$.

Therefore, we suppose that the herding (H_{mt}) evolves over time and follows a dynamic process; for example, assuming a mean zero AR(1), we obtain the model (66.7):

$$\log\left[Std_c\left(\beta^b_{imt}\right)\right] = \mu_m + H_{mt} + \upsilon_{mt} \tag{66.7}$$

$$H_{mt} = \phi_m H_{mt-1} + \eta_{mt}$$

where $\eta_{mt} \sim iid(0, \sigma^2_{m\eta})$.

As a result, we have a standard state-space model, similar to those used in stochastic volatility modeling which is estimated using the Kalman filter. Furthermore, we focus on the movements of the latent variable (H_{mt}).

It should be observed that when $\sigma^2_{m\eta} = 0$, the model (66.7) becomes

$$\log\left[Std_c\left(\beta^b_{imt}\right)\right] = \mu_m + \upsilon_{mt} \tag{66.8}$$

This means that herding does not exist, so $H_{mt} = 0$ for all t.

A significant value of $\sigma^2_{m\eta}$ can be interpreted as the existence of herding, and a significant value of ϕ supports the autoregressive structure considered.

A restriction is that the herding process (H_{mt}) should be stationary, and as we do not expect herding to be an explosive process towards the market portfolio, it must be $|\phi_m| \leq 1$.

66.4.5 Herding with Market and Macroeconomic Variables

We explain above that $Std_c(\beta^b_{imt})$ changes over time depending on the level of herding in the market. However, it is interesting to study whether this behavior, extracted from $Std_c(\beta^b_{imt})$, is robust in the presence of variables that reflect the state of the market: the degree of volatility, the market return, or potential variables that reflect macroeconomic fundamentals.

Therefore, if the herding parameter becomes insignificant when these variables are included, then the changes in $Std_c(\beta^b_{imt})$ could be explained by changes in the fundamentals rather than herding.

In order to consider the influence of market volatility and market return, Hwang and Salmon (2004) include them as independent variables in the model (66.7), obtaining the model (66.9):

$$\log\left[Std_c\left(\beta^b_{imt}\right)\right] = \mu_m + H_{mt} + c_{m1}\log\ \sigma_{mt} + c_{m2}r_{mt} + \upsilon_{mt} \tag{66.9}$$

$$H_{mt} = \phi_m H_{mt-1} + \eta_{mt}$$

where $\log\sigma_{mt}$ and r_{mt} are the market log volatility and the market return at time t, respectively.

In a second step, Hwang and Salmon (2004) include the factors of the Fama and French (1993) in the model (66.9). Nevertheless, we also include the four factors of Carhart's (1997) model, considering the size (SMB), book-to-market (HLM), and momentum (PR1YR) factors, as model (66.10) exhibits:

$$\begin{aligned}\log\left[Std_c\left(\beta^b_{imt}\right)\right] = {} & \mu_m + H_{mt} + c_{m1}\ \log\ \sigma_{mt} + c_{m2}r_{mt} + c_{m3}SMB_t + c_{m2}HML_t \\ & + c_{m3}PR1YR + \upsilon_{mt}\end{aligned}$$

$$H_{mt} = \phi_m H_{mt-1} + \eta_{mt} \tag{66.10}$$

Lastly, we add three macroeconomic variables to the model (66.9) – dividend yield (DY), time spread (TS), and the short-term interest rate (STIR), in order to consider information variables representative of the economic cycle:

$$\begin{aligned}\log\left[Std_c\left(\beta^b_{imt}\right)\right] &= \mu_m + H_{mt} + c_{m1}\log\sigma_{mt} + c_{m2}r_{mt} + c_{m6}DY_t + c_{m7}TS_t \\ &\quad + c_{m8}STIR_t + \upsilon_{mt} \\ H_{mt} &= \phi_m H_{mt-1} + \eta_{mt} \end{aligned} \tag{66.11}$$

66.4.6 Generalized Herding Measurement in Linear Factor Models

In the previous section, we observe that we can measure herding in any factor, employing linear factor models. Therefore, supposing that the excess return of the fund i (r_{it}) follows this linear model:

$$r_{it} = \alpha^b_{it} + \sum_{k=1}^{K} \beta^b_{ikt\ f kt} + \varepsilon_{it}, i = 1, \ldots, N \text{ y } t = 1, \ldots, \mathrm{T} \tag{66.12}$$

where α^b_{it} is the intercept that changes over time, β^b_{ikt} are the coefficients on factor k at time t, f_{kt} is the realized value of factor k at time t, and ε_{it} has a mean zero with a variance σ^2_ε.

The factors in model (66.12) may be risk-specific factors or factors to detect an anomaly. One factor included is the excess market return, as in the conventional linear factor models.[1]

The superscript b on the betas indicates that they are biased betas under herding; therefore, the herding towards the factor k at time t can be captured by (66.13):

$$\beta^b_{ikt} = \beta_{ikt} - h_{kt}(\beta_{ikt} - E_c[\beta_{ikt}]) \tag{66.13}$$

where $E_c[\beta_{ikt}]$ is the cross-sectional expected beta for factor k at time t.

66.4.7 Robust Estimate of the Betas

The first step to calculate the different models considered is to estimate the market betas from the CAPM model (66.14) and from the four-factor Carhart model (66.15):

$$r_{it} = \alpha^b_{it} + \beta^b_{imt} r_{mt} + \varepsilon_{it} \tag{66.14}$$

[1]It should be clear that the linear factor model used does not require that the market is in equilibrium or efficient.

$$r_{it} = \alpha_{it}^{b} + \beta_{imt}^{b} r_{mt} + \beta_{iSt}^{b} SMB_t + \beta_{iHt}^{b} HML_{Ht} + \beta_{iPt}^{b} PR1YR_{Mt} + \varepsilon_{it} \tag{66.15}$$

With these betas we obtain the estimated cross-sectional standard deviation of the betas, and these are used in the state-space model.

Although the ordinary least squares (OLS) estimation is the most common technique to estimate the beta, this has some drawbacks. Firstly, they behave badly when the errors are not from a normal i.i.d. distribution, particularly when the data is heavily tailed, which are very frequent in return data. Furthermore, the existence of outliers may also influence on the OLS beta, thus leading to a distorted perspective on the relationship between asset returns and index returns.

In order to overcome these disadvantages and provide a better fit, Martín and Simin (2002) indicate that a robust estimation of beta should be implemented. One robust regression is the M-estimation method thorough the Huber estimation.

With the different betas estimated, we obtain the cross-sectional standard deviation of the betas on the market portfolio as

$$Std_c\left(\hat{\beta}_{imt}^{b}\right) = \sqrt{\frac{\sum_{i=1}^{N_t}\left(\hat{\beta}_{imt}^{b} - \overline{\hat{\beta}_{imt}^{b}}\right)^2}{N_t}} \tag{66.16}$$

where $\overline{\hat{\beta}_{imt}^{b}} = \frac{1}{N_t}\sum_{i=1}^{N_t}\hat{\beta}_{imt}^{b}$ and N_t is the number of funds in the month t.

Finally, we estimate the four state-space models considered: (66.7), (66.9), (66.10), and (66.11), with the standard deviation of the betas.

66.5 Data and Empirical Results

66.5.1 Data

The database was provided by Thomson Reuters. The data comprises the monthly returns obtained by all private pension funds with European equity investment vocation registered for sale in Spain (84 pension funds) and in the United Kingdom (690 pension funds).

The time period analyzed is from January 1999 to September 2010. We require that the pension funds present data for at least 24 months to ensure the consistency of the analyses. In this way, our database is free of the so-called survivorship bias.

The market benchmark used is the MSCI Europe index, given the European equity vocation of the pension funds, and it is necessary to use European benchmark portfolio to assess performance on an appropriate basis. The representative variable for risk-free asset is the 1-month Euribor rate.

The macroeconomic variables used are as follows:

- *Dividend yield*[2] is the ratio between the dividends paid out by the MSCI Europe in the previous 12 months and the current index price.
- *Time spread* is the annualized difference between the return on the EMU 10-year bond[3] and the 3-month Euribor rate.
- *Short-term interest rate* is the 3-month Euribor rate.

In the investment style analysis, we consider the four factors of the Carhart (1997) model: excess market return, size (SMB), book-to-market (HML), and momentum (PR1YR).

We follow the instructions by Fama and French (1993) to build the size and book-to-market factors. In regard to the size factor (SMB_t), we build the mimicking portfolio as the difference between the portfolio made up of the MSCI Europe small value price, MSCI Europe small core price, and MSCI Europe small growth price indices and the portfolio made up of the MSCI Europe large value price, MSCI Europe large core price, and MSCI Europe large growth price indices.

In relation with the book-to-market factor (HML_t), with the monthly returns obtained by the indices, the mimicking portfolio is the difference between the portfolio made up of the MSCI Europe small value price and MSCI Europe large value price indices and the portfolio made up of the MSCI Europe small growth price and MSCI Europe large growth price indices.

Finally, the 1-year momentum factor ($PR1YR_t$) is approached following the Carhart instructions, in our case, with the monthly returns obtained by a group of market indices representative of the geographic universe studied. As we analyze European equity funds, we use the 16 MSCI indices of the countries integrated in the MSCI Europe index: Austria, Belgium, Denmark, Finland, France, Germany, Greece, Ireland, Italy, the Netherlands, Norway, Portugal, Spain, Sweden, Switzerland, and the United Kingdom. All of the indices have been obtained from the official MSCI website.

Based on these 16 market indices, we build the equal-weight average of indices with the highest 30 % (five) 11-month returns, lagged 1 month, minus the equal-weight average of indices with the lowest 30 % (five) 11-month returns, lagged 1 month.

The descriptive statistics of the different risk factors are displayed on Table 66.1.

The Table 66.1 reveals that the excess market return is the factor with least mean return, presenting the minimum negative value. Nonetheless, the maximum value is also found in this factor; hence the standard deviation is somewhat greater than the rest.

[2]For its calculation we apply the difference between the monthly return obtained by the corresponding MSCI gross and the MSCI price; then we obtain the total of the 12 previous values for a determined month. Information obtained from MSCI: http://www.msci.com/

[3]Data obtained from the Bank of Spain: www.bde.es

Table 66.1 Properties of the risk factors

Variable	Average	Standard deviation	Minimum	Maximum	Kurtosis	Skewness
Market excess return	−0.0005	0.0488	−0.1350	0.1323	3.5650	−0.3032
SMB	0.0051	0.0269	−0.0813	0.0858	3.8340	−0.3169
HML	0.0017	0.0254	−0.0896	0.0972	6.2798	0.3345
PR1YR	0.0042	0.0392	−0.1146	0.1106	3.4888	−0.1526

This table includes the main statistics (average, standard deviation, minimum, maximum, kurtosis, and skewness) for the four risk factors calculated: market excess return, size (SMB), book-to-market (HML), and momentum (PR1YR)

With respect to kurtosis, it is high in all factors (greater than three), indicating leptokurtosis, and therefore, they are not Gaussian. Furthermore, it is also remarkable the negative skewness on all factors.

66.5.2 Empirical Results

Firstly, we estimate the betas of the models (66.14) and (66.15), and next we calculate the cross-sectional deviations, as we describe in Sect. 66.4.7.

The main characteristics of the standard deviations of the estimated betas are reflected in Table 66.2. This table differentiates between the market betas from the CAPM model and the market betas from the Carhart four-factor model. All of them are estimated with the Huber robust technique.

The first two columns of Table 66.2 show all cross-sectional standard deviations of the market betas: $Std_c\left(\hat{\beta}^b_{imt}\right)$. These are significantly different from zero in all cases. However, the betas from the CAPM model present negative skewness, while the skewness is positive in the market betas from the four-factor model, which is common in series with volatility. We also observe a high kurtosis, revealing non-normality. This is confirmed with the Jarque-Bera test, as we reject the null hypothesis of normality; therefore, the standard deviation of the betas is not Gaussian.

The correlation between these two market betas is high; then, if there is herding, this may reveal similar herding between models.

Finally, the properties of the cross-sectional deviations of the betas of the SMB, HML, and PR1YR factors also exhibit similar properties: they are not normal and negative skewness.

66.5.2.1 Results of Herding Towards the Market Factor

In this section we study the herding towards the market factor; that is to say, we start from the market betas of the CAPM and the four-factor models; after that, we calculate the standard deviation of the betas: $Std_c(\beta^b_{imt})$, and with these, we estimate the models (66.7), (66.9), (66.10), and (66.11).

The results of these models are displayed on Tables 66.3 and 66.4 for the Spanish and British pension funds, respectively.

Table 66.2 Properties of the cross-sectional standard deviation of estimated betas

Correlation A–B	0.8935				

This table is divided into two panels (A and B), corresponding to the Spanish and British pension funds. Each panel includes the main statistics (average, standard deviation, minimum, maximum, kurtosis, skewness, and Jarque-Bera normality test) of the cross-sectional standard deviation for the estimated market betas in the CAPM model and the four betas of Carhart (1997) model: market, size (SMB), book-to-market (HML), and momentum (PR1YR) betas. *** represents significance at 1 % level

We interpret the significance of the market variables included in the models (66.9), (66.10), and (66.11) as adjustment in the mean level (μ_m) of $\log[Std_c(\beta^b_{imt})]$ on the equation without herding, so we examine the degree of herding given the state of the market.

The Spanish results (Table 66.3) display that the model (66.7), both in the case of the market betas of the CAPM model as in Carhart model, presents evidence of quite persistent herding, as the coefficient $\hat{\phi}_m$ is large and significant.

Likewise, the standard deviation of n_{mt} (σ_{mn}) is significant; therefore, given the level of market volatility and return, Spanish pension funds lead to herding towards the market portfolio.

The coefficients of the model (66.9) show that the herding is still significant when the two market variables are included: volatility and return, which suggests that the changes in the volatility of the sensitivity factor $[Std_c(\beta^b_{imt})]$ can be explained by herding rather than by changes in fundamentals.

Table 66.3 Estimates of state-space models for herding towards the market factor in Spain

This table displays the estimates of the state-space models for herding towards the market factor in the Spanish pension funds for the period from January 1999 to September 2010. The first column exhibits model (66.7) results, calculated with the market return beta from the CAPM model. The second, third, fourth, and fifth columns show the results for the models (66.7), (66.9), (66.10), and (66.11) estimated with the market return beta from the four-factor Carhart (1997) model. SMB represents the size factor, HML is the book-to-market factor, PR1YR is the momentum factor, DY is the dividend yield, TS is the time spread, and STIR is the short-term interest rate

*, **, and *** represent significance at 10 %, 5 %, and 1 % level, respectively

This table displays the estimates of state-space models for herding towards the market factor in the UK pension funds for the time period from January 1999 to September 2010. The first column exhibits model (66.7) results, calculated with the market return beta from the CAPM model. The second, third, fourth, and fifth columns show the results for the models (66.7), (66.9), (66.10), and (66.11), estimated with the market return beta from the four-factor Carhart (1997) model. SMB represents the size factor, HML is the book-to-market factor, PR1YR is the momentum factor, DY is the dividend yield, TS is the time spread, and STIR is the short-term interest rate

*, **, and *** represent significance at 10 %, 5 %, and 1 % level, respectively

Therefore, the betas' deviation decreases when the market volatility rises, but increases with the level of market return, as the logarithm of market volatility and the market return have significant negative and positive coefficients, respectively.

As a result, when the market becomes riskier and is falling, $Std_c(\beta^b_{imt})$ decreases, while it increases when the market becomes less risky and rises. Therefore, a reduction in the standard deviation due to the herding process suggests that herd behavior is significant and exists independently of a particular state of the market.

The model (66.10) includes the SMB, HML, and PR1YR factors as explanatory variables, but none of them is significant. Moreover, the herding ($\hat{\phi}_m$) increases, so the results are very similar to those of the previous models.

Model (66.11) includes three macroeconomic variables, but none of them is significantly different to zero. Nonetheless, the herding is still persistent because the coefficient $\hat{\phi}_m$ is significant.

On the other hand, the UK results are reported in Table 66.4, where the coefficients $\hat{\phi}_m$ and σ_{mn} are significant and persistent. Equally, the additional variables of the models (66.10) and (66.11) are not significant.

Nonetheless, the market variables (logarithm of the volatility and market return) present signs contrary to the previous results, that is to say, positive and negative, respectively. Nevertheless, these results are consistent with previous studies, which find that herding arises most likely during market instability, in other words, periods of high volatility.

As a consequence, we obtain evidence of herding in the two countries analyzed. Nonetheless, we do not observe significant differences between herding models, as the factors of the investment styles or macroeconomic variables are not significant.

Therefore, herding is not influenced by the size of the company, the relation between book equity and market equity, or the momentum strategy. However, herding varies with the model applied; so the inclusion of additional variables is useful, but does not provide more information.

66.5.2.2 Results of Herding Towards Size, Book-to-Market, and Momentum Factors

Starting with the betas estimated for the different factors (size, book-to-market, and momentum) of the four-factor Carhart model (66.15), we also calculate the standard deviation of these betas: $Std_c(\beta^b_{iSt})$, $Std_c(\beta^b_{iHt})$, and $Std_c(\beta^b_{iPR1YRt})$.

After that, we repeat the above analysis, but, in this case, we study the herding towards the size, book-to-market, and momentum factors.

The results of these analyses are very similar to the previous one; consequently we do not display them,[4] but we show a summary in Table 66.5, indicating if the variables of the different models are significant. Nonetheless, next we discuss the different results.

[4]These tables are available upon request.

Table 66.5 Summary of the state-space models for herding towards style factors in Spain and the United Kingdom

	Herding towards SMB factor		Herding towards HML factor		Herding towards PR1YR factor	
	Spain	United Kingdom	Spain	United Kingdom	Spain	United Kingdom
Existence of herding	Yes, + and significant	Yes, + and significant	Yes, + and significant	Yes, + and significant	Yes, + and significant	Yes, + and significant
Market volatility	Signif.	Signif.	Signif.	Signif.	Signif.	Signif.
Market return	Signif.	Signif.	Signif.	Signif.	Signif.	Signif.
SMB	No signif.	No signif.	No signif.	No signif.	No signif.	No signif.
HML	No signif.	No signif.	No signif.	No signif.	No signif.	No signif.
PR1YR	No signif.	No signif.	No signif.	No signif.	No signif.	No signif.
DY	No signif.	No signif.	No signif.	No signif.	No signif.	No signif.
TS	No signif.	No signif.	No signif.	No signif.	No signif.	No signif.
STIR	No signif.	No signif.	No signif.	No signif.	No signif.	No signif.

This table displays a summary of the state-space models for herding towards the style factors (size, book-to-market, and momentum) in Spain and the United Kingdom, indicating the existence of herding and if the variables of the different models (66.7), (66.9), (66.10), and (66.11) are significant (signif.) or not significant (no signif.)

We find the same behavior in all factors: existence of herding and the herding coefficients ($\hat{\phi}_S$, $\hat{\phi}_H$, $\hat{\phi}_{PR1YR}$) are greater than 0.7, on average. Likewise, all standard deviations are highly significant and persistent ($\sigma_{s\eta}$, $\sigma_{H\eta}$ $\sigma_{PR1YR\eta}$).

However, we notice less degree of herding towards the book-to-market in the Spanish pension funds, presenting a parameter $\hat{\phi}_H$ around 0.3. This behavior is also perceived in the case of the herding towards the momentum factor in Spain and the United Kingdom, where the coefficient $\hat{\phi}_{PR1YR}$ is 0.6, on average.

Although the herding is less intense in these cases, the phenomenon is still significant towards the size (H_{St}), book-to-market (H_{Ht}), and momentum (H_{PR1YRt}) factors, and the results are similar to the herding towards the market (H_{mt}).

Furthermore, we also observe that the additional variables of the four-factor model (66.10) and the macroeconomic variables of the model (66.11) are not significant.

Lastly, the logarithms of market volatility and the market return, especially the latter, explain less the cross-sectional standard deviation of the SMB, HML, and PR1YR betas, as the market return is less significant or not significant.

66.5.2.3 Relationship Between the Herding Towards Factors and Countries

As in the previous section we find similar herding towards factors and between countries, we study the herding patterns in greater detail in Table 66.6, displaying the correlations between the different herding coefficients (coefficients of herding towards the market, size, book-to-market, and momentum factors).

Table 66.6 Relation between the herding of different pension funds in each country

	Spain market	Spain SMB	Spain HML	Spain PR1YR	UK market	UK SMB	UK HML	UK PR1YR
Spain market	1							
Spain SMB	-0.255^{***}	1						
Spain HML	-0.156^{***}	-0.005^{***}	1					
Spain PR1YR	-0.134^{***}	0.111^{***}	0.093^{***}	1				
UK market	0.053^{***}	0.075^{***}	0.022^{**}	0.286^{***}	1			
UK SMB	-0.012^{***}	0.009	-0.068^{***}	-0.051^{***}	0.099^{***}	1		
UK HML	-0.045^{***}	-0.057^{***}	0.041^{***}	0.082^{***}	-0.009^{***}	0.118^{***}	1	
UK PR1YR	0.034^{***}	0.050^{***}	-0.230^{***}	-0.096^{***}	0.129^{***}	0.078^{***}	0.128^{***}	1

This table represents the correlation coefficients of herding measures towards different factors: market return (represented as market), size (SMB), book-to-market (HML), and momentum (PR1YR), from model (66.9) in the different factors and pension funds in Spain and the United Kingdom

*, **, and *** represent significance at 10 %, 5 %, and 1 % level, respectively

Although we do not display the herding towards the last three factors in the previous section, we calculate the correlation between their coefficients, considering the herding measures obtained in the model (66.9), as they are more significant, in general.

This table exhibits the correlation between herding towards factors (h_{mt}, h_{St}, h_{Ht}, and h_{PR1YRt}) at 5 % significance level.

The results show that among the 36 pairwise correlation coefficients, 15 are significantly positive, 12 are significantly negative, and 4 are not significant. We also detect positive negative correlations between common factors in both countries, except in the momentum factor, so we notice international herding.

Overall, we notice more positive correlation between the UK factors and between Spanish and the UK factors than between Spanish factors.

In conclusion, we observe a relationship between the herding coefficients for the same factor in Spain and the United Kingdom.

66.6 Conclusions

The pension fund industry has acquired great significance in recent years, especially in Europe, due to doubts about the future viability of public pensions. For this reason, more works focus on their study, especially in the analysis of their performance and the manager behavior.

However, it is also interesting to study the consequences of their investment on the market, as it can affect the market efficiency. Specifically, we study the existence of herding, a phenomenon that arises when investors decide to imitate the observed decisions of others, instead of following their own beliefs and information. This phenomenon can lead to a situation in which market prices do not reflect all of the information and the market moves towards inefficiency.

We analyze whether the behavior of the pension fund managers studied arises the herding behavior in the equity markets of Spain and the United Kingdom, applying a focus less used in financial literature: the estimated cross-sectional of standard deviations of market betas.

The estimation technique is also less common because we use the state-space models, employing the Kalman filter. Furthermore, in order to carry out a robust estimation of the beta from the CAPM model and from the four-factor model of Carhart (1997), we implement the robust M-estimation with Huber estimator.

We apply different models in order to analyze the existence of herding. Firstly, we only detect the existence and persistence of the phenomenon. After that, we add two market variables (volatility and return), then three style factors (size, book-to-market, momentum), and finally, three macroeconomic variables (dividend yield, time spread, and short-term interest rate), in order to examine their influence on herding.

In addition, we check the existence of herding towards the size, book-to-market, and momentum factors; for this purpose, we use the estimated betas of these factors in Carhart's model. The analysis of the momentum factor is innovative, as we do not find previous studies that analyze this aspect.

The results obtained are similar for the two countries studied, as well as for the different types of investment. These reveal the existence of herding towards the market and the style factors, showing significant movements and persistence independently from and given market conditions. Nonetheless, this effect is smaller in the case of herding towards the different style factors.

Additionally, we do not find relevant influence of the macroeconomic variables, nor the style factors with any of the different models, so these variables do not significantly influence herding. As a consequence, we note that herding arises regardless of the company size, its situation (growing or not), as well as the implemented strategies.

Hence, as we only study equity pension funds, we confirm that the Spanish and British pension fund managers influence the degree of herding in the stock markets.

Moreover, we find the existence of herding in all models and markets, so pension fund managers encourage the existence of herding towards the market, size, book-to-market, and momentum factors. As a consequence, managers follow the performance of the market and the different styles more than they should in equilibrium, so they move towards matching the return on individual assets with that of the market and styles. Additionally, we discover a relationship between the herding coefficients for the same factor in Spain and the United Kingdom.

As a result, the behavior of Spanish and British pension fund managers influences the market and, consequently, the performance of pension funds.

Appendix 1: The State-Space Models

We remark that the herding parameter is not observed, so in order to extract herding parameter we apply state-space models.

A state-space model is defined by two equations:

$$Y_t = c + SX_t + e_t \tag{66.17}$$

$$X_t = d + HX_{t-1} + z_t \tag{66.18}$$

where:

X_t is the hidden vector at time *t*.

Y_t is the observation vector at time *t*.

c and *d* are vectors with constants.

e is the error.

z is the state error.

e and *z* are both multivariate normally distributed, with mean zero and covariance matrices of R and Q, respectively.

Those models can be estimated by using the Kalman filter, which is an algorithm to perform filtering on the state-space model.

The estimate of the state equation by the Kalman filter algorithm also offers a smoothing time series, by performing fixed interval smoothing, i.e., computing $Y_{t|t} = P[Y_t|Y_1, \ldots, Y_{t-1}]$ for $t \leq T$.

The objective is, in the formula (66.17), to minimize the difference between the observation Y_t, and the prediction based on the previous observations, ($Y_{t|t} = P[Y_t|Y_1, \ldots, Y_{t-1}]$) by recursive maximum likelihood estimation.

The Kalman filter can be considered as an online estimation procedure, which is used to estimate the parameters online when new observations are entered after they have already been estimated. On the other hand, the smoothed Kalman filter is a method only used when the total series are observed.

The Kalman filter results are close to the maximum likelihood estimates, while the smoother results are exact to the maximum likelihood estimates.

Appendix 2: Robust Estimate of the Betas

In order to calculate the different betas from the CAPM model and from the four-factor Carhart model, the ordinary least squares (OLS) estimation is the most common technique for estimating betas; however, this has some drawbacks.

Firstly, they behave badly when the errors are not from a normal i.i.d. (independent and identically distributed) distribution, particularly when the data is heavily tailed, which are very frequent in return data.

Furthermore, the existence of outliers may also influence on the OLS beta, thus leading to a distorted perspective on the relationship between asset returns and index returns.

In order to overcome these disadvantages and provide a better fit, Martín and Simin (2002) indicate that a robust estimation of beta should be implemented. One of the most commonly applied methods of robust regression is the M-estimation method, a generalization of maximum likelihood estimation.

In order to explain this estimate method, we considered a linear model as a starting point:

$$y_i = X_i\beta + \varepsilon_i \tag{66.19}$$

where $i = 1,.., n$

Thus, the fitted model is

$$y_t = X_t b + e_t \tag{66.20}$$

The M-estimate principle is to minimize the objective function:

$$\sum_{i=1}^{n} \rho(e_i) = \sum_{i=1}^{n} \rho(y_i - X_i b) \tag{66.21}$$

where the function $\rho(.)$ gives the contribution of each residual to the objective function.

Table 66.7 Objective functions and weight functions for the ordinary least squares estimation and the Huber estimation

Estimation method	Objective function (ρ)	Weight function (w_i)
Ordinary least square (OLS)	e^2	1
Huber estimation	$e^2/2$ when $\|e\| \le k$	1 when $\|e\| \le k$
	$k\|e\| - k^2/2$ when $\|e\| > k$	$k/\|e\|$ when $\|e\| > k$

This table compares the objective functions and weight functions for the ordinary least squares estimator and the Huber estimator

If we define $\psi = \rho'$, as the first order derivative of $\rho(.)$, by differentiating the objective function with respect to b and setting the partial derivatives to zero, we obtain a system of estimating equations:

$$\sum_{i=1}^{n} \psi(y_i - X_i b) X_i' = 0 \tag{66.22}$$

If the weight function is $w(e) = \psi(e)/e$ and $w_i = w(e_i)$, the estimating equations become

$$\sum_{i=1}^{n} w_i e_i X_i' = 0 \tag{66.23}$$

These equations can be solved as a weighted least squares problem, with the objective of minimizing:

$$\sum_{i=1}^{n} w_i^2 e_i^2 \tag{66.24}$$

The weights depend on the residuals, the residuals depend on the estimated coefficients, and the estimated coefficients depend on the weights, so an iteration procedure is needed in order to solve the problem.

To solve this iterative procedure, we apply the Huber estimation, given that this allows us to determine the weighted, the residuals, and the estimated coefficients.

In order to compare the OLS estimator with the robust Huber estimator, Table 66.7 distinguishes the objective functions and weighted functions for each one of the methods.

In Table 66.7 we observe that both functions increase without bound, as the residuals departs from zero; nonetheless, the Huber objective function increases more slowly.

In fact, the least squares assigns equal weight to each observation, but the weights of the Huber estimator decline for $|e| > k$, where e is the residual term and k is called a tuning constant for the Huber estimation.

In the OLS estimation, a smaller k parameter provides more resistance to outliers; however, it offers a lower efficiency when the errors are normally distributed. In contrast, with Huber estimation, k has a general value of $k = 1.345\ \sigma$

(where σ is the conventional standard deviation), producing 95 % efficiency when the errors are normal, and it also offers protection against outliers; therefore, this estimation is better than the OLS estimation.

Estimating the Correlation of Asset Returns: A Quantile Dependence Perspective

67

Nicholas Sim

Contents

Abstract

In the practice of risk management, an important consideration in the portfolio choice problem is the correlation structure across assets. However, the correlation is an extremely challenging parameter to estimate as it is known to vary substantially over the business cycle and respond to changing market conditions. Focusing on international stock markets, I consider a new approach of estimating correlation that utilizes the idea that the condition of a stock market is related to its return performance, particularly to the conditional quantile of its return, as the lower return quantiles reflect a weak market while the upper quantiles reflect a bullish one.

Combining the techniques of quantile regression and copula modeling, I propose the *copula quantile-on-quantile regression* (C-QQR) approach to construct the correlation between the conditional *quantiles* of stock returns. The C-QQR approach uses the copula to generate a regression function for modeling the dependence between the conditional quantiles of the stock returns under consideration. It is estimated using a two-step quantile regression

procedure, where in principle, the first step is implemented to model the conditional quantile of one stock return, which is then related in the second step to the conditional quantile of another return. The C-QQR approach is then applied to study how the US stock market is correlated with the stock markets of Australia, Hong Kong, Japan, and Singapore.

67.1 Introduction

In the practice of risk management, an important consideration in the portfolio choice problem is the correlation structure across assets. The correlation is especially crucial for conveying the level of portfolio risk as it is the parameter that underscores the extent of how well diversified a given portfolio is. Nevertheless in practice, estimating the actual level of correlation is a notoriously difficult task, where existing research has overwhelmingly shown that the true correlation, be it the correlation of equities, bonds, and exchange rates, may fluctuate significantly over the business cycle and during extreme events.[1] Over the past two decades, the literature has offered new ways of estimating asset correlation that depart from the premise that the correlation is constant. To complement these existing methodologies, this chapter offers a new perspective based on the concept of dependence between conditional quantiles to motivate a new approach of modeling correlation structure that takes into account that the correlation may be sensitive to the performance of financial markets.

Since the early findings of Erb et al. (1994) and Longin and Solnik (1995), among others, it is well accepted among academics and practitioners that the correlation may respond to changing economic circumstances.[2] A prime example can be found in the study of how international equity markets are dependent, where the literature has provided ample evidence that the level of dependence tends to be

[1]For instance, equity returns are more highly correlated during business cycle downturns and bear markets (Erb et al. 1994; Longin and Solnik 1995, 2001; Ang and Chen 2002); the same is true for exchange rates returns (Patton 2006; Bouyè and Salmon 2009). Likewise, the deviation in the stock-bond correlation during bear markets is documented by Guidolin and Timmermann (2005).

[2]For example, Erb et al. (1994) examine the dependence of G-7 equity stock markets by computing semicorrelations and find that the correlation is generally larger when the equity returns and output growth of these countries are below than above their respective means, thus when the economies and financial markets in these countries are bearish. Longin and Solnik (1995) examine the dependence of the market returns of Switzerland plus G-7, less Italy, by using a version of the multivariate GARCH model to show that the correlation is larger in times of greater market uncertainties.

stronger when markets become bearish (e.g., Erb et al. 1994). In order to capture such salient features about correlation, it is important to address the possibility that the actual level of correlation is contingent on current market conditions. Recent techniques of modeling asset dependence are developed with this objective in mind. They include regimes-witching frameworks to model jumps in correlation between normal and bearish states (e.g., Ang and Bekaert 2002; Guidolin and Timmermann 2005); extreme value theory that facilitates estimating the level of dependence during extreme events (e.g., Longin and Solnik 2001; Ang and Chen 2002; Poon et al. 2004; Heffernan and Tawn 2004); the copula approach, where the copula is a function that expresses the dependence structure of assets that also delivers an explicit measure of the dependence between the tail distributions of these assets (e.g., Patton 2006; Bouyè and Salmon 2009; Chollete et al. 2011); and the mixed copula approach that combines several copula functions where a different copula may be specified for a different state where financial markets are found (e.g., Hu 2006; Okimoto 2008). These techniques are widely popular in financial applications and are especially powerful for eliciting the properties of correlation across various market conditions. Nevertheless, there are also some limitations in the scope of how they may be used in financial applications.

Take the extreme value theory approach of Longin and Solnik (2001), for example. Extreme value theory is relevant for the study of the conditional correlation between the extreme tail distributions of asset returns, hence is particularly useful for providing results on asymptotic tail dependence. However, as the asymptotic tail dependence is only suitable for describing the level of dependence between markets that are significantly bearish or bullish, the extreme value theory approach may not be amenable for examining the level of dependence when the extent of such market conditions is, loosely speaking, "less severe" or "mild." Similarly, the concept of tail dependence in the copula approach is an asymptotic concept, and like extreme value theory, it does not convey the level of dependence for the different degrees of how bearish or bullish markets are. Regime-switching models can paint a broader picture on the characteristics of correlation, but might also require specifying a large number of regimes that makes them computationally burdensome to estimate.

By focusing on modeling the correlation of international stock markets as the application, this chapter contributes to the existing literature by offering a simple approach to estimate the level of dependence that pertains not only to extreme market conditions but also to varying degrees of market bearishness or bullishness. It does so by simply relating the severity (or a lesser extent) of these market conditions to the distributions of the market returns under consideration. For example, we may associate the lower tail of the return distribution with a bearish market and the upper tail of this distribution with a bullish one. And between, say, the 10th and 30th percentiles of a stock return, the 10th return percentile may be perceived as associated with a market more bearish than the market associated with the 30th return percentile. By taking advantage of the fact that the quantile information of a market return reflects the market performance, concepts such as a market being "mildly" or "severely" bearish or bullish can be expressed more concretely by relating them to certain quantiles on the distribution of that market return.

To estimate the level of dependence for specific market conditions, this chapter proposes a quantile dependence approach that looks at how the conditional *quantiles* of the market returns are correlated. From this perspective, to study how the equity markets of, say, the United States and Japan are dependent when they are bearish (bullish), one suggestion is to construct the correlation between the 10th (90th) conditional percentiles of the United States and Japan market returns. When studying their dependence during less bearish (bullish) times, we may construct the correlation of their return quantiles that are further away from the left (right) tails and closer towards the center of distributions. In other words, from the perspective that the distributional information (in particular, the quantile information) of a market return is indicative of the concurrent market condition, we may model the dependence structure of equity markets in a holistic and flexible way by estimating the correlation between the conditional quantiles of their returns, so that the level of dependence pertaining to a wide range of market conditions may be uncovered.

To model the dependence of the return quantiles, a new framework combining the techniques of quantile regression and copula modeling is proposed. Quantile regression is a statistical tool for examining how the quantile of a variable is dependent on some other conditioning variables and thus is useful in this study as its main objective is to investigate the link between the distributional (or quantile) information on asset returns on the one hand and the correlation between these assets on the other. Together with the quantile regression technique, I use the copula model, which is popular among practitioners for its flexibility in modeling dependence between variables that may have complex, nonstandard joint distributions.[3] When the study of correlation is considered, the copula approach is extremely useful as the correlation structure is summarized by the parameter in the copula function. In the case of the Gaussian or Student-t copula, the copula parameter is itself the correlation coefficient.

Using these techniques to estimate how the conditional *quantile* of an asset return is correlated with the conditional *quantile* of another asset return, this chapter thereby proposes a methodology dubbed as the *copula quantile-on-quantile regression* (C-QQR) approach. The C-QQR approach is computationally convenient to implement as it is based on a two-step quantile regression procedure. Specifically, when computing the correlation between the market returns of, say, the United States and Japan, the C-QQR approach proceeds by first estimating the conditional quantile of the US return by way of quantile regression on an *auxiliary equation*, which is not an equation of main interest. Then, using information from this regression, it proceeds to estimate the correlation between the conditional quantiles of the market returns of Japan and the United States. This is achieved by implementing quantile regression on a *quantile dependence equation*, which contains a parameter that expresses the dependence between the return quantiles of these markets. As the quantile dependence equation articulates how the *quantile* of a return is related to the *quantile* of another return, it can be used to examine the entire dependence structure between these assets where their relationship is assumed to be contingent on their quantile information.

[3]Introduction to copula models can be found in Nelsen (2006) and Trivedi and Zimmer (2007).

The application in this chapter focuses on modeling how the US market return is correlated with the market returns of Australia, Hong Kong, Japan, and Singapore. I employ the C-QQR approach to estimate the correlation between the 10th–90th conditional percentiles of the US return and the 10th–90th conditional return percentiles of Australia, Hong Kong, Japan, or Singapore (in decile intervals), leading to a total of 81 different correlation estimates for each return pair.[4] These estimates exhibit substantial variation, implying that the correlation varies considerably across different levels (thus quantiles) of market returns. In particular, the C-QQR approach shows that the correlation between returns at the center of distributions, such as the correlation between the median returns, is typically weaker. This implies that equity markets are less dependent when conditions are not extreme. It also shows that the correlation is stronger between returns deep in the left tails and that the correlation between the tenth return percentiles is consistently larger than the correlation between the median returns. This observation is in line with the existing evidence that stock markets are more strongly dependent when they are bearish.

After computing the C-QQR correlations, it is straightforward to construct a correlation time series by assigning a correlation estimate (from the pool of 81 C-QQR correlation estimates) to the realized returns in each period t. Calling this the dynamic C-QQR correlation, it is interesting to compare this constructed series against estimates that are obtained using conventional methods, such as the celebrated dynamic conditional correlation (DCC) framework of Engle (2002) that is designed for the study of how correlation evolves across time. Interestingly, although the C-QQR and DCC approaches are based on completely unrelated modeling principles – the C-QQR approach is based on quantile regressions and the DCC approach is based on the GARCH framework – the dynamic C-QQR correlation turns out to have similar visual characteristics as the DCC. This underscores another strength of the C-QQR approach – its ability to capture the salient features of the actual correlation dynamics.

This chapter draws heavily from Sim (2012) on modeling quantile dependence but contains two important differences. First, it considers a different specification of the auxiliary equation as the one in Sim (2012). As it turns out, where the results are suppressed for conciseness sake, the estimation outcomes of the C-QQR correlation are not sensitive to using either the current auxiliary equation or the one in Sim (2012), suggesting at first pass that the C-QQR correlation estimates are fairly robust to mis-specification of the auxiliary equation. Second, the application in Sim (2012) is limited in scope as it focuses on modeling the correlation of the US market return with the market and sectoral returns of Australia. Extending this work, I present new results on the correlation of the US market with the stock markets of Hong Kong, Japan, and Singapore in addition to Australia.

[4]Take the US-Australia return pair, for example. The 81 correlation estimates consist of estimates of the correlation between the tenth US and tenth Australian return percentiles, the tenth US and 20th Australian return percentiles, and so on, up to the 90th US and 90th Australian return percentiles.

67.2 The C-QQR Model

67.2.1 Specification

To construct the C-QQR model, an *auxiliary equation* and a *quantile dependence equation* must be specified. In our application, the auxiliary equation is utilized for modeling the conditional quantile of the US return quantile, and the quantile dependence equation is used for relating the dependence between the conditional quantile of the US market return and the conditional quantile of the market returns of Australia, Hong Kong, Japan, and Singapore. To specify the auxiliary equation, a model is postulated to link the US return (x) to a set of conditioning variables (x) as

$$x_t = \mathbf{b}^\top \mathbf{z}_t + v_t, \tag{67.1}$$

where v_t is the innovation in x_t. In (67.1), x_t is expressed as an autoregression with 12 lags to capture any mean reverting behavior of the US stock return, but it should be emphasized that the final outcome of the correlation estimate is not sensitive to using different numbers of lags. While the auxiliary equation is specified as an autoregression of x_t, another possibility is to motivate a model such that the US return is dependent on certain macroeconomic aggregates[5] or a model that is based on a general equilibrium framework with certain restrictions imposed. For example, instead of an autoregression, Sim (2012) takes into account of these considerations by specifying the auxiliary equation as a function of the US industrial production,[6] which is an important determinant of stock return from both theoretical and empirical perspectives.[7]

To specify the quantile dependence equation, a dependence function h is postulated to relate the return of Australia, Hong Kong, Japan, or Singapore (y) to the US return (x) as

$$y_t = h(x_t; \widetilde{\varphi}(u_t, v_t)), \tag{67.2}$$

[5]According to the seminal work of Chen, Roll, and Ross (1986), asset prices could also be linked to information about the macroeconomic aggregates as they could influence the discount rate or dividend stream, given that asset price is the sum of discounted future dividend stream (e.g., McQueen and Roley 1993; Flannery and Protopapadakis 2002; Shanken and Weinstein 2006).

[6]For example, Balvers et al. (1990) show that the general equilibrium framework with a logarithmic utility function and full capital depreciation can deliver a linear econometric model of stock return on the log of output.

[7]See Balvers et al. (1990) for a theoretical justification of the importance of output as a determinant of stock return. In the empirical study of Shanken and Weinstein (2006), industrial production is found to be an important determinant of stock return. In the empirical study of Shanken and Weinstein (2006), industrial production is found to be an important determinant of stock return among other factors, such as expected and unanticipated inflation, the spread in corporate bonds, and the spread in the treasury yields.

where v_t enters the quantile dependence equation; u_t, the innovation in y_t, is independent of v_t; and y_t is monotonic in u_t for each x_t and v_t.[8] The main parameter of interest is $\widetilde{\varphi}$ which captures the dependence between y and x. In order to allow this dependence parameter to be contingent on information about the US and the other financial market, $\widetilde{\varphi}$ in (67.2) is modeled as a function of u_t and v_t so that shocks to either the United States or the other financial market may influence the extent to which these markets are dependent. To obtain a parameter that provides information about the correlation between y and x, a copula model will be used to generate the function h. In the bivariate case, the copula is a function that combines the marginal distributions of x and y to yield their joint distribution function. Specifically, for variables x and y with marginal distributions F_x and F_y and joint distribution F, there exists a unique copula function C with copula parameter (with an abuse of notation) that satisfies

$$F(x,y) = C\left(F_x(x), F_y(y); \widetilde{\varphi}\right).$$

The copula that is employed in this study is the Gaussian copula, although other copulae such as the Student-t copula may be explored. Letting $\Phi_2(\cdot)$ denote the bivariate Gaussian distribution and $\Phi(\cdot)$ denote the standard normal distribution, the Gaussian copula expresses the joint distribution of x and y as

$$F(y_t, x_t) = \Phi_2\left(\Phi^{-1}\left(F_y(y_t)\right), \Phi^{-1}(F_x(x_t)); \widetilde{\varphi}\right), \tag{67.3}$$

and is especially useful as its parameter $\widetilde{\varphi}$ is the correlation coefficient. One important advantage in adopting the Gaussian copula is the feasibility of transforming it into a regression model that is amenable to the quantile regression technique. For instance, Bouyè and Salmon (2009) show that the τ_y *copula quantile curve* based on the Gaussian copula can be derived from (67.3) as

$$\begin{aligned} \tau_y &\equiv \frac{\partial \Phi_2\left(\Phi^{-1}\left(F_y(y_t)\right), \Phi^{-1}(F_x(x_t)); \widetilde{\varphi}\right)}{\partial F_x(x_t)} \\ &= \Phi\left(\frac{\Phi^{-1}\left(F_y(y_t)\right) - \widetilde{\varphi}\,\Phi^{-1}(F_x(x_t))}{\sqrt{1-\widetilde{\varphi}^2}}\right), \end{aligned} \tag{67.4}$$

where the first line follows by definition.[9] Rewriting (67.4), a regression model can be written as[10]

[8]Monotonicity ensures that conditional on x_t and v_t, the quantile of y can be mapped from the quantile of u.

[9]See p. 726 in Bouyè and Salmon (2009).

[10]When x_t is replaced by y_{t-1}, the model becomes an autoregression in $\Phi^{-1}(F_y(y_t))$, leading to the nonlinear copula quantile autoregression model of Chen et al. (2009).

$$\Phi^{-1}\left(F_y(y_t)\right) = \widetilde{\varphi}\,\Phi^{-1}(F_x(x_t)) + \sqrt{1-\widetilde{\varphi}^2}\Phi^{-1}\left(\tau_y\right). \tag{67.5}$$

If the marginal distributions F_x and F_y are standard normal, (67.5) simplifies further into an elegant regression model of

$$y_t = \widetilde{\varphi}x_t + \sqrt{1-\widetilde{\varphi}^2}\Phi^{-1}\left(\tau_y\right). \tag{67.6}$$

Adapting from (67.6), the quantile dependence equation that is considered in the application can be expressed as

$$y_t = \widetilde{\varphi}(u_t, v_t)x_t + \sqrt{1-\widetilde{\varphi}(u_t, v_t)^2}\Phi^{-1}\left(\tau_y\right), \tag{67.7}$$

where the correlation parameter is modeled as function of u_t and v_t to be consistent with (67.2).

That $\widetilde{\varphi}$ is allowed to be influenced by u_t and v_t is a crucial feature in the quantile dependence approach. First of all, if $\widetilde{\varphi}$ were a constant, the dependence parameter will not be affected by the quantile information of the financial markets. Second, the conditional quantiles of y and x are intertwined with the quantiles of u and v, respectively. By postulating $\widetilde{\varphi}$ as a function of u_t and v_t, we are relating the dependence between y and x given by $\widetilde{\varphi}$ to the quantile information on u and v, which is in turn linked to the quantile information on y and x. Therefore, allowing $\widetilde{\varphi}$ to be dependent on the quantile information of u and v enables us to capture the level of dependence that is specific to the quantile information of y and x.

For example, let us consider how the conditional quantile of the US return can be motivated from the auxiliary equation of (67.1). Equation 67.1 shows that holding the conditioning variables fixed, any extrinsic variation in the US return (x_t) must be attributed to v_t. In other words, the conditional quantile of the US return is linked to the quantile of v_t, so that the τ_x conditional quantile of the US return is given as

$$Q_x(\tau_x|\mathbf{z}_t) = \mathbf{b}^\top\mathbf{z}_t + {F_v}^{-1}(\tau_x), \tag{67.8}$$

where the distribution function of v be $F_v(\cdot)$ and its τ_x quantile is ${F_v}^{-1}(\tau_x)$. Conditioning on $\mathbf{z}$, (67.8) therefore illustrates how the conditional quantile of x, i.e., $Q_x(\tau_x|\mathbf{z}_t)$, is intertwined with the quantile of v. By modeling $\widetilde{\varphi}$ as a function of v, $\widetilde{\varphi}$ may then vary with the quantile information of v and hence of x. Likewise, by modeling $\widetilde{\varphi}$ as a function of u, $\widetilde{\varphi}$ may vary with the quantile information of y as the quantile information of u and y are related.

To express the concept of quantile dependence using the general quantile dependence equation of (67.2) for our discussion, recall from (67.8) that $Q_x(\tau_x|\mathbf{z}_t)$ is linked with ${F_v}^{-1}(\tau_x)$. By conditioning y_t on $Q_x(\tau_x|\mathbf{z}_t)$, logical consistency requires fixing v_t at ${F_v}^{-1}(\tau_x)$ in (67.2) as well. This is because as we have seen in (67.8), v_t cannot vary freely in the construction of $Q_x(\tau_x|\mathbf{z}_t)$. With this in mind, the τ_y quantile of the Australian return conditioning on $Q_x(\tau_x|\mathbf{z}_t)$ can be expressed as

$$\begin{aligned} Q_y\left(\tau_y|Q_x(\tau_x|\mathbf{z}_t)\right) &= h\left(Q_x(\tau_x|\mathbf{z}_t);\widetilde{\varphi}\left(F_u^{-1}\left(\tau_y\right),F_v^{-1}(\tau_x)\right)\right) \\ &\equiv h\left(Q_x(\tau_x|\mathbf{z}_t);\varphi\left(\tau_y,\tau_x\right)\right), \end{aligned} \tag{67.9}$$

where I have defined $\varphi\left(\tau_y,\tau_x\right) \equiv \widetilde{\varphi}\left(F_u^{-1}\left(\tau_y\right),F_v^{-1}(\tau_x)\right)$. Through the dependence parameter $\varphi(\tau_y, \tau_x)$, (67.9) summarizes how the τ_y Australian return quantile is related to the τ_x US return quantile. If the dependence function h in (67.9) is replaced with the copula-based model in (67.7), then (67.9) expresses the *copula quantile-on-quantile regression* (C-QQR) model that is to be estimated in this chapter.

Before we proceed, it should be emphasized why the US return is chosen for the auxiliary model over the other market returns. In formulating (67.1) and (67.2), two assumptions are made. First, in relation to the auxiliary equation of (67.1), which is modeled as an autoregression of x_t, I assume that US economic fundamentals are sufficient for determining the US return beyond the economic fundamentals of the other markets. Hence, information from the other markets would not matter for driving the US return and are excluded from (67.1), which is likely too reasonable for relatively smaller economies such as Australia, Hong Kong, and Singapore and perhaps less so for Japan. By including the United States in the quantile dependence equation of (67.2), the second assumption asserts that the US return information is important for influencing the other stock markets. This would be plausible if US fundamentals contribute towards the global economic forces that drive the co-movement between the United States and the other financial markets. Therefore, if information about US fundamentals has global content, and if this is subsumed in the US return, the US return will be a powerful variable for explaining the variation in the market returns of the Australia, Hong Kong, Japan, and Singapore. This motivates placing the US return, not the other market returns, as a right-hand-side variable in the quantile dependence equation.

Furthermore, it should also be emphasized that (67.1) and (67.2) form a triangular system of simultaneous equation of the type analyzed by Ma and Koenker (2006), who study the dependence between conditional quantiles that is motivated from such a structure. However, there is a fundamental difference between this paper and Ma and Koenker (2006). While Ma and Koenker (2006) study a parametric model, this chapter does not make a parametric assumption about the function $\widetilde{\varphi}(u_t, v_t)$ in order that the data is allowed to speak with respect to the response of $\widetilde{\varphi}$ to the quantile information of u and v. Therefore, this requires an alternative method of estimation from Ma and Koenker (2006) which is discussed in the next section.

67.2.2 Estimation

This section outlines the procedure for estimating the dependence parameter in the C-QQR model, i.e., $\varphi\left(\tau_y,\tau_x\right) \equiv \widetilde{\varphi}\left(F_u^{-1}\left(\tau_y\right),F_v^{-1}(\tau_x)\right)$ in (67.9). In the context of the C-QQR model where the h function in (67.9) is replaced by the copula-based model in (67.7), $\varphi(\tau_y, \tau_x)$ expresses the correlation between τ_y conditional quantile of y and

τ_x conditional quantile of x. Even though the value of $\varphi(\tau_y, \tau_x)$ is based upon the $\widetilde{\varphi}(u_t, v_t)$ parameter in the quantile dependence equation of (67.2),[11] the estimate of $\varphi(\tau_y, \tau_x)$ cannot be obtained by a straightforward application of quantile regression on (67.2) as it is a single equation with two unobservable terms u_t and v_t. In order to estimate $\varphi(\tau_y,\tau_x)$, or equivalently $\widetilde{\varphi}\left(F_u^{-1}(\tau_y), F_v^{-1}(\tau_x)\right)$, I first anchor v_t at $F_v{}^{-1}(\tau_x)$ in the quantile dependence equation while letting u_t be "free" and then implement a τ_y -quantile regression on this resulting equation to set u_t to $F_u^{-1}(\tau_y)$ for an estimate of $\widetilde{\varphi}\left(F_u^{-1}(\tau_y), F_v^{-1}(\tau_x)\right)$.

To elaborate, let us decompose the quantile dependence equation of (67.2) into two parts:

$$y_t = h\left(x_t; \widetilde{\varphi}\left(u_t, F_v^{-1}(\tau_x)\right)\right) + \underbrace{h(x_t; \widetilde{\varphi}(u_t, v_t)) - h\left(x_t; \widetilde{\varphi}\left(u_t, F_v^{-1}(\tau_x)\right)\right)}_{\Omega}. \tag{67.10}$$

In the first part of (67.10), the v-argument in $\widetilde{\varphi}$ is anchored at $F_\upsilon{}^{-1}(\tau_x)$ so that $h\left(x_t; \widetilde{\varphi}\left(u_t, F_v^{-1}(\tau_x)\right)\right)$ is now a function of a single unobservable, u_t. If the Ω portion of (67.10) can be controlled, our target parameter $\varphi(\tau_y,\tau_x)$ can be estimated by implementing a τ_y-quantile regression on (67.10) as doing so would, in principle, deliver an estimate of the conditional function of $h\left(x_t; \widetilde{\varphi}\left(F_u^{-1}(\tau_y), F_v^{-1}(\tau_x)\right)\right)$ which contains our target. To control for Ω, I approximate it by a first-order Taylor expansion of v_t around $F_v^{-1}(\tau_x)$ as

$$\Omega \approx h_{\widetilde{\varphi}}\left(x_t; \widetilde{\varphi}\left(u_t, F_\upsilon^{-1}(\tau_x)\right)\right)\widetilde{\varphi}_v\left(u_t, F_\upsilon^{-1}(\tau_x)\right)\upsilon_t(\tau_x), \tag{67.11}$$

where (67.11) uses the definition $v_t(\tau_x) = v_t - F_v^{-1}(\tau_x)$. The function $h_{\widetilde{\varphi}}$ is the partial derivative of h with respect to $\widetilde{\varphi}$, which is a known expression given that h is specified in (67.7). The parameter $\widetilde{\varphi}_v\left(u_t, F_v^{-1}(\tau_x)\right)$ is the partial derivative of $\widetilde{\varphi}$ with respect to v_t, where its v-argument is evaluated at $F_v{}^{-1}(\tau_x)$. The functional form of this partial derivative is unknown as the functional form of $\widetilde{\varphi}\left(u_t, F_v^{-1}(\tau_x)\right)$ is not specified. With the first-order Taylor approximation leading to (67.11), the initial problem of controlling for v_t in the quantile dependence equation now becomes an issue of controlling for $v_t(\tau_x)$ in (67.11). The new variable $v_t(\tau_x)$ can be estimated as the residual following a τ_x-quantile regression on the auxiliary model of (67.1).[12] Letting $\hat{v}_t(\tau_x)$ denote the estimate of $v_t(\tau_x)$, we can control for Ω using its feasible counterpart:

$$\hat{\Omega} = h_{\widetilde{\varphi}}\left(x_t; \widetilde{\varphi}\left(u_t, F_v^{-1}(\tau_x)\right)\right)\widetilde{\varphi}_v\left(u_t, F_v^{-1}(\tau_x)\right)\hat{v}_t(\tau_x),$$

so that the quantile dependence equation to be taken to the data is

[11] $\varphi(\tau_y, \tau_x)$ can be motivated from $\widetilde{\varphi}(u_t, v_t)$ by anchoring the u , v-arguments in $\widetilde{\varphi}(u_t, v_t)$ at $F_u{}^{-1}(\tau_y)$ and $F_v{}^{-1}(\tau_x)$.

[12] Since $Q_x(\tau_x|\mathbf{z}_t) = \mathbf{b}^\top\mathbf{z}_t + F_v{}^{-1}(\tau_x)$, we may express the auxiliary regression of (67.1), i.e., $x_t = \mathbf{b}^\top\mathbf{z}_t + v_t$, as $x_t = \mathbf{b}^\top\mathbf{z}_t + F_v{}^{-1}(\tau_x) + v_t - F_v{}^{-1}(\tau_x) = Q_x(\tau_x|\mathbf{z}_t) + v_t - F_v{}^{-1}(\tau_x) = Q_x(\tau_x|\mathbf{z}_t) + v_t(\tau_x)$. Therefore, we may estimate $\upsilon_t(\tau_x)$ as the residual from a τ_x -quantile regression on (67.1).

$$
\begin{aligned}
y_t = {} & h\left(x_t; \widetilde{\varphi}\left(u_t, F_v^{-1}(\tau_x)\right)\right) \\
& + h_{\widetilde{\varphi}}\left(x_t; \widetilde{\varphi}\left(u_t, F_v^{-1}(\tau_x)\right)\right) \widetilde{\varphi}_v\left(u_t, F_v^{-1}(\tau_x)\right) \hat{v}_t(\tau_x).
\end{aligned} \tag{67.12}
$$

To a first-order approximation, u_t is the only unobservable term in (67.12). Therefore, $\varphi(\tau_y, \tau_x)$ can now be estimated by implementing a τ_y-quantile regression on (67.12). As compared to the original quantile dependence equation of (67.10), the "revised" quantile dependence equation of (67.12) now contains an additional parameter, $\widetilde{\varphi}_v$, which is to be estimated together with the main parameter of interest, $\widetilde{\varphi}$.

Let $\rho_\tau(\cdot)$ be the "check" function in Koenker and Bassett (1978), defined as $\rho_\tau(u) = u(\tau - \mathrm{I}(u < 0))$, where $\mathrm{I}(\cdot)$ is an indicator function. Using (67.12), the dependence between the quantiles of x and y can be estimated by implementing a two-step quantile regression procedure:

1. *Obtain residuals $\hat{v}_t(\tau_x)$ from a τ_x -quantile regression on* (67.1), *the auxiliary equation*, i.e.,

$$
\min_{\mathbf{b}} \sum_{t=1}^{T} \rho_\tau\left(x_t - \mathbf{b}^\top \mathbf{z}_t\right)
$$

2. *Using $\hat{v}_t(\tau_x)$, estimate $\widetilde{\varphi}$ from a τ_y -quantile regression on* (67.12), *the quantile dependence equation*, i.e.,

$$
\min_{(\widetilde{\varphi}, \widetilde{\varphi}_v)} \sum_{t=1}^{T} \rho_\tau\left(y_t - h(x_t; \widetilde{\varphi}) - h_{\widetilde{\varphi}}(x_t; \widetilde{\varphi}) \widetilde{\varphi}_v \hat{v}_t(\tau_x)\right).
$$

Step 1 is a standard linear quantile regression and Step 2 is a standard nonlinear quantile regression. The second-step estimate of $\widetilde{\varphi}$ will yield the desired estimate of $\varphi(\tau_y, \tau_x)$. Because the C-QQR approach involves a two-step quantile regression procedure, it can be implemented using statistical packages for quantile regression such as the quantreg package of Koenker (2009) within the R software.[13]

67.3 Application

Monthly returns of Australia, Hong Kong, Japan, Singapore, and the United States are constructed from the Datastream-MSCI indices.[14] Table 67.1 provides the summary statistics for the period between March 1974 and February 2010. Among Australia, Hong Kong, Japan, and Singapore, the US market is most strongly correlated with the Singapore market (at 0.60) and most weakly correlated with the Japan market (at 0.41). But these are sample correlation coefficients that could differ significantly from actual levels of correlation especially when equity markets are bearish. By considering how

[13]For instance, the Steps 1 and 2 regressions can be implemented using the rq and nlrq commands of the quantreg package in R.

[14]The monthly returns are constructed as 100 multiplied by the change in the log of the index.

Table 67.1 Summary statistics on monthly stock returns (March 1974 to February 2010)

	Mean	Min	Max	Standard deviation	Correlation with United States
Australia	0.67	−44.79	20.11	5.80	0.58
Hong Kong	1.22	−62.50	36.36	9.19	0.49
Japan	0.39	−24.38	17.51	5.32	0.41
Singapore	0.71	−44.55	44.92	7.70	0.60

the quantiles of these market returns are correlated, the C-QQR approach offers a way of examining their level of dependence that is contingent on specific market conditions.

In this application, the correlation between the τ_x conditional quantile of the US return and the τ_y conditional quantile of the return of Australia, Japan, Hong Kong, or Singapore is computed. The values of τ_y and τ_x are defined on the grid [0.1, 0.2, ..., 0.9], where the total number of τ_y and τ_x combinations on this grid is 81. The C-QQR approach is implemented to estimate the correlation between the 10th–90th percentiles of the US return and the 10th–90th percentiles of the other market return (in decile intervals), for a total of 81 different correlation estimates for each return pair.

To visualize the C-QQR correlation, Fig. 67.1 plots the C-QQR correlation surfaces by relating the level of correlation in the *z*-axis to the return quantiles of Australia, Hong Kong, Japan, or Singapore on the *x*-axis and the return quantiles of the United States on the *y*-axis. The correlation surfaces offer some important insights. First, they show that the level of dependence varies substantially across the distributions of returns. Second, across all the four return pairs, the C-QQR correlations share many common features that echo our existing understanding about how correlations behave under various circumstances. For instance, the C-QQR correlation has the tendency to be weak at the center of the return distributions, implying that markets are less dependent when they are neither bearish nor bullish. As a side remark, while the correlation between centrally located quantiles may be interpreted as the level of dependence when markets are neither bearish or bullish, measures such as the sample correlation coefficient may not deliver the same interpretation. In fact, Table 67.2 shows that the sample correlation coefficient appears to be different from the correlation between centrally located return quantiles such as the median returns, where the correlation between the median returns is *always* smaller than the sample correlation coefficient. This perhaps is not surprising as the sample correlation coefficient is computed without cleaving out the consequence of extreme events that lead to inflating the actual level of dependence when they happen.

Of particular relevance to the practice of risk management is the fact that stock markets are more strongly dependent when they are bearish. Through the C-QQR approach, a similar point is made in terms of the stronger dependence between return quantiles in the left tail distributions. This is demonstrated in Fig. 67.2, which plots the correlation along the main diagonals in Fig. 67.1, i.e., the correlation along $\tau_y = \tau_x$. Figure 67.2 reveals that the correlation usually peaks at around $\tau_y = \tau_x = 0.1$ (the 10th percentiles of returns). Because these lower return quantiles are associated with markets that are bearish, Fig. 67.2 reiterates a familiar result in the existing literature that the correlation between bear markets would be stronger than usual (e.g., Longin and Solnik 2001; Hu 2006; Chollete et al. 2011).

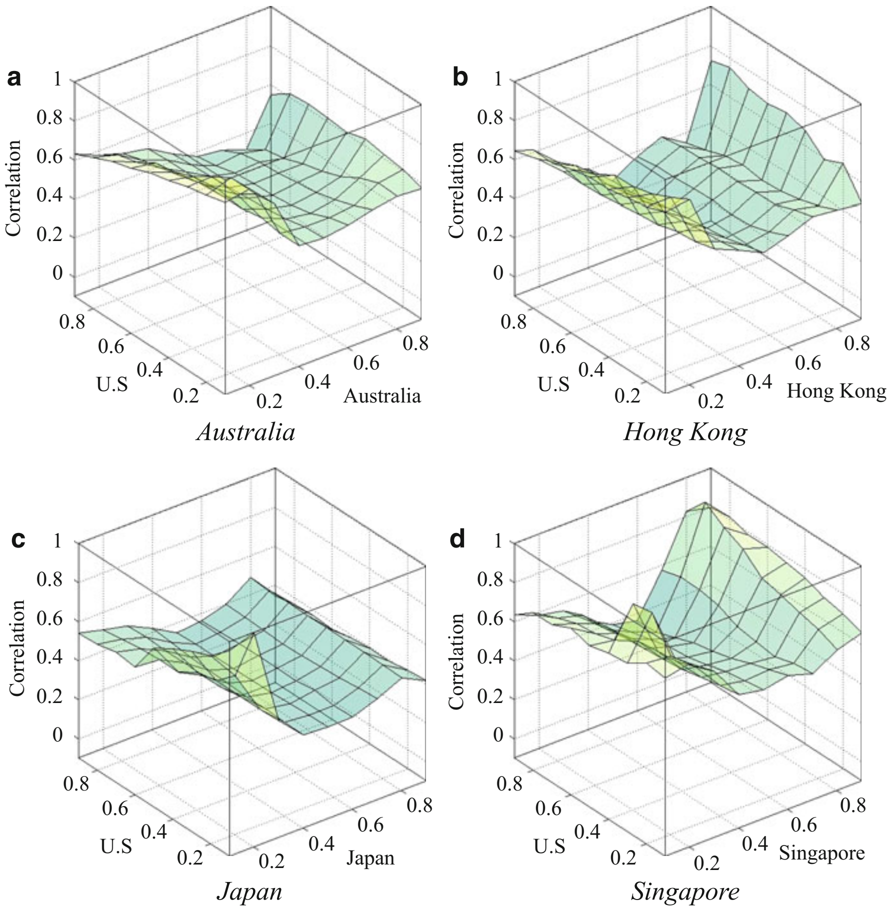

Fig. 67.1 C-QQR correlation
This figure plots the correlation between the quantile of the US market return and the quantile of the market return of Australia, Hong Kong, Japan, or Singapore using the C-QQR approach. The x-axis marks the quantiles of the US return and the y-axis marks the quantile of the other return

Note that the C-QQR approach is useful for showing the key locations in the return distributions where most of the movements in correlation take place. Specifically, it offers a new insight that the correlation may deviate sharply even at less extreme return quantiles. In the case of the US-Australia and US-Singapore return pairs, Fig. 67.2 shows that the correlation rises substantially starting from the 30th return percentiles. If 30th return percentiles are associated with markets that are mildly bearish, this implies that markets do not have to be severely bearish in order to trigger a nontrivial increase in correlation.

To evaluate the "performance" of the C-QQR approach informally, it is useful to compare the average correlation based on the C-QQR approach with the sample

Table 67.2 Sample and C-QQR correlations

	Australia	Hong Kong	Japan	Singapore
Panel A				
Sample	0.5795	0.4867	0.4123	0.5987
Average C-QQR	0.5697	0.5194	0.4657	0.6318
Panel B				
$\tau_y = \tau_x = 0.1$	0.8856	0.8358	0.9541	0.8132
$\tau_y = \tau_x = 0.5$	0.4625	0.3583	0.3552	0.4757
$\tau_y = \tau_x = 0.9$	0.5480	0.7212	0.3439	0.7976

Sample reports the sample correlation coefficient. *C-QQR* reports the average of the 81 correlation estimates, where each estimate $\hat{\varphi}(\tau_y, \tau_x)$ is specific for $\boldsymbol{\tau_y}$ and $\boldsymbol{\tau_x}$ defined on the grid [0.1, . . ., 0.9]. $\tau_y = \tau_x = k$ reports the correlation between the k quantile of the US market return and k quantile of the market return of Australia, Hong Kong, Japan, or Singapore, i.e., $\hat{\varphi}(k, k)$

correlation coefficient, which itself reflects the average level of dependence. This "average C-QQR correlation" can be obtained by averaging up the 81 C-QQR correlation estimates for each return pair. Panel A of Table 67.2 compares the average C-QQR correlation with the sample correlation coefficient and shows that the two measures of average dependence are quite similar. For example, looking at the dependence between the US-Australia return pair, the average C-QQR correlation is 0.57 (rounded to the nearest two decimal places), which is very close the sample correlation of 0.58. However, the closeness between the average C-QQR correlation and the sample correlation coefficient is not specific to the US-Australia correlation. For instance, in the case of the US-Hong Kong and US-Singapore return pairs, their average C-QQR correlations are 0.52 and 0.63, respectively, which are very close to their sample correlation coefficients of 0.49 and 0.60. Even in the largest case of disparity between the two correlation measures, which is found for US-Japan return pair, the difference between the average C-QQR correlation and the sample correlation is only about 0.05. Given that the average C-QQR correlation delivers a reasonable measure of the average level of dependence as benchmarked by the sample correlation coefficient, one may interpret the C-QQR approach as a technique for decomposing the level of average dependence into levels that are specific to different points in the distribution of returns and thus to a wide spectrum of market conditions.

67.3.1 Dynamic C-QQR Correlation

Having obtained the C-QQR correlation estimates, it is straightforward to construct a historical series of correlation. This construction is especially useful for shedding light on the behavior of correlation across time, and in this regard, the C-QQR approach is related to the celebrated Dynamic Conditional Correlation (DCC) framework of Engle (2002) that is designed for the study of the time series behavior of correlation. Therefore, another informal evaluation of the C-QQR approach is to compare its estimates directly with the DCC. This comparison is interesting as the two approaches are completely unrelated – the C-QQR approach is based

Fig. 67.2 C-QQR correlation, $\tau_y = \tau_x$
For $\tau_y = \tau_x$, this figure plots the correlation between the τ_y US return quantile and the τ_x quantile of the market return of Australia, Hong Kong, Japan, or Singapore using the C-QQR approach. The 95 % bootstrap confidence band is provided

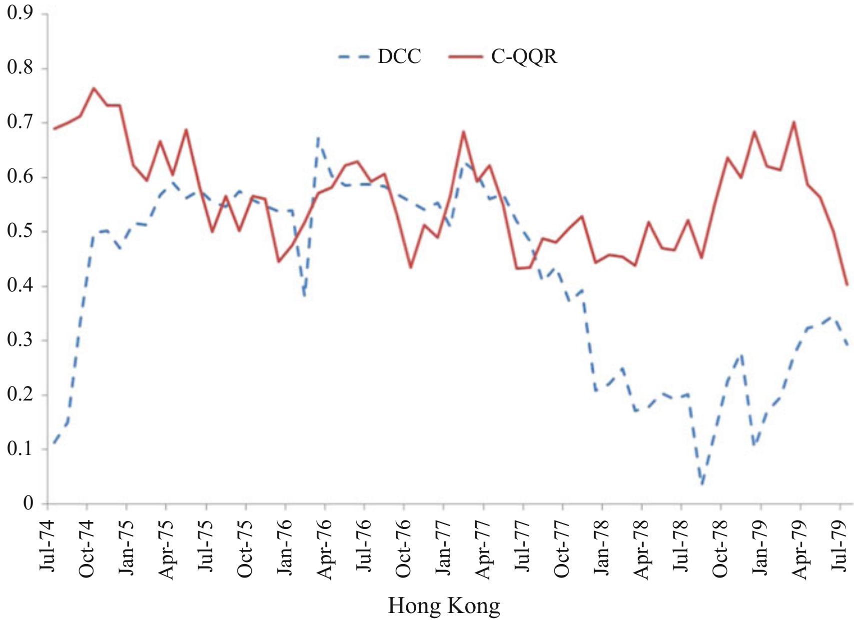

Fig. 67.3 (continued)

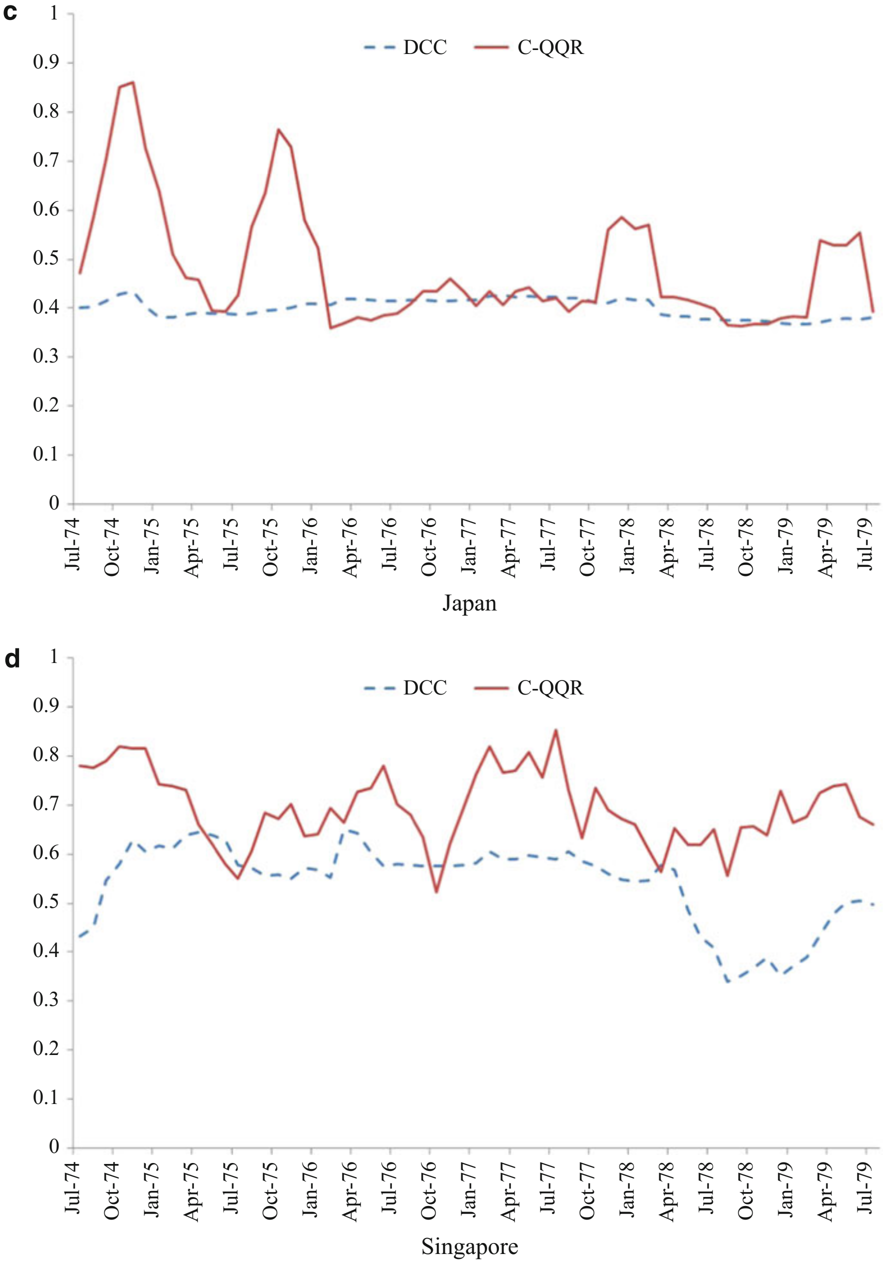

Fig. 67.3 Dynamic C-QQR correlation and DCC in levels, 1974–1979
The C-QQR correlation and the DCC are plotted for the correlation of the US market return with the market return of Australia, Hong Kong, Japan, or Singapore. The *solid line* corresponds to the 4-month moving average C-QQR correlation and the *dotted line* corresponds to the DCC that is estimated using the DCC-GARCH(1,1) specification

on quantile regressions and the DCC approach is based on the GARCH framework. As it turns out, despite the clear difference in the two modeling approaches, the C-QQR approach produces estimates that in some ways are visually comparable to the DCC.

The time series of correlation can be constructed by first matching each realized stock return at period t to the nearest return quantile that is used when estimating the C-QQR correlation. Once that is done for the US return and the return of the other market, we may then match a C-QQR correlation estimate (from the pool of 81 estimates) to these quantiles to obtain an approximate realized correlation at period t. By employing this matching approach for each period, we may construct an approximation of the historical correlation. Calling this the "dynamic C-QQR correlation," the detailed procedure of computing it is outlined as follows:

1. Compute the empirical distributions for the returns to the US market (x) and to the market returns of Australia, Hong Kong, Japan, or Singapore (y) for each period t. Denote them by $\widetilde{F}_x(x_t)$ and $\widetilde{F}_y(y_t)$.
2. If $\widetilde{F}_x(x_t)$ or $\widetilde{F}_y(y_t)$ is less than 0.05, add 0.05. If $\widetilde{F}_x(x_t)$ or $\widetilde{F}_y(y_t)$ is greater than 0.95, subtract 0.05. Call the new series $\widetilde{F}_x(1)(x_t)$ and $\widetilde{F}_y(1)(y_t)$.
3. Round $\widetilde{F}_x(1)(x_t)$ and $\widetilde{F}_y(1)(y_t)$ to the nearest first decimal place. The new series $\widetilde{F}_x(2)(x_t)$ and $\widetilde{F}_y(2)(y_t)$ will be on the grid [0.1, . . ., 0.9].
4. The C-QQR correlation estimates is a 9×9 matrix, where each point on the matrix corresponds to a combination of points on two [0.1, . . ., 0.9] grids, with each grid representing the return percentiles of the US market and the other market, respectively. The correlation at time t is obtained by matching $\widetilde{F}_x(2)(x_t)$ and $\widetilde{F}_y(2)(y_t)$ to the C-QQR correlation matrix of estimates.

For a close-up comparison, Fig. 67.4 plots the dynamic C-QQR correlation (4-month moving average) and the DCC for the first 5-year period in the sample from 1973 to 1979, and Fig. 67.5 plots these correlations for the last 5-year period in the sample from 2005 to 2010. Choosing the first and last 5-year periods allows us to observe how the dynamic C-QQR correlation and DCC compare across the two most distant 5-year periods in the sample. Besides comparing their levels, it is also useful to compare their first difference as doing so would help us to gain further insights on how the dynamic C-QQR correlation behaves relative to the DCC.

Focusing on the 1973–1979 period, Fig. 67.4 shows that the dynamic C-QQR correlation is similar to the DCC in terms of movements, although not necessarily in terms of magnitude. For instance, comparing the C-QQR correlation and the DCC for the US-Australia return pairs, Fig. 67.1 shows a decline in the C-QQR correlation from around July 1974 to April 1975, while the DCC manifests a similar downward motion from January to October 1975. Likewise, the C-QQR correlation trends upwards from April 1976 to January 1977 with the DCC following suit from October 1976 to around the same time. Focusing on their first difference, Fig. 67.5 shows that the peaks in the first difference of the dynamic C-QQR correlation are

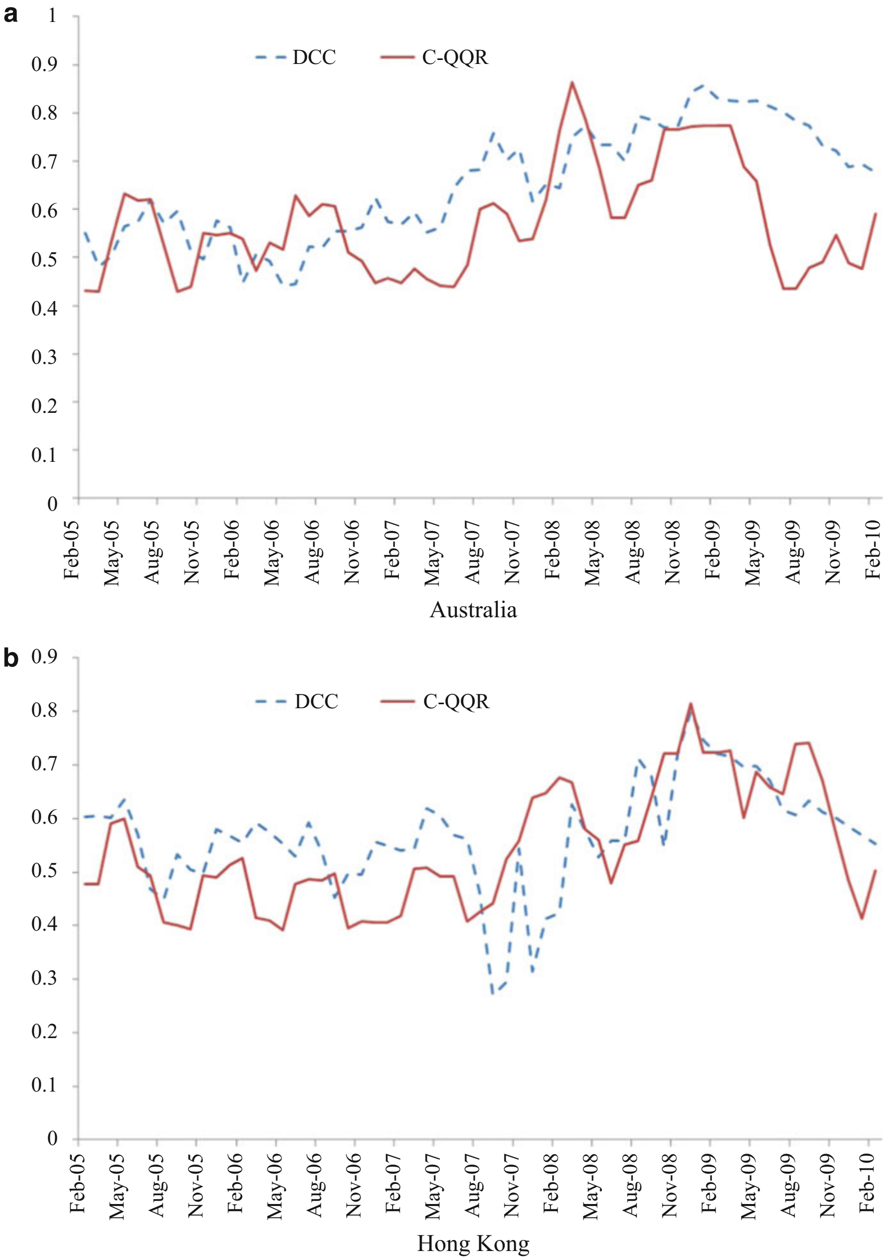

Fig. 67.4 (continued)

c

The C-QQR correlation and the DCC are plotted for the correlation of the US market return with the market return of Australia, Hong Kong, Japan, or Singapore. The *solid line* corresponds to the 4-month moving average C-QQR correlation and the *dotted line* corresponds to the DCC that is estimated using the DCC-GARCH(1,1) specification

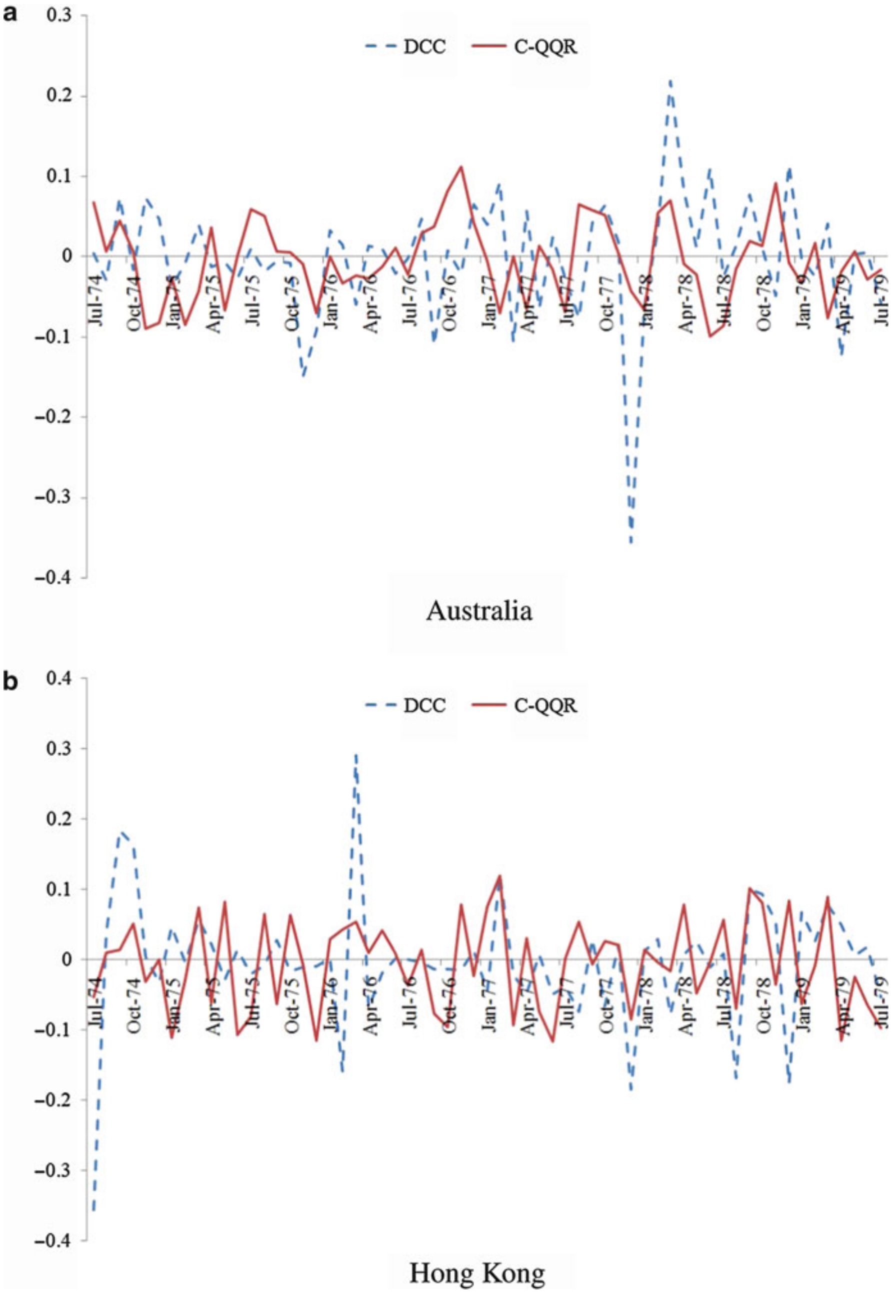

Fig. 67.5 (continued)

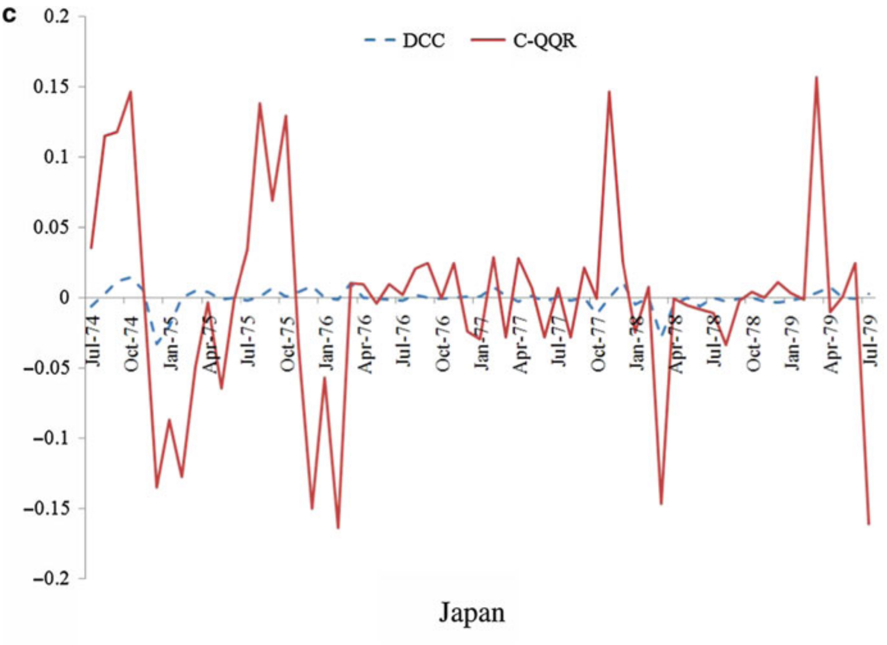

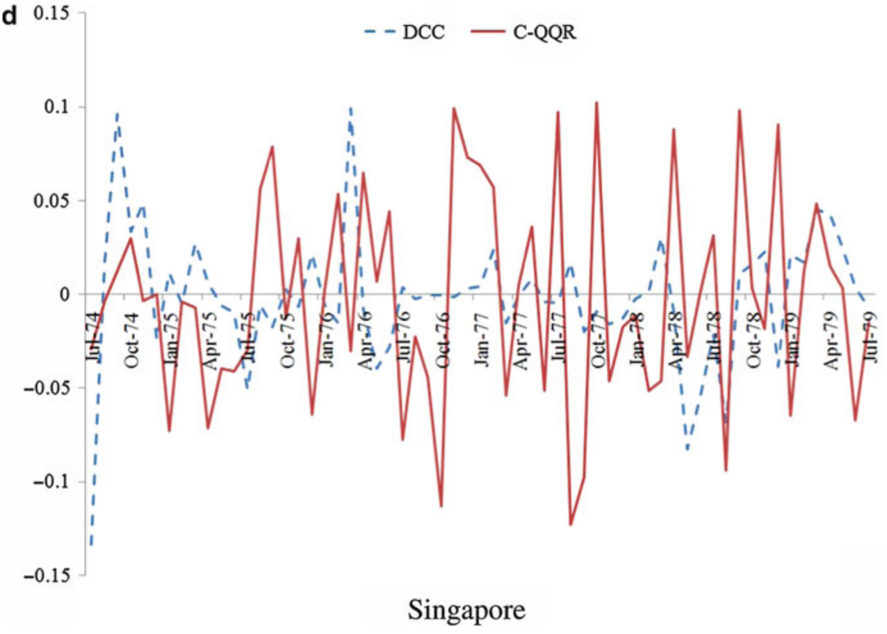

Fig. 67.5 Dynamic C-QQR correlation and DCC in first difference, 1974–1979
The C-QQR correlation and the DCC, in first difference, are plotted for the correlation of the US market return with the market return of Australia, Hong Kong, Japan, or Singapore. The *solid line* corresponds to the 4-month moving average C-QQR correlation and the *dotted line* corresponds to the DCC that is estimated using the DCC-GARCH(1,1) specification

followed by similar peaks in the first difference of the DCC in many occasions, although the size of these changes across the C-QQR correlation and the DCC are somewhat different. Besides the US-Australia return pairs, the C-QQR correlation and the DCC display noticeable similarities with respect to the US-Hong Kong and US-Singapore return pairs, but least resemble each other in the case of US-Japan.

During the 2005–2010 period, not only do the dynamic C-QQR correlation and the DCC display similar trends, they also appear to be moving along the same path. For instance, when focusing on the US-Australia and US-Hong Kong return pairs, Fig. 67.4 shows that the C-QQR correlation and the DCC track each other closely with similar levels. In terms of their first difference, Fig. 67.6 also shows that while changes in the C-QQR correlation and the DCC occur nearly in tandem, the changes in the DCC are usually preceded by changes in the C-QQR correlation in the same direction. For example, in the case of the US-Australia return pairs, Fig. 67.6 shows that the peaks in the first difference of the C-QQR correlation around April 2005, November 2005, and June 2006 are followed by peaks in the first difference of the DCC about a month or two later.

The US-Japan return pair presents an interesting case in the comparison between the dynamic C-QQR correlation and the DCC. For example, I find that the DCC in this context to be more or less steady throughout the sample period, including the 1973–1979 and 2005–2010 periods that saw the 1974–1975 US and global recession triggered by the tripling of the price of oil and the current global financial crisis that started in 2007. Interestingly, while the C-QQR correlation typically meanders around a steady level throughout the sample period, it is also characterized by sharp upward movements during 1974–1975 and starting from the end of November 2007, the periods when global financial markets are bearish. And, during the times when the C-QQR correlation is free from these large deviations, it is nearly identical to the DCC. This can be seen by comparing the two correlation series during April 1976 to August 1977 and April 1978 to March 1979 in Fig. 67.3, and prior to February 2006 in Fig. 67.4, where the two correlation estimates nearly coincide.

While this exercise does not offer a statistical evaluation of the closeness between the dynamic C-QQR correlation and the DCC, visual inspection of the two correlation series reveals some common features between them especially during 2005–2010. That there are some similarities between the dynamic C-QQR correlation and the DCC is somewhat surprising since from the outset, the C-QQR and the DCC approaches based on completely different modeling paradigms.

67.4 Conclusion

This chapter discusses a new perspective of modeling correlation, based on the C-QQR approach, which focuses on the correlation between the conditional quantiles of asset returns as a way of uncovering the level of dependence for specific market conditions. The C-QQR approach has the ability to replicate key features about the correlation between stock returns that have been noted before. For instance, it shows that the correlation between lower return quantiles is stronger than that between

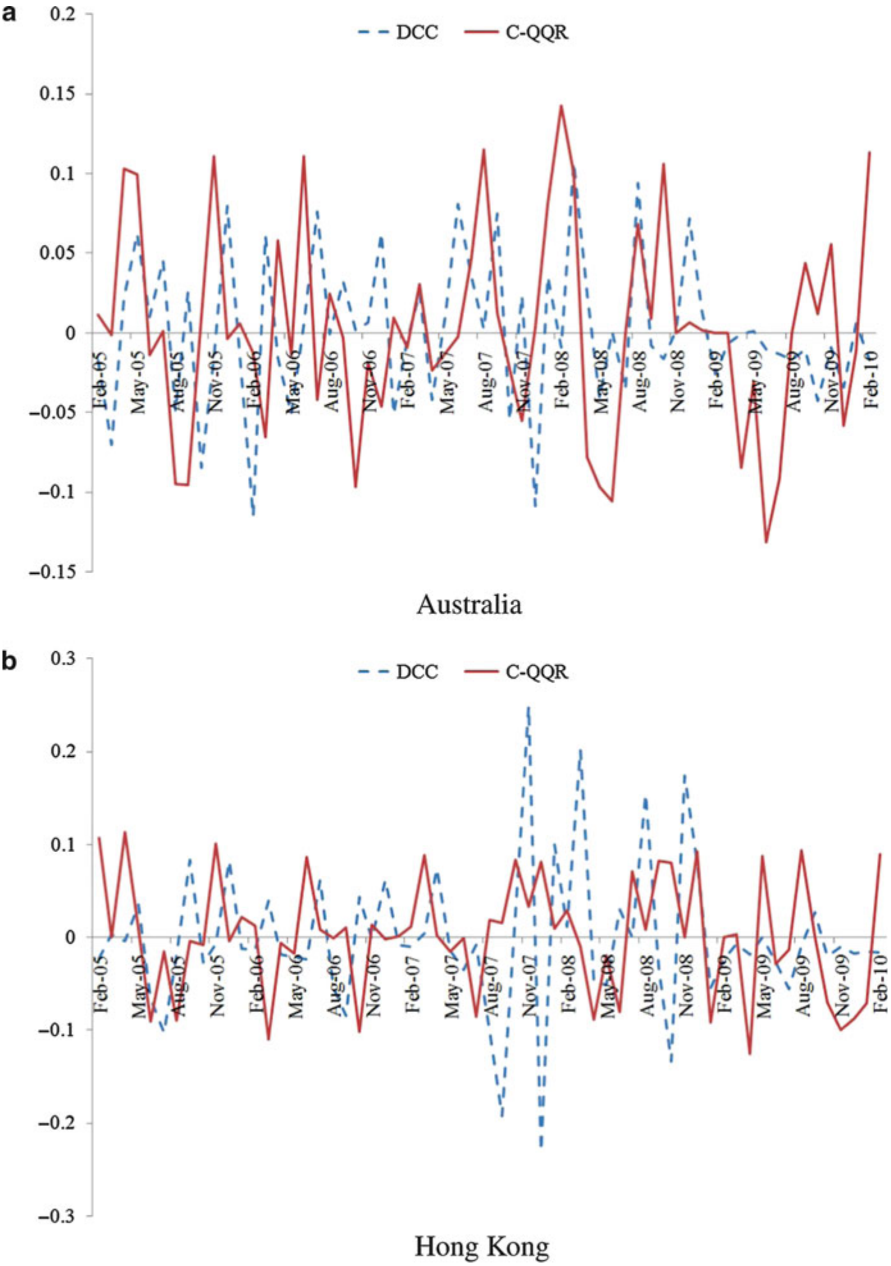

Fig. 67.6 (continued)

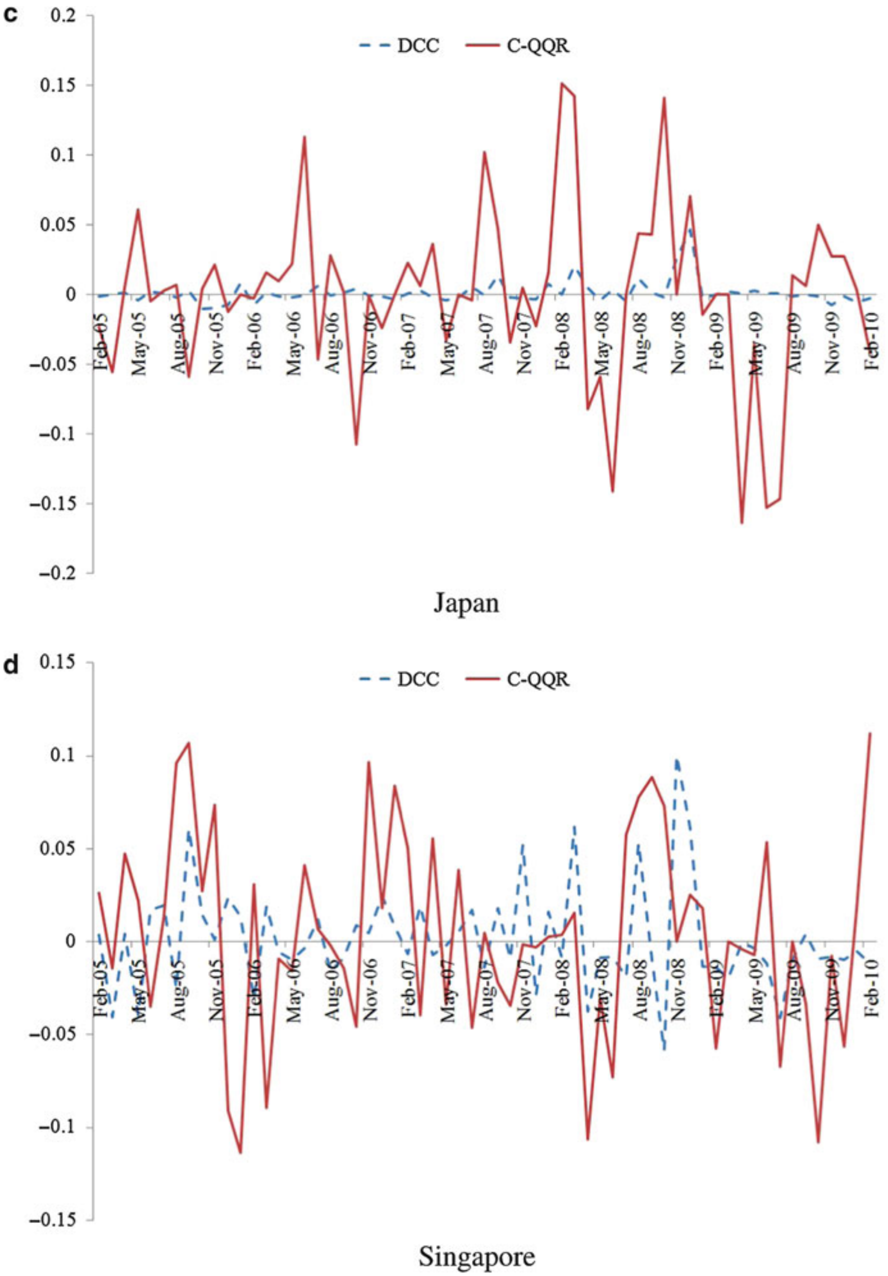

Fig. 67.6 Dynamic C-QQR correlation and DCC in first difference, 2005–2010
The C-QQR correlation and the DCC, in first difference, are plotted for the correlation of the US market return with the market return of Australia, Hong Kong, Japan, or Singapore. The *solid line* corresponds to the 4-month moving average C-QQR correlation and the *dotted line* corresponds to the DCC that is estimated using the DCC-GARCH(1,1) specification

centrally located return quantiles, which corroborates the familiar observation that bear markets are more strongly correlated. The C-QQR approach also has the ability to produce a constructed time series of correlation that resembles the DCC even though the C-QQR and DCC approaches are completely unrelated. Given that the C-QQR framework produces correlation estimates that match the findings of existing non-dynamic-based approaches of modeling correlation and the estimates of the dynamic based DCC approach, it therefore empirically bridges the gap between the dynamic and non-dynamic-based paradigms of modeling correlation.

Nevertheless, the application of the concept of quantile dependence in financial economics is still in the early stage where some issues could be addressed going forward. Firstly, I presented a bivariate version of the C-QQR model for the analysis of pairwise correlation. As financial markets are interrelated, an extension to the multivariate case would be an important direction. Secondly, I use the auxiliary equation to model the US return, and it would be interesting to investigate the implications on the final correlation estimate of doing the opposite, that is, use the auxiliary equation to model the market returns of Australia, Hong Kong, Japan, and Singapore. Finally, in terms of applications, it should be emphasized that the relevance of the C-QQR approach is not confined to the study of equities alone. For instance, one could also look at the correlation between stocks and bonds through the lens of the C-QQR approach and examine "flight to quality" hypothesis, which emphasizes the tendency of investors to underweight equities in favor of bonds in the face of market uncertainties (e.g., Connolly et al. 2005). It would also be interesting to apply the C-QQR approach to examine issues in macroeconomics such as studying the nonlinearity in the relationships between macroeconomic aggregates, which has been a topic of considerable interest in recent research.

Abstract

Investors often need to evaluate the investment strategies in terms of numerical values based upon various criteria when making investment. This situation can be regarded as a multiple criteria decision-making (MCDM) problem. This approach is oftentimes the basic assumption in applying hierarchical system for evaluating the strategies of selecting the investment style. We employ the criteria measurements to evaluate investment style. To achieve this objective, first, we employ factor analysis to extract independent common factors from those criteria. Second, we construct the evaluation frame using hierarchical system composed of the above common factors with evaluation criteria and then derive the relative weights with respect to the considered criteria. Third, the synthetic utility value corresponding to each investment style is aggregated by the weights with performance values. Finally, we compare with empirical data and find that the model of MCDM predicts the rate of return.

Keywords

Investment strategies • Multiple criteria decision making (MCDM) • Hierarchical system • Investment style • Factor analysis • Synthetic utility value • Performance values

68.1 Introduction

The number of mutual funds has increased exceeding the number of stocks listed on the organized exchange, hence making the selection of mutual funds an onerous task for the investor. In addition, the mutual funds are moving rapidly towards financial market development in response to increasing market demand and the mutual fund industry. Therefore the mutual funds have huge market potential and have been gaining momentum in the financial market. The complexities are numerous, and overcoming these complexities to offer successful selections is a mutual fund manager's challenge.

The mutual fund managers need to evaluate aquatic return so as to reduce its risk to find the optimal combination of invested stocks out of many feasible stocks and distribute the amount of investing funds to many stocks. Because of the limited amount of funds invested into mutual funds, the solution of the portfolio selection problem proposed by Markowitz (1952) has a tendency to increase the number of stocks selected for mutual funds. In a real investment, a fund manager first makes a decision on how much proportion of the investment should go to the market, and then he invests the fund to which stocks which is the stock selection ability. After that, many researchers explained in the presence of market-timing ability that actions will affect the performance of mutual funds. When investing mutual funds, some reports also point out that there are 90 % of investors who will consider the rate of return firstly and then the reputation of mutual fund corporation and investment risk. Maximizing the mutual fund performance is the primary goal of mutual fund managers in a corporation. Usually, the mutual fund return reflects the financial performance of a fund corporation for operating and development. This study explores which criteria can lead to high mutual fund performance.

To achieve this purpose, we use the method of multi-criteria decision making (MCDM). MCDM is one of the most widely used decision methodologies in engineering, medicine, economics, law, the environment, and public policy and business. The theory, methodology, and practice of MCDM have experienced a revolutionary process during the last five decades. MCDM methods aim at improving the quality of decisions by making the process more explicit, rational, and efficient. One intriguing problem is that oftentimes, different methods may yield different answers to the same decision problem. Thus, the issue of evaluating the relative performance of different MCDM methods is raised. One evaluating procedure is to examine the stability of an MCDM method's mathematical process by checking the validity of its proposed rankings. However, within a dynamic and diversified decision-making environment, the traditional quantitative method does not solve the non-quantity problems of investment selection. Therefore, what is needed is a useful and applicable strategy that addresses the issues of investment selection. We thus propose a MCDM method to evaluate the hierarchy system for selecting investment strategies.

In this study the hierarchical analytic approach is used to determine the weights of criteria from subjective judgment, and a nonadditive integral technique is utilized to evaluate the performance of investment style. Traditionally, researchers have used additive techniques to evaluate the synthetic performance of each criterion. The rest of the chapter is organized as follows: Mutual fund literature is discussed in the next section. The method of MCDM including the hierarchical analytic approach and non- additive integral evaluation process for MCDM problems is derived in Sect. 68.3. Then an illustrative example is presented in Sect. 68.4, which applies the MCDM method of investment. After which we discuss and show how the MCDM methods in this chapter are effective in Sect. 68.5. Finally, the conclusions are presented in Sect. 68.6.

68.2 Review of Mutual Fund Investment

Mutual fund research abounds in finance literature, and the investment performance of mutual fund managers has been extensively examined. Most of these studies employ a method developed by Jensen (1968, 1969) and later refined by Black et al. (1972) and Blume and Friend (1973). Such a method compares a particular manager's performance with that of a benchmark index fund. Connor and Korajczyk (1986) develop a method of portfolio performance measurement using a competitive version of the arbitrage pricing theory (APT). However, they ignore any potential market timing by managers. One weakness of the above approach is that it fails to separate the aggressiveness of a fund manager from the quality of the information he/she possesses. It is apparent that superior performance of a mutual fund manager occurs because of his/her ability to “time” the market and the ability to forecast the returns on individual assets.

Jensen (1968) demonstrates that the presence of market-timing ability is an important factor in mutual fund selections. Grant (1977) explains how market-timing actions will affect the results of empirical tests that focus only on microforecasting skills. Fama (1972) indicates that there are two ways for fund managers to obtain abnormal returns. The first one is security analysis, which is the ability of fund managers to identify the potential winning securities. The second one is market timing, which is the ability of portfolio managers to time market cycles and takes advantage of this ability in trading securities. Treynor and Mazuy (1966) add a quadratic term to the Jensen function to test for market-timing ability. Chen and Stockum (1986) employ a generalized varying parameter model, which treats Treynor and Mazuy (1966) as a special case, to study the mutual fund’s stock selectivity and market-timing ability. They find mutual funds as a group exhibits some evidence of stock selection ability yet no market-timing ability. Jensen (1972) develops theoretical structures for the evaluation of micro- and macroforecasting performance of fund managers where the basis for evaluation is a comparison of the ex post performance of the fund manager with the returns on the market. Merton (1981) and Henriksson’s (1984) model differs from Jensen’s formulation in that their forecasters follow a more qualitative approach to market timing. Chang and Lewellen (1984) and Henriksson (1984) employ the Merton-Henriksson model in evaluating mutual fund performance and find no evidence of market timing by fund managers. Bhattacharya and Pfleiderer (1983) extend the work of Jensen (1972). By correcting an error made in Jensen, they show that one can use a simple regression technique to obtain accurate measures of timing and selection ability.

Lehmann and Modest (1987) combine the APT performance evaluation method with the Treynor and Mazuy (1966) quadratic regression technique. They found statically significant abnormal timing and selectivity performance by mutual funds. They also examine the impact of alternative benchmarks on the performance of mutual funds and find that performance measures are quite sensitive to the benchmark chosen. Also, Henriksson (1984) finds a negative correlation between the measures of stock selection and market-timing ability. Finally, Lee and Rahman (1990) also empirically examine market timing and selectivity performance of mutual funds. Furthermore, Jorge et al. (2006) deal with the relevance of benchmark choice for mutual fund performance behavior, and Spitz (1970) researches the relationship between mutual fund performance and cash inflows. Blake and Morey (2000) verify the mutual fund performance of Morningstar ratings.

The above mentioned studies concentrate on a fund manager’s security selection and market-timing skills. However, external evaluation, human judgment, and subjective perception also affect the performance of mutual funds. In a real-world setting, the performance of mutual funds involves many criteria. In this article we will discuss these criteria and performance at the same time.

68.3 The Method of Multi-criteria Decision Making

Kuosmanen (2004) and Kopa and Post (2009) use the stochastic dominance criterion test on a portfolio optimality and efficient diversification. In this section we employ factor analysis to extract four independent common factors from those criteria. At the same time we construct the evaluation frame using AHP (analytic hierarchy process), which is composed of the above four common factors with sixteen evaluated criteria, and derive the relative weights with respect to the considered criteria and the synthetic utility value corresponding to each mutual fund investment style.

According to the literature review and our questionnaire survey, we employ factor analysis to extract independent common factors from criteria. At the same time we construct the evaluation framework using a hierarchical system composed of the above common factors with evaluation criteria and derive the relative weights pertinent to the considered criteria. Then the synthetic utility value corresponding to each investment style is aggregated by the weights with performance values. Traditional analytic hierarchy process (AHP) assumes that there is no interaction between any two criteria within the same hierarchy. However, in reality, a criterion is inevitably correlated with another one. In this section, we give a brief to some notions from the theory of measure and integral. We describe a hierarchical analytic approach to determine the weighting of subjective judgments.

68.3.1 λ-Measure

The specification for general measures requires the values $\cap$ of a measure for all subsets in X. Let (X, β, g) be a measure space: $\lambda \in (-1, \infty)$. If A $\in \beta$, B $\in \beta$; and A $\cap$ B$=\phi$, and

$$g(A \cup B) = g(A) + g(B) + \lambda g(A)g(B) \tag{68.1}$$

If this holds, then measure g is λ-additive. This kind of measure is named λ-measure, or the Sugeno measure. In this chapter we denote this λ-measure by g_i to differentiate from other measures. Based on the axioms above, the λ-measure of the finite set can be derived from densities, as indicated in the following equation:

$$g_\lambda(\{x_1, x_2\}) = g_1 + g_2 + \lambda g_1 g_2 \tag{68.2}$$

Where $g_{1,}$ g_2 represents the density.

Let set $X = \{x_1, x_2, .., x_n\}$ and the density of measure $g_i = g_\lambda(\{x_i\})$, which can be formulated as follows:

$$g_\lambda(\{x_1, x_2, \ldots, x_n\}) = \sum_{i=1}^{n} g_i + \lambda \sum_{i_1=1}^{n-1} \sum_{i_2=i_1+1}^{n} g_{i_1} g_{i_2} + \cdots + \lambda^{n-1} g_1 g_2 \cdots g_n \tag{68.3}$$

For an evaluation case with two criteria, A and B, there are three cases based on the above properties:

Case 1: If $\lambda > 0$, i.e., $g_\lambda(A \cup B) > g_\lambda(A) + g_\lambda(B)$, implying that A and B have a multiplicative effect.

Case 2: If $\lambda = 0$, i.e., $g_\lambda(A \cup B) = g_\lambda(A) + g_\lambda(B)$, implying that A and B have an additive effect.

Case 3: If $\lambda < 0$, i.e., $g_\lambda(A \cup B) < g_\lambda(A) + g_\lambda(B)$, implying that A and B have a substitutive effect.

The measure is often used with the integral for aggregating information evaluation by considering the influence of the substitutive and multiplication effect among all criteria.

68.3.2 The Integral

In a measure space (X, β, g), let h be a measurable set function defined in the measurable space. Then the definition of the integral of h over A with respect to g is

$$\int_A h(x)dg = \sup_{\alpha \in [0,1]} [\alpha \wedge g(A \cap H_\alpha)] \tag{68.4}$$

where $H_a = \{$x belonging to Xlh(x) $\geq \alpha\}$. A is the domain of the integral. When A = X, then A can be taken out.

Next, the integral calculation is described in the following. For the sake of simplification, consider a measure g of X, $\aleph$ where X is a finite set. Let $h : X \to [0,1]$ and assume without loss of generality that the function $h\ (x_j)$ is monotonically decreasing with respect to j, i.e., $h(x_1) \geq h(x_2) \geq \cdots \geq h(x_n)$. To achieve this, the elements in X can be renumbered. With this, we then have

$$\int h(x)dg = \mathop{\vee}_{i=1}^{n} [f(x_i) \wedge g(X_i)] \tag{68.5}$$

where $X_i = \{x_1, x_2, \cdots, x_i\}$, i = 1, 2, $\cdots$, n.

In practice, h is the evaluated performance on a particular criterion for the alternatives, and g represents the weight of each criterion. The integral of h with respect to g gives the overall evaluation of the alternative. In addition, we can use the same measure using Choquet's integral, defined as follows:

$$\int hdg = h(x_n)g(X_n) + [h(x_{n-1}) - h(x_n)]g(X_{n-1}) + \cdots + [h(x_1) - h(x_2)]g(X_1) \tag{68.6}$$

The integral model can be used in a nonlinear situation since it does not need to assume the independence of each criterion.

68.3.3 The Integral Multi-criteria Assessment Methodology

The integral is used in this study to combine assessments primarily because this model does not need to assume independence among the criteria. A brief overview of the integral is presented here.

Assume under general conditions, $h(x_1^k) \geq \cdots \geq h(x_i^k) \geq \cdots \geq h(x_n^k)$ where $h(x_i^k)$ is the performance value of the kth alternative for the ith criterion, the integral of the measure $g_\lambda(X_n^k)$ with respect to $h(x_n^k)$ on $\aleph$ (g: $\aleph \longrightarrow [0, 1]$) can be defined as follows:

$$\int^k hdg = h\left(x_n^k\right) g_\lambda\left(X_n^k\right) + \left[h\left(x_{n-1}^k\right) - h\left(x_n^k\right)\right] g_\lambda\left(X_{n-1}^k\right) + \cdots + \left[h\left(x_1^k\right) - h\left(x_2^k\right)\right] g_\lambda\left(X_1^k\right) \tag{68.7}$$

where $g_\lambda(X_1^k) = g_\lambda(\{x_1^k\})$, $g_\lambda(X_2^k) = g_\lambda(\{x_1^k, x_2^k\})$, …, $g_\lambda(X_n^k) = g_\lambda(\{x_1^k, x_2^k, \cdots, x_n^k\})$

The measure of each individual criterion group $g_\lambda(X_n^k)$ can be expressed $\sum_{i=1}^{n} g_\lambda\left(x_i^k\right) + \lambda \sum \sum g_\lambda(\{x_i\}) g_\lambda\left(\{x_j\}\right) + \cdots \lambda^{n-1} g_\lambda(\{x_1\}) \cdots g_\lambda(\{x_n\})$ as follows:

$$\begin{aligned} g_\lambda\left(X_n^k\right) &= g_\lambda\left(\left\{x_1^k, x_2^k \cdots x_n^k\right\}\right) = \sum_{i=1}^{n} g_\lambda\left(x_i^k\right) + \\ &\lambda \sum \sum g_\lambda(\{x_\mathrm{i}\}) g_\lambda\left(\{x_j\}\right) + \cdots \\ &\lambda^{n-1} g_\lambda(\{x_1\}) \cdots g_\lambda(\{x_n\}) = \frac{1}{\lambda}\left[\prod_{i=1}^{n}\left(1 + \lambda g_\lambda\left(x_i^k\right)\right) - 1\right] \end{aligned} \tag{68.8}$$

for $-1 < \lambda < +\infty$.

λ is the parameter that indicates the relationship among related criteria (if λ=0, Eq. 68.7 is an additive form; if $\lambda \neq 0$, Eq. 68.7 is a nonadditive form).

68.4 Evaluation Model for Prioritizing the Investment Strategy

We build up a hierarchical system for evaluating investment strategies of Wang and Lee (2011). Its analytical procedures stem from three steps: (i) factor, (ii) criteria, and (iii) investment style. We employ factor analysis to extract four independent common factors from various criteria, and these factors are (1) market timing, (2) stock selection ability, (3) fund size, and (4) teamwork. We construct the evaluation frame using hierarchical system composed of the above four common factors with sixteen evaluated criteria. We then derive the relative weights pertinent to the considered criteria. According to the risk of investment, mutual funds with different investment styles are classified as S1, asset allocation style; S2, aggressive growth style; S3, equity income style; S4, growth style; and S5, growth income style. Based on the review of literature, personal experience, and interviews with senior mutual fund managers, relevance trees are used to create hierarchical strategies for developing the optimal selection strategy of mutual funds.

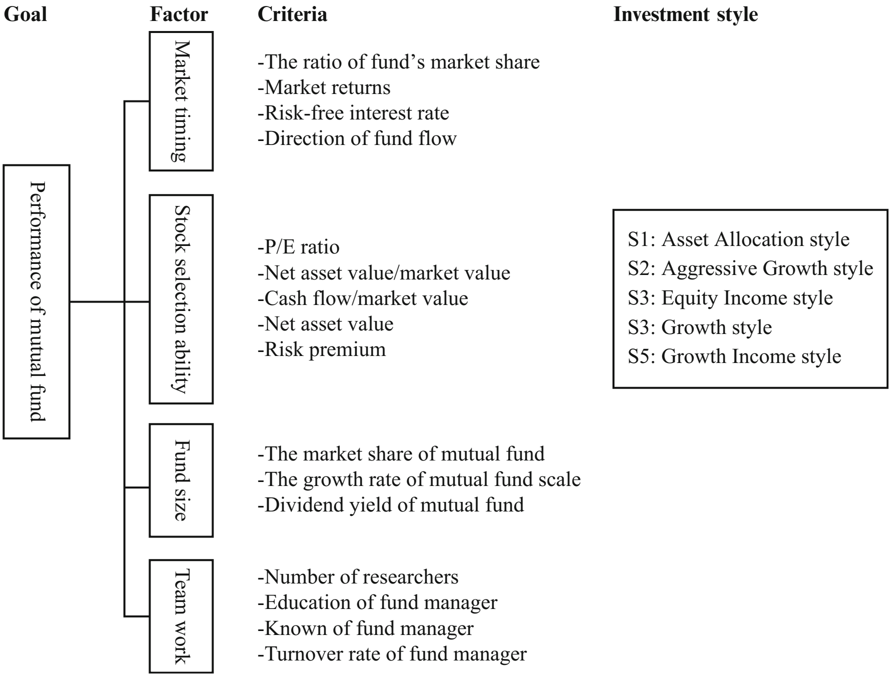

Fig. 68.1 Relevance system of hierarchy tree for evaluating mutual fund strategy

The elements (nodes) of relevance trees are defined and identified in hierarchical strategies, the combination of which consists of an evaluating mechanism for selecting a mutual fund strategy, as shown in Fig. 68.1.

68.4.1 Evaluating the Mutual Fund Strategy Hierarchy System

Minimum risk or maximum return is usually used as the measurement index in traditional financial evaluation methods. Based on the risk of investment, mutual funds are classified into five investment styles and we evaluate the funds' performance by the rate of return. Within a dynamic and diversified decision-making environment, the traditional quantitative method does not solve the non-quantity problems of mutual fund selection. Therefore, what is needed is a useful and applicable strategy that addresses the issues of selecting mutual funds. We propose an MCDM method to evaluate the hierarchy system for selecting mutual fund strategies.

The performance of mutual fund architecture includes four components: market timing, stock selection ability, fund size, and teamwork. We first discuss conceptual and econometric issues associated with identifying four components of mutual fund performance. We have chosen multiple criteria evaluation method for selecting and prioritizing the mutual fund strategies to optimize the real scenarios faced by managers or investors.

68.4.2 The Process for Evaluating and Prioritizing Mutual Fund Strategies

In this study, we use this MCDM method to evaluate various mutual fund strategies and rank them by performance. The following subsection describes the method of MCDM.

68.4.2.1 The Weights for the Hierarchy Process

An evaluator always perceives the weight of a hierarchy subjectively. Therefore, consider the uncertain, interactive effects coming from other criteria when calculating the weight of a specified criterion.

The weights w_j corresponding to each criterion is as follows:

$$w_j = r_j \otimes (r_1 \oplus \cdots \oplus r_m)^{-1} \tag{68.9}$$

where r_j is the geometric mean of each row of AHP reciprocal matrix

$$r_j = \left(a_{j1} \otimes \cdots \otimes a_{jm}\right)^{1/m} \tag{68.10}$$

68.4.2.2 The Synthetic Decision

The weight of the different criteria and the performance value needs to be operated using integral techniques to generate the synthetic performance of each strategy within the same dimension.

Furthermore, we have calculated the synthetic performance of each alternative strategy using different λ values. Additionally, the synthetic performance is conducted by a simple additive weight method assuming the criteria are independent in an environment. Since each individual criterion is not completely independent from the others, we use the nonadditive integral technique to find the synthetic performance of each alternative and to investigate the order of the synthetic performance of different λ values.

68.5 Empirical Examinations and Discussions

To demonstrate the practicality of our proposed method of evaluating mutual fund strategies, we conducted an empirical study based on survey of a total of 30 valid samples from managers of 12 Taiwanese mutual fund companies and researchers of eight research institutions and universities. The majority of the respondents are fund managers responsible for financial or general management. The mutual fund strategy selection process is examined below.

68.5.1 Evaluating the Weights of Criteria

By using the MCDM method, the weights of the factors and criteria are found and are shown in Table 68.1. The empirical evidence shown in Table 68.1 indicates that the weights of each criterion are market timing, 0.524; stock selection ability, 0.318; fund size, 0.141; and teamwork, 0.017, respectively. Therefore, the market timing is the most important factor influencing the performance of mutual funds, followed by the stock selection ability. Prior studies have simultaneously estimated the magnitudes of these portfolio performance evaluation measures. For example, some results show that, on average, mutual fund managers have positive security selection ability but negative market-timing ability (e.g., Chen and Stockum 1986). Since our results suggest that market timing has heavier weight than the stock selection ability, to enhance their performance, mutual fund managers should improve their ability of market timing.

68.5.2 Evaluation and Prioritization of the Mutual Fund Strategy

In this study, the surveyors define their individual range (from 0 to100) for the linguistic variables based on their judgments. By ranking weights and synthetic performance values, we can determine the relative importance of criteria and decide on the best strategies. We apply a λ-measure and nonadditive integral technique to evaluate investment strategies. The synthetic performance of each alternative using different λs is shown in Table 68.2. By ranking the synthetic performance in different λs in Table 68.2, we obtain mutual fund strategy ranking in Table 68.3. In Table 68.3, our empirical results show that when $\lambda < 0$, the aggressive growth style is the most important strategy and growth style is the second most important strategy. When $\lambda \geq 0 – 5$, the results show that growth style is the most important strategy, and equity income style is the second most important strategy. When $\lambda = 10 – 30$, growth style is the most important strategy, followed by the growth income style strategy. When $\lambda \geq 40$, the results show that growth income style replaces growth style becoming the second ranked. On the other hand, when $\lambda \geq 0$, asset allocation style is the worst strategy with the smallest synthetic performance. We can thus infer that the less risky the funds are, the less performance of the funds will be.

68.5.3 Comparing with the Empirical Data

Monthly returns from January 1980 to September 1996 (201 months) for a sample of 65 US mutual funds are used in this study to generate mutual fund performance. The random sample of mutual funds is provided by the MorningStar. The MorningStar segregates mutual funds into four basic investment styles on the basis of manager's portfolio characteristics. Our sample consists of 8 asset allocation (S1), 14 aggressive growth (S2), 10 equity income (S3), 16 growth (S4),

Table 68.1 The weights of criteria for evaluating mutual funds

Criteria	Weight
Market timing	**0.524**
The ratio of fund's market share	0.252
Market returns	0.495
Risk-free interest rate	0.212
Direction of fund flow	0.041
Stock selection ability	**0.318**
P/E ratio	0.252
Net asset value/market value	0.150
Cash flow/market value	0.080
Net asset value	0.187
Risk premium	0.331
Fund size	**0.141**
The market share of mutual fund	0.341
The growth rate of mutual fund scale	0.155
Dividend yield of mutual fund	0.504
Teamwork	**0.017**
Number of researchers	0.293
Education of fund manager	0.182
Known of fund manager	0.429
Turnover rate of fund manager	0.096

Table 68.2 The synthetic performance of mutual fund style

λ	−1.0	−0.5	0.0	1.0	3.0	5.0	10.0	20.0	40.0	100.0	150.0	200.0
S1	395.3	538.0	300.7	299.9	298.8	297.1	296.1	295.9	293.7	292.5	291.6	291.0
S2	616.8	901.2	311.9	310.8	307.6	306.0	303.2	300.2	297.3	294.0	292.0	290.9
S3	457.0	682.5	313.0	311.8	309.5	307.8	304.5	302.1	297.6	294.5	291.7	290.5
S4	552.2	855.7	315.7	312.8	311.7	310.2	308.6	304.4	300.3	298.9	295.8	294.6
S5	363.1	382.9	310.5	309.3	307.2	305.3	304.9	303.5	302.1	301.9	300.1	299.5

S1 is the asset allocation fund, S2 is the aggressive growth, S3 is the equity income, S4 is the growth, and S5 is the growth income fund

Table 68.3 The evaluation results of mutual fund strategy

Mutual fund strategy ranking	
$\lambda = -1, -0.5$	S2 $\succ$ S4 $\succ$ S3 $\succ$ S1 $\succ$S5
$\lambda = 0, 1, 3$	S4 $\succ$ S3 $\succ$ S2 $\succ$ S5 $\succ$ S1
$\lambda = 5$	S4 $\succ$ S3 $\succ$ S5 $\succ$ S2 $\succ$ S1
$\lambda = 10, 20$	S4 $\succ$ S5 $\succ$ S3 $\succ$ S2 $\succ$ S1
$\lambda = 40, 100$	S5 $\succ$ S4 $\succ$ S3 $\succ$ S2 $\succ$ S1
$\lambda = 150, 200$	S5$\succ$ S4 $\succ$ S2 $\succ$ S3 $\succ$ S1

Where S1, asset allocation style; S2, aggressive growth style; S3, equity income style; S4, growth style; and S5, growth income style and 17 growth income (S5) mutual funds. The monthly returns on the S&P 500 Index are used for the market returns. Monthly observations of the 30-day Treasury-bill rate are used as a proxy for the risk-free rate.

Appendix 3 contains summary statistics for the returns of mutual funds. All values are computed in excess of the returns on the US T-bills closest to 30 days to maturity. Data contains mean, standard deviation, maximum, and minimum. Averages of each investment style show that the asset allocation style has the smallest expected return and it also has the smallest standard deviation. However, the aggressive growth style has the largest maximum return but it also has the smallest minimum return and the largest standard deviation. In other words, the more aggressive the funds are, the more volatile the fund returns will be.

The primary purpose of comparing with mutual fund performance data is to find out the true value of λ. Given the true λ value, we can infer other mutual funds' performance during the same period. For example, in Appendix 3, we find the pecking order of mutual funds' performance based upon investment styles is S4 $>$ S5 $>$ S3 $>$ S2 $>$ S1, which is in the same order as shown in Table 68.3 when $\lambda = 10, 20$. Therefore, we find the λ value for certain period when comparing with a sample of mutual fund performance data. Based upon this λ value, we can easily predict the performance of other mutual funds.

68.6 Conclusions

This study focuses on providing a mutual fund strategy for the mutual fund managers so that they could be successful in their decision making. Our empirical study demonstrates the validity of this method. In this study, the mutual fund strategy stems from four aspects: market timing, stock selection ability, fund size, as well as teamwork. Picking a mutual fund from the thousands is not an easy task. Mutual fund managers have difficulty in selecting the proper strategy for reasons such as the uncertain and dynamic environment and numerous criteria that they are facing. Managers are hence overwhelmed by this vague scenario and do not make proper decisions or allocate resources efficiently. The hierarchical method guides the manager how to select the investment style of mutual funds in the uncertainty environment.

We compare our results with the empirical data and find that the model of MCDM predicts the rate of return well in certain ranges of λ. Furthermore, we can use this λ value to compute the performance of different mutual funds; thus the nonadditive integral technique is an effective method to predict the mutual fund performance. By ranking weights and synthetic performance values, we determine the relative importance of criteria, which allows us to decide on the best strategies. We apply a λ-measure and nonadditive integral technique to evaluate investment strategies. By ranking the synthetic performance in different λs, we obtain mutual fund strategy ranking. Our empirical results show that when $\lambda < 0$, the aggressive growth style is the most important strategy; when $\lambda \geq 0 - 5$, the growth style is the most important strategy; when $\lambda = 10 - 30$, growth style is the most important strategy followed by the growth income style strategy. However, when $\lambda \geq 40$, growth income style replaces growth style becoming the second ranked. On the other hand, when $\lambda \geq 0$, asset allocation style is the worst strategy with the smallest synthetic performance. We can thus infer that the less risky the funds are, the less performance of the funds will be, and the more aggressive the funds are, the higher the volatility of the fund performance will be.

Few studies have addressed mutual fund strategy planning. Proposed in this study is a first attempt to formally model the formulation process for a mutual fund strategy using MCDM. We believe that the analysis presented is a significant contribution to the literature and will help to establish groundwork for future research. Even though we are dedicated to setting up the model as completely as possible, there are additional criteria (e.g., tax, expenses, dividend) and methods that could be adopted and added in future research. The mutual fund industry is growing rapidly in the financial markets in response to increasing demand. Therefore, what is needed is a useful and applicable method that addresses the selection of mutual funds. We use a MCDM method to achieve this goal.

Appendix 1

The Description of Evaluative Criteria of Mutual Funds

Criteria	Description
Market timing	The ability of portfolio managers to time market cycles and take advantage of this ability in trading securities
The ratio of fund market share	The ratio of fund invested in securities
The return of market	The fraction of ups or downs of deep bid index in current period divided by the deep bid index in last period
Riskless interest rate	The risk-free interest rate is the interest rate that it is assumed can be obtained by investing in financial instruments with no default risk. In practice most professionals and academics use short-dated government bonds of the currency in question. For Taiwan investments, usually Taiwan bank 1-month deposit rate is used
Flowing of cash	Cash flow refers to the amounts of cash being received and spent by a business during a defined period of time, sometimes tied to a specific project. Measurement of cash flow can be used to evaluate the state or performance of a business or project
Stock selection ability	The ability of fund managers to identify the potential winning securities
P/E ratio	The P/E ratio (price per share/earnings per share) of a mutual fund is used to measure how cheap or expensive its share price is. The lower the P/E, the less you have to pay for the mutual fund, relative to what you can expect to earn from it
Net value/market value	The value of an entity's assets less the value of its liabilities divided by market value

(*continued*)

Criteria	Description
Cash flowing/market value	It equals cash receipts minus cash payments over a given period of time divided by market value or equivalently, net profit plus amounts charged off for depreciation, depletion, and amortization (business) divided by market value
Net value	Net value is a term used to describe the value of an entity's assets less the value of its liabilities. The term is commonly used in relation to collective investment schemes
Risk premium	A risk premium is the minimum difference between the expected value of an uncertain bet that a person is willing to take and the certain value that he is indifferent to
Fund size	The volume and scale of mutual funds
The market share of mutual fund	It can be expressed as a company's sales revenue (from that market) divided by the total sales revenue available in that market. It can also be expressed as a company's unit sales volume (in a market) divided by the total volume of units sold in that market
The growth rate of mutual fund scale	The fraction of the increase or decrease of the fund scale in current period divided by the fund scale in last period
Dividend yield of mutual fund	The dividend yield on a company mutual fund is the company's annual dividend payments divided by its market cap or the dividend per share divided by the price per share
Teamwork	The culture of mutual fund company
Number of researcher	The number of researcher of each fund
Education of fund manager	Fund manager's seniority, quality, and performance
Known of fund manager	Fund manager's rate of exposed in the medium and number of win a prize
Turnover rate of fund manager	Fund manager leaves his job temporarily

Appendix 2

Summary Statistics for Returns of the Mutual Funds

The notations and definition of the investment style of mutual funds are in panel 2.1.
Panel 2.1

Classifications	Investment style	Description
Aa	Asset allocation	A large part of financial planning is finding an asset allocation that is appropriate for a given person in terms of their appetite for and ability to shoulder risk. The designation of funds into various categories of assets
Ag	Aggressive growth	Regardless of the investment style or the size of the companies purchased, funds vary widely in their risk and price behavior which is likely to have a high beta and high volatility

(*continued*)

Classifications	Investment style	Description
Ei	Equity income	It will invest in common stock but will have a portfolio beta closer to 1.0 than to 2.0. It likely favors stocks with comparatively high dividend yields so as to generate the income its name implied
G	Growth	The pursuit of capital appreciation is the emphasis with growth funds. This class of funds includes those called aggressive growth funds and those concentrating on more stable and predictable growth
Gi	Growth income	It pays steady dividends, and it is still predominately an investment in stocks, although some bonds may be included to increase the income yield of the fund

Monthly mutual funds are from January 1980 to September 1996 for a sample of 65 US mutual funds. The data are from Morningstar Company.

Appendix 4

The MCDM proposed approach consists of eight steps: define the problem, define the evaluation criteria, initial screen, define the preferences on evaluation criteria, define the MCDM method for selection, evaluate the MCDM methods, choose the most suitable method, and conduct sensitivity analysis.

Step 1: Define the problem. The characteristics of the decision-making problem under consideration are addressed in the problem definition step, such as identifying the number of alternatives, attributes, and constraints. The available information about the decision-making problem is the basis on which the most appropriate MCDM techniques will be evaluated and utilized to solve the problem.

Step 2: Define the evaluation criteria. The proper determination of the applicable evaluation criteria is important because they have great influence on the outcome of the MCDM method selection process. However, simply using every criterion in the selection process is not the best approach because the more criteria used, the more information is required, which will result in higher computational cost. In this study, the characteristics of the MCDM methods will be identified by the relevant evaluation criteria in the form of a questionnaire. Ten questions are defined to capture the advantages, disadvantages, applicability, computational complexity, etc. of each MCDM method, as shown in the following. The defined evaluation criteria will be used as the attributes of an MCDM formulation and as the input data of decision matrix for method selection:

1. Is the method able to handle MADM, MODM, or MCDM problem?
2. Does the method evaluate the feasibility of the alternatives?
3. Is the method able to capture uncertainties existing in the problem?
4. What input data are required by the method?
5. What preference information does the method use?
6. What metric does the method use to rank the alternatives?
7. Can the method deal changing alternatives or requirements?
8. Does the method handle qualitative or quantitative data?
9. Does the method deal with discrete or continuous data?
10. Can the method handle the problem with hierarchy structure of attributes?

Step 3: Initial screen in the initial screen step. The dominated and infeasible MCDM methods are eliminated by dominance and conjunctive. An alternative is dominated if there is another alternative which excels it in one or more attributes and equals it in the remainder. The dominated MCDM methods are eliminated by the dominance method, which does not require any assumption or any transformation of attributes. The sieve of dominance takes the following procedures. Compare the first two alternatives, and if one is dominated by the other, discard the dominated one; then compare the un-discarded alternative with the third alternative and discard any dominated alternative; and then introduce the fourth alternative and repeat this process until the last alternative has been compared. A set of non-dominated alternatives may possess unacceptable or infeasible attribute values. The conjunctive method is employed to remove the unacceptable alternatives, in which the decision maker sets up the cutoff value he/she will accept for each of the attributes. Any alternative which has an attribute value worse than the cutoff values will be eliminated.

Step 4: Define the preferences on evaluation criteria. Usually, after the initial screen step is completed, multiple MCDM methods are expected to remain; otherwise we can directly choose the only one left to solve the decision-making problem. With the ten evaluation criteria defined in step 2, the decision maker's preference information on the evaluation criteria is defined. This will reflect which criterion is more important to the decision maker when he/she makes decisions on method selection.

Step 5: Define the MCDM method for selection. Existing commonly used MCDM methods are identified and stored in the method base as candidate methods for selection. The simple additive weighting (SAW) method is chosen to select the most suitable MCDM methods considering its simplicity and general acceptability. Basically, the SAW method provides a weighted summation of the attributes of each method, and the one with the highest score is considered as the most appropriate method. Though SAW is used in this study, it is worth noting that other MCDM methods can be employed to handle the same MCDM methods selection problem.

Step 6: Evaluate the MCDM methods. Mathematical formulation of appropriateness index (AI) is used to rank the MCDM methods. The method with the highest AI will be recommended as the most appropriate method to solve the problem under consideration.

Step 7: Choose the most suitable method. For optimization of specification of grinding wheel, the MCDM method which has the highest AI will be selected as the most appropriate method to solve the given decision-making problem. If the DM is satisfied with the final results, he/she can implement the solution and move forward. Otherwise, he/she can go back to step 2 and modify the input data or preference information and repeat the selection process until a satisfied outcome is obtained. Be displayed to provide guidance to DM is provided guidance about how to get the final solution by using the selected method. In addition, the detailed mathematical calculation steps are also built in the MATLAB-based DSS, which highly facilitates the decision-making process. Thus, the DM can input their data according to the instruction and get the final results by clicking one corresponding button.

Step 8: Conduct analysis. In this section, selection of an optimized specification of grinding wheel problem is conducted to improve the capabilities of the grinding operation products by proposed MCDM decision support system. It is observed that different decision makers often have different preference information on the evaluation criteria and different answers to the ten questions; thus, analysis should be performed on the MCDM method selection algorithm in order to analyze its robustness with respect to parameter variations, such as the variation of decision maker's preference information and the input data. If the decision maker is satisfied with the final results, he/she can implement the solution and move forward. Otherwise, he/she can go back to step 2 and modify the input data or preference information and repeat the selection process until a satisfied outcome is obtained. In this implementation, emphasis is put on explaining the holistic process of the intelligent MCDM decision support system. Thus, the step-by-step problem-solving process is explained and discussed for this decision-making problem.

Econometric Analysis of Currency Carry Trade

69

Yu-Jen Wang, Huimin Chung, and Bruce Mizrach

Contents

Abstract

The carry trade is a popular strategy in the currency markets whereby investors fund positions in high interest rate currencies by selling low interest rate currencies to earn the interest rate differential. In this article, we first provide an overview of the risk and return profile of currency carry trade; second, we introduce two popular models, the regime-switch model and the logistic smooth transition regression model, to analyze carry trade returns because the carry trade returns are highly regime dependent. Finally, an empirical example is illustrated.

Keywords

Carry trade • Uncovered interest parity • Markov chain Monte Carlo • Regime-switch model • Logistic smooth transition regression model

69.1 Introduction

According to the international financial theory such as uncovered interest parity (UIP), the exchange rate will depreciated in the future if the country has a high interest rate. Although investors can potentially profit from the interest rate differential between the two countries, the exchange rate differential may offset the interest rate differential. However, in the past two decades, an enormous amount of empirical research has refuted the UIP theory. These evidences suggest that when exchange rate returns combine with time-varying premium, UIP is not usually present in the past.[1]

Carry trade, a common international investment strategy, is a good example that runs contradictory to UIP theory. Carry trade is built by borrowing currency from a lower interest rate country and then investing in a higher interest rate country. A large body of research shows that carry trade is profitable over the long horizon. How the carry trade strategy earns a persistent excess return is an open question. The literature suggests several explanations for the forward premium puzzle. Engel (1984) and Fama (1984) provide the straightforward and theoretically convincing explanation based on the existence of time-varying risk premia for this puzzle. Burnside et al. (2011) refer to the peso problem as an explanation for the high average payoff to the carry trade.[2] Baillie and Chang (2011) provide another explanation for this puzzle that focuses on the trading behavior.

However, because UIP is not always held in the short term, previous empirical studies have adopted several models that allow for temporary deviations from UIP and have discussed regime dependence among other factors to fit the carry trade return. For example, Ichiue and Koyama (2008) provide the regime-switch model to detect how the exchange rate volatility influences UIP. The failures of UIP usually happen at relatively low volatility environment. In particular, they argue that the rapidly unwinding carry trade affects the exchange rate volatility. Recently, using daily data from 1985 to 2008, Christiansen and Ranaldo (2011) analyze carry trade returns with the multifactor model. Their main findings suggest high regime dependence of the carry trade return. Clarida et al. (2009) also find significant volatility regime sensitivity for Fama regressions estimated over low and high volatility periods. Sarno et al. (2006)

---

[1]Meese and Rogoff (1983) assume that exchange rates follow the "near-random walk" model and provide the evidence to reject UIP. Fama (1984) applies the concept of forward rate contained in the time-varying premium to analyze the relation between the forward exchange rate and spot exchange rate and points out that high interest rate currencies tend to appreciate rather than depreciate. Froot and Thaler (1990) replace time-varying premium with the mean return theory to explain foreign exchange anomalies. Burnside et al. (2009) emphasize that the forward premium puzzle can be construed as the adverse selection problems between participants in foreign exchange markets. Brunnermerier et al. (2008) use the liquidity risk factor to explain the excess return of the carry trade. They add the change of VIX index or the TED spread variable to be the liquidity risk factors in the regression and suggest that the market liquidity factor may explain the carry trade's risk premium.

[2]The peso problem is as a generic term for the effects of small probabilities of large events in empirical work. Burnside et al. (2011) approach relies on analyzing the payoffs to a version of the carry trade strategy that does not yield high negative payoffs in the peso state.

provide empirical evidence the deviations from UIP display significant nonlinearities that consistent with theories based on transactions costs or limits to speculation. Menkhoff et al. (2012) explain that low returns occur in times of unexpected high volatility, when low interest rate currencies provide a hedge by yielding positive returns. Empirically, however, the literature has serious problems convincingly claiming that carry trade returns as regime dependence or that the *higher profit opportunities of carry trade usually* occurred in lower volatility regime.

In sum, massive losses associated with the carry trade usually occurred in the higher volatility regime, the positive return usually exists in carry trade at the low volatility regime, and the carry trade return process does not follow the traditional linear models. Baillie and Chang (2011) further find that momentum trading increases carry trade volatility. Brunnermerier et al. (2008) also find the levered market participants gradually build up positions in high-yielding currencies, causing high-yielding currencies to appreciate over time along with speculators' larger positions. In addition, Brunnermerier et al. (2008) find that higher market volatility is associated with carry trade losses. Clarida et al. (2009) use the Fama regression, which produces a positive coefficient that is greater than unity when volatility is in the top quartile.[3] Baillie and Chang (2011) find that UIP is more likely to hold in a regime when volatility is unusually high. These results suggest that the momentum effect in the carry trade perhaps exists in the low volatility regime, but the empirical results are mixed in the high volatility regime. However, the carry trade perhaps confronts crash risk in the high volatility regime whether UIP holds.

Because the carry trade return is highly regime dependent, regime conditions must be considered in the return process model. Ichiue and Koyama (2008) use the regime-switch model to investigate the relation among exchange rate returns, volatilities, and interest rate differentials. Baillie and Chang (2011) use the logistic smooth transition regression (LSTR) model to identify whether the forward FX market is in a regime where the anomaly is present or whether it is in a regime where UIP tends to hold. They find that UIP is more likely to hold in a regime where volatility is unusually high, which may be explained by previous theoretical work that links momentum trading to increased volatility and more pronounced reversion to fundamentals.

In estimating the model, we suggest the Markov chain Monte Carlo (MCMC) methods. The major advantage of the Bayesian MCMC approach is its extreme flexibility. Because the parameters are generated by the random variable from posterior distributions, the MCMC method can avoid the thorny problem of maximum such as the maximum likelihood estimation. This method is well suited to fit realistic models to complex data sets with threshold value, measurement error, censored or missing observations, multilevel or serial correlation structures, and multiple endpoints. This method is suitable for the regime-dependent models because these models usually have a threshold point. For instance, Ichiue and Koyama (2008) use the Bayesian Gibbs sampling method to estimate the parameters

[3]The empirical result of Clarida et al. (2009) indicates that UIP is violated in the high volatility regime.

of the regime-switch model, and early investigations also used MCMC method, such as Albert and Chib (1993), Kim et al. (1998), and Kim and Nelson (1999).

The study provides a more clear analysis of carry trade return behavior in the different volatility regimes. Our main purpose is to construct an investment strategy that can create lower volatility and higher return of the carry trade, where the carry trade returns are produced by exchange rate and 3-month interbank rate data and the volatility variables are determined by VIX, which is calculated from the S&P500 equity-options market, generalized autoregressive conditional heteroskedasticity (GARCH), and exponential GARCH (EGARCH).[4] According to our empirical outputs, we find several results. First, we confirm that carry trade returns display a significant momentum effect at the low volatility regime. Second, the VIX performance of carry trade is better than other volatility measures during the subprime period (2007–2008). Third, we can create lower downside risk strategy than the buy-and-hold strategy in the long run when we used the GARCH volatility measure. Finally, we still have a higher Sortino ratio by using the GARCH volatility measure.

The remainder of this study is organized as follows. We introduce two financial econometrics models, the regime-switch model and LSTR model, in Sect. 69.2.1. Section 69.2.2 discusses our method, based on the MCMC method. We discuss the carry trade return behavior and provide a new carry trade trading strategy of carry trade in Sect. 69.3. Section 69.4 concludes.

69.2 Overview of Model and Methodology for Carry Trade

Based on past study, the regime-dependent model is most popular to analyze carry trade returns because the behaviors of carry trade returns are diversely in the different volatility regimes. We will introduce two popular regime-dependent models, the regime-switching and logistic smooth transition regression models, in this section. The regime-dependent models usually have threshold value such as regime-switching model. We suggest using the MCMC methods to avoid this thorny problem of parameter estimation.

69.2.1 The Regime-Switching and Logistic Smooth Transition Regression Models

The covered interest parity (CIP) is a non-arbitrage condition. It postulates that the nominal interest differential between two countries ($i_t^* - i_t$) should equal the forward premium ($f_t - s_t$). It is expressed as

$$E_t[\Delta s_{t+1}] = i_t^* - i_t = f_t - s_t, \tag{69.1}$$

[4]Wang et al. (2012) suggest that GARCH models with skew density innovations may be another suitable volatility measure for carry trade return.

where s_t is the logarithm of the spot exchange rate quoted as the foreign price of domestic currency, f_t is the logarithm of the forward rate for a one-period ahead transaction, and i_t and i_t^* are the one-period risk-free domestic and foreign interest rates, respectively. The standard test of UIP to estimate the regression is

$$\Delta s_{t+1} = \alpha + \beta(f_t - s_t) + u_{t+1}. \tag{69.2}$$

Under UIP, the null hypothesis is that $\alpha = 0$ and $\beta = 1$ that the error term, u_{t+1}, is serially uncorrelated. The forward premium anomaly generally refers to the widespread phenomenon of a negative slope coefficient being obtained by the ordinary least square estimation of Eq. 69.2. Baillie and Chang (2011) further use the LSTR model, which postulates that the slop coefficient is related nonlinear to the degree of carry and momentum trading over time; a natural approach is to specify the UIP relation in terms of the LSTR model:

$$\begin{aligned}\Delta s_{t+1} = {} & [\alpha_1 + \beta_1(f_t - s_t)](1 - G(z_t;\gamma,c)) \\ & + [\alpha_2 + \beta_2(f_t - s_t)]G(z_t;\gamma,c) + u_{t+1},\end{aligned} \tag{69.3}$$

where $G(\cdot)$ is a logistic transition function as follows:

$$G(z_t;\gamma,c) = \left(1 + \exp\left(\frac{-\gamma(z_t - c)}{\sigma_{z_t}}\right)\right)^{-1}, \gamma > 0, \tag{69.4}$$

where z_t is the transition variable, σ_{zt} is the standard deviation of z_t, γ is a slope parameter, and c is a location parameter. Baillie and Chang choose various transition variables, z_t, related to carry and consider momentum trading. Specifically, they use the interest differentials and the conditional volatility of exchange rates as measured by GARCH(1,1) models of spot exchange rate returns. This model approach works well for carry trade analysis because it allows for smooth and continuous adjustment between regimes.

Another popular regime-dependent model is the regime-switch model. After Hamilton (1989) proposed the regime-switching model to examine the persistency of recessions and booms, many studies applied this model to exchange rate data. Engel and Hamilton's (1990) two-regime model specifies currency returns as

$$s_{t+1} - s_t = \alpha_i + \sigma_i \eta_{t+1}, \tag{69.5}$$

where $i \in \{1, 2\}$ denotes the regime; α_i and σ_i denote the trend of exchange rate and the volatility of exchange rate return under regime i, respectively; and $\eta_{t+1} \sim^{i.i.d.} N(0, 1)$. Ichiue and Koyama (2008) employ the four-regime model to discuss carry trade returns. First, they use the following nesting model:

$$s_{t+1} - s_t = \alpha_i + \beta_i\left(i_t - i_t^*\right) + \sigma_i \eta_{t+1}. \tag{69.6}$$

According to the views of market participants, regime switches in exchange rate returns should be interpreted as switches in the relation between the returns and interest rate differentials or switches in market participants' activities between the carry trade and its unwinding, rather than just switches in trends. Ichiue and Koyama assume that the intercept α_i does not switch, that is, $\alpha_i = \alpha$ for all $i = 1, 2$. Second, they define a regime indicator variable that spans the regime space for both the slope and volatility regimes as

$$S_t = \begin{cases} 1 \;\; if \;\; S_{\beta_t} = 1 \; and \; S_{\sigma_t} = 1 \\ 2 \;\; if \;\; S_{\beta_t} = 2 \; and \; S_{\sigma_t} = 1 \\ 3 \;\; if \;\; S_{\beta_t} = 1 \; and \; S_{\sigma_t} = 2 \\ 4 \;\; if \;\; S_{\beta_t} = 2 \; and \; S_{\sigma_t} = 2 \end{cases}, \tag{69.7}$$

where S_{β_t} is the slope regime, which indicates the relation between exchange rate returns and interest rate differentials, and at time t is β_i when $S_{\beta_t} = i, i = 1, 2$. S_{σ_t} is defined as the volatility regime, with the volatility at time t being σ_j when $S_{\sigma_t} = j$, $j = 1, 2$. Finally, Ichiue and Koyama's model can be described as

$$s_{t+n} - s_t = \alpha + \beta_t \left(i_{t,n} - i^*_{t,n} \right) + \sigma_t \eta_{t+n}. \tag{69.8}$$

$$\beta_t = \beta_1 (I_{1t} + I_{3t}) + \beta_2 (I_{2t} + I_{4t}). \tag{69.9}$$

$$\sigma_t = \sigma_1 (I_{1t} + I_{2t}) + \sigma_2 (I_{3t} + I_{4t}), \tag{69.10}$$

where $I_{kt} = 1$ if $S_t = k$ and $I_{kt} = 0$ if $S_t \neq k$, $k = 1, 2, 3, 4$, where $\beta_1 < \beta_2$ and $0 < \sigma_1 < \sigma_2$. And $\Pr[S_{t+1} = k | S_t = l] = p_{kl}$ are the transition probabilities in the transition matrix P^n, for $k, l = 1, 2, 3, 4$, where $\sum_{k=1}^{4} p_{kl} = 1$. This model provides four kinds of regimes for carry trade returns. For instance, when $S_t = 1$, the carry trade return will be with lower slope coefficient β_1 and low volatility. Ichiue and Koyama refer to this regime the negative/low regime. The remainder of the regimes are positive/low, when $S_t = 2$; negative/high, when $S_t = 3$; and positive/high, when $S_t = 4$.[5]

The parameters of these regime-dependent models can be estimated by the MCMC method, especially regime-switch models, because regime-switch models have threshold points to separate the regimes. We introduce this method in the next subsection.

69.2.2 The MCMC Method

Bayesian inference using the MCMC method is a popular technique for parameter estimation. We can estimate parameters easily via this technique. MCMC includes

[5]The empirical results shown β_1 and β_2 are negative and positive, respectively.

two major algorithms, Gibbs sampling and Metropolis-Hustings (M-H) algorithm. The algorithms are sampled from probability distributions based on constructing a Markov chain that has the desired distribution as its equilibrium distribution.

Metropolis et al. (1953) introduced the M-H algorithm. Setting the interest distribution $\pi = \{\pi_j, j \in S\}$ with $\sum_j \pi_j = 1$ and an arbitrary irreducible transition matrix $Q = [q_{ij}]$ on the state space S with the elements satisfying $q_{ij} = q_{ji}$, the MCMC $\{x_t, t \geq 0\}$ is constructed by the following steps. First, set $x_k =$ i where i is any realization from π. Second, generate j from the $\{q_{ij}; j = 1, 2, \ldots\}$ where q_{ij} is often called the proposal or candidate generating function. Third, set $\alpha = \pi_j/\pi_i$; if $\alpha \geq 1$, set $x_{k+1} = q_{ij}$. Otherwise generate $u \sim U(0, 1)$ if $u < \alpha$; set $x_{k+1} = q_{ij}$, else $x_{k+1} = x_k$. Finally, set $k = k + 1$ and go to the first step.

The Gibbs sampler is a generally applicable method, which is an algorithm for generation values from the full conditional distributions. The algorithm for Gibbs sampling is as follows: First, give an initial value $\boldsymbol{\Theta}^{(0)} = (\theta_1^{(0)}, \theta_2^{(0)}, \ldots, \theta_p^{(0)})$ for parameter $\boldsymbol{\Theta} = (\theta_1, \theta_2, \ldots, \theta_p)$. Second, draw θ_i from the full conditional $\pi(\theta_i | \boldsymbol{\Theta}^{(k)}_{-i})$ for $i = 1, \ldots, p$ at k th iteration, where $\boldsymbol{\Theta}^{(k)}_{-i}$ is defined by $\boldsymbol{\Theta}^{(k)}_{-i} = \left(\theta_1^{(k)}, \theta_2^{(k)}, \ldots, \theta_{i-1}^{(k)}, \theta_{i+1}^{(k-1)}, \ldots, \theta_p^{(k-1)}\right)$. Third, set $k = k + 1$; return to second step until convergence is achieved. We can use the M-H algorithm to generate the random variables for parameters if they are difficult to generate by full conditional distributions.

For example, we review the regime-switch model. We can find Eq. 69.8 following the normal distribution as

$$(s_{t+n} - s_t) \sim N\left(\alpha + \beta_t\left(i_{t,n} - i^*_{t,n}\right), \sigma_t^2\right). \tag{69.11}$$

Ichiue and Koyama (2008) employ the noninformation priors for all the parameters of the model as $\alpha \sim N(0, 10)$, $\beta_1 \sim N(-1, 10)$, $\beta_2 \sim N(1, 10)$, $\sigma_1^2 \sim IG(4{,}300)$, $\sigma_2^2/\sigma_1^2 \sim IG(4{,}8)$, and $(p_{k1}, \ldots, p_{k4}) \sim Dirichlet(p_{0,k1}, \ldots, p_{0,k4})$ where $p_{0,\,kk} = 4$ and $p_{0,\,kl} = 1$ if $k \neq l$. The selection of priors can be based on prior knowledge or user experience. The noninformation (diffuse) priors are useful to be able to conveniently calculate full conditional distributions. For instance, the conditional distribution (posterior distribution) of α can be found as

$$\pi\left(\alpha \middle| \boldsymbol{\Theta}^{(k)}_{-i}\right) \sim N\left(s_{t+n} - s_t, \sigma_t^2\right), \tag{69.12}$$

where $\boldsymbol{\Theta}^{(k)}_{-i} = \left(s_{t+n} - s_t, \beta_1^{(k)}, \beta_2^{(k)}, \sigma_1^{(k)}, \sigma_2^{(k)}, P^{n(k)}\right)$. All parameters can be draw from full conditional distributions via the MCMC method.

69.3 Empirical Result

In this section, we discuss the relation between carry trade return and volatility measures. We calculate a series of long Australian dollars (AUD) and short

Japanese Yen (JPY) weekly carry trade return and three kinds of volatility measure (VIX, GARCH, and EGARCH) from 4 January 2001 to 18 August 2010. Our sample consists of 503 observations.

We calculate weekly return of short JPY and long AUD carry trades using the following formula:

$$y_{t+1} = \log\left(1 + (i_t^* - i_t)\right) - \Delta s_{t+1}, \tag{69.13}$$

where i_t^* is Australia interest rate at time t and i_t is Japan interest rate. Therefore, log $(1 + (i_t^* - i_t))$ is log return of interest rate differential and $\Delta s_{t+1} = s_{t+1} - s_t$ with S_j denotes logarithm of the nominal exchange rate at time j (unit of AUD per JPY).

Table 69.1 presents the summary statistics for the weekly return from investing in a long position in the Australian dollar (AUD) financed by borrowing in the Japanese Yen (JPY) and three volatility measures, VIX, GARCH, and EGARCH, from 4 January 2001 to 18 August 2010. Panels B and C show the summary statistics for the weekly return in the low and high volatility regimes, respectively. We can observe that, relative to the normal distribution, the density of the weekly returns exhibits skewness and excess kurtosis, especially the returns in the high volatility regime. Brunnermerier et al. (2008) explained that carry trade returns have crash risk that caused the negative skewness and excess kurtosis. They pointed out that "exchange rates go up by the stairs and down by the elevator." Based on the VaR results, we find the losses at high volatility regime are larger than low volatility regime. However, Table 69.1 clearly shows that the behaviors of carry trade returns are diversely in the different volatility regimes.

First, we use the AR(1) model to discuss the relation between momentum effect and volatility regimes.[6] We consider following the AR(1) model:

$$y_{t+1} = \phi_0 + \phi_1 y_t + \varepsilon_{t+1}, \tag{69.14}$$

where ε_{t+1} is serially uncorrelated. If parameter ϕ_1 is positive, we assume that the momentum effect exists because the directions of returns are the same between the now and future. We show the results in the four kinds of volatility regimes in Table 69.2, in which we use three volatility measures, VIX, GARCH, and EGARCH, to capture the volatility of carry trade.

However, based on results of Table 69.2, we create a new carry trade trading strategy that results in higher return and downside risk. At the low volatility, we have a momentum trading strategy of carry trade. On the other hand, we do nothing during the high volatility regime. For robustness, we separate our sample into 2, 5, and 10 years. We use buy-and-hold strategy as our benchmark to

[6]Based on Eq. 69.6, we divide the long AUD and short JPY carry trade from 4 January 2001 to 18 August 2010 into four kinds of volatility regimes and try to use the MCMC method to test whether UIP is existing in these intervals, but we cannot find any evidences to support it.

p-value	0.0000	0.0001	0.0206	0.9470
ϕ_1	0.1149	0.0627	−0.1244	0.0142
p-value	0.1820	0.4841	0.1444	0.8780

*, **, and *** denote significance at the 10 %, 5 %, and 1 % levels, respectively
Based on these data, we find results consistent with previous investigations: the carry trade displays the momentum effect only in the low volatility regime. In addition, the EGARCH volatility measure has a significant result. The negative relation between now and future returns are usually found in the high volatility regime. This phenomenon may imply the carry trade's exposure to crash risk but the parameter ϕ_1 is always insignificant

Table 69.3 We compare the total return of four types of strategy. First, we calculate the third quartiles (Q3) with three different volatility measures. Second, if the return in the low volatility regime where the volatility measure is smaller than Q3, we do the momentum trading strategy of carry trade. Otherwise, we do nothing

[a]Denotes the maximum Sortino ratio among the four strategies

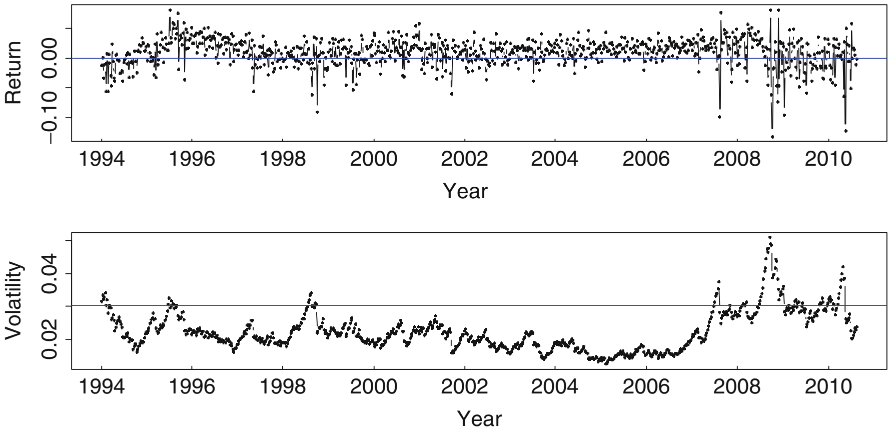

Fig. 69.1 Weekly return of long AUD and short JPY carry trade from 13 January 1994 to 18 August 2010 and weekly volatilities, calculated by AR(1)-EGARCH(1,1) model

the highest performance (0.5285), which explains why prior studies commonly employ VIX as a proxy variable for global risk. During the same tumultuous period, the buy-and-hold strategy shows lower returns than other periods. The reason may be that traders suffered the risk from the low interest rate country's currency appreciated, and thus UIP tends to hold. Although the buy-and-hold strategy often has the highest returns, it also may suffer from the highest crash risk. To consider the downside risk of the carry trade strategy, we use the Sortino ratio criteria to compare the performance of strategies. Sortino ratio measures how many units of return are received per unit of downside risk experienced (Riddles 2001). Table 69.4 provides the results of the comparison of the Sortino ratio of four types of strategy.

As Table 69.4 shows, using the GARCH volatility measure, our trading strategy produces the highest return per unit of the downside risk in the long run.

It also shows that the GARCH is the best variable to explain our trading strategy, which usually has a higher Sortino ratio. Thus, although the buy-and-hold strategy often has the highest returns, our strategy effectively avoids loss at high volatility regime. Figure 69.1 explicitly expresses the benefits of our strategy.

Figure 69.1 shows that carry trade returns are negatively related to the EGARCH volatility measure. Base on the threshold value, we can precisely capture the 1997–1998 Asian financial crisis and the 2007–2008 American subprime risk. The volatility level is far above our threshold during these tumultuous episodes. In addition, we find that the carry trade usually has a positive return during the low volatility regime.

69.4 Conclusion

The literature provides several explanations for why the carry trade has persistent excess returns including time-varying risk premia, illiquidity spirals, the peso problem, and trading behavior. Regime-dependent models, such as the regime-switch model and the LSTR model, are commonly used for currency markets. This study employs characteristics of the carry trade to build a new trading strategy that can earn higher returns with lower volatility. We use three measures of volatility, VIX, GARCH, and EAGRCH, to capture the volatility of carry trade returns.

Our main results are threefold. First, we find that carry trade returns have a significant momentum effect at the low volatility regime. Second, the results show that although the buy-and-hold strategy often has higher returns, our strategy effectively avoids losses at the high volatility regime. Third, carry trade returns often suffer higher losses at the high volatility regime. Compared with the buy-and-hold strategy, our method thus bears less downside risk. We use the Sortino ratio criteria to provide this evidence.

Questions remain to be addressed. The United States is maintaining a low interest rate policy right now. Is the US dollar the new carry trade currency? This and other questions are worth discussing. For example, future research may be usefully directed at incorporating such trading strategies with more conventional models of regime dependence. The emerging and developing currency market has dissimilar volatility structures, which may be another issue discussed in the future.

Appendix: Empirical Study Process

1. We find the first, second, and third quartiles from each volatility measures to determine the volatility regimes.
2. We sort the carry trade returns by the volatility regimes.
3. We test the momentum effects for AR(1) model.

4. We use the third quartile of the volatility measures to discriminate returns between high and low volatility regimes.
5. Based on our trading strategy, we calculate the cumulative return and compare the performance with the buy and hold strategy.
6. We use the cumulative returns to calculate the Sortino ratio for each strategy.

These processes can run in the R programming. If you need programming assistance, please contact authors.

Abstract

This chapter examines the Ederington hedging effectiveness (EHE) comparisons between unconditional OLS hedge strategy and other conditional hedge strategies. It is shown that OLS hedge strategy outperforms most of the optimal conditional hedge strategies when EHE is used as the hedging effectiveness criteria. Before concluding that OLS hedge is better than the others, however, we need to understand under what circumstances the result is derived. We explain why OLS is the best hedge strategy under EHE criteria in most cases and how most conditional hedge strategies are judged as inferior to OLS hedge strategy by an EHE comparison.

Keywords

Futures hedging • Portfolio management • Ederington hedging effectiveness • Variance estimation • Unconditional variance • Conditional variance • OLS hedging strategy • GARCH hedging strategy • Regime switching hedging strategy • Utility-based hedging strategy

70.1 Introduction

Futures market provides a useful tool for hedgers to reduce the overall risk. The extent of the usefulness is, however, determined by the hedging strategy adopted by the hedger. In this regard, the hedging effectiveness measure proposed by Ederington (1979) has been the most popular criterion to evaluate the usefulness. Different hedging strategies are compared in terms of Ederington hedging effectiveness (EHE). The strategy possessed with the greatest EHE is deemed the best strategy.

Specifically, EHE is the percentage reduction in the return variance of the hedged portfolio relative to the return variance of the unhedged portfolio. While the variance could be conditional or unconditional, in empirical studies EHE is always calculated on the basis of unconditional variance. This is natural as Ederington (1979) considers only unconditional constant hedge strategies. Further development in futures hedging literature focuses on conditional dynamic hedge strategies. However, EHE remains the major criterion to evaluate the usefulness of these strategies. This approach is inappropriate since the conditional hedge strategy is constructed to minimize conditional variance, but its usefulness is measured by unconditional variance. As long as there is not a linear relationship between conditional and unconditional variances, the EHE should not serve as a benchmark to evaluate the conditional hedge strategy.

This paper examines the EHE comparisons between the OLS hedge strategy (i.e., the unconditional strategy) with various conditional hedge strategies, assuming spot and futures returns are described by different statistical framework. It is shown that, for most statistical models, the OLS hedge strategy is most likely to outperform the optimal conditional hedge strategy. For example, in a vector error correction model (VECM), the optimal conditional hedge ratio should take into account the cointegration relationship. The resulting EHE from this optimal ECM hedge ratio, however, underperforms the OLS hedge ratio (where the cointegration relationship is ignored). Similarly, when spot and futures returns follow a multivariate generalized autoregressive conditional heteroskedasticity (MGARCH) model, the GARCH hedge ratio is likely to be inferior to the OLS hedge ratio in terms of EHE.

The above results are not surprising as OLS hedge ratio is chosen to minimize the unconditional variance, whereas ECM and GARCH hedge ratios minimize their corresponding conditional variances. By definition, EHE is biased in favor of OLS hedge ratio over other hedge ratios. The only possible exception is the regime switching (RS) hedge ratio. It is analytically shown that RS-OLS hedge ratio would outperform the conventional OLS hedge ratio under certain assumptions.

Besides EHE, another popular hedging effectiveness measure is certainty equivalent derived from expected utility comparisons from hedged and unhedged portfolios. It is shown that the sample certainty equivalent estimator, similar to the sample EHE estimator, is biased. On the other hand, this utility-based effectiveness measure does not necessarily favor the OLS hedge ratio except when the futures price is a martingale or when the hedger is extremely risk averse.

The remaining of the paper is organized as follows. In Sect. 70.2, we discuss the Ederington hedging effectiveness measure and demonstrate the superiority of the OLS hedge ratio. The next sections consider two specific dynamic hedging strategies; Sect. 70.3 examines the GARCH specifications and Sect. 70.4 the regime switching models. The two models provide contradicting conclusions regarding the relative performance to the OLS hedge ratio. In Sect. 70.5, we analyze the utility-based hedging effectiveness. Finally, conclusions are provided in Sect. 70.6.

70.2 Ederington Hedging Effectiveness

The fundamental idea of Ederington (1979) originates from Johnson (1960) and Stein (1961) who introduce portfolio theory into the area of hedging. Most of the previous hedging theories consider only the "naive" hedging, which is done by trading the hedging instrument in the same amount as the asset being hedged. Ederington shows that the hedge ratio, which is the ratio of the amount of the hedging instrument being used relative to the amount of the asset being hedged, must be adjusted to obtain the maximum hedging effectiveness. To derive this result, Ederington proves that there exists an optimal hedge ratio which minimizes the variance of the portfolio value.

70.2.1 Definition

Ederington shows that if we construct a hedged portfolio P which consists of the asset being hedged, S, and a hedging instrument, F, the optimal hedge ratio is the value where the partial derivative of the portfolio return variance with respect to the hedge ratio becomes zero. This partial derivative is given by

$$\frac{\partial Var(p)}{\partial h} = X_s^2[2hVar(f) - 2Cov(s,f)], \tag{70.1}$$

where X_s and X_f are the positions of the asset and the hedging instrument, respectively; $h = -X_f/X_s$ is the hedge ratio; s and f are the returns of S and F, respectively; p is the return of the portfolio: $p = X_s s + X_f f = X_s(s - hf)$. Var(.) and Cov(.,.) are the variance and covariance operators, respectively. Given this formula, the optimal hedge ratio h^* can be easily derived by setting Eq. 70.1 equal to zero, i.e.,

$$h^* = Cov(s,f)/Var(f). \tag{70.2}$$

As shown in Eqs. 70.1 and 70.2, Ederington regards hedging as an act of “minimizing variance.” When devising his measure of hedging effectiveness, he also takes this property as the main criteria. Specifically, the Ederington hedging effectiveness (EHE hereafter) is defined as

$$H = 1 - \frac{Var(p)}{Var(s)}. \tag{70.3}$$

Equation 70.3 shows that EHE is directly related to the percentage reduction of the variance in the asset return after hedging.

70.2.2 Some Properties

The most evident characteristic of EHE is its simplicity. The variance and covariance in Eq. 70.3 are both unconditional and are assumed to be constant over time. While this aspect of EHE is one of the reasons why it is being widely used, it also has caused some controversies about its appropriateness. It was argued that, given the information set, the hedger is concerned with the conditional variance of the portfolio return. Accordingly, unconditional variance and covariance in Eq. 70.3 should be replaced by their conditional counterparts. Various variables were taken into account to derive conditional variance and covariance, including past prices and inventories. In addition, recent research emphasizes the nonconstancy nature of conditional variance and covariance and recommends time-varying hedge ratios.

In empirical implementation, the complete sample is divided into two subsamples. The first subsample is applied to construct the most appropriate (within-sample) statistical models for conditional variance and covariance. Based upon the estimated model, optimal hedge ratios are obtained for the second subsample. Returns for the hedged portfolio are calculated for this subsample. The unconditional variance of the return series is adopted to calculate the so-called post-sample

EHE which serves as a benchmark to compare various hedge strategies. Thus, the within-sample model is chosen to minimize conditional variance, whereas the post-sample hedging effectiveness is evaluated at unconditional variance. The inconsistency in criteria raises a concern for the appropriateness of EHE to be used as the criteria to compare conditional hedge strategies. Moreover, one would suspect the hedge strategy constructed by minimizing the within-sample unconditional variance may have the best out-of-sample EHE.

To address this question, Lien (2005a) introduces several assumptions:

1. The size of the estimation sample is sufficiently large.
2. The size of the evaluation sample is sufficiently large.
3. There is no structural change between the estimation sample and the evaluation sample.

Under these conditions, it is shown that the ratio of unconditional covariance to the conditional variance provides the best EHE. This ratio can be obtained by the ordinary least squares (OLS) method when regressing the spot price change on the futures price change.

The first two assumptions ensure sample unconditional variance and sample unconditional covariance both to be close enough to their population counterparts. The third assumption requires the estimation and evaluation samples to be drawn from the same population such that the hedge ratio derived from the former is applicable to the latter. When there is a structural change across the two samples, nothing can be guaranteed. However, Lien (2005a, b) warns that it is a tautology to prove the superiority of OLS hedge ratio to other hedge ratios with EHE. Since the OLS hedge ratio is the hedge ratio which produces the minimal unconditional variance, it cannot be inferior to any other hedge ratios when compared in terms of EHE, which measures the unconditional variance reduction. Alternatively, one can argue that it is not appropriate to compare conditional hedge strategies on the basis of EHE.

Lien (2005b) illustrates the superiority of the OLS hedge ratio with a simple example:

$$f_t = \alpha_0 + \alpha_1 f_{t-1} + u_t, \tag{70.4}$$

$$s_t = \beta_0 + \beta_1 s_{t-1} + v_t, \tag{70.5}$$

where both $\{u_t\}$ and $\{v_t\}$ are white noises. Let σ_u^2 and σ_v^2 denote the variances of u_t and v_t, respectively, and let σ_{uv} denote the covariance between u_t and v_t. In addition, to ensure stationarity, we require $|\alpha_1| < 1$ and $|\beta_1| < 1$. The unconditional hedge ratio (i.e., OLS hedge ratio) is

$$h_u = \left(\frac{1-\alpha_1^2}{1-\alpha_1\beta_1}\right)\left(\frac{\sigma_{uv}}{\sigma_u^2}\right), \tag{70.6}$$

whereas the conditional hedge ratio is simply $h_c = \sigma_{uv}/\sigma_u^2$. By construction, h_u performs better than h_c in terms of EHE.

Upon incorporating the cointegration relationship between spot and futures prices into Eqs. 70.4 and 70.5, Lien (2005a) demonstrates the superiority of the OLS hedge ratio over the error correction hedge ratio. For the importance of the error correction term for futures hedging and further comparisons between the two hedge ratios, see Lien (1996, 2004).

70.2.3 Estimation Bias

In Lien (2006), it is shown that the usual EHE estimator is downward biased and, therefore, tends to underestimate the true hedging performance, even when the estimator for optimal hedge ratio is unbiased. This is because the estimated optimal hedge ratio itself is a random variable so that its variance affects the expected EHE. Lien explains this by decomposing the EHE formula (70.3) as follows.

Let $M = I_k - (e_k e_k^{'}/k)$ where I_k is a $(k \times k)$-dimensional identity matrix and e_k is a k-dimensional vector such that all elements are equal to 1. Then Eq. 70.3 can be decomposed to

$$H = 1 - \frac{w^{'}Mw}{p^{'}Mp}, \tag{70.7}$$

where p and w are k-dimensional vectors consisting of k unhedged asset returns and hedged portfolio returns, respectively. Because the estimated hedge ratio $\hat{h}$ substitutes the optimal hedge ratio h^*, the EHE one calculates based on $\hat{h}$ is also in fact an estimated EHE, $\hat{H}$. That is,

$$\hat{H} = 1 - \frac{\hat{w}^{'}M\hat{w}}{p^{'}Mp}, \tag{70.8}$$

where $\hat{w}$ is a k-dimensional vector consisting of the portfolio returns which are hedged with $\hat{h}$. Since $\hat{w} = w + \left(h^* - \hat{h}\right)f$, Eq. 70.7 can be rewritten as

$$1 - \hat{H} = \frac{w^{'}Mw}{p^{'}Mp} + 2\left(h^* - \hat{h}\right)\left[\frac{f^{'}Mw}{p^{'}Mp}\right] + \left(h^* - \hat{h}\right)^2\left[\frac{f^{'}Mf}{p^{'}Mp}\right], \tag{70.9}$$

and therefore,

$$\hat{H} = H - 2\left(h^* - \hat{h}\right)\left[\frac{f^{'}Mw}{p^{'}Mp}\right] - \left(h^* - \hat{h}\right)^2\left[\frac{f^{'}Mf}{p^{'}Mp}\right]. \tag{70.10}$$

As a consequence,

$$E(\hat{H}) = H + 2b\left[\frac{f'Mw}{p'Mp}\right] - \left[b^2 + Var(\hat{h})\right]\left[\frac{f'Mf}{p'Mp}\right], \tag{70.11}$$

where $b = E(\hat{h} - h^*)$ and $b^2 + Var(\hat{h})$ are the estimation bias and mean squared error of $\hat{h}$, respectively. If $\hat{h}$ is an unbiased estimator of h^*, b becomes zero and Eq. 70.11 is reduced to

$$E(\hat{H}) = H - Var(\hat{h})\left[\frac{f'Mf}{p'Mp}\right]. \tag{70.12}$$

This shows that $\hat{H}$ is a downward biased estimator of H, even when $\hat{h}$ is an unbiased estimator of h^*.

We provide two further remarks. First, Chen and Sutcliffe (2007) examine the benefits of a composite hedge where multiple hedging instruments are adopted over a simple hedge where only one hedging instrument is adopted. The benefit is measured by the improvement in EHE. Lien (2008) demonstrates the empirical estimator is biased. Secondly, through empirical studies, Lien and Shreshta (2008) concludes that the downward bias of the EHE estimator is negligible and therefore bias correction seems to be redundant.

70.3 GARCH Hedging Strategy

The previous analysis assumes the conditional second moments of spot and futures returns are constant over time. This assumption is frequently rejected through empirical data analysis. To describe time-varying second moments, researchers rely upon different versions of multivariate GARCH (generalized autoregressive conditional heteroskedasticity) models. The standard univariate GARCH model is an extension of the ARCH (autoregressive conditional heteroskedasticity) model proposed by Engle (1982).

70.3.1 GARCH Specification

Specifically, consider a time series $\{y_t\}$ such that

$$y_t = b'x_t + \varepsilon_t, \tag{70.13}$$

where x_t is the vector of exogenous variables contained in the information set previous to time $t-1$, ϑ_{t-1}. The error term is normally distributed conditional on the information set, i.e., $\varepsilon_t|\vartheta_{t-1} \sim N(0, \sigma_t^2)$. Bollerslev (1986) proposed the following process for the conditional variance:

$$\sigma_t^2 = \omega + \sum_{i=1}^{q} \alpha_i \varepsilon_{t-i}^2 + \sum_{j=1}^{p} \beta_j \sigma_{t-j}^2. \tag{70.14}$$

The model is termed as GARCH (p, q) process. If we set $p = 0$ and $q \neq 0$, the process is reduced to an ARCH(q) process. When $p = q = 0$, it is further reduced to a process with a constant variance.

For futures hedging purpose, we need to consider multivariate GARCH models which specify the process for the conditional covariance as well. Various specifications are available in the literature, e.g., constant correlation, BEKK, and DCC (dynamic conditional correlation) models. Different dynamic hedge ratios are then generated and compared on the basis of EHE; for example, see Baillie and Myers (1991), Myers (1991), Kroner and Sultan (1993), Dawson et al. (2000), and Kavussanos and Visvikis (2008).

70.3.2 GARCH Hedging Strategy

Under GARCH models, the optimal hedge ratio is determined by the ratio of the conditional covariance to the conditional variance,

$$h_{t-1}^c = \frac{Cov_{t-1}(s_t, f_t)}{Var_{t-1}(f_t)}, \tag{70.15}$$

where $Cov_{t-1}(s_t, f_t)$ is the conditional covariance between spot and futures returns at time t based upon information available at time $t-1$ and $Var_{t-1}(f_t)$ is the conditional variance of the futures return at time t based upon information available at time $t-1$. As both conditional moments are time varying, the conditional hedge ratio is expected to change over time as well.

That is, although OLS and GARCH hedge ratios have the same object of variance minimization, they differ in terms of the target variance. While OLS hedge ratio considers the unconditional variance, GARCH hedge ratio focuses on conditional variance under the GARCH assumptions. This difference suggests a concern about the appropriate procedure of assessing and comparing their effectiveness. Since their objectives are different, the relative superiority of one hedge ratio over the other can vary when one applies a different effectiveness measure. In particular, since EHE depends upon the reduction in the unconditional variance, OLS hedge ratio is naturally favored. Lien (2009) explains this result as follows.

70.3.3 EHE and GARCH Hedging Strategy

Let us assume that there are two portfolios P0 and P1, both consisting of an asset S and a hedging instrument F. The first portfolio is constructed from the OLS hedge ratio, $h_0 = Cov(s_t,f_t)/Var(f_t)$, whereas the second portfolio is constructed from the GARCH hedge ratio, $h^c_{t-1} = Cov_{t-1}(s_t,f_t)/Var_{t-1}(f_t)$. We can decompose the unconditional variance of the return from portfolio P1 as

$$Var(P1) = Var\left(s_t - h^c_{t-1}f_t\right) = E\left[Var_{t-1}\left(s_t - h^c_{t-1}f_t\right)\right] + Var\left[E_{t-1}\left(s_t - h^c_{t-1}f_t\right)\right], \tag{70.16}$$

where $E(.)$ is the unconditional expectation operator and $E_{t-1}(.)$ is the conditional expectation operator based upon information available at time $t-1$. We can rewrite the first term of Eq. 70.16 as follows:

$$E\left[Var_{t-1}(s_t) - \frac{Cov^2_{t-1}(s_t,f_t)}{Var_{t-1}(f_t)}\right] = Var(s_t) - E\left[\frac{Cov^2_{t-1}(s_t,f_t)}{Var_{t-1}(f_t)}\right], \tag{70.17}$$

using the definition of h^c_{t-1}. Suppose that the sample size is sufficiently large, we can approximate the second term of Eq. 70.17 by

$$E\left[\frac{Cov^2_{t-1}(s_t,f_t)}{Var_{t-1}(f_t)}\right] \approx \frac{E\left[Cov^2_{t-1}(s_t,f_t)\right]}{E[Var_{t-1}(f_t)]} = \frac{Cov^s(s_t,f_t)}{Var(f_t)}. \tag{70.18}$$

Consequently,

$$Var(P1) \approx Var(s_t) - \frac{Cov^2(s_t,f_t)}{Var(f_t)} + Var[E_{t-1}(s_t - h_{t-1}f_t)]. \tag{70.19}$$

On the other hand, by the definition of h_0, the unconditional variance of the return from portfolio P0 is

$$Var(P0) = Var(s_t - h_0 f_t) = Var(s_t) - \frac{Cov^2(s_t,f_t)}{Var(f_t)}. \tag{70.20}$$

Therefore,

$$Var(P1) \approx Var(P0) + Var[E_{t-1}(s_t - h_{t-1}f_t)], \tag{70.21}$$

implying $Var(P1)$ tends to be larger than $Var(P0)$. That is, the OLS hedge ratio is likely to have a greater hedging effectiveness than the GARCH hedge ratio, in terms of EHE.

Note that the derivation of Eqs. 70.16, 70.17, 70.18, 70.19, 70.20, and 70.21 does not rely on any specific properties of the GARCH model. The above conclusion, therefore, applies to any general dynamic hedge strategy that aims at minimizing the conditional variance; see also Lien (2010). In other words, when adopting EHE as the effectiveness measure, the OLS hedge ratio is likely to outperform any dynamic hedge ratio. However, we should be careful when interpreting this result. As Lien (2005a) points out, EHE is focused on the unconditional variance and it would be an abuse to use EHE to assess a conditional variance minimization strategy.

Kavussanos and Nomikos (2000) suggest that for the GARCH hedge strategy to outperform the OLS hedge strategy, the variability of the resulting GARCH ratio must be sufficiently large. On the other hand, Park and Jei (2010) find an inverse relationship between the variability of the GARCH hedge ratio and corresponding hedging effectiveness (i.e., EHE).

70.4 Regime Switching Hedging Strategy

Lien (2010) provides a theoretical analysis on the relationship between the variability of the hedge ratio and hedging performance in support of the finding from Park and Jei (2010). Extending the result to general dynamic hedge strategy, there is a small window for the strategy to outperform the OLS strategy, that is, when the variability of the hedge ratio cannot be too small or too large. We therefore turn to regime switching hedge strategies.

70.4.1 Definition of Regime Switching

Both GARCH and regime switching models belong to the family of nonlinear time series. Hamilton (1988, 1989) characterizes the concept of "regime switching" (RS hereafter) and proposes an approach to model the RS process. The simplest RS model specification of RS is the first-order Markov process with two states. If $S_t \in \{0, 1\}$ denotes the (not directly observable) state of the system in which the source of the time-series data exists, the transition between two states is driven by the following first-order Markov process:

$$\begin{aligned}
&\Pr\left(S_t = 1 | S_{t-1} = 1\right) = p,\\
&\Pr\left(S_t = 0, | S_{t-1} = 1\right) = 1 - p,\\
&\Pr\left(S_t = 0 | S_{t-1} = 0\right) = q,\\
&\Pr\left(S_t = 1, | S_{t-1} = 0\right) = 1 - q.
\end{aligned} \tag{70.22}$$

Thus, the probability of state transition depends only upon the state of the previous period.

In each state, the spot and futures returns can be described by linear models such as ECM or nonlinear models such as GARCH processes. For the former case, there will be two constant hedge ratios each pertaining to one state; for the latter case, there will be two dynamic hedge ratios instead. The literature on RS hedge strategies began with the former case and recently extended to the latter case. For example, Sarno and Valente (2000) and Alizadeh et al. (2008) combine RS with ECM; Alizadeh and Nomikos (2004) and Lee and Yoder (2007a, b) add RS into the GARCH models; Lee (2010) combines RS with dynamic conditional correlation (DCC) models. In most cases, it is shown that the hedging performance is improved when regime switching is incorporated into the econometric framework.

70.4.2 RS Hedging Strategy

Although RS can be introduced in various ways, it is most understandable when we combine RS with the OLS hedging strategy. Lien (2012b) explains the basic framework of the RS-OLS strategy as follows. Suppose that RS process is given as Eq. 70.22. Assume futures returns in the two states equal to each other. When $S_{t-1} = 1$, the OLS hedge ratio in Eq. 70.2 is modified to

$$h_1^* = \frac{pCov_1(s_t, f_t) + (1-p)Cov_0(s_t, f_t)}{pVar_1(f_t) + (1-p)Var_0(f_t)}, \tag{70.23}$$

where $Var_n(.)$ and $Cov_n(.,.)$ denote the variance and covariance operators in state n, respectively, $n = 0, 1$. Similarly, when $S_{t-1} = 0$, the corresponding OLS hedge ratio is

$$h_0^* = \frac{qCov_0(s_t, f_t) + (1-q)Cov_1(s_t, f_t)}{qVar_0(f_t) + (1-q)Var_1(f_t)}. \tag{70.24}$$

The pair of hedge ratios (h_0^*, h_1^*) constitutes the optimal RS-OLS hedge ratio. To apply this hedge strategy, it requires the hedger to be able to identify the state at the moment of making the hedging decision.

Lien (2012b) compares the RS-OLS hedge strategy to the conventional OLS hedge strategy. To calculate the conventional OLS hedge ratio under the RS framework, we first derive the steady-state probability for each state. Let α and $1 - \alpha$ denote the steady-state probability of state 1 and 0, respectively. Thus,

$$(1-\alpha)p + \alpha(1-q) = \alpha, \tag{70.25}$$

or equivalently

$$\alpha = \frac{1-q}{2-p-q}. \tag{70.26}$$

Given the steady-state probability of each state, we can obtain the conventional OLS hedge ratio as follows:

$$h^* = \frac{\alpha Cov_1(s_t, f_t) + (1-\alpha)Cov_0(s_t, f_t)}{\alpha Var_1(f_t) + (1-\alpha)Var_0(f_t)}. \tag{70.27}$$

Let $h^*_{RS} = \alpha h^*_1 + (1-\alpha)h^*_0$, the expected RS-OLS hedge ratio. Lien (2012b) shows the expected RS-OLS hedge ratio exceeds the conventional OLS hedge ratio:

$$h^*_{RS} \geq h^*. \tag{70.28}$$

Thus, more transaction cost is incurred when implementing the RS-OLS hedge strategy.

70.4.3 Hedging Effectiveness

To compare the hedging effectiveness, let $V(h)$ denote the variance of the return from the hedged portfolio, where $h = h^*_0$, h^*_1, or h^*. The expected variance of the RS-OLS hedged portfolio is then $V_{RS} = \alpha V(h^*_1) + (1-\alpha)V(h^*_0)$. Lien (2012b) demonstrates that

$$V_{RS} \leq V(h^*), \tag{70.29}$$

that is, the RS-OLS hedged portfolio has a smaller variance than the conventional OLS hedged portfolio. Consequently, the RS-OLS strategy outperforms the OLS strategy in terms of EHE.

While the RS-OLS seems to be very promising, a serious problem with this result is that, as Lien (2012a) points out, the superiority of the RS-OLS strategy is based on the assumption that a hedger can always correctly identify the prevailing state at the decision time correctly. To successfully conduct the above hedging strategy, we must succeed in at least three tasks to complete the correct identification:

1. We must identify the entire set of possible states.
2. We must identify the prevailing state.
3. We must identify the relationship between spot and futures returns in each state.

In reality, it is unlikely to complete any of these tasks without errors. Hamilton (1989) is well aware of these issues and emphasizes the importance of "optimal probabilistic inference" to find the turning points. One may try to go around this problem by a weighted average strategy such that the optimal hedge ratio is chosen to be

$$\hat{h}^* = \beta h^*_1 + (1-\beta)h^*_0, \tag{70.30}$$

where β is the estimated probability that the prevailing state is state 1. However, as Lien (2012b) points out, this again dilutes the relative superiority of RS-OLS strategy, since at least one of the states is false at any time t. We can conclude that, therefore, one must succeed in the structural definition of possible states and correct identification of the current state to fully take advantage of the RS framework.

70.5 Utility-Based Hedging Effectiveness

Up to now, we assume that the sole objective of hedging is variance reduction, and correspondingly the optimal hedge ratio is the one that minimizes variance. This is quite intuitive because risk minimization is the most important reason that hedging is actually being done. In the real world, however, the variance-minimizing hedge ratio is not always the optimal one. To understand why this is true, we must know that there are some other factors than variance minimization about which a hedger should consider. For example, if a hedger assumes that a price process is sub-martingale and wants to take advantage of positive expected return, he or she will try to afford some risk by a non-perfect hedging. In this situation, variance reduction cannot be the perfect measure for hedging effectiveness.

70.5.1 Definition of Utility-Based Hedging

Given these restrictions, we can adopt a multivariable function as the alternative and consider additional factors other than variance to measure the hedging effectiveness. In particular, we can consider how large the expected return will be after hedging cost is offset, how much risk a hedger can afford to retain a certain amount of expected return, as well as how large the variance will be. Many previous studies, e.g., Kroner and Sultan (1993), Gagnon et al. (1998), Follmer and Leukert (1999, 2000), and Monoyios (2004), introduce the idea of utility function to construct a framework for this multivariate relationship.

A basic framework of utility-based hedging effectiveness measure is provided in Lien (2012a). Consider a two-date one-period model. The expected utility of an unhedged portfolio can be defined as

$$E\left[U\left(w_{1,u}\right)\right] = E[U(w_0 + s_1 - s_0)], \tag{70.31}$$

where w_0 is the initial wealth (i.e., the wealth at time 0), s_1 is the random value of the spot asset at time 1, s_0 is the value of spot asset at time 0, and $w_{1,u}$ is the random value of wealth at time 1 when there is no hedging conducted. If we adopt a hedging strategy, the expected utility of the hedged portfolio is

$$E\left[U\left(w_{1,h}\right)\right] = E[U(w_0 + s_1 - s_0 - h(f_1 - f_0))], \tag{70.32}$$

where f_1 is the random value of the hedging instrument at time 1, f_0 is the value of the hedging instrument at time 0, and $w_{1,\ h}$ is the random value of wealth at time 1 when hedging is conducted. Hedging performance is measured by the certainty equivalent C:

$$E\left[U\left(w_{1,u}+C\right)\right]=E\left[U\left(w_{1,h}\right)\right]. \tag{70.33}$$

70.5.2 Utility Function and Risk Aversion

One of the simplest types of utility function, which can be used as a hedging effectiveness measure, is the expected mean-variance utility function. It is also quite popular since it can consider all the factors above within a simple framework; see, for example, Kroner and Sultan (1993), Gagnon et al. (1998), and Lafuente and Novales (2003). Suppose that a hedger is endowed with a strictly increasing and twice-differentiable concave utility function $U(x)$, such that $U'(x) > 0$ and $U''(x) < 0$. Then the expected utility of the hedged portfolio P at time $t-1$ can be defined as

$$E_{t-1}[U(P)]=E_{t-1}(p_t)-\lambda Var_{t-1}(p_t), \tag{70.34}$$

where p is the return of the portfolio P and λ is a positive risk-aversion parameter.

The existence of the risk aversion parameter is suggested by Merton (1973). Chou (1988) explains that there exists a linear relationship between the equity premium π and return variance in the inter-temporal CAPM model of Merton (1973), such that

$$\pi_t=\lambda_m Var(M_t), \tag{70.35}$$

where M_t is the instantaneous market return and λ_m is the harmonic mean of individual investor's risk-aversion parameter. Various studies, e.g., Grossman and Shiller (1981) and Pindyck (1986), show that the idea of premium can explain much of the stock price changes beyond changes in dividends and interest rates. Also, their estimation results show that λ ranges approximately from 3 to 4.5.

One thing we should note is that the estimation of λ relies on the variance estimation method. Poterba and Summers (1986) employ a two-stage OLS procedure to estimate the variance and conclude that shocks to the volatility decay rapidly so that it is skeptical to claim that fluctuations in risk premia account for much of the variation in prices. On the other hand, Chou (1988) introduces GARCH-M model and argues that the persistence of volatility shocks is significant such that fluctuations in risk premia can explain much of the price changes. Given that the other aspects of both researches are quite similar, this observation implies that different variance estimation method will lead to different estimates for λ.

70.5.3 Utility-Based Hedging Effectiveness

Similar to the EHE case, Lien (2012a) shows that the sample utility-based hedging effectiveness estimator is downward biased and therefore tends to underestimate the true hedging performance, even when the sample estimator for the optimal hedge ratio is unbiased. To explain in detail why this happens, Lien first assumes that a hedger is endowed with a mean-variance expected utility function, i.e., Eq. 70.34. Given Eqs. 70.33 and 70.34, we obtain

$$E\left[U\left(w_{1,u}+C\right)\right]=w_0+C+E(\Delta s)-\lambda Var(\Delta s), \tag{70.36}$$

$$E\left[U\left(w_{1,h}\right)\right]=w_0+E(\Delta s-h\Delta f)-\lambda Var(\Delta s-h\Delta f), \tag{70.37}$$

where $\Delta s=s_1-s_0$ and $\Delta f=f_1-f_0$. From the above two equations, we derive

$$C=-hE(\Delta f)+\lambda[Var(\Delta s)-Var(\Delta s-h\Delta f)]. \tag{70.38}$$

The sample estimator of C is then

$$\hat{C}=-\hat{h}E(\Delta f)+\lambda\left[Var(\Delta s)-Var\left(\Delta s-\hat{h}\Delta f\right)\right]. \tag{70.39}$$

From Eqs. 70.38 and 70.39, we obtain

$$\hat{C}=C-\left(h-\hat{h}\right)E(\Delta f)..+\lambda\left[Var(\Delta s-h\Delta f)-Var\left(\Delta s-\hat{h}\Delta f\right)\right]. \tag{70.40}$$

After algebraic manipulations, Eq. 70.40 becomes

$$\hat{C}=C-\left(h-\hat{h}\right)E(\Delta f)+2\lambda\left(\hat{h}-h\right)Cov(\Delta s,\Delta f)-\lambda\left(\hat{h}^2-h^2\right)Var(\Delta f). \tag{70.41}$$

Suppose that $\hat{h}$ is an unbiased estimator of h, i.e., $E\left(\hat{h}\right)=h$, then

$$E\left(\hat{C}\right)=C-\lambda E\left(\hat{h}^2-h^2\right)Var(\Delta f)=C-\lambda Var\left(\hat{h}\right)Var(\Delta f)<C. \tag{70.42}$$

That is, the expected value of $\hat{C}$ is downward biased. Lien (2012a) shows that the downward bias result can be extended to the case when a hedger is endowed with another type of strictly increasing concave utility function.

Because the certainty equivalent is not a strictly monotonically decreasing function of the portfolio variance (except when $E\ (\Delta f)=0$ or when λ is infinitely large), the solution to variance minimization is not the same as the solution to certainty equivalent maximization. Therefore, OLS hedge ratio is not necessarily favored by the utility-based performance measure.

70.6 Conclusions

This paper analyzes the properties of Ederington hedging effectiveness (EHE) in general and within different statistical framework. The most popular EHE is measured by the percentage reduction in the unconditional return variance of the hedged portfolio relative to the unconditional return variance of the unhedged portfolio. Because of this emphasis on "unconditional" statistics, the OLS hedge strategy (which does not take into account any other information except current spot and futures returns) is most likely to outperform the optimal conditional hedge strategy.

This superiority of the OLS hedge ratio is challenged by the concern of the appropriateness to evaluate conditional hedging strategies by EHE. Nonetheless, the regime switching (RS) hedge ratio seems to be an exception. Under specific assumptions, the RS-OLS hedge ratio will outperform the conventional OLS hedge ratio.

Utility-based hedging effectiveness is another popular measure examined in the literature. The sample estimator of this effectiveness is, similar to the sample EHE estimator, biased. On the other hand, the measure does not necessarily favor the OLS hedge ratio except when the futures price is a martingale or when the hedger is extremely risk averse.

Recently there have been several alternative effectiveness measures related to tail risk such as lower partial moment, value at risk, and conditional value at risk. Similar problems prevail. That is, a hedge strategy may be chosen to minimize the conditional value at risk. However, when in the evaluation stage, it is the unconditional value at risk that counts. We do not address these issues in the current paper. It will be left for future research.

Abstract

The pricing of delivery options, particularly timing options, in Treasury bond futures is prohibitively expensive. Recursive use of the lattice model is unavoidable for valuing such options, as Boyle (1989) demonstrates. As a result, the main purpose of this study is to derive upper bounds and lower bounds for Treasury bond futures prices.

This study employs a maximum likelihood estimation technique presented by Chen and Scott (1993) to estimate the parameters for two-factor Cox-Ingersoll-Ross models of the term structure. Following the estimation, the factor values are solved for by matching the short rate with the cheapest-to-deliver bond price. Then, upper bounds and lower bounds for Treasury bond futures prices can be calculated.

This study first shows that the popular preference-free, closed-form cost of carry model is an upper bound for the Treasury bond futures price. Then, the next step is to derive analytical lower bounds for the futures price under one- and two-factor Cox-Ingersoll-Ross models of the term structure. The bound under the two-factor Cox-Ingersoll-Ross model is then tested empirically using weekly futures prices from January 1987 to December 2000.

Treasury bond futures • Delivery options • Cox-Ingersoll-Ross models • Bounds • Maximum likelihood estimation • Term structure • Cheapest-to-deliver bond • Timing options • Quality options • Chicago board of trade

71.1 Introduction

Delivery options in Treasury bond futures are generally known as the quality option and three timing options. The *quality* option gives the short the right to deliver any eligible bond (no less than 15 years to maturity or first call) and various timing options give the short the flexibility to make the delivery decision at any time in the delivery month. The *end-of-month timing* option refers to the deliveries occurring during the last 7 business days in the delivery month when the futures market is closed to trading. During the remaining approximately 15 business days of the delivery month, the *wildcard timing* option describes the period from 2:00 p.m. to 8:00 p.m. (Chicago time) every day when the futures market is closed but the bond market is open, while the *accrued interest timing* option refers to the period from 7:20 a.m. to 2:00 p.m. when both the futures and its underlying bond markets are open.

Delivery options in T bond futures are difficult to price. Recursive use of the lattice model is unavoidable for valuing such options, as Boyle (1989) demonstrates, the futures price is effectively a forward price. Furthermore, as demonstrated later, the wildcard timing option is actually a compound forward price – one on top of the other – which cannot be accurately calculated without a multi-recursive system. Consequently, accurate valuation of these delivery options is very costly. This study thus derives fast bounds for the T bond futures price. These bounds can be quickly computed and can provide a crude conservative estimate for the T bond futures price.

Early discussion of the valuation of the quality option appears in Cox et al. (1981), who state that their valuations can be applied to futures with the quality option when the single spot bond price is replaced with the minimum price from the deliverable set. Hemler (1990) uses the exchange option formula of Margrabe's (1978) to price the quality option, but the pricing formula becomes intractable as the number of deliverable bonds increases. Carr (1988) was the first to use factor models to price the quality option, and Carr and Chen (1996) extend the Carr model to include a second factor. Ritchken and Sankarasubramanian (1992) use the Heath et al. (1992) framework to identify the quality option value. Finally, Livingston (1987) analyzes the quality option on the forward contract.

Timing options generally have no closed-form solutions and therefore are studied with lattice methods. Kane and Marcus (1986) lay out a general framework for analyzing the wildcard option. In their analysis, discounting is not considered in the wildcard period. Broadie and Sundaresan (1987) develop a lattice model to value the end-of-month option. They focus strictly on the futures price during the end-of-month period. Boyle (1989) uses a two-period model to demonstrate that the timing option could have a significant impact. His analysis assumes constant interest rates and does not apply directly to T bond futures.

Empiricists generally agree that the quality option has a nontrivial value.[1] However, unlike the evidence for the quality option, the evidence for the timing option is not so clear. This is because most studies do not distinguish between the quality option value and the value from the other timing options, let alone distinguish values among various timing options.[2]

Treasury bond futures contracts are one of the most liquid and widely traded interest rate derivative contracts worldwide and consequently have tight bid-ask spread and high volume. Practitioners thus typically use the market to calibrate the models they use to price other less liquid contracts. Hence, a pricing model that accurately prices both the quality and timing options is necessary to perform this task. However, as demonstrated later, such a model is too expensive since it involves a recursive search for the futures price at the beginning of the delivery month. To have a rough feel for the cost of computation of directly modeling the quality and timing options, this study uses a similar two-factor Cox-Ingersoll-Ross model to the one we use in this paper to compute six futures contract prices. Using a Dell Dimension 2400 with an Intel Celeron processor 2.4 GHz CPU, an average of 9,719.52 seconds (or 2.7 hours) per calculation is required under 102 steps. Clearly such high computational costs are too expensive for real-world applications.

This study derives several results regarding the lower and upper bounds for the futures price. First, this study derives the upper bounds in a model-free format and

[1]See, for example, Carr and Chen (1996), Kilcollin (1982), Benninga and Smirlock (1985), Kane and Marcus (1986), and Hedge (1990).

[2]See, for example, Arak and Goodman (1987), Hedge (1988), and Gay and Manaster (1986).

the lower bound in a semi-model-dependent format. This study proves that the model-free upper bond is the cost of carry model, which is closed form. The lower bond is in the format of an expectation. Since the bounds are almost model-free, violating them implies arbitrage profits. Secondly, this study derives an analytical lower bound for the Treasury bond futures price under the Cox-Ingersoll-Ross model. The study then provides empirical results to show that these bounds are reasonably tight – about 2–3 % above and below the futures price.[3]

The remainder of this paper is organized as follows. The next section studies the quality option. We first study the quality option under continuous marking to market or MTM (i.e., both futures and bond markets are open all the time). Next, the futures price with the quality option is demonstrated effectively to be a forward price when the futures market is closed but the bond market is open. Section 71.3 then provides the theoretical analysis and derives lower and upper bounds for the futures price. Lower bounds are obtained for the futures price under both the quality option and the timing options. We then show that the preference-free cost of carry formula is an upper bound for the futures price. Section 71.4 derives analytical formulas for the lower bound of the futures price (note that the cost of carry formula is model-free) under one- and two-factor Cox-Ingersoll-Ross models. Section 71.5 presents an empirical study where a two-factor equilibrium term structure model is estimated using the Chen and Scott (1993) technique. Finally, Section 71.6 gives a conclusion.

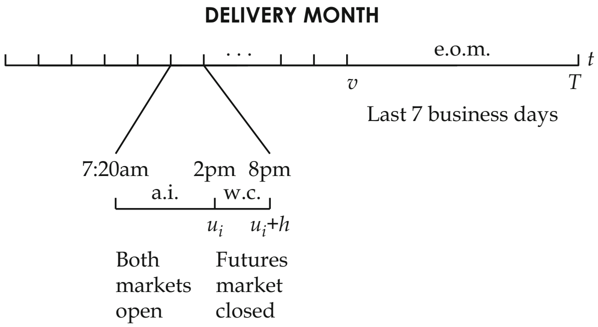
71.2 The Quality Option and the Futures Price

The delivery option that has the highest economic value is the quality option, which gives the short of the futures contract the right to choose the cheapest bond to deliver on the delivery date. Other delivery options that are embedded in T bond futures are known as the three timing options. The short can make a delivery at any time during the delivery month. The short can make a delivery even when the futures market is closed. At the end of the delivery month, for 7 business days, the futures market is closed but the short can still make a delivery. This is understood as the end-of-month timing option. For the remaining approximately 15 business days of the delivery month, the short can deliver either between 7:20 a.m. and 2:00 p.m. (Chicago time) when both the futures market and the underlying bond market are open or after 2:00 p.m. when the futures market is closed.[4]

[3]These bounds are not to be violated, or arbitrage profits should take place. As it will become clear (in Sect. 71.4), in the case of the upper bound that is model-free, a simple trading strategy can be formed to arbitrage against the violation (under perfect markets). In the case of the semi-model-dependent lower bound, arbitrage profits exist only if the assumed model is correct.

[4]T bond market is an over the counter market that has no official closing time, even though market practice adopts 3:00 p.m. Eastern time as a symbolic closing time. The futures market allows the short up to 8:00 p.m. Eastern time to make the delivery announcement, and hence theoretically there is a 5-h window for the wild card.

The former timing option is called the accrued interest timing option and the latter timing option is also known as the daily wild card play. The following picture graphically explains various timing options.



The last 7 business days of the month comprises the end-of-month period. This study uses v to denote the starting time and T to represent the ending time of this period. For the rest of the delivery month, there are two sections of each day, the accrued interest period and the wildcard period. For a regular futures trading day i between 7:20 a.m. and 2 p.m. Chicago time, both the bond and futures markets are open simultaneously. The futures market closes at 2 p.m., but there is no official closing time for the bond market (while conventionally 3 p.m. Eastern time is marked as a symbolic closing time for the bond market). Since the short has till 8 p.m. to make the delivery decision, the wildcard period is defined over 2 p.m. (u_i) to 8 p.m. ($u_i + h$).

The notation and symbols used in the paper are also summarized as follows:
$\Phi(t)$ = "quoted" futures price with all delivery options
$\Phi^*(t)$ = futures price with the quality option and continuous marking to market
$\Phi^{**}(t)$ = futures price with the quality option at the absence of continuous MTM
$\overline{\Phi(t)}$ = upper bound
$\Phi(t)$ = lower bound
$\overline{\Phi_i(t)}$ = futures price of the ith quoted bond price
$\Psi_i(t)$ = forward price of the ith quoted bond price
$a_i(t)$ = accrued interest of the ith bond
$P(t, T)$ = discount bond price at time t of \$1 at time T
$Q_i(t)$ = "quoted" coupon bond price of the ith bond
q_i = conversion factor of the ith bond
$\delta(t, T)$ = random discount factor between t and T

Note that under a specific model for the term structure (e.g., Vasicek or Cox-Ingersoll-Ross), the futures price of a specific bond can be priced in an analytical form (see Sect. 71.4). Before we start our analysis, we need Jamshidian's separation theorem (1987) and his definition of the forward measure.[5]

[5]Also see Hull (2009).

Theorem 1 (Forward Measure) *Let P(t, T) be the price of a pure discount bond delivering* \$1 *at some future date and it follows the dynamics as:*

$$\frac{dP(t,T)}{P(t,T)} = r(t)dt + b(t,T)dW^{Q}(t)$$

where r is the instantaneous risk-free rate, b is maturity dependent bond volatility, and $dW^{Q}(t)$ is the standard Wiener process defined under the risk-neutral space. Then the forward measure is defined as:

$$\frac{dP(t,T)}{P(t,T)} = \left(r(t) - b(t,T)^2\right)dt + b(t,T)dW^{F(T)}(t)$$

where $dW^{F(T)}(t) = dW^{Q}(t) + b(t, T)dt$. Under this forward measure, all expected values taken will be forward prices, that is:

$$\begin{aligned} E_t^Q[\delta(t,T)X(T)] &= E_t^Q[\delta(t,T)]E_t^{F(T)}[X(T)] \\ &= P(t,T)E_t^{F(T)}[X(T)] \end{aligned}$$

where $\delta(t,T) = \exp(-\int_t^T r(u)du)$ and $E_t^{F(T)}[X(T)]$ computes the forward price of X.

A simple proof of this theorem is given in an appendix although the original proof is available in Jamshidian (1987).

71.2.1 The Quality Option with Continuous Marking to Market

In the absence of all timing options, the quality option gives the short the right to deliver the cheapest bond only at maturity, T, and the short receives the following payoff:

$$\max\{q_i\Phi(T) - Q_i(T)\} \quad (71.1)$$

Note that the accrued interests of both bond and futures contracts are equal and canceled. Since the delivery value of Eq. 71.1 has to be identically 0 for all states, we can solve for the futures price at maturity as:

$$\Phi(T) = \min\left\{\frac{Q_i(T)}{q_i}\right\} \quad (71.2)$$

and today's futures price is merely a risk-neutral expectation of this payoff:

$$\begin{aligned}\Phi^*(t) &= E_t^Q\left[\min\left\{\frac{Q_i(T)}{q_i}\right\}\right]\\ &= \frac{E_t^Q[Q_1(T)]}{q_1} - E_t^Q\left[\max\left\{\frac{Q_1(T)}{q_1} - \frac{Q_i(T)}{q_i}\right\}\right]\\ &= \frac{\Phi_1(t)}{q_1} - E_t^Q\left[\max\left\{\frac{Q_1(T)}{q_1} - \frac{Q_i(T)}{q_i}\right\}\right]\end{aligned} \tag{71.3}$$

Note $\Phi_1(t) = E_t^Q[Q_1(T)]$ is the futures price of the first bond with no option and $\Phi^*(t)$ is that of the cheapest bond at maturity. This result has previously been shown by Carr (1988) and others. This equation says that the futures contract with the quality option is equivalent to a futures contract without the quality option (only bond 1 is eligible for delivery) with an exchange option held by the short. With a specific term structure model, Eq. 71.3 becomes an analytical solution.[6]

71.2.2 The Quality Option with No Marking to Market When the Futures Market Is Closed

Equation 71.3 is correct only if marking to market is applied continuously throughout the life of the futures contract. Unfortunately, during the last 7 business days of the delivery month, the futures market is not open and the futures contract is not marked to market. The futures price used for settlement in this period is the last settlement price at the beginning of the 7-day period. Since the futures price is already determined, the actual payoff at the last delivery day, T, is not necessarily 0. The short thus can actually gain or lose. To avoid arbitrage, the futures price at the beginning of the 7-day period should be set so that the expected present value of payoffs at maturity is 0. Under this circumstance, the futures price at the beginning of the 7-day period is a *forward price*, not a futures price. Formally, labeling the futures price as $\Phi^{**}(v)$ to represent the futures price at the beginning of the end-of-month period, v, should be so set that

$$E_v^Q[\delta(v,T)\max\{\Phi^{**}(v)q_i - Q_i(T)\}] = 0 \tag{71.4}$$

where δ is the stochastic discount factor assumed to be strictly less than 1. Using Theorem 1, we can then rewrite Eq. 71.4 as:

$$E_v^{F(T)}[\max\{\Phi^{**}(v)q_i - Q_i(T)\}] = 0 \tag{71.5}$$

which can be expanded as follows:

[6]For example, the closed-form solution under the one-factor Cox-Ingersoll-Ross model can be found in Carr (1988).

$$
\begin{aligned}
0 &= E_v^{F(T)}[\max\{\Phi^{**}(v)q_i - Q_i(T)\}] \\
0 &= E_v^{F(T)}[\Phi^{**}(v)q_1 - Q_1(T) + \max\{\Phi^{**}(v)(q_i - q_1) - (Q_i(T) - Q_1(T)), 0\}] \\
0 &= \Phi^{**}(v)q_1 - \Psi_1(v) + E_v^{F(T)}[\max\{Q_1(T) - Q_i(T) - \Phi^{**}(v)(q_1 - q_i), 0\}]
\end{aligned}
\tag{71.6}
$$

and the futures price at time v can be written as:

$$
\Phi^{**}(v) = \frac{\Psi_1(v)}{q_1} - \frac{1}{q_1} E_v^{F(T)}\left[\max\left\{Q_1(T) - Q_i(T) - K_i^{**}, 0\right\}\right] \tag{71.7}
$$

where $K_i^{**} = (q_1 - q_i)\Phi^{**}(v)$. Note that $\Psi_1(v) = E_v^{F(T)}[Q_1(T)]$ is the forward price of the first bond. The interpretation of this result is similar to that of Eq. 71.3, except that the risk-neutral measure is replaced by the forward measure defined in Theorem 1 and the futures price becomes the forward price. However, unlike Eq. 71.3, the futures price at time v has no easy solution, because it appears on both sides of the equation. This futures price has to be solved recursively using a numerical method. In a lattice framework suggested by Boyle (1989), we first choose an initial value for the futures price at time v, calculate payoffs at various states at maturity T, and then work backwards along the lattice. We adjust the futures price until the discounted payoff computed from the lattice is 0. Once the futures price at time v is set, we can then travel back along the lattice and use the risk-neutral probabilities till the end of the last wildcard period, $u_n + h$. Then the similar procedure for the end-of-month period is repeated for the last wildcard period to arrive at the futures price at the beginning of the wildcard period u_n. Again, the risk-neutral expectation is taken at $u_{n-1} + h$ and a recursive search is to compute the futures price at u_{n-1}. The process is repeated until the delivery month is over. Since the futures price becomes a forward price which cannot be obtained without a recursive search. The search for the "forward price" takes place at every node at all the times (i.e., $u_1, u_2, \ldots, u_n, v$). As a result, to compute the futures price with the quality option is prohibitively expensive.

With the presence of the end-of-month timing option, the futures price computed by Eq. 71.7 is an overestimate because the short has additional flexibility of choosing the best timing. If the short is allowed to deliver at any time in this 7-day period, then we need to compare the expected present value of future payoffs with the current delivery value. Higher current delivery value will trigger early deliveries. This is very similar to the American option pricing methodology where the intrinsic value is compared with the expected present value of future payoffs.

71.3 The Timing Options and Futures Price Bounds

In the previous section, we see that under the end-of-month and a series of wildcard periods, even the quality option alone is very complex to compute, let alone those timing options. In this section, we derive upper and lower bounds for these options in a general framework and analytical formulas are derived in the next section when a specific term structure model is chosen.

71.3.1 The Accrued Interest Timing Option

The accrued interest timing option refers to the flexibility for the short to deliver the cheapest bond any time in the delivery month when both futures and spot markets are open. This is every day from 7:20 a.m. to 2:00 p.m. (Chicago time) from the first day of the delivery month to right before the end-of-month period. Since the futures market is open, the futures contract is marked to market and deliveries can take place any time. As a result, the futures price can never be greater than the cheapest-to-deliver bond price. If the futures price were greater than the cheapest bond price, then deliveries would take place instantly. The short will sell the futures, buy the cheapest bond, make the delivery, and earn an arbitrage profit. Formally, for $t < v$, if the futures price is greater than the delivery value,

$$\begin{aligned} &\Phi(t) > \min\left\{\frac{Q_i(t)}{q_i}\right\} \\ &\text{iff} \\ &\max\{\Phi(t)q_i - Q_i(t)\} > 0 \end{aligned} \tag{71.8}$$

which represents arbitrage profit. Therefore, the futures price in the period where both markets are open must be less than the cheapest-to-deliver bond price to avoid arbitrage. On the other hand, if the futures price is lower, one can long futures and short spot, but the delivery will not occur because the short position of the futures contract will lose money if he makes a delivery. Consequently, the delivery will be postponed and there is no arbitrage profit to be made. If the futures price is always less than the cheapest-to-deliver bond price (adjusted by its conversion factor), the delivery payoff now is negative as opposed to 0 at the end. As a result, the short will never deliver until the last day. Consequently, the accrued interest timing option has no value. We restate this result in the following proposition:

Proposition 1 *The accrued interest timing option without the wildcard and end-of-month options has no value.*[7] □

The existence of the other timing options will lower the current futures price, further reducing the incentive for the short to deliver early. We state this result in the following Corollary:

Corollary 1-1 *The accrued interest timing option with the wildcard and end-of-month options has no value.* □

While the accrued interest timing option is worthless, the timing options at the end-of-month and the wildcard periods are not. When the futures market is closed, there is no marking to market in the futures market and the futures contract becomes a forward contract. Boyle (1989) demonstrates that in a case of forward contracts,

[7]The name "accrued interest" comes in because in the delivery month, the bond price increases due to accrued interests. Here, Q is a traded price that included accrued interests.

timing options will have value. We shall extend Boyle's analysis to stochastic interest rates so that we can evaluate T bond futures timing options.

71.3.2 The End-of-Month Timing Option

Without the end-of-month timing option, we know that the futures price should be set according to Eq. 71.7. With the end-of-month timing option, deliveries can occur any time in the end-of-month period as long as the current delivery payoff is more than the present value of the expected payoff.

When both quality and timing options exist, the short makes a rational delivery decision when the immediate delivery value is higher than the expected discounted value should delivery take place later. This is like the early exercise of an American option. There is no closed-form solution to compute American option prices. Precisely as Boyle (1989) observes, the pricing of quality and timing options do need a lattice model.

To avoid arbitrage, today's futures price needs to be set so that the expected discounted payoff is nil. As a result, if we can identify a function that is always greater than both the delivery payoff and the discounted present value, this function is guaranteed to have a positive present value at time v. This is in spirit similar to the application in Chen and Yeh (2002). The trick is to identify a function that is always greater than the delivery value and the continuation value (ft: Continuation value is the value if it is not optimal to exercise (i.e., delivery). In the binomial model, the continuation value is the value at the node that reflects all possible exercises.)

We guess the function of the following, for $v < t < T$:

$$\begin{aligned} E_t^Q\left[\max\left\{\frac{1}{\delta(t,T)}\Phi(v)q_i - Q_i(T)\right\}\right] &> E_t^Q[\max\{\Phi(v)q_i - \delta(t,T)Q_i(T)\}] \\ &> \max\{\Phi(v)q_i - Q_i(t)\} \end{aligned} \tag{71.9}$$

where δ is the stochastic discount factor which is assumed to be strictly less than 1. This value is greater than the present value of the delivery payoff at any time $t \in [v, T]$. Equation 71.9 states that the upper bound is always greater than the exercise value of the futures contract. The last line is obtained as follows. Note that the martingale result states that: $E_t^Q[\delta(t, T)(Q_i(T) + a_i(T))] = Q_i(t) + a_i(t)$, in other words, discounted market price of a bond should equal its current value, assuming there is no coupon in between t and T.[8] Since the accrued interest is linear but discounting is not (i.e., $P(t, T)a_i(T) > a_i(t)$) it follows that $E_t^Q[\delta(t, T)Q_i(T)] < Q_i(t)$ but the difference is small.

[8]If there is a coupon in between t and T, we simply subtract the coupon value from the expected value.

Equation 71.9 shows that the proposed function is greater than the delivery value at any time. We can also show that the function has a higher value at an earlier time than at a later time. That is:

$$
\begin{aligned}
&E_t^Q\left[\max\left\{\frac{1}{\delta(t,T)}\Phi(v)q_i - Q_i(T)\right\}\right]\\
&> E_t^Q\left[\max\left\{\frac{1}{\delta(t+\Delta t,T)}\Phi(v)q_i - Q_i(T)\right\}\right]\\
&> E_t^Q\left[\delta(t,t+\Delta t)E_{t+\Delta t}^Q\left(\max\left\{\frac{1}{\delta(t+\Delta t,T)}\Phi(v)q_i - Q_i(T)\right\}\right)\right]
\end{aligned}
\tag{71.10}
$$

It is seen that the proposed function is always greater than the delivery value and the discounted continuation value. It must be the case that it is an upper bound for the end-of-month period timing option value. Hence, at time v, the payoff should be positive:

$$
E_v^Q\left[\max\left\{\frac{1}{\delta(v,T)}\Phi(v)q_i - Q_i(T)\right\}\right] > 0 \tag{71.11}
$$

which can be expanded as follows:

$$
\begin{aligned}
&E_v^Q\left[\frac{1}{\delta(v,T)}\Phi(v)q_1 - Q_1(T) + \max\left\{\frac{1}{\delta(v,T)}\Phi(v)(q_i-q_1) - (Q_i(T)-Q_1(T))\right\}\right] > 0\\
&E_v^Q\left[\frac{1}{\delta(v,T)}\right]\Phi(v)q_1 - \Phi_1(v) + E_v^Q\left[\max\left\{Q_1(T) - Q_i(T) - \frac{1}{\delta(v,T)}\Phi(v)(q_1-q_i)\right\}\right] > 0
\end{aligned}
\tag{71.12}
$$

This implies that the futures price should be bounded from below as follows:

$$
\begin{aligned}
\Phi(v) &> \frac{\Phi_1(v)\Delta(v,T)}{q_1} - \frac{\Delta(v,T)}{q_1}E_v^Q\left[\max\left\{Q_1(T) - Q_i(T) - \frac{1}{\delta(v,T)}K_i, 0\right\}\right]\\
&> \frac{\Phi_1(v)\Delta(v,T)}{q_1} - \frac{\Delta(v,T)}{q_1}E_v^Q[\max\{Q_1(T) - Q_i(T) - K_i, 0\}]
\end{aligned}
\tag{71.13}
$$

where

$$
K_i = (q_1 - q_i)\Phi(v) \text{ and}
$$

$$
\Delta(v,T) = \frac{1}{E_v^Q[1/\delta(v,T)]}
$$

Note that the second inequality holds because δ is strictly less than 1. Therefore, the right hand side of the above equation is a lower bound. The lower bound for any time t, $\Phi(t)$, is the risk-neutral expectation of the above lower bound at time v:

$$
\begin{aligned}
\Phi(t) &= E_t^Q\left\{\frac{\Phi_1(v)\Delta(v,T)}{q_1} - \frac{\Delta(v,T)}{q_1}E_v^Q[\max\{Q_1(T) - Q_i(T) - K_i, 0\}]\right\} \\
&= \frac{\Phi_1(t)\Delta(v,T)}{q_1} - \frac{\Delta(v,T)}{q_1}E_t^Q[\max\{Q_1(T) - Q_i(T) - K_i, 0\}]
\end{aligned}
\tag{71.14}
$$

Note that K_i is a function of $\Phi(v)$ which cannot be solved without a recursive search procedure. To arrive at an analytical lower bound, we replace this value with a closed-form futures price $\Phi^*(v)$. We state this result in a following proposition:

Proposition 2 *The futures price under only the end-of-month timing option is bounded from below by the following risk-neutral expectation*:

$$
\frac{\Phi_1(t)\Delta(v,T)}{q_1} - \frac{\Delta(v,T)}{q_1}E_t^Q\left[\max\left\{Q_1(T) - Q_i(T) - K_i^*, 0\right\}\right] \tag{71.15}
$$

where $K_i^* = (q_1 - q_i)\Phi^*(v)$ *and* $\Phi^*(v)$ *is the futures price with only the quality option defined in* Eq. 71.3. □

It is interesting to note that the end-of-month option has a value even if the quality option does not exist. When there is no quality option but the timing option is allowed, the delivery may occur early. The short always compares the delivery payoff $\Phi(v)q - Q(t)$ where $v < t < T$ with the expected present value of the delivery payoff at maturity. We can show that:

$$
E_t^Q[\delta(t,T)(\Phi(v)q - Q(T))] > P(t,T)\Phi(v)q - Q(t) < \Phi(v)q - Q(t) \tag{71.16}
$$

Since the direction of the inequality can go either way, it is likely that early deliveries can take place. This demonstrates that the timing option, even in the absence of the quality option, does have value. The difference between the first two terms in Eq. 71.16 is $P(t,T)a(T) - a(t)$ where a is the accrued interest and the difference of the last two terms is $(1 - P(t,T))\Phi(v)$. As a result, whether or not deliveries will occur early depends upon which effect is larger. This result should not be confused with the result from Boyle (1989) where the timing option is defined differently.

71.3.3 The Wild Card Timing Option

In addition to the end-of-month period where the futures market is closed but the bond market is open, there is a 6-h period every day for about 15 days where the futures market is also closed. This is called the daily wild card timing option. The wild card option is different from the end-of-month option in that the futures market will reopen after each wild card period and the futures contract will be marked to market. If bond prices drop in the wild card period, given that the futures price is fixed, the short can benefit from delivering a cheaper bond. However, the short can equally benefit from the marking to market when the futures market reopens. As a result, the incentive for the short to deliver in the wild card period is minimal. Delivery can take place in a wildcard period only when the payoff from immediate delivery exceeds the expected present value of marking to market on the next day.

We now proceed to derive the bound of the wild card option. For each daily wild card period, $(u, u + h)$, we define the following function as the upper bound of the delivery payoff (for $u < t < u + h$):

$$E_t^Q[\max\{\Phi(u)q_i - \delta(t, u+h)Q_i(u+h)\}] \tag{71.17}$$

This is an upper bound of the payoff because it is greater than (i) the payoff from immediate delivery:

$$\begin{aligned} E_t^Q[\max\{\Phi(u)q_i - \delta(t, u+h)Q_i(u+h)\}] &\geq \max\{\Phi(u)q_i - E_t^Q[\delta(t, u+h)Q_i(u+h)]\} \\ &> \max\{\Phi(u)q_i - Q_i(t)]\} \end{aligned} \tag{71.18}$$

where the second line is obtained by the fact that $E_t^Q[\delta(t,T)Q_i(T)] < Q_i(t)$ proved earlier and (ii) the discounted expected payoff from delivering at the end of the wild card period:

$$\begin{aligned} &E_t^Q[\max\{\Phi(u)q_i - \delta(t, u+h)Q_i(u+h)] \\ &\quad > E_t^Q[\delta(t, u+h)\max\{[\Phi(u)q_i - Q_i(u+h)]\}] \end{aligned} \tag{71.19}$$

Hence, Eq. 71.19 is indeed an upper bound for the wild card option value, which is greater than 0:

$$\begin{aligned} &E_t^Q[\max\{\Phi(u)q_i - \delta(t, u+h)Q_i(u+h)\}] > 0 \\ &E_t^Q\left[\max\left\{\Phi(u) - \delta(t, u+h)\frac{Q_i(u+h)}{q_i}\right\}\right] > 0 \\ &\Phi(u) - E_t^Q\left[\delta(t, u+h)\min\left\{\frac{Q_i(u+h)}{q_i}\right\}\right] > 0 \\ &\Phi(u) > P(t, u+h)E_t^{F(u+h)}\left[\min\left\{\frac{Q_i(u+h)}{q_i}\right\}\right] \end{aligned} \tag{71.20}$$

Note that $\min\left\{\frac{Q_i(u+h)}{q_i}\right\} \geq \Phi(u+h)$ when both markets are open from Sect 71.3.1.[9] Therefore, $\Phi(u) > P(t, u+h)E_t^{F(u+h)}[\Phi(u+h)]$. This is no surprise because the end-of-month option will reduce the futures price prior to time v, which in turn will reduce the futures price at time $u + h$. Hence, it is

[9]Note that in the second line of Eq. 71.17 where q_i is divided through is due to the fact that there exists a bond i such that $\max\{\Phi(u)q_i - \delta(t, u+h)Q_i(u+h)\} > 0$ in all states.

Proposition 3 *Given the futures price next morning (i.e., $\Phi(u_i + h)$) when the futures market reopens at day $i + 1$ (assuming continuous marking to market), the futures price prior to each wildcard period (i.e., $\Phi(u_i)$) is bounded from below by*

$$P(u_i, u_i + h)E_t^{F(u_i+h)}[\Phi(u_i + h)] \tag{71.21}$$

where u_i is the beginning of a wild card period depicted on page 4 and $u_i + h$ is end of the wild card period (which is assumed to be the same as the time when the futures market reopens the next morning). □

71.3.4 Putting It All Together for the Lower Bound

So far, we have derived the lower bound for the futures price of the end-of-month period, $\Phi(v)$, and each of the wildcard period, $\Phi(u)$, where u represents the beginning time of any wildcard period. The futures price of any given time is a recursive calculation of Eq. 71.21. The easiest way to understand the calculation is to picture a univariate lattice model. The lower bound for the futures price at time v is calculated by Eq. 71.15. We shall label it $\underline{\Phi(v)}$ for the lower bound at time v. Then, the regular risk-neutral expectation is taken until the end of the last wildcard period, $u_n + h$ where u_n represents the beginning of the nth (last) wildcard period, is reached. The correct futures price, $\Phi(u_n + h)$, at this moment is unknown since it requires a repeated recursive process described in Sect. 71.3. But we can replace it with the lower bound $\underline{\Phi(u_n + h)} = E^Q_{u_n+h}\left[\underline{\Phi(v)}\right]$. Then, we apply Eq. 71.21 to compute the lower bound at time u_n to get $\underline{\Phi(u_n)} = P(u_n, u_n + h)E^{F(u_n+h)}_{u_n}\left[\underline{\Phi(u_n + h)}\right]$. Repeat this process through all the wildcard periods, u_{n-1}, u_{n-2}, $\ldots$, u_1 to get $\underline{\Phi(u_1)} = P(u_1, u_1 + h)$ $E^{F(u_1+h)}_{u_1}\left[\underline{\Phi(u_1 + h)}\right]$. Then the regular risk-neutral expectation is taken to the current time: $\underline{\Phi(t)} = E^Q_t\left[\underline{\Phi(u_1)}\right]$. Repeated substitutions yield the following general result for the lower bound at the current time $t < u_1$,

$$\begin{aligned}
\underline{\Phi(t)} &= E^Q_t\left[\underline{\Phi(u_1)}\right] \\
&= E^Q_t\left[\delta(u_1, u_1 + h)E^Q_{u_1+h}\left[\underline{\Phi(u_2)}\right]\right] \\
&= E^Q_t\left[\delta(u_1, u_1 + h)E^Q_{u_2}\left[\delta(u_2, u_2 + h)\left[\underline{\Phi(u_2 + h)}\right]\right]\right] \\
&= \cdots \\
&= E^Q_t\left[\prod_{j=1}^{n}\delta(u_j, u_j + h)\underline{\Phi(v)}\right] \\
&= E^Q_t\left[\prod_{j=1}^{n}\delta(u_j, u_j + h)\left(\frac{\Phi_1(v)\Delta(v,T)}{q_1} - \frac{\Delta(v,T)}{q_1}\max_i\{Q_1(T) - Q_i(T) - K_i^*\}\right)\right]
\end{aligned} \tag{71.22}$$

The second line of the above equation is obtained by substituting the lower bound for $\underline{\Phi(u_1)}$ (i.e., $\underline{\Phi(u_1)} = E^Q_{u_1}\left[\delta(u_1, u_1 + h)\left[\underline{\Phi(u_1 + h)}\right]\right.$) and the law of iterative expectations under the risk-neutral measure. We summarize in a proposition:

Proposition 4 *The futures price is bounded from below by the following risk-neutral expectation*:

$$\underline{\Phi(t)} = E^Q_t\left[\prod_{j=1}^{n}\delta\left(u_j, u_j + h\right)\left(\frac{\Phi_1(v)\Delta(v,T)}{q_1} - \frac{\Delta(v,T)}{q_1}\max_i\left\{Q_1(T) - Q_i(T) - K_i^*\right\}\right)\right] \tag{71.23}$$

□

71.3.5 The Cost of Carry Model: The Upper Bound

After deriving the lower bound of the futures price, in the next proposition, we show that the cost of carry model provides an upper bound for the futures price. The well-known cost of carry formula is the following:

$$\Phi_*(t) = \frac{\frac{Q_*(t)+a_*(t)}{P(t,T)} - a_*(T)}{q_*} \tag{71.24}$$

where Q_*, q_*, and a_* are quoted price, conversion factor, and accrued interest of the cheapest bond at time t. Rearranging terms to get:

$$\begin{aligned}\Phi_*(t) &= \frac{\frac{Q_*(t)+a_*(t)}{P(t,T)} - a_*(T)}{q_*} \\ &= E_t^{F(T)}\left[\frac{Q_*(T)}{q_*}\right] \\ &= E_t^{F(T)}\left[\min\left\{\frac{Q_i(T)}{q_i}\right\}\right] \\ &> E_t^{Q}\left[\min\left\{\frac{Q_i(T)}{q_i}\right\}\right]\end{aligned} \tag{71.25}$$

As we can see, the cost of carry model is equal to a forward expectation of the payoff. The futures price without the timing options is a risk-neutral expectation of the payoff (see Eq. 71.3). The last inequality is obtained due to the following:

$$\operatorname{cov}\left[\delta(t,T), \min\left\{\frac{Q_i(T)}{q_i}\right\}\right] > 0 \tag{71.26}$$

This is easy to see because when r increases (decreases), both discount factor, δ, and all quoted bond prices, Q_i's, decrease (increase), and the sign of the covariance is therefore positive. Note that the futures price without timing options is already an upper bound; the cost of carry model used by practitioners is a more conservative upper bound of the futures price. We state the result in the following proposition:

Proposition 5 *The futures price is bounded from above by the cost of carry model.*

$$\overline{\Phi(t)} = \Phi_*(t) \tag{71.27}$$

□

It is generally believed that the futures price with the quality option (Eq. 71.3) is the upper bound of the futures price, since it ignores the timing options. Indeed, if Eq. 71.3 can be evaluated accurately, it is a much tighter lower bound than the cost of carry model shown above. However, note that the cost of carry model is a "model-free" result, while Eq. 71.3 relies upon a specific term structure model. As a result, if the term structure model is not correctly specified, Eq. 71.3 may not serve the role of upper bound well. As we shall see in the empirical section, under a two-factor Cox-Ingersoll-Ross model, Eq. 71.3 does not always provide an upper bound. On the other hand, the violation of the cost of carry upper bound implies arbitrage opportunities.

71.4 Analytical Bounds for Explicit Term Structure Models

The study of the bounds of option prices starts as early as the beginning of modern option pricing theory. There are different approaches to find bounds for option prices. Like Lo (1987) develops the semi-parametric upper bounds of the expected payoffs of options. Zhang (1994) extends the methodology to obtain tighter upper and lower bounds for option prices. In this section, we use the one- and two-factor Cox-Ingersoll-Ross (1985) models to demonstrate how one can calculate the upper bounds of the delivery options and the lower bound of the futures price analytically. Quoted coupon bond price should be equal to:

$$Q(t) = \sum_{j=1}^{m} P\left(t, T_j\right) c_j - a(t), \tag{71.28}$$

Define additional notation $\Phi(t, T_i, T_j) = E_t^Q[P(T_i, T_j)]$ to be the futures price of a pure discount bond delivered at time T_i and $\Psi(t, T_i, T_j) = P(t, T_i)/P(t, T_j)$ to be the forward price of a pure discount bond. These general results are independent of model assumption and of the number of factors.

71.4.1 Single-Factor Model

For the sake of easy exposition and no loss of generality, we shall derive analytical lower bound for the futures price at time v (beginning of end-of-month period).

The lower bound at an arbitrary time t can be derived similarly. Assume $Q_1 > Q_i$ for $i \neq 1$. We follow Carr (1988) that in a single-factor model, the whole distribution of r can be partitioned into n disjoint segments, denoted by $\Omega_i \equiv [r^*_{k(i)-1},\ r^*_{k(i)}]$ where $r_0{}^* = 0$ and $r_n{}^* = \infty$, each of which represents a segment where Q_i maximizes the payoff function: $\max\{Q_1 - Q_i - K_i^*,\}$. The analytic result of the expected value (taken at time v) of Eq. 71.15 is then derived as follows:

$$\begin{aligned} W_v &= E_v^Q\left[\max\left\{Q_1 - Q_i - K_i^*, 0\right\}\right] \\ &= \sum\nolimits_{i=2}^{n} \int\limits_{\Omega_i} \left[\sum\nolimits_{j=1}^{b(1)} c_{1j} P\left(T, T_{1j}\right) - \sum\nolimits_{j=1}^{b(i)} c_{ij} P\left(T, T_{ij}\right) - K_i^*\right] \varphi(r) dr \\ &= \sum\nolimits_{j=1}^{b(1)} c_{1j} \int\limits_{\Sigma_{i=2}^{n}\Omega_i} P\left(T, T_{1j}\right) \varphi(r) dr - \sum\nolimits_{i=2}^{n} \sum\nolimits_{j=1}^{b(i)} c_{ij} \int\limits_{\Omega_i} P\left(T, T_{ij}\right) \varphi(r) dr - K_i^* \end{aligned} \tag{71.29}$$

where $b(i)$ is the last coupon payment time for bond i, $K_i^* = (q_1 - q_i)\Phi^*(v)$, and $\Phi^*(v)$ is the futures price under continuous marking to market (defined by Eq. 71.3). Note that in each region Ω_i, bond i maximizes the payoff $\max\{Q_1 - Q_i - K_i, 0\}$ and $\varphi(r)$ is the risk-neutral density of the interest rate.

Without the consideration of any wild card, the lower bound for the futures price at any arbitrary time t is a risk-neutral expectation of Eq. 71.29:

$$\begin{aligned} \underline{\Phi(t)} &= E_t^Q\left[\prod\nolimits_{j=1}^{n} \delta\left(u_j, u_j + h\right)\left(\frac{\Phi_1(v)\Delta(v,T)}{q_1} - \frac{\Delta(v,T)}{q_1}\max_i\left\{Q_1(T) - Q_i(T) - K_i^*\right\}\right)\right] \\ &= \int_{-\infty}^{\infty} dr(u_1) \int_{-\infty}^{\infty} dr(u_2) \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} dr(u_n) \prod\nolimits_{j=1}^{n} \delta\left(u_j, u_j + h\right) \int_{-\infty}^{\infty} dr(v) \frac{\Phi_1(v)\Delta(v,T)}{q_1} \\ &\quad - \frac{\Delta(v,T)}{q_1} \int_{-\infty}^{\infty} dr(T) \max_i\left\{Q_1(T) - Q_i(T) - K_i^*\right\} \varphi(r(u_1), \cdots, r(T)) \\ &= \int_{-\infty}^{\infty} dr(u_1) \int_{-\infty}^{\infty} dr(u_2) \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} dr(u_n) \prod\nolimits_{j=1}^{n} \delta\left(u_j, u_j + h\right) \int_{-\infty}^{\infty} dr(v) \frac{\Phi_1(v)\Delta(v,T)}{q_1} \\ &\quad - \frac{\Delta(v,T)}{q_1} \sum\nolimits_{i=2}^{n} \int_{\Omega_i} \left[\sum\nolimits_{j=1}^{b(1)} c_1 P\left(T, T_{1j}\right) - \sum\nolimits_{j=1}^{b(i)} c_i P\left(T, T_{ij}\right) - K_i^*\right] \varphi(r(u_1), \cdots, r(T)) \\ &= \int_{-\infty}^{\infty} dr(u_1) \cdots \int_{-\infty}^{\infty} dr(u_n) \prod\nolimits_{j=1}^{n} \delta\left(u_j, u_j + h\right) \int_{-\infty}^{\infty} dr(v) \frac{\Phi_1(v)\Delta(v,T)}{q_1} - \frac{\Delta(v,T)}{q_1} W_v \varphi(r(u_1), \cdots, r(v)) \end{aligned} \tag{71.30}$$

where W_v is defined in Eq. 71.29.

In the case of CIR, the interest rate process follows the square root process:

$$dr = (\alpha\mu - (\alpha + \varsigma)r)dt + \sigma\sqrt{r}dW^Q \tag{71.31}$$

where a is the reverting speed, μ is the reverting level, σ is the volatility parameter, and ς is the market price of risk which is constant under log utility. The futures price with only the quality option is in Carr (1988) as:

$$\Phi^*(t) = \sum_{i=1}^{n}\sum_{j=1}^{b(i)}\frac{c_{ij}}{q_i}\Phi\left(t,T,T_{ij}\right)\sum\nolimits_{k=1}^{m(i)} I_{ik}\left[\chi_j^2\left(r_{ik}^*\right) - \chi_j^2\left(r_{ik-1}^*\right)\right] \tag{71.32}$$

where

$\Phi(t, u, v) = C(t, u, v)e^{-\,r(t)D(t,u,v)}$, futures price under the CIR model without any options

$$C(t,u,v) = A(u,v)\left(\frac{\eta(t,u)}{\eta(t,u)+B(u,v)}\right)^{\frac{2\alpha\mu}{\sigma^2}}$$

$$D(t,u,v) = \frac{B(u,v)\eta(t,u)e^{-(\alpha+\varsigma)(u-t)}}{\eta(t,u)+B(u,v)}$$

$$A(u,v) = \left(\frac{2\gamma e^{(\alpha+\varsigma+\gamma)(v-u)/2}}{(\alpha+\varsigma+\gamma)(e^{\gamma(v-u)}-1)+2\gamma}\right)^{\frac{2\alpha\mu}{\sigma^2}}$$

$$B(u,v) = \frac{2\left(e^{\gamma(v-u)}-1\right)}{(\alpha+\varsigma+\gamma)(e^{\gamma(v-u)}-1)+2\gamma}$$

$$\eta(t,u) = \frac{2(\alpha+\varsigma)}{\sigma^2(1-e^{-(\alpha+\varsigma)(u-t)})}$$

$$\chi_j^2(r^*) = \chi^2\left[2\eta(t,u)r^*;\frac{4\alpha\mu}{\sigma^2},2\eta(t,u)re^{-(\alpha+\varsigma)\left(T_{ij}-t\right)}\right]$$

$m(i)$ represents the domain where bond i can be the cheapest to deliver, similar to Ω_i in Eq. 71.29. T_{ij} represents the time of the jth coupon of bond i. c_{ij} represents the jth cash flow (coupon or coupon and principal) of bond i. For example, when $j < b(i)$, c_{ij} is coupon, and when $j = b(i)$, c_{ij} is coupon plus principal. In addition, note that I_{ik} is the indicator function equal to 1 for the ith bond and between the critical values of r^*_{ik-1} and r^*_{ik} and $\chi^2(x, y, z)$ is a noncentral chi-square probability function with limit x, degrees of freedom y, and degrees of noncentrality z.

Under the CIR model, Eq. 71.29 becomes

$$\begin{aligned} W_v^{\mathrm{CIR}} &= E_v^Q\left[\max\left\{Q_1 - Q_i - K_i^*, 0\right\}\right] \\ &= \left\{\sum\nolimits_{i=1}^{n-1}\left[\sum\nolimits_{j=1}^{b(i)} c_1\Phi\left(v,T,T_{1j}\right)\chi^2(\bar{r}_1) - \sum\nolimits_{j=1}^{n} c_i\Phi\left(v,T,T_{ij}\right)\chi^2(\bar{r}_i) - K_i^*\chi^2(\bar{r}_1)\right]\right\} \end{aligned} \tag{71.33}$$

$\bar{r}_1$ and $\bar{r}_i$ denote crossover rates that are over a plausible range of interest rates; there exists only one such rate that determine regions where one bond is cheaper and regions where the other is cheaper. Then the lower bound under the CIR model of the term structure is still Eq. 71.30 but with W_v^{CIR} replacing W_v.

71.4.2 Two-Factor Model

We use the two-factor model of the following kind:[10]

$$r = y_1 + y_2 \tag{71.34}$$

where each factor follows a square root process as in Eq. 71.31:

$$dy_i = (\alpha_i\mu_i - (\alpha_i + \varsigma_i)y_i)dt + \sigma_i\sqrt{y_i}dW_i^Q \tag{71.35}$$

where $i = 1, 2$ and $dW_1^Q dW_2^Q = 0$. Under this framework, the two-factor model works the same way as the one-factor models. The difference is that the univariate integrals in the one-factor models are replaced with two-dimensional integrals:

$$\begin{aligned}\underline{\Phi(t)} =& \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} dr(u_1)\cdots\int\int_{-\infty}^{\infty} dr(u_n)\prod\nolimits_{j=1}^{n}\delta\left(u_j, u_j + h\right)\\ & \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} dr(v)\frac{\Phi_1(v)\Delta(v,T)}{q_1} - \frac{\Delta(v,T)}{q_1}W_v^{\mathrm{CIR}(2)}\hat{\varphi}(r(u_1),\cdots,r(v))\end{aligned} \tag{71.36}$$

where

$$\begin{aligned}W_v^{\mathrm{CIR}(2)} =& \left\{\sum\nolimits_{i=1}^{n-1}\left[\sum\nolimits_{j=1}^{b(1)} c_1\Phi\left(v,T,T_{1j}\right)\iint\limits_{\Omega_i}\hat{\varphi}(y_1,y_2)dy_1dy_2\right.\right.\\ & \left.\left. -\sum\nolimits_{j=1}^{b(i)} c_i\Phi\left(v,T,T_{ij}\right)\iint\limits_{\Omega_i}\widehat{\varphi}(y_1,y_2)dy_1dy_2 - K_i^*\iint\limits_{\Sigma_{i=1}^{n-1}\Omega_i}\hat{\varphi}(y_1,y_2)dy_1dy_2\right]\right\}\end{aligned}$$

The bivariate integrals may become quadruple integrals as we move backwards in time. The lattice approach proposed by Longstaff and Schwartz (1992) can be efficiently implemented to calculate the result. Since the lower bound requires only risk-neutral expectations, it can be computed without recursive loops and be extremely fast.

[10] This two-factor model is adopted by a number of authors. See Chen and Scott (1993), Turnbull and Milne (1991), Langetieg (1980), and Hull and White (1990).

Chen-Scott estimates are taken from Exhibit 2, Panel B on page 21 of Chen and Scott (1993) who take Thursday weekly prices of 13-week, 26-week, 5-year, and longest maturity Treasuries. The period of study is from January 1980 to December 1988. The new estimates use Friday weekly T-Bill rates of 3 months and 6 months and CMT rates of 5 years and 30 years. The period of study is from January 1991 to December 1998. The new estimates are estimated with RATS where the number of usable observations in the estimation is 387

71.5 Empirical Study

This section empirically examines the magnitude of each bound using a two-factor CIR model. Evidence is presented for two non-overlapping periods: 1987–1991 and 1992–2000. Both in-sample and out-of-sample tests are performed during each period. Results are similar for both periods, implying the model is robust. Furthermore, for both periods, out-of-sample performance is pleasantly satisfactory.

71.5.1 Term Structure Model Estimation

In estimating the two-factor CIR term structure model, this study uses weekly (Friday) four Treasury interest rate series: the 3-month and 6-month Treasury bills and the 5-year and 30-year Constant Maturity Treasury (CMT) interest rates to estimate the parameters for the two-factor CIR model. Weekly data is obtained from January 4, 1991 to December 29, 1998, comprising 416 observations in total. Data is from the Aremos USFIN databank.

Parameter estimation is important because without good estimates, the two-factor CIR model cannot work properly. Several estimation techniques regarding term structure models have recently been developed. Duan and Simonato (1999) use the state space model with the Kalman filter to estimate exponential-affine term structure models. The estimation procedure is identical to that described in Chen and Scott (1993). Its methodology employs maximum likelihood estimation for a time-series bond price data. Hamilton (1994) provides a detailed introduction for maximum likelihood estimation applied in time-series data. Furthermore, Yeh and Lin (2003) use curve fitting techniques and also used cross-sectional bond price data to estimate the Vasicek (1977) and the CIR models. In addition to our estimates, as a robustness comparison, we also use the results from Chen and Scott (1993) who used a weekly dataset from 1980 to 1988, and Table 71.1 lists the estimates obtained using both estimations. The estimates change little from one period to another, while the new estimates show slightly lower reverting level and slower mean reversion. The first factor remains strong mean reversion while the second remains close to a random walk.

The term structure estimation must also estimate the factor values. Chen and Scott (1993) compute factor values by fitting the long and short rates of the yield curve. For the purpose of this study (correctly pricing the cheapest-to-deliver bond correctly),[11] the factor values are solved for by matching the short rate with the cheapest-to-deliver bond price. In reality, the delivery options are priced based on the cheapest-to-delivery bond and a series of exchange options to the next cheapest, the third cheapest, and so on. Calibrating the term structure model of Chen-Scott to the cheapest-to-delivery bond yields the most accurate valuation of the delivery options using the two-factor CIR model. The two-factor CIR model is generally understood not to closely fit the yield curve.[12] To mitigate the concerns of Jagannathan et al. (2003), this study examines how our term structure best fits the set of deliverable bonds. Unlike Ho et al. (1992), this study is not particularly concerned with the whole yield curve fit because most of the risk of the delivery options resides in the set of deliverable bonds. Furthermore, as a practical concern, we present the fitting performance of the three most relevant bonds – the cheapest, second cheapest, and third cheapest. The probability of other bonds becoming the cheapest is small and the impact of other deliverable bonds is believed to be negligible.

Theoretically, the cheapest bond at any time should be fitted perfectly by tweaking the second factor, since there is one equation and one unknown. However, no solution exists for the second factor at the following dates when trying to fit the cheapest bond: 980903, 980910, 980917, 980924, 981001, 981015, 981029, 981203, 981210, and 981217. Figure 71.1 plots the yield curves for a subperiod (January 2, 1998, to December 28, 2000) from the CMT dataset. The above dates, where the second factor fails to coincide (CTD bond fails to fit) with the period, occur when the yield curve is steeply sloped and the short rates are small. This problem has already been described in Chen and Scott (1993). Chen and Scott recommend a three-factor model to improve the fit. However, because this problem only exists for 10 out of 722 cases (252 observations in the first subperiod, 1987–1991, and 470 observations in the second subperiod, 1992–2000)[13] and because of the complexity of estimating a three-factor model, the two-factor model is retained.[14] Alternatively, the first factor can be left flexible until the CTD bond can be fitted. However, to maintain consistency, the CTD bond is allowed to

[11]T bond futures prices are affected by all bonds underlying the yield curve, and yet doubtlessly the cheapest-to-deliver bond has the most influence.

[12]See, for example, Chen and Scott (1993) and Jagannathan et al. (2003).

[13]All 10 cases are in the second subperiod: 1992–2000.

[14]Chen and Scott (1993) argue that the three-factor model does not necessarily dominate the two-factor model; in that, the three-factor model, although fits better the term structure, generates extra volatility. See Chen and Scott for details.

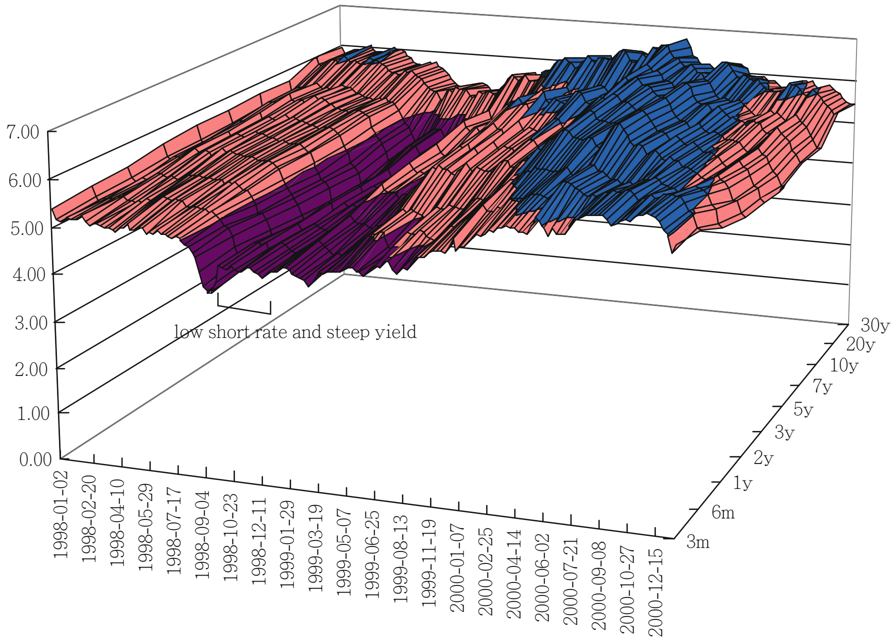

Fig. 71.1 Yield curves for the selected period

imperfectly fit those 10 dates.[15] The ill-fitted CTD bonds for those 10 dates thus hurt the tightness of the bounds. The following summary illustrates the cheapest bond that fails to be fitted and the difference between the market and the model prices.

Date	Coupon	Maturity	Market price	Model price	% diff
980903	11.250	150215	164.6250	159.2477	3.38
980910	11.250	150215	167.9063	158.6218	5.85
980917	11.250	150215	167.2500	163.3068	2.41
980924	11.250	150215	168.3438	163.2337	3.13
981001	11.250	150215	171.7188	163.7861	4.84
981015	11.250	150215	169.3438	165.2365	2.49
981029	11.250	150215	168.2813	164.6084	2.23
981203	11.250	150215	168.7813	162.1672	4.08
981210	11.250	150215	169.3438	161.4943	4.86
981217	11.250	150215	167.9688	161.1123	4.26

Notably, other than these ten dates, the CTD bond fits perfectly. To mitigate the criticism of Jagannathan et al. (2003), the fitting performance of the second cheapest and the third cheapest must also be examined. Figure 71.2 presents the

[15]The result of the alternative fitting is available upon request.

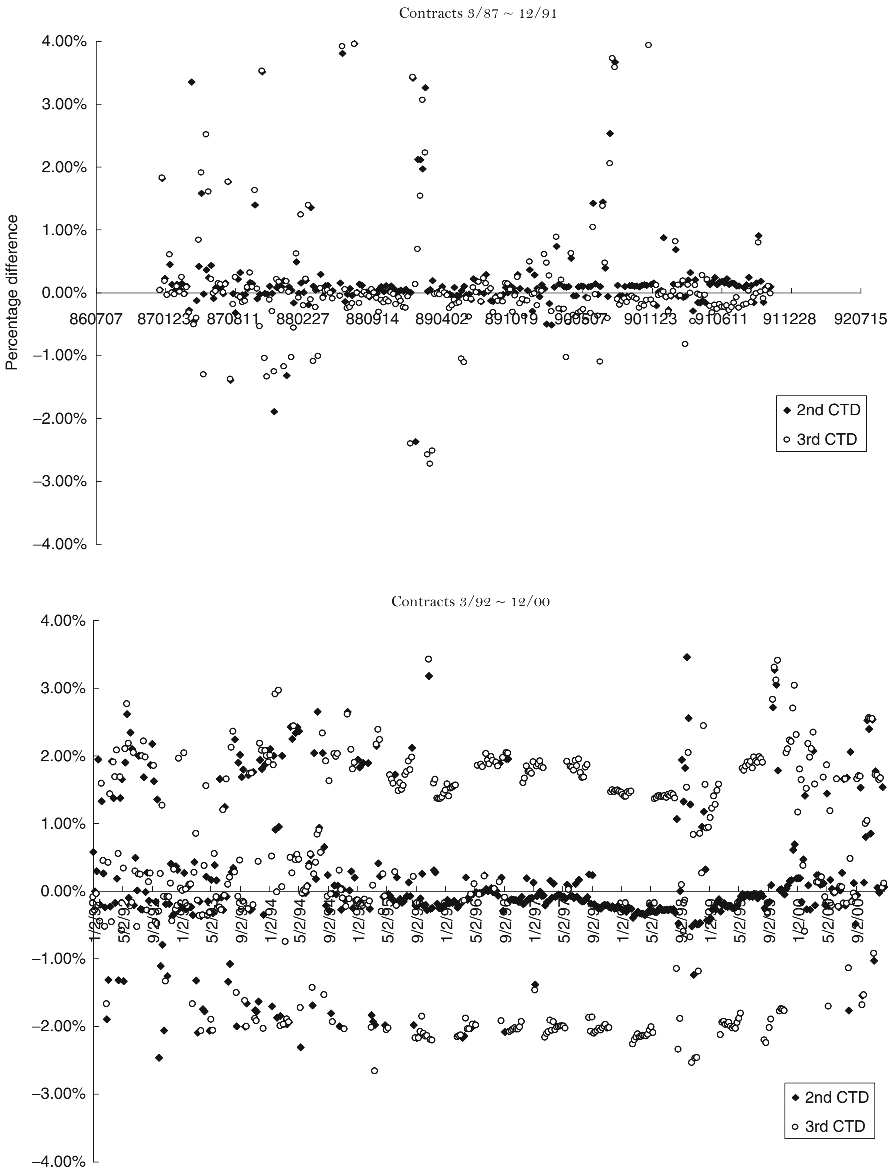

Fig. 71.2 Fitting performance of the second and third cheapest-to-deliver bonds
Note: The pricing error is measured as percentage error of the market price: model price ÷ market price – 1. The average percentage errors are 30 basis points and 14 basis points for the 2nd CTD and 3rd CTD, respectively. The root mean square errors are 1.07 % and 1.20 %, respectively
Note: The pricing error is measured as percentage error of the market price: model price ÷ market price – 1. The average percentage errors are 10 basis points and 26 basis points for the 2nd CTD and 3rd CTD, respectively. The root mean square errors are 1.04 % and 1.61 %, respectively

fitting performance of the two-factor model (with the 3-month short rate and the CTD bond perfectly fitted). The percentage fitting error (theoretical price ÷ market price – 1) is plotted. The second CTD bonds are fitted very well. The average percentage error (APE) is 30 basis points in the first period (1987–1991) and 10 basis points in the second subperiod (1992–2000). The root mean square errors (RMSE) for both periods are 1.07 % and 1.04 %, respectively. The numbers may seem to suggest that the second sample period provides better fit, but eyeballing the graphs reveals good fit during most of the first sample period; the second CTD is well fitted and only half of the time in the second period is well fitted.

The fitting performance of the third CTD bonds displays a very different profile. The third CTD bonds presents equal fit to the second CTD bonds during the first sample period (1987–1991), but the former have worse fit than the later during the second subperiod (1992–2000). As opposed to 30 basis points APE and 1.07 % RMSE for the second CTD bond, the APE and the RMSE for the third CTD bond are 14 basis points and 1.2 % in 1987–1991. However, during 1992–2000, the APE and RMSE increase from 10 basis points and 1.04 %, respectively, for the second CTD bond to 26 basis points and 1.61 %, respectively, for the third CTD bond. The worse fit of the third CTD bond and the 10 cases of unsuccessful fit of the CTD during the second subperiod might explain the slightly worse bound performance (show later) during the second period.

71.5.2 Futures Data

Daily futures prices are obtained from the Chicago Board of Trade (CBOT) between January 1987 and December 2000. Table 71.2 lists the summarized statistics. Notably, the decline in the futures price for March 2000 contract results from the change of the discount rate in the conversion factor (from 8 % to 6 %). However, this study collects the futures prices weekly (Thursday) for two different (non-overlapping) periods. One period is from January 8, 1987 through October 31, 1991 (252 observations) and the other runs from November 7, 1991 through November 2, 2000 (470 observations). The first period, which covers the quarterly contracts during March 1987 through December 1991, uses the Chen-Scott estimates, and the second period, which covers contracts during March 1992 through December 2000, uses the new estimates. Weekly futures prices with maturity ranging from 6 weeks to 4½ months are selected from the CBOT daily price dataset.

The cost of carry model requires the knowledge of all deliverable bonds at the trade date. All deliverable bonds are collected from the Wall Street Journal for all the trade dates and the average of the bid and ask is taken as the bond price. This study also uses the 3-month T bill rates for the cost of carry model. There are about 26 deliverable bonds for any given trade date. Conversion factors are computed using the CBOT formula.[16]

[16]Hull (2009) has an excellent demonstration of such a computation.

Table 71.2 Summary statistics of daily futures prices

Contract month	N	Mean	Std. dev	Min	Max

Daily futures prices are taken with maturity between 6 weeks and 4½ months for each contract. Such a selection enjoys high liquidity and rare overlapping between contracts

71.6 Results

This study assumes no gap between the close of the bond market for any given day and the open of the futures market in the next morning. As a result, correctly dating all the timing periods in the lattice requires counting the number of trading days. As has been pointed out previously, each month contains about 22 trading days. The last 7 days attribute to the end-of-month period. For each of the remaining 15 days, there are about 6 h for the day period where both bond and futures markets are open and another about 6 h for the night period where only the bond market is open. To accurately calculate various timing option values, the time to maturity in this study is not measured using calendar days but business days.[17] Accurate day counting is necessary because we need to calculate expectations at various times.

First, all deliverable bonds are ranked by their conversion factors. The bond with the largest conversion factor is then chosen as the primary bond for delivery and its futures price is calculated using the two-factor version of the Cox-Ingersoll-Ross model (1981). Various timing options provide the short additional flexibility of choosing the best timing.

Calculating the upper bound value for the end-of-month option for any given time prior to v requires calculating Eq. 71.36 and then using Eq. 71.14. As noted earlier, the wildcard value can be ignored if the lower bound of the futures price at the beginning time of the end-of-month period, v, is already sufficiently low. That is, if the lower bound for the end-of-month option is employed to substitute for $\Phi(v)$, the

[17] That is, we do the business day count between trade day and the last day of the delivery month and assume 252 trading days for a given year.

loss of the wildcard value is translated into the end-of-month option. Restated, the wildcard value can be efficiently incorporated into the lower bound for the end-of-month option. If the wildcard value is completely eliminated by this substitution, then the lower bound for the end-of-month option becomes a lower bound for both the end-of-month and wildcard options. As we shall see, this is indeed the case for the periods examined. Finally, the cost of carry model of Eq. 71.24 is computed and compared with the actual futures price.

The empirical examination of the upper and lower bounds is presented in two periods where the term structure model is estimated separately. The first period contains the futures contracts from March 1987 to December 1991. The empirical results during this period use the parameter estimates of Chen and Scott (1993), which use data from January 1980 to December 1988 to estimate the term structure. Hence, contracts from March 1987 to December 1988 are considered in-sample and contracts from March 1989 to December 1991 are considered out of sample. The second period contains the futures contracts from March 1992 to December 2000. The parameters are reestimated using the Treasury data from January 1991 through December 1998 to estimate the term structure, and in-sample and out-of-sample tests are also performed. The parameters are reestimated because significantly lower interest rates are observed during the later period.

The first part of Table 71.3 lists results in averages for the 20 contracts (8703–9112) studied in this investigation. The first three columns of Table 71.3 present actual futures prices, lower bound futures prices using Eq. 71.36 which considers only the end-of-month option and upper bound futures prices using which is the cost of carry model. The average for the whole period is listed at the bottom of the table. The estimates obtained using the cost of carry model are on average 2 % higher than the actual futures price, while the lower bound is 2 % lower than the actual futures price. Weekly prices of these three series are plotted in Fig. 71.3.

The end-of-month option bound values are listed in column 4. This value includes both the quality option and the timing option values. Separating these two values is difficult because no consistent method exists for measuring the quality option. Figure 71.3 shows that the lower bound for the futures price provided by this upper bound is sufficiently conservative to include all daily wildcard values. Furthermore, the bound is as tight as the cost of carry model, approximately 2 % on average lower than the actual futures price.

This study also estimates the two-factor Cox-Ingersoll-Ross term structure model for a more recent dataset (weekly, from January 4, 1991 through December 29, 1998). The in-sample test is for the contracts from March 1991 to December 1998 and the out-of-sample test is for the contracts from March 1999 to December 2000. Somewhat different and yet very interesting results can be observed. Similar to the first half of Table 71.3, the second half of the table presents the results from the second period in a parallel fashion. First, the model-free upper bound, the cost of carry model, performs as well as in the first period, remaining roughly 2 % above the actual price, a very robust result.

The most surprising result involves the lower bound. Using the same term structure model, the lower bound, on average, remains within about 2 % below

(1) Is actual futures price
(2) Is lower bound (Eq. 71.36)
(3) Is cost of carry price, also upper bound (Eq. 71.24)
(4) Is average of (1)−(2), a measure of bound tightness
The theoretical values are computed using the Chen-Scott estimates (left panel of Table 71.1)
The theoretical values are computed using the new estimates (right panel of Table 71.1)

the actual futures price. Notably, the term structure estimation fitting performance result during the first period (March 1987 to December 1991) is different from that during the second period (March 1992 to December 2000). The term structure model performs poorly during the second period but it performs well during the first period. However, the lower bound still performs well during both periods. This is due to the fact that the lower bound, on the other hand, is only "semi-model-dependent" in that its theory is model-free and only the implementation requires a term structure model. Hence, in theory, the lower bound is a "looser" bound and thus unsurprisingly can perform well no matter what the term structure model fits. Furthermore, from Table 71.3 (second part), throughout all contracts, the lower bound constantly falls below the actual futures price. The weekly lower bound performance can be seen in the second part of Fig. 71.3. This observation raises an interesting issue, namely, that using an ill-fitted term structure model to estimate contract value, the performance of the estimate relies extremely on the performance of the underlying model. However, when estimating a range of values for the contract, the accuracy of the underlying model becomes less sensitive. In reality, no trader is seeking "the price," since model assumptions are always inconsistent with reality. However, robust models (models that are robust to parameter changes) are useful in that they provide useful implications traders can use to gain insights. What we have learned from this empirical test precisely demonstrates this point.

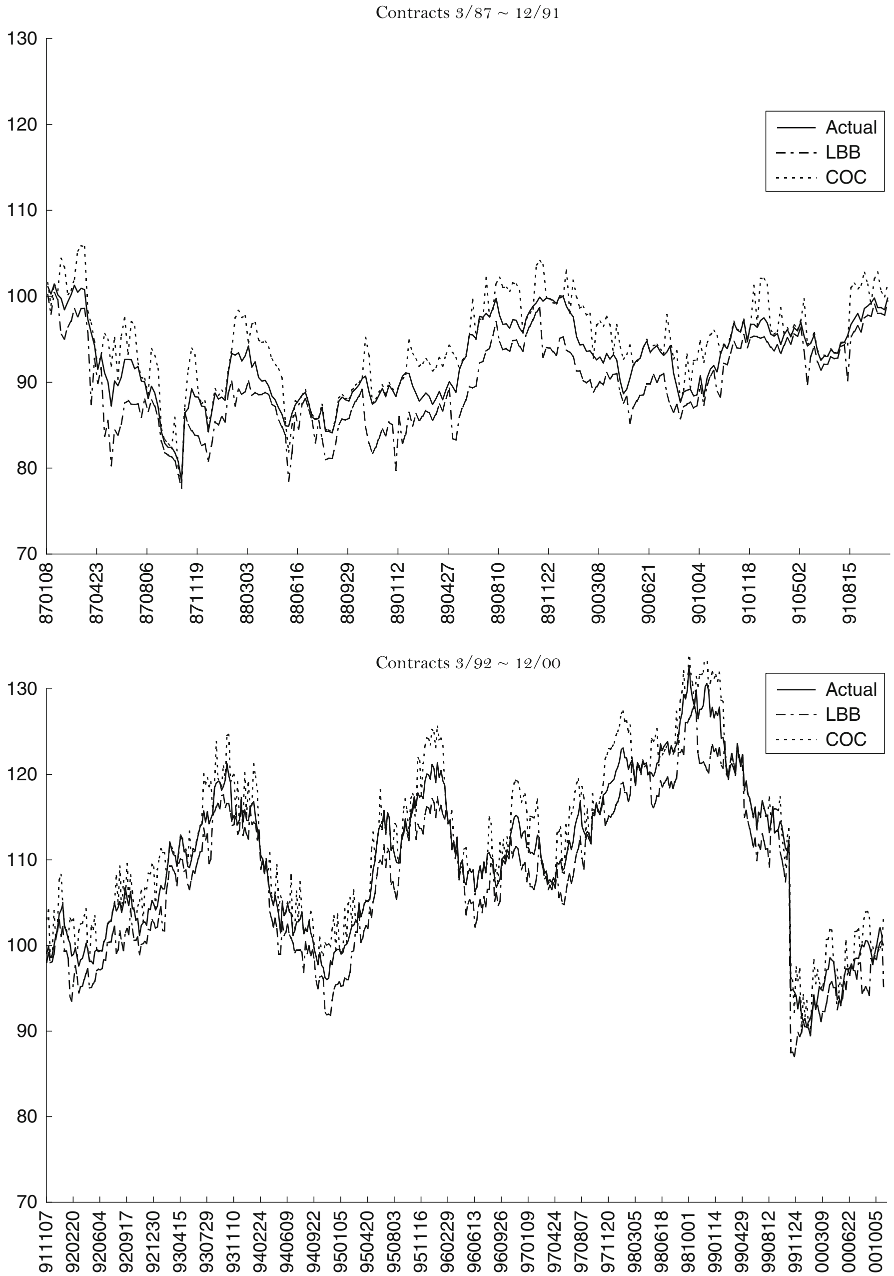

Fig. 71.3 Weekly time-series plot of actual futures prices (actual), their upper (COC) and lower (LBB) bounds

71.7 Discussions

The importance of the bounds becomes clear if one realizes that it is nearly impossible to compute the delivery options accurately. However, it is almost equally important to recognize that violating such bounds implies arbitrage opportunities. This is particularly interesting for the upper bound because the upper bound of the futures price – the cost of carry – is model-free. The calculation results show that the futures price exceeded its upper bound in 164 out of 722 (or 22.71 %) weeks. The magnitude of violation is on average 28.6 basis points (annualized) or half a basis point a week in the event that violation occurs. At such times, investors can sell futures and buy the CTD bond and then dynamically switch to the new CTD bond if necessary. Such a strategy, as suggested by the forward measure, should yield an arbitrage profit of half a basis point each time. This profit must exceed the transaction costs to be profitable.

The violation of the lower bound only generates arbitrage profits when the adopted model is true. The calculation results show that the lower bound is violated in 32 out of 722 cases (or 4.4 %). Notably, the fewer violations of the lower bound than upper bounds result mainly from the more conservative estimate of the lower bound (i.e., we compound upper bound values of the embedded delivery options). The results suggest that a more efficient lower bound remains to be discovered. Future research can examine this question.

From Fig. 71.3, we note that there are periods where bounds are tight and others where bounds are loose. To examine any potential systematic biases, this study runs regressions of the "tightness" of the bound against a number of possible factors that affect the futures price. For consistency, this study runs the following regressions[18] for the period of January 2, 1992, to November 2, 2000, containing 462 weekly observations:

$$\begin{aligned}
\Phi_t - \underline{\Phi}_t &= a_0 + a_1(\mathrm{CTD}_t - \mathrm{SCTD}_t) + a_2(3\mathrm{MTB}_t - 3\mathrm{MTB}_{t-1}) \\
&\quad + a_3(30\mathrm{YTB}_t - 30\mathrm{YTB}_{t-1}) + a_4(\mathrm{CF}_t) + e_t \\
\overline{\Phi}_t - \Phi_t &= b_0 + b_1(\mathrm{CTD}_t - \mathrm{SCTD}_t) + b_2(3\mathrm{MTB}_t - 3\mathrm{MTB}_{t-1}) \\
&\quad + b_3(30\mathrm{YTB}_t - 30\mathrm{YTB}_{t-1}) + b_4(\mathrm{CF}_t) + u_t
\end{aligned}$$

where
Φ = market futures price
$\overline{\Phi}$ = upper bound (COC)
$\underline{\Phi}$ = lower bound
CTD = cheapest to deliver bond
SCTD = second cheapest to deliver bond
3MTB = 3-month T bill rate
30YTB = 30-year T bond rate
CF = conversion factor of the cheapest bond

[18] Lee et al. (2000) provide excellent introductions about how to conduct multiple regressions.

Table 71.4 Regression results

	Lower bound			Upper bound		
	Coefficient	Std. err.	t	Coefficient	Std. err.	t

Adjusted R^2	2.28 %			1.87 %		
# of obs.	462			462		

Regression period is from January 2, 1992 till November 2, 2000, total of 462 weekly observations. Regression equations are

$$\Phi_t - \underline{\Phi}_t = a_0 + a_1(\mathrm{CTD}_t - \mathrm{SCTD}_t) + a_2(3\mathrm{MTB}_t - 3\mathrm{MTB}_{t-1}) + a_3(30\mathrm{YTB}_t - 30\mathrm{YTB}_{t-1}) + a_4(\mathrm{CF}_t) + e_t$$

$$\overline{\Phi}_t - \Phi_t = b_0 + b_1(\mathrm{CTD}_t - \mathrm{SCTD}_t) + b_2(3\mathrm{MTB}_t - 3\mathrm{MTB}_{t-1}) + b_3(30\mathrm{YTB}_t - 30\mathrm{YTB}_{t-1}) + b_4(\mathrm{CF}_t) + u_t$$

where
Φ = market futures price
$\overline{\Phi}$ = upper bound (COC)
$\underline{\Phi}$ = lower bound
CTD = cheapest to deliver bond
SCTD = second cheapest to deliver bond
3MTB = 3-month T bill rate
30YTB = 30-year T bond rate
CF = conversion factor of the cheapest bond

and the results are reported in Table 71.4. Interestingly, the lower bound performance is more sensitive to the fitting of the second cheapest bond and the upper bound performance is more sensitive to the long rate. This result is unsurprising because the lower bound is a model-driven result while the upper bound is model-free and hence relies on the long rate.

Finally, this study argues that the timing options are more valuable during the first period than the second period. Notably, the timing options are negatively related to the interest rates. Lower interest rates during the second period reduce the value of the timing options.

71.8 Conclusion

This study derives lower and upper bound formulas for the Treasury bond futures prices. The lower bound of the futures price is obtained by integrating all upper bounds for the delivery options. The cost of carry model is found to be an upper bound of the futures price. These bounds are model free and can be used with any choice of the term structure model. Analytical results are obtained when using a two-factor Cox-Ingersoll-Ross model. The results provide investors with an efficient range of how far futures prices can move. During the two sample periods of 1987–1991 and 1992–2000, the cost of carry model is found to be about 2 % above the actual futures price and the lower bound is found to be about 2 % below.

As opposed to recursively using the lattice model to iteratively obtain an accurate estimate of the futures price, which is prohibitively expensive, as Boyle (1989) demonstrates, the bounds provided in this paper can be computed quickly and accurately. Thus, these bounds can then provide traders with a useful guide to the true futures price.

Appendix

From Theorem 1, we have:

$$\begin{aligned} E_t^Q[\delta(t,T)X(T)] &= E_t^Q[\delta(t,T)]E_t^{F(T)}[X(T)] \\ &= P(t,T)E_t^{F(T)}[X(T)] \end{aligned} \tag{71.37}$$

where δ is strictly less than 1. Due to the risk-neutral pricing result we have, the LHS must equal $X(t)$, and hence:

$$X(t) = \frac{E_t^{F(T)}[X(T)]}{P(t,T)} \tag{71.38}$$

Note that the forward measure is maturity dependent. Clearly, the Radon-Nikodym derivative (RND) is

$$\eta(t,T) = \frac{\delta(t,T)}{P(t,T)} \tag{71.39}$$

Since the measure is T-dependent, so should be the RND (usually, RND is just $\eta(t)$). Let the interest rate process be

$$dr(t) = \hat{\mu}(r,t)dt + \sigma(r,t)dW^Q(t) \tag{71.40}$$

Applying Ito's lemma,

$$
\begin{aligned}
0 &= \ln\ P(T,T) = \ln P(t,T) + \int_t^T \frac{1}{P(u,T)}\Bigg[P_u(u,T)du + P_r(u,T)dr \\
&\quad + \frac{1}{2}P_{rr}(u,T)(dr)^2\Bigg].d\hat{W}(u) - \int_t^T \frac{1}{2}\left[\frac{\sigma(r,u)P_r(u,T)}{P(u,T)}\right]^2 du \\
&= \ln\ P(t,T) + \int_t^T \frac{1}{P(u,T)}\left[P_u(u,T)du + P_r(u,T)\hat{\mu}(r,u) + \frac{1}{2}P_{rr}(u,T)\sigma(r,u)^2\right]du \\
&\quad + \int_t^T \frac{1}{P(u,T)}P_r(u,T)\sigma(r,u)d\hat{W}(u) - \int_t^T \frac{1}{2}\left[\frac{\sigma(r,u)P_r(u,T)}{P(u,T)}\right]^2 du \\
&= \ln\ P(t,T) + \int_t^T r(u)du + \int_t^T \frac{1}{P(u,T)}P_r(u,T)\sigma(r,u)d\hat{W}(u) - \int_t^T \frac{1}{2}\left[\frac{\sigma(r,u)P_r(u,T)}{P(u,T)}\right]^2 du
\end{aligned}
\tag{71.41}
$$

Letting:

$$
\theta(t,T) = -\frac{\sigma(r,t)P_r(t,T)}{P(t,T)} \tag{71.42}
$$

and moving the first two terms to the left:

$$
\begin{aligned}
-\int_t^T r(u)du - \ln\ P(t,T) &= \int_t^T -\theta(u,T)d\hat{W}(u)\ - \int_t^T \frac{1}{2}\theta(u,T)^2 du \\
\frac{\delta(t,T)}{P(t,T)} = \eta(t,T) &= \exp\left(\int_t^T -\theta(u,T)d\hat{W}(u) - \int_t^T \frac{1}{2}\theta(u,T)^2 du\right)
\end{aligned}
\tag{71.43}
$$

This implies the Girsanov transformation of the following:

$$
W^{F(T)}(t) = W^Q(t) + \int_t^T \theta(u)dt\ = W^Q(t) - \int_t^T \sigma(r,u)\frac{P_r(u,T)}{P(u,T)}du \tag{71.44}
$$

The interest rate process under the forward measure henceforth becomes:

$$
dr(t) = \left[\hat{\mu}(r,t) + \sigma(r,t)^2\frac{P_r(t,T)}{P(t,T)}\right]dt + \sigma(r,t)dW^{F(T)}(t) \tag{71.45}
$$

Note that the forward measure is quite general. It does not depend on any specific assumption on the interest rate process.

preeminent method to estimate the probability that an issuer survives in its current rating grade at any point in time t over the time horizon T. In this study, estimation is based on two Cox's hazard models, including a proportional hazard model (Cox, Journal of Royal Statistical Society Series B (Methodological) 34:187–220, 1972) and a dynamic hazard model. The first model employs a static estimation approach and time-independent covariates, whereas the second uses a dynamic estimation approach and time-dependent covariates. To allow for any dependence among rating states of the same issuer, the marginal event-specific method (Wei et al., Journal of The American Statistical Association 84:1065–1073, 1989) was used to obtain robust variance estimates. For validation purpose, the Brier score (Brier, Monthly Weather Review 78(1):1–3, 1950) and its covariance decomposition (Yates, Organizational Behaviour and Human Performance 30:132–156, 1982) were applied to assess the forecast performance of estimated models in forming time-varying survival probability estimates for issuers out of sample.

It was found that FAs and their peers exhibit strong but markedly different dependences on rating history, industry sectors, and macroeconomic conditions. These factors jointly, and in several cases separately, are more important than the current rating in determining future rating changes. A key finding is that past rating behaviors persist even after controlling for the industry sector and the evolution of the macroeconomic environment over the time for which the current rating persists. Switching from a static to a dynamic estimation framework markedly improves the forecast performance of the upgrade model for FAs. The results suggest that rating history provides important diagnostic information and different rating paths require different dynamic migration models.

72.1 Introduction

Market participants are interested in the rating migration propensity of fallen angels (FAs) which were initially rated as investment grades but experienced deterioration in credit quality and fell to speculative grades. Such dramatic downgrades are consistently associated with a statistically significant negative return in the stock market (Holthausen and Leftwich 1986; Ederington and Goh 1999) and in the bond market (Hite and Warga 1997). Furthermore, bad news associated with a rating downgrade is transferred from the downgraded company to its rivals. The rivals of downgraded firms with speculative grade-rated debts experience significant downward revisions of earnings forecasts (Caton and Goh 2003).

Institutional investors such as investment grade bond funds, due to restricted risk levels, may not be able, or may be limited, to hold a small percentage of speculative grade-rated bonds (Altman and Kao 1992b, p. 73; Cantor and Packer 1997). They may be forced to sell bonds that drop into the speculative grade ratings (fallen angels) and may buy back bonds that regain the investment grade status (rising stars). Accurately estimating the migration probabilities of FAs is important in the context of portfolio construction and credit risk management. Tsaig et al. (2011) showed that credit migration can explain as much as 51 % of volatility and 35 % of economic risk capital for a typical loan portfolio.

In practice, the discrete time cohort Markov approach has been widely used by credit rating agencies to model rating migration processes. This approach assumes that the departure probability out of the current rating depends entirely on the current rating (Markov process) and remains constant over time (time-homogeneous). The time-homogeneous Markov property, however, is not strongly supported by empirical studies. Frydman and Schuermann (2008) found that obligors of the same rating grade migrate at different rates and the heterogeneity persists after controlling for the state of the business cycle or the industry sector. The sources of issuer-heterogeneity in the rating process can be attributed to several aspects of rating history such as the direction of the prior rating change,[1] the duration of the previous rating states,[2] the first rating received,[3] and the period of time since first rated.[4] Failing to consider issuer-heterogeneity can result in inaccurate estimates of value at risk and a misleading picture of the economic risk capital (Kadam and Lenk 2008).

An interesting question then arises: Does one migration model fit all, or do different rating histories require different models? Specifically, do FAs exhibit the same issuer dependence and time dependence as their speculative grade-rated peers? Literature confirms some established perceptions about FAs and supports the notion that FAs exhibit different rating dynamics compared to their peers.[5]

This study adopts the survival analysis framework (Allison 1984) to examine a wide variety of issuer-heterogeneity and time-heterogeneity in the rating dynamics of US nonfinancial FAs and their speculative grade-rated peers. I estimate rating migration models of FAs, after their fall dates. Comparator speculative grade-rated issuers that experienced a downgrade but not a FA event at lag-one rating state (FA peers) are identified, and rating migration models are estimated for these peers. FAs that are further downgraded are compared to speculative grade-rated peers experiencing a downgrade, and FAs that regain investment grade status are compared to their peers experiencing an upgrade.

Cox's hazard model (Cox 1972) is considered a preeminent method to estimate the probability that an issuer survives in its current rating grade (*start rating*) at any

point in time t over the time horizon T. In this study, estimation is based on two hazard models including a Cox's proportional hazard model (Cox 1972) and a Cox's dynamic hazard model. The Cox's proportional hazard model (static model) employs a static estimation framework and incorporates time-independent covariates. The Cox's dynamic hazard model (dynamic model) departs from the conventional Cox's proportional hazard model by adopting a dynamic estimation framework and including both time-independent and time-varying covariates. The dynamic model captures the evolution of the macroeconomic environment over the time during which the current rating persists. Time-varying survival probability estimates were generated by the static and the dynamic hazard models for FAs and FA peers out of sample. The Brier score (Brier 1950) was used to assess the predictive accuracy of survival probability estimates. The covariance decomposition of the Brier score (Yates 1982) provides insights into the sources of forecast errors.

The results of the proportional and dynamic hazard models for upgrades and downgrades of FAs and their peers offer an improved understanding of the following questions: First, how can rating history, after controlling for the industry sector and the economic environment, explain and predict subsequent rating changes for FAs and their peers? Second, does the development of economic factors over rating durations matter, and if so, how does it affect the migration hazards of FAs and FA peers? Third, does the impact of rating history on the migration process persist in a dynamic estimation framework? Fourth, does the dynamic estimation framework improve the forecast performance of rating history?

Comparing the proportional and the dynamic hazard models for FA issuers with the respective models for FA peers, the results show that the significant variables differ. In a dynamic estimation framework, the downgrade process of FAs exhibits strong dependence on macroeconomic factors, whereas the upgrade process is entirely determined by the current rating and rating history. For FA peers, downgrades are substantially influenced by past rating behaviors, whereas upgrades are strongly impacted by the industry sector. It is clear that issuer-heterogeneity (rating history, industry sectors) and time-heterogeneity (macroeconomic environment) jointly, and in several cases separately, are more important than the current rating in determining future rating changes. A key finding is that past rating behaviors persist even after controlling for the industry sector and the evolution of the macroeconomic climate over rating durations. Switching from a static to a dynamic estimation framework markedly improves the forecast performance of the upgrade hazard model for FAs.

The contribution of this study is threefold. First, it enriches and strengthens the evidence of issuer-heterogeneity and time-heterogeneity in the rating dynamics of FAs and their peers observed in both static and dynamic estimation frameworks. The study incorporates well-documented empirical properties and presents new evidence on additional aspects of rating history which has received little attention in previous studies. Second, the study contributes to the framework for estimating rating migration models. Cox's hazard model with time-varying covariates is well suited to model recurrent rating migration events. The study overcomes computational challenges in forming dynamic survival estimates when the standard proportionality assumption of the Cox's hazard model does not hold. The dynamic predictions allow the survival probability estimates of holdout issuers to vary over the forecast horizons. Finally, the study enriches the literature on the framework for evaluating probability forecasts. The Brier score has received little attention in finance studies[6] though it is a popular measure for ex post evaluation of probability forecasts in meteorology (Murphy and Winkler 1977; Winkler 1996). The covariance decomposition (Yates 1982) of the Brier score offers the possibility to evaluate forecast characteristics in terms of discrimination, calibration, and variance.

This study is structured as follows: Sect. 72.2 provides a discussion of the literature on rating migration dynamics. Section 72.3 presents the method used, followed by a description of the data in Sect. 72.4. Section 72.5 summarizes the results of the models for FAs and their peers. Section 72.6 presents the Brier scores and Yates's covariance decompositions. Section 72.7 summarizes the main findings.

72.2 Literature Review

This section provides a summary of the literature on corporate rating dynamics of FAs and their speculative graded-rated peers, with a focus on issuer-heterogeneity (rating history, industry sector) and time-heterogeneity (business cycle).

The literature suggests that various aspects of rating history such as rating momentum, duration dependence, aging effect, and the first rating impact on future rating distribution. Issuers downgraded to a given rating, compared with those upgraded to the same rating grade, are more likely to drop to lower rating categories (Altman and Kao 1992b; Carty and Fons 1994; Bangia et al. 2002; Lando and Skodeberg 2002; Hamilton and Cantor 2004; Mah and Verde 2004; Figlewski et al. 2012). Issuers of different lagged rating durations have different departure probabilities out of the current rating (Carty and Fons 1994; Lando and Skodeberg 2002). Newly rated firms, compared with seasoned firms of the same rating class, exhibit a smaller probability of rating migrations within a few years (Altman and Kao 1991; Altman 1992, 1998). The longer since a firm was first rated, the more likely it will default (Figlewski et al. 2012). Furthermore, new issues of different ratings retain their original ratings in a different manner and their rating stability varies over time. For example, originally BB-rated bonds, which were in the speculative grade barrier, exhibit the least stability in retaining the initial rating and do not show a clear propensity to migrate in either direction (Altman and Kao 1991, pp. 19–20, 1992b, pp. 65–67).

[6]Samuelson and Rosenthal (1986), Bessler and Ruffley (2004), Yao et al. (2005), Grunert et al. (2005), and Dang (2010) are among the few studies in finance that applied this scoring rule to assess the predictive accuracy of estimated models. Johnstone (2002) suggested that the Brier score performs better than categorical measures in accurately assessing forecast performance.

For a FA, the rating it received on the fall date strongly impacts on its future rating changes (Mann et al. 2003). FAs which plunge to the speculative grade barrier (Moody's Ba or Standard & Poor's BB class) exhibit a greater propensity to rise to the investment grade territory and are less vulnerable to default. The higher the rating a FA received prior to and after the fall date, the more likely it will become a "prodigal son" and regain investment grade status. FAs, during the initial years of financial distress, experience strong downward momentum (Mann et al. 2003) and tend to travel multiple notches downward in a drastic and quick succession rather than through gradual, mild steps (Johnson 2004). This pattern is understandable as once FAs lose their investment grade status, their operations are impaired due to regulations or private contracts (Cantor and Packer 1997; Standard & Poor's 2001).

Industry risk is an important determinant of rating distribution. In general, ratings from the utility sector are more stable than those from the industrial sector due to a smaller volatility of future revenues (Kadam and Lenk 2008). For FAs, utilities are more likely to be upgraded for every horizon, whereas nonutilities do not exhibit exceptional performance or a favorable tendency towards upgrades (Altman and Kao 1992a, p. 19). The magnitude of subsequent rating changes for nonutility FAs is dramatic. Public utility FAs exhibit strong negative serial correlation and are more likely to rise up the rating scales after the fall date. In contrast, nonutility FAs display a positive serial correlation and tend to continue the downward journey after losing the investment grade status (Altman and Kao 1992a). FAs in high-velocity sectors such as telecommunications exhibit rapid deterioration in their credit profile. Distressed FAs tend to be weeded out during shakeouts while surviving FAs cling to life and show strong recovery within 5 years from their fall date. In contrast, FAs in low-velocity sectors such as leisure and media experience slow decline in creditworthiness, but they do not make a strong rebound in the subsequent years (Vazza et al. 2005a, p. 17).

In terms of time-heterogeneity, speculative grade-rated issuers exhibit different migration patterns as time extends (Carty and Fons 1994). Issuers of low credit ratings such as B and Caa are vulnerable to a downgrade in the short term and have a migration probability that decreases with time. If they survive but fail to substantially improve their credit quality, they tend to retain their existing ratings over a long time. Issuers in the middle rating grades such as Ba can either go up or go down the rating scale and have a migration probability that varies constantly with time.

FAs, following the fall date, exhibit a faster rate of migration, a greater likelihood to default, and a shorter median time to default compared with their peers[7] (Mann et al. 2003; Vazza et al. 2005a). However, as time passes FAs gained a robust franchise value, enhanced business strength, and improved profitability (Vazza et al. 2005a).

[7]Vazza et al. (2005a) defined FA peers as those originally rated in speculative grades and have identical rating distribution characteristics as FAs. Mann et al. (2003) defined FA peers as speculative grade-rated issuers that were of the same ratings as FAs at the time they lost investment grade status and never rated in the investment grade spectrum.

In the long term, FAs are less risky, display a greater tendency to survive, and are more likely to rise back to the investment grade territory. Non-defaulted FAs appear to cling to life for many more years than their peers.

The time-heterogeneity in the rating migration dynamics of FAs and their peers can partly be attributed to macroeconomic conditions. The state of the economy is a major driver of systematic credit risk (Blume et al. 1991), and low ratings are more sensitive to business cycles than high ratings. The occurrence of downgrades and the generation of FAs soar as market conditions deteriorate (Nickell et al. 2000; Vazza et al. 2005a). Furthermore, rating volatility increases during business cycle troughs and decreases during peaks. Thus, failure to account for the state of the economy may result in an underestimation of "downward potential of high-yield portfolio" in contraction periods or "suboptimal capital allocation in lending business" (Bangia et al. 2002, p. 469).

The above evidences emphasize the need to account for rating history, industry sector, and the business cycle in modelling the rating migrations of FAs and their peers.

72.3 Models

72.3.1 Rating States

The substantive processes that govern the occurrence and timing of downgrade and upgrade events to FAs/FA peers were examined using the survival analysis framework (Allison 1984; Blossfeld et al. 1989; Yamaguchi 1991; Hosmer et al. 2008; Dang 2010; Figlewski et al. 2012). A rating state starts from the time an issuer is downgraded to a rating class (*start rating*) subsequent to the commencement date of the study. For a FA, the *start rating* is also the rating it receives on the fall date upon its entrance to speculative grade territory. The rating state ends at the time the issuer migrates to another rating class (*end rating*), withdraws from being rated, or the observation period terminates. The time a firm keeps the same rating grade is the survival time (survival duration). If a firm exits from a rating class due to any reason other than the migration event of interest, the survival time is treated as censored. In the upgrade model, down states (rating states with the *start rating* better than the *end rating*) are censored and vice versa for the downgrade model. Rating states finishing after the end of the model estimation period are also treated as censored. Survival analysis addresses this type of censoring by examining only that part of the duration in the estimation period (Yamaguchi 1991; Blossfeld and Rohwer 1995).

Rating states are pooled across issuers and time. Rating states that pass the screening test of having experienced at least two migrations (i.e., non-censored lag-one and lag-two rating states[8]) will remain in the sample and be incorporated in

[8]To get enough observations to make meaningful inference of the effect of rating history, the study considers lag-one and lag-two rating states. By definition, all FAs and FA peers in the study experienced a downgrade at lag-one rating state.

the estimation process. The estimation procedure makes use of event time risk sets, which are composed of all the firm ratings that are at risk of a rating change at event time t. In the process of estimating the model, a new risk set is formed at each event time t when a rating transition occurs. Firm ratings leave the risk set once they experience a rating transition or when they are censored.

An issuer may contribute several rating transitions to the dataset. The presence of repeated rating transitions for the same firm is likely to introduce dependence among the observations. This problem is reduced to the extent that covariates in the models control for dependence. To allow for any dependence, the marginal event-specific method (Wei et al. 1989) is used to obtain robust variance estimates. Under this approach, rating states contribute to an event time risk set as long as they are under observation at the event time t the risk set is formed. The event time risk set arrangement "resets the clock" after a migration event occurs and time is measured from the last downgrade event. The emphasis is on the duration between the last downgrade event and the subsequent migration event and "each migration event is analyzed as a separate process" (Hosmer et al. 2008, pp. 290–294).

72.3.2 Cox's Hazard Models

Cox's proportional and dynamic hazard models were developed for two generic migration outcomes (upgrade and downgrade) and were estimated separately for FAs and FA peers over the period 1984–2000. Survival analysis in general and Cox's hazard model in particular offer several advantages over the discrete time cohort Markov approach widely used by credit rating agencies. The hazard model uses both completed transitions and censored observations in the estimation process (Yamaguchi 1991), resulting in consistent parameter estimates (Allison 1995). It does not make any assumptions about the distribution of survival times (Allison 1995) and provides descriptive information of the survivor function of event times (Lee 1980). It is possible to incorporate time-varying covariates into the model to capture the evolution of risk factors over time (Allison 1995, p. 183). It also allows a rigorous testing of issuer-heterogeneity and time-heterogeneity in rating dynamics (Lando and Skodeberg 2002).

72.3.2.1 Cox's Proportional Hazard Model

The Cox's proportional hazard model (Cox 1972) can be expressed as follows:

$$h_m(t, Z) = h(0, t)\exp\left[Z_j^m \beta_{\mathrm{j}}\right] \tag{72.1}$$

where $h_m(t, Z)$ is the migration hazard of rating state m at time t given its time-fixed covariate vector Z_j^m. $h(0,t)$ is the unspecified nonnegative baseline hazard, which is the hazard with the covariate vector set to zero, at time t. β_j is the vector of estimated coefficients for time-fixed covariate vector Z_j^m.

The likelihood $L_{t_m}^m$ that rating state m experiences a rating migration of interest at ordered time t_m is calculated as follows:

$$L_{t_m}^m = \frac{\exp\left(\beta_j Z_j^m\right)}{\sum_{i \in R(t_m)} \exp\left(\beta_j Z_j^i\right)} \tag{72.2}$$

where i represents a rating state in the risk set formed at ordered event time $t_{m,}$ $R(t_m)$.

The baseline hazard $h(0,t)$ cancels out in the numerator and denominator when forming the likelihood function and is not required in the estimation process. Taking the product of the likelihoods, for all states that migrated, across N ordered migration times t_m gives the full partial likelihood, PL, as follows:

$$PL = \prod_{m=1}^{N} L_{t_m}^m = \prod_{m=1}^{N} \left[\frac{\exp\left(\beta_j Z_j^m\right)}{\sum_{i \in R(t_m)} \exp\left(\beta_j Z_j^i\right)} \right] \tag{72.3}$$

The vectors of the estimated coefficients $\hat{\beta}_j$ can be obtained in the absence of knowledge of the baseline hazard $h(0,\ t)$ by maximizing the full partial likelihood in Eq. 72.3 (Kalbfleisch and Prentice 1980; Namboodiri and Suchindran 1987; Lawless 2003). Appendix 1 presents further details of the estimation approach.

The Cox's proportional hazard model has the property that the hazards for any two firms m and n in the risk set $R(t_m)$ does not vary between observed event times (Lawless 2003). Taking the ratio of the hazards for firms m and n and applying Eq. 72.1,

$$\frac{h_m(t,Z)}{h_n(t,Z)} = \frac{h(0,t)\exp\left[Z_j^m \beta_{\mathrm{j}}\right]}{h(0,t)\exp\left[Z_j^n \beta_{\mathrm{j}}\right]} = \exp\left[\beta_j\left(Z_j^m - Z_j^n\right)\right] \tag{72.4}$$

In the presence of time-fixed covariates Z_j, this property can be used to derive the estimated baseline hazard $\hat{h}(0,t)$ (see Lawless 2003).

The estimated hazard function of holdout state q at time t, $\hat{h}_q[t,Z]$, can be obtained by substituting in Eq. 72.1 the estimated baseline hazard $\hat{h}(0,t)$ derived from in-sample analysis, the estimated coefficient vector $\hat{\beta}_j$ obtained from Eq. 72.3, and state q's actual covariate vector Z_j^q. The estimated survival function of holdout state q at time t is

$$\hat{S}_q[t,Z] = \exp - \left(\sum \hat{h}_q[t,Z]\right) \tag{72.5}$$

72.3.2.2 Dynamic Cox's Hazard Model

The dynamic Cox's hazard model can be expressed as follows:

$$h_m[t, Z, Z(t)] = h(0, t)\exp\left[Z_j^m \beta_\mathrm{j} + Z_p^m(t)\beta_\mathrm{p}\right] \tag{72.6}$$

where $h_m(t, Z, Z(t))$ is the migration hazard of rating state m at time t given its time-fixed covariate vector Z_j^m and its time-varying covariate vector $Z_p^m(t)$. $h(0, t)$ is the unspecified nonnegative baseline hazard at time t. β_p is the vector of estimated coefficients for time-varying covariate vector $Z_p^m(t)$, and β_j is the vector of estimated coefficients for time-fixed covariate vector Z_j^m.

The likelihood $L_{t_m}^m$ is constructed similarly as in Eq. 72.2:

$$L_{t_m}^m = \frac{\exp\left[\beta_j Z_j^m + \beta_p Z_p^m(t_m)\right]}{\sum_{i \in R(t_m)} \exp\left[\beta_j Z_j^i + \beta_p Z_p^i(t_m)\right]} \tag{72.7}$$

The full partial likelihood PL is constructed similarly as in Eq. 72.3:

$$PL = \prod_{m=1}^{N} \left[\frac{\exp\left[\beta_j Z_j^m + \beta_p Z_p^m(t_m)\right]}{\sum_{i \in R(t_m)} \exp\left[\beta_j Z_j^i + \beta_p Z_p^i(t_m)\right]} \right] \tag{72.8}$$

The estimation process requires the updated values of time-varying covariates $Z_p(t)$ at each event time for all states i in the risk set formed at that event time (Andersen 1992). The vectors of the estimated coefficients $\hat{\beta}_j$ and $\hat{\beta}_p$ can be obtained by maximizing the full partial likelihood in Eq. 72.8.

In the presence of the time-varying covariates $Z_p(t)$, the ratio of the hazards for firms m and n is not constant between observed event times:

$$\frac{h_m[t, Z, Z(t)]}{h_n[t, Z, Z(t)]} = \frac{h(0, t)\exp\left[Z_j^m \beta_\mathrm{j} + Z_p^m(t_m)\beta_\mathrm{p}\right]}{h(0, t)\exp\left[Z_j^n \beta_\mathrm{j} + Z_p^n(t_m)\beta_\mathrm{p}\right]} \tag{72.9}$$

$$\frac{h_m[t, Z, Z(t)]}{h_n[t, Z, Z(t)]} = \exp\left\{\beta_j\left(Z_j^m - Z_j^n\right) + \beta_p\left[Z_p^m(t_m) - Z_p^n(t_m)\right]\right\}$$

It is therefore not possible to extract the baseline hazard $h(0, t)$ from the dynamic Cox's hazard model regression results. To resolve this issue, this study takes an approach proposed by Andersen (1992) and adapts the SAS codes published by Chen et al. (2005). The integrated baseline hazard function $H(0, t)$ can be estimated given the vectors of the estimated coefficients $\hat{\beta}_p$ and $\hat{\beta}_j$ obtained from Eq. 72.8:

$$\hat{H}(0,t) = \sum_{t_m \le t} \frac{D_m}{\sum_{i \in R(t_m)} \exp\left(\hat{\beta}_j Z_j^i + \hat{\beta}_p Z_p^i(t_m)\right)} \tag{72.10}$$

where D_m is the indicator for whether the migration event occurred to state m at ordered time t_m within the interval $[0, t]$.

The integrated baseline hazard function $H(0, t)$ can also be expressed as a step function discontinued at ordered event time t_m (Chen et al. 2005):

$$H(0,t) = \sum_{t_m \in t} [h(0, t_{m-1})(t_m - t_{m-1})] \tag{72.11}$$

The estimated baseline hazard function $\hat{h}(0,t)$ can be derived from Eqs. 72.10 and 72.11. The use of a step function is well suited to speculative grade-rated issuers given their volatile ratings and rapid migration propensity. The narrow gaps between successive event times allow relatively accurate estimation of the baseline hazards.

The estimated hazard function of holdout state q at time t, $\hat{h}_q[t, Z, Z(t)]$, can be obtained by substituting in Eq. 72.6 the estimated baseline hazard function $\hat{h}(0,t)$ derived from Eqs. 72.10 and 72.11, the estimated coefficient vector $\hat{\beta}_p$ and $\hat{\beta}_j$ obtained from Eq. 72.8, and state q's actual covariate vector Z_j^q and $Z_p^q(t)$. The estimated survival function of holdout state q at time t is

$$\hat{S}_q[t, Z, Z(t)] = \exp - \left(\sum \hat{h}_q[t, Z, Z(t)]\right) \tag{72.12}$$

72.3.3 Forecast Evaluation

72.3.3.1 Forecast Horizons

The conventional forecast horizon is 1 year, and credit rating agencies, in practice, publish annual transition matrices. In this study, survival probability estimates for holdout issuers were formed at 1- and 2-year horizons. These forecast horizons were selected for the following reasons: First, there are noticeable concentrations of estimation rating states in survival durations of 1–2 years, resulting in consistent estimates of the baseline hazard at time $t = 1$ year and $t = 2$ years. The availability of holdout observations at 1- and 2-year horizons allows an unbiased accuracy assessment of the models' forecast performance. Second, as implied by Mann et al. (2003), the 2-year time frame highlights the relative risk of FAs as compared to their peers. The 1- and 2-year forecast horizons also provide a short-term and near-intermediate-term prospective which is relevant to speculative grade-rated issuers. Third, it is of particular interest to examine the predictive accuracy of rating history at 1- and 2-year horizons given the evidence that the Markov property adequately holds within 1 or 2 years (Kiefer and Larson 2007; Frydman and Schuermann 2008).

72.3.3.2 Brier Score

The actual survival status of each issuer in the holdout sample was recorded and mapped against the survival probability estimate generated by the static/dynamic hazard models at forecast time t. The Brier score (Brier 1950) at forecast time t, B_t, is defined as follows:

$$B_t = \frac{\sum_{q=1}^{N_t} \left(f_t^{state\_q} - a^{state\_q} \right)^2}{N_t} \tag{72.13}$$

where

N_t is the number of survival forecasts at time t (the number of holdout rating states at time t)

$f_t^{state\_q}$ indicates the survival probability forecast that the holdout state q will survive at forecast time t[9]

a^{state_q} is the known survival outcome of holdout state q. If holdout state q survives, $a^{state\_q} = 1$, and if holdout state q experienced the migration event of interest (i.e., a downgrade in the downgrade model or an upgrade in the upgrade model), $a^{state\_q} = 0$.

72.3.3.3 Covariance Decomposition

Using the covariance decomposition (Yates 1982), the Brier score can be broken down into skill components including slope (discrimination), bias (calibration), and scatter (variance).[10] The most basic form of the covariance decomposition of Brier score at the forecast time t, B_t, is given as

$$B_t = \underbrace{\overline{d}_t\left(1 - \overline{d}_t\right)}_{\text{Uncertainty}} + \underbrace{\left(\overline{f}_t - \overline{d}_t\right)}_{\text{Bias square}}{}^2 + \underbrace{S_{f_t}^2}_{\text{Scatter}} \underbrace{-2S_{f_t d_t}}_{\text{Covariance}} \tag{72.14}$$

where

$\overline{d}_t$, or $\overline{d}$ for short, is the overall mean survival index, or the survival base rate at time t

$\overline{d}_t\left(1 - \overline{d}_t\right)$, or $\overline{d}\left(1 - \overline{d}\right)$ for short, is the variance of the outcome index at the forecast time t

$\overline{f}_t$, or $\overline{f}$ for ease of notation, is the overall mean survival forecast at the forecast time t

$\left(\overline{f}_t - \overline{d}_t\right)$, or $\left(\overline{f} - \overline{d}\right)$ for short, is the bias of forecasts at the forecast time t

[9]The notation was changed from $\hat{S}_q[t, Z]$ Eq. 72.5 or $\hat{S}_q[t, Z, Z(t)]$ Eq. 72.12 to $f_t^{state\_q}$ to provide a compact presentation of the formula in a form consistent with the literature review on the Brier score.

[10]The covariance decomposition proposed by Yates (1982) provides components of forecast accuracy that are more basic than the Sander (1963) and Murphy (1973) decompositions (Yates 1982, p. 141).

$S^2_{f_t}$, or S^2_f for short, is the variance of the forecasts, or scatter, at the forecast time t
$S_{f_t d_t}$, or S_{fd} for short, is the covariance of the survival outcome index and the survival probability forecasts at the forecast time t.

The component, $\bar{d}(1-\bar{d})$, namely, the outcome index variance, is determined by "natural forces." It reflects an aspect of forecast accuracy that does not depend on the predictive power of the estimated model (Yates 1982, p. 139).

The first skill component, $(\bar{f}-\bar{d})$, or bias, indicates the ability of the estimated model to match the overall mean survival probability forecast $\bar{f}$ to the mean survival outcome index $\bar{d}$ (Yates 1982). Bias reflects the overall pessimism or optimism of the forecaster in assigning probability survival forecasts to holdout observations. This term can be either positive or negative. The smaller the absolute value of bias, the lower the Brier score.

The second skill component, scatter or S^2_f, is the pooled variance of the forecasts. This term is derived from the distribution of the probability survival forecasts assigned to survived states f_1 and forecasts assigned to non-survived states f_0 (Arkes et al. 1995, p. 121). Scatter represents the "noisiness" of survival probability forecasts and reflects the sensitivity of the model to information that is not related to the event occurrence. The smaller the scatter, the lower the Brier score. The scatter, or variance of forecasts, S^2_f, takes a minimum value of zero when the model produces constant forecasts.

The third term of the skill components, covariance S_{fd}, can be expressed as

$$S_{fd} = (\bar{f}_1 - \bar{f}_0)\left[\bar{d}(1-\bar{d})\right] \tag{72.15}$$

where
$\bar{f}_1$ is the mean survival forecasts assigned to rating states that actually survived
$\bar{f}_0$ is the mean survival forecasts assigned to non-survived states, i.e., states that experienced the migration event of interest.

Since the outcome index variance $\bar{d}(1-\bar{d})$ is determined by "natural forces," the covariance is determined by the term $(\bar{f}_1 - \bar{f}_0)$ (Yates 1982, p. 138). This term is equal to the slope of the regression line for a survival forecast on the outcome index. Given a base rate $\bar{d}$, the larger the term $(\bar{f}_1 - \bar{f}_0)$ or the steeper the slope, the lower the Brier score. The slope indicates the ability of the model to distinguish between the group of survived states f_1 and the group of non-survived states f_0. A steeper slope reflects the model's ability to assign higher probability survival forecasts to survived states than to non-survived states. It also shows the model's sensitivity to the information that is related to the event occurrence.

72.3.4 Variables

72.3.4.1 Measurements of Variables

Rating Scales

Corporate issuer ratings were obtained from Standard & Poor's CreditPro 2005 dataset. The data does not include rating outlooks and credit watch listings.

Standard & Poor's alphabetical rating scale includes 10 major rating categories varying from excellent credit quality (AAA) to default (D) as follows: AAA, AA, A, BBB, BB, B, CCC, CC, C, and D. A plus (+) or a minus (−) can be added to ratings from AA to CCC to capture the relative ranking within each rating class.[11] Ratings from AAA to BBB− are investment grade and ratings from BB+ to C are speculative grade.

This study employs a numerical rating scale to represent Standard & Poor's alphabetical rating scale. For the rating classes above AA+ and below CCC−, the plus (+) and minus (−) notches are not employed by Standard & Poor's. The omission of notches for AAA, CC, and C classes may lead to different gap lengths in rating scales. It is suggested that a one notch rating change in low rating grades implies a larger increase in default risk (Jorion and Zhang 2007). An issue arising here is the treatment of the rating gap between AAA and AA+ and the gap between ratings below CCC−. Similar to Dang (2010), this study assumed that the gap between AAA and AA+ is not one notch but two, implicitly including AAA− in the rating scale. A similar approach has been applied to rating classes below CCC−. As a result, the numeric rating scales were coded from 0 to 26 with 0 indicating the default class (D) and 26 indicating the AAA class. This numerical conversion maintains the rank order of the letter ratings, captures fine revisions intra-ratings, and reduces the effect of nonlinearity in the top and bottom rating classes. In addition, a dummy variable (*dummy junk boundary*) was also created to capture any nonlinearity between speculative grade rating boundary (BB−, BB, BB+) and adjacent rating grades.

Macroeconomic Time Series

Seven macroeconomic variables[12] were included in the static and dynamic hazard models. The *dummy recession* indicates the state of the business cycle. The Chicago Fed National Activity Index (*CFNAI*), the output growth gap (*RealGDPg actual minus potential*), and the *industrial production change* capture general economic activity. The *S&P500 quarterly return* and *S&P500 annualized standard deviation* represent the performance of the stock market, while the *term structure slope* reflects credit conditions.

As macroeconomic conditions are likely to affect rating migrations with a lag, this study uses an exponentially weighted average of lagged observations computed quarterly to construct five macroeconomic covariates (except *dummy recession* and *CFNAI*). The construction of macroeconomic lagged values is similar to the approach applied by Dang (2010) and Figlewski et al. (2012). The exponentially weighted average value X_t for the quarterly series x for a given macroeconomic variable in quarter t is calculated using data up to the previous quarter as

[11] http://www.standardandpoors.com/ratings/definitions-and-faqs/en/us/ (Accessed 17 August 2012)

[12] Seventeen macroeconomic candidate variables were considered and those that exhibited strong multicollinearity were eliminated.

$$X_t = \frac{\sum_{k=1}^{K} \delta^{k-1} x_{t-k}}{\sum_{k=1}^{K} \delta^{k-1}} \tag{72.16}$$

where $K = 6$ is the length of the lagged window and $\delta = 0.6815$ is the decay factor.

The *CFNAI* is published as a 3-month moving average and is used without further transformation.

Of seven macroeconomic covariates, one (*dummy recession*) is constructed as time-fixed in the static and dynamic hazard models, and six were constructed as either time-fixed in the static models or time-varying in the dynamic models. The value of the time-fixed covariate vector Z_j was measured at the beginning of each estimation and holdout rating state. The value of the time-varying macroeconomic covariate vector $Z_p^m(t)$ for estimation state m was taken quarterly over its rating duration, and the value used in Eq. 72.8 was updated to the most recent quarterly value as each risk set was formed. For holdout state q, the known information of the macroeconomic environment is limited to its commencement. Thus, the value of the macroeconomic covariate vector $Z_p^q(t)$ used to form survival forecasts for holdout state q was measured at state q's beginning and entered in Eqs. 72.6 and 72.12 without being subsequently updated. So, $Z_p^q(t) = Z_p^q(t = 0)$. The disadvantage is that the macro data for holdout observations become static in relation to time.

72.3.4.2 Definitions of Variables

The candidate variables that capture issuer-heterogeneity (rating history, industry sector) and time-heterogeneity (business cycle) in rating migration dynamics were identified from the literature.

Rating Variables

Start rating: The rating at the beginning of the current rating state. For a FA experiencing a plunge from an investment grade rating to a speculative grade rating at lag-one state, the *start rating* is also the rating on the fall date.

Dummy junk boundary: This dummy takes the value of one if the *start rating* falls within the speculative (junk) boundary BB−, BB, BB+, and zero otherwise.

Original rating: The rating of the firm when it was first rated.

Rate prior change: This indicates the average number of rating changes per year over the rating history of an issuer. It is calculated as the number of prior migrations (downgrades and upgrades) observed between the entry of the firm to the study and the beginning of the current rating state divided by the period from the time of entry till the start of the current rating state.

Rate prior down: This equals the average number of downgrades per year over the rating history of an issuer. It is calculated similar to *rate prior change* except that the numerator is the number of downgrades observed between the entry of the firm to the study and the beginning of the current state.

Lag one: The duration (in years) of the rating state that ends with a downgrade[13] and immediately precedes the current rating.

Lag two: The duration (in years) of the rating state that ends with either a downgrade or an upgrade (i.e., is not censored) and immediately precedes the lag-one rating.

Dummy lag2 down: This variable captures the direction of the lag-two regrade and takes the value of one if the lag-two rating ends with a downgrade and zero otherwise.

Number NR (*not rated*): This indicates the number of times a firm underwent a break in rating history (a rating withdrawal[14]) from the entry of the firm to the study until the beginning of the lag-one rating state.

Number prior fallen angel (FA): This indicates the number of times an issuer experienced a FA event (a downgrade from an investment grade rating to a speculative grade rating) from the entry of the firm to the study until the beginning of the lag-one rating state.[15]

Number rising star (RS): This indicates the number of times a firm experienced a RS event (an upgrade from a speculative grade rating to an investment grade rating) from the entry of the firm to the study until the start of the lag-one rating state.

Number big down: This indicates the number of times a firm experienced a substantial downgrade jump, defined as a jump of at least three rating notches,[16] from the entry of the firm to the study until the beginning of the current rating state.

Number big up: This variable indicates the number of times a firm experienced a substantial upgrade jump, defined as a jump of at least two rating notches, from the entry of the firm to the study until the beginning of the lag-one rating state.

Age since first rated: The rating age of the firm, which is equal to the length in years from the time the firm was first rated until the beginning of the current state.

---

[13]By definition, all FAs and FA peers in this study experienced a downgrade at lag-one rating state.

[14]Rating withdrawals bear negative credit implications if there is a lack of information to accurately assess debt issues (Carty 1997, p. 10). Issuers are likely to withdraw from being rated when they expect a downgrade. In this case, being unrated (censored) substitutes for being downgraded. The characteristics of issuers lost to non-independent (informative) censoring are often associated with the [migration] process under study (Blossfeld and Rohwer 1995; Kalbfleisch and Prentice 1980). There is no statistical test to check for and no standard methods for handling informative censoring (Allison 1995, p. 14). In this study, two sensitivity tests suggested by Allison (1995, pp. 249–252) to examine the effect of informative censoring on the main results have been applied to the proportional hazard models for FAs and their peers. It is found that being unrated is not informative.

[15]*Number prior FA* does not take into account the FA event FAs experienced at lag-one rating state. By definition, none of FA peers in this study experienced a FA event at lag-one rating state.

[16]Substantial rating changes of more than one letter grade (i.e., three rating notches) were more frequently observed in the ratings B through C (Lucas and Lonski 1992) and were less frequent than rating revisions of small magnitude (Carty and Fons 1994; Carty 1997). Downgrades involved a much bigger change in credit rating than upgrades (Jorion and Zhang 2007).

Control Variables

Industry dummies: Firms' industry sectors, as given by Standard & Poor's, were used to control for industry effects. The industry dummy took a value of one if the firm was in an industry sector and zero otherwise. Due to their unique business nature and credit risk exposure, firms in the *financial institution* sector[17] were excluded from the study. The data include 11 sectors, which resulted in ten dummy variables with the *insurance* sector left uncoded.

Industrial production change: As published by the US Federal Reserve Board.

RealGDPg actual minus potential (output growth gap): This variable measures the deviation of the actual real GDP growth (as published by the US Bureau of Economic Analysis) from the potential real GDP growth (as published by the St. Louis Federal Reserve).

CFNAI (Chicago Fed National Activity Index): This composite index is published by the Chicago Federal Reserve and is computed as a 3-month moving average of 85 monthly economic series.

Dummy recession: This variable takes the value of one if the rating state starts at the time of a recession, defined by the National Bureau of Economic Research, as 1 August 1990 to 31 March 1991 or 1 April 2001 to 30 November 2001, and zero otherwise.

S&P500 quarterly return: Definition sourced from Datastream.

S&P500 annualized standard deviation: Daily returns for the quarter are used to compute the standard deviation and this is expressed as an annual standard deviation.

Term structure slope: The slope is measured as the spread between 3-month and 10-year US Treasury Constant Maturity rates as published by the US Federal Reserve.

72.4 Data

72.4.1 Estimation and Holdout Periods

The rating behaviors of FAs and their peers in the USA were examined over the period 1984–2000.[18] This period covers different phases of the business cycle in the USA including the economic recession from July 1990 to March 1991.

[17] According to Lando and Skodeberg (2002), most financial institutions were assigned investment rating grades. As confidence- and capital-sensitive entities, it is difficult for financial institutions to run business with a poor credit profile or low credit rating. Lando and Skodeberg (2002) found that the duration dependence and the downward momentum are less pronounced for issuers in the financial institution sector than for issuers in other sectors. As this study examines the question of rating history dependence in the rating dynamics of speculative grade-rated issuers, financial institution sector was excluded from this study.

[18] The year 1984 was selected as the starting point for several reasons. 1982 is as far back as all macro data are available, and Standard & Poor's rating scales were changed in 1983. The growth of the US high-yield bond market and rating migrations from 1984 also constitute a significant source of events to this study.

The estimation period also captures major market downturns such as the stock market crash in 1987 and the collapse of the Long-Term Capital Market Hedge Fund in 1998. The period subsequent to the estimation period, 2001–2005, was used to construct holdout samples for FAs and their peers. The holdout period observed the 9/11 terrorist attack, the internet bubble burst, and the economic recession from March 2001 to November 2001. This period also witnessed altered business dynamics stemming from deregulations, the shakeouts that weeded out vulnerable FAs in high-velocity sectors, and the notorious collapse of tainted FAs such as WorldCom and Enron.

The descriptive statistics of the time series for the exponentially weighted average (except *CFNAI*) of macroeconomic variables are presented in Table 72.1. Additional analysis (not reported) indicates that macroeconomic time series in the estimation and holdout periods have statistically different mean and median values (except *term structure slope*).

72.4.2 Estimation and Holdout Samples

The estimation population includes 276 FAs and 1,102 FA-peer candidates. From the pool of 1,102 peer candidates, 276 observations were randomly chosen to form the FA-peer estimation sample. The holdout population includes 141 FAs and 937 FA-peer candidates. The FA-peer holdout sample with 141 observations was created randomly from the universe of 937 FA-peer candidates.[19]

The frequency of downgrades and upgrades for FA and FA peers in the estimation and the holdout samples are presented in Table 72.2. The migration propensity of estimation and holdout FAs differed markedly. Compared to estimation FAs, hold-out FAs are more vulnerable to downgrades and are less likely to regain investment grade status. This reinforces the notions that trends in corporate credit quality change over time (Carty and Fons 1994), with downgrades outnumbering upgrades (Altman and Kao 1991; Lucas and Lonski 1992; Lando and Skodeberg 2002).

72.4.3 Survival Time Distribution

The descriptive statistics of the survival time (survival duration) of FA/FA-peer down states and up states in the estimation and holdout periods are summarized in Panel A/Panel B of Table 72.3, respectively. Additional analysis (not reported) shows that FA and FA-peer down states (up states) in the estimation (holdout) period have statistically different mean survival time values.

[19]The FA sample and the universe of FA-peer candidates in the estimation/holdout period have markedly different distribution of issuers in the upper speculative rating classes (BB, BB+). Thus, it is impossible to construct from the candidate pool a FA-peer sample with the same current rating distribution and the same sample size as the FA sample for either the estimation or the holdout period.

Table 72.1 Descriptive statistics of macroeconomic variables

	Sample	Mean	Median	Standard deviation	Minimum	Maximum	Skewness	Kurtosis
Chicago Fed National Activity Index (CFNAI)	1984–2000	0.113	0.155	0.447	−1.287	1.156	−0.677	1.711
	2001–2005	−0.301	−0.353	0.466	−1.109	0.352	−0.197	−1.087
RealGDPg actual minus potential (%)	1984–2000	0.131	0.153	0.348	−0.927	1.126	0.045	2.623
	2001–2005	−0.16	−0.194	0.352	−0.795	0.32	−0.258	−1.286
Industrial production change (%)	1984–2000	0.939	1.011	0.662	−0.853	2.521	−0.108	0.071
	2001–2005	0.183	0.42	0.655	−1.293	1.085	−1.02	0.138
SP500 quarterly return (%)	1984–2000	3.609	3.294	2.99	−3.869	9.484	−0.077	−0.458
	2001–2005	−0.501	0.157	4.33	−9.267	6.385	−0.344	−0.71
SP500 annual standard deviation	1984–2000	1.769	1.678	0.612	0.649	3.789	1.014	1.303
	2001–2005	2.284	2.467	0.68	1.27	3.233	−0.279	−1.435
Term structure slope (%)	1984–2000	1.716	1.718	0.943	0.165	3.363	−0.018	−1.299
	2001–2005	2.14	2.621	1.029	−0.128	3.156	−1.2	0.248

Table 72.2 Downgrade and upgrade frequency

	FAs			FA peers		
	Total	Down states	Up states	Total	Down states	Up states
Estimation sample, 1984–2000	276	102 (37 %)	104 (37.7 %)	276	163 (59 %)	46 (16.7 %)
Holdout sample, 2001–2005	141	83 (58.9 %)	13 (9.2 %)	141	71 (50.4 %)	22 (15.6 %)

The survival duration histograms of FA/FA-peer down states and up states in the estimation sample are depicted in Fig. 72.1. The time-to-event distributions are quite different between down states and up states. For down states, particularly FA peers, the histograms suggest that further decline in survival duration tends to be swift. There is a noticeable concentration of FA/FA-peer down states in durations within 1 year, whereas the durations for FA/FA-peer up states tend to be longer.

As shown in Table 72.3 and Fig. 72.1, estimation FA peers are riskier than estimation FAs as evidenced by a higher (lower) likelihood to downgrade (upgrade) and a shorter median time to downgrade. The reverse applies in the holdout period. Holdout FAs are more vulnerable to downgrades and experience a shorter (longer) median time to downgrade (upgrade) than holdout FA peers (Table 72.3). This is consistent with the notion that FAs display faster downward migration and greater rating velocity than their peers within few years since the fall date.

72.5 Estimation Results

The Cox's proportional hazard models and the Cox's dynamic hazard models were estimated for FAs/FA peers over the period 1984–2000. The results of the estimated hazard models are given in Panel A – Table 72.4. Panel B – Table 72.4 – is appended to Panel A and provides statistics on the fit of the models. The backward stepwise estimation procedure was employed. Significant variables were retained in the models according to the log-likelihood ratio test, at the 10 % level or better, derived from the maximum likelihood procedure used to estimate the models. In interpreting Panel A of Table 72.4, a negative coefficient reduces the hazard of the migration event being modelled. The reported hazard ratios represent the relative change in the hazard for a one-unit change in the independent variable. The discussion that follows focuses on the effect of past rating behaviors on the downgrade and upgrade hazard of FAs and their peers.

72.5.1 Cox's Proportional Hazard Models

72.5.1.1 Control Variables

With respect to macroeconomic variables and industry sector dummies, several key results are observed (Panel A of Table 72.4). FAs, particularly with respect to upgrades, are sensitive to the economic environment prevailing on the fall date.

Table 72.3 Descriptive statistics of survival time

Samples	Rating states	No. of obs (sample size)	Mean (years)	Median (years)	Standard deviation	Minimum (days)	Maximum (years)	Skewness	Kurtosis
Panel A: Descriptive statistics of FAs' survival time									
1984–2000	Down states	102 (276)	1.12	0.83	1.07	2	5.08	1.44	1.9

**1 % $< p$-value ≤ 5 %

*5 % $< p$-value ≤ 10 % based on Wald chi-square tests

The partial likelihood ratio test is calculated as twice the difference between the log partial likelihood of the model containing the covariate and the log partial likelihood for the model not containing the covariate. As shown in Panel B, the likelihood ratio statistics are significant at better than 1 % level, rejecting the global null hypothesis that all coefficients are equal to zero

For example, changes in *CFNAI* have no impact on the downward journey of FAs, whereas a one-unit increase in *CFNAI* makes a return to the investment grade universe 799.3 % more likely. On the other hand, FA peers are more vulnerable to industry risk. Those in the *utility s* ector are 135.8 % more vulnerable to downgrades. This is in contrast to the notion that issuers in *utility* sector have a stable rating process (Kadam and Lenk 2008). It is noticeable that macroeconomic conditions are not significant, whereas industry sectors are the key determinants of the upgrade probability of FA peers. Those in *high technology/computers/office equipment*, *forest and building products/homebuilders*, or *transportation* sectors are hundreds of percentage points more likely to become rising stars.

72.5.1.2 Rating Behaviors

FAs and their peers exhibit different dependence on the current rating and past rating behaviors (Panel A of Table 72.4). The *start rating* – the rating a FA received on the fall date – and *dummy lag2 down* are not significant in determining the downgrade hazard of FAs. The absence of *start rating* in the downgrade model is in direct contrast to the Markov property and is inconsistent with the "destination pattern" – the lower a rating a FA descends to, the more likely it will default (Mann et al. 2003, p. 5). On the other hand, the absence of *dummy lag2 down* reinforces the notions that the strong effect of a previous rating change become weaker with the passage of time (Hamilton and Cantor 2004, p. 10) and does not persist after 2 or 3 years (Fledelius et al. 2004).

Two rating history variables (*number big up* and *lag one*) are significant in the downgrade model for FAs. The effect of *number big up* seems to contradict credit rating agencies' policy to "limit rating reversal and dampen rating volatility" (Hamilton and Cantor 2004, p. 3). A substantial jump to higher rating grades (*number big up*) makes a rating bounce 148.4 % more likely. In contrast to *number big up*, *lag one* has a smaller impact. Extending the duration of *lag-one* rating state by 1 year merely increases the probability that the current rating persists by 15 %. The effect of *lag one* is consistent with the duration dependence phenomenon suggested by Lando and Skodeberg (2002).

The downgrade process of FA peers exhibit substantial dependence on past rating behaviors. Those experiencing a downgrade at lag-two rating state (*dummy lag2 down*) are 270 % more likely to descend to lower rating classes. The strong impact of *dummy lag2 down* is consistent with the downward momentum in corporate rating dynamics.[20] Prior rating volatility (*rate prior change*) and prior downgrade volatility (*rate prior down*) have reverse coefficient signs, of which the earlier dominates with a 10 times stronger effect. Increasing prior rating volatility

[20]The effect of a previous rating change decays as time passes (Hamilton and Cantor 2004, p. 10). Thus, the shorter the *lag-one* rating state, the more influential the rating change at lag-two state (*dummy lag2 down*). Additional analysis (not reported) indicates that FA peer down states have a shorter *lag one* than FAs down states. Consequently, the effect of *dummy lag2 down* on the probability of a subsequent downgrade persists on FA peers but does not hold on FAs (as discussed earlier).

(*rate prior change*) by one migration per year makes a further downgrade for FA peers 917.5 % more likely. In comparison to *dummy lag2 down* and *rate prior change*, the current raring (*start rating*) and rating age (*age since first rated*) have a modest effect. The better the current rating (*start rating*) and the longer the time since an issuer was first rated (*age since first rated*), the more likely a FA peer will retain its current rating. The effect of *age since first rated* contrasts with the notion that aging issuers are vulnerable to downgrades and default (Altman and Kao 1991; Altman 1992, 1998; Figlewski et al. 2012).

The upgrade models for FAs and FA peers share two common variables; both capture the current rating state (*start rating* and *dummy junk boundary*). FAs and their peers with a better *start rating* are more likely to stay in their current rating grade. Those in the speculative grade barrier, BB+, BB, or BB− (*dummy junk boundary*), have a favorable tendency towards upgrades and are several times more likely to be rising stars. The effect of *dummy junk boundary* is more pronounced than the effect of the *start rating* and is stronger for FAs than FA peers. The effect of *dummy junk boundary* is consistent with the "destination pattern" – a higher rating assigned to a FA upon its entrance to the speculative rating spectrum makes a return to the investment rating universe more likely. This is most apparent in the speculative grade boundary (Mann et al. 2003, p. 5).

Only one rating history variable is significant in the upgrade models for FAs and FA peers. FAs with a prior rating withdrawal (*number not rated*) are 133 % more likely to regain the investment grade status. In contrast, FA peers with a frequent migration history (*rate prior change*) are 25.8 % less likely to ascend to higher rating grades.

Overall, in a static estimation framework, several aspects of rating history are key determinants of the migration hazard of FAs/FA peers. The question is whether the impact of rating history persists in a dynamic estimation framework?

72.5.2 Dynamic Cox's Hazard Models

Some noticeable changes were observed when switching from a static to a dynamic estimation framework. The following discussion focuses on the distinguishing features between the respective proportional models and the dynamic models for FAs and their peers (Panel A of Table 72.4).

72.5.2.1 Control Variables

In a dynamic estimation framework, the downgrade process of FAs and their peers exhibit strong dependence on macroeconomic conditions, whereas their upgrades are entirely driven by the current rating, past rating behaviors, and industry sectors. This reinforces the concept that upgrades are more sensitive to firm-specific risk factors than macroeconomic shocks.

FAs, with respect to downgrades, are very sensitive to the economic environment prevailing at each migration time. During an economic recession (*dummy recession*) or a period of large output growth gap (*RealGDPg_actual_minus_potential*) and large *industrial production change*, FAs exhibit rapid deterioration and are hundreds of percentage points more vulnerable to downgrades.

72.5.2.2 Rating Behaviors

For downgrades, relative to the corresponding static model, the dynamic model for FAs/FA peers includes the same set of significant rating variables; all of them retain the same coefficient signs. The substantial effect of past rating volatility (*rate prior change*) on FA peers diminishes though it still dominates other rating behaviors. In both estimation frameworks, the current rating (*start rating*) is either not significant or has a minimal impact on the downgrade process of FAs and their peers.

For upgrades, the results of the proportional and dynamic models for FA peers are consistent, with one exception. *Rate prior down* replaces *rate prior change* and has a similar coefficient. FA peers with a frequent downgrade history (*rate prior down*) are less likely to become rising stars. In both estimation frameworks, the upgrade process of FA peers is entirely driven by endogenous risk factors, of which industry sectors are more influential than rating history and the current rating.

Noticeable changes were observed in the upgrade model for FAs. None of macroeconomic factors/industry sectors affects FAs' probabilities to regain the investment grade status. In other words, the upgrade process of FAs is entirely determined by the current rating and rating history, of which rating history dominates the current rating. Relative to the corresponding static model, the dynamic model for FAs features a stronger effect and a greater number of rating history variables. Variables significant in the proportional model (*start rating*, *dummy junk boundary*, *number not rated*) are also present in the dynamic model and retain the same coefficient signs. The current rating, specifically *dummy junk boundary*, is less influential; its hazard ratio is about 200 basis points smaller when switching to a dynamic estimation procedure. *Age since first rated* and the *original rating* become significant. Aging FAs (*age since first rated*) are less likely to make an uphill climb, whereas originally high-rated FAs (*original rating*) exhibit a favorable tendency towards upgrades.

In summary, past rating behaviors persist even after controlling for the industry sector and the development of macroeconomic conditions over the time for which the current rating persists. As suggested by Lando (2004, p. 97), the Markov chain assumptions do not hold if ratings vary across the business cycle or depend on the age of the bond. The results of this study therefore suggest that rating changes for FAs and FA peers are non-Markovian, and rating history variables can be used in estimating future rating changes. The question is how accurate are such forecasts?

72.6 Forecast Accuracy Assessment

The Brier scores (Brier 1950) of survival probability forecasts generated by the static and dynamic hazard models for FAs/FA peers were calculated as in Eq. 72.13

and decomposed into forecast components as in Eq. 72.14. A Brier score of zero indicates perfect predictive ability and a Brier score of one indicates no predictive ability. Variation in the Brier score through time is a consequence of both the passage of time and the changing holdout sample composition.[21]

Table 72.5 summarizes the covariance decompositions of the Brier scores at 1- and 2-year forecast horizons. Removing the outcome index variance $\overline{d}_t\left(1-\overline{d}_t\right)$ from the overall Brier score B_t results in the skill component score, which "levels the playing field" and enhances the validity of comparative forecast assessments (Yates 1982). The following discussion focuses on the skill components (calibration or bias, variance or scatter, and discrimination or slope) of the Brier score. In the interests of brevity, the covariance graphs which illustrate the covariance components of the Brier scores are not presented. However, an example of a covariance graph can be found in Appendix 2.

72.6.1 The Predictive Accuracy of Cox's Proportional Hazard Models

72.6.1.1 Upgrade Models for FAs/FA Peers

The proportional (static) upgrade models for FAs and FAs peers exhibit modest forecast performance as evidenced by relatively small skill component scores. A lower skill component score implies better forecast performance.

The upgrade model for FAs demonstrates excessive pessimism and underestimates survival estimates by a large margin. Additional analysis of the covariance graphs indicates that the model generally places 1- and 2-year survival forecasts in the middle and pessimistic probability categories that are substantially beneath the survival base rate ($\overline{d}_1 = 90.78\ \%$ and $\overline{d}_2 = 75\ \%$). This corresponds to a large bias of $-21.98\ \%$ (Appendix 2) and $-19.85\ \%$ at 1- and 2-year horizons, respectively.

In contrasts, the model for FA peers demonstrates well-calibrated survival estimates across forecast horizons. Additional analysis of the covariance graphs (not reported) indicates that the model for FA peers assigns 1- and 2-year survival estimates in the optimistic probability categories that are close to the mean survival index ($\overline{d}_1 = 84.4\ \%$ and $\overline{d}_2 = 72.2\ \%$). This tendency translates into a negligible bias at both forecast horizons.

Both the upgrade models for FAs and their peers do well in removing irrelevant information and achieve small variability (scatter) in estimates. However, survival forecasts for survived and upgraded issuers concentrate in few probability deciles, reflecting poor discrimination ability.

[21] In forming the survival forecasts for holdout FAs/FA peers, the approach of Chen et al. (2005) is followed. As the time horizon unfolds, Chen et al. (2005) deleted from the holdout sample at time t those cases which are censored, or have experienced the event, before time t. The approach of Chen et al. (2005) results in a holdout sample that reduces with the passage of time. The number of survival forecasts N_t Eq. 72.13 accordingly reduces as the forecast time t gets longer.

Table 72.5 Brier score of time-varying survival forecasts for FAs and their peers in the holdout period 2001–2005

72.6.1.2 Downgrade Models for FAs/FA Peers

The proportional downgrade models for FAs and FA peers perform poorly. Additional analysis of the covariance graphs (not reported) shows that most of the 1-year estimates for FAs were placed in the probability categories that are substantially higher than the survival base rate $\left(\overline{d}_1 = 41.13\ \%\right)$. The marked tendency to endorse upper optimistic categories in 1-year survival forecasts is a major cause of the large positive bias of 39.15 %. For FA peers, a majority of 1-year survival estimates were assigned to the middle probability deciles that are slightly above the mean survival index $\left(\overline{d}_1 = 49.65\ \%\right)$, resulting in a relatively small bias of 8.8 %. Both downgrade models for FAs/FA peers assign 2-year survival forecasts to the probability categories that are lower than the survival base rate ($\overline{d}_2 = 77.27\ \%$ for FAs and $\overline{d}_2 = 72.22\ \%$ for FA peers), resulting in a negative bias.

On the index of slope, the downgrade models for FAs/FA peers perform poorly in discriminating survived states from downgraded states. Both models, however, achieve negligible scatters (variance).

72.6.1.3 Sources of Forecast Errors

For both FAs and their peers, the static upgrade models exhibit some predictive ability, whereas the static downgrade models perform poorly. The following discussion focuses on two factors that may contribute to the forecast performance of the static models.

The macroeconomic conditions in the estimation and holdout periods markedly differ (Table 72.1). Similarly, the migration propensity of FAs in the estimation period is not representative of the migration pattern in the holdout period. Relative to estimation FAs, holdout FAs are more vulnerable to downgrades and exhibit an unfavorable tendency towards upgrades (Tables 72.2 and 72.3). The poor economic development and the rapid deterioration in the credit quality of FAs in the holdout period present challenges to both downgrade and upgrade models.

The proportional models employ a static estimation framework and include time-fixed covariates which capture the economic conditions at the beginning of each rating state. The information embedded in the time-fixed macroeconomic covariates becomes increasingly stale and less relevant as the rating duration unfolds. As suggested by Amato and Furfine (2004), the date of a rating change is generally close to the time the actual credit review takes place. Any decision by credit rating agencies is influenced by the economic conditions prevailing at the time of the rating change. Downgrades departing from low ratings are particularly sensitive to the prevailing economic environment. This suggests the need to develop dynamic hazard models that include time-varying macroeconomic covariates updated at each event time.

72.6.2 The Predictive Accuracy of Dynamic Cox's Hazard Models

The following discussion focuses on the comparative performance of the dynamic models for FAs/FA peers in comparison to the respective static models examined above (Table 72.5).

72.6.2.1 Upgrade Models for FAs/FA Peers

The dynamic upgrade model for FA peers exhibits similar good forecast performance at the 1-year horizon and outperforms the respective static model at the 2-year horizon. Both the static and dynamic models for FA peers show strong calibration ability as evidenced by a minimal bias across forecast horizons. Of particular interest, the dynamic model achieves a zero (perfect) bias at the 1-year horizon. On the index of slope, the dynamic model performs slightly better in discriminating rating states that survived from states that were upgraded at the 2-year forecast horizon. This corresponds to a 5 % steeper slope and a smaller Brier score.

The dynamic upgrade model for FAs performs far better than the corresponding static model and achieves a competitive skill component score at both 1- and 2-year forecast horizons. The predictive accuracy is particularly good at the 1-year horizon. Relative to the corresponding static model, the dynamic upgrade model for FAs uses the optimistic probability category above 80 % to a much greater extent and employs middle and lower probability deciles to a lesser extent. Unlike the respective proportional model, the dynamic model seldom makes pessimistic survival forecasts. The marked propensity to place a majority of 1- and 2-year survival estimates into the optimistic categories that are close to the survival base rate ($\overline{d}_1 = 90.78\ \%$ and $\overline{d}_2 = 75\ \%$) translates into a small (superior) positive bias.

72.6.2.2 Dynamic Downgrade Models for FAs and FA Peers

The forecast performance of the dynamic downgrade models for FAs and FA peers at 1-year horizon is disappointing. This can be attributed to the deterioration in their calibration ability. Relative to the respective static models, the dynamic downgrade models for FAs/FA peers use optimistic probability categories to a greater extent and employ middle and lower probability deciles to a lesser extent. As a result, the dynamic downgrade models overestimate the 1-year survival forecasts by a larger margin and exhibit a larger (inferior) positive bias.

However, at the 2-year forecast horizon, both dynamic downgrade models have an edge over the respective static models. The dynamic models underestimate the 2-year survival forecasts by a smaller margin and obtain a smaller (more competitive) negative bias. It is noticeable that the dynamic model for FAs offers well-calibrated 2-year survival estimates.

72.6.2.3 Limitations

This study suffers from some limitations which contribute to the poor forecast performance of the downgrade models for FAs/FA peers at the 1-year horizon.

Speculative grade issuers, particularly FAs, are naturally under the close scrutiny of market participants and are potential targets for negative rating reviews and downward revisions following their fall dates. The common concept is that credit rating agencies focus more resources on quantifying deteriorations in the credit profile of speculative grade issuers than analyzing any improvement in their earnings (Holthausen and Leftwich 1986). Downgrades tend to be quick, whereas upgrades tend to lag behind credit quality improvement. Furthermore, ratings are assigned in a pro-cyclical manner.[22] Amato and Furfine (2004) suggested that credit rating agencies exhibit a propensity to overreact to the prevailing macroeconomic conditions when they revise ratings. They tend to exhibit excessive pessimism during economic downturns. This tendency could contribute to an acceleration of credit deterioration in the volatile holdout period 2001–2005. The survival forecasts based on the "average" migration experience in the estimation period 1984–2000 fail to capture the rapid deterioration in the credit quality of holdout FAs.

Furthermore, the employment of static macroeconomic data to form forecasts for holdout issuers in Eq. 72.12 is likely to dampen the predictive accuracy of the dynamic downgrade models. This is more pronounced given the strong effect of macroeconomic variables on downgrades (Panel A of Table 72.4) and the dramatically changing economic conditions in the holdout period (Table 72.1).

The absence of rating outlook and credit watch data in this study is also likely to diminish the predictive power of the downgrade models. It is suggested that rating outlook and CreditWatch data diminish the impact of rating history (Hamilton and Cantor 2004) and exhibit predictive accuracy in forecasting future rating changes (Vazza et al. 2005b; Hill et al. 2010; Guttler 2011).

72.7 Conclusion

Using Standard & Poor's CreditPro 2005 dataset and the survival analysis framework (Allison 1984), this study aimed to address two issues: first, to examine issuer-heterogeneity and time-heterogeneity in the rating migration dynamics of FAs and their speculative grade-rated peers over the period 1984–2000 and, second, to assess the predictive accuracy of the static and dynamic hazard models in

[22]The pro-cyclicality in rating actions may be attributed to the possibility that business cycle fluctuations coincide with permanent changes in credit quality (Loffler 2012).

forecasting future rating changes over the subsequent period, 2001–2005. The principal conclusions emerging from this study are as follows:

Past rating behaviors, industry sectors, and macroeconomic conditions are the key determinants of the rating migration process. The significant factors differ between FAs and their peers and vary between downgrades and upgrades. A key finding is that past rating behaviors persist and have a strong effect in the presence of time-varying macroeconomic covariates. As seen in the dynamic model, a prior rating withdrawal makes a FA 185 % more likely to return to the investment grade universe. A one-migration increase in the annual regrade volatility and a downgrade at lag-two rating state, respectively, makes a FA peer 725 % and 248 % more likely to continue the downward journey.

In both static and dynamic estimation frameworks, FAs and FA peers close to the speculative grade boundary (BB+, BB, BB−) are resilient and several times more likely to become rising stars. The current rating – the rating a FA received on the fall date – is not significant in determining its subsequent downgrade probability. For other rating migration processes, the current rating has a modest impact compared to past rating behaviors.

Volatile macroeconomic conditions and accelerated credit deterioration in the holdout period bring challenges to the models' forecast performance. In the aggregate, all models do well in removing irrelevant information but at some expense of failing to incorporate important information. The tendency to assign survival estimates in the probability categories that are either beyond or below the survival base rate results in some bias.

Switching from a static to a dynamic estimation framework improves the calibration power of the downgrade and upgrade models for FAs/FA peers, mostly at the 2-year forecast horizon. Of particular interest, the dynamic upgrade model for FAs, which includes only rating variables and features a strong effect of rating history, substantially outperforms the respective static model at both the 1- and 2-year forecast horizons. The results are in direct contrast to the evidence that the Markov property adequately holds within 1 or 2 years (Kiefer and Larson 2007; Frydman and Schuermann 2008).

The implication is that rating history provides important diagnostic information in making well-calibrated estimates for FAs. Financial institutions and regulators should condition models of rating migrations by reference to the path an issuer has followed to the current rating state. If, for example, an issuer is a FA, then it may need a FA dynamic hazard model to obtain appropriate time-varying survival probability estimates.

A natural extension of this study would be to employ rating outlook or credit watch data as a time-varying covariate to capture the changing credit quality of issuers over rating durations. The study could also be extended by using a moving window and continually updating/recalibrating the models to capture the acceleration in credit deterioration. Future work could also be directed to estimate separate dynamic hazard models over economic contraction and expansion periods and to examine credit quality changes under favorable and unfavorable macro environment.

Appendix 1: Maximum Partial Likelihood Estimation

The expression in Eq. 72.1 for the Cox's proportional hazard model and the expression in Eq. 72.3 for the full partial likelihood are repeated here as Eqs. 72.17 and 72.18 for convenience:

$$h_m[t, Z] = h(0, t)\exp[Z^m \beta] \tag{72.17}$$

$$PL = \prod_{m=1}^{N} L_{t_m}^m = \prod_{m=1}^{N} \left[\frac{\exp(\beta \ Z^m)}{\sum_{i \in R(t_m)} \exp\left(\beta \ Z^i\right)} \right] \tag{72.18}$$

The log partial likelihood function can be written as

$$PL = \sum_{m=1}^{N} \left[(\beta \ Z^m) - \ln \left[\sum_{i \in R(t_m)} \exp\left(\beta \ Z^i\right) \right] \right] \tag{72.19}$$

The derivative of Eq. (72.19) with respect to β is

$$\frac{\partial PL}{\partial \beta} = \sum_{m=1}^{N} \left[Z^m - \frac{\sum_{i \in R(t_m)} Z^i \exp\left(\beta \ Z^i\right)}{\sum_{i \in R(t_m)} \exp\left(\beta \ Z^i\right)} \right] \tag{72.20}$$

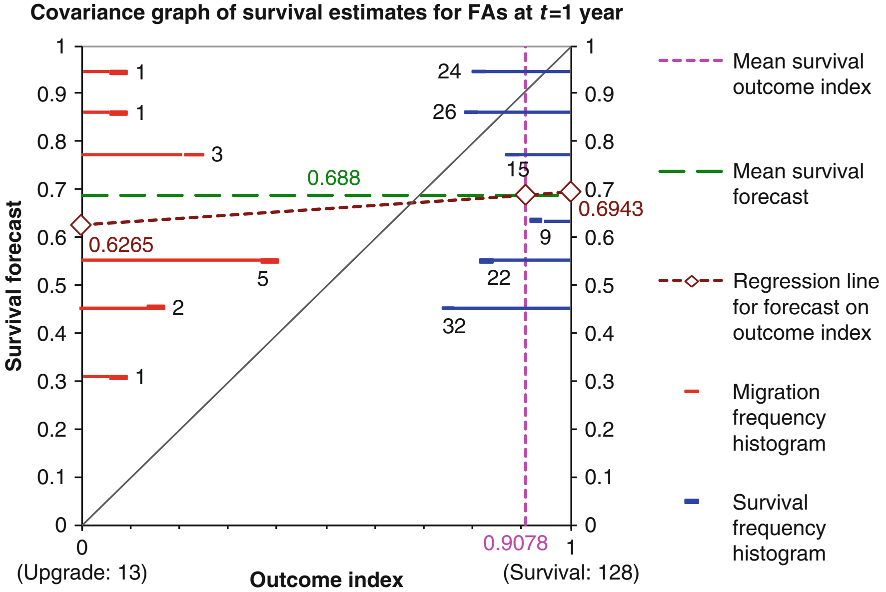
$$\frac{\partial PL}{\partial \beta} = \sum_{m=1}^{N} \left[Z^m - \sum_{i \in R(t_m)} w_{im}(\beta) Z^i \right]$$

$$\frac{\partial PL}{\partial \beta} = \sum_{m=1}^{N} \left[Z^m - \overline{Z}^{w_{im}} \right]$$

where $w_{im}(\beta) = \frac{\exp\left(\beta \ Z^i\right)}{\sum_{i \in R(t_m)} \exp\left(\beta \ Z^i\right)}$ and $\overline{Z}^{w_{im}} = \sum_{i \in R(t_m)} w_{im}(\beta) Z^i$

The estimated coefficient vector $\hat{\beta}$ can be obtained by setting the derivative in Eq. 72.20 equal to zero and solving for the unknown parameter (Hosmer et al. 2008, pp. 75–76).

Appendix 2: Covariance Graph



Brier score $B_t = 0.1578$; outcome index variance $\overline{d}_t(1-\overline{d}_t) = 0.0837$; bias $\overline{f}_t - \overline{d}_t = -0.2198$; slope $\overline{f}_1 - \overline{f}_0 = 0.0677$; forecast variance (Scatter) $S^2_{f_t} = 0.0372$

Yates (1982, pp. 143–148) and Arkes et al. (1995, pp. 121–123) provide detailed descriptions of a covariance graph. For illustration purpose, the above covariance graph depicts the characteristics of the 1-year survival forecasts generated by the proportional Cox's hazard upgrade model for FAs.

The abscissa shows the survival outcome index. The two possible outcomes for a FA in the upgrade model are "upgrade," which is denoted as 0 on the left, and "survival" (non-upgrade), which is denoted as 1 on the right. Of 141 holdout FAs available at 1-year lead time (forecast time $t = 1$ year), 128 FAs survived, and 13 FAs were upgraded. A vertical dotted line is located at the survival base rate, or the overall mean survival outcome index $\overline{d} = 0.9078$, on the abscissa. On the ordinate are the probability survival forecasts, categorized in deciles. A horizontal dotted line is located at the overall mean survival forecasts $\overline{f} = 0.688$ on the ordinate. The 45° solid line represents unbiased estimates. Bias can be measured as the vertical distance from the 45° line to the point where the vertical survival base rate line and the horizontal mean survival forecast line cross (marked as ◊). If a model produces unbiased forecasts, the vertical and horizontal dotted lines will cross on the 45° line, corresponding to a zero bias. If the two dotted lines meet below (above) the diagonal line, the model underestimates (overestimate) the survival outcome, corresponding to a negative (positive) bias.

In the covariance graph, the static upgrade model for FAs is 21.98 % too pessimistic in making 1-year survival forecasts.

On the vertical lines above the survival outcome (1) and the upgrade outcome (0) indices are the histograms for survival forecasts of 128 FAs that actually survived and 13 FAs that were upgraded, respectively. Survived and non-survived holdout FAs are stratified into distinct decile categories in the order of estimated survival probabilities. In this setting, FAs with survival forecasts varying from 0 % to 10 % are put together, those with forecasts ranging from 11 % to 20 % in another decile category and so on. The bars on the histograms illustrate the percentage of survival forecasts made at the individual probability deciles. The number of survival forecasts observed within each decile was attached to the corresponding bar for an easy reference. The further the histogram bars spread along the vertical lines, the greater the scatter (variance) of the survival forecasts.

The outcome index line extending vertically from 1 (on the right edge) includes the mean survival forecasts given to FAs that actually survived, $\bar{f}_1 = 0.6943$. The outcome index line drawn vertically from 0 (on the left edge) contains the average survival forecasts given to FAs that were actually upgraded, $\bar{f}_0 = 0.6265$. The dotted line linking $\bar{f}_1$ and $\bar{f}_0$ is the regression line for survival forecast on outcome index. The slope of the regression line is the difference between $\bar{f}_1$ and $\bar{f}_0$, or $\left(\bar{f}_1 - \bar{f}_0\right) = 6.77\ \%$. The further the regression line diverges from the horizontal line, the more discriminative the forecasts of the survived and upgraded groups.

Acknowledgments I am grateful to Capital Market Cooperative Research Center (CMCRC) for funding support. I wish to thank Paul Allison, Tony Hsiu His Chen, Sam Li Sheng Chen, and Amy Ming-Fang Yen for programming advice. Thanks are also due to Bob Kelly, Cheng-Few Lee, Graham Partington and Margaret Woods and for participants of the CEQURA Conference on Advances in Financial and Insurance Management for helpful comments.

Abstract

Persistent divergence of an asset price from its fundamental value has been a subject of much theoretical and empirical discussion. This chapter takes an alternative approach of inquiry – that of using laboratory experiments – to study the creation and control of speculative bubbles. The following three factors are chosen for analysis: the compensation scheme of portfolio managers, wealth and supply constraints, and the relative risk aversion of traders. Under a short investment horizon induced by a tournament compensation scheme, speculative bubbles are observed in markets of speculative traders and in mixed markets of conservative and speculative traders. These results maintain with super-experienced traders who are aware of the presence of a bubble. A binding wealth constraint dampens the bubbles as does an increased supply of securities. These results are unchanged when traders risk their own money in lieu of initial endowments provided by the experimenter.

The primary method of analysis is to use live subjects in a laboratory setting to generate original trading data, which are compared to their fundamental values. Standard statistical techniques are used to supplement analysis in explaining the divergence of asset prices from their fundamental values.

Keywords

Speculative bubbles • Laboratory experimental asset markets • Fundamental asset values • Tournament • Market efficiency • Behavioral finance • Ordinary least squares regression • Correlation

73.1 Introduction

The purpose of this study is to investigate the formation of speculative bubbles in asset prices under a laboratory setting.[1] Specifically, we investigate how to create, control, and dismantle bubbles as well as the conditions in which bubbles may or may not arise.

Speculative bubbles are induced in this study under a laboratory setting, where a New York Stock Exchange type of double-oral auction market (without a specialist) involving many traders is modeled. Speculative bubbles occur when buyers are willing to bid higher and higher prices for an asset which, in retrospect, are far in excess of its worth based on fundamentals. The bubbles ultimately burst and prices drop to a much lower level.[2] The stock market crash in

[1]The paper was previously published as Ang et al. (2009). The creation and control of speculative bubbles in a laboratory setting. In Lee, A., and Lee, C.F. (Eds.), *Handbook of Quantitative Finance and Risk Management* (pp. 137–164). Springer, New York.

[2]Stiglitz (1990), in his overview of a symposium on bubbles, defines the existence of bubbles to be: "if the reason that the price is high today is only because investors believe that the selling price will be high tomorrow – when 'fundamental' factors do not seem to justify such a price." Similarly, he defines the breaking of a bubble as marked price declines which occur without any apparent new information.

the USA in 1987 and in Japan in 1991–1992, the dot-com bubble in 2,000, and the recent housing bubble in the USA are examples.[3] In recent years, academicians and practitioners are slowly but grudgingly coming to the realization that the extant theories of stock market behavior, e.g., efficient market hypothesis and capital asset pricing theory, fail to explain the magnitude of fluctuations in the stock market. Not only have stock prices been found to fluctuate too much relative to fundamentals, but also there have been occurrences of speculative bubbles that could not be explained by arrival of new information. Several plausible explanations for bubbles are offered such as rational bubbles (Shiller 1988; West 1988), irrational bubbles (Ackert et al. 2002; Lei et al. 2001), judgement error (Ackert et al. 2006), and herding behavior (Froot et al. 1992).[4]

While some work has been done to show that bubbles can be abated with experience (Dufwenberg et al. 2005), an understanding of the formation of speculative bubbles is still important to researchers for several reasons. First, bubbles could cause significant disruptions in the asset market, not only by creating a large redistribution of wealth among investors but also by adversely affecting the supply of funds to the market as well as resource allocation among and within firms. Second, the identification of factors affecting the formation of bubbles is crucial in aiding regulators in designing policies to reduce the occurrence or magnitude of bubbles. In particular, if bubbles can be replicated in a laboratory setting, then various proposals to dampen bubbles could also be tested and compared for their effectiveness. Roll (1989) summarizes the difficulty with examining recent empirical results of the 1987 crash in this regard. Third, an understanding of the dynamic process of bubble formation would contribute to our knowledge of how to model the behavior of asset prices DeLong et al. (1989), Cutler et al. (1989).

In spite of some interesting recent theoretical developments, empirical research on the existence of bubbles tends to be inconclusive and with low power, e.g., Gurkaynak (2005), West (1988), Flood and Hodrick (1990). A major problem is the difficulty of specifying the fundamental value of an asset, since bubbles are defined as the price in excess of the fundamental values Bierman (1995), Robin and Ruffieux (2001). Without being able to calculate the time series of the asset's fundamental value, price movement could simply be caused by factors affecting the fundamental valuation of the asset, e.g., change in risk aversion and arrival of

---

[3]Other notable examples of bubbles include the Dutch tulip mania in the seventeenth century, the South Sea Islands Company bubbles Voth and Temin (2003), John Law's Mississippi Company scheme bubbles of the eighteenth century, the US stock market boom of the late 1920s, the Florida land price bubbles of the 1920s, the great bull market of the 1950s and 1960s, the high-tech stock boom of the early 1980s, and the boom and bust of the California and Massachusetts housing markets in recent years. However, due to the difficulties in specifying the fundamentals, there are still disagreements as to whether these cases could be explained by the fundamental, e.g., Garber (1990) versus White (1990).

[4]Outstanding surveys of this literature are provided by Porter and Smith (2003), Camerer (1989), Sunder (1992).

new information. And if the fundamental value could only be measured imperfectly using proxies such as past dividends, the imprecise estimates would, of course, reduce the power of any test.

The experimental approach reduces this problem (Cason and Noussair 2001). By design, the value of the fundamentals can be specified in advance; hence, there is no measurement problem. Any gross and persistent divergence of the asset price from the prespecified fundamental value can now be attributed to bubbles (Siegel 2003). In addition to reducing the identification/measurement problem, performing laboratory experiments to study asset bubbles has two other advantages. First, it allows different characteristics of the market institutions and participants to be introduced in a controlled manner. That is, relevant factors may be manipulated to create or discourage the formation of bubbles. This is an important feature because some of these factors may not be isolated in the real world for detailed study, while other factors are simply proposals in the design of market institutions of the future. Second, by controlling the information available to market participants, we can control the role played by unrelated or exogenous events, e.g., sunspots. Thus, the laboratory experiment approach to study asset market behavior complements the theory/model building process. The three types of variables chosen for analysis in this study are:

1. The compensation scheme of a portfolio manager. Allen and Gorton (1988) have argued that compensation schemes for portfolio managers may induce bubbles even in a finite horizon. Also, recent literature on tournaments (see James and Issac (2000), Ehrenberg and Bognanno (1990), and others) has shown that the level and structure of relative compensation influence participant behavior, while Hirota and Sunder (2005) have found that short horizons are important factors in the emergence of bubbles. Three types of compensation structure are used in these experiments: a linear compensation scheme based on portfolio performance and two versions of compensation based on relative performance in a short-term horizon.
2. Wealth constraint (tight/loose), supply of securities. An infinite number of trades (e.g., overlapping generations and the availability of credit) are often cited as a prerequisite for bubbles. Ricke (2004) discusses how credit made available from margin could generate bubbles. High liquidity leads to bubbles in the work of Caginalp et al. (2001). Scheinkman and Xiong (2003) and Hong et al. (2004) analyze the effect of a short sales constraint on the formation of bubbles. Therefore, experimenting with wealth constraints may provide valuable insights into the effectiveness of certain policies (such as margin rule change, credit availability) to control bubbles.
3. The type of investors in the market (speculative/conservative). This variable tests the Keynes-Hicks theory of speculation where differences in traders' willingness to take risks are the foundation of speculative markets. Traders in the experiments are pretested for attitudes toward risk taking.

   Bubbles are observed under the following conditions:

1. A market of speculators with short-term investment horizon.
2. A market of mixed conservative and speculative traders with short-term investment horizon.

3. A market of mixed trader types with short-term investment horizon using their own money.

On the other hand, bubbles are dampened under the following investment environments:

1. A market of conservative traders with a short-term horizon;
2. A market of mixed trader types with a long-term investment horizon;
3. A market of mixed trader types when the wealth of the traders, especially the bulls, is constrained;
4. A single-period trading environment.

The remaining part of this chapter is organized into four sections. Section 73.1 presents the hypotheses to be tested by incorporating them into the experimental design, which is discussed in greater detail in Sect. 73.2. The results are reported in Sect. 73.3 with Sect. 73.4 summarizing and concluding the chapter.

73.2 Bubbles in the Asset Markets

The possibility of asset bubbles has long been recognized; however, more formal theoretical development is of relatively recent vintage. Harrison and Kreps (1978), for instance, suggest that in general the right to resell the asset makes traders willing to pay more for it than they would if obliged to hold it forever. Thus, market price could exceed fundamental value. Literature on rational bubbles emphasizes that once a bubble is started, it would be rational to price the bubble component even if it is expected to burst with positive probability. Brunnermeier and Nagel (2003) examine stockholdings of hedge funds during the recent Nasdaq tech bubble and find that the portfolios of these sophisticated investors were heavily tilted toward (overpriced) technology stocks. However, this does not seem to be the result of unawareness of the bubble on the part of hedge funds.[5] At an individual stock level, hedge funds reduced their exposure before the prices collapsed, suggesting awareness and implicit pricing of the bubble component. On the other hand, whether bubbles can even get started has been questioned (Diba and Grossman 1987). Essentially, if there are a finite number of periods, starting from the next to the last period, the expectation that the bubble might end may be sufficient to keep it from ever starting. By the process of backward induction or an unraveling argument, bubbles will not exist. Moreover, if the number of trades is finite, withdrawal of early trades at a profit means the remaining traders would be at a negative sum game, i.e., with finite trades, will there be a "greater fool" who gets stuck when the bubble bursts.

[5]Griffin et al. (2003) examine the extant theoretical literature about bubbles which includes models where naive individuals cause excessive price movements and smart money trades against (and potentially eliminates) a bubble versus models where sophisticated investors follow market prices and help drive a bubble. In considering these competing views over the tech bubble period on Nasdaq, they find evidence which supports the view that institutions contributed more than individuals to the spectacular Nasdaq rise and fall.

Still, perturbing the model by adding uncertainties on the length of the horizon among traders or market size may preserve the possibility of asset bubbles.

Smith et al. (1988) are among the first to investigate the incidence of bubbles. Their design was to give traders common beliefs (according to one of Tirole's requirements) and long horizons of up to 15 trading periods. Bubbles are observed in several of their experimental markets. It is unclear, however, what institutional setting, other than long trading periods, induces bubbles in their study.

In a speculative market where bubbles could be present, speculative traders are more likely to purchase shares (and even more so, if bubbles are rationally priced) than risk-averse traders. Not only are they more willing to put a higher value on risky assets, they are also more likely to take the chance that they might not be able to sell out their inventory before the bubble bursts. Therefore, our first hypothesis is that bubbles are more likely to be formed in a market of risk-taking traders (speculators).

The compensation scheme could also affect the behavior of traders. For instance, Allen and Gorton (1988) and Allen and Gale (2002) show that an option-type compensation scheme for portfolio managers could induce speculative bubbles in asset prices. Portfolio managers are encouraged via incentive rewards to generate short-term trading gains even in a finite horizon world. The current practice of publishing and ranking the short-term investment performance of portfolio managers and the very substantial incentives to hedge fund managers' performance that may be based on unrealized gains on illiquid assets could give rise to adverse incentives. Portfolio managers who are concerned about these rankings will either take on a riskier strategy for the possibility of outshining their peers or they will simply play it safe and follow the crowd. Both portfolio strategies could lead to the formation of bubbles. The play safe by "following the herd" strategy will cause asset prices to have a strong positive correlation in the short term. Portfolio managers would be buying when others are buying, thus creating an upward price trend, and selling when others were selling, thus bursting the bubble it created. On the other hand, the pursuit of a risky strategy may be sufficient to create price leadership that is followed by others in the market. This would be more likely in an uncertain valuation environment. Temin and Voth (2003) suggest that riding the bubble may actually be a profitable strategy.

Portfolio managers are subject to an occupational hazard: unless they produce winning results, they stand a good chance of being fired. On the other hand, star performers receive seven or even eight figure incomes as new cash flows into the funds they manage. This compensation system is similar to tournament models where participants are paid according to their relative performance among a group of peers rather than on their absolute performance. Tournament systems are likely to produce increased performance when (1) there is difficulty in monitoring the activities of the agent (Rosen 1981), (2) when the agent possesses valuable information (Baker 1992), and (3) when good performance measures are available (Baker 1992). All three of these conditions exist in the realm of professional money management, and therefore it is probable that a relative performance compensation system will be effective in increasing manager performance.[6] Thus, it is hypothesized that a tournament incentive scheme that encourages a short-term horizon for portfolio managers is more likely to create bubbles.[7]

Finally, an important policy question has been whether restricting the availability of credit or the supply of securities in a market (by raising the margin requirement or allowing short sales) could reduce or even eliminate the formation of speculative bubbles. Ackert et al. (2006) find that price run-ups and crashes are moderated when traders are allowed to short sell). Most countries, including the USA and Japan, have adjusted these conditions in the recent past through adjustments in the use of stock index futures and by easing credit conditions. These changes have tended to occur subsequent to large declines in the country's equity markets. With limited or asymmetric ability to go short versus long, speculators on the long side have an advantage in acquiring funds for investment. Additionally, if the life of a bubble is uncertain and relatively long lasting, costly short sell will not be profitable even if the bubbles eventually burst. The usual experimental design often endows traders with a relatively large initial wealth such that the budget constraint is not binding. This experiment will test the effect of a tighter budget constraint by both reducing the initial endowment and increasing the supply of securities. It is hypothesized that a wealth constraint and/or relative increase in the supply of securities will reduce the incidence of bubbles.

To summarize, the effect of three factors, attitude toward risk, investment horizon, and wealth constraint, is examined as to their contribution to the creation and control of asset bubbles. They are tested by incorporating them into the experimental design of a laboratory setting described below; the importance of these factors in the formation and control of asset price bubble, singly and jointly, can now be formally examined.

73.3 Experimental Design

The evolutionary nature of laboratory experimental research is such that the results of any study act as a catalyst for new questions and therefore new experiments. As with Smith et al. (SSW) (1988), we note that many of our latter experiments were directly motivated by the results obtained from our earlier ones. This progression of thought and analysis will be apparent in the later section on results. Herein, however, we present the method of our investigation in comprehensive form.

[6]Becker and Huselid (1992), Ehrenberg and Bognanno (1990) have documented in field studies that such tournament compensation systems are effective in raising performance in professional golf and auto racing competitions.

[7]It is possible that if there is sufficient number of short horizon portfolio managers herding in the manner described by Froot et al. (1992), a bubble can start on basis of any information. Shleifer and Vishny (1990) also propose that the portfolio managers have short horizon; however, it is the risk of uncertain return from investing in the longer horizon that prevented disequilibrium to be arbitraged away.

Table 73.1 Experimental design

Participant groups[a]	Design	Initial endowment[b]	Investment horizon[c]	Risk aversion[d]	Experiments[e]
Las Vegas	1	2 securities 10,000 francs	Two period	Mixed	1, 2, 3, 5$
Las Vegas	2	2 securities 10,000 francs	ShortenedMixed		4m, 6m$
Las Vegas	3	5 securities 3,000 francs	ShortenedMixed		7x, 8x, 9t, 10t
FSU1	4	2 securities 10,000 francs	Two period	Single type	11s, 13c
FSU1	5	2 securities 10,000 francs	ShortenedSingle	Type	12sm, 14cm
FSU2	2	2 securities 10,000 francs	ShortenedMixed		15, 16
FSU2	6	10 securities 1,000 francs	ShortenedMixed		17, 18
Albania	1	2 securities 10,000 francs	Two period	Mixed	23
Albania	2	2 securities 10,000 francs	ShortenedMixed		24, 25
Albania	6	10 securities 1,000 francs	ShortenedMixed		26
Albania	7	2 securities 5,000 francs	Single Period	Mixed	19
Albania	8	2 securities 5,000 francs	Single Period/ Tournament	Mixed	20, 21
Albania	9	20 securities 500 francs	Single Period/ Tournament	Mixed	22

This table categories five designs of 14 experiments used to examine the impact of risk aversion, investment horizon, and credit/supply constraints (initial endowment) upon the formation and control of asset bubbles.

[a]The participant groups consist of the following:

Las Vegas represents students from the University of Las Vegas at Nevada.

FSU1 and FSU2 represent students from the Florida State University at two different time periods.

Albania represents students from the University of Tirana in Albania.

[b]The initial endowment refers to traders wealth position at the beginning of each trading year of an experiment. This endowment allows traders to sell (using provided securities) or buy (using francs, the currency used in these experiments). The additional securities and reduced currency endowments provided in Design 3 serves to better equate relative purchase and selling abilities.

[c]Investment horizon refers to the horizon within which traders effectively operate. A two-period horizon refers to a market where period A securities are based on the dividends paid in both periods (A and B) of a trading year. In a shortened investment horizon, the trader is induced (via the tournament compensation schedule of Table 73.3) to operate with a horizon which is shorter than the two-period environment in which the securities will pay dividends.

[d]Mixed risk aversion means that traders with various risk preferences were participants within the same market. Single type means that only speculative (s) or conservative (c) traders made up that market. The designations (s) and (c) appear next to experiments 11–14 in the last column.

[e]Notation is as follows:

$ represents a market where traders provided $20 of their own money to trade, the sum of which became the pool of money dispersed according to relative profit performance.

m,x,t represents the number of traders receiving the tournament prize as outlined in Table 73.3. This tournament compensation was used to induce a shortened horizon market and was differentially paid to the top two (t) or the top six (x) traders. In experiments marked (m), the first three trading years paid a bonus to the top six traders followed by years where only the top two traders received bonuses.

The creation of "bubbles" within asset markets is examined under the control of three primary factors: (1) the degree of trader risk aversion, (2) trader investment horizon, and (3) available investment capital/supply of securities. Table 73.1 summarizes the design of 14 experiments used to investigate these factors upon the presence of asset bubbles. Each of these experiments uses a common market mechanism that builds upon the earlier work of Forsythe et al. (1982), Plott and Sunder (1982), Ang and Schwarz (1985). These common features are summarized below.

73.3.1 General Market Design

1. A double-oral auction, similar to that used on the floor of major US exchanges, is replicated. The recruited traders are physically present within a single room during the course of trading. These traders are independent and trade solely for their own account. There are no specialists or other privileged traders.
2. Only those shares of a single generic security are traded. The sole attribute of these shares is the payment of dividends at the end of each period.
3. Each market (experiment) has ten trading periods. These periods are further categorized into five trading years, each of which consists of two contiguous trading periods (A and B). Endowments (discussed below) are reinitialized at the end of the second period of each year. Thus, the initial market represents a two-period model with each security entitled to two payoffs (dividends), one at the end of period A and the other at the end of period B.[8]
4. Each trading period lasts for 6 min, with opening, warning (at 5 and 5 1/2 min), and closing bells. Consequently, each experiment has a total of 60 (6 min $\times$ 10 periods) trading minutes. During the 6-min periods, traders can observe the continually updated bid-ask and past transacted prices.

73.3.2 Dividend Design

1. At the beginning of each year, each trader is endowed with trading capital and shares of the generic security. Each share pays dividends at the end of the first (A) and second (B) periods. The second period dividend is a liquidating dividend. Reinitializing of position at the beginning of each year allows for replication of decision making in experimental markets.[9]

---

[8]In the experiment, a trader has at least the following choices available:

(a) Maintain the endowed position by not trading and receiving the stochastic payoffs at the end of each period.
(b) Hold the securities through period A and sell in period B, in which case the investor will receive the first period dividend and the selling price.
(c) Sell the initial holdings in period A to receive the sale price.
(d) Buy additional shares in period A, receive dividends at the end of the period, and then sell the securities in period B.
(e) Sell the securities in period A and then buy back securities in period B in order to receive the dividends.
(f) Purchase a net amount of shares in both periods.
(g) Purchase and sell shares within each period.

[9]See Smith et al. (1988) for an example of when reinitialization is not used.

2. The dividends to be paid at the end of each period are stochastic. Two equally likely dividend outcomes are possible, the good (G) state and the bad (B) state. The realized state is announced at the end of each 6-min trading period as determined by the flip of a coin by the experimenter.
3. The dollar amount of the dividends paid at the end of each period depends upon the trader's type and the realized state. The 12 traders who make up each market are classified into three types to allow for differences in induced values. The dividend payouts for these three trader types are summarized in Table 73.2. As an example, at the beginning of year 1, the four traders of type I are privately informed that for period A they will receive either 350 or 110 for the good (G) and bad (B) states, respectively, and for period B either 250 or 150 for the good and bad states, respectively.
4. The trader type with the highest expected dividend (.5 × good dividend +.5 × bad dividend) is rotated each period so as to enhance trader uncertainty about equilibrium prices. Virtually all previous experimental studies have documented that given sufficient learning (through repeated trading) in a stationary dividend payout environment, prices will rather quickly approach the rational equilibrium level. This learning has two sources: (a) observation that one's own payouts are not changing and (b) observation that market-generated bids, offers, and transacted prices are not changing. Our expectation is that the greater the trader's reliance upon market-generated (as opposed to prior dividend) information, the more likely bubbles are to occur due to bandwagon and other crowd psychologies. If, instead of bubbles, we should observe that prices converge to rational equilibrium prices (as in the constant dividend studies), then this would strengthen our knowledge concerning efficiency in these laboratory markets. This result would also suggest that trading methods based upon historical prices alone would not have value.

73.3.3 Investment Horizon

1. Three types of investment horizon are provided within these experiments: a single-period, a two-period, and a shortened horizon. Initially, at the beginning of each trading year, a trader is entitled to two stochastic dividends for each security held, one each at the end of periods A and B. Therefore, at the beginning of period A, a rational trader will value the security for both its period A and period B stochastic dividends. Hence, all A period pricing should reflect a two-period investment horizon. Subsequent to the termination of period A trading and the announcement and payment of the period A dividend, period B trading proceeds. As the security is now only entitled to the B period dividend, a single-period investment horizon results for all B periods. Our hypothesis is that a shortened investment horizon increases the possibility of an asset pricing bubble. We test for this by creating

Table 73.2 Dividend design

Years[a]	Trader type[b]	Period A dividend state[c] G	B	Expected dividend[d]	Period B dividend state[c] G	B	Expected dividend[d]	Yearly expected dividend[e]
1	I	350	110	230*	250	150	200	430*
	II	250	150	200	200	140	170	370
	III	200	140	170	350	110	230*	400
2	I	200	140	170	350	110	230*	400
	II	350	110	230*	250	150	200	430*
	III	250	150	200	200	140	170	370
3	I	250	150	200	200	140	170	370
	II	200	140	170	350	100	230*	400
	III	350	110	230*	250	150	200	430*
4	I	350	110	230*	250	150	200	430*
	II	250	150	200	200	140	170	370
	III	200	140	170	350	110	230*	400
5	I	200	140	170	350	110	230*	400
	II	350	110	230*	250	150	200	430*
	III	250	150	200	200	140	170	370

This table presents the cash flow payoffs which a single asset will provide to its owner. This payoff is different for Trader Types I, II, and III and therefore provides for different fundamental valuations. Rational Expectations Equilibrium are determined by the trader type with the highest valuation for that period.

[a]Each experiment is composed of five trading years, each of which contains two trading periods A and B. Ownership of an asset in period A entitles the bidder of both period A and Period B dividends (two-period valuation) whereas period B ownership merits only that period's dividend (single-period valuation).

[b]There are three trader types in each trading year with four traders in each category. These trader types only differ by the amount of dividend cashflows that the single traded asset will provide its holder. The four traders within each category are rotated within the other categories so as to maintain an uncertain valuation environment.

[c]Dividend States refer to the stochastic payoff that will be provided to specific trader types given the occurrence of the G (Good) or B (Bad) state. The realization of the state of nature is determined at the end of each trading period by flipping a fair coin.

[d]Given equal fifty percent probability of occurrence of G or B, the expected dividend is the simple average of period G and B payoffs.

[e]The yearly expected dividend represents the summation of expected dividend for both periods A and B.

*Signifies trader type with the highest expected value

a tournament compensation package in period A. The incentive for traders is to concentrate upon their single (A)-period performance over the concerns of a rational two-period price. This incentive results in a shortened investment horizon.[10]

[10]It is important to note that there is a difference between a one- and two-period horizon and a shortened horizon. In a one-period model, only a single dividend is valued. In a two-period model, two dividends are valued. In our shortened investment horizon, the trader is induced to operate within a horizon that is different from that of his operating environment. That is, within

2. In this study, initially, a trader's dollar compensation is defined by the following in which we alter the compensation structure to induce a change in the length of a trader's investment horizon profit function:

$$P_i = f\left[d_{i,j,A} \cdot X_{i,A} + d_{i,j,B} \cdot X_{i,B} + (R_i - C_i)\right] \tag{73.1}$$

where:

P_i = dollar profit per trading year for trader i. It consists of dividend income and trading gains (losses) from both periods.

f = the conversion rate of francs into dollars.[11]

$d_{i,j,t}$ = the dividend paid in francs to trader i, given state j occurs in period t; j = G or B; t = A or B.

$X_{i,t}$ = the number of shares held by trader i at the end of period t; t = A or B.

R_i = revenues in francs for trader i for all shares sold during periods A and B.

C_i = costs in francs for trader i for all shares purchased during periods A and B.

In order to induce pressure for a shortened investment horizon, an additional compensation package is introduced in period A of some experiments as identified in Table 73.1. This tournament compensation system is based on the traders' relative performance as measured by the Tournament Performance Index (TPI) below:

$$TPI_i = R_i - C_i + MX_{i,A} \tag{73.2}$$

where R_i, C_i, and $X_{i,A}$ are as previously defined and M represents the closing market value of the shares. This closing market value is taken to be the price of the second to last transacted price for that period. This procedure is introduced in order to reduce the possibility of manipulating market value by collaboration on a final transaction. It represents a simplified version of the price-averaging process that takes place on most organized exchanges for the setting of opening and closing prices.

3. The tournament compensation system provides traders with an incentive to outperform each other in period A only. This incentive system increases the importance of single-period performance (in A) over two-period concerns; that is, it induces a shorter investment horizon in period A. A trader's compensation is dependent upon his relative rank as summarized in Table 73.3. In Schedule Six, the top six (of 12) traders are rewarded with francs ranging from 1,500 to 200.

---

a two-period operating environment, the trader is given an incentive to operate with a shorter (possibly single)-period horizon. This is quite different from a single-period model. This shortened horizon is a stronger test of market efficiency, in that the pressures are away from rather toward rational equilibrium prices, (as defined in Eq. 73.4, subsequently). The methodology is meant to emulate modern portfolio managers operating in an environment of perpetual horizon stock securities yet receiving tournament incentives to outperform colleagues on a short-term basis.

[11] Francs are the currency used within this study. They have been used successfully by Plott and Sunder (1982), Ang and Schwarz (1985), as well as others. Their primary benefit is to avoid the technical problem of dealing with small dollar amounts.

Table 73.3 Tournament compensation schedule

Schedule	Rank	TPI	Compensation
	1	Highest	1,500 francs
Six	2		1,000
(s)	3		700
	4		400
	5		200
	6		200
	7–12	Lowest	0
	1	Highest	3,000 francs
Two	2		1,000
(t)	3–12	Lowest	0

This table presents the additional tournament compensation schedule provided to traders based on their relative profitability in period A of certain experiments (see shortened investment horizon listed in Table 1). Relative profitability is measured by:

$$TPI_i = R_i - C_i + MX_{i,A}$$

where TPI_i is the tournament performance index for trader i, R_i is the revenues received from the sale of assets in period, C_i is the cost of assets purchased, M is the closing market value for the period, and $X_{i;A}$ represents the end-of-period asset holdings. Together the index measures the total of realized and unrealized capital gains. The addition of the tournament compensation to period A provides an incentive for traders to prefer period A capital gains over equivalent period B dividends and thereby induces a shortened (from the two period model) investment horizon.

[a]Two compensation schedules are introduced. The first provides for those traders who do better than the average (i.e., the top six) receive the additional compensation list. In the second schedule, only the top two "superstars" are richly rewarded. The tournament literature (e.g., Baker 1991) suggests that tournament systems, and especially schedule two, provide effective incentive systems to increase performance. This design is meant to emulate the short-term performance pressures faced by professional money managers.

Schedule Two is an alternative schedule which is hypothesized to induce even greater competitive pressure as only the top two traders are compensated greatly.[12] Ehrenberg and Bognanno (1990), Becker and Huselid (1992) find that the reward spread does cause increased performance incentives. Therefore, we expect Schedule Two to increase incentives for short-term pricing behavior. Table 73.1 summarizes the experimental use of the performance reward schedule.

[12]The compensation schemes depict the different ways portfolio managers are being rewarded: those who are above the average or beaten the market (Schedule Six) and those who are the superstars (Schedule Two).

73.3.4 Risk Aversion

1. Prior to selection, each potential trader was given a lengthy questionnaire. Intermingled within this material were two psychological tests on risk taking: the Jackson Personality Inventory (1976) and the Jackson et al. (1972) tests.[13] These two tests have been applied in laboratory Ang and Schwarz (1985) and field studies (Durand et al. 2006) and are more practical to administer than the theoretical risk measures found in the economics literature.[14] Those persons who score in the top 12, signifying the least risk averse, and the bottom 12, or the most risk averse, are invited to participate in the second stage of the experiment.
2. Traders for experiments 1–10 were students from the University of Las Vegas at Nevada and were recruited from a senior-level options class. These students had all taken two statistics, a corporate finance, a valuation, a portfolio analysis, and an options course. They were well trained in arbitrage, present value, and expected value. From this pool of students, 12 were chosen to participate based upon their attribute ranking in risk aversion. Participants were chosen so that a mix of risk aversion types was represented in the same market. Included were those who ranked at all levels of the scale, from high- to low-risk aversion. This was done so that differences in individual risk behavior could be tracked within an identical market environment.
3. Experiments 11–14 were conducted at Florida State University (FSU1), and as summarized in Table 73.1, these experiments were designed so that an experimental market consisted entirely of traders who were either relatively more risk averse (conservatives) or less risk averse (speculators). This experimental form allowed for evaluation of whether risk aversion is uniquely a necessary or sufficient condition for the presence of bubbles.
4. Experiments 15–26 were conducted at a later date at Florida State University (FSU2) and the University of Tirana in Albania. This was done to confirm the robustness of our results. We intentionally chose students from two

[13]The authors are aware of the work of Holt and Laury (2002) which was not available at the time of this study. According to Holt and Laury, their experiment shows that increases in the payoff level increase RRA. However, when estimating RRA, Holt and Laury assume that subject's utilities depend only on payments in the experiment. They fail to account for the wealth subjects have from other sources (see Heinemann 2003).

[14]The Jackson Personality Inventory is scientifically designed questionnaire for the purpose of measuring a variety of traits of interest in the study of personality. It was developed for use on populations of average or above average ability. Jackson states (1976, p. 9), "It is particularly appropriate for use in schools, colleges, and universities as an aid to counseling, for personality research in a variety of settings, and in business and industry." Of the 16 measurement scales of personality presented, one scale directly measures monetary risk taking using a set of 20 true and false questions. Mean and standard deviation measures for 2,000 male and 2,000 female college students are provided. Jackson et al. (1972) demonstrate four facets of risk taking: physical, monetary, social, and ethical. The authors' questionnaires are situational in that the respondent is asked to choose the probability that would be necessary to induce the respondent to choose a risky over a certain outcome. Jackson (1977) presents high internal consistency correlation between the risk measurement techniques.

different universities with different backgrounds to represent the two extremes in our test. Experiments 19–26 were administrated to subjects in Albania, who have a low degree of familiarity with capital markets, while experiments 15–18 were administered to Florida State University students (FSU2) who had taken a financial engineering course and completed another more involved laboratory asset market experiment. Hence, we consider these FSU2 students to be super-experienced relative to the students from Albania.

73.3.5 Validation Procedures

The following procedures are incorporated into the experimental design to ensure the reliability and external validity of the results:

1. To guard against the possibility that subjects' experience with trading could change their attitudes toward risk taking, they were retested. Subsequent to the first four experiments, additional risk questionnaires were given to the participants. A Spearman rank correlation (with initial risk rankings) was .902 with a t-statistic of 6.61 indicating that there had been no significant change in the relative risk attributes of the traders.
2. Videos were used to verify recorded information, to identify possible irregularities, and to train new subjects.
3. Subjects were given extensive training on the operation of the game; the main experiments were conducted on groups of experienced, if not super-experienced, traders.
4. Lengthy post-experiment questionnaires were also given to the subjects. Among other things, these were used to verify that the traders considered their trading strategies taken at the time of trade to be rational.

73.4 Results and Analysis

73.4.1 Control Experiments

For experiments 1–14, 5 experimental designs were used to test for the effects of risk aversion, investment horizon, and capital endowment upon the presence of asset bubbles. These designs are summarized in Table 73.1. The first design consisting of experiments 1, 2, 3, and 5 was control market where the two-period model was tested without extraneous influence from the three treatment variables mentioned above. Figures 73.1–73.5 plot the series of resulting prices. Bid and ask prices are represented by a "+" symbol and are connected by a vertical solid line. Transacted prices are identified by a solid horizontal line connecting each trade. From earlier laboratory studies, we would expect prices to converge to rational expectation equilibrium levels after an initial period of learning.

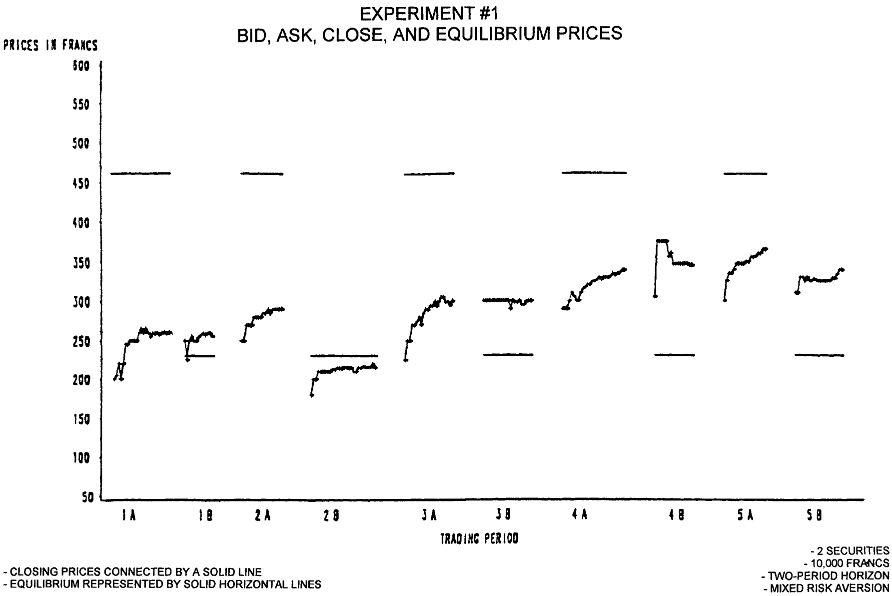

Fig. 73.1 Experiment 1: bid ask, close and equilibrium prices, two dividends with five trading periods each, and mixed risk aversion. Subjects are from Las Vegas

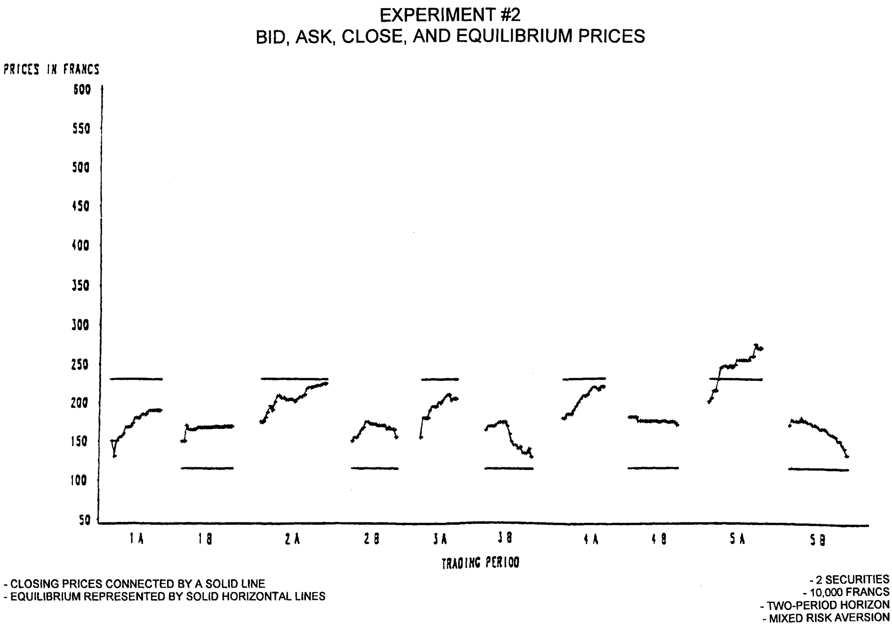

Fig. 73.2 Experiment 2: bid ask, close and equilibrium prices, two dividends with five trading periods each, and mixed risk aversion. Subjects are from Las Vegas

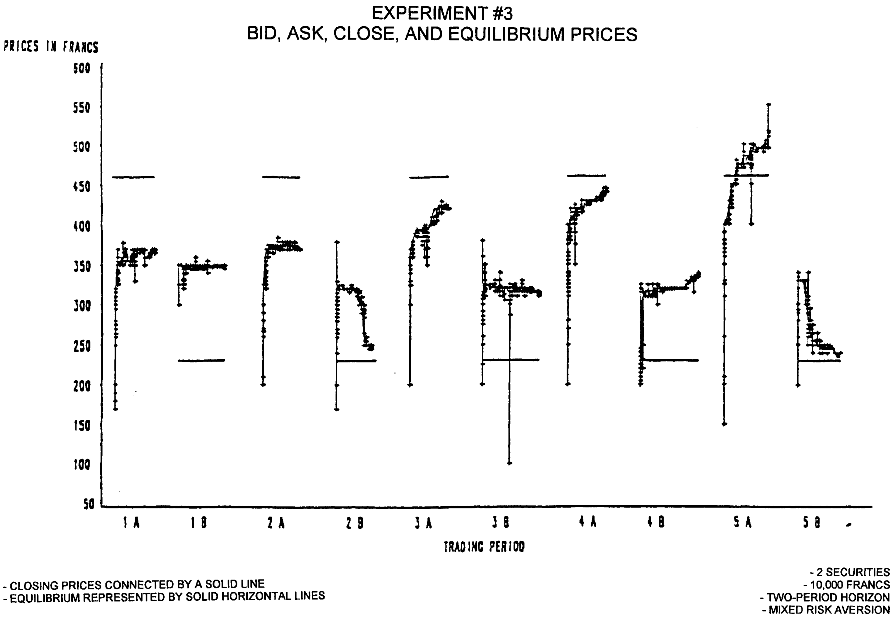

Fig. 73.3 Experiment 3: bid ask, close and equilibrium prices, two dividends with five trading periods each, and mixed risk aversion. Subjects are from Las Vegas

Two relevant concepts of equilibrium prices in these markets have been proposed (see Forsythe et al. 1982). The first is the naive equilibrium (NE) price. The NE is the highest price any trader in the market is willing to pay based upon his individual valuation of the expected dividends for the two periods or:

$$\mathrm{NE} = \mathrm{Max}_{\mathrm{k}}\left[\mathrm{E}\left(\mathrm{D}_{\mathrm{A,\,k}}\right) + \mathrm{E}\left(\mathrm{D}_{\mathrm{B,\,k}}\right)\right] \tag{73.3}$$

where:

k classifies the trader type (1, 2, or 3) based upon prior expected dividend valuations (see Table 73.2).

$E(D_{A,k})$ and $E(D_{B,k})$ are the values of expected dividends in periods A and B to the kth trader type.

The NE price is the market price that will prevail if the traders use only their private information to determine value. It is naïve in the sense that traders do not learn about the valuations of other traders from the market trading information. These traders also ignore the option value to trade, e.g., hold a security for a period and then sell it to another trader who would value it most in the remaining period.

The second is the perfect foresight equilibrium (PFE) price. It is equal to the highest total value that successive owners of the same share will pay or, in the experiment, the sum of the highest expected payoffs for periods A and B for all traders or:

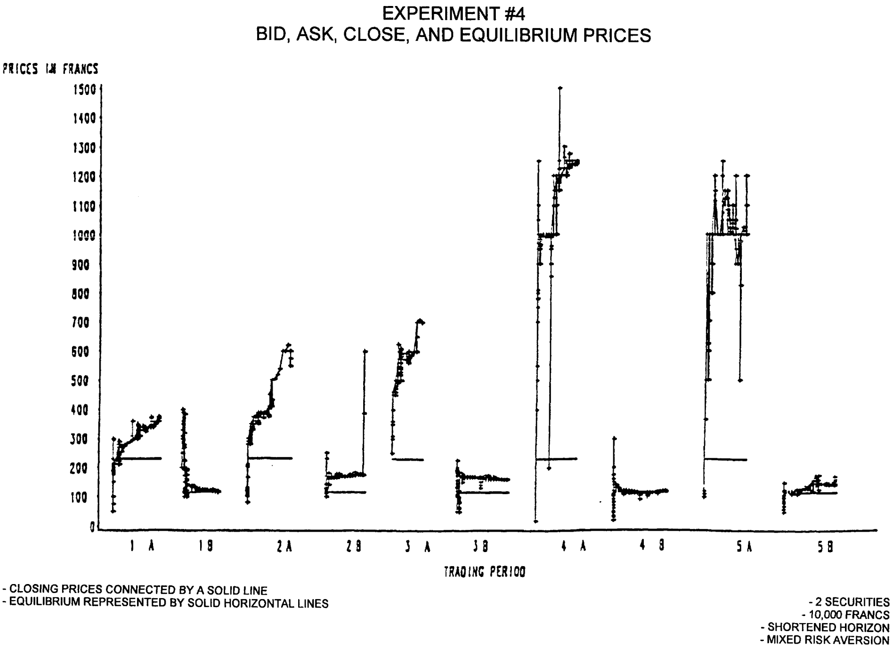

Fig. 73.4 Experiment 4: bid ask, close and equilibrium prices, one dividend with 5 trading periods, and mixed risk aversion. Subjects are from Las Vegas. Mixed bonus: to top 6 traders in first half and top 2 traders only in the second half

$$\mathrm{PFE} = \mathrm{Max}_k\,\mathrm{E}\big(\mathrm{D}_{A,k}\big) + \mathrm{Max}\,\mathrm{E}\big(\mathrm{D}_{B,k}\big) \tag{73.4}$$

These prices represent two extreme benchmarks in the continuum of the value of capital market in discovering information through trading. The NE price gives no role to capital market in price discovery, while the PFE price assumes full discovery, i.e., trading in capital market can correctly identify the share's highest value in each future holding period. They define, respectively, the lower and upper bounds of the share's fundamental value. Thus, with payoffs to traders and across holding periods under the control of the experimenters, we can now identify with certainty whether a stock is undervalued (when price is below NE) or overvalued (when price is above PFE) or is in a bubble (when price is grossly below NE or above PFE, as in a negative or positive bubble). If the experimental market captures a well-functioning capital market, learning and repeated trials would cause prices to converge toward PFE.

There are two properties in Eqs. 73.3 and 73.4 that are worth noting. First, NE and PFE prices are identical in a one-period world when price determination is closer to a simple auction of a single-period payoff. Second, when the payoff in the equations is dollars, as in cash dividends and capital gains or losses, NE and PFE give the risk neutral prices. In the absence of risk neutrality, a negative

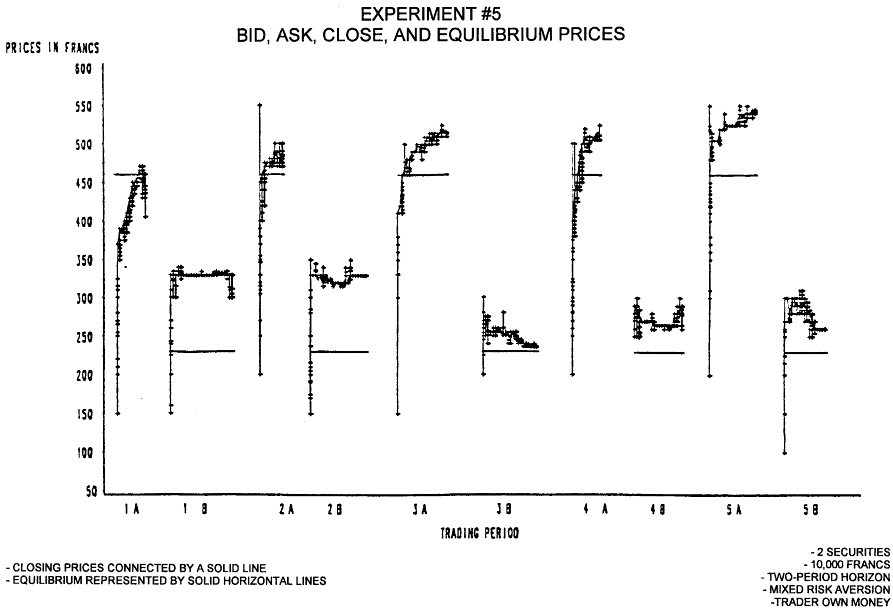

Fig. 73.5 Experiment 5: bid ask, close and equilibrium prices, two dividends periods with five trading periods each, and mixed risk aversion. Subjects are from Las Vegas and *use own funds*

difference between observed prices and these prices may be interpreted as a risk premium.

The results illustrated in Figs. 73.1–73.3 establish the validity of our experimental design as we are able to produce results similar to those obtained in previous experimental studies. In particular, we are able to reproduce the result that prices converge to PFE with learning and repeated trials. These prices are plotted as a solid horizontal line and are greater than the NE prices.[15] The inexperience of traders in experiment 1 is greatly reduced in experiments 2 and 3 as traders learn to cope with the large uncertainty in valuations (introduced by design). This pricing uncertainty

[15]Note that all odd-numbered experiments used the dividend design in Table 73.2. In order to differentiate between (1) learning about a stationary environment and (2) learning efficient valuation within laboratory markets, we created nonstationarity in equilibrium prices across experiments. In particular, for all even-numbered experiments, the dividend payoffs of Table 73.2 were simply cut in half so that rational equilibrium prices were also one-half that of the odd-numbered experiments. When this equilibrium dividend rotation is viewed in conjunction with the previously mentioned rotation of trader types, it becomes apparent that each individual trader was likely to view the environment (at least initially) as nonstationary. Consequently, any results that we show regarding equilibrium pricing and convergence would suggest that learning about valuation methods rather than a stationary environment creates rational valuation. That is, we are concerned about learning which takes place within the trader (how he values) not about the environment (stationary value). We are able to pursue this expanded question due to our debt to earlier authors who have already well established the presence of the latter.

increases the traders' reliance upon "market-generated information" in order to determine valuation. A microanalysis of traders' accounts in experiment 2 shows that some traders became actively involved in arbitrating between the A and B periods of a trading year. As a consequence, these prices tended toward their PFE equilibrium levels.

Traders' learning contributed to further pricing efficiencies in experiment 3. Some earlier "irrational" trades by selected individuals had resulted in substantial losses creating a "once-bitten" effect, and more rational decisions were followed subsequently. By the end of this experiment, prices in both the A and B periods were close to the PFE price.[16] A final examination of the validity of the experimental design was performed by requiring each trader from Las Vegas experiments 5 and 6 to "invest" his own money ($20) into the markets. As a result, it was possible for traders to lose as well as to win. The results, illustrated in Fig. 73.5, show continued price convergence toward equilibrium levels.[17] Of interest is the pattern of the bid-ask spread within a period. The data suggests that the primary resolution of uncertainty is obtained during the first transaction of a period. Subsequent trading tends to vary little from earlier levels with subsequently smaller bid-ask spread levels.

We conclude the control section noting that the experimental design creates price-revealing trades that foster PFE equilibrium pricing. While consistent with earlier research, these results extend our knowledge into a much more uncertain (nonstationary) valuation environment more typical of real-world asset markets. In addition, the validity of these results is not affected by whether or not a dollar investment is required from traders; trading behavior is similar under both environments.

73.4.2 The Formation of Bubbles

With a well-functioning experimental design established, we now sequentially introduce our hypothesized treatment variables. In experiment 4, we introduce the shortened trading horizon with a tournament prize as described in the experimental design. At this point, we have an advantage over previous studies in that we were able to recruit the identical 12 traders back. This level of experience will lead to converging equilibrium prices as opposed to bubble formation.[18]

[16]While period A prices exceeded the calculated PFE price of 460, this price is somewhat unknown to traders at this point. Prior trading results had created a history of B period prices averaging 320. Consequently, it was rational for a PFE trader to pay up to 550 (230 for A period plus 320 for B period sales price). The last trade in period 5A of 505 was well below that level. A more detailed presentation of the experimental results further reveals the rationality of these prices and is available from the authors upon request.

[17]Again, period A prices seem to drift upward due to initial excess pricing in period B.

[18]Our design is to eliminate the bubble effect of miscalculation caused by inexperienced traders as suggested by White (1990) and King et al. (1990). It is more useful and realistic to study the formation and control of bubbles in markets of experienced traders.

The effect of the tournament compensation is to shorten the traders' investment horizon in period A from a PFE two-period model. By providing tournament payment based on period A relative ranking, there is an increased incentive to generate period A capital gains over equivalent period B dividends. The tournament compensation, while increasing the incentive to win, does not necessarily equate to higher equilibrium prices. The prize is paid to the largest (realized and unrealized) relative capital gains which can be achieved in either a bull or bear market.

Extraordinary results are shown in Fig. 6.4 where five massive price bubbles are observed in each of the A periods. At this point, a new learning phase was initiated as traders competed strategically for the tournament prize. The dominant initial strategy centered on buying all available assets at increasing price levels, thereby creating artificial price support for capital gains. While this often resulted in achieving the prize, it also meant dealing with an inventory of overvalued assets in period B. Some traders actually lost money for the year even though they obtained the prize. It is important to note that the bubbles did not discourage the traders from participating, and at least for awhile the number willing to participate actually increased. Examination of asset holdings reveals that there were four to five active prize seekers in later bubbles versus one to two initially. In addition, seven to nine traders continued to hold securities at the periods' end rather than to sell out at extremely high bubble levels.

The much higher increased tournament reward structure for "superstar" performers of periods 4 and 5 (see Schedule Two of Table 73.3) resulted in the largest bubbles (consistent with our predictions) and with the greatest variability in prices and bid-ask spreads. Again, the buying frenzy in period 5 was lead by different traders than those in period 4. This continued rotation in trading leadership highlights that the results are not driven by a few misinformed traders. In fact, period B prices are very stable and efficiently priced. Furthermore, a trader questionnaire survey at the end of experiment 4 revealed that traders were fully cognizant of expected dividend value, yet they looked to both dividends and market-generated information to determine value. Traders stated that they were influenced by the behavior of their peers and were motivated to earn as much as possible. Several traders noted that the introduction of the tournament compensation stimulated them to take on more risk. The net result of these effects was to create a herd or bandwagon effect centered on market-generated information.

Despite the earlier findings of experiment 5, we tested the validity of these bubbles in an environment where traders used their own money rather than the experimenters.[19] Would such wild speculation occur when a trader's own money was at risk? Figure 73.6 clearly shows this answer to be yes. In all five A periods, average prices are over twice the equilibrium value. As before, period B pricing is very efficient and stable. That is, even though our traders engaged in bubble pricing, they arrived at it through rational means (Figures 73.7–73.10).

[19]To the author's knowledge, this is the first time traders in an experimental market of this type have used their own money to trade and still produced bubbles.

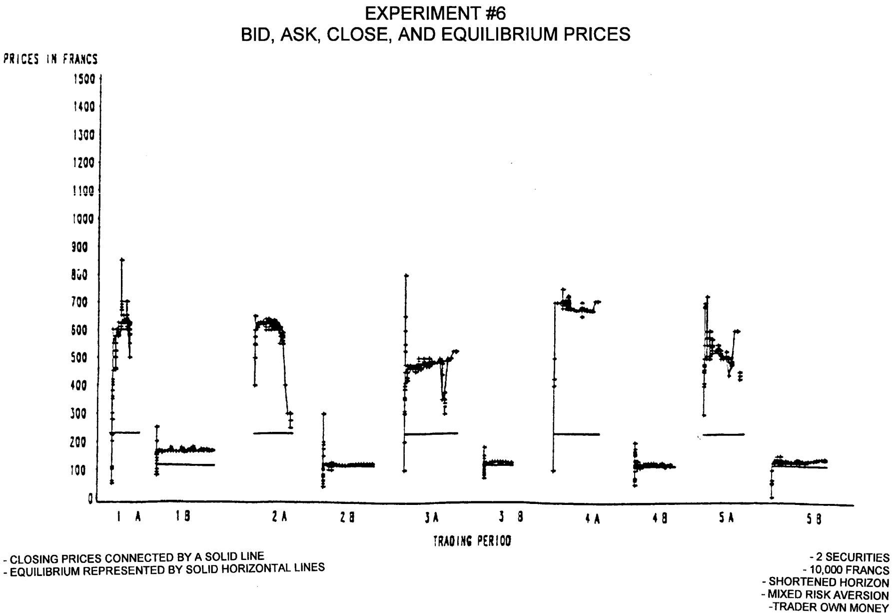

Fig. 73.6 Experiment 6: bid ask, close and equilibrium prices, one dividend with 5 trading periods, mixed risk aversion. Mixed bonus: to top 6 traders in first half and top 2 traders only in the second half. Subjects are from Las Vegas and *use own funds*

The traders in these markets had now participated in six experiments, the most of any research to date. Yet, even in the presence of super-experienced traders, we continue to find bubble formation. In addition, these traders were aware of the situation and made every opportunity to profit from the bubble.[20]

73.4.3 The Control of Bubbles

It became readily apparent from the earlier experiments that restrictions on the supply side of the market were having an influence on market prices. Many traders found themselves bound in their actions by the institutional makeup of the

[20]For instance, new strategies were employed at various stages (which perpetuated continuing uncertainty in the markets). At one time, the market actually stood still for an extended period. Then traders began to liquidate at any price rather than to replicate their earlier strategy of waiting until late in the period to sell out at bubble prices. Other traders began to try and scalp the market by driving prices both up and down, thereby generating capital gains in both price directions. Even others began to try and force losses on traders with large inventories and thereby improve their relative ranking. This was accomplished successfully in period 2A by selling at a loss (at a price below market prices) in order to create a low settle price, M (the second to last trade). Other attempts at this strategy followed in all remaining A periods. Nevertheless, bubbles persisted and many traders were frustrated in their inability to arbitrage them away.

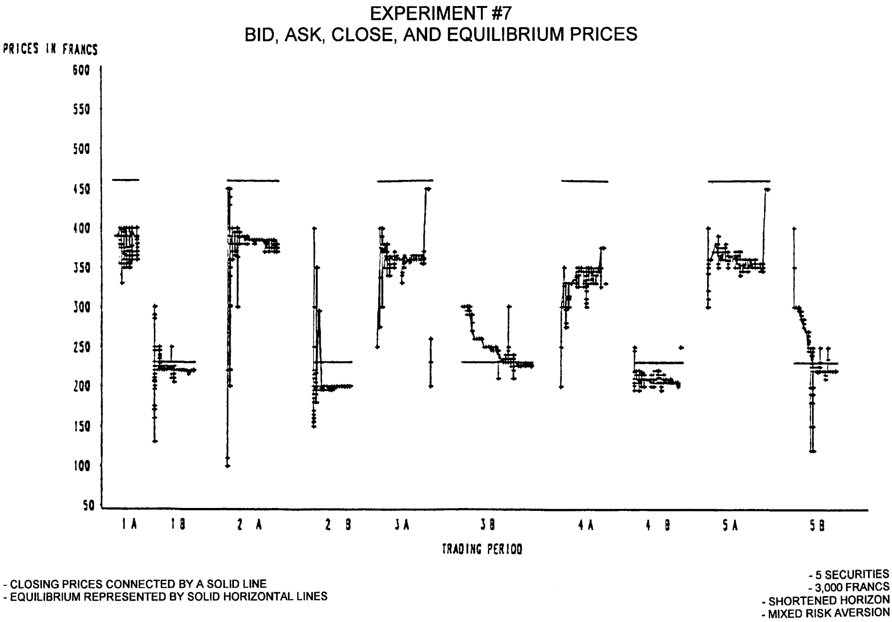

Fig. 73.7 Experiment 7: bid ask, close and equilibrium prices, one dividend with 5 trading periods, mixed risk aversion, and increase supply of shares. Bonus to top six traders. Subjects are from Las Vegas

experimental markets. Many of the traders suggested that they be allowed to short sell in future experiments so as to implement sell strategies in overvalued markets.

As previously mentioned, the tournament compensation system does not alter PFE prices since the prize can be achieved in any type of market environment and with any type of price pattern. Given the results of our previous experiments as well as traders' comments,[21] it appeared that buyers (longs) had an advantage over sellers (shorts). Is it possible that the bubbles we observe were due to differential market position in addition to a shortened investment horizon? In order to answer this question, we conducted four more experiments that provided traders with initial endowments and better equated the position of buyers and sellers. Rather than being endowed with two securities and 10,000 francs of trading capital as before, each trader is initially endowed with five securities and 3,000 francs (see Table 73.3).[22]

[21]Traders completed survey questionnaire at the completion of experiments 4, 6, and 10.

[22]Given that in experiment 6, period A prices averaged around 600, initial trading capital of 3,000 francs would provide buying power of roughly five securities. Consequently, the new buying power and selling power were a priori relatively equal. Even though period A prices turned out to be quite a bit lower in experiments 7–10, this did not create a great advantage to buyers since the supply of securities (5 traders $\times$ 12 traders $=$ 60) was relatively large for a 6-min trading period. As such, there was an ample supply of securities relative to buying power in order to drive prices down should traders turn bearish.

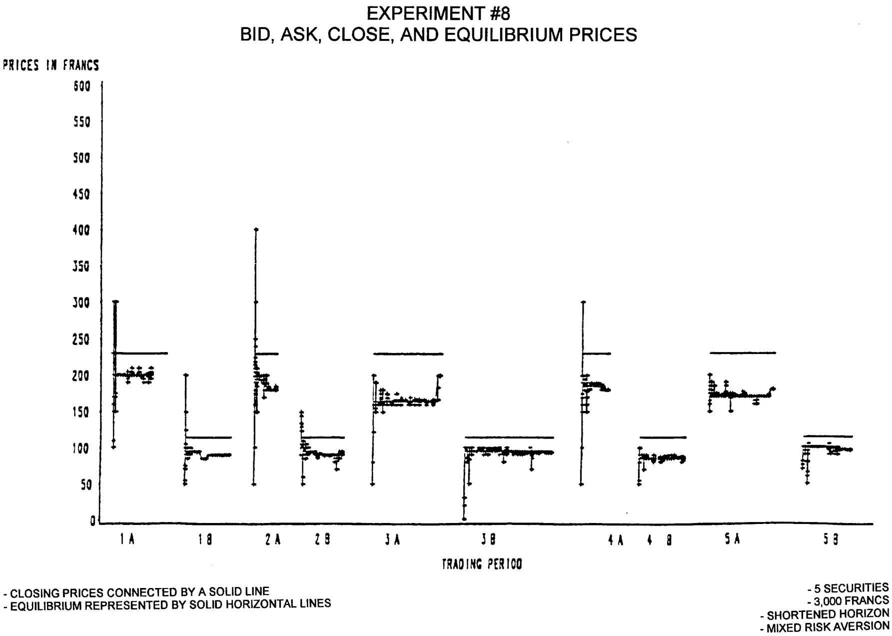

Fig. 73.8 Experiment 8: bid ask, close and equilibrium prices, one dividend with 5 trading periods, mixed risk aversion and increase supply of shares. Bonus to top six traders. Subjects are from Las Vegas

The price patterns of experiments 7–10 are as startling as the dramatic bubbles earlier. We find that the market is immediately priced at a discount to PFE.[23] This had never happened in any of the tournament periods before. If this had been simply the result of learning, we would have expected a gradual decline from the lofty levels of experiments 4 and 6. Rather, we see an immediate discount price which generally remains at a discount throughout all four experiments.[24] Overall, we consider this to be strong evidence that a necessary condition for the creation of

[23]We are unable to recruit all 12 traders back for experiments 7–10 due to graduation, taking of jobs, etc. We were, however, able to retain 7 of the original 12 traders. These traders had now participated in six previous experiments. The five replacements were drawn from the original pool of subjects that had completed the risk attribute questionnaires. These new traders were chosen to replace the risk types that had vacated so that in general, we maintained a wide dispersion of risk types within the market. In addition, some of these new traders had sat in as observers to previous experiments. Others viewed videos of the earlier experiments. All were instructed in the past experimental results, and the various strategies previously used were explained. As such, we do not believe that this change is a critical factor in the continuation of our investigation.

[24]An analysis of many of the last trades of period A for experiments 7–10 often shows either a sharp spike up or down. This illustrates that the traders had become very efficient (through learning) in their manipulation of closing prices. Given the large supply of securities available to squelch a price bubble, speculators were no longer singularly (due to large initial endowments of

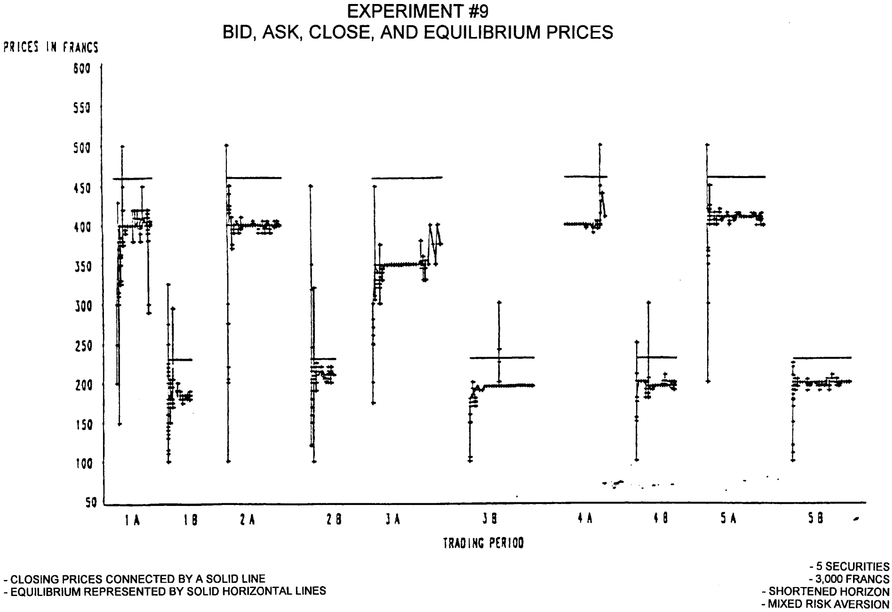

Fig. 73.9 Experiment 9: bid ask, close and equilibrium prices, one dividend with 5 trading periods, mixed risk aversion and increase supply of shares. Bonus to top two traders. Subjects are from Las Vegas

the large bubbles of these markets is that the institutional environment be biased toward more purchasing ability relative to that of selling.

In summary, experiments 7–10 highlight the importance of the supply of securities and the supply of investable funds that may be augmented by short selling. Bubbles observed in experiments 4 and 6 are immediately eliminated when the relative purchasing advantage of long traders is removed. Rational pricing

---

trading capital) able to create capital gains by driving market prices up. With this constraint, they quickly learned that all they needed to accomplish was to purchase the most securities at present prices and then drive the market up on the final few trades. This was often easily accomplished in that 1) only the second to last trade needed to higher in line with the calculation rules of the TPI and 2) as no surprise, there were always many traders who were willing to sell their securities at a price above the current level. The art to this strategy became a matter of timing; do not try to buy the market too early lest you run out of capital, and do not be too late lest you be unable to make the second to the last trade. There did not appear to be too much of a problem for buyers in accomplishing this in experiments 7 and 8; however, starting in experiment 9, some short traders, having become annoyed at bullish traders getting the tournament prize, began jockeying in these last seconds with the long traders in order to drive prices down. The results of such feuds appear in periods 3A, 4A, and 5A of experiment 9 and each A period of experiment 10. The winner of these duels increasingly became the trader who was best able to execute his trade. Eventually, trading activity become so enraged in the last 15 s of trading that the open outcry systems of double-oral auction began to break down.

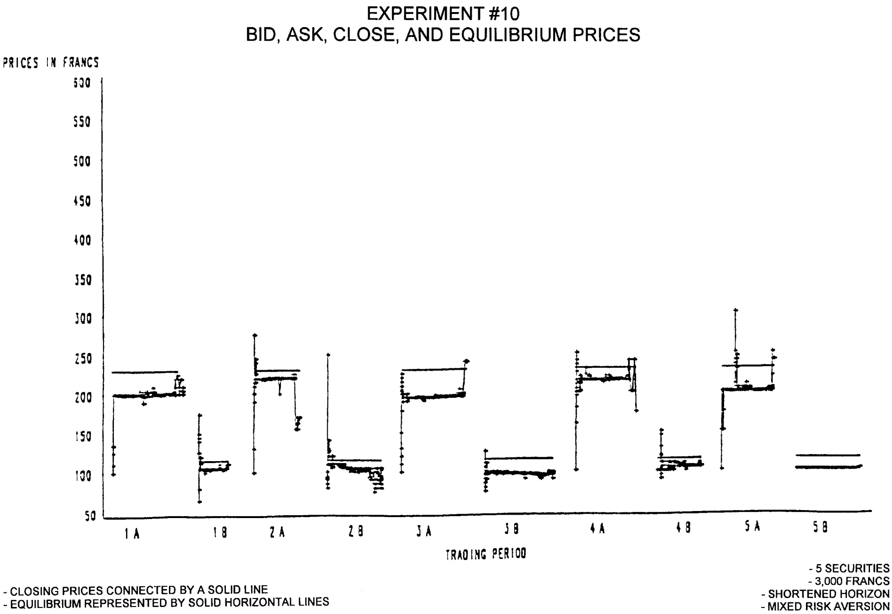

Fig. 73.10 Experiment 10: bid ask, close and equilibrium prices, one dividend with 5 trading periods, mixed risk aversion and increase supply of shares. Bonus to top two traders. Subjects are from Las Vegas

reflecting a modest risk premium results even when traders are faced with a shortened investment horizon.

73.4.4 The Impact of Risk Aversion

The results of previous experiments, especially 6, showed that trader risk aversion was an important factor in determining trader strategy and therefore price patterns. In general, it was found that speculative traders were more likely to seize upon the opportunity created by the introduction of uncertainty (via the tournament period) in search of capital gains. In contrast, the more conservative traders were likely to allow the speculators to act first by creating a positive price trend and would simply sell at inflated prices, or they would allow speculators to first initiate the "burst" of the bubble and then follow in their footsteps. Consequently, the conservative traders were often those responsible for the perpetuation of a direction initially set by speculators. The purpose of experiments 11–14 was to further test these relationships.[25]

[25]Experiments 11–14 were conducted at a second university, and therefore, the results provide information about the external validity of our experiments outside the setting of a single university.

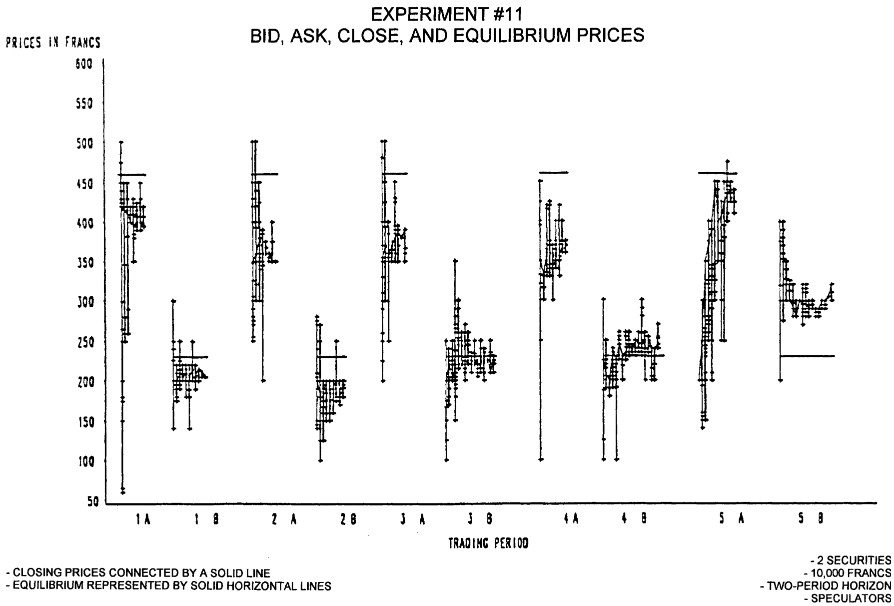

Fig. 73.11 Experiment 11: bid ask, close and equilibrium prices, two dividends and five trading periods each, with speculative traders. Subjects are from FSU, experiment 1

We chose at this time to create two separate trading groups according to risk aversion, each composed of 12 traders. These 24 traders were chosen from a pool of 70 students that completed the risk ranking questionnaire described earlier. The 70 respondents were rank ordered from highest to lowest in risk aversion. The top 12 and bottom 12 students were chosen to participate in the experiments. This method allows us to obtain good separation according to risk aversion. Contrary to our previous experiments, these markets would be made up entirely of one risk aversion class. We label these two risk classes as speculators and conservatives. This is a relative nomenclature as all of these traders are considered to be risk averse, and we only presume to provide an ordinal measure of risk aversion.

The design of these experiments follows that of experiments 1–6, as we wish to test for the presence of bubbles, and the initial endowments of experiments 7–10 have already been shown to eliminate bubbles. All of these traders had previously participated in two experimental markets and therefore can be considered experienced. Nevertheless, we test for rationality of pricing in experiments 11 and 13 before introducing the shortened horizons in experiments 12 and 14.

Figures 73.11–73.14 reveal that both markets are quite rational in that they charge a discount from PFE as a risk premium. As expected, the conservative traders of experiment 13 charge a larger risk premium than the speculative traders of experiment 11. This result provides strong evidence in support of our

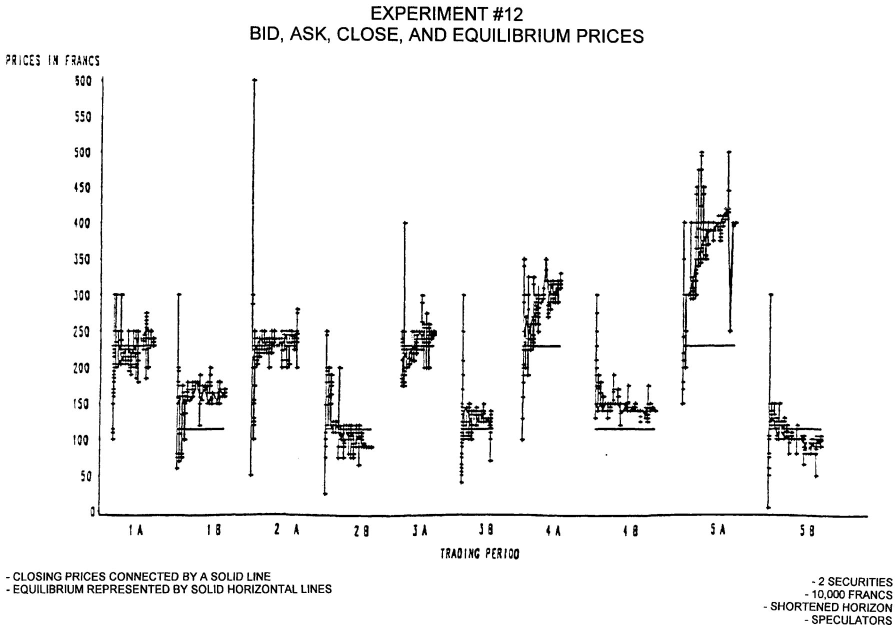

Fig. 73.12 Experiment 12 bid ask, close and equilibrium prices, one dividend with 5 trading periods, with speculative traders. Subjects are from FSU, experiment 1. Mixed bonus: to top 6 traders in first half and top 2 traders only in the second half. Subjects are from FSU, experiment 1

measure/separation of risk aversion. We also note that the speculative group exhibits prices above the PFE levels of period B. This is consistent with our earlier results where this was found in the single-period case.

Experiments 12 and 14 introduce the tournament compensation schedule to induce a shorter investment horizon. As expected, the speculative group seizes upon the opportunity and price bubbles are generated in the latter periods. Also to no surprise, the conservative group does not create the pressure necessary to cause bubbles to form. As a result, we conclude that a necessary condition for asset bubbles is the presence of speculators.[26]

[26]A detailed examination of individual trades reveals the speculative group of traders who are found to be more innovative in designing new trading strategies both in the creating and bursting of bubbles. The finding is consistent with the observation made by Benjamin Friedman (1992) in his review of a dozen NBER working papers on asset pricing. He finds these recent research results demonstrate that rational speculative behaviors such as an attempt by investors to learn from other investors, to affect another's opinion, or to simply engage in protective trading could in some context, such as imperfect information, magnify price fluctuations.

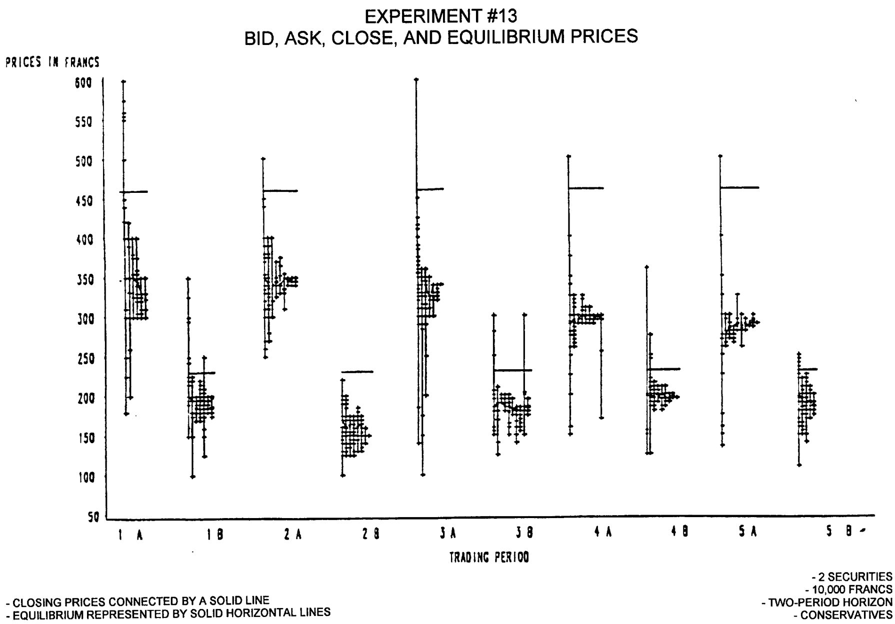

Fig. 73.13 Experiment 13 bid ask, close and equilibrium prices, two dividends and five trading periods each, with speculative traders. Subjects are from FSU, experiment 1. Mixed bonus: to top 6 traders in first half and top 2 traders only in the second half. Subjects are from FSU, experiment 1

73.4.5 The Formation of Negative Bubbles

We have just learned that the effect of the reduced investment horizon is to increase the incentive for short-term speculative gains and that speculative traders are those most eager to earn these profits. We now extend the research design to investigate the question of whether negative bubbles are also possible. We test this proposition by conducting four new experiments (labeled as experiments 15–18 in Table 73.1). We conduct experiments 15 and 16 as "controls" to replicate the positive bubble environment found in experiments 4, 6, and 12. Experiments 15 and 16 validate our previous results with a new set of experimental subjects, while Figs. 73.15 and 73.16 plot the pattern of close prices relative to the equilibrium level (horizontal line). In both experiments, large positive bubbles emerge in most trading years.

We now pose the following question, "Would an environment opposite to that of Design 2 lead to negative bubbles?" We keep the structure of Design 2, but since it was the unequal endowment effect (more purchasing power versus selling pressure, under 2 securities, 10,000 francs) that created the ability to pursue profits in a positive bubble environment, we reverse the endowment effect in experiments 17 and 18 by providing 10 securities and 1,000 francs to each trader. This one change provides traders in experiments 17 and 18 with a much greater ability to buy relative to sell.

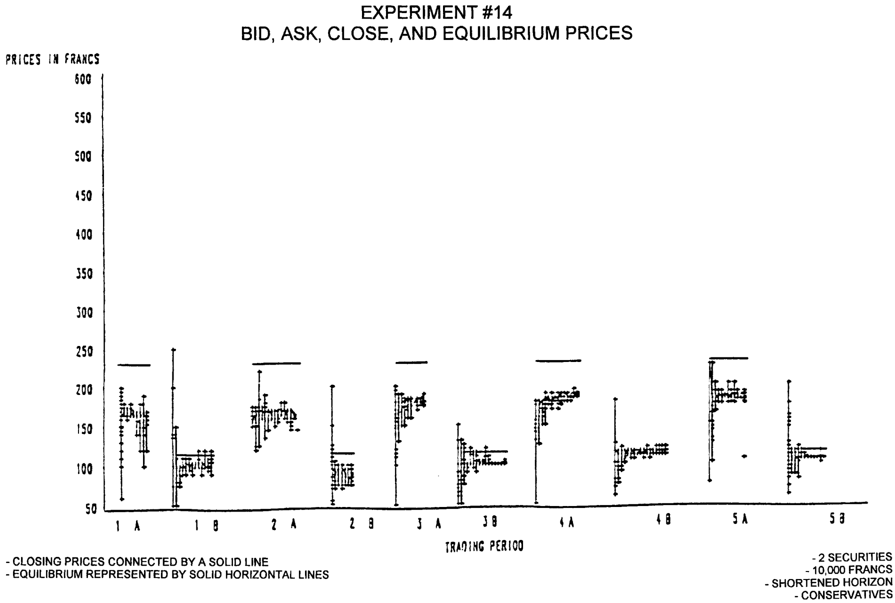

Fig. 73.14 Experiment 14 bid ask, close and equilibrium prices, one dividend with 5 trading periods, with conservative traders. Mixed bonus: to top 6 traders in first half and top 2 traders only in the second half. Subjects are from FSU, experiment 1

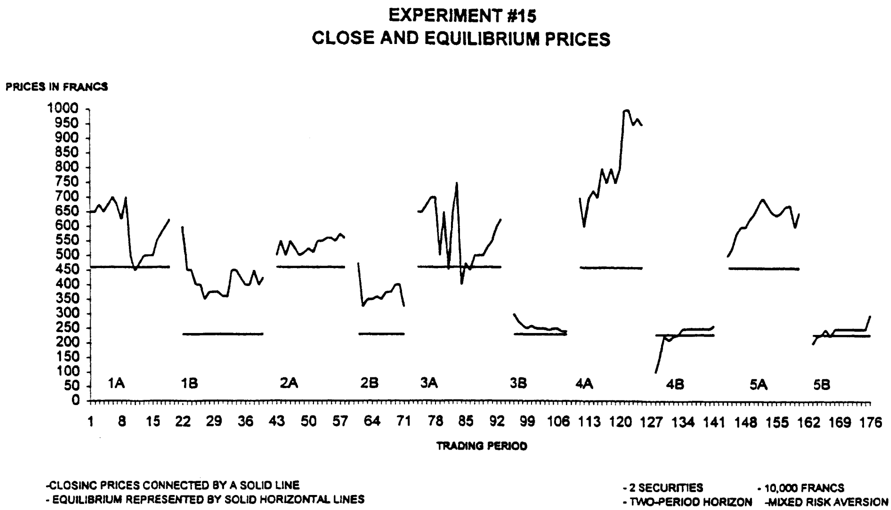

Fig. 73.15 Experiment 15 bid ask, close and equilibrium prices, two periods, mixed risk aversion. Subjects are from FSU, experiment 2. Considered most sophisticated

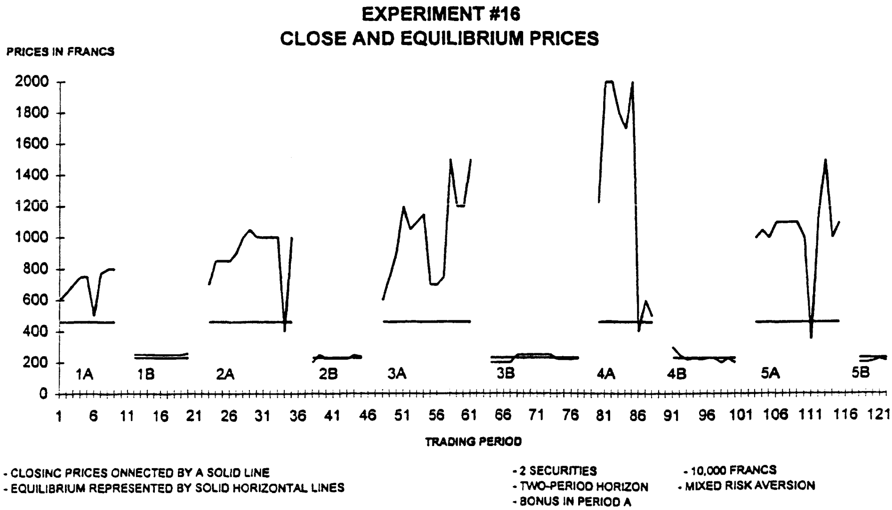

Fig. 73.16 Experiment 16 bid ask, close and equilibrium prices, one dividend with 5 trading periods, and mixed risk aversion. Subjects are from FSU, experiment 2. Considered most sophisticated

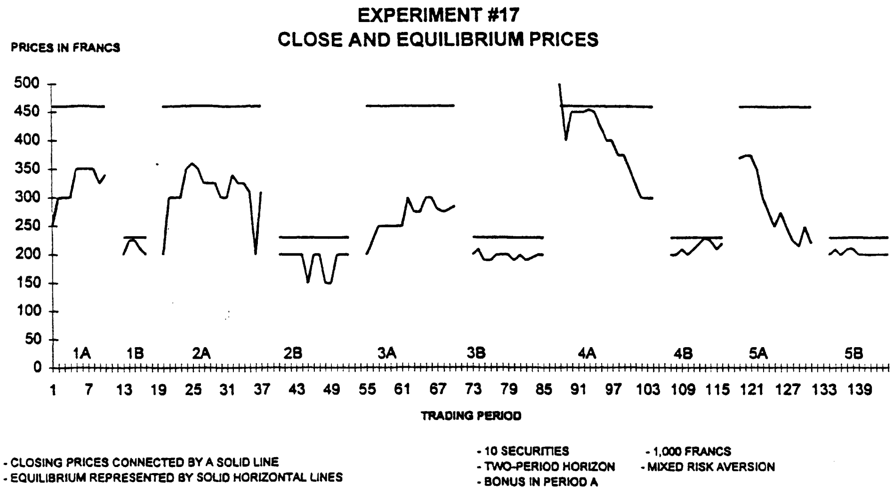

Fig. 73.17 Experiment 17 bid ask, close and equilibrium prices, two periods, and mixed risk aversion. Increase supply of shares. Subjects are from FSU, experiment 2. Considered most sophisticated

The results plotted in Figs. 73.17 and 73.18 show a preponderance for negative bubbles. While the initial 4 years of experiment 17 show some learning adjustment to this new and difficult trading scheme, large price discounts emerge to the extent that period 5A's closing price is insignificantly different than period 5B's which is

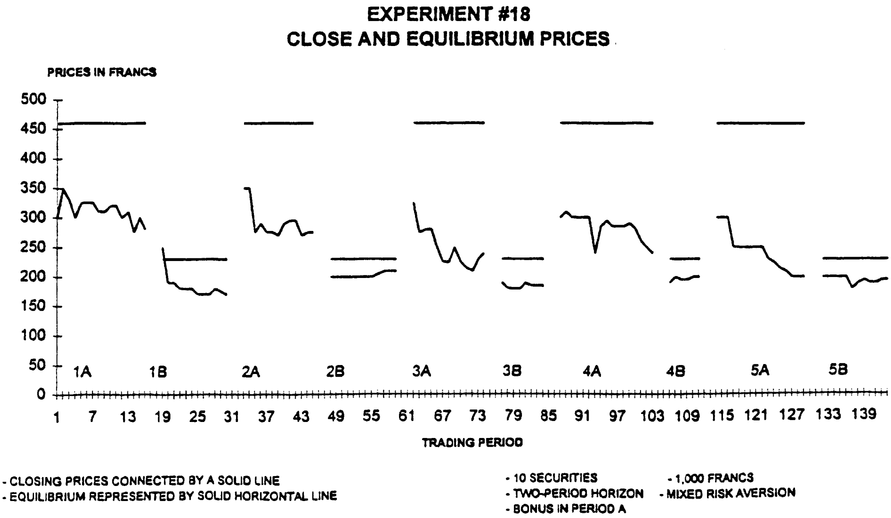

Fig. 73.18 Experiment 18 bid ask, close and equilibrium prices, two period, and mixed risk aversion. Increase supply of shares. Subjects are from FSU, experiment 2. Considered most sophisticated

a single period receiving only a single dividend. By experiment 18, each year shows downward trending markets in each A period. The reader may notice that the positive bubbles seem to burst, while the negative bubbles don't. However, since our design did not allow more cash to be made available through borrowing or infusion, correction may not be observed in the short trading period.

73.5 Conclusions

The results of this study have a number of implications for real-world markets. Experiments 1–6 seem to imply that within an environment that restricts selling pressures, a shortened investment horizon is sufficient to create asset bubbles. In application to the real world, short-term performance of traders, portfolio managers, etc., could create pressures leading to price bubbles. Experiments 7–10 provide restrictions to the previous conclusion in that a shortened investment horizon creates bubble pressure only when the market environment favors buyers over sellers. Unfortunately, most of our real-world securities markets do have such a bias via restricted short sales, asymmetric leverage for longs versus shorts, restricted options and futures, and the like. Experiments 11–14 add to the puzzle by demonstrating the role of speculators within bubble formation. As a whole, the study suggests that necessary and sufficient conditions for the formation of asset bubbles are a shortened investment horizon, restricted selling activity relative to buyers, and the presence of speculators. We have also shown that repeated replication of these experiments under different settings still produces robust results.

The first and third variables are a matter of fact within US securities markets, while restricted selling activity relative to buyers can take many forms. Either enhancing the buyer's position or restricting the seller's position is sufficient. Examples include increasing purchasing (speculative) ability through reduced stock margin levels, introduction of high leverage stock index futures, and, in macroeconomic terms, a growing money supply or savings level. This latter variable may help explain the previous high levels of the Japanese equity market. The high level of Japanese savings creates very large endowments available for investment purchase. Given a limited supply of securities, our experimental markets show that these conditions will lead to a bubble. They also suggest that the bubble will burst when there is greater equating between the supply and demand. Recent changes in the Japanese institutional framework may, as predicted by this study, have led to the bursting of that bubble.

The primary prescription put forth for regulatory authorities in eliminating unnecessary market volatility resulting from asset bubbles is to create an institutional environment that does not restrict the transfer of information to the market. Structure the variables so that both bulls and bears have equal costs in executing their trades.

Appendix 1: Statistical Analysis

Table 73.4 summarizes the ordinary least squares regression analyses of the impact upon the divergence of asset prices from their PFE levels in period A.[27] In particular, we test the following relation:

$$\mathrm{P^L - PFE} = f(\mathrm{I, E, I * E, T, I * E * T, S, I * S, A, I * A, \ \$}) \tag{73.5}$$

where:

$\mathrm{P^L}$ – PFE = the deviation from equilibrium for period A of each trading year where $\mathrm{P^L}$ is the last trade of the period and PFE is the perfect foresight equilibrium price,

f = a linear additive model,

I = a dummy variable representing the shortened investment horizon according to Table 73.1 I = 1 for shortened horizon and 0 otherwise (i.e., experiments 4, 610, 12, 14),

E = a dummy variable representing the endowment effect according to Table 73.1. E = 1 when 2 securities are issued and 0 otherwise (i.e., experiments 1–6, 11–14),

I*E = an interaction dummy variable representing both a shortened investment horizon and two-security endowment (i.e., experiments 4, 6, 12, 14),

[27] See the classic textbooks by Greene (2012), Wooldridge (2010), or Hayashi (2000) for details on the implementation and interpretation of OLS.

This table shows the extent to which certain variables cause a deviation from perfect foresight equilibrium values.[a] The following regression is estimated separately for experiments 1–10 and 11–14 according to the experimental design of Table 1.

P^L-PFE = f(I, E, I^*E, T, I^*E^*T, S, I^*S, A, I^*A, \$)

[a] t-values in parentheses. Variables defined as follows:

PL-PFE represents the deviation from equilibrium for Period A of each trading year where PL is the last trade of the period and PFE is the Perfect Foresight Equilibrium price

I is a dummy variable representing the shortened Investment horizon according to Table 73.1. I = 1 for shortened horizon, and 0 otherwise (i.e., experiments 4,6–10,12,14)

E is a dummy variable representing the Endowment effect according to Table 73.1 E = 1 when 2 securities are issued, and 0 otherwise. (i.e., experiments 1–6, 11–14)

I*E is an interaction dummy variable representing both a shortened investment horizon and two security endowment (i.e., experiments 4,6,12,14)

T is a dummy variable representing the Tournament effect according to Table 73.1. T = 1 when there is a tournament prize for two traders only, and 0 otherwise (i.e., experiments 4,6,12,14 (years 4&5) and 9,10)

I*E*T is an interaction dummy variable representing a shortened investment horizon, a two security endowment, and a tournament effect (i.e., experiments 4,6 (years 4&5), and 9, 10)

S is a dummy variable representing experiments composed entirely of Speculators according to Table 73.1. S = 1 for experiments 11 and 12 and 0 otherwise

I*S is an interaction dummy variable representing the shortened investment horizon and a pure speculative trader market (i.e., experiment 12)

A represents the ratio of end-of-period Asset inventory for speculative traders to total asset holdings. Speculative traders are those who scored in the top one-half of the risk measurement questionnaires

I*A is an interaction variable for shortened investment horizon and ratio asset holdings for speculators (experiments 4,6–10,12,14)

$ is a dummy variable representing experiments where traders risked their own money according to Table 73.1. $ = 1 when own money is used, and 0 otherwise (i.e., experiments 5 and 6)

[b]As reported in Table 73.1, experiments 1–10 consisted of traders with a wide range (mixed) of risk aversion. Experiments 11 and 12 were composed only of speculative traders with experiments 13 and 14 composed of conservatives.

[c]NOINT means the regression was run by suppressing the intercept.

*, **, ***Signify statistical significance levels at .10, .05, and .01, respectively.

T = a dummy variable representing the tournament effect according to Table 73.1. T = 1 when there is a tournament prize for two traders only and 0 otherwise (i.e., experiments 4, 6, 12, 14 (years 4 and 5), 9, and 10),

I*E*T = an interaction dummy variable representing a shortened investment horizon, a two-security endowment, and a tournament effect (i.e., experiments 4, 6, 9, 10 (years 4 and 5)),

S = a dummy variable representing the extent to which speculators participated in the experiments according to Table 73.1. S = 1 for experiments 11 and 12 and 0 otherwise,

I*S = an interaction dummy variable representing the shortened investment horizon and a pure speculative trader market (i.e., experiment 12),

A = the ratio of end-of-period asset inventory for speculative traders to total asset holdings. Speculative traders are those who scored in the top one-half of the risk measurement questionnaires,

I*A = an interaction variable for shortened investment horizon and ratio asset holdings for speculators (experiments 4, 6–10, 12, 14),

$ = a dummy variable representing experiments where traders risked their own money according to Table 73.1. $ = 1 when their own money is used and 0 otherwise (i.e., experiments 5 and 6).

Due to their differential design, the results for experiments 1–10 appear separately in Panel A and those for experiments 11–14 in Panel B.

Model 1 of Panel A tests the impact of (1) I = 1, a shortened horizon; (2) E = 1, a restricted endowment effect (wealth and supply effects); and (3) I = 1, E = 1, an interaction of a shortened horizon with restricted initial endowment. Given that the regression was run with no intercept, the coefficients represent estimates of each variable's independent impact. The results suggest that neither a shortened investment horizon nor a biased endowment effect (advantage to "bulls" versus "bears") is sufficient to induce bubble behavior. However, the interaction of these two variables is highly significant in explaining the bubble results of these experiments. That is, an environment that provides both the incentive and the ability to profit from a bubble will likely result in positive price divergence.

As hypothesized earlier, we test for the heightened effect of tournament incentives (i.e., T = 1) by examining the effect of "superstar" prizes paid to only the top two traders (as outlined in Tables 73.1 and 73.3). We also test for an interaction effect with a shortened horizon (I = 1) and restricted endowment (E = 1). Model 2 results are consistent with Model 1 in that a tournament effect is not sufficient in itself (t = 0.13 on T variable); however, in conjunction with a reduced horizon and restricted endowment, the tournament interacts to explain a significant part (t = 4.57 on I*E*T) of the bubbles in these experiments.

In Model 3, we observe the impact of speculative traders vis-á-vis conservatives by introducing a measure of asset purchase activity. The end-of-period asset holdings for the speculative group (the top one-half of traders in risk ratings) are compared to the total asset endowment for all traders. In the absence of any effect, assets should be evenly divided, and this ratio, A, should be equal to.5. The results of Model 3 indicate that speculators independently do not impact the presence of a bubble (t = 0.01 for A); however, when speculators operate within a shortened horizon (I*A), they do significantly differentiate themselves from conservatives by buying more and contributing to positive price bubbles. Finally, the impact of the use of the trader's own money is shown not to significantly alter the effects of the price bubbles (t = −0.54 for $). The R2 of .80 suggests that the vast majority of price deviation from PFE levels can be explained by investment horizon, endowment effects, and risk aversion.

Panel B reports the results for experiments 11–14 where markets were composed of either all speculators (11, 12) or all conservatives (13, 14). Due to this makeup, variables A and I*A are not defined in these regressions although S and I*S are substituted in their place and represent the speculative markets (11 and 12) and the interaction of shortened horizon with a speculative market (12). In addition, a restricted endowment effect (E = 1) is imposed for experiments 11–14 since experiments 7–10 clearly established their necessity in creating bubbles. Model 4 results highlight the significant positive effect of the combined shortened horizon/restricted endowment effect (t = 6.98 for I). More importantly, the speculative group statistically differs from conservatives with an additional mean price difference of 89.9 (t = 4.92). Model 5 supports the results of experiments 1–10 in that 1) a shortened investment horizon with restricted endowments leads to price bubbles (t = 2.71) for I, 2) a heightened tournament incentive will heighten short-term horizons and lead to positive price effects (t = 2.83 for I*T), and 3) speculators contribute to positive price bubbles in restricted endowment environments (t = 3.17 for S).[28]

The visual analysis of experiments 15–18 (negative bubble experiments) is confirmed by the regression results reported in Table 73.5. The variables are as defined earlier under Eq. 73.5 albeit the EN representing a dummy variable for the negative endowment effect. EN = 1 when the initial endowment equals 10 securities and 1,000 firms and 0 otherwise. In addition, since the shortened horizon variable I occurs for all years except 1A of each experiment, I and E are highly correlated. The design is therefore set to only measure the interaction effects of a shortened horizon and endowment. The four periods (1A of each experiment) are the control periods where a shortened horizon is not present (dummy NI = 1 for not I).

The parameter estimates of Model 6 show significant positive results for both positive and negative bubbles. The joint presence of a shortened horizon induced by a tournament payoff along with a buy side endowment (2 securities, 10,000 firms), that is, I*E = 1, leads to an average increase of 400.6 francs in price levels. The single alteration of the endowment to sell side (10 securities, 1,000 francs) in the presence of a tournament leads to an average decrease in price of 201.3 francs. The estimate for NI reflects the insignificant impact of the control periods where the endowment effect is present but without the tournament payoff inducing a shortened horizon. So as in the earlier results, the combined effect of the incentive

[28]Furthermore, although insignificant, the p-value for I*S is equal to.14, suggesting that the speculative difference may be even greater under a shortened investment horizon.

Table 73.5 Negative bubble and single period results

Model	Intercept	NI	$I^{*}E$	$I^{*}E^{N}$	R^2
Panel A					
Experiments 15–18 (n = 20)					
6	NOINT[b]	45.0 (0.37)	400.6*** (4.67)	−201.3** (−2.34)	.55
Panel B					
Experiments 19–22 (n = 40)					
7	NOINT[b]	−22.8 (−1.60)	22.5** (2.36)	−92.9***(−6.89)	.57
Panel C					
Experiments 23–26 (n = 20)					
8	−130.0** (−3.61)		174.5*** (3.95)	−208.0*** (−4.08)	.80

This table shows the extent to which endowment in conjunction with other variables causes a deviation from perfect foresight equilibrium values[a]. The following regression is estimated separately for experiments 15–18, 19–22, and 23–26 according to the experimental design of Table 73.1.

P^{L}-PFE = *f*(.NI; E; I*E; EN; I*E^{N})

[a]t-values in parentheses. Variables defined as follows:

PL-PFE represents the deviation from equilibrium for Period A of each trading year where P^{L} is the last trade of the period and PFE is the Perfect Foresight Equilibrium price

I is a dummy variable representing the shortened Investment horizon according to Table 73.1. I = 1 for shortened horizon, and 0 otherwise

E is a dummy variable representing the Endowment effect according to Table 73.1. E = 1 when 2 securities are issued, and 0 otherwise

I*E is an interaction dummy variable representing both a shortened investment horizon and two security endowment

E^{N} is a dummy variable representing the sell side of the Endowment effect hypothesized to lead Negative bubbles. E = 1 when 10 securities are issued and 0 otherwise

I*E^{N} is an interaction dummy variable representing both a shortened investment horizon and a ten security environment

[b]NOINT means the regression was run by suppressing the intercept.

*, **, ***Signify statistical significance levels at .10, .05, and .01, respectively.

(i.e., the tournament) and the ability (i.e., the endowment) works to create both positive and negative price bubbles.

Appendix 2: Additional Tests

To check the robustness of our results, we conduct eight final experiments in a unique and different setting, the former Communist country of Albania.[29] Of its many unique characteristics, one of the most important is its history of being the most isolated (politically and economically) country in Europe since World War II. Since democratic reforms opened in 1991, a new business school was opened in the second largest city of Albania, Shkodra, where the third year students served as traders. Would the students whose country didn't have a securities market

[29]In addition, we perform further OLS regressions and report the results in Table 73.5.

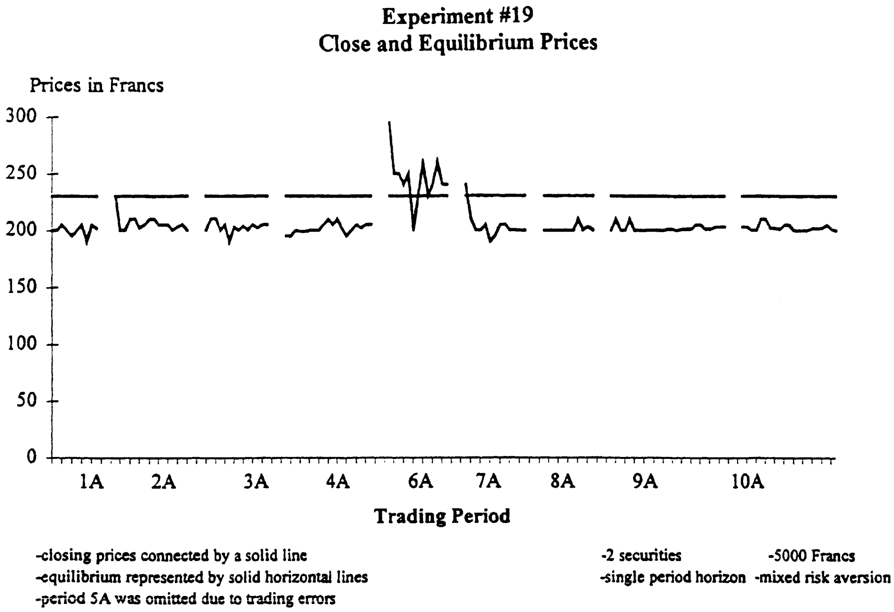

Fig. 73.19 Experiment 19 bid ask, close and equilibrium prices, one dividend with 5 trading periods, mixed risk aversion. Subjects are from Albania

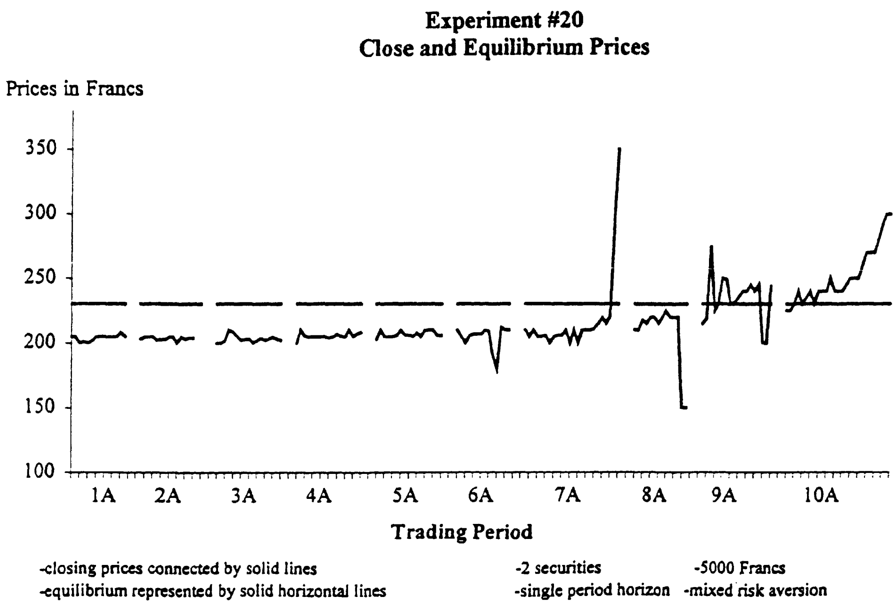

Fig. 73.20 Experiment 20 bid ask, close and equilibrium prices, one dividend with 5 trading periods, mixed risk aversion, and bonus to top traders. Subjects are from Albania

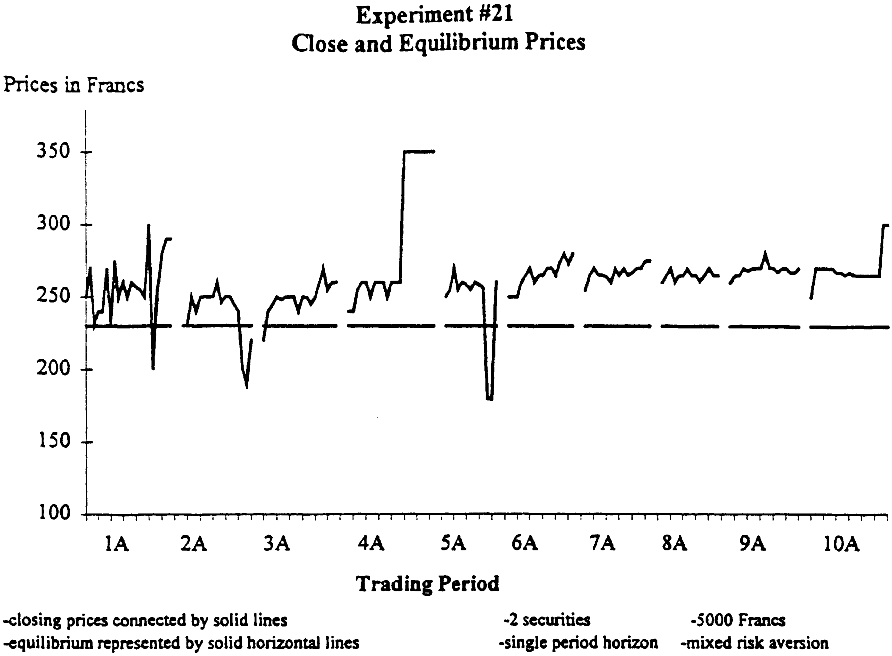

Fig. 73.21 Experiment 21 bid ask, close and equilibrium prices, one dividend with 5 trading periods, mixed risk aversion and bonus to top traders. Subjects are from Albania

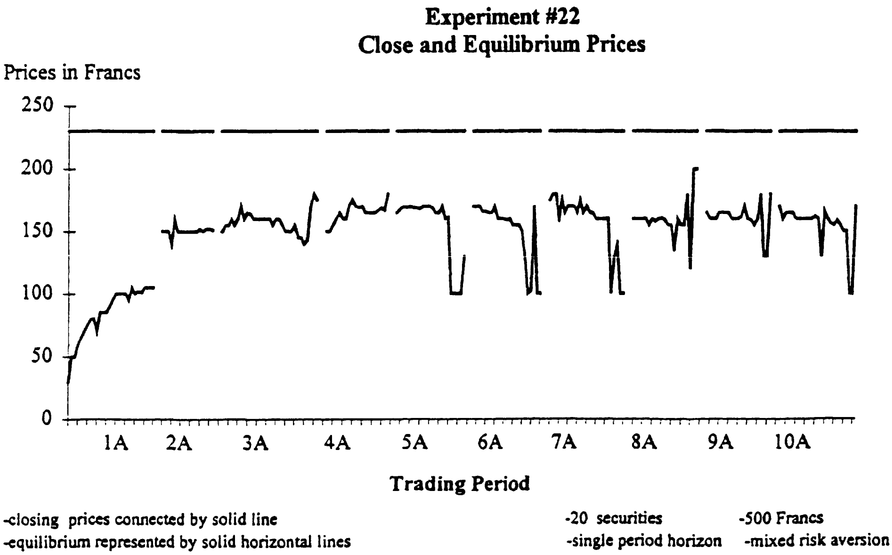

Fig. 73.22 Experiment 22 bid ask, close and equilibrium prices, two periods, mixed risk aversion, and bonus to top traders. Increase supply of shares. Subjects are from Albania

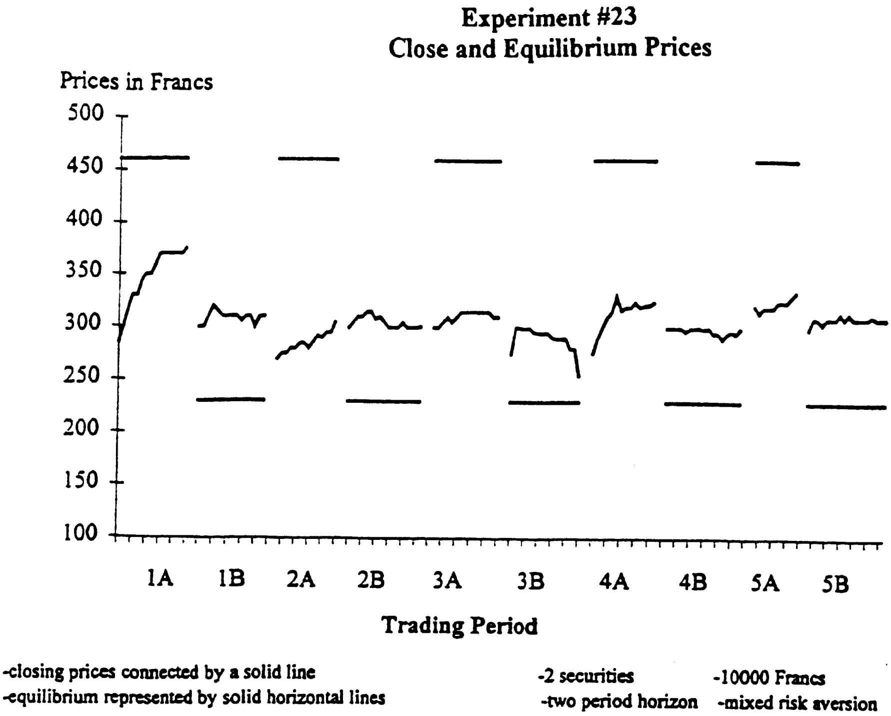

Fig. 73.23 Experiment 23 bid ask, close and equilibrium prices, two dividends with five trading periods each, and mixed risk aversion. Subjects are from Albania

or a history of free market trade show the same results as we had found at US universities? While our previous experiments had the most experienced traders ever used in a study, these may indeed represent the least experienced traders examined to date which may be regarded as an extreme test of the validity of our results.

Because of the newness of the trading experience for these students, a single-period design was used in the first four experiments. For each experiment's ten trading years (no period B), asset payoffs were for a single dividend payoff. The amounts used were the same as those of Table 73.2 so that equilibrium levels remained at 230 for each year. As shown in Table 73.1, Design 7 (experiment 19) consists of a single-period security without a tournament effect. Design 8 (experiments 20 and 21) introduces the tournament payoff of Table 73.3 (Schedule Two) within the single-period environment. This allows us to test for the presence of bubbles in the simpler pricing environment while also easing the learning experience of the Albanian students toward two-period tournament pricing.

The pricing results for these three experiments can be seen in Figs. 73.19–73.21. Without the tournament in experiment 19, pricing is rational and typical showing a discount (risk premium) of about 30 francs from the equilibrium level of 230. Near the end of experiment 20, the tournament effect appears to have created some

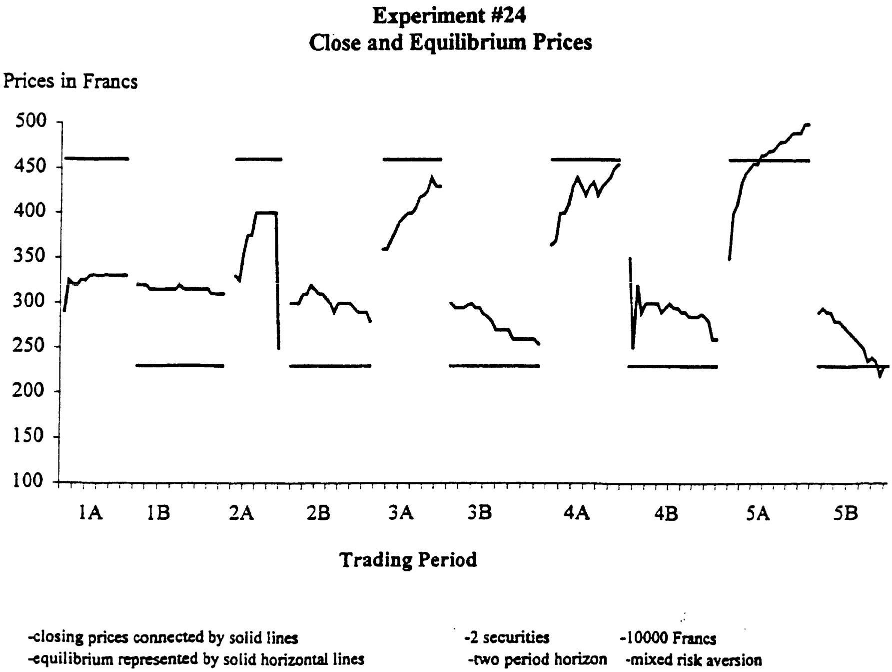

Fig. 73.24 Experiment 24 bid ask, close and equilibrium prices, one dividend with 5 trading periods, and mixed risk aversion. Subjects are from Albania

price movement above equilibrium. This pressure continues into experiment 21 where prices trade at an average premium of 30 francs. While these premiums do not constitute a bubble, it is clear they had a significant positive impact on pricing levels. Would this effect be eliminated (reversed) by changing the buy/sell pressure as was done earlier under Design 6 where negative bubbles were induced? Design 9 tests this proposition by changing the endowment from 2 securities and 5,000 francs to 20 securities and 500 francs. The results, reported in Fig. 73.22, show that even in these simple markets, the endowment effect combined with tournament payoff leads to pricing away from equilibrium. These observations are confirmed by the regression results of Model 7 in Table 73.5 where buy side preference (I*E = 1) leads to significant increase in prices, while sell side preference (I*EN = 1) leads to lower prices. The absence of a tournament payoff (NI = 1) leads to insignificant price effects as investment horizon cannot be altered in a single-period market.

The Albanian students had now participated in four single-period experiments and were ready to attempt two-period pricing. Experiment 23 was a simple two-period pricing environment without any tournament payoff as in Design 1 (control). The plot of prices in Fig. 73.23 shows that the students initially struggled with two-period pricing since period A prices (two payoffs) differed little

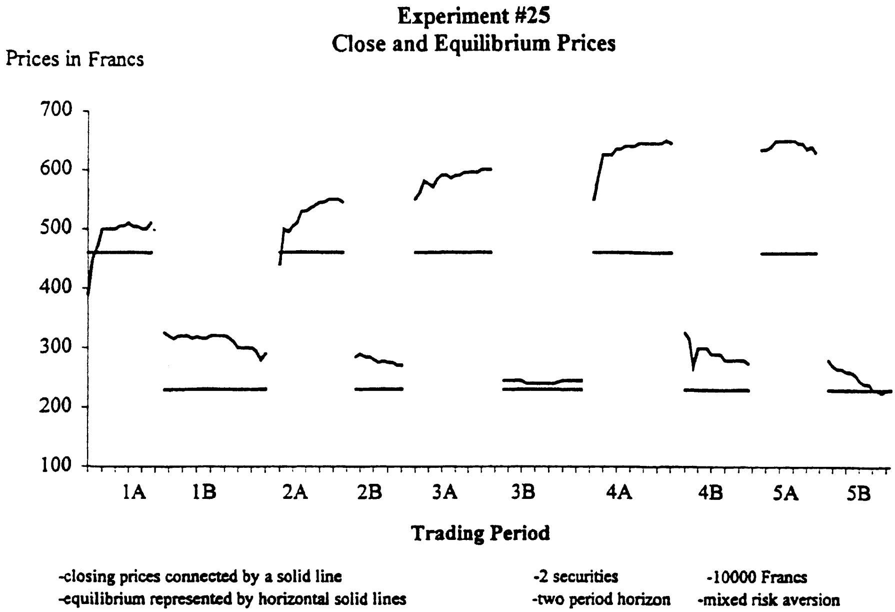

Fig. 73.25 Experiment 25 bid ask, close and equilibrium prices, one dividend with 5 trading periods, mixed risk aversion. Subjects are from Albania

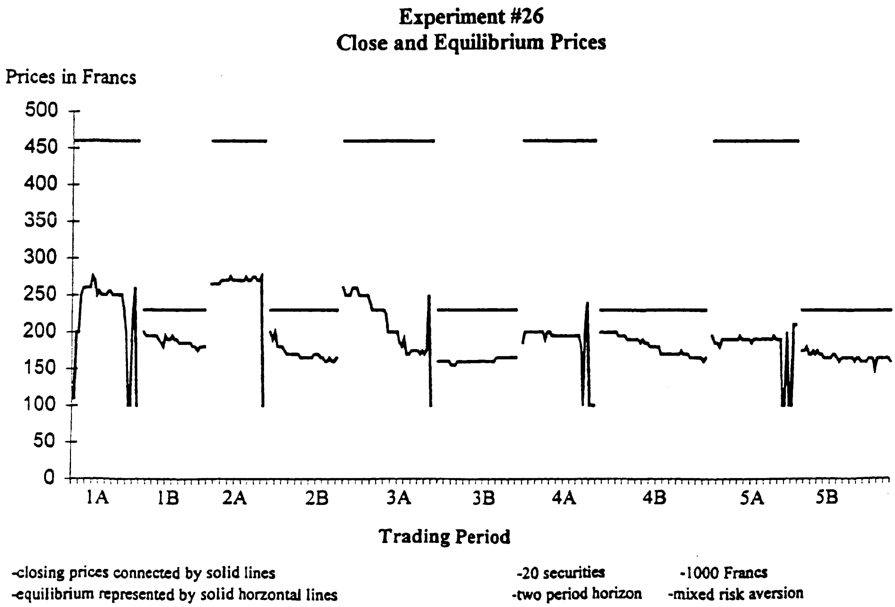

Fig. 73.26 Experiment 26 bid ask, close and equilibrium prices, one dividend with 5 trading periods, and mixed risk aversion. Increase supply of shares. Subjects are from Albania

from period B prices (single payoff), though by the end of the experiment enough learning had developed.

Experiments 24 and 25 introduce the shortened investment horizon (tournament effect) within the two-period framework as in Design 2 earlier. The price patterns in Figs. 73.24 and 73.25 show the creation of positive price bubbles to levels approaching 650 francs. Despite the historical background of this country and these students, they responded to market pressures in the same bubble-like manner. The last experiment, 26, alters the endowment to the sell side as before to see if negative bubbles can also be obtained. Price paths in Fig. 73.26 show a general downward trend of prices. The prices in period A show significant and growing discounts from the equilibrium levels of 460. These observations are confirmed by the regression results reported in Panel C of Table 73.5 with buy side endowment contributing 174.5 francs and sell side endowment reducing levels by 208.0 francs.

Abstract

The literature on range volatility modeling has been rapidly expanding due to its importance and applications. This chapter provides alternative price range estimators and discusses their empirical properties and limitations. Besides, we review some relevant financial applications for range volatility, such as value-at-risk estimation, hedge, spillover effect, portfolio management, and microstructure issues.

In this chapter, we survey the significant development of range-based volatility models, beginning with the simple random walk model up to the conditional autoregressive range (CARR) model. For the extension to range-based multivariate volatilities, some approaches developed recently are adopted, such as the dynamic conditional correlation (DCC) model, the double smooth transition conditional correlation (DSTCC) GARCH model, and the copula method. At last, we introduce different approaches to build bias-adjusted realized range to obtain a more efficient estimator.

Keywords

Range • Volatility forecasting • Dynamic conditional correlation • Smooth transition • Copula • Realized volatility • Risk management

74.1 Introduction

Financial volatility is a key input in derivative pricing, asset allocation, investment decisions, hedging, and risk analysis; volatility modeling thus has became an important task in financial markets, and it has held the attention of academics and practitioners over the last three decades. Nevertheless, following Barndorff-Nielsen and Shephard (2005) or Andersen et al. (2003), financial volatility is a latent factor and hence it cannot be observed directly. Financial volatility thus can only be estimated using its signature on certain known market price processes; when the underlying process is more sophisticated or when observed market prices suffer from market microstructure noise effects, the results are less clear.

It is well known that the time series of asset prices usually exhibit volatility clustering or autocorrelation. In incorporating the characteristics into the dynamic process, the generalized autoregressive conditional heteroskedasticity (GARCH) family of models proposed by Engle (1982) and Bollerslev (1986) and the stochastic volatility (SV) models advocated by Taylor (1986) are two popular and useful alternatives for estimating and modeling time-varying conditional financial volatility.

However, as pointed by Alizadeh et al. (2002), Brandt and Diebold (2006), Chou (2005), and others, both GARCH and SV models are inaccurate and inefficient, because they are based on the closing prices of the reference period, failing to use the information content inside the reference. In other words, the path of the price inside the reference period is totally ignored when volatility is estimated by these models. Especially in turbulent days with drops and recoveries in the markets, the traditional close-to-close volatility indicates a low level, while the daily price range shows correctly that the volatility is high.

The price range, also known as high/low range or range volatility, is basically defined as the difference between the highest and lowest market prices over a fixed sampling interval. The price range has been known for a long time and has recently experienced renewed interest as a proxy of the latent volatility. The information contained in the opening, highest, lowest, and closing prices of an asset is widely used in Japanese candlestick charting techniques and other technical analysis indicators, such as the directional movement indicator (DMI). Early applications of range in the field of finance can be traced to Mandelbrot (1971) and the academic work on the range-based volatility estimator which began in the early 1980s. Several authors, back to Parkinson (1980), developed several volatility measures which were far more efficient than the classical return-based volatility estimators.

Building on the earlier results of Parkinson (1980), many studies[1] showed that one can use the price range information to improve volatility estimation. In addition to being significantly more efficient than the squared daily return, Alizadeh et al. (2002) also demonstrated that the conditional distribution of the *log range* is approximately Gaussian, thus greatly facilitating maximum likelihood estimation of stochastic volatility models. Moreover, as pointed out by Alizadeh et al. (2002) and Brandt and Diebold (2006), the range-based volatility estimator appears robust to microstructure noise such as bid-ask bounce. By adding microstructure noise to the Monte Carlo simulation, Shu and Zhang (2006) also supported the finding of Alizadeh et al. (2002) that range estimators are fairly robust toward microstructure effects.

Cox and Rubinstein (1985) explained the problem that despite the elegant theory and the support of simulation results, the range-based volatility estimator has performed poorly in empirical studies. Chou (2005) argued that the failure of all the range-based models in the literature is caused by their ignorance of the temporal movements of price range. Using a proper dynamic structure for the conditional expectation of range, the conditional autoregressive range (CARR) model, proposed by Chou (2005), successfully resolves this puzzle and retains its superiority in empirical forecasting abilities. The in-sample and out-of-sample volatility forecasting using S&P 500 index data shows that the CARR model does provide more accurate volatility estimator compared with the GARCH model. Similarly,

[1]See Garman and Klass (1980), Beckers(1983), Ball and Torous (1984), Wiggins (1991), Rogers and Satchell (1991), Kunitomo (1992), Yang and Zhang (2000), Alizadeh et al. (2002), Brandt and Diebold (2006), Brandt and Jones (2006), Chou (2005, 2006), Cheung (2007), Martens and van Dijk (2007), Chou and Wang (2007), Floros (2009), Chou et al. (2009), and Chou and Liu (2010, 2011).

Brandt and Jones (2006) formulated a model that is analogous to Nelson's (1991) EGARCH model but uses the square root of the intraday price range in place of the absolute return. Both studies find that the range-based volatility estimators offer a significant improvement over their return-based counterparts. Moreover, Chou et al. (2009) extended CARR to a multivariate context using the dynamic conditional correlation (DCC) model proposed by Engle (2002a). They found that this range-based DCC model performs better than other return-based volatility models in forecasting covariances. In this chapter, we also review alternative range-based multivariate volatility models in Sect. 74.3.

Recently, many studies have used high-frequency data to get an unbiased and highly efficient estimator for measuring volatility; see Andersen et al. (2003) and McAleer and Medeiros (2008) for a review. The volatility built by nonparametric methods is called *realized volatility*, which is calculated by the sum of nonoverlapping squared returns within a fixed time interval. Martens and van Dijk (2007) replaced the squared return with the price range to get a more efficient estimator, namely, the realized range. In their empirical study, the realized range was a significant improvement over realized return volatility. In addition, Christensen and Podolskij (2007) independently develop the *realized range* and showed that this estimator is consistent and relatively efficient under some specific assumptions.

The remainder of the chapter is laid out as follows. Section 74.2 introduces the price range estimators. Section 74.3 describes the range-based volatility models, including univariate and multivariate ones. Section 74.4 presents the realized range. The financial applications of range volatility are provided in Sect. 74.5. Finally, the conclusion is showed in Sect. 74.6.

74.2 The Price Range Estimators

A few price range estimators and their estimation efficiency are briefly introduced and discussed in this section. The price ranges which can be calculated by the daily opening, highest, lowest and closing prices are readily available for many assets. Most data suppliers provide daily highest/lowest prices as summaries of intraday activity. For example, Datastream records the intraday price range for most securities, including equities, currencies, and commodities, going back to 1955. Thus, range-based volatility proxies are easily calculated. When using this record, the additional information yields a great improvement when used in financial applications. Roughly speaking, knowing these records allows us to get closer to the real underlying process, even if we do not know the whole path of asset prices. For an asset, let's define the following variables:

$O_t =$ the opening price of the tth trading day.
$C_t =$ the closing price of the tth trading day.
$H_t =$ the highest price of the tth trading day.
$L_t =$ the lowest price of the tth trading day.

The efficiency for the Parkinson (1980) estimator intuitively comes from the fact that the price range of intraday trading gives more information regarding the future volatility than two arbitrary points in this series (the closing prices). Assuming that the asset price follows a simple diffusion model without a drift term, his estimator $\hat{\sigma}_P^2$ can be written as follows:

$$\hat{\sigma}_P^2 = \frac{1}{4\ln 2}(\ln H_t - \ln L_t)^2. \tag{74.1}$$

But instead of using two data points, the highest and lowest prices, four data points, the opening, closing, highest, and lowest prices, might also give extra information. Garman and Klass (1980) proposed several volatility estimators based on the knowledge of the opening, closing, highest, and lowest prices. Like Parkinson (1980), they assumed the same diffusion process and proposed their estimator $\hat{\sigma}_{GS}^2$ as

$$\begin{aligned}\hat{\sigma}_{GK}^2 = {} & 0.511[\ln(H_t/L_t)]^2 - 0.019\{\ln(C_t/O_t)[\ln(H_t) + \ln(L_t) - 2\ln(O_t)] \\ & -2[\ln(H_t/O_t)\ln(L_t/O_t)]\} - 0.383[\ln(C_t/O_t)]^2.\end{aligned} \tag{74.2}$$

As mentioned in Garman and Klass (1980), their estimator can be presented practically as $\hat{\sigma}_{GK'}^2 = 0.5[\ln(H_t/L_t)]^2 - [2\ln 2 - 1][\ln(C_t/O_t)]^2$. Molnár (2012) showed that in the absence of high-frequency data, returns normalized by their estimator are, approximately, distributed normally.

The price path cannot be monitored when markets are closed; however, Wiggins (1991) found that both the Parkinson estimator and Garman-Klass estimator were still biased downward compared to the traditional estimator, because the observed highs and lows were smaller than the actual highs and lows. Garman and Klass (1980) and Grammatikos and Saunders (1986), nevertheless, estimated the potential bias using simulation analysis and showed that the bias decreases with an increasing number of transactions. Therefore, it is relatively easy to adjust the estimates of daily variances to eliminate the source of bias.

Because the Parkinson (1980) and Garman and Klass (1980) estimators implicitly assumed that log-price follows a geometric Brownian motion with *no* drift term, further refinements were made by Rogers and Satchell (1991) and Kunitomo (1992). Rogers and Satchell (1991) added a drift term in the stochastic process that could be incorporated into a volatility estimator using only daily opening, highest, lowest, and closing prices. Their estimator $\hat{\sigma}_{RS}^2$ can be written as follows:

$$\begin{aligned}\hat{\sigma}_{RS}^2 = \frac{1}{N}\sum_{n=t-N}^{t} & \ln(H_n/O_n)[\ln(H_n/O_n) - \ln(C_n/O_n)] \\ & + \ln(L_n/O_n)[\ln(L_n/O_n) - \ln(C_n/O_n)].\end{aligned} \tag{74.3}$$

Rogers et al. (1994) reported that the Rogers-Satchell estimator yields theoretical efficiency gains compared to the Garman-Klass estimator. They also reported that the Rogers-Satchell estimator appears to perform well when changing drift with as few as 30 daily observations.

Different from Rogers and Satchell (1991), Kunitomo (1992) used the opening and closing prices to estimate a *modified* range corresponding to a hypothesis of a Brownian bridge of the transformed log-price. This basically tries to correct the highest and lowest prices for the drift term:

$$\hat{\sigma}_K^2 = \frac{1}{\beta_N} \sum_{p=t-N}^{t} \left[\ln\left(\hat{H}_n / \hat{L}_n \right) \right], \tag{74.4}$$

where. two estimators $\hat{H}_n = \underset{t_i}{\text{Arg}} \left[\underset{P_{t_i}}{\text{Max}} \{ P_{t_i} - [O_n + (C_n - O_n)/t_i] + (C_n - O_n) \mid t_i \in [n-1, n] \} \right]$ and $\hat{L}_n = \underset{t_i}{\text{Arg}} \left[\underset{P_{t_i}}{\text{Min}} \{ P_{t_i} - [O_n + (C_n - O_n)/t_i] + (C_n - O_n) \mid t_i \in [n-1, n] \} \right]$ are denoted as the end-of-the-day drift correction highest and lowest prices. $\beta_N = 6/(N\pi^2)$ is a correction parameter.

Finally, Yang and Zhang (2000) made further refinements by deriving a price range estimator that is unbiased, independent of any drift, and consistent in the presence of opening price jumps. Their estimator $\hat{\sigma}_{YZ}^2$ thus can be written as follows:

$$\begin{aligned} \hat{\sigma}_{YZ}^2 = {} & \frac{1}{(N-1)} \sum_{n=t-N}^{t} \left[\ln(O_n/C_{n-1}) - \overline{\ln(O_n/C_{n-1})} \right] \\ & + \frac{k}{(N-1)} \sum_{n=t-N}^{t} \left[\ln(O_n/C_{n-1}) - \overline{\ln(O_n/C_{n-1})} \right] + (1-k)\, \hat{\sigma}_{RS}^2, \end{aligned} \tag{74.5}$$

where $k = \frac{0.34}{1.34 + (N+1)/(N-1)}$. The symbol $\overline{X}$ is the unconditional mean of X, and σ_{RS}^2 is the Rogers-Satchell estimator. The Yang-Zhang estimator is simply the sum of the estimated overnight variance, the estimated opening market variance, and the Rogers and Satchell (1991) drift-independent estimator. The resulting estimator therefore explicitly incorporates a term for the closed market variance.

Shu and Zhang (2006) investigated the relative performance of the four range-based volatility estimators including Parkinson, Garman-Klass, Rogers-Satchell, and Yang-Zhang estimators for S&P 500 index data and found that the price range estimators all perform very well when an asset price follows a continuous geometric Brownian motion. However, significant differences among the various range estimators are detected if the asset return distribution involves an opening jump or a large drift.

In terms of efficiency, all previous estimators exhibit substantial improvements. Defining the efficiency measure of a volatility estimator $\hat{\sigma}_i^2$ as the variance estimation compared with the close-close estimator, $\hat{\sigma}^2$, that is,

$$Eff\left(\hat{\sigma}_i^2\right) = \frac{Var\left(\hat{\sigma}^2\right)}{Var\left(\hat{\sigma}_i^2\right).} \tag{74.6}$$

Parkinson (1980) reported a theoretical relative efficiency gain ranging from 2.5 to 5, which means that the estimation variance is 2.5–5 times lower. Garman and Klass (1980) reported that their estimator has an efficiency of 7.4; while the Yang and Zhang (2000) and Kunitomo (1992) variance estimators resulted in a theoretical efficiency gain of 7.3 and 10, respectively.

In addition to the variance estimation, Rogers and Zhou (2008) proposed a new estimator for the correlation based on the opening, closing, high, and low prices of two asset prices. However, they concluded that the range-based estimator of correlation does not perform better than the simpler estimator based only on the opening and closing prices. Nevertheless, it still points to new possibilities for future research.

74.3 The Range-Based Volatility Models

This section provides a brief overview of the models used to forecast range-based volatility. In what follows, the models are presented in increasing order of complexity. For an asset, the range of the log-prices is defined as the difference between the daily highest and lowest prices in a logarithm type. It can be denoted by

$$R_t = \ln(H_t) - \ln(L_t). \tag{74.7}$$

According to the Christoffersen's (2002) result applied to the S&P 500 data, the range-based volatility R_t showed more persistence than the squared return based on estimated autocorrelations. Thus, the range-based volatility estimator of course could be used instead of the squared return for evaluating the forecasts from volatility models, and with the time series of R_t, one can easily construct a volatility model under the traditional autoregressive framework.

Instead of using the data of range, nevertheless, Alizadeh et al. (2002) focused on the variable of the log range, $\ln(R_t)$, since they found that in many applied situations, the log range follows an approximately normal distribution. Therefore, all the models introduced in the section except for Chou's CARR model are estimated and forecasted using the log range.

The following range-based volatility models were first introduced with some simple specifications, including random walk, moving average (MA), exponentially weighting moving average (EWMA), and autoregressive (AR) models.

Hanke and Wichern (2005) thought that these models were fairly basic techniques in the applied forecasting literature. Additionally, we also provide some models with a much higher degree of complexity, such as the stochastic volatility (SV), CARR, and range-based multivariate volatility models.

74.3.1 The Random Walk Model

The log range $\ln(R_t)$ can be viewed as a random walk. It means that the best forecast of the next period's log range is this period's estimate of log range. As in most papers, the random walk model is used as the benchmark for the purpose of comparison.

$$E[\ln(R_{t+1})|I_t] = \ln(R_t), \tag{74.8}$$

where I_t is the information set at time t. The estimator $E[\ln(R_{t+1})|I_t]$ is obtained conditional on I_t.

74.3.2 The MA Model

MA methods are widely used in time series forecasting. In most cases, a moving average of length N where $N = 20$, 60, 120 days is used to generate log range forecasts. Choosing these lengths is fairly standard because these values of N correspond to 1 month, 3 months, and 6 months of trading days, respectively. The expression for the N day moving average is shown below:

$$E[\ln(R_{t+1})|I_t] = \frac{1}{N}\sum_{j=0}^{N-1} \ln\left(\mathrm{R}_{t-j}\right). \tag{74.9}$$

74.3.3 The EWMA Model

EWMA models are also very widely used in applied forecasting. In EWMA models, the current forecast of log range is calculated as the weighted average of the one period past value of log range and the one period past forecast of log range. This specification appropriately provides the underlying log range series with no trend.

$$E[\ln(\mathrm{R}_{t+1})|I_t] = \lambda E[\ln(R_t)|I_{t-1}] + (1-\lambda)\ln(\mathrm{R}_t). \tag{74.10}$$

The smoothing parameter, λ, lies between zero and unity. If λ is zero then the EWMA model is the same as a random walk. If λ is one, then the EWMA model places all of the weight on the past forecast. In the estimation process the optimal value of λ was chosen based on the root mean squared error criteria. The optimal λ is the one that records the lowest MSE.

Like the above-mentioned EWMA model, Harris and Yilmaz (2010) combined the Parkinson range estimator and the open-to-close return to propose a hybrid EWMA variance model.

$$\hat{\sigma}_{t+1}^{\text{Hybrid}} = \lambda \hat{\sigma}_{t}^{\text{Hybrid}} + (1-\lambda)\hat{\sigma}'_{P,t}, \tag{74.11}$$

where $\hat{\sigma}'_P = \frac{1}{4\ln 2}(\ln H_t - \ln L_t)^2 + (O_t - C_{t-1})^2$.

74.3.4 The AR Model

This model uses an autoregressive process to model log range. It combines the dynamic volatility with the range information. There are n lagged values of past log range to be used as drivers to forecast one period ahead.

$$E[\ln(\mathrm{R}_{t+1})] = \beta_0 + \beta_i \sum_{i=1}^{n} \ln(\mathrm{R}_{t+1-i}). \tag{74.12}$$

Li and Hong (2011) introduced the range-based autoregressive volatility (AV) model which was first proposed by Hsieh (1991, 1993). Their empirical study showed that the range-based AV model performs better than the GARCH model in the in-sample and out-of-sample comparisons.

74.3.5 The Discrete-Time Range-Based SV Model

Alizadeh et al. (2002) presented a formal derivation of the discrete-time SV model from the continuous-time SV model. The conditional distribution of log range is approximately Gaussian:

$$\ln R_{t+1} \big| \ln R_t \sim N\left[\ln \overline{R} + \rho\left(\ln R_{t-1} - \ln \overline{R}\right), \beta^2 \Delta t\right], \tag{74.13}$$

where $\Delta t = T/N$, T is the sample period, and N is the number of intervals. The parameter β models the volatility of the latent volatility. Following Harvey et al. (1994), a linear state space system including the state equation and the signal equation can be written as

$$\ln R_{(i+1)\Delta t} = \ln \overline{R} + \rho_{\Delta t}\left(\ln R_{i\Delta t} - \ln \overline{R}\right) + \beta\sqrt{\Delta t}\upsilon_{(i+1)\Delta t}. \tag{74.14}$$

$$\ln\left|f\left(s_{i\Delta t,\,(i+1)\Delta t}\right)\right| = \gamma \ln R_{i\Delta t} + E\left[\ln\left|f\left(s^{*}_{i\Delta t,\,(i+1)\Delta t}\right)\right|\right] + \varepsilon_{(i+1)\Delta t}. \tag{74.15}$$

Equation 74.14 is the state equation and Eq. 74.15 is the signal equation. In Eq. 74.15, E is the mathematical expectation operator. The state equation errors are i.i.d. $N(0,1)$ and the signal equation errors have a mean of zero.

A two-factor model can be represented by the following state equation:

$$\begin{aligned} \ln R_{(i+1)\Delta t} &= \ln \overline{R} + \ln \overline{R}_{1,(i+1)\Delta t} + \ln \overline{R}_{2,(i+1)\Delta t}. \\ \ln R_{1,(i+1)\Delta t} &= \rho_{1,\Delta t} \ln R_{1,i\Delta t} + \beta_1 \sqrt{\Delta t}\upsilon_{1,(i+1)\Delta t}. \\ \ln R_{2,(i+1)\Delta t} &= \rho_{2,\Delta t} \ln R_{2,i\Delta t} + \beta_2 \sqrt{\Delta t}\upsilon_{2,(i+1)\Delta t}. \end{aligned} \tag{74.16}$$

The error terms υ_1 and υ_2 are contemporaneously and serially independent $N(0, 1)$ random variables. Compared with one-factor volatility model for currency future prices, the two-factor model shows more desirable regression diagnostics. Asai and Unite (2010) extended this model to capture the leverage and size effects, but their empirical result did not support Alizadeh et al. (2002) theory; on the contrary, they showed that the conditional distributions of the selected returns are non-normal.

74.3.6 The Range-Based EGARCH Model

Brandt and Jones (2006) incorporated the range information into the EGARCH model, named by the range-based EGARCH model. The model significantly improves both in-sample and out-of-sample volatility forecasts. The daily log range and log returns are defined as the followings:

$$\ln(R_t)\big|I_{t-1} \sim N\left(0.43 + \ln h_t, 0.29^2\right), \quad r_t\big|I_{t-1} \sim N\left(0, h_t^2\right), \tag{74.17}$$

where h_t is the conditional volatility of the daily log return r_t. Then, the range-based EGARCH for the daily volatility can be expressed by

$$\ln h_t - \ln h_{t-1} = \kappa(\theta - \ln h_{t-1}) + \phi X_{t-1}^R + \delta r_{t-1}/h_{t-1}, \tag{74.18}$$

where θ is denoted as the long-run mean of the volatility process and κ is denoted as the speed of mean reversion. The coefficient δ decides the asymmetric effect of lagged returns. The innovation

$$X_{t-1}^R = \frac{\ln(R_{t-1}) - 0.43 - \ln h_{t-1}}{0.29} \tag{74.19}$$

is defined as the standardized deviation of the log range from its expected value. It means ϕ is used to measure the sensitivity to the lagged log ranges. In short, the range-based EGARCH model replaces the innovation term with the standardized log range.

74.3.7 The CARR Model

This section provides a brief overview of the CARR model used to forecast range-based volatility. The CARR model is also a special case of the multiplicative error model (MEM) of Engle (2002b) extended from the GARCH approach. The MEM model is used to model a nonnegative valued process, such as trading volume, duration, realized volatility, and range.[2] The MEM model provides conditional expectations of the variables like the GARCH approach and avoids the effect of zeros as resorting to logs. It can be extended to a multivariate case through the use of copula functions (Cipollini et al. 2009).

Instead of modeling the log range in the previous parts of this section, Chou (2005) focused the process of the price range directly. With the time series data of price range R_t, Chou (2005) presented the CARR model of order (p, q) or CARR (p, q) as

$$\begin{aligned} R_t &= \lambda_t \varepsilon_t, \varepsilon_t \sim f(.), \\ \lambda_t &= \omega + \sum_{i=1}^{p} \alpha_i R_{t-i} + \sum_{j=1}^{q} \beta_j \lambda_{t-j}, \end{aligned} \tag{74.20}$$

where λ_t is the conditional mean of the range based on all information up to time t and the distribution of the disturbance term ε_t, or the normalized range, is assumed to have a density function $f(.)$ with a unit mean. Since ε_t is positively valued given that both the price range R_t and its expected value λ_t are positively valued, a natural choice for the distribution is the exponential distribution.

The equation of the conditional expectation of range can easily be extended to incorporate other explanatory variables, such as trading volume, time to maturity, and lagged return:

$$\lambda_t = \omega + \sum_{i=1}^{p} \alpha_i R_{t-i} + \sum_{j=1}^{q} \beta_j \lambda_{t-j} + \sum_{k=1}^{L} l_k X_k. \tag{74.21}$$

This model is called the CARR model with exogenous variables, or the CARRX model. The CARR model essentially belongs to a symmetric model. In order to describe the leverage effect of financial time series, Chou (2006) divided the whole price range into two single-side price ranges, upward range and downward range. Further, he defined UPR_t, the upward range, and DNR_t, the downward range, as the differences between the daily highs, daily lows, and the opening price, respectively, at time t. This can be expressed as follows:

$$UPR_t = \ln(H_t) - \ln(O_t), \tag{74.22}$$

$$DNR_t = \ln(O_t) - \ln(L_t). \tag{74.23}$$

[2]Please refer to Engle and Russell (1998), Engle and Gallo (2006), and Manganelli (2005).

Similarly, with the time series of single-side price range, UPR_t or DNR_t, Chou (2006) extended the CARR model to the asymmetric CARR (ACARR) model. In volatility forecasting, the asymmetric model also performed better than the symmetric model. Chen et al. (2008) proposed a range-based threshold conditional autoregressive (TARR) model which has superior ability in volatility forecasting. In addition, Lin et al. (2012) proposed a nonlinear smooth transition CARR model to capture smooth volatility asymmetries in international financial markets.

74.3.8 The Range-Based Multivariate Volatility Model

The multivariate volatility models have been extensively researched in recent studies. They provide relevant financial applications in various areas, such as asset allocation, hedging, and risk management. Bauwens et al. (2006) offered a review of the multivariate volatility models. As to the extension of the univariate range models, Fernandes et al. (2005) proposed one kind of multivariate CARR (MCARR) model using the formula $\mathrm{Cov}(X, Y) = [V(X + Y) - V(X) - V(Y)]/2$. Moreover, Lee and Shin (2008) drove conditions for stationarity, geometric ergodicity, and β-mixing with exponential decay. Analogous to Fernandes et al. (2005)) work, Brandt and Diebold (2006) used no-arbitrage conditions to build the covariances in terms of variances. However, this kind of method could substantially apply to a bivariate case.

Chou et al. (2009) combined the CARR model with the DCC model of Engle (2002a) to propose a range-based volatility model, which uses the ranges to replace the GARCH volatilities in the first step of DCC. They concluded that the range-based DCC model performs better than other return-based models (MA100, EWMA, CCC, return-based DCC, and diagonal BEKK) through the statistical measures, RMSE and MAE, based on four benchmarks of implied and realized covariance.

The DCC model is a two-step forecasting model which estimates univariate GARCH models for each asset and then calculates its time-varying correlation by using the transformed standardized residuals from the first step. The related discussions about the DCC model can be found in Engle and Sheppard (2001), Engle (2002a), and Cappiello et al. (2006). It can be viewed as a generalization of the constant conditional correlation (CCC) model proposed by Bollerslev (1990). The conditional covariance matrix $\mathbf{H}_t$ of a $k \times 1$ return vector $\boldsymbol{r}_t$ in CCC ($\mathbf{r}_t|\Omega_{t-1} \sim N(0, \mathbf{H}_t)$) can be expressed as

$$\mathbf{H}_t = \mathbf{D}_t\mathbf{R}\mathbf{D}_t, \tag{74.24}$$

Where $\mathbf{D}_t$ a $k \times k$ diagonal matrix with time-varying standard deviations $\sqrt{h_{i,t}}$ of the ith return series from GARCH on the ith diagonal. $\mathbf{R}$ is a sample correlation matrix of $\mathbf{r}_t$.

The DCC is formulated in the following specification:

$$\begin{aligned}
&\mathbf{H}_t = \mathbf{D}_t\mathbf{R}_t\mathbf{D}_t, \\
&\mathbf{R}_t = diag\{\mathbf{Q}_t\}^{-1/2}\mathbf{Q}_t diag\{\mathbf{Q}_t\}^{-1/2}, \\
&\mathbf{Q}_t = \mathbf{S}\circ\left(\boldsymbol{\iota}\boldsymbol{\iota}' - \mathbf{A} - \mathbf{B}\right) + \mathbf{A}\circ\mathbf{Z}_{t-1}\mathbf{Z}_{t-1} + \mathbf{B}\circ\mathbf{Q}_{t-1}, \mathbf{Z}_t = \mathbf{D}_t^{-1}\times\mathbf{r}_t,
\end{aligned} \tag{74.25}$$

where $\boldsymbol{\iota}$ is a vector of ones and $\circ$ is the Hadamard product of two identically sized matrices which are computed simply by element multiplication. $\mathbf{Q}_t$ and $\mathbf{S}$ are, respectively, the conditional and unconditional covariance matrices of the standardized residual vector $\mathbf{Z}_t$ that came from GARCH. For the CARR case, the standardized residual vector $\mathbf{Z}_t^*$ is calculated from the adjusted conditional range.[3] $\mathbf{A}$ and $\mathbf{B}$ are estimated parameter matrices. Most cases, however, set them as scalars. In a word, DCC differs from CCC by only allowing $\mathbf{R}$ to be time varying.

It is difficult to introduce the exogenous variables into the DCC model because of the technical limitations for the mean reverting process. Chou and Cai (2009) proposed a double smooth transition conditional correlation CARR (DSTCC-CARR) model.[4] In addition to the multi-asset CARR part, the DSTCC-CARR model builds the smooth transition correlation structure through the standardized residuals $\mathbf{Z}_t^*$ of the rescaled range.

$$E\left[\mathbf{Z}_t^*\mathbf{Z}'^*_t|\Omega_{t-1}\right] = P_t, \tag{74.26}$$

$$\begin{aligned}
P_t = &(1-G_{2t})\big((1-G_{1t})P_{(11)} + G_{1t}P_{(21)}\big) \\
&+ G_{2t}\big((1-G_{1t})P_{(12)} + G_{1t}P_{(22)}\big),
\end{aligned} \tag{74.27}$$

where the transition logistic functions are $G_{jt} = \left(1 + e^{-\gamma_j(s_{jt}-c_j)}\right)^{-1}, \gamma_j > 0, j = 1, 2.$ The symbols c_j and γ_j in the transition function are location and speed parameters, respectively. Please see Chou and Cai (2009) for the details. Base on this framework, Cai et al. (2009) used CPI and VIX as transition variables to investigate the correlations among six international stock indices.

74.3.9 Other Model Extensions

In addition to the classification of range models, Harris et al. (2011) developed a cyclical volatility model which employs the range to investigate the short and long

---

[3]For asset i, $z_{i,t}^* = r_{i,t}/\lambda_{i,t}^*$, where $\lambda_{i,t}^* = adj_i \times \lambda_{i,t}$ and $adj_i = \frac{\overline{\sigma}_i}{\overline{\hat{\lambda}}_i}$. The scaled expected range $\lambda_{i,t}^*$ is computed by a product of $\lambda_{i,t}$ and the adjusted coefficient adj_i which is the ratio of the unconditional standard deviations $\overline{\sigma}_i$ for the return series to the sample mean $\overline{\hat{\lambda}}_i$ of the estimated conditional range.

[4]Silvennoien and Terasvirta (2008, 2009) proposed the smooth transition conditional correlation GARCH (STCC-GARCH) model and the double smooth transition conditional correlation GARCH (DSTCC-GARCH) model.

dynamics of exchange rate volatility. Their results indicated that the cyclical volatility model performed better than the range-based EGARCH and FIEGARCH models in computational efficiency and out-of-sample forecast. In contrast to modeling range directly, some studies put the range into existing models to increase the explanatory power. For example, Lin and Rozeff (1994) put the estimated range process into the GARCH model and showed that the range estimator was still useful in explaining the conditional variance.

74.4 The Realized Range Volatility

There has been much research investigating the measurement of volatility due to the use of high-frequency data. In particular, the realized volatility, calculated by the sum of squared intraday returns, provides a more efficient estimate for volatility. The review of realized volatility has been discussed in Andersen et al. (2001), Andersen et al. (2003), Barndorff-Nielsen and Shephard (2005), Andersen et al. (2006, 2007), and McAleer and Mederos (2008). Martens and van Dijk (2007) and Christensen and Podolskij (2007) replaced the squared intraday return with the high/low range to get a new estimator called realized range.

Initially, we assumed that the asset price P_t follows the geometric Brownian motion:

$$dP_t = \mu P_t dt + \sigma P_t dz_t, \tag{74.28}$$

where μ is the drift term, σ is the constant volatility, and z_t is a Brownian motion. There are τ equal-length intervals divided into a trading day. The daily realized volatility RV_t at time t can be expressed by

$$RV_t = \sum_{i=1}^{\tau} \left(\ln P_{t,i} - \ln P_{t,i-1}\right)^2, \tag{74.29}$$

where $P_{t,i}$ is the price for the time $i \times \Delta$ on the trading day t and Δ is the time interval. Then, $\tau \times \Delta$ is the trading time length in a trading day. Moreover, the realized range RR_t is

$$RR_t = \frac{1}{4\ln 2} \sum_{i=1}^{\tau} \left(\ln H_{t,i} - \ln L_{t,i-1}\right)^2, \tag{74.30}$$

where $H_{t,i}$ and $L_{t,i}$ are the highest price and the lowest price of the ith interval on the tth trading day, respectively.

As mentioned before, several studies suggest improving efficiency by using the open and close prices, like Garman and Klass (1980). Furthermore, assuming that P_t follows a continuous sample path, Martingale, Christensen, and Podolskij (2007) proposed integrated volatility and showed this range estimator remains consistent in the presence of stochastic volatility.

$$\ln P_t = \ln P_0 + \int_0^t \mu_s ds + \int_0^t \sigma_{s-} dz_t, \;\; for \;\; 0 \le t < \infty. \tag{74.31}$$

The obvious and important question is that the realized range should be seriously affected by microstructure noise. Martens and van Dijk (2007) considered a bias-adjustment procedure, which scales the realized range by using the ratio of the average level of the daily range and the average level of the realized range. Christensen et al. (2009) provided another bias correlation for the realized range to help divide the high-frequency data to minimize its asymptotic conditional variance. Both found that the scaled realized ranges perform better than the (scaled) realized volatility. Todorova (2012) also showed that the adjusted realized ranges perform better than the daily range for the DAX 30 index.

It is interesting to note that the realized range can be extended to estimate covariance. Bannouh et al. (2009) used the concept of Brandt and Diebold's (2006) non-arbitrage portfolio to propose a realized co-range estimator:

$$RCR_t = \frac{1}{2\lambda_1\lambda_2}\left(RR_{P,t} - \lambda_1^2 RR_{1,t} - \lambda_2^2 RR_{2,t}\right), \tag{74.32}$$

where $RR_{p,t}$, $RR_{1,t}$, and $RR_{2,t}$ are the realized ranges of the portfolio P, asset 1, and asset 2. λ_1 and λ_1 are the weights of two assets in the portfolio ($\lambda_1 + \lambda_2 = 1$).

74.5 The Financial Applications of Range Volatility

The range mentioned in this chapter is a measure of volatility. From the theoretical points of view, it indeed provides a more efficient estimator of volatility than the return. It is intuitively reasonable due to the further information provided by the range data. In addition, the return volatility neglects the price fluctuation, especially when existing a short distance between the closing prices of the two trading days. We can therefore conclude that the high/low range volatility should contain some additional information compared with the close-to-close volatility. Moreover, the range is readily available, which has low cost. Hence, most research related to volatility may be applied to the range. Bollerslev et al. (1992) and Poon and Granger (2003) provided extensive discussions on the application of volatilities in the financial markets.

Before the range was adapted by the dynamic structures, however, its application was very limited.[5] Based on the SV framework, Gallant et al. (1999) and Alizadeh, Brandt, and Diebold incorporated the range into the equilibrium asset pricing models. Chou (2005) and Brandt and Jones (2006), on the other hand, filled the

[5]In some studies, range was used as one of the estimators to improve the explanatory power of models.

gap between a discrete-time dynamic model and range. Their work creates many opportunities for future research. In the following sections, we will give a classified review for the financial applications of range volatility.

74.5.1 Value at Risk

Value at Risk (VaR) is designed to measure the potential loss of the asset. It is widely used in the financial markets. We can calculate it by $\mathrm{VaR}_t^{\alpha} = \mu_t + f_{\alpha}\sigma_t$, where α is the given significant level and f_{α} is the left quantile of the distribution F at α. Asai and Brugal (2012) used an asymmetric heterogeneous ARMA model to fit range for estimating VaR and showed that the one-step-ahead VaR forecast of the log range performed well during the global financial crisis. Chen et al. (2012) proposed a range-based threshold conditional VaR (CAViaR) model which also outperformed other models during the crisis. Moreover, Brownlees and Gallo (2010) showed that the daily range performed as well as the ultra-high-frequency data (UHFD) volatility measure they proposed for VaR prediction. In addition, Shao, Lian and Yin (2009) used the CARR model to model the realized range in estimating VaR, but it only performed the same with the realized volatility model. However, Louzis et al. (2012) found that the adjusted realized range can generate superior VaR estimates.

74.5.2 Hedge

With the development of conditional volatility models, there has been a dramatic increase in future hedging. From the calculation of minimum variance hedging, the optimal dynamic hedge ratio can be expressed as $h_t = \rho\sigma_{S,t}/\sigma_{F,t}$, where ρ is the correlation of spot and futures returns and $\sigma_{s,t}$ and $\sigma_{F,t}$ are the standard deviations of spot and futures returns, respectively. Within frameworks of a constant conditional correlation (CCC) model and a dynamic conditional correlation (DCC) model, Chou and Liu (2011) showed that the range-based multivariate volatility model has more efficiency gain than the return-based approaches.

74.5.3 Volatility Spillover

Volatility spillover can reflect the information flow among financial markets. Most studies analyze the behavior of volatility spillover by estimating the conditional variance and covariance. Gallo and Otranto (2008) estimated the weekly range through a new Markov Switching bivariate model to show the relevant role of Hong Kong as a dominant market. Engle et al. (2012) applied daily range to a multivariate MEM approach which is used to discuss the volatility transmission across East Asian markets. Chiang and Wang (2011) combined copula functions with a time-varying logarithmic CARR (TVLCARR) model to investigate the volatility contagion for the G7 stock markets.

74.5.4 Portfolio Management

Covariance process plays an important role in asset allocation. Based on the conditional mean-variance framework, Chou and Liu (2010) used Chou et al. (2009) method to show that the economic value of volatility timing for the range is significant in comparison to the return. Wu and Liang (2011) did similar work by incorporating dynamic copulas into an asymmetric CARR model. The results imply that the range volatility can be extended to practical applications.

74.5.5 Microstructure Issues

In recent years, there has been a shift in attention to high-frequency data for some financial assets. It must be noted that the microstructure analysis often accompanies different levels of microstructure noise.[6] Martens and van Dijk (2007) claimed that the realized range also cannot avoid the bias caused from the microstructure noise.[7] However, Akay et al. (2010) showed that the alternative range-based volatility estimates are relatively efficient and removed the upward bias caused by the microstructure noise. Kalev and Duong (2008) utilized Martens and van Dijk's (2007) realized range to test the Samuelson Hypothesis for the futures contract.[8]

74.5.6 Other Financial Applications

As mentioned above, range is available and can easily be applied to volatility issues. Chou et al. (2103) adopted the CARR model to investigate the long-term impact of terrorist attacks on the maturity, volume, and open interest effects for the S&P 500 index futures. Corrado and Truong (2007) reported that the range estimator has similar forecasting ability of volatility compared with the implied volatility. However, the implied volatilities are not available for many assets and the option markets are insufficient in many developed countries. In such cases, the range is more practical. Besides, range is often used as one of volatility proxies. Please refer to Liu and Hung (2010), Patton (2011), Liu et al. (2012), Chen and Wu (2009), Karanasos and Kartsaklas (2009), and Gallo and Otranto (2008).

In contrast to the range itself, some studies pay more attention to the high and low prices. Cheung et al. (2009) employed a vector error correlation model (VECM)

[6]In general, it mainly comes from bid-ask bounce and varies with the sampling frequency.

[7]For low-frequency data, Alizadeh et al. (2002) showed that the range estimator is efficient and free of microstructure noise.

[8]The Samuelson (time-to-delivery) effect means that volatility increases when a futures contract approaches its delivery date. Ripple and Moosa (2009) also used the realized range to test the effect of maturity, trading volume, and open interest on crude oil futures. In contrast, Karali and Thurman (2010) just used the daily range to prove the Samuelson effect.

to model the dynamic relationship between the high and low prices of stock indices. Please also see He and Wan (2009) and He et al. (2010) for the relevant applications.

74.6 Conclusion and Limitations

Volatility plays a central role in many areas of finance. In view of the theoretical and practical studies, the price range provides an intuitive and efficient estimator of volatility. In this study, we began our discussion by reviewing the price range estimators. There has been a dramatic increase in the number of publications on this work since Parkinson (1980) introduced the high/low range. From then on, some new range estimators have been considered with opening and closing prices. The new price range estimators are distributed feasible weights according to the differences among the highest, lowest, opening, and closing. Through the analysis, we can gain a better understanding of the nature of range.

Some dynamic volatility models combined with price range are also introduced in this chapter. They led to broad applications in finance, especially the CARR model, which incorporates both the superiority of range in forecasting volatility and the elasticity of the GARCH model. In addition, the range-based volatility models contribute significantly to the financial applications. Last, the realized range replaced the squared intraday return of realized volatility with the high/low range to obtain a more efficient estimator. Although the financial applications of range volatility are still in its infancy, the possible areas such as risk management, investment, and microstructure issues are explained in this chapter. Future studies are obviously required for this topic.

The range estimator undoubtedly has some inherent shortcomings. It is well known that the financial asset price is very volatile and is easily influenced by instantaneous information. In statistics, the range is very sensitive to the outliers. Chou (2005) provided an answer by using the quantile range to get a robust measure of price range. For example, the new range estimator can be calculated by the difference between the top and the bottom 5 % observations on average. Also see Yeh et al. (2009) for further discussion.

In theory, many range estimators in previous sections depended on the assumption of continuous-time geometric Brownian motion. The range estimators derived from Parkinson (1980) and Garman and Klass (1980) required a geometric Brownian motion with zero drift. Rogers and Satchell (1991) allowed a nonzero drift, and Yang and Zhang (2000) further allowed overnight price jumps. Moreover, only finite observations can be used to build the range. It means the range will appear with some unexpected bias, especially for the assets with lower liquidity and finite transaction volume. Garman and Klass (1980) pointed out that this will produce the later opening and early closing. They also said the difference between the observed highs and lows will be less than that between the actual highs and lows. It means that the calculated high/low estimator should be downward biased. In addition, Beckers (1983) pointed that disadvantaged buyers and sellers may trade the highest and lowest prices, so the range values might be less representative for measuring volatility. Because of the limitations involved and the importance of range volatility measure, range-based volatility modeling will continue to be a specialist subject and studied vigorously.

Abstract

This chapter describes a business model in a contingent claim modeling framework. The model defines a "primitive firm" as the underlying risky asset of a firm. The firm's revenue is generated from a fixed capital asset and the firm incurs both fixed operating costs and variable costs. In this context, the shareholders hold a retention option (paying the fixed operating costs) on the core capital asset with a series of growth options on capital investments. In this framework of two interacting options, we derive the firm value.

The chapter then provides three applications of the business model. Firstly, the chapter determines the optimal capital budgeting decision in the presence of fixed operating costs and shows how the fixed operating cost should be

accounted by in an NPV calculation. Secondly, the chapter determines the values of equity value, the growth option, and the retention option as the building blocks of primitive firm value. Using a sample of firms, the chapter illustrates a method in comparing the equity values of firms in the same business sector. Thirdly, the chapter relates the change in revenue to the change in equity value, showing how the combined operating leverage and financial leverage may affect the firm valuation and risks.

Bottom-up capital budgeting • Business model • Capital budgeting • Contingent claim model • Equity value • Financial leverage • Fixed operating cost • Gross return on investment (GRI) • Growth option • Market performance measure • NPV • Operating leverage • Relative value of equity • Retention option • Return attribution • Top-down capital budgeting • Wealth transfer

75.1 Introduction

A "business model" often simply describes "ways that a firm makes money." It is a general description of the business environment, forecasts of earnings, and the proposed business strategies, and it often lacks the rigorous specification of a financial model. Despite the ambiguity, business models are important to corporate finance, investments, portfolio management, and many aspects of financial businesses.

They provide a framework to determine a firm's value, to evaluate corporate strategies, and to distinguish one firm from another firm or one business sector to another. The prevalent use of business models cannot be understated. Yet, despite the tremendous growth in applications of financial modeling in capital markets, the use of financial principles in developing business models is largely unexplored.

An early example of financial modeling of a business is pioneered by Stoll (1976). He presents a business model of a market maker. Demsetz (1968) suggests that market makers are in the business of providing liquidity to a market and they are compensated by the market via their bid-ask spreads. Stoll then develops the optimal dealer's bid-ask prices within Demsetz's business environment and shows precisely how a trader should set their bid-ask quotes, their trading strategies relating to their inventory positions, and finally the profits to the traders under competition. In short, Stoll provides the business model of a trading firm, leading to the subsequent growth of the microstructure theory. The successful use of the "dealer's business model" in microstructure theory demonstrates the importance of insights gained in modeling a business. For example, Ho and Marcis (1984) extend the business model to incorporate the fixed operating costs of a market making firm to determine the equilibrium number of market makers in the AMEX market.

However, to date, few rigorous business models have been proposed in the corporate finance literature. There are some examples. Trigeorgis (1993) values projects as multiple real options on the underlying asset value. Botteron et al. (2003) use barrier options to model the flexibility in production and sales of multinational enterprises under exchange rate uncertainties. Brennan and Schwartz (1985) determine the growth model of a mining firm. Cortazar et al. (2001) develop a real option model for valuing natural resource exploration investments such as oil and copper when there is joint price and geological-technical uncertainty. Gilroy and Lukas (2006) formalize the choice of market entry strategy for an individual multinational enterprise from a real option perspective. Fontes (2008) addresses investment decisions in production systems by using real options. Sodal et al. (2008) value the option to switch between the dry bulk market and wet bulk market for a combination carrier. Villani (2008) combines the real option approach with the game theory to examine an interaction between two firms that invest in R&D. Wirl (2008) investigates optimal maintenance of equipment under uncertainty and the options of scrapping versus keeping the equipment as a backup while paying the keeping cost. These models explore the use of contingent claim models in various corporate financial decisions ranging from abandoning or increasing the mining capabilities to scrapping versus maintenance of equipment. In reality, real option approach is in three different corporate uses. There are a strategic way of thinking, an analytical valuation tool, and an organization-wide process for evaluation, monitoring, and managing capital investment according to Triantis and Borison (2001).

This chapter extends the real option literature to describe the business models in a more general context. The purpose of the chapter is twofold: firstly we propose the use of real option approach to describe a business and secondly we show how such a business model can be used in some applications.

Our model is a discrete time, multi-period, contingent claim model. We assume that a firm is subjected to a business risk. The revenues are generated from a capital asset. It has to incur a fixed operating cost, making a fixed payment continually (a perpetual payment) to stay in business, and has the options to invest in future projects. That is, the firm must pay an exercise price continually to retain the option in business and at the same time maintains the growth options of Myers (1984). Such retention options and the growth options cannot be separated.

The model is applicable to many business sectors, including the retail chain companies, airlines, software companies, and other businesses whose revenues are generated from a core capital investment and whose expense structure consists of both fixed operating costs and variable costs. The inputs to the business model can be drawn from the published financial statements and market data, and therefore, the model is empirically testable.

We then show how the business model can be used in three important areas in corporate finance: (1) to determine the optimal capital budgeting decision given a fixed operating cost, (2) to relative value firms in the same business sector with different business models, and (3) to relate the change of the firm's revenue to the change of the equity value.

The first application deals with what Myers (1984) describes as two approaches in capital budgeting, the discounted cash flow and strategic planning approaches, as "two cultures and one problem" in the valuation of a firm. The bottom-up method (the discounted cash flow approach) determines the net present value of a project, and the manager accepts the project if the net present value is positive and rejects it otherwise. The top-down method (the strategic planning approach) considers all future state-dependent investments simultaneously and determines the optimal investment strategies that maximize the firm value.

While the two approaches are related by the valuation of a firm, corporate finance literature has not described how they are related to each other explicitly. Specifically, in the presence of fixed operating costs, how should the "expenses" of a project, at the margin, be incorporated in the NPV calculation? We show that the standard one period model cannot describe the relationships between the cost of the project to the future inflow of the project and the outflows of the project cost as well as the firm's fixed operating costs. In this chapter, we show how the NPV method is related to the top-down method via the implied fixed-cost measure. Relating to this issue, McDonald (2006) argues that the discounted cash flow and the real option valuation should provide the same answer when the methods are used correctly. However, he further argues that to the extent that the managers who use the real option valuation have effectively adopted a different business model, there is a real and important difference between the discounted cash flow and the real option valuation.

The second application of a business model deals with measuring the impact of the growth option, the debt, and the fixed operating cost on the observed equity value. These results are illustrated by applying the model to a sample of retail chain companies.

The third application focuses on the relationship between the firm's revenues and the stock valuation. We show how the operating leverage and the financial leverage together affect the change in the equity value with a change in the revenue. The model provides a return attribution of the equity returns based on the firm's business model. This approach enables corporate managers to evaluate the impact of the firm's operating leverage and the financial leverage on the risk of the firm's earnings.

The chapter proceeds as follows. Section 75.2 provides the business model of a firm. Section 75.3 provides the numerical simulations of the capital budgeting problem, comparing the optimal capital budgeting decisions based on the bottom-up and top-down decisions. Section 75.4 provides the application of the business model to the equity value decomposition. Section 75.5 describes return attribution results using the business model. Finally, Sect. 75.6 contains the conclusions.

75.2 The Model Assumptions

Many retail chain stores must incur significant fixed operating costs in setting up the distribution system, producing or buying the products, managing the core business processes. At the same time, the retail chain store invests in new distribution centers, and each investment is a capital budgeting decision. Each product development is a capital budgeting decision, which should increase the firm value at the margin. These are some of many examples where capital budgeting decision on each project is part of the business model of the firm, which must include the management of a significant fixed operating cost.

The model uses the standard basic assumptions in real option literature. We assume a multi-period discrete time model where all agents make their decisions at specific regular intervals; the one period interest rate is R_F, a constant; the firm seeks to maximize the shareholders' wealth; and the market is efficient. We assume a frictionless market with no corporate taxes and personal taxes, and therefore, the capital structure is irrelevant to the maximization of shareholders value. The following assumptions describe the model of the firm of this chapter.

Assumption 1. The Business Risk of the Firm (GRI) In this model, unlike many standard real option models, we use the sales (or revenue) of the firm as the risk driver and not the operating profits, as commonly used. The sales represent the business risk of the firm, while the operating profits are affected by the business model of the firm. We assume that the firm is endowed with a capital asset (CA). For example, the capital asset can be a factory that produces goods and services resulting in sales. The sales generated by one unit of the capital asset are called the *gross return on investment* (*GRI*). GRI is the risk driver of the model, and the risk represents the uncertain demand for the products. Therefore, the sales are stochastic, given by the following equation.

$$\text{Sales} = \text{GRI} \times \text{CA} \tag{75.1}$$

When the GRI increases, the firm would increase its sales for the same capital asset. When there is a down turn in GRI, the sales would fall. Extending the model to multiple risk sources should provide a more realistic model but may obscure the basic insights that the model provides.

We assume that GRI follows a binomial lattice process that is lognormal with no drift. The upstate and downstate are given by a proportional increase of $\exp(-\sigma)$ with probability q and a proportional decrease of $\exp(-\sigma)$ with probability (1 – q). σ is the volatility assumed to be constant. The market probability q is chosen so that the expected value of GRI over one period is the observed GRI at the beginning of each step. That is, the risk follows a martingale process.

While GRI follows a recombining binomial process, we will use a non-recombining tree notation. Specifically, we let $n = 0, 1, 2,\ldots$, and for each time n, we let the index i denote the state variable $i = 0, 1, 2,\ldots, 2^n - 1$. Then at any node of the tree (n, i), the binomial upstate and downstate nodes of the following step are denoted by (n, 2i + 1) and (n, 2i), respectively. Then the martingale process is specified by the following equation:

$$\begin{aligned} &GRI(n,i) = q \times GRI(n+1, 2i+1) + (1-q) \times GRI(n+1, 2i), \\ &q = \frac{1 - e^{-\sigma}}{e^{\sigma} - e^{-\sigma}}, \text{where } \sigma \text{ is the volatility of GRI} \end{aligned} \tag{75.2}$$

for $n = 0, 1, 2,\ldots$ and $i = 0, 1, 2,\ldots, 2^n - 1$

Let ρ be the cost of capital for the business risk, which is the required rate of return for that business risk, GRI. Note that the standard cost of capital of a firm reflects the risk of the firm's free cash flows taking the operating leverage into account, not the firm's sales risk as we do here. Since the firm risk is the same at each node, the cost of capital ρ is constant in all states and time periods on the lattice.

Assumption 2. The Primitive Firm (V_p) To apply the contingent claim valuation approach to value the firm, we begin with the definition of the primitive firm as the "underlying security." The primitive firm is a simple corporate entity which has no debt or claims other than the common shares, which are publicly traded.

The firm has one unit capital asset. The capital asset does not depreciate, and the value does not change. We can think of the capital assets as the distribution centers of a retail chain store. Let m be the gross profit margin. For simplicity, in this section, we assume that there are no costs associated in generating the sales, and that m equals unity. And therefore, the firm's sales are the profits, which are distributed to all the shareholders. Equation 75.2 presents the sales risk, and the $GRI(n,i)$ and ρ are the sales and cost of capital of the primitive firm at each node (n,i) on the lattice.

Note that the sales (and hence the profits) are always positive, because GRI follows a multiplicative process. By the definition of the cost of capital, the primitive firm value at each node point on the binomial lattice is

$$V_P(n,i) = \frac{GRI(n,i) \times m \times CA}{\rho}, \text{where m} = 1 \tag{75.3}$$

for $n = 0, 1, 2, \ldots$ and $i = 0, 1, 2, \ldots, 2^n - 1$.

Given the binomial process of the primitive firm, which we will use as the "underlying security," we can derive the risk-neutral probabilities, $p(n, i)$, at time n and state i. The derivation is given in Appendix 1.

$$p = \frac{A - e^{-\sigma}}{e^{\sigma} - e^{-\sigma}}, \text{where } A = \frac{1 + R_F}{1 + \rho} \tag{75.4}$$

When the cost of capital equals the risk-free rate and when the volatility σ is sufficiently small, the risk-neutral probability is approximately 0.5. That is, when σ is small, the upward movement is approximately the same as the downward movement, and therefore, the expected value with the binomial probability of 0.5 shows that the GRI must follow a martingale process. When the cost of capital is high relative to the risk-free rate, the risk-neutral probability would assign a lower weight to the upward movement, according to Eq. 75.4, to balance the use of the risk-free rate, a lower rate than the cost of capital, for discounting the future value. The use of the risk-neutral probability ensures the valuation method is consistent with that of the market valuation of Eq. 75.3.

Note that as long as the volatility and the cost of capital are independent of the time n and state i, the risk-neutral probability is also independent of the state and time and is the same at each node point on the binomial lattice. We will value our firm relative to the primitive firm. Therefore, using the standard relative valuation argument, we may assume that the primitive firm follows a drift at the risk-free rate. The market probability q is relevant only to the extent of determining the cost of capital ρ, but q is not used explicitly in the model.

The use of the risk-neutral probabilities enables us to discount all cash flows of our firm by the risk-free rate in all states of the world. The primitive firm value V_p specifies the stochastic process of the "underlying security," and Eq. 75.4 is the standard assumption made in the contingent claim valuation model.

Assumption 3. The Firm's Cash Flows (CF) and Value (V) *V* is the value of a firm that has fixed operating costs, fixed expenditures for operating purposes. The fixed operating cost (FC) is independent of the units of the goods sold and is paid at the end of each period. Payments to the vendors and suppliers and the employees' salaries and benefits are some examples of the fixed operating costs, and they may constitute a significant part of the firm's cash outflow.

The net profit of the firm, using Eq. 75.1, is given by

$$CF(n,i) = (GRI(n,i) \times CA(n,i) - FC) \tag{75.5}$$

for n = 0, 1, 2, . . . and i = 0, 1, 2,. . ., $2^n - 1$

Note that GRI is the only source of risk to the firm's net income. The firm pays all the net income as dividends. In the case of negative income, the firm issues equity to finance the short fall of cash for simplicity. Therefore, the firm's net income is the free cash flows, and the present value of which is the firm value V.

Assumption 4. The Planning Horizon (T) and the Terminal Conditions We assume that there is a strategic planning time horizon T. We will value the firm at each node at planning horizon T. Conditional on the firm not defaulted before reaching the horizon T, we can determine the firm value at time T.

Without the loss of generality, we make some simplifying assumptions at the terminal date. In this model, we assume that all future fixed operating cost is capitalized at time T to be a constant FC(T). After the horizon date T, the firm may default on the fixed operating cost. And therefore, the capitalized value of the fixed operating cost should depend on the primitive firm value at time T. The value of this capitalized value is also a contingent claim. The value, based on Merton (1973), is provided in Appendix 2 and result will be used later. For clarity of the presentation at this point, we keep the model simple without affecting the main results. Therefore, at the terminal date T, the firm value is given by

$$V(T,i) = Max\begin{bmatrix} V_p - FC(T) + (GRI(T,i) \times CA(T,i) - FC), \\ V_p - FC(T) + (GRI(T,i) \times (CA(T,i)) + I) - FC - I), 0 \end{bmatrix} \tag{75.6}$$

where $V_p = \frac{GRI(T,i) \cdot CA(T,i)}{\rho}$ for i = 0, 1, 2,. . ., 2n − 1.

That is, the firm value at time T is the primitive firm value with the capital asset CA, plus the cash flow of the firm over the final period, net of the capitalized fixed costs. The limited liability of a corporation is assumed in this model, and therefore, the firm value is bounded from being negative.

Assumption 5. Investment Decisions The firm has an option to make $I capital investment at each node, (n, i) every year over the planning horizon. For simplicity, we assume that the decisions are not reversible in that the firm cannot undo the investments in any future state of the world.

The increase of the capital investment leads to a direct increase in the firm's capital assets. And, we have

$$CA(n+1, 2i) = CA(n+1, 2i+1) = CA(n, i) + I(n, i) \tag{75.7}$$

The GRI of the business is not affected by the increase in the firm size, and hence, the business risk is independent of the capital investment. However, the sales are affected by the capital budgeting decisions. The marginal increase in sales to the firm with the investment at the node (n,i) is given by

$$Sales(n, i) = I(n, i) \times GRI(n, i) \tag{75.8}$$

Finally, the investment decisions are made at all the nodes such that the firm value is maximized. It is important to note that since the firm can decide on the investment at each state of the world, $CA(n,i)$ at each node depends on the path to that node. Therefore, the model is a path-dependent model.

These assumptions complete the description of the model. Assumption (1) describes the risk class of the business. Assumption (2) introduces the primitive firm enabling us to relate the cost of capital ρ to the risk-neutral valuation framework. Assumption (3) specifies the business model of the firm, identifying the firm's free cash flows as the residual of all the claims, like the fixed costs, on the firm's sales. We use the simplest business model in this chapter, but this assumption can be generalized to study different business models, which can be specified by different cost and sales structure. Assumption (4) specifies the terminal condition, following the standard assumptions made on the horizon in strategic planning. Assumption (5) specifies the marginal investment $I(n,i)$ that increases the capital asset $CA(n,i)$ The marginal returns of the investments can be generalized, even though, we choose the simplest relationship here. Given the above assumptions, we can now determine the maximum value of the firm based on the optimal capital investment decisions.

Let us use the following numerical example to illustrate the model in Table 75.1. Consider a particular scenario over two periods, where n = 0, 1, 2.

The stochastic variable is GRI. Given the investment schedule on line 3, the capital asset over time is given by line 4. Sales are determined by GRI and CA. The fixed cost is constant over time. The free cash flow is then determined following the standard income statements.

Table 75.1 The numerical example for scenario

Time	0	1	2
GRI	0.05	0.1	0.15
Investment		1	0
CA	30	31	31
Sales		3.1	4.65
FC		3	3
Investment		1	0
Free cashflows		−0.9	1.65

75.3 Simulation Results of the Capital Budgeting Decisions

The firm seeks to maximize the firm value by using the control variables, which are the capital investments, at all the node points along the scenario paths in the binomial lattice to the horizon date. There are $\sum_{n=1}^{T} 2^n$ capital investment decisions.

We use the backward substitution method based on the non-recombining tree. We first assume a set of investment decisions, $I(n, i)$, at each node along all paths. Note that $I(n, i)$ can equal to 0 in some of the nodes. At the horizon date, we can determine the firm value at each node. Then we use the risk-neutral probability and determine the firm value at time $T - 1$, such that the firm value at that node point has a risk-free return based on the risk-neutral probability, V*. Specifically,

$$V^*(T-1, i) = \frac{(p \cdot V(T, 2i+1) + (1-p)V(T, 2i))}{1 + R_F} \tag{75.9}$$

for i = 0, 1, . . .$2^{T-1} - 1$.

Note that we are rolling back a non-recombining tree and not a recombining lattice. Therefore, the state i here denotes a state along a scenario path of a tree, and the states (2i + 1) and 2i refer to the binary states of the subsequent period.

If the firm value is less than the value FC + I, which is the cash outflow, the firm declares bankrupt and has value zero; otherwise, the firm value is $V^* - FC - I$. That is,

$$V(T-1, i) = max\left[\begin{array}{l}(V^*(T-1, i) + \\ GRI \cdot CA(T-1, i) - FC - I(T-1, i), 0\end{array}\right] \tag{75.10}$$

Note that we have assumed that the firm has decided on all the investment decisions at the beginning of the period. Therefore, at each node, the firm is obligated to invest I(n,i), a nonnegative value. We continue with this process recursively, rolling back one period at a time. We then determine the firm value. That is, we recursively apply the following Eq. 75.11 till n = 0.

$$V(n-1,i) = \max\left[\begin{array}{ll}\dfrac{(p\cdot V(n,2i+1)+(1-p)V(n,2i))}{1+R_F}+ & \\ GRI(n-1,i)\times CA(n-1,i)-FC-I(n-1,i), & 0\end{array}\right] \tag{75.11}$$

for n = 0, 1, ...T − 1 and i = 0, 1, ..., $2^n - 1$.

We now seek a set of investment decisions $I(n, i)$ along all the paths to determine the highest value of the firm. This search can be accomplished by a nonlinear optimization procedure.

For clarity of the exposition, we have chosen to use a non-recombining tree and a nonlinear optimization to determine the firm value. However, the model can be specified using a recombining binomial lattice, and the firm value can be determined using the standard roll back method, without the use of any numerical nonlinear optimization method. The model is presented in Appendix 3. We have shown that the two approaches are equivalent.

We simulate the model with the following inputs: the risk-free rate of 10 %; the cost of capital ρ of 10 % with volatility σ of 30 %; a risk-neutral probability p of 0.425557; an initial capital asset CA of \$30 million; and the capitalized fixed cost of FC/0.1, where the capitalized fixed cost is assumed to present value of the perpetual fixed-cost payment discounted at the risk-free rate. We consider the problem over 5 years where the firm can invest \$1 million on a new distribution center at each node on the binomial lattice. The optimal investment decisions (top-down capital budgeting decisions) are determined by a nonlinear optimal search algorithm[1], where the investment decisions are the choice variables with the objective function being the firm value.

The optimal decision can be related to the capital budgeting decisions. When the capital investment is made, the free cash flow (CF) is given by

$$CF = GRI \times CA - FC \tag{75.12}$$

Investment decisions should be made at the margin, and therefore, one may argue that the fixed operating cost is not needed to be considered. Given that the cost of capital is ρ, then the net present value of the project is

$$NPV = \frac{GRI \times I}{\rho} + GRI \times I - I \tag{75.13}$$

The capital investment is made when NPV > 0.[2] This capital budgeting decision can be called a bottom-up approach. In this approach, line managers deal with the capital budgeting decisions, maximizing the net present value of each project which

[1]We use an optimization subroutine, GlobalSearch, written in Mathematica. The description of the procedure is provided at www.loehleenterprises.com.

[2]For clarity of the exposition, let the NPV be defined by Eq. 75.13. To be precise, the expected cash flow may not be perpetual in the presence of default. We will explain the implication of default on the free cash flow later in this section.

they manage. The capital budgeting decisions are made from the line manager's point of view rather than the headquarters' overall view, in the sense that the line manager accepts or rejects a project by focusing on the project's cash flows. If we assume that there is no fixed operating cost, the bottom-up approach can be shown to be the same as the top-down approach. In sum, the net present value maximization at the local level should lead to the global optimization for the firm that has no fixed operating costs.

Figure 75.1 shows the capital budgeting decisions using the bottom-up approach, where 1 and 0 denote the acceptance and rejection decision, respectively. For example, 0 at the top node represents that the firm rejects the project at time 0 and state 0. Since we assume the non-recombining tree, we have 2^n states at period n.

However, if we optimize the capital budgeting decisions using the top-down method, we have different optimal decisions shown in Fig. 75.2, where the shaded nodes represent the states where the capital budgeting decisions differ between the bottom-up and top-down methods.

When we compare Figs. 75.1 and 75.2, the results show that the firm accepts projects using the bottom-up approach that are rejected by the top-down approach. That means many NPV positive projects may have negative impact to firm value.

Note that our model is consistent to that of Myers (1977). By viewing the fixed operating cost as claims to the value of the primitive firms, positive net present value project may not be accepted by the global optimization to maximize the firm value. Our model interprets the result to suggest that portion of the fixed operating costs should be incorporated in the calculation of the net present value of the project. Therefore, our valuation framework provides a model to adjust for the presence of fixed operating costs in capital budgeting in a multi-period context, something that the Myers model does not cover.

Specifically, we define the marginal present value $MPV(n, i)$ at any node point (n, i) to be the marginal increase in the firm value in accepting a project at node (n, i) based on the top-down optimized solution. It is computed

$$MPV(n,i) = FV^{*}(n,i) - FV(n,i) \tag{75.14}$$

where $FV^{*}(n, i)$ and $FV(n, i)$ are the firm values at the node (n, i) with the investment and without the investment, respectively, while holding all the investment decisions in other nodes constant. This definition of the marginal change in the firm value isolates the effect of the investment at a specific node from the growth options at the other nodes.

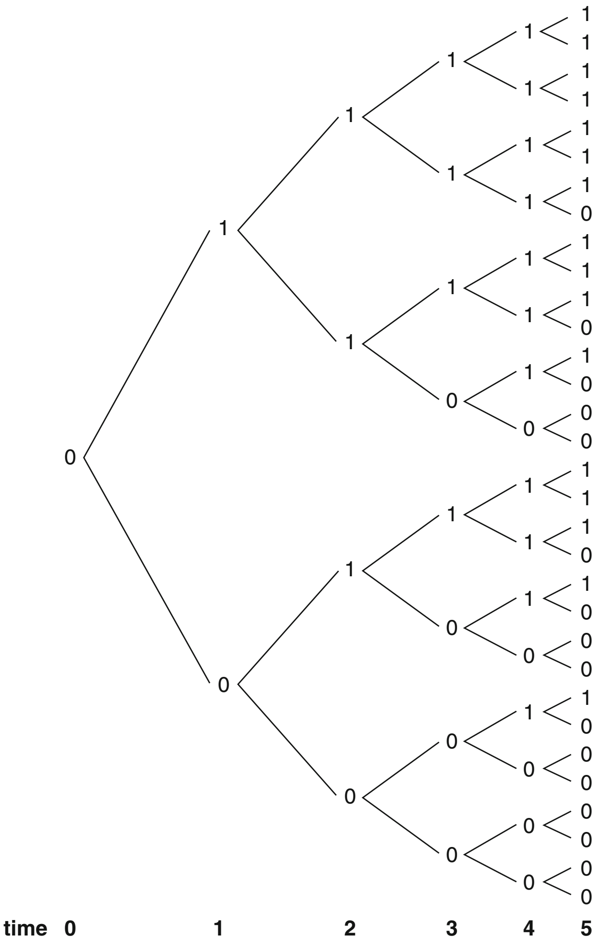
Let $NPV(n, i)$ be the net present value of the project at node (n, i) such that

$$NPV = PV - I \tag{75.15}$$

and let the present value of the fixed cost as a function of the primitive firm value at node (n, i) be

$$F(n,i) = F\left(V_p\right) \tag{75.16}$$

Fig. 75.1 Bottom-up capital budgeting decisions



Then the "wealth transfer," WT, the loss of the shareholders value in taking the project in the presence of the fixed cost, is given by

$$WT(n,i) = \frac{dF}{dV_p} PV(n,i) \tag{75.17}$$

It follows that the marginal change in the firm value is the NPV net of the wealth transfer effect.

$$MPV(n,i) = NPV(n,i) - WT(n,i) \tag{75.18}$$

Rearranging Eqs. 75.15, 75.17, and 75.18, we have

$$MPV(n,i) = PV(n,i) \cdot D - I \tag{75.19}$$

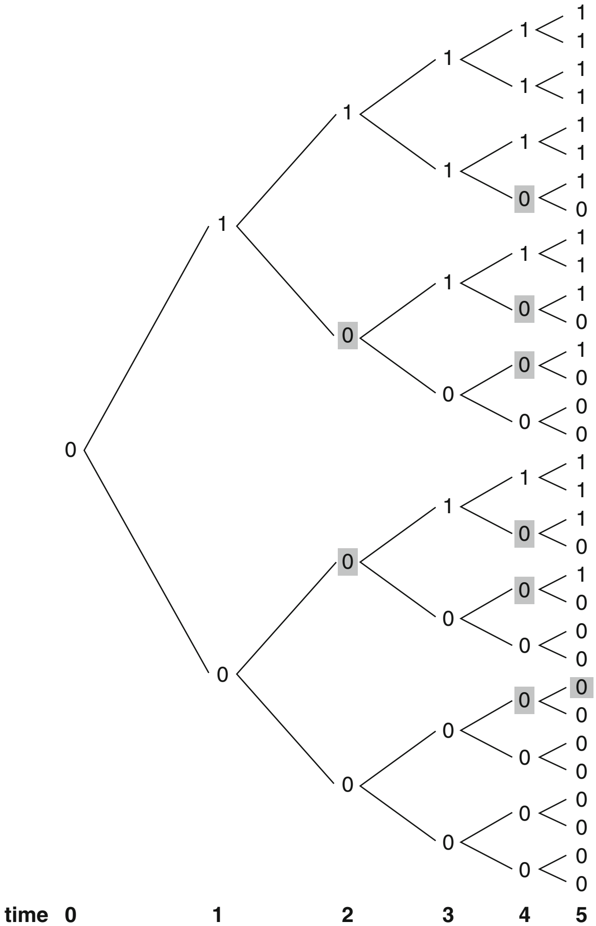


Fig. 75.2 Top-down capital budgeting decisions

$$D = 1 - \frac{dF}{dV_p} \tag{75.20}$$

Note that D as a function of the firm value is determined by the fixed-cost structure. Since we assume that the fixed cost is a fixed cash flow at any time and state, the function is the same at any node. Equation 75.19 can be interpreted intuitively. In the presence of a fixed cost, the capital budgeting decision depends on the fixed-cost factor. Portion of the present value of the incoming cash flow should first be adjusted by the fixed-cost factor and the project is taken (rejected) if MPV > (<) 0.

D can be derived in our model, as the fixed cost can be valued. The plot of the fixed-cost factor as a function of the percentage change in the firm value is provided in Fig. 75.3 below.

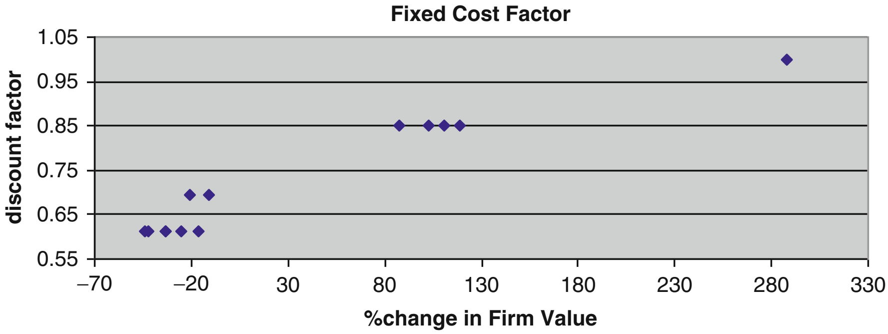

Fig. 75.3 Fixed-cost factor

As expected, the fall in the firm value would lead to a lower discount factor, resulting in more positive NPV projects being rejected. When the firm value is significantly high, the fixed-cost factor is one, and then the NPV and the top-down approach are the same. In general, given a firm's business model, the fixed-cost factor function can be derived. And this function provides the link between the bottom-up and top-down capital budgeting problem.

The model assumes that all the projects are independent of each other in the sense that the capital budgeting decision of one project is independent of the other projects. Using the bottom-up method, the independence of projects would lead to independence in the capital budgeting decisions across the projects. Yet in the presence of the fixed operating cost, it is straightforward to show that optimal decisions of the projects are related. For example, referring to Fig. 75.2 in the top-down capital budgeting decision, we would optimally invest in the upstate for period 1 and would again optimally invest in period 2 in both the upstate and downstate. However, if we do not invest in period 1, then the top-down optimal solution would lead to no investment in the subsequent downstate in the second period. Therefore, the model shows that these projects are not independent in the capital budgeting decision, contrary to the bottom-up capital budgeting decision rule.

75.4 Relative Valuation of Equity

In this section, we decompose the value of the primitive firm into its components. We recognize that the firm's capitalization is a compound option on the underlying business risk. These embedded options are options on the financial leverage, operating leverage and the strategic value. We estimate these option values using a sample of retail chain stores, and we show that such decomposition can provide us useful insights into the valuation the firms' equities.

In deriving the value of the firm, we assume that the firm pays out all the free cash flows and we construct a recombining lattice from the tree described in

Table 75.2 Inputs to the business model

	Target	Lowe's	Wal-Mart	Darden
GRI	2.9769	2.5807	4.8082	2.2823
Gross profit margin(m)	0.3169	0.2880	0.2274	0.2222
Fixed cost/total asset(FC/CA)	0.6564	0.4684	0.7907	0.2293
Capital investment (I/CA)	0.1563	0.2381	0.1530	0.1130
Leverage(CA/E)	1.7218	1.2965	1.3033	1.7190

GRI = Sales/Capital assets
Gross profit margin = (Sales − cost of goods sold)/Sales
I/A = Capital investment/Capital assets
Leverage = Capital assets/Equity

the previous section, such that the firm value is derived by the rolling back procedure. The recombining lattice is described in Appendix 3.

We consider the following retail chain stores: Wal-Mart, Target, Lowe's and Darden. We will describe these firms in brief. Wal-Mart (WMT) is now the largest retailer in North America. The company is operating approximately 4,000 stores worldwide. WMT is also a leader in developing and implementing retail information technology. Target (TGT) is the fourth largest US general merchandise retailer. It has approximately 1,000 stores, with much of their revenue derived from its discount stores. Lowe's Companies (LOW) is the second largest US home improvement retailer, selling retail building materials and supplies through more than 600 stores. Darden Restaurants, Inc (DRI) has over 600 restaurants and is a leader in the casual dining sector. The details of implementing the model using the observed data are provided in Appendix 4.

In this sample of firms, they all share the basic business model of retail chain business. They focus on their core production of their products and they sell the products through their distribution networks. The turnover, which is the sales to the total asset, depends on consumer spending. In times of recession, consumers may lower their spending on merchandizing, dining, and expenditures. As such, we may consider these firms as belonging to the similar risk class with similar cost of capital for the business.

We have shown that the inputs to the business model are profit margin m, fixed operating costs FC, turnover x, capital investment rate I, and leverage l. All these inputs can be derived or observed from the financial statements. The business model then derives the market value of equity, which is also observed in the market. We can calibrate the cost of capital of the business and the business volatility such that the equity value and the model inputs best fit the observed values.

Specifically, we use the data below, based on January 31, 2002 financial statements, as input to the business model in Table 75.2.

We then determine the implied volatility of the business risk driver (volatility) and the implied cost of capital of the business by minimizing the sum of squares of the observed market performance measures and the corresponding model value. The results are presented in Table 75.3.

Table 75.3 Reported and estimated market performance measures

	Target		Lowe's		Wal-Mart		Darden	
	Reported	Estimated	Reported	Estimated	Reported	Estimated	Reported	Estimated
S/E	5.1009	5.3231	5.3543	5.4717	7.6893	7.8420	3.1623	3.2699
S/V	0.8321	0.8500	0.9054	0.9089	0.9351	0.9363	0.8634	0.8779
Cost of capital	0.0860		0.0821		0.0702		0.1036	
Volatility	0.2776		0.3908		0.3149		0.3772	

The cost of capital and volatility are used to calibrate the model such that the sum of squares of the difference between reported and the estimated S/E, p/e and S/V is minimized

The results show that the cost of capital implied from the firm's equity value for Wal-Mart is particularly low when compared with the other retail chain stores. Darden has the highest cost of capital, which is 12.42 %. Target and Lowe's has similar cost of capital of about 9 %.

We can now decompose the primitive firm value of each firm into it building blocks of value. We have shown that the market equity value is a compound option of three options. Equity is an option on the firm value, which has an embedded real option net of the "perpetual risky coupon debt" of the fixed costs. Or the market equity value can be built from the underlying firm value. Starting from the underlying firm value, we can add the real option and net of the perpetual debt. Then all equity firms with a real option (which is an all equity growth firm) are the underlying risky assets, whose European call option is the market value of equity.

Let V_p be the value of the firm without debt, growth, or fixed costs, which we called the primitive firm. It can be calculated by using the valuation model assuming that the fixed cost and capital investment rate are zero. Let V_{fc} be the value of the firm without debt and growth, but has the fixed costs, which we call the fixed-cost firm. F is the market value of the fixed costs, which is defined as

$$F = V_p - V_{fc} \tag{75.21}$$

Let V be the value of the firm without debt, but with optimal capital investment strategy and fixed cost. Then G is the value of the growth option, which can be calculated as the difference between the firm value V and the firm without growth, V_{fc}.

$$G = V - V_{fc}. \tag{75.22}$$

D is the market value of the debt, relatively valued to the firm value V. Then the market capitalization of the firm (market value of the equity) is the underlying firm with the growth option net of the fixed costs and the debt.

$$S = V - D \tag{75.23}$$

Or the equity value can be reexpressed as

Table 75.4 The value decomposition of the capitalization value S

	Target	Lowe's	Wal-Mart	Darden
Mkt equity (S)	41,840	36,520	275,270	3,385
Primitive firm (V*)	161,313	84,728	762,427	9,612
Mkt value fixed cost (F)	129,766	60,269	568,304	6,438
Growth option (G)	17,674	15,722	99,878	682
Mkt value of debt (D)	7,382	3,661	18,732	471
Book equity (E)	7,860	6,674	35,102	1,035
Estimated (S/E)	**5.3231**	**5.4717**	**7.8420**	**3.2699**

Table 75.5 Determinants of the market multiples

	Target	Lowe's	Wal-Mart	Darden
$\mathbf{V_p/CA}$	11.9200	9.7913	16.6651	5.4017
$\mathbf{V_{fc}/V_p}$	0.1956	0.2887	0.2546	0.3302
$\mathbf{V/V_{fc}}$	1.5602	1.6428	1.5145	1.2148
CA/E	1.7218	1.2965	1.3033	1.7190
S/V	0.8500	0.9089	0.9363	0.8779
S/E	**5.3231**	**5.4717**	**7.8420**	**3.2699**
Book value(E/shares)	8.7062	8.6044	7.8004	5.8818

$$S = V_p - F + G - D \tag{75.24}$$

The decomposition of the value is summarized in Table 75.4.

To compare the results across the firms, we can normalize the equity value by the firm's book equity value, by considering the market-to-book multiples (S/E), as reported in the last row of Table 75.4. The results show that Wal-Mart has the highest multiple of 7.8420.

Now, Table 75.5 provides insights into the determinants of the market multiples of the firms. We can use the above results and derive the values in proportions as reported below.

Note that the multiple (S/E) is the product of all the ratios presented in the rows above. And therefore, the table provides a decomposition of the equity multiples. The result shows that the firms have significant fixed operating costs. For example, Target's fixed operating cost is 80.44 % of the primitive firm value. However, the market assigns a significant growth value to Target. In fact, the firm with growth option is a multiple of 1.5602 to the firm without growth option. The results also show that Wal-Mart attains the high multiple because of its high value of the primitive firm value to its total asset. As we have shown above, the high multiple value is mainly the result of a market low cost of capital to the firm business.

The business model provides a systematic approach to determine the building blocks of value to the market observed equity value. And therefore, this approach provides us insight into the determinants of the market value of equity.

Table 75.6 Stock return decomposition by firm values

	Target	Lowe's	Wal-Mart	Darden
$\ln(V_p/CA)$	0.0100	0.0100	0.0100	0.0100
$\ln(V_{fc}/V_p)$	0.0138	0.0085	0.0107	0.0070
$\ln(V/V_{fc})$	–0.0022	–0.0014	–0.0022	0.0003

ln(CA/E)	0.0000	0.0000	0.0000	0.0000
ln(Book value(E/shares))	0.0000	0.0000	0.0000	0.0000
ln(Stock price)	**0.0244**	**0.0180**	**0.0197**	**0.0189**

75.5 Equity Return Attribution

The business model can also provide insights into the relationship between the equity value and the firm's revenue. In this section, we use the business model to determine the impact of a 1 % increase in the gross investment return on the stock returns. And in the process, we determine impact of the operating leverage, financial leverage, and the growth option on the equity returns.

First note that the stock price multiple to the book value can be expressed as follows.

$$\frac{S}{E} = \frac{V_p}{CA} \times \frac{V_{fc}}{V_p} \times \frac{V}{V_{fc}} \times \frac{S}{V} \times \frac{CA}{E} \tag{75.25}$$

It follows that

$$\ln\frac{S}{E} = \ln\frac{V_p}{CA} + \ln\frac{V_{fc}}{V_p} + \ln\frac{V}{V_{fc}} + \ln\frac{S}{V} + \ln\frac{CA}{E} \tag{75.26}$$

Given in proportional increase of GRI by 1 %, the change of the equity to book multiple is given by

$$\Delta\ln\frac{S}{E} = \Delta\ln\frac{V_p}{CA} + \Delta\ln\frac{V_{fc}}{V_p} + \Delta\ln\frac{V}{V_{fc}} + \Delta\ln\frac{S}{V} + \Delta\ln\frac{CA}{E} \tag{75.27}$$

This equation provides an attribution of the proportional change in the stock multiple. The changes of the components are simulated and are provided in Table 75.6.

Note that the sum of the rows equal to the stock price change (the last row). For example, consider Wal-Mart; 1 % increase in the gross return on investment, and hence 1 % increase in sales, would lead to 1.97 % increase in the equity value. The return attribution shows that a significant portion of this return comes from the increase in the primitive firm value (1 %) and the effect of the operating leverage (1.07 %). The % increase of the primitive firm value is directly proportional to the % increase in revenue, by definition. The increase in the growth option value is impacted less by the revenue change, resulting in a negative contribution of the equity returns (–0.22 %). The financial leverage has an insignificant impact (0.13 %) because of the relatively low financial leverage of Wal-Mart measured in market value. The capital asset and book equity value are not affected by the change in revenues. This result seems to apply approximately to other stores in this sample of retail chain stores, showing that these stores are quite similar in the sense that they are industry leaders in their specific businesses. However, for retail chain stores with higher operating leverage relative to the firm's value, then the relationships are more complex.

The analysis shows that the business model enables us to identify how the operating leverage and financial leverage affect the equity returns and thus provides useful insights into the relationship between the market valuation and the profitability of the business. The use of the contingent claim approach to formulate the business risk enables us to incorporate the risk of the business (the volatility of the gross return on investment) to the debt structure and the operating leverage of the firm, something that the traditional financial ratio approach cannot capture.

75.6 Conclusions

This chapter provides a parsimonious model of a firm. The model enables us to value the firm as a contingent claim on the business risks. Using a contingent claim valuation framework, we can then relate the firm maximization to the capital budgeting rule, the fixed operating costs, and the cost of capital of the project as well as that of the firm. The model enables us to determine the impact of the fixed costs on the NPV valuation of a project. The business model also enables us to gain insight into the building blocks of value for the firm's equity and the relationship of the equity returns to its revenues.

Specifically, we have shown that the top-down and bottom-up decisions are related by the fixed-cost factor, which is a function of the firm value. This function can be specified given the business model of the firm. The lower the firm value is, the deeper the discount on the present value of the project is. Therefore, this may lead to a rejection of a positive NPV project. This result has several implications in corporate finance. For some firms with high operating leverage, for example, communication companies, seeking to acquire other firms, the model suggests that the acquisition analysis should focus not only on the synergic effect in the capital budgeting decision but the fixed-cost factor opposing effect. For a start-up company, the extensive use of the operating cost substituting the variable costs would adversely affect its capital budgeting decisions.

While we use retail chain stores to describe the business model, other businesses also share a similar model. Also, the model can be generalized to incorporate multiple risk sources or perpetual fixed operating costs with more complex fixed-cost schedules. These and other extensions of the model are not expected to change the key insights provided in the chapter.

Furthermore, the model assumptions can be relaxed to further investigate other corporate finance issues. For example, the model can analyze the impact of the fixed operating costs on the debt structure. Debts can be viewed as junior debt to the "perpetual debt," the fixed operating cost. The underlying security in this contingent claim valuation is the primitive firm. The impact of the fixed operating costs on the firm's debt may explain the bond behavior observed in the market, as the bond would behave like a junior debt (Ho and Lee 2004b).

Appendix 1: Derivation of the Risk-Neutral Probability

The risk-neutral probabilities $p(n,i)$ can be calculated from the binomial tree of V_p. Let $V_p(n,i)$ be the firm value at node (n,i). In the upstate, the firm value is

$$V_p(n,i) = \frac{GRI(n,i) \times CA}{\rho}$$

By the definition of the binomial process of the gross return on investment,

$$V_p(n+1, 2i+1) = V_p(n,i)e^{\sigma}$$

Further, the firm pays a cash dividend of $C_u = V_p(n,i) \times \rho \times e^{\sigma}$. Therefore, the total value of the firm V_p^u, an instant before the dividend payment in the upstate, is

$$V_p^u = V_p \times (1+\rho) \times e^{\sigma} \tag{75.28}$$

Similarly, the total value of the firm V_p^d, an instant before the dividend payment in the downstate, is

$$V_p^d = V_p \times (1+\rho) \times e^{-\sigma} \tag{75.29}$$

Then the risk-neutral probability p is defined as the probability that ensures the expected total return is the risk-free return.

$$p \times V_p^u + (1-p) \times V_p^d = (1+R_F) \times V_p \tag{75.30}$$

Substituting V_p, V_p^u, V_p^d into equation above and solve for p, we have

$$p = \frac{A - e^{-\sigma}}{e^{\sigma} - e^{-\sigma}} \tag{75.31}$$

Where $A = \frac{1+R_F}{1+\rho}$.

Appendix 2: The Model for the Fixed Operating Cost at Time T

When the firm may default the fixed operating cost, the fixed operating cost can be viewed as a perpetual debt of a risk bond. The valuation formula of the perpetual debt is given by Merton (1973).

$$\Phi(V,\infty) = \frac{FC}{r_f}\left\{1 - \frac{\left(\frac{2FC}{\sigma^2 V}\right)^{\frac{2r_f}{\sigma^2}}}{\Gamma\left(2+\frac{2r_f}{\sigma^2}\right)} M\left(\frac{2r_f}{\sigma^2}, 2+\frac{2r_f}{\sigma^2}, \frac{-2FC}{\sigma^2 V}\right)\right\},$$

Where

V = the primitive firm value

FC = fixed cost per year

r_f = risk free rate

Γ = the gamma function (defined in the footnote)

σ = the standard deviation of $\widetilde{GRI}$

M (•) = the confluent hypergeometric function (defined in the footnote)

$$M\left(a, 2+a, -\frac{2FC}{\sigma^2 V}\right)$$
$$= \frac{1}{br_f} e^{\frac{b}{V}} \left[-(a+a)bFC\left(\frac{b}{V}\right)^a + e^{\frac{b}{V}} FC(aV\Gamma(2+a) + (1+a)(b-aV)\Gamma\left(1+a, \frac{b}{V}\right) \right]$$

where

$$a = \frac{2r_f}{\sigma^2}, b = \frac{2FC}{\sigma^2}, \Gamma(x) = \int_0^\infty t^{x-1}e^{-t}dt,$$
$$and\ \Gamma(a,x) = \int_0^\infty t^{x-1}e^{-t}dt.$$

Appendix 3: The Valuation Model Using the Recombining Lattice

In this model specification, we assume that the GRI stochastic process follows a recombining binomial lattice:

$$GRI(n,j) = q \times GRI(n+1,j+1) + (1-q) \times GRI(n+1,j),$$
$$q = \frac{1-e^{-\sigma}}{e^{\sigma}-e^{-\sigma}}, \text{where } \sigma \text{ is the volatility of GRI},$$

where n = 0, 1,... T and j = 0, ..., n.

At time T, the horizon date, consider the node (T, j); j is the state on a recombining lattice. Suppose that the firm has made k investments in the period T, where $0 \leq k \leq T - 1$. The firm value is given by Eq. 75.32:

$$V(T,j;k) = Max \begin{bmatrix} \dfrac{GRI(T,j) \cdot (CA + (k+1)I)}{\rho} - FC(T) + \\ (GRI(T,j) \times (CA + (k+1)I) - FC - I), \\ \dfrac{GRI(T,j) \cdot (CA + kI)}{\rho} - FC(T) + \\ (GRI(T,j) \times (CA + kI) - FC), 0 \end{bmatrix}, \tag{75.32}$$
$$\text{for k} = 0, \ldots, \text{T and j} = 0, \ldots, \text{T}$$

and CA is the initial capital asset.

Now we roll back one period. We then compare the firm value with or without making an investment I. Given that the firm at the end of the period T − 1 has already invested k times and would not invest at time T − 1, the firm value is

$$\begin{aligned} &\frac{p \cdot V(T,j+1;k) + (1-p) \cdot V(T,j;k)}{1+R_F} \\ &+GRI(T-1,j) \cdot (CA + kI) - FC \end{aligned} \tag{75.33}$$

If the firm at that time invests in the capital asset, then the firm value is

$$\begin{aligned} &\frac{p \cdot V(T,j+1;k) + (1-p) \cdot V(T,j;k)}{1+R_F} \\ &+GRI(T-1,j) \cdot (CA + (k+1)I) - FC - I \end{aligned} \tag{75.34}$$

Optimal decision is to maximize the values of the firm under three possible scenarios: taking the investment, not taking the investment, or defaulting. Therefore, the value of the firm at the node (T − 1, j) with k investments is

$$\begin{aligned} v &= V(T-1,j;k) \\ &= Max \begin{bmatrix} \dfrac{p \cdot V(T,j+1;k+1) + (1-p) \cdot V(T,j;k+1)}{1+R_F} + \\ GRI(T-1,j) \cdot (CA + (k+1)I) - FC - I, \\ \dfrac{p \cdot V(T,j+1;k) + (1-p) \cdot V(T,j;k)}{1+R_F} + \\ GRI(T-1,j) \cdot (CA + kI) - FC, 0 \end{bmatrix}, \\ &for = 0,1, \ldots, T-1, and\ j = 0,1, \ldots, T-1. \end{aligned} \tag{75.35}$$

Now we can determine the firm value recursively for each n, n = T − 1, T − 2,. . .1.

At the initial period,

$$\begin{aligned} &V(T,j;k) = \\ &Max\left[\begin{array}{l}\dfrac{p\cdot V(T,j+1;k)+(1-p)\cdot V(T,j;k)}{1+R_F}+\\ GRI(T,j)\cdot(CA+kI)-FC,0\end{array}\right], \\ &for\ T=j=k=0. \end{aligned} \tag{75.36}$$

The firm value at the initial time can then be derived by recursively rolling back the firm value to the initial point, where $n = 0$. We follow the method of the fiber bundle modeling approach in Ho and Lee (2004a).

To illustrate, we use a simple numerical example. Following the previous numerical example, we assume that the GRI is 0.1, the capital asset CA is 30, the risk-free rate and the cost of capital are both 10 %, the risk-neutral probability is 0.425557, the volatility 30 %, the fixed cost FC is 3, and finally the investment is 1.

Given the above assumption, the binomial process is presented below.

The binomial lattice of GRI

Time	0	1	2	3
j	GRI			
3				0.245960311
2			0.18221188	0.134985881
1		0.134985881	0.1	0.074081822
0	0.1	0.074081822	0.054881164	0.040656966

Given the GRI binomial lattice, we can now derive the firm value lattices. The values are derived by backward substitution. The firm value depends on the capital asset level CA, the state j, and the time n.

		Firm value	V(n,j,CA)		
State j					CA
3				55.2836	32
2				14.9999	32
1				0.0000	32
0				0.0000	32
j					
3				52.5780	31
2			31.0516	13.5150	31
1			5.3286	0.0000	31
0			0.0000	0.0000	31
j					
3				49.8725	30
2			29.0473	12.0302	30
1		14.9802	4.6541	0.0000	30
0	6.329610	1.0230	0.0000	0.0000	30
Time n	**0**	**1**	**2**	**3**	

At time 3, the firm values are derived by Eq. 75.32 for each level of outstanding capital asset level at time 3, an instant before the investment decision. Then the firm values for time 2 are derived by Eq. 75.34. Once again, the firm value depends on the outstanding CA level. The firm value at time 0 does not involve any investment decision, and therefore, it is derived by rolling back from the firm values where the CA level is 30.

Appendix 4: Input Data of the Model

The input data of the model are derived from the balance sheets and income statements of the firms.

Contents

Abstract

Vector autoregression (VAR) models have been used extensively in finance and economic analysis. This paper provides a brief overview of the basic VAR approach by focusing on model estimation and statistical inferences. Applications of VAR models in some finance areas are discussed, including asset pricing, international finance, and market microstructure. It is shown that such approach provides a powerful tool to study financial market efficiency, stock return predictability, exchange rate dynamics, and information content of stock trades and market quality.

76.1 Introduction

Following seminar work by Sims (1980), the vector autoregression (VAR) approach has been developed as a powerful modeling tool for studying the interactions among economic and financial variables and for forecasting. As basic VAR models focus on the statistical representation of the dynamic behavior of time-series data but without much restriction on the underlying economic structure and can be easily estimated, they have gained increasing popularity in both economics and finance. In this chapter, we provide an overview of basic VAR models and some of their most popular applications in financial economics.

76.2 A Brief Discussion of VAR Models

A basic p-lag VAR model has the following form:

$$X_t = A + \Phi_1 X_{t-1} + \Phi_2 X_{t-2} + \ldots + \Phi_p X_{t-p} + \varepsilon_t, t = 1, 2, \ldots T, \tag{76.1}$$

where $X_t = (x_{1,t}, x_{2,t}, \ldots, x_{n,t})'$, and it is an $(n \times 1)$ vector of economic time series. In addition, Φ are coefficient matrices and ε_t is an $(n \times 1)$ vector of residuals. The residual vector is assumed to have zero mean, zero autocorrelation, and time invariant covariance matrix Ω. For example, a p-lag bivariate VAR model can be expressed as

$$\begin{aligned}\begin{pmatrix} x_{1,t} \\ x_{2,t} \end{pmatrix} &= \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} + \begin{pmatrix} \phi_{1,1}^1 & \phi_{1,2}^1 \\ \phi_{2,1}^1 & \phi_{2,2}^1 \end{pmatrix} \begin{pmatrix} x_{1,t-1} \\ x_{2,t-1} \end{pmatrix} \\ &\quad + \cdots + \begin{pmatrix} \phi_{1,1}^p & \phi_{1,2}^p \\ \phi_{2,1}^p & \phi_{2,2}^p \end{pmatrix} \begin{pmatrix} x_{1,t-p} \\ x_{2,t-p} \end{pmatrix} + \begin{pmatrix} \varepsilon_{1,t} \\ \varepsilon_{2,t} \end{pmatrix},\end{aligned} \tag{76.2}$$

where $\text{cov}(\varepsilon_{1,t}, \varepsilon_{2,s}) = \sigma_{12}$ if $t = s$ and $\text{cov}(\varepsilon_{1,t}, \varepsilon_{2,s}) = 0$ otherwise.

76.2.1 Estimation

In order to estimate a VAR model, the number of lags of endogenous variables has to be determined first, as the results and hence inferences from estimation can be very sensitive to the lag choice. The general rule is to choose the lag p to minimize some model selection criteria. Two most common information criteria include the Akaike (AIC) and the Schwarz-Bayesian (SBC):

$$\mathrm{AIC}(p) = \ln\left|\bar{\sum}(p)\right| + \frac{2}{T}pn^2 \tag{76.3}$$

and

$$\mathrm{SBC}(p) = \ln\left|\bar{\sum}(p)\right| + \frac{\ln T}{T}pn^2, \tag{76.4}$$

where $\bar{\sum}(p) = T^{-1}\sum_{t=1}^{T}\hat{\varepsilon}_t\hat{\varepsilon}_t{}'$, and p, T, and n represent the lag, sample size, and number of variables, respectively. Once the lag is determined, the VAR model can be estimated using either the ordinary least squares (OLS) method or the maximum likelihood method.[1]

76.2.2 Inferences

Since a p-lag VAR model contains many parameters, interpreting the estimation results can be difficult especially when p is large. Instead of focusing on interpreting each individual parameter estimated, some summary measures are usually employed to provide useful information on the dynamics among variables included in the model. In this section, we focus on three major kinds of summary analysis.

76.2.2.1 Granger-Causality Tests

One important application of the VAR approach is forecasting. Specifically, this approach can be used to address such questions as whether some variables contain valuable information about the future dynamics of other variables in the model. Granger (1969) proposes a test on the forecasting relationship between two variables, which was further developed in Sims (1972).

According to Granger (1969), in a bivariate VAR model as discussed above, if x_1 helps predict x_2, then x_1 *Granger-causes* x_2. Otherwise, x_1 *fails to Granger-cause* x_2. More formally, x_1 *fails to Granger-cause* x_2 if for all $s > 0$, the mean squared error (MSE) of a forecast of $x_{2,t+s}$ based on $(x_{2,t}, x_{2,t-1}, \ldots)$ is the same as the MSE of a forecast of $x_{2,t+s}$ based on $(x_{1,t}, x_{1,t-1}, \ldots)$ and $(x_{2,t}, x_{2,t-1}, \ldots)$.

To test whether x_1 Granger-causes x_2, we can estimate the following model:

[1]For further discussions on VAR techniques, see Watson (1994); Lutkepohl (1991), and Stock and Watson (2001), among others.

$$x_{2,t} = a_2 + \phi^1_{2,1}\, x_{1,t-1} + \ldots + \phi^p_{2,1}\, x_{1,t-p} + \phi^1_{2,2}\, x_{2,t-1} + \ldots + \phi^p_{2,2}\, x_{2,t-p} + \varepsilon_{2,t}. \tag{76.5}$$

Then we can conduct an F-test on the null hypothesis:

$$\mathrm{H}_0\colon \phi^1_{2,1} = \ldots = \phi^p_{2,1} = 0.$$

If the null hypothesis is rejected, we can conclude that x_1 *Granger-causes* x_2.

While Granger-causality tests provide useful information on the forecasting ability of the model variables, the predicative power of one variable is not equivalent to its true causality ability. Therefore, results from Granger-causality tests need to be interpreted with great caution.

76.2.2.2 Impulse Response Analysis

Another approach to examine the interactions among variables in the VAR model is to use impulse response functions, which represent the reactions of model variables to shocks hitting the system. In order to estimate the impulse response function, we first transform the VAR model into vector moving average form:

$$X_t = \mu + \varepsilon_t + \Psi_1\varepsilon_{t-1} + \Psi_2\varepsilon_{t-2} + \Psi_3\varepsilon_{t-3} + \ldots, \tag{76.6}$$

where $\frac{\partial X_{t+s}}{\partial \varepsilon_t'} = \Psi_s$. Therefore, the (i, j) component of Ψ_s, $\psi_s^{i,j}$ captures the effects of a one-unit shock to variable j at time t (ε_t^j) on variable i at time $t + s$ $(x_{i,t+s})$ and hence is interpreted as the impulse response function.

However, such interpretation is only possible if the elements of ε_t are not correlated, i.e., the variance-covariance matrix of ε_t is a diagonal matrix. Sims (1980) proposes a *recursive causal ordering* to solve this problem. For example, if $X_t = (x_{1,t}, x_{2,t}, x_{3,t})$, then the variables in the X_t can be ordered in a way so that $x_{1,t}$ affects $x_{2,t}$ and $x_{3,t}$ but not vice versa and $x_{2,t}$ affects $x_{3,t}$ but not vice versa. Which particular order to use should be determined by the specific context and economics models being examined. With such recursive causal reordering, the VAR model can be rewritten as

$$\begin{aligned}
x_{1,t} &= a_1 + \Pi_{1,1}X_{t-1} + \Pi_{1,2}X_{t-2} + \ldots + \Pi_{1,p}X_{t-p} + \eta_{1,t} \\
x_{2,t} &= a_2 + \beta_{2,1}x_{1,t} + \Pi_{2,1}X_{t-1} + \Pi_{2,2}X_{t-2} + \ldots + \Pi_{2,p}X_{t-p} + \eta_{2,t} \\
&\vdots \\
x_{n,t} &= a_n + \beta_{n,1}x_{1,t} + \ldots + \beta_{n,n-1}x_{n-1,t} + \Pi_{n,1}X_{t-1} + \Pi_{n,2}X_{t-2} \\
&\quad + \ldots + \Pi_{n,p}X_{t-p} + \eta_{n,t}.
\end{aligned} \tag{76.7}$$

Transform this VAR model into the Wold representation:

$$X_t = \mu + \Theta_0\eta_t + \Theta_1\eta_{t-1} + \Theta_2\eta_{t-2} + \Theta_3\eta_{t-3} + \ldots, \tag{76.8}$$

where Λ_0 is a lower triangular matrix. The impulse response function can be estimated as

$$\frac{\partial x_{i,\,t+s}}{\partial \eta_{j,\,t}} = \theta^s_{i,j} \tag{76.9}$$

where $i, j = 1, 2, \ldots, n$ and $s > 0$.

76.2.2.3 Variance Decomposition

A related issue on the influence of a one-unit shock to the system is its contribution to the variance of the forecast error in predicting the future value of each variable in the system. Specifically, if we write the forecast error of X_{t+s} at time t as

$$X_{t+s} - \hat{X}_{t+s|t} = \varepsilon_t + \Lambda_1 \varepsilon_{t+s-1} + \Lambda_2 \varepsilon_{t+s-2} + \cdots + \Lambda_{s-1} \varepsilon_{t+1}, \tag{76.10}$$

the MSE of this forecast is

$$\begin{aligned} \mathrm{MSE}\left(\hat{X}_{t+s|t}\right) &= E\left[\left(X_{t+s} - \hat{X}_{t+s|t}\right)\left(X_{t+s} - \hat{X}_{t+s|t}\right)'\right] \\ &= \Omega + \Lambda_1 \Omega \Lambda_1{}' + \cdots + \Lambda_{s-1} \Omega \Lambda_{s-1}{}'. \end{aligned} \tag{76.11}$$

For one variable in the model, x_1, the forecast error has the form:

$$x_{i,\,t+s} - \hat{x}_{i,\,t+s|t} = \sum_{h=0}^{s-1} \rho^h_{i,\,1} \eta_{1,\,T+s-h} + \cdots + \sum_{h=0}^{s-1} \rho^h_{i,\,n} \eta_{n,\,T+s-h}. \tag{76.12}$$

With the same *recursive causal ordering* as discussed in the previous section, the variance and covariance matrix is orthogonal. Therefore, the variance of the forecast error for $x_{i,t+s}$ is

$$\mathrm{var}\left(x_{i,\,t+s} - \hat{x}_{i,\,t+s|t}\right) = \sigma^2_{\eta_1} \sum_{h=0}^{s-1} \left(\rho^h_{i,\,1}\right)^2 + \cdots + \sigma^2_{\eta_n} \sum_{h=0}^{s-1} \left(\rho^h_{i,\,n}\right)^2. \tag{76.13}$$

76.3 Applications of VARs in Finance

The VAR models have been used very broadly in the finance literature. In this chapter, we focus on a few important applications to illustrate the advantages and some potential concerns when applying this methodology in empirical studies.

76.3.1 Stock Return Predictability and Optimal Asset Allocation

The VAR has been widely regarded as a useful model to study stock return predictability. Campbell and Shiller (1987) propose the following VAR model for asset returns:

$$\begin{bmatrix} \Delta y_t \\ S_t \end{bmatrix} = \begin{bmatrix} a(L) & b(L) \\ c(L) & d(L) \end{bmatrix} \begin{bmatrix} \Delta y_{t-1} \\ S_{t-1} \end{bmatrix} + \begin{bmatrix} u_{1t} \\ u_{2t} \end{bmatrix}. \tag{76.14}$$

where in the case of the present value model of stock prices, y_t is dividend and S_t is the difference between stock price and a multiple of dividends; and in the case of the term structure of interest rates, y_t is one-period interest rate and S_t is the spread between long-term and short-term interest rates.

For stock market data, they use real annual prices and real dividends on a broad stock index from 1981 to 1986. For term structure data, they use monthly US Treasury 20-year yield series and 1-month Treasury bill rate. They find that y_t is nonstationary and its first difference Δy_t is stationary, while S_t is in general stationary in both the stock market and term structure cases. There is weak evidence of cointegration between stock prices and dividends, although the cointegration relationship in the term structure is more significant. They find that the yield spread Granger-causes short-rate changes and that excess returns on long-term bonds are significantly predictable, although the expectation hypothesis of the term structure is formally rejected. As for stock market, dividend changes are found to be highly predictable and the dividend-price spreads Granger-cause dividend changes. The present value model of stock price is however rejected.

Using a log-linear approximation for stock prices and dividends, Campbell and Shiller (1989) estimate the following bivariate VAR:

$$\begin{bmatrix} \delta_t \\ r_{t-1} - \Delta d_{t-1} \end{bmatrix} = \begin{bmatrix} a(L) & b(L) \\ c(L) & d(L) \end{bmatrix} \begin{bmatrix} \delta_{t-1} \\ r_{t-2} - \Delta d_{t-2} \end{bmatrix} + \begin{bmatrix} u_{1t} \\ u_{2t} \end{bmatrix} \tag{76.15}$$

where d_t is log dividends, δ_t is log dividend-price ratio, r_t is ex post discount rate, and $r_t - \Delta d_t$ is interpreted as the growth-adjusted discount rate. Campbell and Shiller (1989) find that stock returns are somewhat predictable. The lagged log dividend-price ratio has a positive impact on stock returns, and lagged real dividend growth rate has a negative impact. The findings that dividend-price ratio has predicting power for future stock returns are consistent with earlier studies (e.g., Shiller 1984; Flood et al. 1986). Log dividend-price ratio Granger-causes real dividend growth. Short-term discount rates are not helpful in explaining stock-price movements.

Hodrick (1992) studies the statistical properties of three models for predicting stock returns on long horizons. The three model specifications are (1) OLS regression of stock return on past dividend yield originally proposed by Fama and French (1988), (2) a reorganization of the first specification where log stock return is regressed by cumulative past dividend yields, and (3) a first-order VAR in three variables: log stock returns, dividend yields, and 1-month Treasury bill return relative to its previous 12-month moving average. Using simulations, Hodrick (1992) finds that the VAR alternative has the correct size, and provides unbiased long-horizon statistics, and therefore is the preferred technique to the other two model specifications in the prediction of stock return over long horizons. Empirically, the VAR tests provide strong evidence of predictive power of the 1-month-ahead return. The VAR approach is a useful alternative way to properly calculate various statistics in long-horizon predictions, including the implied regression slope coefficients, implied R^2, and variance ratios.

Several authors report that the log of earnings, dividends, and stock prices are integrated of order one processes, and both dividend payout and dividend yields are stationary (e.g., Cochrane 1992; Mankiw et al. 1991; Lee 1996). That is, log earnings and dividends series are cointegrated of order one. Log stock prices and log dividends are also cointegrated of order one. Lee (1998) employs a tri-variate structural VAR model to identify the various components of stock price and examine the response of stock prices to different types of shocks: permanent and temporary changes in earnings and dividends and changes in discount factors and nonfundamental factors. The variables in the structural VAR are the change in log earnings, the spread between log dividends and earnings, and the spread between log stock prices and dividends. Lee (1998) finds that about half of the stock-price variation is unrelated to earnings or dividend changes. Time-varying excess stock returns account for much of the remaining deviation of stock prices. Deviation of stock prices from fundamentals does not persist for a long time, suggesting a fad interpretation of stock market movements.

The VAR has been employed to study optimal consumption and portfolio decisions over long horizons when asset returns are not i.i.d. For example, Campbell and Viceira (1999) use a restricted VAR consisting of the excess stock market returns over the risk-free rate and the log dividend-price ratio. The VAR parsimoniously describes the changing investment opportunity over time for the long-horizon investor. The predictability of asset returns over time significantly increases the complexity of the optimal consumption and portfolio solution. Using a log-linear approximation, Campbell and Viceira (1999) nicely obtain an analytic solution. Optimal portfolio consists of two components. The first component is the myopic demand which is what one would obtain in the absence of asset return predictability. This is the classical result on optimal asset allocation. The second component is the hedging demand which arises due to the serial correlation of asset returns. Campbell et al. (2003) extend the model to allow multiple assets in the VAR. Viceira (2001) examines long-horizon consumption and portfolio decisions with nontradable labor income. These studies demonstrate how the VAR can be conveniently employed to yield interesting and important insight in the consumption and portfolio optimization.

76.3.2 Exchange Rate Prediction

The VAR is widely used to study exchange rate dynamics. We summarize several papers on exchange rate predictability. There is a large literature on exchange rates forecasting, started from the seminal work of Meese and Rogoff (1983), who report that most structural and time-series exchange rate models, including an unconstrained VAR consisting of exchange rate and six key macroeconomic variables, cannot produce a better forecast of future spot exchange rates than the naïve random walk model. Subsequent authors develop various models and techniques to better understand exchange rate dynamics, hoping to produce more accurate forecast of exchange rates than the naïve random walk.

Bekaert and Hodrick (1992) consider the following VAR model for two countries (e.g., the United States which is called country 1 and Japan which is called country 2):

$$Y_t = A_0 + A_1 Y_{t-1} + u_{t+1} \tag{76.16}$$

where
$Y_t = [r_{1t}, r_{2t}, rs_{2t}, dy_{1t}, dy_{2t}, fp_{2t}]'$,
r_{jt} is the excess equity market return in country j,
rs_{jt} is the excess dollar rate of return on a currency j money market investment,
dy_{jt} is the dividend yield in country j,
fp_{jt} is the forward premium on currency j in terms of the US dollars.

They find that dividend yields that are known to have predictive power for equity returns can predict excess returns in foreign exchange market. Similarly, forward premiums that are known to predict excess returns in the foreign exchange market have predictive power for equity excess returns. They also find that excess returns in the foreign exchange market have strong positive persistence.

Baillie and Bollerslev (1989) employ a VAR to study the long-run and short-run dynamics of spot and forward exchange rates for seven major currencies against the US dollar. They report that spot and forward exchange rates can be characterized as unit-root processes, and spot and forward exchange rates are cointegrated for each currency pair. Furthermore, one common unit root, or stochastic trend, is detected in the multivariate time-series models for the seven spot and forward exchange rates. These findings suggest that the seven exchange rates possess one long-run relationship and that the disequilibrium error around the long-run relationship can partly explain the subsequent short-run movements in the exchange rates.

Diebold et al. (1994) examine one immediate implication of the Baillie and Bollerslev (1989) finding that spot and forward exchange rates are cointegrated. That is, cointegration implies an error-correction representation of spot and forward exchange rates that should better forecast the change in future spot exchange rate than the naïve random walk model. Empirical findings of Diebold et al. (1994) are however quite negative. The VAR model with the cointegration restriction does not produce more accurate out-of-sample forecast of exchanges rates than the simple martingale model in short horizons. Mark (1995) and Mark and Sul (2001) however find substantial predictability of exchange rates over longer horizons (3–4 years) when monetary fundamental variables are employed.

Numerous papers study the information contents of the forward foreign exchange rate premium in predicting future spot exchange rate changes. According to the uncovered interest rate parity, when the forward exchange rate is traded at a 1 % premium relative to the current spot exchange rate, the future spot exchange rate should be expected to depreciate by 1 %. However, empirically the uncovered interest rate parity is strongly rejected. Furthermore, the forward premium often forecasts the change in future spot exchange rate in the opposite direction. Hai et al. (1997) propose a permanent-transitory components model for the spot and forward exchange rates. The permanent component which is shared by the spot and forward exchange rates is a random walk without drift, while the transitory components of spot and forward exchange rates are assumed to follow a vector autoregressive moving average process. The model is estimated using the Kalman filter. They report that this simple parametric model is useful in understanding why the forward rate may be an unbiased predictor of future spot rate even though an increase in forward premium predicts a dollar appreciation. The estimates of the expected excess return on short-term dollar-denominated assets are persistent and reasonable in magnitude.

Mark and Wu (1998) find that a vector error correction model for the spot and forward exchange rates can account for many salient features of the data. In particular, the estimated risk premium series is highly persistent, the risk premium and the expected future depreciation of the spot exchange rate alternate between positive and negative values and change sign infrequently. They show that standard intertemporal asset pricing model is not capable of generating reasonable foreign exchange risk premiums and therefore does not help to explain why the forward exchange premium forecasts future spot exchange rate changes in the wrong direction. On the other hand, a noise-trader model along the line of De Long et al. (1990) is potentially promising in explaining the anomaly.

76.3.3 Measuring Market Quality and Informational Content of Stock Trades

The VAR approach has also been applied to high-frequency data to measure informational content of stock trades and the quality of security markets. For example, Hasbrouck (1991) uses the following vector autoregressive system to model the interaction of trades and quote revisions:

$$r_t = \sum_{i-1}^{I} a_i r_{t-i} + \sum_{i=0}^{I} b_i x_{t-i}^0 + v_{1,t}, \tag{76.17}$$

and

$$x_t^0 = \sum_{i-1}^{I} c_i r_{t-i} + \sum_{i=1}^{I} d_i x_{t-i}^0 + v_{2,t}, \tag{76.18}$$

where t indexes transactions and r_t and x_t^0 represent price changes and trade direction, respectively. Within this framework, the information content of a trade is measured as the ultimate impact of the trade innovation on the stock price and can be inferred from the impulse respond function of price changes to a shock to x_t^0. Specifically, if an order arrives at time t, its cumulative impact on quote revisions through step m is represented by

$$\alpha_m\left(v_{2,t}\right) = \sum_{i=0}^{m} E\left[r_{t+i}|v_{2,t}\right]. \tag{76.19}$$

As m increases, $\alpha_m(v_{2,t})$ can be shown to converge to the revisions in the efficient price resulting from the shock $v_{2,t}$.

Notably, this model differs from usual VAR specification since the contemporaneous net trading volume appears as one of the independent variables in explaining quotes returns. This is largely due to the trades/quote timing convention assumed in the study. According to Hasbrouck (1991), trades (x_t) take place after market makers post bid and ask quotes (r_{t-1}). Based on the trades occurred, market makers revise their quotes (r_t) and more trades follow. Therefore, even though x_t and r_t carry the same subscript t, they are not determined simultaneously. In fact, r_t takes place after x_t and hence cannot influence x_t. Such *recursive causal ordering* is also necessary in order to estimate the impulse response function.

In another influential paper, Hasbrouck (1993) uses the VAR specification to discuss a new measure of market quality. In this model, security transaction prices are decomposed into a random walk component, identified as the efficient price, and a residual stationary component, termed the pricing error. Specifically, the (logarithm of) the actual transaction price at t, p_t, is modeled as

$$p_t = m_t + s_t \tag{76.20}$$

where m_t is the efficient price which follows a random walk and s_t is the pricing error which is a zero-mean covariance-stationary stochastic process.

As discussed in Hasbrouck (1993), the pricing error consists of two components, an information uncorrelated component (e.g., arising from inventory effects) and an information correlated component (which arises from adverse selection effects). This dispersion of the pricing error, denoted σ_s, measures how closely the real transaction price tracks the efficient price and hence measures the market quality: the smaller the σ_s, the higher the market quality.

To empirically determine σ_s, Hasbrouck (1993) estimates a vector autoregressive (VAR) model over a set of four price and trade variables $\{r_t, x_t^0, x_t, x_t^{1/2}\}$, where $r_t = p_t - p_{t-1}$, x_t^0 is the trade direction (which is equal to 1 for buys and -1 for sells), and x_t and $x_t^{1/2}$ represent signed size and signed square root of size, respectively. The σ_s is then calculated for each firm as a function of the estimated variance-covariance matrix and the coefficient matrix of the VAR model under the Beveridge-Nelson identification restriction (1981).[2] Applying this measure to a sample of NYSE firms, Hasbrouck (1993) finds that the average σ_s is about 0.33 % of the stock price, and it exhibits elevation at both the beginning and end of the trading session.

76.3.4 Relative Informational Efficiency

The relative informational efficiency of related asset markets has been of great interests to finance scholars for decades. Numerous studies have employed the VAR approach to address substantial questions such as whether prices/trading activities in one market reflect new information faster than that in the other markets. Following seminal work by Black (1975), there has been a huge literature studying inter-market relationships between the stock and option markets. The underlying rationale is that any information related to the value of a firm's equity security should also be reflected in its derivative contracts, and which market moves first in response to the arrival of new information is determined to a large degree by informed traders' preferences for trading. According to Black (1975), the option market might be more attractive to informed traders than the market for the underlying stock because options offer higher financial leverage, and the option market is characterized by less stringent margin requirements and no uptick rule for short selling.

Whether the option market is indeed leading the stock market in reflecting new information has been directly examined in numerous empirical studies. One approach is to analyze the dynamic relationship between the stock and option markets using a VAR model. For example, Chan et al. (2002) propose the following multivariate VAR model on the trades and quotes revisions in options and their underlying stocks:

$$r_t = a_1 r_{t-1} + \cdots + a_p r_{t-p} + b_0 x_t + b_1 x_{t-1} + \cdots b_p x_{t-p} + \varepsilon_{1,t}, \tag{76.21}$$

and

$$x_t = c_1 r_{t-1} + \cdots + c_p r_{t-p} + d_1 x_{t-1} + \cdots d_p x_{t-p} + \varepsilon_{2,t}. \tag{76.22}$$

In this model, $r_t = [r_t^s, r_t^c, r_t^p]'$ and $x_t = [x_t^s, x_t^c, x_t^p]'$, where r_t^s, r_t^c, and r_t^p denote returns calculated using quote midpoints and x_t^s, x_t^c, and x_t^p represent net trading volume (buyer-initiated volume minus seller-initiated volume) in the stock, call, and put option markets during time interval t, respectively. Further, the error terms $\varepsilon_{1,t}$ and $\varepsilon_{2,t}$ are assumed to have zero means and are jointly and serially uncorrelated. This specification is in the same spirit as in Hasbrouck (1991) since the

[2]For more estimation details, refer to Hasbrouck (1993).

contemporaneous net trading volume appears as one of the explanatory variables for quote returns but not vice versa.

The quote returns and net trading volumes are calculated on a 5-min intervals for a sample of 14 most actively traded NYSE stocks with options traded on CBOE for a total of 231 trading days. The authors find that stock net trading volume, but not option trading volume, carries explanatory power for both contemporaneous and subsequent stock and option quote revisions. On the other hand, both stock and option quote revisions predict subsequent quote changes in both markets. These findings suggest that informed traders only initiate trades in the stock market. However, they also trade in the option market by submitting limit orders. This is consistent with the notion that the less liquidity in the option market might discourage informed traders to trade using market orders, despite the high financial leverage it offers.[3]

The VAR approach has also been used in a recent literature on the relative informational efficiency of stocks and corporate bonds. As both stocks and corporate bonds are claims on the issuing firms' assets, any information on the value of these assets will affect their prices. The analysis on the lead-lag relationships between the stock and bond price movements can then be used to address the question as to whether stocks lead bonds in reflecting firm-specific information:

$$R_{s,t} = \alpha_s + \sum_{i=1}^{I} \beta^i_{s,s} R_{s,t-i} + \sum_{i=1}^{L} \gamma^i_{s,b} R_{b,t-i} + \varepsilon_{s,t}, \tag{76.23}$$

and

$$R_{b,t} = \alpha_b + \sum_{i=1}^{I} \beta^i_{b,s} R_{s,t-i} + \sum_{i=1}^{L} \gamma^i_{b,b} R_{b,t-i} + \varepsilon_{b,t}, \tag{76.24}$$

[3]Whether options lead stocks in the price discovery process is still a question open to debate. Early studies in this literature present strong evidence in favor of the option lead in prices. For example, Latane and Rendleman (1976) and Beckers (1981) show that the volatility implied in option prices predicts future stock-price volatility. Consistently, Manaster and Renleman (1982) find that the option-implied stock prices contain valuable information about the equilibrium prices of the underlying stocks that has not been revealed in the stock market. However, Vijh (1988) questions the results in Manaster and Rendleman (1982), since using daily closing prices introduces a bias associated with the bid-ask spread and nonsynchronous trading. After purging the effects of bid-ask spreads, Stephan and Whaley (1990) find that the stock market leads the option market. Nevertheless, Chan et al. (1993) argue that the stock lead is due to the relative smaller stock tick. If the average of the bid and ask is used instead of transaction prices, neither market leads the other. Latter studies on the stock option lead-lag analysis have been focused more on the trading volume. Easley et al. (1998) show that "positive news option volumes" and "negative news option volumes" have predictive power for future stock-price changes. See also Pan and Poteshman (2006) and Cao et al. (2003). By measuring the relative share of price discovery occurring in the stock and option markets, Chakravarty et al. (2004) conclude that informed trading takes place in both stock and option markets, suggesting an important role for option volume.

where $R_{s,t}$ ($R_{b,t}$) represents the return on the stock (bond) at time t. Within this framework, Granger-causality tests are conducted to identify the lead-lag relationships.

Hotchkiss and Ronen (2002) examine pre-TRACE (FIPS) transaction price summaries for 55 high-yield bonds and find that stocks do not lead bonds, consistent with Zhou (2009) who finds that lagged TRACE 50 high-yield bond prices contain valuable information about current stock returns, and that they serve an important role in disseminating firm-specific information.[4] In contrast, Downing et al. (2009) conclude that stock returns do lead nonconvertible bond returns at the hourly level in times of financial distress and that therefore the corporate bond market is less informationally efficient.[5] Gurun et al. (2011) also find significant stock leads for daily bond indices, which diminish with certain information releases. The findings of less informational efficiency of corporate bonds seem to be consistent with the notion that the liquidity (transaction costs) for corporate bonds is much lower (higher) than that for stocks. However, in a recent study by Ronen and Zhou (2012), the authors question the ability of VAR in capturing the information flow between stocks and bonds. Since for any given firm there typically is multiplicity of bond issues (in contrast to a single or very few stock issues), VAR analysis on pair-wise comparisons of each bond with the issuer's stock can be misleading. In fact, it cannot reveal the information most desired by a single trader: whether there exists at least one bond constituting an information-based trading venue. For more discussions, see Ronen and Zhou (2012).

76.4 Summary

This chapter endeavors to summarize the basic structure of a VAR model and some related estimation methods and structural analysis. It also offers a quick overview of some important applications of the VAR approach in both economics and finance. Despite all the advantages for the VAR models, it is important to realize that VAR models can only be applied to stationary time-series data. Therefore, in order to properly implement this approach in empirical studies, certain tests on the stationarity of the time-series data have to be conducted first. If null hypothesis of stationarity is rejected, a vector error correction model (VECM) should be used instead. For more details on VAR and VECM models, please refer to Hamilton (1994).

[4]Zhou's (2009) analysis incorporates the option market trades in addition to the stock and bond market transactions. Chava and Tookes (2005) also incorporate the option markets and examine the volatility reaction of stock, bond, and options to macroeconomic and firm specific information, finding significant effects near announcements. Overall, they find that corporate bond and option trades have information content for future stock price movements.

[5]For convertible bonds, Downing et al. (2009) find that these results also hold, but only for those with conversion options deep in the money. Kwan (1996) first examines the relation between individual stocks and bonds using weekly quote data and also finds evidence in support of stock leads.

Model Selection for High-Dimensional Problems

77

Jing-Zhi Huang, Zhan Shi, and Wei Zhong

Contents

Abstract

High-dimensional data analysis is becoming more and more important to both academics and practitioners in finance and economics but is also very challenging because the number of variables or parameters in connection with such data can be larger than the sample size. Recently, several variable selection approaches

have been developed and used to help us select significant variables and construct a parsimonious model simultaneously. In this chapter, we first provide an overview of model selection approaches in the context of penalized least squares. We then review independence screening, a recently developed method for analyzing ultrahigh-dimensional data where the number of variables or parameters can be exponentially larger than the sample size. Finally, we discuss and advocate multistage procedures that combine independence screening and variable selection and that may be especially suitable for analyzing high-frequency financial data.

Penalized least squares seek to keep important predictors in a model while penalizing coefficients associated with irrelevant predictors. As such, under certain conditions, penalized least squares can lead to a sparse solution for linear models and achieve asymptotic consistency in separating relevant variables from irrelevant ones. Independence screening selects relevant variables based on certain measures of marginal correlations between candidate variables and the response.

Keywords

Model selection • Variable selection • Dimension reduction • Independence screening • High-dimensional data • Ultrahigh-dimensional data • Generalized correlations • Penalized least squares • Shrinkage • Statistical learning • LASSO • SCAD penalty • Oracle property

77.1 Introduction

High-dimensional data analysis has now become increasingly frequent and necessary in various research fields, such as finance, genetics, computer science, and geography. For example, the price of a stock may depend on a huge number of variables, such as the company's dividend yields and price-to-earnings ratios, past values of the stock, related bond and derivative prices, other relevant companies' stock prices, overall market information, and some other macroeconomic factors. How to select significant variables for the price of this stock is important and yet challenging given the high-dimensional space of potential predictors. Another example is the estimation of covariance matrix in portfolio problem. Suppose we want to construct an optimal portfolio using, say, 200 stocks. In this case, there are 20,100 parameters in the covariance matrix to estimate. As the number of stocks to be included in the analysis increases, the number of such parameters to be estimated will increase dramatically. It is also challenging to estimate this large covariance matrix using the traditional statistical methods. For more examples, see Fan and Li (2006), Hastie et al. (2009), and Fan et al. (2011b).

One method often used in the literature to make high-dimensional problems tractable is to assume the sparsity condition – namely, only a small number of predictors are assumed to contribute to the response variable. Under the sparsity principle, variable selection approaches play a fundamental role in model selection. For instance, traditional subset selection methods combined with variable selection criteria, such as the Akaike (1973) information criterion (AIC) and the Bayesian information criterion (Schwartz 1978), may perform well in the relatively low dimensional space. However, these methods suffer from expensive computational cost and model instability for high-dimensional data (Breiman 1996). Recently, various regularization methods have been proposed for variable selection in high-dimensional data analysis. Examples include the least absolute shrinkage and selection operator (LASSO) of Tibshirani (1996), the smoothly clipped absolute deviation (SCAD) (Fan and Li 2001; Zou and Li 2008), the least-angle regression (LARS) algorithm (Efron et al. 2004), the elastic net (Zou and Hastie 2005; Zou and Zhang 2009), the adaptive LASSO (Zou 2006), and the Dantzig selector (Candes and Tao 2007), among others. With the sparsity assumption, regularization methods can improve both the prediction accuracy and the model interpretability in the high-dimensional setting. Some of these newly proposed variable selection methods have been used in economics and finance recently, in areas such as macroeconomic forecasting (Bai and Ng 2008), term structure of interest rates (Huang and Shi 2010), and portfolio choice (Goto and Xu 2010).

Nonetheless, one very important challenge facing both researchers and practitioners nowadays is to better understand ultrahigh-dimensional data, where the number of predictors, say, p, is usually much larger than the sample size, say, n ($p \gg n$) – namely, $\log p = O(n^{\alpha})$ for some $\alpha > 0$. Issues such as computational expediency, statistical accuracy, and algorithmic stability call for new statistical modeling techniques for dimension reduction and model selection (Fan et al. 2009). One such idea is a two-stage procedure: In the first stage (the "screening" stage), some kind of screening is used to reduce the dimension of the original data set; in the next stage (the "cleaning" stage), well-established variable selection methods are used to simultaneously select significant variables and estimate statistical effects of those selected variables. Ji and Jin (2012) show that under certain settings, the two-stage approach has advantages over the one-stage LASSO and subset selection in identifying important predictors in the ultrahigh-dimensional analysis.

One way to implement the first step is to use the independence screening framework developed recently in the theoretical statistics literature. Specifically, at the screening stage, independence screening procedures are used to remove as many irrelevant variables as possible in order to reduce the dimensionality from ultrahigh p to a relatively large-scale d that may be less than n. As such, the independence screening procedures can dramatically reduce the computational complexity. Fan and Lv (2008) propose the sure independence screening (SIS) via Pearson correlation ranking to effectively narrow down the ultrahigh dimensionality to a moderate scale, in which the aforementioned regularization methods can be applied. The authors further show that the SIS enjoys a sure screening property within the context of linear regressions with Gaussian predictors and responses. That is, all truly important predictors can be selected with probability approaching one as the sample size goes to the infinity. Hall and Miller (2009) use the generalized correlation learning to capture nonlinear dependence between predictors and the response. Fan et al. (2009) and Fan and Song (2010) consider a more general version of independent learning that ranks the maximum marginal likelihood estimators or the maximum marginal likelihood for generalized linear models. Some other studies are based on nonparametric methods. For instance, Fan et al. (2011a) propose independence screening based on spline approximation in sparse ultrahigh-dimensional additive models; Zhu et al. (2011) use a model-free sure independent ranking and screening (SIRS) to select important predictors in a general class of multi-index models; and Li et al. (2012) study a unified screening framework via distance correlation learning.

It is also worth mentioning that these screening procedures can possess some favorable theoretical properties, such as the sure screening property (Fan and Lv 2008) and the ranking consistency property (Zhu et al. 2011).

We should also note that two important methods in the literature albeit not focused in this review are factor models and principal component analysis (PCA). Factor models are widely used in unsupervised learning as a means of dimension reduction. The factor structure provides a sequence of best linear approximations to multivariate data set, by seeking nonredundant components that are as statistically independent as possible. In the Gaussian setting, it suffices to find linear orthogonal components, as high-order cross dependence is determined by second moments alone. Consequently, PCA becomes a standard procedure in multivariate analysis and is described in any textbooks on multivariate analysis (see, e.g., Mardia et al. 1980). Extensions of PCA include principal curves and surfaces (Hastie 1994), curvilinear component analysis (Demartines and Hérault 1997), and independent component analysis (Comon 1994). The factor approach has been used widely in finance and economics. For instance, it has been applied to macroeconomic forecasting (Stock and Watson 2002) and asset volatility prediction (Anderson and Vahid 2007). See Campbell et al. (1997) for a more complete reference.

The rest of this chapter is organized as follows. Section 77.2 reviews well-established variable selection methods within the framework of penalized least squares. In Sect. 77.3, we provide a brief review of the existing independence screening methods and call for application in financial studies. Section 77.4 discusses model selection versus dimension reduction. Section 77.5 concludes.

77.2 Variable Selection Approaches

Variable selection techniques play an increasingly important role in the high-dimensional problems. Here, the high dimensionality means that $p = O(n^{\alpha})$ with $0 < \alpha < 1$. In the early stages of statistical modeling, it is typical to include as many as potential influential predictors into a model in order to reduce possible model bias. Nonetheless, it is natural to assume that only a subset of predictors contribute to the response in the true model. Under this sparsity assumption, variable selection can improve both the prediction accuracy and the interpretability of the fitted model.

Consider the following linear regression model:

$$y = \mathbf{X}\beta + \varepsilon, \tag{77.1}$$

where $\mathrm{y} = (Y_1, \ldots, Y_n)^T$ is an $n \times 1$ vector of responses, $\mathbf{X} = (\mathrm{x}_1, \ldots, \mathrm{x}_n)^T$ is an $n \times p$ random design matrix, $\beta = (\beta_1, \ldots, \beta_p)^T$ is a $p \times 1$ vector of parameters, and $\varepsilon = (\varepsilon_1, \ldots, \varepsilon_n)^T$ is an $n \times 1$ vector of independent and identically distributed (i.i.d.) random errors.

When the dimension parameter p is large, it is natural to assume that the model is sparse – namely, only a small subset of predictors, say, true predictors $\{X_j : \beta_j \neq 0, j = 1, \ldots, p\}$, contribute to the response y. We can use variable selection techniques to help identify true predictors.

77.2.1 Classic Variable Selection Criteria

A variable selection criterion is a statistic of a fitted model that measures the goodness of fit. The literature on this issue is extensive. Two well-known examples are the Akaike (1973) information criterion (*AIC*) and the Bayesian information criterion (*BIC*) developed by Schwartz (1978). Another example is the generalized cross-validation statistic (*GCV*) proposed by Craven and Wahba (1979). Also, Shao (1997) discusses the consistency and efficiency of variable selection, and Miller (2002) provides a comprehensive review of the subset selection in regression.

Below we review some widely used variable selection criteria:

- *Residual sum of squares* (*RSS*). For the linear regression model (77.1), many variable selection criteria are built on the residual sum of squares (*RSS*) that is defined as follows:

$$RSS = \left\| \mathrm{y} - \mathrm{X}\hat{\beta} \right\|^2 = \sum_{i=1}^{n} \left(Y_i - \mathrm{x}_i \hat{\beta} \right)^2, \tag{77.2}$$

where $\hat{\beta}$ is an estimate of β. Because $\mathrm{x}_i\hat{\beta}$ is the fitted value of the ith observation Y_i, *RSS* can measure the goodness of model fit.

- R^2 *and adjusted* R^2. R^2 is a commonly used statistic for model fitting and is related to *RSS*. Specifically, we have

$$R_d^2 = 1 - \frac{RSS_d}{RSS_0}, \tag{77.3}$$

where RSS_d is the residual sum of squares when an intercept and d predictors are fitted in the model, where $1 \leq d \leq p$, and RSS_0 is the *RSS* with only the intercept fitted. R^2 can measure how well the fitting of the d predictors is. However, it is known that R^2 increases with the number of predictors used in the model. Therefore, R^2 cannot serve as a variable selection criterion. The adjusted R^2 addresses this concern of R^2 by penalizing the number of predictors used. The more predictors used, the higher the penalty.

The adjusted R^2 is also called Fisher's A-statistic. The latter is defined as follows:

$$\begin{aligned} A_d &= 1 - \left(1 - R_d^2\right)\frac{n-1}{n-d} \\ &= 1 - \frac{RSS_d/(n-d)}{RSS_0/(n-1)}. \end{aligned} \tag{77.4}$$

Fisher's A-statistic A_d does not necessarily increase when a new predictor is added to the model. Therefore, it can serve as a variable selection criterion for model fitting.

- *Prediction sum of squares* (*PRESS*). This is a prediction-based variable selection criterion proposed by Allen (1974). When a model includes d predictors, $PRESS_d$ is defined as follows:

$$PRESS_d = \sum_{i=1}^{n} \left(Y_i - \widehat{Y}_{id}\right)^2, \tag{77.5}$$

  where $\widehat{Y}_{id}$ is the predicted value of Y_i from the fitted model using all observations but the ith one.
- *Cross-validation* (*CV*). Cross-validation can be considered to be a generalization of *PRESS*. The idea of *CV* is that we randomly set a small number of observations (the testing set) aside, use the remaining observations (the training set) to fit the model, predict the testing data set, and then summarize the performance of the prediction.

  If we set only one observation aside each time, we obtain the so-called leave-one-out *CV*, that is, essentially the *PRESS*. In practice, we can partition the data set into K equivalent subsets, leave one subset out each time, and predict this subset using the remaining $K - 1$ ones. Both *CV* and *PRESS* can be used to estimate the prediction errors of the fitted model and provide a good measure of how well the prediction of the proposed model is.

  A related statistic is the generalized cross-validation statistic (*GCV*) for linear regression models proposed by Craven and Wahba (1979) and is defined by the following:

$$GCV = \frac{RSS_d/n}{(1 - d/n)^2}. \tag{77.6}$$

  It is shown that under the mild conditions, if n is much larger than d, the *PRESS* statistic can be asymptotically approximated by

$$\begin{aligned} PRESS_d &\approx \frac{n^2}{(n-d)^2} RSS_d \\ &= \frac{RSS_d}{(1 - d/n)^2} = nGCV. \end{aligned} \tag{77.7}$$

Therefore, GCV is also a widely used variable selection criterion.

- *Akaike information criterion* (AIC). Proposed by Akaike (1973), AIC is related to the Kullback-Leibler mean information and is defined as follows:

$$AIC = RSS_d + 2d\sigma^2. \tag{77.8}$$

It is known that AIC is equivalent to Mallows' C_p (Mallows 1973) measure in linear regression models. For such a model with d predictors, Mallows' C_p of the model is given by the following:

$$C_p = \frac{RSS_d}{\sigma^2} - (n - 2d). \tag{77.9}$$

- *Bayesian information criterion* (BIC). The BIC, suggested by Schwartz (1978), is defined by the following:

$$BIC = RSS_d + \log(n)d\sigma^2. \tag{77.10}$$

In practice, we choose a model with the smallest information criterion to achieve variable selection. It can be shown that the BIC is a consistent criterion. That is, when assuming there exists a true model with finite parameters, the BIC can determine the true model as the sample size approaching the infinity. However, the AIC may provide an overfitted model. On the other hand, the AIC is an asymptotically less efficient criterion (Shao 1997), but the BIC is not.

77.2.2 Penalized Least Squares

Although the best subset selection with classic variable selection criteria can perform well in practice, the method suffers from the highly expensive computational cost, especially for the high-dimensional regression models. Furthermore, the subset selection approaches lack stability, and their theoretical properties are difficult to examine (Breiman 1996).

For linear regression models (77.1), penalized least squares (PLS) methods provide one alternative that can overcome the aforementioned limitations of the subset selection approaches. Consider the following objective function $Q(\beta)$:

$$Q(\beta) = \frac{1}{2}\|\mathrm{y} - \mathbf{X}\beta\|^2 + n\sum_{j=1}^{p} p_\lambda\left(|\beta_j|\right), \tag{77.11}$$

where $p_\lambda(\cdot)$ is the penalty function and λ is the regularity parameter that controls the size of the penalty. We can obtain the PLS estimate $\hat{\beta}^{PLS}$ by minimizing the objective function $Q(\beta)$. If there is no penalty, then we recover the objective function of ordinary least squares and obtain the OLS estimate $\hat{\beta}^{OLS}$.

In the balance of this subsection, we will discuss some well-known penalty functions as well as how to choose a good penalty function. Moreover, we will provide connections between the penalized least squares (77.11) and the classic best subset selection and the ridge regression.

77.2.2.1 L_q Penalties with $0 \leq q \leq 2$

- **L_0 Penalty: Best Subset Selection**

The best subset selection with classic variable selection criteria can be written as the form of PLS with some L_0 penalty functions. Notice that choosing a model with the minimum C_p is equivalent to minimizing the following PLS objective function:

$$Q(\beta) = \frac{1}{2}\|\mathrm{y} - \mathbf{X}\beta\|^2 + \sigma^2 \sum_{j=1}^{p} I\left(\left|\beta_j\right| \neq 0\right). \tag{77.12}$$

Motivated by (77.12), the best subset selection with classic variable selection criteria is equivalent to minimizing the objective function (77.11) with the following L_0 penalty function:

$$p_\lambda\left(\left|\beta_j\right|\right) = \frac{\lambda^2}{2} I\left(\left|\beta_j\right| \neq 0\right) \tag{77.13}$$

with a different tuning parameter λ.

For example, *AIC* is asymptotically equivalent to the following PLS:

$$Q(\beta) = \frac{1}{2}\|\mathrm{y} - \mathbf{X}\beta\|^2 + n\frac{\left(\sigma\sqrt{2/n}\right)^2}{2} \sum_{j=1}^{p} I\left(\left|\beta_j\right| \neq 0\right) \tag{77.14}$$

with $\lambda = \sigma\sqrt{2/n}$. Another example is *BIC*, which is asymptotically equivalent to the PLS as follows:

$$Q(\beta) = \frac{1}{2}\|\mathrm{y} - \mathbf{X}\beta\|^2 + n\frac{\left(\sigma\sqrt{\log(n)/n}\right)^2}{2} \sum_{j=1}^{p} I\left(\left|\beta_j\right| \neq 0\right) \tag{77.15}$$

with $\lambda = \sigma\sqrt{\log(n)/n}$.

- **L_2 Penalty: Ridge Regression**

The well-known ridge regression is proposed by Hoerl and Kennard (1970) in order to deal with the collinearity problem in predictors. Although ridge regression cannot possess the variable selection feature, it is a solution of penalized least squares (77.11) with an L_2 penalty – namely, $p_\lambda\left(\left|\beta_j\right|\right) = \frac{\lambda}{2}\left|\beta_j\right|^2$. Therefore, the ridge regression estimates can be obtained by minimizing the following PLS objective function:

$$Q(\beta) = \frac{1}{2}\|\mathrm{y} - \mathbf{X}\beta\| + \frac{n\lambda}{2}\sum_{j=1}^{p}|\beta_j|^2. \tag{77.16}$$

Like the ordinary least squares, the ridge regression also has the explicit solution:

$$\hat{\beta} = \left(\mathbf{X}^{\mathrm{T}}\mathbf{X} + n\lambda I_p\right)^{-1}\mathbf{X}^{\mathrm{T}}\mathrm{y}, \tag{77.17}$$

where I_p is a $p \times p$ identity matrix.

- ***L_q* Penalty: Bridge Regression**

This regression is proposed by Frank and Friedman (1993) and corresponds to the following objective function:

$$Q(\beta) = \frac{1}{2}\|\mathrm{y} - \mathbf{X}\beta\|^2 + \frac{n\lambda}{q}\sum_{j=1}^{p}|\beta_j|^q, \tag{77.18}$$

where $0 < q < 2$. The penalty function used here, the L_q penalty, bridges the L_0 and L_2 penalties. The current literature focuses on bridge regressions with $0 < q < 1$ (Friedman 2008; Zou and Li 2008), as they perform well in the presence of noised surrogates correlated with a true explanatory variable. In these situations, the penalty function is concave over $(0, \infty)$. In the appendix, we discuss the thresholding operator induced by the $L_{0.5}$ penalty and investigate its implementation based on local linear approximation.

- ***L_1* Penalty: LASSO**

The least absolute shrinkage and selection operator (LASSO) is first proposed by Tibshirani (1996). Specifically, the LASSO estimate is the solution to the following problem:

$$\begin{gathered}\min_{\beta}\frac{1}{2}\|\mathrm{y} - \mathbf{X}\beta\|^2,\\ \text{subject to}\ \sum_{j=1}^{p}|\beta_j| \le s,\end{gathered} \tag{77.19}$$

where the tuning parameter s controls the regularization size. The main advantage of LASSO is that it allows us to shrink regression coefficients and select significant predictors simultaneously.

The LASSO solutions are shown to be equivalent to the penalized least squares with the L_1 penalty as follows:

$$Q(\beta) = \frac{1}{2}\|\mathrm{y} - \mathbf{X}\beta\|^2 + n\lambda\sum_{j=1}^{p}|\beta_j|. \tag{77.20}$$

Therefore, the LASSO is a special case of the bridge regression with $q = 1$. It can be shown that the LASSO can exactly shrink some coefficients to zero and hence gives a sparse model, which enhances the model interpretability.

Although penalized L_0 regressions can be used to conduct variable selection, the computation involved is usually extensive, and the set of selected predictors can be unstable. Penalized L_2 regressions (ridge regressions) can shrink the estimated coefficients and make the model stable, but these regressions do not possess the variable selection feature. Penalized L_1 regressions (LASSO) can provide both shrinkage estimation and variable selection, but the estimators are biased even for large true coefficients. The natural question is then: "What kind of penalty functions is good for variable selection and parameter estimation?"

77.2.2.2 The SCAD Penalty

Fan and Li (2001) argue that good penalty functions should provide the estimators with the following three properties in the high-dimensional regression problems:

1. **Unbiasedness**: The penalized estimator should be nearly unbiased to reduce model bias, especially for the large true coefficients.
2. **Sparsity**: The penalized estimator can automatically set small estimated coefficients to zero to achieve variable selection and reduce model complexity.
3. **Continuity**: The penalized estimator is continuous in the data in the sense that it can avoid instability in model prediction.

To proceed, Fan and Li (2001) consider the linear regression model (77.1) with the design matrix $\mathbf{X}$ satisfying $\mathbf{X}^{\mathbf{T}}\mathbf{X} = nI_p$, where I_p is a $p \times p$ identity matrix. It then follows that (77.11) can be rewritten as the following:

$$\begin{aligned} Q(\beta) &= \frac{1}{2}\left\|\mathrm{y} - \mathrm{X}\hat{\beta}_0\right\|^2 + \frac{n}{2}\left\|\hat{\beta}_0 - \beta\right\|^2 + n\sum_{j=1}^{d} p_\lambda(|\beta_j|), \\ &= \frac{1}{2}\left\|\mathrm{y} - \mathbf{X}\hat{\beta}_0\right\|^2 + n\sum_{j=1}^{d}\left\{\frac{1}{2}\left(\hat{\beta}_{0j} - \beta_j\right)^2 + p\lambda(|\beta_j|)\right\}, \end{aligned} \tag{77.21}$$

where $\hat{\beta}_0 = \mathbf{X}^{\mathrm{T}}\mathrm{y}/n$ is the ordinary least squares estimate. The first term of (77.21) is constant with respect to β, so minimizing the object $Q(\beta)$ reduces to a componentwise regression problem. Consider the univariate minimization problem:

$$\hat{\theta}(z) = \arg\min_{\theta\in\mathrm{R}}\left\{\frac{1}{2}(z-\theta)^2 + p\lambda(|\theta|)\right\}. \tag{77.22}$$

Antoniadis and Fan (2001) and Fan and Li (2001) examine the conditions under which the univariate penalized estimator $\hat{\theta}(z)$ can possess the above three properties:

1. **Unbiasedness** if $p'_\lambda(\theta) = 0$ for large θ
2. **Sparsity** if $\min_{\theta \geq 0}\{\theta + p'_\lambda(\theta)\} > 0$
3. **Continuity** if and only if $\arg\min_{\theta \geq 0}\{\theta + p'_\lambda(\theta)\} = 0$

where $p_\lambda(\theta)$ is nondecreasing and continuously differentiable on $[0, \infty)$ and $p'_\lambda(0)$ means $p'_\lambda(0+)$ here. In general, a good penalty function $p_\lambda(\theta)$ should be singular at the origin to generate sparse estimators in variable selection and concave when θ is large to reduce the model bias.

It has been shown in the literate that an L_q penalty does not satisfy the unbiasedness condition. As such, such a penalty function increases the model bias. To construct a penalty function satisfying all the three conditions mentioned above, Fan and Li (2001) introduce the smoothly clipped absolute deviation (SCAD) penalty, whose first derivative is given by the following:

$$p'_\lambda(\theta) = \lambda\left\{I(\theta \le \lambda) + \frac{(a\lambda - \theta)_+}{(a-1)\lambda} I(\theta > \lambda)\right\}, \tag{77.23}$$

where $\theta > 0$, $p_\lambda(0) = 0$, and $a > 2$. Here, $a = 3.7$ is often suggested by a Bayesian argument. Another penalty function, called minimax concave penalty (MCP) by Zhang (2010), has the same spirit as SCAD, and its first derivative is given by the following:

$$p'_\lambda(\theta) = \frac{(a\lambda - \theta)_+}{a}. \tag{77.24}$$

For more theoretical and numerical studies of SCAD and MCP, see Fan and Li (2001), Zou and Li (2008), and Zhang (2010).

77.2.2.3 The Oracle Property

In addition to the aforementioned properties, another equally important property established in Theorem 2 of Fan and Li (2001) is the oracle property. Ensuring the optimal asymptotic performance, the oracle property entitles statistician the power to work as well as if they had an oracle.

Specifically, assume that the true parameter vector $\beta_0 = [\beta_{10}^T, \beta_{20}^T]^T$ and $\beta_{20}^T = 0$, and under some regularity conditions, the $\sqrt{n}$-consistent local minimizer $\hat\beta = \left[\hat\beta_1^T, \hat\beta_2^T\right]^T$ of the above $Q(\beta)$ with SCAD penalty satisfies the following conditions:

- Sparsity: $\hat\beta_2 = 0$.
- Asymptotic normality:

$$\sqrt{n}(I_1(\beta_{10}) + \Sigma)\left\{\hat\beta_1 - \beta_{10} + (I_1(\beta_{10}) + \Sigma)^{-1}\mathrm{b}\right\} \to N(0, I_1(\beta_{10})),$$

in distribution, where $\Sigma = \mathrm{diag}\{p''_\lambda(|\beta_{10}|)\}$, $I_1(\beta_{10}) = I_1(\beta_{10}, 0)$ is the Fisher information with knowing $\beta_{20} = 0$ in advance, and $\mathrm{b} = \mathrm{sgn}(\beta_{10}) \circ p'_\lambda(|\beta_{10}|)$ with $\circ$ denoting the componentwise product.

As shown in Fan and Li (2001), hard thresholding and SCAD have oracle property when $\lambda_n \to 0$ and $\sqrt{n}\lambda_n \to \infty$, and are thus more efficient than least squares directly applied to the full model if the model is sparse. The authors further conjecture that the LASSO may not have the oracle property because of the bias problem. This conjecture is recently proven in Zou (2006), who also proposes a variation of the LASSO – the adaptive LASSO – to make oracle property attainable for the L_1 penalty.

The basic idea underlying the adaptive LASSO is adding the adaptive weights for penalizing different coefficients in the L_1 penalty. Specifically, the objective function of the adaptive LASSO is given as follows:

$$Q(\beta) = \frac{1}{2}\|\mathrm{y} - \mathbf{X}\beta\|^2 + n\lambda\sum_{j=1}^{p}\hat{w}_j|\beta_j|, \tag{77.25}$$

where $\{\hat{w}_j\}_{j=1}^{p}$ can be estimated by $\hat{w}_j = \left(\left|\widetilde{\beta}_j\right|\right)^{-\gamma}$ with any root-n-consistent estimates $\widetilde{\beta}$. Zou (2006) shows that with an appropriately chosen λ, the adaptive LASSO performs as well as the oracle.

Another issue with L_1 penalty concerns its difficulty in dealing with highly correlated variables in the predictor set. In their simulation study, Zou and Hastie (2005) show that the LASSO solution paths are unstable in the presence of multicollinearity. To fix this problem, these authors propose another generalization of the LASSO via combining L_1 penalty and L_2 penalty, called elastic net (EN), that is given by the following:

$$Q(\beta) = \frac{1}{2}\|\mathrm{y} - \mathbf{X}\beta\|^2 + n\lambda_1\sum_{j=1}^{p}|\beta_j| + n\lambda_2\sum_{j=1}^{p}\beta_j^2. \tag{77.26}$$

This method can be used to encourage a grouping effect. Furthermore, Zou and Hastie (2005) suggest that the estimator $\hat{\beta}^{enet} = \left(1 + \frac{\lambda_2}{n}\right)$ argmin $Q(\beta)$ be used in order to correct for the double-shrinkage problem in the implementation of the elastic net method.

Notice that in Eq. 77.26, the L_1 part performs automatic variable selection, while the L_2 part stabilizes the solution paths and hence improves the prediction performance. In order for the elastic net to have the oracle property, Zou and Zhang (2009) propose the adaptive elastic net as a combination of the L_2 penalty and the adaptive L_1 penalty. They show that the adaptive elastic net enjoys the oracle property under the assumption that the model dimension diverges with the sample size.

77.2.3 Computational Algorithms

So far we have reviewed a number of representative model selection methods used in the literature. In this subsection, we discuss the implementation of some of these methods:

- **The LQA algorithm**. When the convex penalty function (e.g., the L_1 penalty) is used, the objective function (77.11) is convex, and hence convex optimization algorithms can be applied. However, some penalty functions (e.g., the SCAD penalty) are used, and then the object is not convex anymore. Fan and Li (2001) propose a unified and effective local quadratic approximation (LQA) algorithm for optimizing a nonconvex penalized objective function.

The idea is to use the quadratic curve to locally approximate the objective function. To be specific, for a given initial value $\beta_0 = (\beta_0, \ldots, \beta_{p0})^T$ which is not close to 0, the penalty function $p_\lambda(\cdot)$ can be locally approximated by a quadratic function as follows:

$$[p_\lambda(|\beta_j|)]' = p'_\lambda(|\beta_j|)\mathrm{sgn}(\beta_j) \approx \{p'_\lambda(|\beta_{j0}|)/|\beta_{j0}|\}\beta_j, \quad \text{for} \quad \beta_j \approx \beta_{j0}. \tag{77.27}$$

In another word, we have

$$p_\lambda(|\beta_j|) \approx p_\lambda(|\beta_{j0}|) + \frac{1}{2}\frac{p'_\lambda(|\beta_{j0}|)}{|\beta_{j0}|}\left(\beta_j^2 - \beta_{j0}^2\right), \quad \text{for} \quad \beta_j \approx \beta_{j0}. \tag{77.28}$$

With the LQA, the objective function (77.11) with nonconvex penalty becomes a convex function and admits a closed-form solution. The LQA algorithm sets the sufficiently small coefficients to zero and hence produces a sparse model. However, a drawback of this algorithm is that once a coefficient is shrunken to zero, it will remain to be zero in subsequent iterations.

- **The LLA algorithm**. Instead of using LQA, Zou and Li (2008) suggest a better approximation by using the local linear approximation (LLA) as follows:

$$p_\lambda(|\beta_j|) \approx p_\lambda(|\beta_{j0}|) + p'_\lambda(|\beta_{j0}|)(|\beta_j| - |\beta_{j0}|), \quad \text{for} \quad \beta_j \approx \beta_{j0}. \tag{77.29}$$

The LLA is the minimum convex majorant of the concave function on $[0, \infty)$. With the LLA, the objective function (77.11) with a nonconvex penalty becomes an iteratively reweighted penalized L_1 regression. Zou and Li (2008) show that the one-step LLA estimator naturally adopts a sparse representation and enjoys the oracle properties. In the appendix, we would illustrate the execution of this one-step sparse estimator with the $L_{0.5}$ and SCAD penalty.

- **LARS algorithm**. Efron et al. (2004) develop the least-angle regression (LARS) algorithm for penalized variable selection. This fast and efficient algorithm can produce the entire LASSO solution path $\left\{\hat{\beta}(\lambda), \lambda > 0\right\}$, which is piecewise linear in λ. See Efron et al. (2004) for details.

77.3 Independence Screening Procedures

Modern technology for data collection allows researchers to collect ultrahigh-dimensional data at relatively low cost in economics, finance, and scientific fields. Here, ultrahigh dimensionality means that the number of predictors (p) is highly greater than the number of observations (n). Specifically, $p = O(\exp(\alpha n))$ with $\alpha > 0$.

That is, the dimensionality p is allowed to increase as the sample size n at the exponential rate. However, for such ultrahigh-dimensional data, the aforementioned regularization methods may fail because of issues on computational cost, statistical accuracy, and algorithmic stability (Fan et al. 2009). To solve these problems, statisticians and econometricians proposed a two-stage screening and cleaning approach. That is, an independence screening procedure is applied first and then followed by regularization methods. Ji and Jin (2012) further theoretically demonstrate that under some regularity conditions, the two-stage approach can outperform the one-stage LASSO and subset selection. In this section, we briefly review the recent developments of independence screening procedures for ultrahigh-dimensional data.

77.3.1 Sure Independence Screening

For ultrahigh-dimensional linear regression model, Fan and Lv (2008) propose the sure independence screening (SIS) via Pearson correlation learning to reduce the ultrahigh dimension down to a relative large scale.

Consider the following linear regression model, as defined earlier in Eq. (77.1):

$$\mathrm{y} = \mathbf{X}\beta + \varepsilon.$$

Under the sparsity assumption, denote the true model as $\mathcal{M}_* = \{1 \le j \le p : \beta_j \ne 0\}$ with the model size $s = |\mathcal{M}_*|$, where $|\mathcal{M}_*|$ represents the number of elements in the set $\mathcal{M}_*$. Then denote the standardized columnwise design matrix as $\mathbf{X}_s$ and define $\omega = (\omega_1, \ldots, \omega_p)^{\mathrm{T}}$ as follows:

$$\omega = \mathbf{X}_s^{\mathrm{T}} \mathrm{y}. \tag{77.30}$$

Note that ω_j is the marginal Pearson correlation between the jth predictor X_j and the response Y scaled by its standard deviation. On the other hand, ω_j can also be considered as the least squares estimated coefficient for standardized X_j in the marginal regression $\mathrm{y} = X_j\beta_j + \varepsilon$. Therefore, $|\omega_j|$ can characterize the magnitude of marginal relationship between the predictor X_j and the response Y.

The SIS ranks the importance of all predictors according to $|\omega_j|$ and removes those predictors weakly correlated with the response Y, i.e., ones with small absolute values of ω_j. To be specific, for any given $\gamma \in (0,1)$, the SIS selects predictors with the first $[\gamma n]$ largest $|\omega_j|$ and defines the submodel

$$\hat{\mathcal{M}}_\gamma = \left\{1 \le j \le p : \left|\omega_j\right| \text{ is among the first } [\gamma n] \text{ largest of all}\right\},$$

where $[\gamma n]$ denotes the integer part of γn. Under some regularity conditions, Fan and Lv (2008) show that

$$P\left(\mathcal{M}_* \subseteq \hat{\mathcal{M}}_\gamma\right) \to 1, \quad \text{as } n \to \infty. \tag{77.31}$$

That is, the proposed SIS can efficiently shrink the ultrahigh dimension p down to a relatively large-scale $d = [\gamma n]$, while all truly important predictors can be selected into the submodel $\hat{\mathcal{M}}_\gamma$ with probability approaching one as the sample size tends to the infinity. This desirable theoretical property is called sure screening property by Fan and Lv (2008).

77.3.2 Generalized Correlation Ranking

Sure independence screening via Pearson correlation learning can perform well in the ultrahigh-dimensional linear regression model. However, Pearson correlation can only capture the linear relationship between each predictor X_j and the response Y. When Pearson correlation $\rho(X_j, Y)$ is zero, it only means that the response Y is linearly uncorrelated with the predictor X_j. If the predictor X_j is nonlinearly but not linearly influential to the response Y, the SIS is most likely to miss this important predictor. In order to capture the nonlinearity in the ultrahigh-dimensional problems, Hall and Miller (2009) suggest techniques based on ranking generalized empirical correlation between the response Y and each predictor X_j, which can capture both linearity and nonlinearity.

Hall and Miller (2009) define the generalized correlation between two random variables X and Y as follows:

$$\rho_g(X, Y) = \sup_{h \in \mathcal{H}} \frac{\operatorname{cov}\{h(X), Y\}}{\sqrt{\operatorname{var}\{h(X)\}\operatorname{var}(Y)}},$$

where $\mathcal{H}$ is a class of functions including all linear functions. For example, it is a class of polynomial functions up to a given degree. Notice that if $\mathcal{H}$ is restricted to be a class of all linear functions, $\rho_g(X, Y)$ is the absolute value of Pearson correlation $\rho(X, Y)$. Therefore, $\rho_g(X, Y)$ can be naturally considered as a generalization of the conventional Pearson correlation.

Assume that (X_1, Y_1), (X_2, Y_2), ... ,(X_n, Y_n) are independent and identically distributed observed pairs of two random variables X and Y. The generalized correlation $\rho_g(X, Y)$ between X and Y can be estimated as follows:

$$\hat{\rho}_g(X, Y) = \sup_{h \in \mathcal{H}} \frac{\sum_{i=1}^n \left\{h(X_i) - \overline{h}\right\}\left(Y_i - \overline{Y}\right)}{\sqrt{\sum_{i=1}^n \left\{h(X_i)^2 - \overline{h}^2\right\} \cdot \sum_{i=1}^n \left(Y_i - \overline{Y}\right)^2}}, \tag{77.32}$$

where $\overline{h} = n^{-1}\sum_{i=1}^n h(X_i)$ and $\overline{Y} = n^{-1}\sum_{i=1}^n Y_i$.

The proposed generalized correlation characterizes both linear and nonlinear relationships between two random variables. Therefore, the generalized correlation $\rho_g(X_j, Y)$ can be considered as a marginal utility to measure the influential effort of the predictor X_j on the response Y.

Hall and Miller (2009) suggest that in practice we rank the predictors based on the magnitude of estimated generalized correlation $\hat{\rho}_g(X_j, Y)$. As such, we order $\hat{\rho}_g\left(X_{\hat{j}_1}, Y\right) \geq \hat{\rho}_g\left(X_{\hat{j}_2}, Y\right) \geq \ldots \geq \hat{\rho}_g\left(X_{\hat{j}_p}, Y\right)$ and have

$$\hat{j}_1 \succeq \hat{j}_2 \succeq \cdots \succeq \hat{j}_p$$

denote the empirical ranking of the indices of all predictors. Intuitively, the higher ranking the predictor has, the more important it is on the response in terms of the generalized correlation. Therefore, given a suitable cutoff, one can select predictors with higher rankings and thus reduce the ultrahigh dimensionality to a relatively low scale.

Hall and Miller (2009) suggest a bootstrap procedure to choose a cutoff. To illustrate this procedure, let $S = \{(X_1, Y_1), (X_2, Y_2), \ldots, (X_n, Y_n)\}$ represent the original data set and $S^* = \{(X_1^*, Y_1^*), (X_2^*, Y_2^*), \ldots, (X_n^*, Y_n^*)\}$ be a resample drawn randomly from S with replacement. Denote by $r(j)$ the ranking of the jth predictor X_j such as $\hat{j}_{r(j)} = j$. Let $r^*(j)$ be the ranking of X_j using the bootstrapped resample S^*. Given a value α, such as 0.05, compute a nominal $(1 - \alpha)$-level two-sided prediction interval of the ranking, $[\hat{r}_-(j), \hat{r}_+(j)]$. Hall and Miller (2009) propose a criterion to regard the predictor X_j as influential if $\hat{r}_+(j) < \frac{1}{2}p$. In practice, the cutoff can also be replaced by some smaller fraction of p, such as $\frac{1}{4}p$. Therefore, the proposed generalized correlation ranking reduces the ultrahigh p down to the size of the selected model $\hat{\mathcal{M}}_k = \{j : \hat{r}_+(j) < kp\}$, where $0 < k < 1/2$ is a constant multiplier to control the size of the selected model $\hat{\mathcal{M}}_k$.

77.3.3 Sure Independence Screening for GLIM

The SIS procedure (Fan and Lv 2008) provides one possible method for dealing with ultrahigh-dimensional problems. However, the procedure applies to ordinary linear regression models only, and the theoretical properties of SIS rely heavily on the joint normality assumptions on the response and predictors. These constraints limit significantly the applicability of the SIS for categorical variables, even within the context of linear models.

To this end, Fan and Song (2010) propose a more general version of sure independence screening procedure for generalized linear models. They considered the maximum marginal likelihood estimator (the MMLE, for short) or the marginal likelihood ratio as a marginal utility to rank the importance of each predictor. The conditions under which the proposed MMLE possesses the sure screening property are also explored. Moreover, Fan and Song (2010) discuss how to choose the size of the selected model.

First, consider the generalized linear model (GLIM) with canonical link. That is, the response variable Y conditional on the predictors $\mathrm{x} = (X_1, \ldots, X_p)^{\mathrm{T}}$ is from an exponential family, whose probability density function takes the canonical form

$$f_{Y|\mathrm{x}}(y|\mathrm{x}) = \exp\{y\theta(\mathrm{x}) - b(\theta(\mathrm{x})) + c(y)\}, \tag{77.33}$$

for some known functions $b(\cdot)$, $c(\cdot)$, and $\theta(\mathrm{x}) = \mathrm{x}^{\mathrm{T}}\beta$. Without loss of generality, assume that the dispersion parameter $\phi = 1$ and each predictor are standardized with mean 0 and variance 1.

Therefore, the log-likelihood for the natural parameter θ of the GLIM is

$$\ell(\theta, y) = b(\theta) - y\theta. \tag{77.34}$$

Parallel to Fan and Lv (2008), let $\mathcal{M}_* = \{1 \le j \le p : \beta_j \ne 0\}$ be the true model with the model size $s = |\mathcal{M}_*|$. Fan and Song (2010) defined the maximum marginal likelihood estimator (MMLE) $\hat{\beta}_j^M$ of the jth predictor X_j as

$$\hat{\beta}_j^M = \left(\hat{\beta}_{j,0}^M, \hat{\beta}_j^M\right) = \arg\min_{\beta_0, \beta_1} \sum_{i=1}^{n} \ell\left(\beta_0 + \beta_1 X_{ij}, Y_i\right), \tag{77.35}$$

where Y_i is the ith observed response and X_{ij} is the ith observation of the jth predictor. Although the MMLE $\hat{\beta}_j^M$ is a wrong estimated coefficient for jth predictor X_j in the joint model, the $\hat{\beta}_j^M$ can preserve useful non-sparsity information of X_j in the joint model for variables screening under some mild conditions. Therefore, it is reasonable to consider the magnitude of $\hat{\beta}_j^M$ as a marginal utility to rank the importance of X_j and select a submodel, given a prespecified threshold γ_n:

$$\hat{\mathcal{M}}_{\gamma \mathrm{n}} = \left\{1 \le j \le p : \left|\hat{\beta}_j^M\right| \ge \gamma_n\right\}. \tag{77.36}$$

Theorem 4 of Fan and Song (2010) shows that the MMLEs are uniformly convergent to the population values and establishes the sure screening property of the MMLE screening procedure under some regularity conditions.

Fan and Song (2010) further discuss how large the selected model $\hat{\mathcal{M}}_{\gamma \mathrm{n}}$ should be. Under certain regularity assumptions, they show that with probability approaching one,

$$\left|\hat{\mathcal{M}}_{\gamma \mathrm{n}}\right| = O\left\{n^{2\kappa}\lambda_{\max}(\Sigma)\right\}, \tag{77.37}$$

where k determines how large the thresholding parameter γn is and $\lambda_{\max}(\Sigma)$ is the maximum eigenvalue of the covariance matrix Σ of predictors x, which controls how correlated the predictors are. If $\lambda_{\max}(\Sigma) = O(n^{\tau})$, the size of $\hat{\mathcal{M}}_{\gamma \mathrm{n}}$ has the order $O(n^{2\kappa+\tau})$, which can guide practitioners to choose the thresholding rule.

77.3.4 Model-Free Feature Screening

Zhu et al. (2011) propose a model-free feature screening, called sure independent ranking and screening (SIRS), for ultrahigh-dimensional data. Compared with the SIS and other model-based sure independence screening approaches, the SIRS works for a very general multi-index model framework including many commonly used parametric and semiparametric models. Therefore, the proposed SIRS is more robust to possible model misspecification and can be considered as model-free.

Let Ψ_y be the support of the response Y and denote the conditional distribution function of Y given x as $F(y|\mathrm{x}) = P(Y \leq y|\mathrm{x})$. Define the index sets of active predictors and inactive predictors, respectively, by

$$\mathcal{A} = \left\{k : F(y|\mathrm{x}) \quad \text{functionally depends on } X_k \text{ for some } \quad y \in \Psi_y\right\},$$

$$\mathcal{I} = \left\{k : F(y|\mathrm{x}) \text{ does not functionally depend on } X_k \text{ for any } y \in \Psi_y\right\}.$$

X_k for $k \in \mathcal{A}$ is called an active predictor, whereas X_k for $k \in \mathcal{I}$ is called an inactive predictor.

Considering a general model framework, we assume that $F(y|\mathrm{x})$ depends on x only through $\beta^{\mathrm{T}}\mathrm{x}_{\mathcal{A}}$ for some $p_1 \times K$ constant matrix β. That is,

$$F(y|\mathrm{x}) = F_0\left(y|\beta^{\mathrm{T}}\mathrm{x}_{\mathcal{A}}\right), \tag{77.38}$$

where $F_0(\cdot|\cdot)$ is an unknown function.

Without loss of generality, assume that $E(X_k) = 0$ and $\mathrm{var}(X_k) = 1$ for $k = 1, \ldots, p$. Define

$$\Omega(y) = E\{\mathrm{x}F(y|\mathrm{x})\} = E\{\mathrm{x}E[1(Y \leq y)|\mathrm{x}]\} = \mathrm{cov}\{\mathrm{x}, 1(Y \leq y)\}.$$

Then define a new marginal utility ω_k at the population level by

$$\omega_k = E\left\{\Omega_k^2(Y)\right\}, \quad k = 1, \ldots, p,$$

where $\Omega_k(y)$ is the kth element of $\Omega(y)$. Intuitively, if X_k and Y are independent, then X_k and $1(\mathrm{Y} \leq \mathrm{y})$ for any $y \in \Psi_y$ are independent resulting in that $\omega_k = 0$. On the other hand, if X_k and Y are correlated, then X_k and $1(Y \leq y)$ for some $y \in \Psi_y$ are correlated and thus $\omega_k > 0$.

For a random sample $\{(X_{i1}, \ldots, X_{ip}, Y_i), i = 1, \ldots, n\}$ from $\{\mathrm{x}, Y\}$, the sample moment estimator of ω_k is derived by

$$\hat{\omega}_k = \frac{1}{n}\sum_{j=1}^{n}\hat{\Omega}_k^2(Y_j) = \frac{1}{n}\sum_{j=1}^{n}\left\{\frac{1}{n}\sum_{i=1}^{n}X_{ik}1(Y_i \leq Y_j)\right\}^2, \quad k = 1, \ldots, p,$$

Zhu et al. (2011) suggest to employ the sample estimate $\hat{\omega}_k$ to rank all the candidate predictors and select the top ones as the estimate of the active predictors. Further, Theorem 2 of Zhu et al. (2011) theoretically shows that under some regularity conditions, for $\delta = \min_{k\in\mathcal{A}} \omega_k - \max_{k\in\mathcal{I}} \omega_k$, there exists a sufficiently small constant $s_\delta > 0$ such that

$$\mathbf{P}\left(\max_{k\in\mathcal{I}}\hat{\omega}_k < \min_{k\in\mathcal{A}}\hat{\omega}_k\right) \leq 2p\exp\{n\log(1-\delta s_\delta/4)/3\}. \tag{77.39}$$

This theorem demonstrates the ranking consistency property of the SIRS — namely, the SIRS screening method using $\hat{\omega}_k$ always ranks an active predictor ahead of an inactive one with the probability tending to one. This property provides a clear separation between the active and inactive predictors. Thus, the SIRS is asymptotically consistent in selection for the ultrahigh-dimensional problems.

For the independence screening, Fan and Lv (2008) suggest a hard threshold rule to choose the top variables in the order of $O(n/\log\, n)$, while Zhu et al. (2011) recommend a soft thresholding rule based on adding artificial auxiliary variables to the data. First, randomly generate q auxiliary variables $\{Z_1, \ldots, Z_q\}$ which are independent of both $\mathbf{x}$ and $\mathbf{Y}$. Then, consider the (p + q) dimensional vector $(X1, \ldots, X_p, Z_1, \ldots, Z_q)$ as the predictors and apply the independence screening method to pick top variables. In details, denote ω_k as the marginal utility for kth predictor for $k = 1, \ldots, p + q$. Because $\{Z_1, \ldots, Z_q\}$ are truly inactive, it can be shown that under some mild conditions, $\max_{l=1,\ldots,q}\hat{\omega}_{p+l} < \min_{k\in\mathcal{A}}\hat{\omega}_k$ holds with probability tending to one. Then one can select the predictor subset $\hat{\mathcal{M}}_s = \left\{k : \hat{\omega}_k > \max_{l=1,\ldots,q}\hat{\omega}_{p+l}\right\}$. Zhu et al. (2011) suggest to choose $q = p$ empirically and used numerical studies to show that the soft thresholding rule with this choice can work quite well.

77.3.5 Extensions of Independence Screening

77.3.5.1 Iterative Version of Independence Screening

Fan and Lv (2008) have shown that the SIS can perform very well when the assumed conditions are satisfied. However, when these restrictive conditions fail, the SIS procedure may be problematic. For example, when a variable is jointly correlated, but marginally uncorrelated with the response, the SIS is unlikely to select this important variable, resulting in high false-negative rate. On the other hand, when a variable is jointly uncorrelated but highly marginally correlated with the response, the SIS is likely to select this unimportant variable, resulting in high false-positive rate. To overcome this problem, Fan and Lv (2008) provide an important methodological extension of the SIS, called the iterative sure independence screening (ISIS).

The steps of the ISIS procedure are provided as follows:

Step 1: Apply the SIS to the full data set and select an index set $\hat{\mathcal{A}}_1$ of size $d = [n/\log n]$. Then implement the variable selection approaches, such as penalized least squares with SCAD penalty, on the index set $\hat{\mathcal{A}}_1$ to select a submodel $\hat{\mathcal{M}}_1$. Let $\hat{\mathcal{M}} = \hat{\mathcal{M}}_1$.

Step 2: Compute the residuals from regressing the response Y over $\left\{X_j : j \in \hat{\mathcal{M}}\right\}$. Then treat these residuals as the new responses and apply the same procedure in Step 1 to the remaining variables with indices $\{1,\ldots,p\}\backslash\hat{\mathcal{M}}$ to obtain another submodel1 $\hat{\mathcal{M}}_2$. Let $\hat{\mathcal{M}} = \hat{\mathcal{M}}_1 \cup \hat{\mathcal{M}}_2$.

Step 3: Iterate the process until $|\hat{\mathcal{M}}| \leq d'$, where d' is the prescribed number and $d' < n$. The index set $\hat{\mathcal{M}}$ is the final selected submodel by the ISIS.

Fan and Lv (2008) demonstrate empirically that the ISIS procedure can outperform the ordinary SIS.

Also, Fan et al. (2009) extend this version of ISIS by using the marginal likelihood to rank the importance of variables. Fan et al. (2011a) provide iterative nonparametric independence screening for the sparse ultrahigh-dimensional additive models. Finally, Zhu et al. (2011) develop an iterative version of the model-free independence screening with iteratively transforming the space of predictors.

77.3.5.2 Reduction of False-Positive Rate

The independence screening procedures are commonly used for feature selection, but they are usually conservative and result in many false-positive variables. Fan et al. (2009) propose a simple resampling technique that can help reduce the false-positive rate.

Let $\mathcal{A}$ be the set of active indices. We partition the samples randomly into two parts with the same sample size and then apply one independence screening, such as the SIS and the ISIS, to these two subsamples. Denote $\hat{\mathcal{A}}_1$ and $\hat{\mathcal{A}}_2$ as the selected submodel based on the first half and the second half of the samples, respectively. Under some conditions, both $\hat{\mathcal{A}}_1$ and $\hat{\mathcal{A}}_2$ possess the sure screening property. That is, both $\hat{\mathcal{A}}_1$ and $\hat{\mathcal{A}}_2$ can contain all active indices (i.e., $\mathcal{A}$) with the probability tending to one, i.e.,

$$P\left(\mathcal{A} \subseteq \hat{\mathcal{A}}_1\right) \to 1, \;\; P\left(\mathcal{A} \subseteq \hat{\mathcal{A}}_2\right) \to 1, \text{ as } n \to \infty.$$

Then define $\hat{\mathcal{A}} = \hat{\mathcal{A}}_1 \cap \hat{\mathcal{A}}_2$ as a new estimate of the active set $\mathcal{A}$. Therefore, the estimate $\hat{\mathcal{A}}$ also satisfies the sure screening property:

$$P\left(\mathcal{A} \subseteq \hat{\mathcal{A}}\right) \to 1, \text{as } \; n \to \infty.$$

Intuitively, the probability that one unimportant variable has to be selected twice into both $\hat{\mathcal{A}}_1$ and $\hat{\mathcal{A}}_2$ is very small, so $\hat{\mathcal{A}}$ can be expected to contain much fewer unimportant variables which may be falsely selected into $\hat{\mathcal{A}}_1$ or $\hat{\mathcal{A}}_2$. In the result, this simple resampling approach reduces the false-positive rate efficiently.

77.4 Variable Selection Versus Sufficient Dimension Reduction

Of course, methods for analyzing (ultra)high-dimensional data are by no means limited to those aforementioned. In particular, dimension reduction techniques have constituted an appealing alternative to feature selection in dealing with the curse of dimensionality (Bellman 1961). While both variable selection and dimension reduction are regularized approaches aiming to alleviate the high variance and overfitting problems in (ultra) high-dimensional analysis, it might be useful to draw a broad comparison between them.

There has been a growing interest in dimension reduction methods for regression analysis since the early 1990s, perhaps due to the introduction of sliced inverse regressions (Li 1991) and sliced average variance estimation (Cook and Weisberg 1991). Notably, the proposition of sufficient dimension reduction theory (SDR) by Cook (1998) offers a unified paradigm that can help reduce the dimension of the predictor vector X without loss of information about the response y. The underlying idea is to replace X with a minimal set of their linear combinations $\eta' X$, which concentrates the relevant information in X. More formally, SDR seeks a subspace $\mathcal{S}$ based on η such that $Y \perp (X \backslash P_{\mathcal{S}} X)$, where $\perp$ stands for independence and $P_{\mathcal{S}}$ denotes the orthogonal projection onto $\mathcal{S}$.

As can be seen from their definitions, the fundamental difference between variable selection and SDR lies in their assumptions about the model structure. While variable selection approaches are underpinned by the sparsity principle that assumes that only a small number of original predictors X contribute to the response y, SDR grounds on the existence of latent variables $\eta' X$, the common sources of systematic variation in y. As to the analysis of high-dimensional data in finance, there is no obvious conclusion which framework is preferable. Consider the empirical model where y denotes the aggregate return/volatility of a particular asset class and X consists of hundreds of macroeconomic and financial indicators. On the one hand, the classic asset pricing theory postulates that variations in y depend on a few key risk factors, e.g., aggregate consumption surplus, endowment volatility, and investor sentiment, which typically cannot be directly measured. Thus, the “latent factor” interpretation seems more relevant in this situation. On the other hand, most existing SDR methods suffer because the estimated linear reductions usually involve all of candidate predictors X. As a consequence, the results can be hard to interpret, the return-driving force may be difficult to identify, and the efficiency gain may be less than that possible with variable selection.

To sum, there are several methods available for conducting an ultrahigh-dimensional analysis. Depending on the type of application, some methods rely on dimension reduction, some others rely on variable selection, and a few employ both tactics. How to maximize dimension reduction and simultaneously improve model interpretability poses a significant challenge to financial econometricians. Recent developments in sparse sufficient dimension reduction theory (Li 2007; Zhou and He 2008; Chen et al. 2010) show promise in providing a unified method that can screen out irrelevant and redundant predictors and at the same time lead to a few linear combinations of active predictors.

77.5 Conclusion

One important development in the financial markets over the past decade or so is the explosion of financial data of unprecedented size and complexity, such as intraday transaction data on both exchange-traded securities (e.g., TAQ) and OTC market securities (e.g., TRACE). As such, high- and ultrahigh-dimensional data analysis has attracted a lot of attention from both researchers and practitioners. In this chapter, we have reviewed several existing variable selection methods and independence screening procedures developed recently in the statistics literature that are used to estimate a sparse model and select significant variables simultaneously.

While shrinkage-based variable selection methods have been successfully applied in many high-dimensional analyses, their direct applications to ultrahigh-dimensional statistical learning problems may raise issues associated with computational expediency and algorithm stability. In these situations, feature screening seems to be an essential step, as it is only concerned with the marginal response of the dependent variable to individual candidate predictors and thus enjoys great computational efficiency.

Appendix 1: One-Step Sparse Estimates

This appendix outlines the local linear approximation (LLA) algorithm, discussed in Sect. 77.2.3, for finding a solution of penalized least squares for a broad class of penalty functions. For illustration, we focus on the nondifferentiable, nonconvex $L_{0.5}$ and SCAD penalties introduced in Sect. 77.2.2, as both are ideally suited to the LLA algorithm (Zou and Li 2008). Recall that these two penalty functions are given by Eqs. (77.18) and (77.23), respectively. We note that $L_{0.5}$ and SCAD apparently lead to concave objective functions that are singular at the origin. We illustrate later that in linear regressions this optimization problem can be reduced into solving penalized least squares with an L_1 penalty.

We begin with the following one-step LLA estimator:

$$\hat{\beta} = \arg\min_{\beta} \left\{ \frac{1}{2} \|\mathrm{y} - \mathbf{X}\beta\|^2 + n \sum_{j=1}^{p} p'_{\lambda}\left(\left| \widetilde{\beta}_j \right| \right) |\beta_j| \right\}, \tag{77.40}$$

where the initial estimate $\widetilde{\beta}$ is usually represented by the ordinary least squares estimator in practice if $n > p$. Theoretically, $\widetilde{\beta}$ could be any root-n-consistent estimator for β. In the case where $n < p$, the plain vanilla L_1 estimator (LASSO) would be employed instead.

Following Zou and Li (2008), we discuss separately algorithms for the objective function $Q(\beta)$ with two different types of penalty functions, which correspond to $L_{0.5}$ and SCAD, respectively. Nonetheless, the idea underlying the two algorithms is the same – namely, using a data transform to simplify the penalized least squares to a standard L_1 regularization problem, for which we can take advantage of the related efficient algorithms. In particular, the LARS algorithm (Efron et al. 2004) has been widely applied to obtain the entire solution path of LASSO and forward stage-wise regressions. The relevant R package can be downloaded from http://www.stanford.edu/~hastie/swData.htm#SvmP.

Consider first type one of penalty functions.

Type 1. The tuning parameter could be disentangled from the penalty function, i.e., $p_\lambda(\theta)$ satisfies that $p_\lambda(\theta) = \lambda p_\lambda(\theta)$ and $p'_\lambda(\theta) > 0$. For example, bridge penalties $p_\lambda(|\theta|) = \lambda|\theta|^q$ for $0 < q < 1$ and the logarithm penalty $p_\lambda(|\theta|) = \lambda \log|\theta|$.

Algorithm 1

Step 1. *Create working data by* $x_j^* = x_j / p'_\lambda\left(\left|\widetilde{\beta}_j\right|\right)$, *for* $j = 1, \ldots, p$.

Step 2. *Apply the LARS algorithm to solve the penalized* $L1$ *regression*:

$$\hat{\beta}^* = arg\min_{\beta}\left\{\frac{1}{2}\|y - \mathbf{X}^*\beta\|^2 + n\lambda\sum_{j=1}^{p}\left|\beta_j\right|\right\}.$$

Step 3. *Let the final one-step estimator be* $\hat{\beta}_j = \hat{\beta}_j^* / p'_\lambda\left(\left|\widetilde{\beta}_j\right|\right)$ *for* $j = 1, \ldots, p$.

As we can see, through the one-step sparse estimator, LLA for the $L_{0\cdot 5}$ penalty is equivalent to the adaptive LASSO, with $\hat{w}_j = \left|\widetilde{\beta}_j\right|^{-0.5}$ (see Eq. 4 in Zou 2006). In computing the LARS estimates, tuning parameter λ can be chosen using the *cv.lars* routine embedded in the "lars" package. For example, the following command

$$cv.lars(xstar, y, K = 5, plot.it = TRUE, se = TRUE, type = \text{"}lasso\text{"})$$

instructs the R to plot fivefold cross-validated mean squared prediction error (MSE) for different values of λ. Then we are able to pick the λ with the smallest MSE and find out the step in LARS corresponding to that λ value. The main function of the package

$$lars(xstar, y, type = \text{"}lasso\text{"})$$

provides the entire sequence of coefficients and fits, starting from zero to the least squares fit.

Next, consider type 2 of penalty functions.

Type 2. $p_\lambda(\theta)$ satisfies that the derivative $p'_\lambda(\theta)$ is zero for some values. In addition, the regularization parameter λ cannot be separated from $p_\lambda(\theta)$. For example, the SCAD penalty with the first derivative

$$p'_\lambda(\theta) = \lambda\left\{I(\theta \le \lambda) + \frac{(a\lambda - \theta)_+}{(a-1)\lambda} I(\theta > \lambda)\right\}, \tag{77.41}$$

where $\theta > 0$, $p_\lambda(0) = 0$, and $a > 2$.

We define $U = \{j : p'_\lambda(\theta) = 0\}$ and $V = \{j : p'_\lambda(\theta) > 0\}$. Accordingly, we write $\mathbf{X} = [\mathbf{X}_U, \mathbf{X}_V]$ and $\hat{\beta} = \left(\hat{\beta}_U^T, \hat{\beta}_V^T\right)^T$.

Algorithm 2

Step 1. *Create working data by* $x_j^* = x_j \lambda / p'_\lambda\left(\left|\widetilde{\beta}_j\right|\right)$, *for* $j \in V$. *Let* H_U *be the projection matrix in the space of* $\{x_j^*, j \in U\}$. *Compute* $\widetilde{y} = (I - H_U)y$ *and* $\widetilde{X}_V^* = (I - H)X_V^*$.

Step 2. *Apply the LARS algorithm to solve the penalized* L_1 *regression*:

$$\hat{\beta}_V^* = arg\ \min_\beta \left\{ \frac{1}{2} \left\| \widetilde{\mathrm{y}} - \widetilde{\mathrm{X}}_V^* \beta \right\|^2 + n\lambda \sum_{j=1}^{p} |\beta_j| \right\}.$$

Step 3. *Compute* $\hat{\beta}_U^* = \left(\mathbf{X}_U^{*T}\mathbf{X}_U^*\right)^{-1}\mathbf{X}_U^{*T}\left(\widetilde{\mathrm{y}} - \mathbf{X}_V^*\hat{\beta}_V^*\right)$. *Then, the final one-step estimator* $\hat{\beta}$ *is obtained by*

$$\hat{\beta}_U = \hat{\beta}_U^* \ \ and\ \ \hat{\beta}_j = \hat{\beta}_j^* \lambda / p_\lambda' \left(\left| \widetilde{\beta}_j \right| \right) \ \ for\ \ j \in V.$$

We note that cross-validation routine is not applicable in this situation, as the sets U and V could change as λ varies. In other words, different values of the tuning parameter lead to different transforms of observations. As a result, the SCAD-type penalty requires reexecuting the cross-validation and solving the one-step estimator for each fixed λ. Alternatively, we can determine λ by a non-data-driven approach such as the BIC-based tuning parameter selector. Indeed, Wang et al. (2007) show that the commonly used generalized cross-validation tends to overshoot the correct number of nonzero coefficients. Instead, BIC can be used to consistently identify the true model. For practitioners, it would be more convenient to directly call the procedure *getfinalSCADcoef* included in the "SIS" package (Fan et al. 2010). The option *tune.method* = *c* ("*AIC*", "*BIC*") is used to specify the selection criterion.

Finally, we use a simple numerical example to illustrate the performance of one-step sparse estimates. In this example, simulation data is generated by executing the following command in the R 2.15.0 program:

$$\begin{aligned}
&set.seed(0)\\
&b <- \ c(4,4,4,\ -6 * sqrt(2))\\
&n = 150\\
&p = 300\\
&x = matrix(rnorm(n * p, mean = 0, sd = 1), n, p)\\
&y <- x[, 1:4]\% * \%b + rnorm(150)
\end{aligned}$$

The one-step sparse estimates with the $L_{0 \cdot 5}$ and SCAD penalty are summarized as follows. Both selection methods include all four significant variables, and the $L_{0.5}$ penalty falsely selects one noise variable. The estimated nonzero coefficients under these two methods are reported in the following:

$$\begin{aligned}
b_{scad} &= [3.986, 3.937, 3.944,\ -8.369],\\
b_{L05} &= [3.942, 3.964, 3.997,\ -8.388, 0.237].
\end{aligned}$$

Note that this example alone does not mean that the SCAD outperforms the $L_{0.5}$ penalty, because a valid Monte Carlo simulation study usually requires at least 1,000 simulated data sets.

Hedonic Regression Models

78

Ben J. Sopranzetti

Contents

Abstract

This provides a basic overview of the nature and variety of hedonic empirical pricing models that are employed in the economics literature. It explores the history of hedonic modeling and summarizes the field's utility-theory-based, microeconomic foundations. It also provides a discussion of and potential solutions for common problems associated with hedonic modeling.

This paper examines three specific, different hedonic specifications, the linear, semilog, and Box–Cox transformed hedonic models, and applies them to real estate data. It also discusses recent innovations related to hedonic models and how these models are being used in contemporary studies.

Keywords
Hedonic models • Regression • Real estate • Box–Cox • Pricing • Price indexes • Semilog • Least squares • Housing • Property

78.1 Introduction

Hedonic modeling first originated as a method for valuing the demand and the price of farm land.[1] Although Court (1939) is widely considered to be the father of hedonic modeling, his paper had nothing to do with real estate; instead, Court created a hedonic pricing index for automobiles. Regardless of how they are used, hedonic regressions deconstruct the price of an asset into the asset's component parts and then use some form of ordinary least squares regression analysis to examine how each individual piece uniquely contributes to the item's overall value.

The consumer price index is probably the most famous example of the use of hedonic regressions as a control mechanism for differences in the quality of products over time. The consumer price index measures the change over time in the price of a bundle of goods. But, if the quality of the goods in the bundle changes over time, then one can imagine that obtaining a high quality prediction of the value of the index at some future point in time can be problematical. For example, imagine trying to predict the price of an automobile today, based upon pricing information from the 1963. A Chevrolet Corvette costs substantially more money today that it did back in 1963. Some of the increase in the car's price is due to inflation, but another part of the price increase is because Corvettes are far safer, faster, and lighter today than they were back then. Corvettes nowadays enjoy a vast technical superiority over their vintage forbearers. The technical improvements clearly add value. As we will see below, they add "hedonic utility." So when trying to predict the price of a new Corvette with a turbo-charged engine, air conditioning, 6-speed transmission, airbags, and a sport-tuned suspension, one cannot examine the simple inflationary price increase of a Corvette, but in addition one must examine the price increases of the additional individual improvements.

Although the consumer price index might arguably be the most famous use of hedonic modeling techniques, hedonic pricing models are also widely utilized to price other items, such as electronics, clothing, and, in particular, real estate

[1] Hass (1922) and Wallace (1926) both use hedonic-style models to value farmland in the Midwestern United States.

(the focus of this paper), where they are most often utilized to correct for the heterogeneity among properties and houses. Since each house has idiosyncratic characteristics that make it unique, estimating demand or prices from real estate data can be challenging. Rather than pricing a given house or property directly, a researcher can deconstruct the house and property into their value-adding components, such as lot size, square feet, the number of bathrooms, the number of bedrooms, and neighborhood quality. A well-specified hedonic model will estimate the contribution to the total price of each of these features separately. If it is the price that is estimated, then the hedonic model is called an "additive" model. If, instead, the elasticity is estimated, then it is called a "log" model. This short primer will explore in some detail the nature and variety of hedonic pricing models and should provide a solid foundation for any researcher interested in employing this widely utilized empirical technique.

78.2 The Theoretical Foundation

Although many empirical papers using hedonic modeling techniques were published in the years that followed Court's work, Lancaster's (1966) seminal paper is the first attempt to create a theoretical foundation for hedonic modeling. To this end, Lancaster presented a groundbreaking theory of hedonic utility. Lancaster argues that it is not necessarily a good itself that creates utility, but instead the individual "characteristics" of a good that create utility. Specifically, an item's utility is simply the aggregated utility of the individual utility of each of its characteristics. For example, the utility that comes from owning an expensive car comes not so much from the car itself, but from the fact that it provides not only transportation but also fast acceleration, enhanced safety, attractive styling, increased prestige, etc. Furthermore, he argues that items can be arranged into groups based on the characteristics they contain. Consumers make their purchasing decisions within a group based on the number of characteristics a good possesses per unit cost. For example, people make their home purchase decisions based upon the number of bedroom, number of bathrooms, etc.

Although Lancaster is the first to discuss hedonic utility, he says nothing about pricing or pricing models. Rosen (1974) is the first to present a theory of hedonic pricing. Rosen argues that an item can be valued as the sum of its utility generating characteristics; that is, an item's total price should be the sum of the individual prices of its characteristics. This implies that an item's price can be regressed upon the characteristics to determine the way in which each characteristic uniquely contributes to the price. Although Rosen did not formally present a functional form for the hedonic pricing function, his model clearly implies a nonlinear pricing structure.

For a more thorough review of the extant literature, please see the excellent surveys by Follain and Jimenez (1985) and Sheppard (1999).

78.3 The Data

The data are 7,088 observations of real estate transactions of properties that are located in the Klein School District, of suburban Houston, between January 1, 1992 and December 31, 1995. The data set provides information on property, home, and transaction characteristics. Property characteristics include the lot size in square feet, distance to the central business district, and information on neighborhood submarkets within the overall Klein area. Home characteristics include the size of the house in square feet, year built, number of bathrooms, number of bedrooms, a dummy variable for the existence of a pool, and whether the house has any known defects. Transaction characteristics include the list price, the transaction price, the list date, the number of days that the property remained on the market prior to being sold, whether the property is sold "as is," whether the home was sold by a financial institution that had previously foreclosed on the property, and the identity of the listing and selling real estate brokers.

Out of the initial 7,088 observations, 146 observations are deleted due to missing or obviously incorrect data. In addition, several screens are employed to increase the homogeneity of the properties in our sample and to eliminate observations in which data may not have been entered correctly. Properties are omitted if their:

1. Age exceeds 30 years old (24 observations).
2. Lot size is smaller than 5,000 or larger than 50,000 ft^2 (165 observations).
3. Living space exceeds 4,000 ft^2 (362 observations).
4. Number of bathrooms (full and half) exceeds six (six observations).

The final sample includes 6,385 observations. Table 78.1 includes the summary statistics for the dependent variables.

Table 78.1 Summary statistics

78.4 The Linear Model

The basic additive hedonic equation is one where the value of an asset is regressed against the characteristics that determine its value. This linear model is appropriate when there are heterogeneous products and heterogeneous buyers, and the heterogeneous items to be valued can be easily replaced/restocked once they have been purchased, i.e., there is a continuous, uninterrupted supply of the item to be priced. In this case, the pricing model of the item is very simply the sum of the prices of its component parts, where

$$\mathrm{Value} = \mathrm{f}(\mathrm{S}, \mathrm{N}, \mathrm{L}, \mathrm{C}, \mathrm{T})$$

where

S represents the structural characteristics of the home and property, e.g., square footage, property size, and number of bedrooms

N represents the neighborhood characteristics

L represents the location within a giving market

C represents the contract conditions, e.g., is the property sold as is and is there a condo fee?

T represents the date or time that the transaction price is observed.

For ease of notation, we allow the matrix X to represent the combination of the individual vectors S, N, L, C, and T

$$VALUE = X\beta + \varepsilon \tag{78.1}$$

Thus an item's expected price is the characteristics X times β, where β represents a vector of marginal prices.

78.5 Empirical Specification

78.5.1 The Dependent Variable

In real estate modeling, it is common to use the most recent transaction price as a dependent variable. There are also studies that use rent as the dependent variable, but rents are problematical since different apartments may have different terms in the rental agreement; for example, some might include heat and hot water or parking. One way of dealing with the "rent" problem is to obtain the cost of utilities (or parking) for properties where the utilities are not included in the rental agreement and add these costs to the base rental price to get an adjusted rental price. Another possibility is to use the actual rental price as a dependent variable and then add a dummy-independent variable that equals one if the unit includes utilities or parking and zero otherwise. Using actual transaction prices circumvents these problems but exposes the researcher to another problem that current transactions may not be representative of the total housing stock: a selection bias.

78.5.2 Independent Variables

One of the principal criticisms of the hedonic modeling of real estate prices is the severity of the omitted variable problem: the coefficient estimates are often not robust to changes in the model's specification. This implies that researchers must be very careful when interpreting the coefficients of a hedonic regression. A sampling of recent hedonic real estate models yields the following common dependent variables:

Structural characteristics of the home and property: square footage of the unit, square footage of the property, total number of rooms, total number of bedrooms, total number of bathrooms, the existence of a pool, any known defects, structural type (single family, duplex, condominium, etc.), age, air conditioning, finished basement, fireplaces, garages, etc.

Neighborhood characteristics: quality of the school system, quality of the neighborhood, median salary.

Location within a giving market: distance from the central business district, proximity to a train station, distance to supermarket, distance to schools, flooding area.

Contract conditions: was the property sold as is? Was it a foreclosure?

For a more complete discussion of the potential explanatory variables, please see Hocking (1976), Leamer (1978), and Amemiya (1980).

78.5.3 Example Using the Linear Model

Table 78.2 presents the results of a linear hedonic pricing model where the dependent variable is the property's transaction price. The independent variables include the square footage of the home and its square, the age of the home and its square, the size of the lot and its square, the number of bedrooms and its square, dummy variables representing the number of bathrooms, the proximity in miles to the central business district, a dummy variable for a pool, foreclosure, sold as is, if there are defects, if the home is brand new, and if the property was listed in the summer.

The results of the hedonic regression will likely not be surprising to anyone that has ever shopped for a home. The hedonic model has parceled out the value of the home/property into its component parts and has succeeded in explaining 84.3 % of the value of transaction price. The relationship between real estate transaction prices and the square footage of the home is concave; for small homes small increases in size have a larger marginal impact than for larger homes. The same is true for the square footage of the property and the bedrooms. The relationship between transaction price and age is convex; implying that the market price of young houses depreciates at a larger rate than that of older houses. It is not surprising that given the hot summers in Texas, a pool adds substantial value (in this case $11,447 of value), nor is it surprising that foreclosed upon properties and properties that are sold as is tend to sell for less money than other properties.

R^2	84.3 %	

Properties farther from the central business district also tend to sell for higher prices. Interestingly, properties listed in the summer tend to sell for on average \$1,260 higher prices than those not listed in the summer.

The principal use of a linear hedonic model is to help researchers construct a property's transaction price from its component parts. So, using the above model, a 3-year-old, 1,800 ft^2 home, with a 200 ft by 200 ft lot, three bedrooms and two baths, and a pool, sold at a foreclosure sale, with no known defects, which is located 7 miles from the central business district and listed in the summertime, would have a predicted transaction price of \$102,092.

78.6 The Semilog Model

When the item to be priced cannot be easily restocked, for example, a home, then nonlinearities arise in the hedonic pricing structure. To deal with this, it is common for researchers to employ the following semilogarithmic functional form for the hedonic model:

$$VALUE = e^{x\beta\varepsilon} \tag{78.2}$$

thus

$$\ln VALUE = X\beta + \varepsilon \tag{78.3}$$

In this case, the log of an item's expected price is the sum of its characteristics $\boldsymbol{X}$ times $\boldsymbol{\beta}$, and the marginal price of each individual attribute $\boldsymbol{x}$ is

$$PRICE(x) = e^{xb} \tag{78.4}$$

where $\boldsymbol{x}$ is the current level of the characteristic and $\boldsymbol{b}$ is the regression coefficient. Notice that the semilog form implies that the price of a given characteristic varies with its level, i.e., the prices are nonlinear.

The semilog structural hedonic pricing model has several advantages over its linear counterpart. The principal advantage is that it permits the value of a given characteristic (e.g., the number of bathrooms) to vary proportionately with the value of other characteristics (the number of bedrooms). This is not the case with a linear model, where a second bathroom adds the same value to a house that has one bedroom as it does to one that has five bedrooms.

78.6.1 Example Using the Semilog Model

Table 78.3 presents the results of a linear hedonic pricing model where the dependent variable is the log of the property's transaction price. Again, the results are not surprising. An advantage of the semilog form is that the model's coefficients are easily interpreted. The percentage change in the value of the house for a unit change in the dependent variable can be represented as $e^b - 1$, where $\boldsymbol{b}$ is the regression coefficient.[2] For example, if the coefficient on the variable that represents a pool equals 0.104, then adding a pool to a house would increase its value by $e^{0.104} - 1 = 10.96\%$.

78.7 The Box–Cox Model

Although not as widely employed due to the difficulty of interpreting the coefficients, a more general form of the hedonic pricing model was first presented by Halvorsen and Pollakowski (1981), which applies the seminal work of Box and Cox (1964) to hedonic modeling. The basic Box–Cox transformation is

[2]See Halvorsen and Palmquist (1980).

Table 78.3 OLS regression of LOGSALE on the dependent variables

OLS LOGSALE		
Coefficient	T-stat	
FT	6.76E-04	28.68

SUMMER	1.38E-02	3.69
CONSTANT	9.5387	183.40
R^2	87.5 %	

$$X^{(\lambda)} = \frac{X^{\lambda} - 1}{\lambda}, \quad \text{if } \lambda \neq 0, X > 0 \tag{78.5}$$

$$= \ln X, \quad \text{if } \lambda = 0$$

So the basic form of the Box–Cox model is given by

$$VALUE = X^{(\lambda)}\beta + \varepsilon \tag{78.6}$$

Please see the Appendix for a discussion of how the Box–Cox coefficients are estimated. Notice that when λ equals one, the Box–Cox structural form reduces to the linear form. A more general form of the Box–Cox model can be expressed by

$$VALUE^{(\theta)} = \beta_0 + \sum_j \beta_j X_j^{\lambda} + \frac{1}{2}\sum_j \sum_k \gamma_{jk} X_j^{\lambda} X_k^{\lambda} \tag{78.7}$$

In this case, when θ and λ are both equal to one and the cross products γ_{jk} are all zero, then Eq. 78.7 reduces down to a simple linear regression model. When θ and λ are both equal to zero and the cross products γ_{jk} are all also equal to zero, then the model reduces down to a straightforward log-log functional form.

The Box–Cox model was first introduced into the mainstream finance literature by C. F. Lee in his seminal 1976 paper, which examines the Functional Form and the Dividend Effect of the Electric Utility Industry. Other excellent examples of the application of the Box–Cox model to finance include Lee and Kau (1976), and (Lee et al. 1980).

One of the most innovative uses of Box–Cox hedonic models in real estate has been to back out property depreciation rates for federal tax reasons. Hulton and Wykcoff (1981) present evidence of a constant geometric rate derived from a hedonic model with a Box–Cox transformation of the value industrial and commercial buildings. The more flexible Box–Cox approach permits relationships to emerge instead of forcing a predetermined, and perhaps ad hoc, functional form.

78.7.1 Example Using the Box–Cox Model

Table 78.4 presents the results of a linear hedonic pricing model where the dependent variable is the Box–Cox transformation of the property's transaction price. Notice that lambda emerges from the model and is not exogenously imposed.

78.8 Problems with Hedonic Modeling

78.8.1 The Identification Problem

There is an inherent identification problem that occurs when one attempts to model an item's demand function when the prices that one has to work with come from the interaction of the item's supply and demand functions: it is difficult to separate out the supply and demand impact on price. There is a second problem with hedonic modeling that comes from the nonlinear nature of the pricing structure. In a simple demand model, the price of an item is taken as given, and consumers make their purchase decision (quantity) based upon the exogenous price, i.e., consumers are price takers. But, as seen above, nonlinear hedonic models imply that the price of a characteristic is correlated with quantity; so consequently, buyers will select not only the quantity of a characteristic but, by design, also its price. Several authors, Blomquist and Worley (1982) or Diamond and Smith (1985), have attempted to solve this problem through the use of instrumental variables.

78.8.2 The Equilibrium Pricing Problem

A key aspect of demand modeling is that observed prices are assumed to be equilibrium prices. Unfortunately, in markets such as real estate where adjustment costs can be large, the notion of observed prices being equilibrium ones becomes problematical. There are several papers that attempt to deal with the disequilibrium character of real estate transaction prices. See Maclennan (1977, 1982) for a good overview of the disequilibrium problem.

There are several ways in which researches have attempted to deal with the disequilibrium problem. Bowden (1978) addresses the problem by utilizing only those observations that are either at or near equilibrium. He employs a switching regression technique. See Anas and Eum (1984) for an application of this "disequilibrium" hedonic modeling technique. Although switching regression models can be effective at mitigating the disequilibrium problem, they are not without their challenges. The major problem is how to differentiate between equilibrium and disequilibrium prices. Another problem is that modelers are often more interested in predicting actual future transaction prices rather than so-called equilibrium prices.

Another way to deal with the disequilibrium problem is to find a way to adjust prices back to their equilibrium levels. There are several papers that use this technique.[3] The technique involves estimating a time series index of prices and then finding a way to determine which prices are equilibrium ones (e.g., prices may be deemed to be near their equilibrium values if there was little or no price change from period to period). Take this set of equilibrium prices and estimate their determining

[3]See Abraham and Hendershott (1996), Malpezzi (1998), and Drieman and Follain (2000).

characteristics, so that for each period there is an actual price, and estimated index price, and an estimated equilibrium price. From these prices it is possible to determine the extent to which the price is out of equilibrium. The last step is to find the determinants of the disequilibrium and adjust the initial prices accordingly.

78.9 Recent Developments

There have been some interesting recent developments in the area of hedonic modeling. Below is a brief synopsis of a few recent papers and issues that are on the cutting edge of the literature. Costanigro et al. (2007) argue that when researchers disregard heterogeneity across assets, they introduce an aggregation bias into their estimated prices. They suggest that a model that estimates hedonic functions that are specific to price ranges yields more accurate predictions. Collins et al. (2007) examine a similar uniqueness problem but with respect to art rather than wine.

Goetzmann and Peng (2006) analyze and present a model that adjusts for the bias that occurs because of a house seller's reservation price in transaction-based hedonic price indexes. They present a hedonic model where the ratio of sellers' reservation prices to the actual market value has an impact on trading volume and can lead to a bias in the observed transaction prices. They find that there is an upward bias to index returns when trading volume decreases.

Diewert (2002) and Feenstra and Knittel (2004) examine the problem of quality adjustments in a hedonic model. These papers examine whether the output price index for a durable good can also be used as (partial) input price index. Although these papers focus on the producer price index, the quality adjustments can be applied more widely. The authors find that the relevant input price is the value of the characteristic bundle of the underlying asset (i.e., the market price) divided by the quantity of the individual characteristics associated with the bundle. For example, if one were to buy a cleaning service, one would take the price of the cleaning service divided by the total number of benefits provided by the service (e.g., the time savings, the convenience, the trustworthiness, the quality of the work).

Bajari and Benkard (2005) reexamine hedonic models of demand for differentiated products. They nicely generalize Rosen's original hedonic model to allow for unobservable product characteristics and for the hedonic pricing function to have a nonseparable form. They use a semi-parametric approach to demonstrate that if there are only a few products, one can construct bounds on an individual's utility parameters, and in addition other important considerations, for example, aggregate demand and consumer surplus.[4] Heckman et al. (2010) examine nonadditive

[4]Please see Bontemps et al. (2008), Jensen and Webster (2007), Ferreira and McMillan (2007), Hahn and Mathews (2007), and Epple et al. (2006) for additional work on this interesting theme.

hedonic models. In specific, they examine the issue of nonparametric identification and estimation of these models.

Recently, hedonic models that have been employed examine issues of substantial political importance. Sander and Polasky (2009), Poudyal et al. (2009), Hoshino and Kuriyama (2010), Cutter et al. (2011), (Brander and Koeste 2011), and Nordman and Wagner (2012) all provide evidence on the high value of wide-open spaces in the United States. Jiao and Liu (2010) examines this same issue in Wuhan, China. Donovan and Butry (2010) examine a related issue: the value of trees that line city streets. Gopalakrishnan et al. (2011) examine the value of disappearing beaches due to beach erosion. Kim et al. (2010) and Bayer et al. (2009) utilize hedonic models to measure the value of air quality. Lastly, Bishop and Murphy (2011) have an innovative paper that utilized a dynamic hedonic model to estimate the willingness to pay in order to avoid violent crime.

Hedonic regressions are being increasingly used to better understand the drivers of prices for consumer products. Costanigro et al. (2007, 2009), and Panzone (2011) have utilized hedonic models to examine fluctuations in wine prices. Thrane (2009) uses a hedonic model to determine whether sensory or objective attributes drive wine prices. Benfratello et al. (2009) examine the issue of taste versus reputation. Kassie et al. (2011) utilize a hedonic model to examine the prices of cattle.

78.10 Summary

This short primer provides an overview of the literature and the microeconomic theory that underpins modern hedonic pricing models. At their most basic, hedonic pricing models deconstruct an asset's price into the price of the asset's individual component parts and then use some form of ordinary least squares regression analysis, using either a linear, semilog, or Box–Cox structural form, to examine how each individual component part uniquely contributes to the item's overall value. This paper explores each of these aforementioned structural forms and their associated problems and in addition offers some guidance on common treatments of the dependent and independent variables.

Appendix

This appendix describes the maximum likelihood technique used for the estimation of the nonlinear parameters of the Box–Cox transformation. Given the functional form specified in Eqs. 78.5–78.7 and employing the assumption that there is some λ for which the error term in Eq. 78.6 has an approximate normal distribution with mean of zero and a variance of σ^2, then for the nth observation, the density function can be represented as

$$f(z|\beta,\Sigma) = \frac{e^{\left[-\frac{1}{2}(z-\mu)'\sum^{-1}(z-\mu)\right]}}{(2\pi)^{\frac{n}{2}}|\Sigma|^{\frac{1}{2}}}, \text{where } z = y^{(\lambda)} \tag{78.8}$$

If $E(y)$ is linear, that is, $\mu = X\beta$ and $\sum = \sigma^2 I$, then the density function transforms into something more tractable:

$$f(z|\beta,\Sigma) = \frac{e^{\left[-\frac{1}{2\sigma^2}(z-X\beta)'(z-X\beta)\right]}}{(2\pi\sigma^2)^{\frac{n}{2}}} \tag{78.9}$$

Next, in order to get the density function for y rather than z, we must multiply the density function for z by its Jacobian. If we do so, then we obtain

$$f(y|\beta,\Sigma,\lambda) = \frac{e^{\left[-\frac{1}{2\sigma^2}(z-X\beta)'(z-X\beta)\right]}}{(2\pi\sigma^2)^{\frac{n}{2}}}\prod_{i=1}^{n} y_i^{\lambda-1} \tag{78.10}$$

the corresponding log-likelihood function of which is delineated as

$$\begin{aligned}\ln L\left(\beta,\sigma^2,\lambda|y\right) = -\frac{1}{2\sigma^2}(z-X\beta)'(z-X\beta) - \frac{n}{2}\ln\left(2\pi\sigma^2\right)\\ + (\lambda-1)\sum_{i-1}^{n}\ln y_i\end{aligned} \tag{78.11}$$

Now that we have the log of the likelihood function, the values of the parameters β, λ, and σ are determined by maximum likelihood estimation.

Abstract

We theoretically extend the proposition of DeAngelo and DeAngelo's (*Journal of Financial Economics* 79, 293–315, 2006) optimal payout policy in terms of the flexibility dividend hypothesis. We also introduce growth rate, systematic risk, and total risk variables into the theoretical model. Our empirical findings show that based on flexibility considerations, a company will reduce its payout when the growth rate increases. In addition, a nonlinear relationship exists between the payout ratio and the risk. In other words, the relationship between the payout ratio and risk is negative (or positive) when the growth rate is higher (or lower) than the rate of return on total assets.

We use a panel data collected in the USA from 1969 to 2009 to empirically investigate the impact of growth rate, systematic risk, and total risk on the optimal payout ratio in terms of the fixed-effects model. Furthermore, we implement the moving estimates process to find the empirical breakpoint of the structural change for the relationship between the payout ratio and risks and confirm that the empirical breakpoint is not different from our theoretical breakpoint. Our theoretical model and empirical results can therefore be used to identify whether flexibility or the free cash flow hypothesis should be used to determine the dividend policy.

79.1 Introduction

Corporate dividend policy has long engaged the attention of financial economists, dating back to the irrelevance theorem of Miller and Modigliani (1961; M&M hereafter), in which they state that a rational and perfect economic environment is free of illusion. Since then, their rather controversial findings have been challenged and tested by weakening the assumptions or introducing imperfections into the analysis. For example, the signaling models developed by Bhattacharya (1979), Miller and Rock (1985), and John and Williams (1985) and the free cash flow hypothesis proposed by Easterbrook (1984) and Jensen (1986) are the two well-known propositions challenging M&M's dividend irrelevance theorem; however, empirical studies examining signaling and free cash flow hypotheses have yielded mixed results.

DeAngelo and DeAngelo (2006) reexamine the irrelevance of the M&M dividend irrelevance theorem by allowing partial dividend payout. They argue that the original M&M (1961) irrelevance result is due to the fact that they consider either paying out all earnings or not paying any of them at all. Therefore, payout policy might be relevant if partial payout is allowed. In other words, DeAngelo and DeAngelo (2006) use dividend flexibility hypothesis to show their dividend relevance results. Underlying the flexibility hypothesis, the current paper (1) develops a theoretical model to support the proposition of DeAngelo and DeAngelo's (2006) optimal payout policy when the partial payout is allowed, (2) reconciles the dispute between free cash flow hypothesis and flexibility hypothesis in dividend policy literature, and (3) performs empirical tests in terms of theoretical results derived in this paper.

First of all, following DeAngelo and DeAngelo (2006), we develop a dynamic model allowing firms to hold some amount of cash into a positive NPV project for the reason of financial flexibility. Under the assumption of stochastic rate of return and the dividend flexibility hypothesis, we carry out the optimization procedure to maximize firm value, and the final expression of the optimal dividend policy of the firm is thus derived. The model is comprehensive and allows structural analysis of different variables that could be relevant for corporate dividend policy. For example, the model incorporates the rate of return on assets, growth rate, and risk (systematic, firm-specific, and total risk) to name a few variables that could affect corporate dividend decisions. Comparative statics provide insights into the effect of each of these parameters on corporate dividend policy, and this is followed by an analysis of the interaction effects of these variables on corporate dividend policy.

Second, the implications of the optimization results are explained. Our results show that the relationship between the optimal payout ratio and the growth rate is negative in general. We investigate the separate and then the combined effects of market-dependent and market-independent components of risk on the optimal dividend policy. We perform comparative static analyses of the relationships between the payout ratio and (1) change in total risk, (2) change in systematic risk, (3) simultaneous changes in both total risk and systematic risk, and (4) no change in risk. We examine in detail the effects of variations in the profitability rate, its distribution parameters, and their dynamic behavior on the optimal dividend policy of the firm. The theoretical relationship between the payout ratio and the growth ratio implies that high growth firms need to reduce the payout ratio and retain more earnings to build up "precautionary reserves" for flexibility considerations, but low growth firms are likely to be more mature and already build up their reserves. More importantly, the relationship between the payout ratio and the risks reflects different dividend policies at high growth firms and low growth firms. With higher risk, the costs of external funds increase; therefore, to optimize shareholders' wealth, high growth firms tend to reduce their payouts and keep more relatively low-cost funds to sustain their high growth, whereas low growth firms tend to pay more dividends and reduce the risk for shareholders.

Third, our theoretical model and its implications lead us to three testable hypotheses. Although a large and growing body of empirical research on the optimal dividend payout policy has emerged, none of it has a solid theoretical model to support findings or introduces a nonlinear structured model on payout policy.[1] We here try to empirically examine three hypotheses derived from our theoretical optimal payout model. Using data collected in the USA from 1969 to 2009, we analyze 28,333 dividend-paying firm-years. Our empirical results show that firms' payout ratios are negatively related to firms' growth, and a negative (or positive) relationship exists between firms' risks and the dividend payout ratios among firms with higher (or lower) growth rates relative to their rate of return on assets. Our empirical results are consistent with our theoretical model under the dividend flexibility hypothesis. We also find that growth and risk interact in explaining the payout ratio, indicating that the payout ratio is not linearly related to the growth rate or to the risk of the firm. Furthermore, we implement the moving estimates process to find the empirical breakpoint of the structural change for the relationship between the payout ratio and risks and confirm that the empirical breakpoint is not different from our theoretical breakpoint.

The primary contributions of this paper are our theoretical derivation of an optimal payout ratio under the dividend flexibility hypothesis and our demonstration of a negative but nonlinear relationship between the payout ratio and the growth rate. More importantly, we theoretically and empirically locate a structural change point for the relationship between the payout ratio and the growth rate. Rozeff (1982), Aivazian et al. (2003), Blau and Fuller (2008), and others conclude that a firm's risk and optimal payout are negatively related. Contrary to these conclusions and generally held beliefs, the dynamic optimization model developed here shows that the optimal payout is not necessarily negatively related to risk but implies that payout policies differ in high growth firms and low growth firms. High growth firms pay out their dividends for flexibility considerations, but low growth firms pay out their dividends to reduce their free cash flow problem. In addition, this paper also shows that the relationship between firms' payouts and their growth rates (or risks) can be affected by their risks (or growth rates). Contrary to earlier studies, the theoretical model developed here shows that the optimal payout ratio is not linearly related to the growth rate or to the risk of the firm, and whether the rate of return on assets is higher or lower than the growth rate has significant effect on the relationships between these variables. The results are borne out by rather extensive empirical research done in this paper based on 40 years of data collected in the USA from 1969 to 2009.

The stochastic dynamic optimization model developed here challenges many commonly held beliefs and results obtained from earlier studies. It provides more meaningful relationships among total risk and its separate components (systematic and firm-specific), growth rate, rate of return on assets, and optimal

[1]For example, Rozeff (1982), Jagannathan et al. (2000), Grullon et al. (2002), Aivazian et al. (2003), and Blau and Fuller (2008).

dividend policy. Our results represent an advance in corporate finance literature because all the important variables included in this study were never simultaneously included in those earlier studies, and more importantly, the interaction effects among these variables were neither recognized nor fully appreciated. We believe that this study is the first of its kind to provide a theoretical basis for relating dividend policies with firm risks, growth rates, and return on assets (ROAs) in an interrelated fashion.

The remainder of this paper is organized as follows: Section 79.2 contains a review of the literature on dividend-relevant theories and the findings of empirical work on dividend policy. In Sect. 79.3 we lay out a dynamic model used in subsequent sections to examine the existence, or nonexistence, of an optimal dividend policy. Section 79.4 provides the final expression of the optimal dividend policy of the firm derived from the optimization procedure to maximize firm value. In Sect. 79.5 we present both a detailed form and an approximated form of the relationship between the optimal dividend payout ratio and the growth rate. Section 79.6 includes a discussion of the effects of -market-dependent and market-independent components of risk on the optimal dividend policy. Section 79.7 includes empirical evidence supporting the model and implications in previous sections, and the conclusion appears in Sect. 79.8.

79.2 Review of the Literature

Corporate dividend policy has puzzled financial economists, dating back to the dividend irrelevance theorem proposed by M&M (1961). Since then, their controversial findings have been challenged and tested by weakening the assumptions or introducing imperfections into the analysis. The signaling models developed by Bhattacharya (1979), Miller and Rock (1985), and John and Williams (1985) suggest that because of the asymmetric information between managers and shareholders, managers use dividends as a signal to release private information to the market; however, empirical studies examining the signaling hypothesis have yielded mixed results. Nissim and Ziv (2001), Brook et al. (1998), Bernheim and Wantz (1995), Kao and Wu (1994), and Healy and Palepu (1988) support the signaling (asymmetric information) hypothesis by finding a positive association between dividend increases and future profitability. Kalay and Lowenstein (1986) and Asquith and Mullins (1983) find that dividend changes are positively associated with stock returns in the days surrounding dividend announcements, and Sasson and Kolodny (1976) identify that there is a positive association between the payout ratio and average rates of return. Studies by Benartzi et al. (1997), DeAngelo et al. (1996), and Grullon et al. (2002), however, reveal no support for the hypothesized relationship between dividend changes and future profitability.

Using agency cost theory, Easterbrook (1984) and Jensen (1986) propose the free cash flow hypothesis, arguing that because managers cannot credibly precommit to shareholders, they will not invest excess cash in negative-NPV projects. Dividend changes may convey information about how the firm will use future cash flow. Again, the results of empirical studies have been mixed at best. Several researchers, including Agrawal and Jayaraman (1994), Jensen et al. (1992), and Lang and Litzenberger (1989), find positive supports for the agency cost hypothesis, but others find no support for this hypothesis, for example, Howe et al. (1992), Denis et al. (1994), and Yoon and Starks (1995).

DeAngelo and DeAngelo (2006) argue that M&M's (1961) dividend irrelevance occurs because they consider either paying out all earnings or not paying any of them at all; therefore, payout policy might have impact on firm value if partial payout is allowed. In other words, DeAngelo and DeAngelo (2006) use the dividend flexibility hypothesis to show their dividend relevance results. Blau and Fuller (2008) have theoretically and empirically shown that the dividend flexibility hypothesis is indeed a reasonable dividend policy. In addition, several empirical studies show evidence of firms preferring financial flexibility, for example, Lie (2005), DeAngelo et al. (2006), Denis and Osobov (2008), and Gabudean (2007).

Besides focusing on the relevance of dividend policy, a growing body of literature deals with the determinants of optimal dividend payout policy. For example, Rozeff (1982) shows that the optimal dividend payout is related to the fraction of insider holdings, the growth of the firm, and the firm's beta coefficient. He also finds evidence that the optimal dividend payout is negatively correlated to beta risk, and supporting that beta risk reflects the leverage level of a firm. Jagannathan et al. (2000) empirically show that operation risk is negatively related to the propensity to increase payouts. Grullon et al. (2002) show that dividend changes are related to the change in the growth rate and the change in the rate of return on assets. They also find that dividend increases should be associated with subsequent declines in profitability and risk. Aivazian et al. (2003) examine eight emerging markets and show that, similar to US firms, dividend policies in emerging markets can also be explained by profitability, debt, and the market-to-book ratio. None of the foregoing scholars, however, has a solid theoretical model to support their finding.

We use these authors' works as a springboard to deal with the flexibility hypothesis and develop the theoretical underpinnings and a stochastic dynamic optimization model determining the conditions for an optimal dividend policy. We believe that ours is the first attempt ever made to include growth rate, risks, and more importantly, the rate of return and its distribution parameters in a single model deriving the conditions for an optimal dividend policy; furthermore, this paper empirically tests the findings and conclusions of the theoretical model developed here, using an extensive data set involving 28,333 dividend-paying firm-years from 1969 to 2009. The results of the empirical tests confirm and validate the findings of the theoretical model and provide new insights in the determination of optimal dividend policy, the influence of each explanatory variable listed above, and more importantly, their interaction effects on the corporate dividend policy. Notably, some of these results run counter to categorically stated conclusions reached in earlier studies.

79.3 The Model

We develop the dividend policy model under the assumptions that the capital markets represent the closest approximation to the economists' ideal of a perfect market – zero transaction costs, rational behavior on the part of investors, and the absence of tax differentials between dividends and capital gains. It is assumed that the firm is not restricted to financing its growth only by retained earnings and that its rate of return, $\widetilde{r}(t)$, is a nonstationary random variable, normally distributed with mean, μ, and variance, $\sigma(t)^2$.

Let $A(0)$ represent the initial assets of the firm and h be the growth rate. Then the earnings of this firm are given by Eq. 79.1, which is

$$\widetilde{x}(t) = \widetilde{r}(t)A(0)e^{ht} \tag{79.1}$$

where $\widetilde{x}(t)$ represents the earnings of the firm, and the tilde ($\sim$) denotes its random character.

Based upon DeAngelo and DeAngelo's (2006) assumption, we allow that the firm partially pay out its earnings and retain a certain amount of earnings in support of its growth.[2] The retained earnings of the firm, $y(t)$, can therefore be expressed as follows:

$$y(t) = \widetilde{x}(t) - m(t)\widetilde{d}(t), \tag{79.2}$$

where $\widetilde{d}(t)$ is the dividends per share and $m(t)$ is the total number of shares outstanding at time t.

Equation 79.2 further indicates that the focus of the firm's decision making is on retained earnings, which implies that dividend $\widetilde{d}(t)$ also becomes a random variable. The growth of a firm can be financed by retained earnings or by issuing new equity.

The new equity raised by the firm at time t can be defined as follows:

$$e(t) = \delta p(t)\dot{m}(t), \tag{79.3}$$

Where

$p(t)$ = price per share;

$\dot{m}(t) = dm(t)/dt;$

δ = degree of market perfection, $0 < \delta \leq 1$.

The value of δ equal to one indicates that new shares can be sold by the firm at current market prices.

[2]DeAngelo and DeAngelo (2006) carefully explain why partial payout is important to obtain an optimal ratio under perfect markets. In addition, they also argue that partial payout is important to avoid the suboptimal solution for optimal dividend policy.

From Eqs. 79.1, 79.2 and 79.3, investment in period t is the sum of retained earnings and funds raised by new equity, so the investment in period t can be written as follows:

$$hA(0)e^{ht} = \tilde{x}(t) - m(t)\tilde{d}(t) + \delta\dot{m}(t)p(t). \tag{79.4}$$

This implies that

$$\tilde{d}(t) = \left\{[\tilde{r}(t) - h]A(0)e^{ht} + \delta\dot{m}(t)p(t)\right\}/m(t), \tag{79.5}$$

and the mean and variance of the dividends per share can be expressed as follows:

$$E\left[\tilde{d}(t)\right] = \left\{[\mu - h]A(0)e^{ht} + \delta\dot{m}(t)p(t)\right\}/m(t) Var\left[\tilde{d}(t)\right] = A(0)^2\sigma(t)^2e^{2th}/m^2(t). \tag{79.6}$$

Also, let us postulate an exponential utility function of the following form[3]:

$$U\left[\tilde{d}(t)\right] = -e^{\alpha\tilde{d}(t)}, \text{ where } \alpha > 0. \tag{79.7}$$

Following the moment generating function, we have

$$E\left(-e^{-\alpha\tilde{d}(t)}\right) = -e^{-\alpha E\left[\tilde{d}(t)\right] + \frac{\alpha^2}{2}Var\left[\tilde{d}(t)\right]}, \tag{79.8}$$

where $\overline{d}(t)$ is the certainty equivalent value of $\tilde{d}(t)$.[4]

From Eqs. 79.6 and 79.8, the certainty equivalent dividend stream can be written as

$$\overline{d}(t) = \frac{(\mu - h)A(0)e^{th} + \delta\dot{m}(t)p(t)}{m(t)} - \frac{\alpha' A(0)^2\sigma(t)^2e^{2th}}{m(t)^2}, \tag{79.9}$$

where $\alpha' = \alpha/2$. Therefore, taking advantage of exponential utility, we can obtain a risk adjusted dividend stream. Furthermore, $\overline{d}(t)$ will reduce to the certainty case if we assume $\sigma(t)^2 = 0$.

In accordance with the capital asset pricing theory developed by Sharpe (1964), Lintner (1963), and Mossin (1966), the total risk can be decomposed into systematic risk and unsystematic risk; that is, $\tilde{r}(t)$ can be defined as follows:

$$\tilde{r}(t) = a + b\tilde{I}(t) + \tilde{\varepsilon}(t), \tag{79.10}$$

[3]Pratt (1964) provides a detailed analysis of the various utility functions. Exponential, hyperbolic, and quadratic forms have been variously used in the literature, but the first two seem to have preference over the quadratic form because the latter has the undesirable property that it ultimately turns downwards.

[4]From the moment generating function discussed in Hogg and Craig (2004), we know that $E(-e^{ty}) = -e^{tE(y) + \frac{1}{2}t^2Var(y)}$. Let $t = -\alpha$, then the right-hand side of (8) is easily obtained.

where $\widetilde{I}(t)$ is the market index; $\widetilde{\varepsilon}(t) \sim N\left(0, \sigma_{\varepsilon}^{2}\right)$; a and b are regression parameters; and $Var\left(b\widetilde{I}(t)\right)$ and $Var(\widetilde{\varepsilon}(t))$ represent the systematic and unsystematic risk, respectively.

Following Eqs. 79.10 and 79.6 can be rewritten as

$$\begin{aligned} E\left[\widetilde{d}(t)\right] &= \left[\left(a+b\bar{I}-h\right)A(o)e^{ht} + \delta\dot{m}(t)p(t)\right]/m(t)Var\left[\widetilde{d}(t)\right] \\ &= A(0)^{2}\left[b^{2}Var\left(\widetilde{I}(t)\right) + Var(\varepsilon(t))\right]e^{2th}/m(t)^{2} \\ &= A(0)^{2}\left[\rho(t)^{2}\sigma(t)^{2} + \left(1-\rho(t)^{2}\right)\sigma(t)^{2}\right]e^{2th}/m(t)^{2}, \end{aligned} \tag{79.11}$$

where
$\rho(t)$ = the correlation coefficient between $\widetilde{r}(t)$ and $\widetilde{I}$;
a = market-independent component of the firm's rate of return;
$b\bar{I}$ = market-dependent component of the firm's rate of return;
$\rho(t)^{2}\sigma(t)^{2}$ = nondiversifiable risk; and
$(1-\rho(t)^{2})\sigma(t)^{2}$ = diversifiable risk.

The unsystematic risk usually can be diversified away by the investors,[5] so the certainty equivalent value in Eq. 79.9 should be revised as

$$\hat{d}'(t) = \frac{\left(a+b\bar{I}-h\right)A(o)e^{th} + \delta\dot{m}(t)p(t)}{m(t)} - \frac{\alpha' A(o)^{2}\rho(t)^{2}\sigma(t)^{2}e^{2th}}{m(t)^{2}}. \tag{79.12}$$

Following Lintner (1962), we observe that the stock price should equal the present value of this certainty equivalent dividend stream discounted at a riskless rate of return. Therefore,

$$p(0) = \int_{0}^{T} \hat{d}'(t)e^{-kt}dt, \tag{79.13}$$

where
$p(0)$ = the stock price at $t = 0$;
k = the risk free rate of return;
T = the planning horizon.

This model will be used in subsequent sections to find the functional form of $m(t)$ and optimize the payout ratio. The formulation of our model is different from that of M&M (1961), Gordon (1962), Lerner and Carleton (1966a), and Lintner (1964). For example, in contrast to our model, M&M consider neither the nonstationarity of the firm's rate of return in their model nor explicitly incorporated uncertainty in their valuation model. Their models are also essentially static and would not permit an extensive analysis of the dynamic process of moving from one equilibrium state to another; furthermore, the formulation of our model is different from those who propose to capitalize the market-dependent and market-independent components of

[5] See Lintner (1965), Mossin (1966), and Sharpe (1964).

the uncertain stream of earnings at the risky and riskless rates, respectively.[6] Instead, we view the market value of a firm as the present value of certainty equivalents of random future receipts. In the next section, we carry out the optimization of Eq. 79.13 and derive the final expression for the optimal payout ratio.[7]

79.4 Optimum Dividend Policy

Based upon the evaluation model developed in the previous section, in this section we will derive an optimal dividend payout ratio.

Substituting Eq. 79.12 into Eq. 79.13, we obtain

$$p(0) = \int_0^T \left[\frac{\left(A + b\bar{I} - h\right)A(0)e^{th} + \delta \dot{m}(t)p(t)}{m(t)} - \frac{\alpha' A(0)^2 \rho(t)^2 \sigma(t)^2 e^{2th}}{m(t)^2} \right] e^{-kt} dt. \tag{79.14}$$

To maximize Eq. 79.14, we observe that

$$p(t) = \int_t^T \hat{d}'(s) e^{-k(s-t)} ds = e^{kt} \int_t^T \hat{d}'(s) e^{-ks} ds, \tag{79.15}$$

where $s =$ the proxy of time in the integration.

From Eq. 79.15, we can formulate a differential equation as

$$\frac{dp(t)}{d(t)} = \dot{p}(t) = kp(t) - \hat{d}'(t). \tag{79.16}$$

Substituting Eq. 79.12 into Eq. 79.16, we obtain the differential equation

$$\dot{p}(t) + \left[\delta \frac{\dot{m}(t)}{m(t)} - k \right] p(t) = -G(t), \tag{79.17}$$

Where

$$G(t) = \frac{\left(a + b\bar{I} - h\right)A(0)e^{th}}{m(t)} - \frac{\alpha' A(o)^2 \rho(t)^2 \sigma(t)^2 e^{2th}}{m(t)^2}. \tag{79.18}$$

Following Kreyszig (2010) and Lee and Shi (2010), we solve the differential Eq. 79.17 and obtain the solution as indicated in Eq. 79.19.

$$p(t) = \frac{e^{kt}}{m(t)^\delta} \int_t^T G(s) m(s)^\delta e^{-ks} ds. \tag{79.19}$$

[6]See Brennan (1973).

[7]For further explanation of the optimization of the deterministic and stochastic control models and their applications to economic problems, please see Aoki (1967), Bellman (1990 and 2003), and Intriligator (2002).

Then, Eq. 79.20 can be obtained from Eqs. 79.18 and 79.19, implying that the initial value of a stock can be expressed as the summation of present values of its earnings stream adjusted by the risk taken by the firm.

$$p(0) = \frac{1}{m(0)^{\delta}} \int_0^T \left\{ \left(a + b\overline{I} - h\right) A(0) e^{th} m(t)^{\delta-1} - \alpha' A(0)^2 \rho(t)^2 \sigma(t)^2 e^{2th} m(t)^{\delta-2} \right\} e^{-kt} dt. \tag{79.20}$$

To maximize firm value, the Euler-Lagrange condition for the optimization of $p(o)$ is given by Eq. 79.21,[8]

$$(\delta - 1)\left(a + b\overline{I} - h\right) A(0) e^{th} m(t)^{\delta-2} - \alpha' A(0)^2 \rho(t)^2 \sigma(t)^2 e^{2th} m(t)^{\delta-3} (\delta - 2) = 0. \tag{79.21}$$

Therefore, the optimal shares outstanding at time t can be derived.

$$m(t) = \frac{(2-\delta)\alpha' A(0) e^{th} \rho(t)^2 \sigma(t)^2}{(1-\delta)\left(a + b\overline{I} - h\right)}. \tag{79.22}$$

From Eqs. 79.18, 79.19 and 79.22, we can obtain the maximized stock value

$$p(t) = \frac{\left(a + b\overline{I} - h\right)^2 (1-\delta) e^{kt - th\delta} \int_t^T e^{\delta hs - ks} \left(\rho(s)\sigma(s)\right)^{2\delta-2} ds}{\alpha' (2-\delta)^2 \rho(t)^{2\delta} \sigma(t)^{2\delta}}. \tag{79.23}$$

From Eq. 79.22, we also obtain the optimal number of shares of new equity issued at time t

$$\dot{m}(t) = \frac{\left\{ h(2-\delta)\alpha' A(0) e^{th} \rho(t)^2 \sigma(t)^2 + (2-\delta)\alpha' A(0) e^{th} [\rho(t)^2 \dot{\sigma}(t)^2 + \sigma(t)^2 \dot{\rho}(t)^2 \right\}}{(1-\delta)\left(a + b\overline{I} - h\right)}. \tag{79.24}$$

From Eqs. 79.23 and 79.24, we have the amount generated from issuing new equity

$$\dot{m}(t)p(t) = \frac{\left(a + b\overline{I} - h\right) e^{kt-(\delta-1)th} A(0) \left(h\rho(t)^2 \sigma(t)^2 + \rho(t)^2 \dot{\sigma}(t)^2 + \sigma(t)^2 \dot{\rho}(t)^2\right) \int_t^T e^{s(\delta h - k)} \left(\rho(s)\sigma(s)\right)^{2\delta-2} ds}{(2-\delta)\rho(t)^{2\delta}\sigma(t)^{2\delta}}. \tag{79.25}$$

From Eqs. 79.5 and 79.25, we can obtain $\overline{D}(t) = m(t)\overline{d}(t)$. From Eqs. 79.1 and 79.10, we can obtain $\overline{x}(t) = \left(a + b\overline{I}\right) A(0) e^{ht}$. When δ approaches unity, we can derive the optimal payout ratio as

---

[8]For the derivation of Eq. 79.21, please refer to the Appendix 2.

$$\frac{\overline{D}(t)}{\overline{x}(t)} = \frac{\left(a + b\overline{I} - h\right)}{\left(a + b\overline{I}\right)} \left\{ 1 + \frac{\left[e^{(h-k)(T-t)} - 1\right]}{(h-k)} \left(h + \frac{\dot{\sigma}(t)^2}{\sigma(t)^2} + \frac{\dot{\rho}(t)^2}{\rho(t)^2} \right) \right\}. \quad (79.26)$$

Equation 79.26 implies an optimal payout ratio when we use an exponential utility function to derive the stochastic dynamic dividend policy model. This result does not necessarily imply that the dividend policy results derived by M&M (1961) are false because we allowed free cash flow to be paid out partially as assumed by DeAngelo and DeAngelo (2006) instead of paying out all free cash flows as assumed by M&M (1961).

In the following section, we use Eq. 79.26 to explore the implications of the stochasticity, the stationarity (in the strict sense), and the nonstationarity of the firm's rate of return for its dividend policy.[9] We also investigate in detail the differential effects of variations in the systematic and unsystematic risk components of the firm's stream of earnings on the dynamics of its dividend policy.

79.5 Relationship Between the Optimal Payout Ratio and the Growth Rate

In this section, we investigate the relationship between the optimal payout ratio and the growth rate in terms of both exact and approximate approaches. Taking the partial derivative of Eq. 79.26 with respective to the growth rate, we obtain

$$\begin{aligned}\frac{\partial\left[\overline{D}(t)/\overline{x}(t)\right]}{\partial h} &= \left(-\frac{1}{a + b\overline{I}}\right)\left[\frac{-k + he^{(h-k)(T-t)}}{h-k}\right] \\ &\quad + \left(1 - \frac{h}{a + b\overline{I}}\right)\left[\frac{[(-k) + h(h-k)(T-t)]e^{(h-k)(T-t)} + k}{(h-k)^2}\right].\end{aligned} \quad (79.27)$$

The sign of Eq. 79.27 is affected not only by the growth rate (h) but also by the expected rate of return on assets ($a + b\overline{I}$), the duration of future dividend payments ($T-t$), and the cost of capital (k).

Since the sign of Eq. 79.27 cannot be analytically determined, we use a sensitivity analysis approach to investigate the sign of Eq. 79.27. Table 79.1 shows the sign of partial derivatives of Eq. 79.27 under different values of the growth rate and the rate of return on assets as well as duration ($T-t$). We find that the relationship between the optimal payout ratio and the growth rate is always negative when the growth rate is higher than the rate of return on assets. If the growth rate is lower than the rate of return on asset, the direction of relationship essentially depends on the duration of the dividend payment ($T-t$). We find that the sign of Eq. 79.27 is

[9] See Hamilton (1994), pp. 45–46.

negative if the duration ($T - t$) is small and the growth rate and rate of return on assets are within a reasonable range. In addition, the curved lines in Table 79.1 also indicate a nonlinear relationship between the growth rate and the optimal payout ratio. We can therefore conclude that the relationship between the optimal payout ratio and the growth rate is nonlinear and generally negative.

Based upon Eq. 79.27, Fig. 79.1 plots the change in the optimal payout ratio with respect to the growth rate in different durations of dividend payments and costs of capital. We find a negative relationship between the optimal payout ratio and the growth rate, indicating that a firm with a higher rate of return on assets tends to pay out less when its growth opportunities increase. Moreover, a firm with a lower growth rate and higher expected rate of return will not decrease its payout when its growth opportunities increase, but a firm with a lower growth and a higher expected rate of return on asset is not a general case in the real world. We also find that the duration of future dividend payments is an important determinant of the dividend payout decision, but the effect on the cost of capital is relatively minor.

In the finite growth case, if $(h–k)(T–t) < 1$, then following the Maclaurin expansion, the optimal payout ratio under no change in risk defined in Eq. 79.26 can be written as

$$\left[\overline{D}(t)/\overline{x}(t)\right] \approx \left(1 - \frac{h}{a + b\overline{I}}\right)(1 + h(T - t)). \tag{79.28}$$

The partial derivative of Eq. 79.28 with respective to the growth rate is

$$\frac{\partial\left[\overline{D}(t)/\overline{x}(t)\right]}{\partial h} \approx \left(\frac{\left[\left(a + b\overline{I}\right) - h\right](T - t) - h(T - t) - 1}{a + b\overline{I}}\right). \tag{79.29}$$

Equation 79.29 indicates that the relationship between the optimal dividend payout and the growth rate depends on firm's level of growth, the rate of return on assets, and the duration of future dividend payment.[10] Equation 79.29 is negative when the rate of return on assets is lower than the growth rate. This implies that the firm will reduce its payout when its growth rate increases. The higher growth rate (h) and the lower rate of return on assets ($a + b\overline{I}$) will lead to a more negative relationship between dividend payout ratio and growth rate. More specifically, the condition of Eq. 79.29 will lead to a negative relationship between the optimal payout ratio and the growth rate.

$$h > \frac{1}{2}\left[\left(a + b\overline{I}\right) - \frac{1}{(T - t)}\right]. \tag{79.30}$$

Consistent with the sensitivity analysis of Eq. 79.27, when a firm with a high growth rate or a low rate of return on assets faces a growth opportunity, it will decrease its dividend payout to generate more cash to meet such a new investment.

A possible explanation is that high growth firms need more retained earnings to meet their future growth opportunities because the growth rate is the main

[10]Please see the Appendix 3 for the derivation of Eq. 79.28 and 79.29.

This table shows the sensitivity analysis of the relationship between the optimal payout and the growth rate. Panel A presents, when the duration of dividend payments (T–t) is equal to 3 years and the cost of capital is equal to 7 %, the values of Eq. 79.32 under different settings of the rate of return on assets and the growth rate. Similar to Panel A, Panel B and Panel C present the values of Eq. 79.32 when the duration of dividend payments is equal to 3 years and 5 years and the cost of capital is equal to 7 %

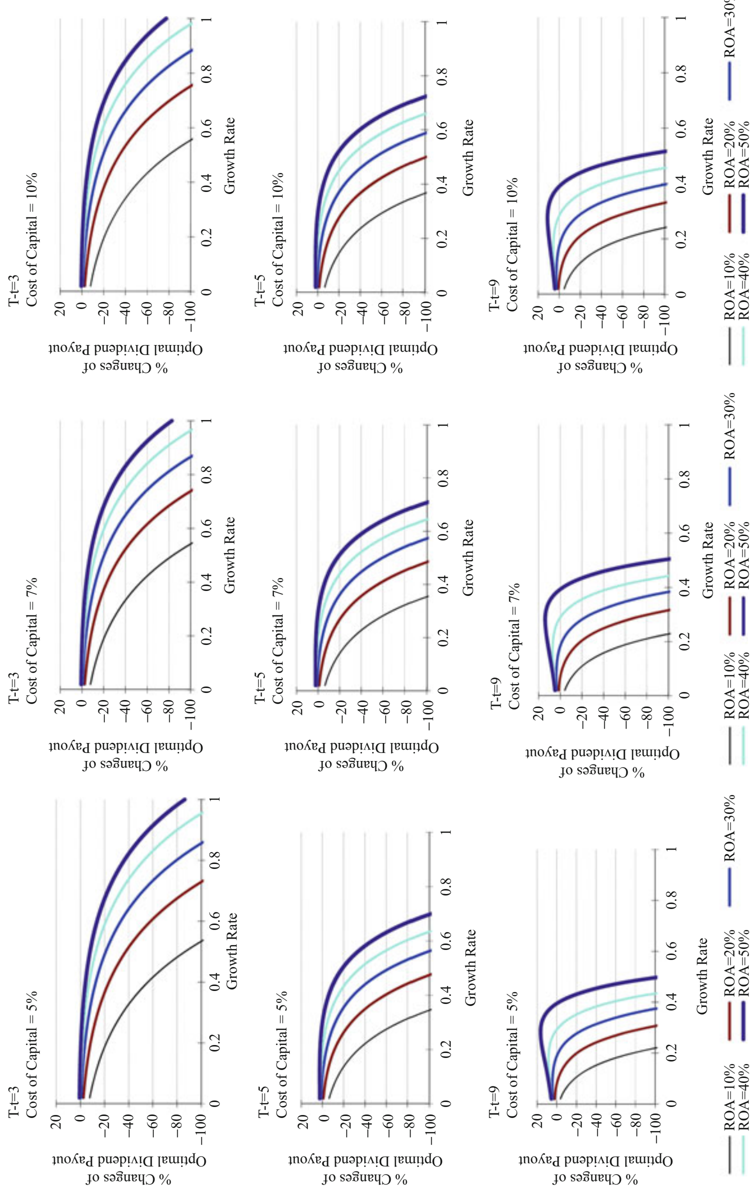

Fig. 79.1 **Sensitivity analysis of the relationship between the optimal payout and the growth rate**. The figures show the sensitivity analysis of the relationship between the optimal payout and the growth rate. In each figure, each *line* shows the percentage change of the optimal dividend payout with a 1 % change in the growth rate. The *various lines* represent different levels of the rate of return on assets. The figures present different durations of dividend payments ($T-t$) and costs of capital

determinant of value in the case of such companies, but low growth firms do not need more earnings to maintain their low growth perspective and can afford to increase their payouts. Based on the flexibility concerns, the relationship between firms' payout ratios and their growth rates is therefore negative.

79.6 Relationship Between Optimal Payout Ratio and Risks

Equation 79.26 implies that the optimal payout ratio is a function of the expected profitability rate ($a + b\bar{I}$), growth rate (h), cost of capital (k), age (T–t), total risk ($\sigma(t)^2$), and the correlation coefficient between profit and market rate of return ($\rho(t)^2$). In addition, Eq. 79.26 is also a function of two dynamic variables – the relative time rate of change in the total risk of the firm, $\left[\dot{\sigma}(t)^2/\sigma(t)^2\right]$, and the relative time rate of change in the covariability of the firm's earnings with the market, $\left[\dot{\rho}(t)^2/\rho(t)^2\right]$. This theoretical dynamic relationship between the optimal payout ratio and other determinants can be used to do empirical studies to determine dividend policy. The dynamic effects of variations in $\left[\dot{\sigma}(t)^2/\sigma(t)^2\right]$ and $\left[\dot{\rho}(t)^2/\rho(t)^2\right]$ on the time path of optimal payout ratio can be investigated under the following four cases: (1) changes in total risk, (2) changes in correlation between profit and the market rate of return (i.e., systematic risk), (3) changes in total risk and systematic risk, and (4) no changes in risk.

79.6.1 Case 1: Total Risk

First, we examine the effect of $\left[\dot{\sigma}(t)^2/\sigma(t)^2\right]$ on the optimal payout ratio. By differentiating Eq. 79.26 with respect to $\left[\dot{\sigma}(t)^2/\sigma(t)^2\right]$, we obtain

$$\frac{\partial\left[\overline{D}(t)/\overline{x}(t)\right]}{\partial\left[\dot{\sigma}(t)^2/\sigma(t)^2\right]} = \left(1 - \frac{h}{a + b\bar{I}}\right)\left[\frac{e^{(h-k)(T-t)} - 1}{h - k}\right]. \tag{79.31}$$

In Eq. 79.31 the cost of capital, k, can be either larger or smaller than the growth rate h. We can show that $\frac{e^{(h-k)(T-t)}-1}{h-k}$ is always larger than 0, regardless of whether k is larger or smaller than h.[11] Thus, the sign of Eq. 79.31 depends on the sign of $\left(1 - \frac{h}{a+b\bar{I}}\right)$, which depends on the growth rate h relative to $\left(a + b\bar{I}\right)$.

[11]If $h > k$, then $e^{(h-k)(T-t)} > 1$, and both the numerator and denominator are greater than zero, resulting in a positive value; if $h < k$, then $e^{(h-k)(T-t)} < 1$, and both the numerator and denominator are less than zero, resulting in a positive value. Thus, $\frac{e^{(h-k)(T-t)}-1}{h-k}$ is always larger than 0, regardless of whether k is larger or smaller than h.

If the growth rate h is equal to $\left(a + b\bar{I}\right)$, then $\left(1 - \frac{h}{a+b\bar{I}}\right)$ is equal to zero. Equation 79.31 is thus zero, and the change in total risk will not affect the payout ratio because the first derivative of the optimized payout ratio, Eq. 79.26, with respect to $\left[\dot{\sigma}(t)^2/\sigma(t)^2\right]$ is always zero.

If growth rate h is larger than $\left(a + b\bar{I}\right)$, then the entire first derivative of Eq. 79.26 with respect to $\left[\dot{\sigma}(t)^2/\sigma(t)^2\right]$ is negative (i.e., Eq. 79.31 is negative); furthermore, $h > \left(a + b\bar{I}\right)$ implies that the growth rate of a firm is larger than its expected profitability rate. An alternative case is $h < \left(a + b\bar{I}\right)$, which implies that the growth rate of a firm is less than its expected profitability rate. This situation can occur when a company is either in a low growth, no growth, or negative growth stage. Under this situation, a company will increase its payout ratio as shown in Eq. 79.31. If $h < \left(a + b\bar{I}\right)$, then Eq. 79.31 is positive, indicating that a relative increase in the risk of the firm would increase its optimal payout ratio. This implies that a relative increase in the total risk of the firm would decrease its optimal payout ratio. Lintner (1965) and Blau and Fuller (2008) have found this kind of relationship, yet they did not theoretically show how it can be derived.

Jagannathan et al. (2000) empirically show that operation risk is negatively related to the propensity to increase payouts in general and dividends in particular. Our theoretical analysis in terms of Eq. 79.31 shows that the change in total risk is negatively or positively related to the payout ratio, conditional on the higher growth rate relative to the expected profitability rate. We find negative relationships between payout and the change in total risk for high growth firms $\left(h > \left(a + b\bar{I}\right)\right)$. A possible explanation is that in the case of high growth firms, a firm must reduce the payout ratio and retain more earnings to build up "precautionary reserves," which become all the more important for a firm with volatile earnings over time. High growth firms thus tend to retain more earnings when they face higher risk. By contrast, in the case of established low growth firms $\left(h < \left(a + b\bar{I}\right)\right)$, low growth firms are likely to be more mature and have most likely already built such reserves over time. They probably do not need more earnings to maintain their low growth perspective and can afford to increase the payout; consequently, when facing higher risk on their earnings, low growth firms can reduce their shareholders' risk by paying more dividends to their shareholders.

The age of the firm (T–t), which is one of the variables in Eq. 79.31, becomes an important factor because the very high growth firms are also the newer firms with very little builtup precautionary reserves.

Under more dynamic conditions, we provide further evidence of the validity of Lintner's (1965) observations that, ceteris paribus, optimal dividend payout ratios vary directly with the variance of the firm's profitability rates. The rationale for such relationships, even when the systematic risk concept is incorporated into the analysis, is obvious, that is, holding $\rho(t)^2$ constant and letting the $\sigma(t)^2$ increase imply that the covariance of the firm's earnings with the market does not change though its relative proportion to the total risk increases.

79.6.2 Case 2: Systematic Risk

To examine the effect of a relative change in $\left[\dot{\rho}(t)^2/\rho(t)^2\right]$ (i.e., systematic risk) on the dynamic behavior of the optimal payout ratio, we differentiate Eq. 79.26 to obtain

$$\frac{\partial\left[\overline{D}(t)/\overline{x}(t)\right]}{\partial\left[\dot{\rho}^2(t)/\rho^2(t)\right]} = \left(1 - \frac{h}{a + b\overline{I}}\right)\left[\frac{e^{(h-k)(T-t)} - 1}{h-k}\right]. \tag{79.32}$$

The sign of Eq. 79.32 can be analyzed as with Eq. 79.31, so the conclusions of Eq. 79.32 are similar to those of Eq. 79.31. A relative change in $\rho(t)^2$ can either decrease or increase the optimal payout ratio, all things being equal. The effect of nonstationarity in the firm's nondiversifiable risk would tend to be obliterated should both the systematic and the unsystematic components of total risk not be clearly identified in the expression for optimal payout ratio. Although the total risk of the firm is stationary (i.e., $\left[\dot{\sigma}(t)^2/\sigma(t)^2\right]$ is equal to zero), a change in the total risk complexion of the firm could still conceivably occur because of an increase or decrease in the covariability of its earnings with the market. Equations 79.26 and 79.32 clearly identify the effect of such a change in the risk complexion of the firm on its optimal payout ratio.

An examination of Eq. 79.26 indicates that only when the firm's earnings are perfectly correlated with the market (i.e., $\rho^2 = 1$), whether the management arrives at its optimal payout ratio using the total variance concept of risk or the market concept of risk does not matter. For every other case, the optimal payout ratio followed by management using the total variance concept of risk would be an overestimate of the true optimal payout ratio for the firm based on the market concept of risk underlying the capital asset pricing theory.

Management may decide not to use the truly dynamic model and instead substitute an average of the long run systematic risk of the firm, but for $\dot{\rho}^2(t) > 0$, because the initial average is higher than the true $\rho^2(t)$, the management would pay out less or more in the form of dividends than is optimal. In other words, the payout ratio followed in the initial part of the planning horizon would be an overestimate or an underestimate of the optimal payout under truly dynamic specifications.

Rozeff (1982) empirically shows a negative relationship between the β coefficient (systematic risk) and the payout level. The theoretical analysis in terms of Eq. 79.32 provides a more detailed analytical interpretation of his findings. The explanations of these results are similar to those discussed for findings in previous sections.

79.6.3 Case 3: Total Risk and Systematic Risk

In our third case, we attempt to investigate the compounded effect of a simultaneous change in the total risk of the firm and also a change in its decomposition into the market- dependent and market-independent components. Taking the total differential of Eq. 79.26 with respect to $\left[\dot{\sigma}(t)^2/\sigma(t)^2\right]$ and $\left[\dot{\rho}(t)^2/\rho(t)^2\right]$, we obtain

$$d\left[\overline{D}(t)/\overline{x}(t)\right] = \gamma d\left(\frac{\dot{\sigma}(t)^2}{\sigma(t)^2}\right) + \gamma d\left(\frac{\dot{\rho}(t)^2}{\rho(t)^2}\right), \tag{79.33}$$

where $\gamma = \left(1 - \frac{h}{a+b\overline{I}}\right)\left[\frac{e^{(h-k)(T-t)} - 1}{h-k}\right]$. Also, γ can be either negative or positive, as shown above.

Now from Eq. 79.33, the greatest decrease or increase in the optimal payout ratio would obviously occur when both $\dot{\sigma}(t)^2$ and $\dot{\rho}(t)^2$ are positive. This implies that the total risk of the firm increases, and in addition, its relative decomposition into systematic and unsystematic components also changes, making the firm's earnings still more correlated with the market. Under this circumstance, the decrease or increase in the optimal payout would now represent the compounded effect of both these changes; however, it is conceivable that although $\dot{\sigma}(t)^2$ is positive, $\dot{\rho}(t)^2$ is negative, tending to offset the decrease or increase in the optimal payout ratio resulting from the former. Alternatively, $\dot{\sigma}(t)^2$ could be negative, indicating a reduction in the total risk of the firm and may offset the increase in the optimal payout ratio resulting from a positive $\dot{\rho}(t)^2$.

To what extent the inverse variations in the total risk and the risk complexion of the firm will offset each other's effects on the optimal payout ratio for the firm would, of course, be dependent upon the relative magnitudes of $\dot{\rho}(t)^2$ and $\dot{\sigma}(t)^2$. To see the precise trade-off between the two dynamic effects of $\left[\dot{\sigma}(t)^2/\sigma(t)^2\right]$ and $\left[\dot{\rho}(t)^2/\rho(t)^2\right]$ on the optimal payout ratio, let the total differential of Eq. 79.26, given in Eq. 79.33, be set equal to zero, yielding

$$d\left[\dot{\sigma}(t)^2/\sigma(t)^2\right] = -d\left[\dot{\rho}(t)^2/\rho(t)^2\right]. \tag{79.34}$$

Equation 79.34 implies that the relative increase (or decrease) in $\sigma(t)^2$ has a one-to-one correspondence with the relative decrease (or increase) in $p(t)^2$, so in Eq. 79.34 conditions are established for relative changes in $p(t)^2$ and $\sigma(t)^2$, which lead to a null effect on the optimal dividend payout ratio.

79.6.4 Case 4: No Change in Risk

Now we consider the least dynamic situation, in which no changes exist in total risk or systematic risk, assuming $\dot{\sigma}(t)^2 = 0$ and $\dot{\rho}(t)^2 = 0$. Under this circumstance, Eq. 79.26 reduces to

$$\left[\overline{D}(t)/\overline{x}(t)\right] = \left(1 - \frac{h}{a+b\overline{I}}\right)\left[\frac{-k + he^{(h-k)(T-t)}}{h-k}\right]. \tag{79.35}$$

Thus, when the firm's total risk and covariability of its earnings with the market are assumed stationary, Eq. 79.35 indicates that a firm's optimal payout ratio is independent of its risk. Notice that neither $\sigma(t)^2$ nor $\rho(t)^2$ now appears in the expression for the optimal payout ratio given in Eq. 79.35. These conclusions, like those of Wallingford (1972a, b), for example, run counter to the intuitively appealing and well-accepted theory of finance emphasizing the relevance of risk for financial decision making.[12] Our model clearly shows that the explanation for such unacceptable implications of the firm's total risk and its market-dependent and market-independent components for the firm's optimal payout policy lies, of course, in the totally unrealistic assumptions of stationarity underlying the derivation of such results as illustrated in Eq. 79.35.

79.7 Empirical Evidence

A growing body of literature focuses on the determinants of optimal dividend payout policy. Rozeff (1982), Jagannathan et al. (2000), Grullon et al. (2002), Aivazian et al. (2003), Blau and Fuller (2008), and others empirically investigate the determination of dividend policy, but none of them has a solid theoretical model to support their findings. Based upon our theoretical model and its implications discussed in the foregoing sections, we develop the three testable hypotheses that follow:

Hypothesis 1 Firms generally reduce their dividend payouts when their growth rates increase.

The negative relationship between the payout ratio and the growth ratio in our theoretical model implies that high growth firms need to reduce the payout ratio and retain more earnings to build up "precautionary reserves," but low growth firms are likely to be more mature and already build up their reserves for flexibility considerations. Rozeff (1982), Fama and French (2001), Blau and Fuller (2008), and others argue that high growth firms will have higher investment opportunities and tend to pay out less in dividends. Based upon flexibility concerns, we predict that high growth firms pay higher dividends. This result is obtained when risk factor is not explicitly considered.

Following Eqs. 79.31 and 79.32, we theoretically find that the relationship between the payout ratio and the risk can be either negative or positive, depending upon whether the growth rate is higher or lower than the rate of return on total assets. Based upon this finding, we develop two other hypotheses.

Hypothesis 2 The relationship between the firms' dividend payouts and their risks is negative when their growth rates are higher than their rates of return on asset.

High growth firms need to reduce the payout ratio and retain more earnings to build up "precautionary reserves," which become more important for a firm with

[12]For example, Lintner (1963).

volatile earnings over time. For flexibility considerations, high growth firms tend to retain more earnings when they face higher risk. This theoretical result is consistent with the flexibility hypothesis.

Hypothesis 3 The relationship between the firms' dividend payouts and their risks is positive when their growth rates are lower than their rates of return on asset.

Low growth firms are likely to be more mature and have most likely already built such reserves over time, and they probably do not need more earnings to maintain their low growth perspective and can afford to increase the payout (see Grullon et al. 2002). Because the higher risk may involve higher cost of capital and make the free cash flow problem worse, for free cash flow considerations, low growth firms tend to pay more dividends when they face higher risk. This theoretical result is consistent with the free cash flow hypothesis.

79.7.1 Sample Description

We collect the firm information, including total asset, sales, net income, and dividends payout, from Compustat. Stock price, stock returns, share codes, and exchange codes are retrieved from the Center for Research in Security Prices (CRSP) files. The sample period is from 1969 to 2009. Only common stocks (SHRCD = 10, 11) and firms listed on NYSE, AMEX, or NASDAQ (EXCE = 1, 2, 3, 31, 32, 33) are included in our sample. We exclude utility services (SICH = 4900–4999) and financial institutions (SICH = 6000–6999).[13] The sample includes those firm-years with at least 5 years of data available to compute average payout ratios, growth rate, return on assets, beta, total risk, size, and book-to-market ratios. The payout ratio is measured as the ratio of the dividend payout to the net income. The growth rate is the sustainable growth rate proposed by Higgins (1977). The beta coefficient and total risk are estimated by the market model over the previous 60 months. For the purpose of estimating their betas, firm-years in our sample should have at least 60 consecutive previous monthly returns. To examine the optimal payout policy, only firm-years with five consecutive dividend payouts are included in our sample.[14] Considering the fact that firm-years with no dividend payout one 1 year before (or after) might not start (or stop)

[13]We filter out those financial institutions and utility firms based on the historical Standard Industrial Code (SIC) available from COMPUSTAT. When a firm's historical SIC is unavailable for a particular year, the next available historical SIC is applied instead. When a firm's historical SIC is unavailable for a particular year and all the years after, we use the current SIC from COMPUSTAT as a substitute.

[14]To avoid creating a large difference in dividend policy, on one hand managers partially adjust firms' payout by several years to reduce the sudden impacts of the changes in dividend policy. On the other hand, they use not only 1-year firm conditions but also multiyear firm conditions to decide how much they will pay out. In examining the optimal payout policy, we use the 5-year rolling averages for all variables.

their dividend payouts in the first (fourth) quarter of the year, we exclude from our sample firm-years with no dividend payouts 1 year before or after to ensure the dividend payout policy reflects the firm's full-year condition.

Table 79.2 shows the summary statistics for 2,645 sample firms during the period from 1969 to 2009. Panel A of Table 79.2 lists the number of firm-year observations for all sample high growth firms and low growth firms, respectively. High growth firm-years are those firm-years that have 5-year average sustainable growth rates higher than their 5-year average rate of return on assets. Low growth firm-years are those firms with 5-year average sustainable growth lower than their

This table presents the descriptive statistics for those major characteristics of our sample firms. Sample includes those firms listed on NYSE, AMEX, and NASDAQ with at least 5 years of data available to compute average payout ratios, growth rate, return on assets, beta, total risk, size, and book-to-market ratios. All financial service operations and utility companies are excluded. Panel A lists the numbers of firm-years observations for all sample firms, high growth firms, and low growth firms, respectively, during the period between year 1969 and year 2009. High growth firm-years are defined as firm-years with sustainable growth rates higher than their rates of return on assets. Low growth firm-years are defined as firm-years with sustainable growth rates lower than their rate of return on assets. Panel B lists the mean, median, and standard deviation values of the 5-year average of the payout ratio, growth rate, rate of return on assets, beta risk, total risk, size, and book-to-market ratio. The payout ratio is measured as the ratio of the dividend payout to the earnings. Growth rate is the sustainable growth rate proposed by Higgins (1977). The beta coefficient and total risk are estimated by the market model over the previous 60 months. Size is defined as market capitalization calculated by the closing price of the last trading day of June of that year times the outstanding shares at the end of June of that year

5-year average rate of return on assets. The sample size increases from 345 firms in 1969 to 1,203 firms in 1982, while declining to 610 firms by 2009. A total of 28,333 dividend-paying firm-years are included in the sample. When classifying high growth firms and low growth firms relative to their return on assets, the proportion of high growth firms increases over time. The proportion of firm-years with a growth rate higher than return on assets increases from less than 50 % during the late 1960s and early 1970s to 80 % in 2008. Panel B of Table 79.2 shows the 5-year moving averages of mean, median, and standard deviation values for the measures of payout ratio, growth rate, rate of return, beta coefficient, total risk, market capitalization, and market-to-book ratio across all firm-years in the sample. Among high growth firms, the average growth rate is 12.33 %, and the average payout ratio is 31.80 %; but for low growth firms, the average growth rate is 4.13 %, and the average payout ratio is 57.62 %. High growth firms undertake more beta risk and total risk, indicating that high growth firms undertake both more systematic risk and unsystematic risk to pursue a higher rate of return.

79.7.2 Univariate Analysis

To examine Hypothesis 1, we divide our sample into five groups by growth rate. As Table 79.3 Panel A indicates, the average (median) payout ratio is 48.64 % (48.35 %) for the lowest growth group and is 22.13 % (19.67 %) for the highest growth group. The argument of "precautionary reserves" for flexibility concerns

Table 79.3 Payout ratios partitioned by growth rate and risks

		Low total risk				High total risk
		1	2	3	4	5
All sample	*Mean*	0.4274	0.4058	0.3618	0.3285	0.3041
	Median	0.4099	0.3808	0.3333	0.2899	0.2588
High growth firms	*Mean*	0.3499	0.3286	0.2957	0.2698	0.2531
	Median	0.3381	0.3138	0.2745	0.2431	0.2190
Low growth firms	*Mean*	0.6078	0.6202	0.6269	0.6091	0.6115
	Median	0.5732	0.5942	0.6062	0.5863	0.6025

This table presents the average and the median payout ratios in different groups partitioned by growth rate, beta risk, or total risk during the sample period from 1969 to 2009. Panel A reports the average and the median payout ratios by one-way sort on the growth rate. Panel B reports the average and the median payout ratios by independent two-way sort on the growth rate and the beta. Panel C reports the average and the median payout ratios by independent two-way sort on the growth rate and the total risk. High growth firm-years are defined as firm-years with sustainable growth rates higher than their rates of return on assets. Low growth firm-years are defined as firm-years with sustainable growth rates lower than their rate of return on assets

and Hypothesis 1 can therefore be confirmed. We further divide our sample in to five groups by beta risk and total risk indicated in Panel B and Panel C of Table 79.3. We can observe a monotonic decrease in payout ratios when the beta risk or the total risk increases, which is consistent with the findings of Rozeff (1982), Fenn and Liang (2001), Grullon et al. (2002), Aivazian et al. (2003), and Blau and Fuller (2008), but they do not consider the relationship between the payout ratio, and the risk may alter by the growth. To examine the Hypothesis 2 and Hypothesis 3, we further divide our sample by 2-way sorts on the growth rate and risks. High growth groups are firm-years with sustainable growth rates higher than their rate of return on total assets. Low growth groups are firm-years with sustainable growth rates lower than their rate of return on total assets. In Table 79.3 Panel B, among high growth firms, the average (median) payout ratio decreases from 31.73 % (30.10 %)

to 28.86 % (25.88 %) when the beta risk increases. Among low growth firms, however, the average (median) payout ratio increases from 61.15 % (58.64 %) to 62.92 % (60.90 %) when the beta risk increases. Similar to Panel B, Panel C also shows a negative relationship between the payout ratio and the total risk among high growth firms and a positive relationship between the payout ratio and the total risk among low growth firms. Above all, the static analysis results of Panel B and Panel C support Hypotheses 2 and 3 that the relationship between the payout ratio and the risk depends upon the growth rate of a firm.

79.7.3 Multivariate Analysis

To examine the relationship between the payout ratio and other financial variables, we propose fixed-effects models of the payout ratio as follows[15]:

$$
\begin{aligned}
ln\left(\frac{payout\ ratio_{i,t}}{1-\left(payout\ ratio_{i,t}\right)}\right) = {} & \alpha + \beta_1 Risk_{i,t} + \beta_2 D_{i,t}\left(g_{i,t} < c \cdot ROA_{i,t}\right) \cdot Risk_i \\
& + \beta_3 Growth_{i,t} + \beta_4 Risk_{i,t} \times Growth_{i,t} \\
& + \beta_5 \ln(Size)_{i,t} + \beta_6 ROA_{i,t} + e_{i,t}.
\end{aligned} \tag{79.36}
$$

In the regression, the dependent variable is the logistic transformation of the payout ratio. Independent variables include risk measure (beta coefficient or total risk), the interaction of dummy variable and risk measure, growth rate, the interaction of risk measure and growth rate, log of size, and rate of return on total assets.[16] Based upon the theoretical model and its implications from Sect. 79.6, we assume that c is equal to 1. The dummy variable (D_i) is equal to 1 if a firm's 5-year average growth rate is less than its 5-year average rate of return on assets and 0 otherwise. Such structure allows us to analyze the relationship between payout ratio and growth rate and the relationship between payout ratio and risk under different growth rate levels.

Thompson (2010), Peterson (2009), and Cameron et al. (2006) have pointed out that standard errors of 2-way fixed-effects estimates can be biased if 2-dimensional clustering (clustering in the cross-sectional errors and clustering in time-series errors) is not controlled for. Thompson (2010) and Boehmer et al. (2010) have empirically found that these clustering effects are not important for large samples.

[15]The dummy variable $D_{i,t}(g_{i,t} < c\ .\ ROA_{i,t})$ used in Eq. 79.36 implies that the relationship between the payout ratio and risks is nonlinear (piecewise regression). In other words, the breakpoint of the structural change is at $g_{i,t} = c\ .\ ROA_{i,t}$. Based upon our theoretical model, we assume that c is equal to 1 in our empirical work.

[16]Besides merely adding an interaction dummy as indicated in Eq. 79.36, we include an intercept dummy to take care of the individual effect of two groups. We also run regressions for high growth firms and low growth firms separately. Results from both models are qualitatively the same as those from Eq. 79.36 and also support Hypotheses 1–3.

The robust standard errors are very similar to standard errors for ordinary least square (OLS), suggesting that the fixed effects and control variables are removing most of the correlation that is present across observations. In addition, our dataset cannot be meaningfully applied to the clustering effect model[17]; therefore, statistical inferences in this paper are conducted using fixed-effects standard errors.

Table 79.4 provides the results of fixed-effects regressions for 2,645 firms during the period 1969 to 2009. *Model* (*1*) and *Model* (*2*) show that the estimated coefficients of the growth rate are −0.03 with a *t*-statistics of −4.85 and −0.03 with a *t*-statistics of −4.85, respectively. Such significantly negative coefficients confirm Hypothesis 1, which states that high growth firms will pay less in dividends for the consideration of flexibility. We also include an interaction term of risk and growth rate into *Model* (*3*) and *Model* (*4*). The results in *Model* (*3*) and *Model* (*4*) also support Hypothesis 1.

Models (*1–4*) show that the relationship between the payout ratio and the risk is significantly negative. The results are similar to the findings of Rozeff (1982), Jagannathan et al. (2000), and Grullon et al. (2002), indicating that dividend payouts are negatively correlated to firm risks; but our theoretical model shows that if firms follow their optimal dividend payout policy, the relationship between dividend payouts and firm risks depends on their growth rates relative to their rate of return on total assets as our theoretical analysis presented in Sect. 79.6. In Table 79.2, we find the number of firms with a higher growth rate with respect to their rate of return on assets greater than the number of firms with a lower growth rate with respect to their rates of return on assets. When pooling high growth firms and low growth firms together, the negative risk effect of high growth firms will dominate the positive risk effect of low growth firms due to the larger proportion of high growth firms in the observations. The results of the negative relationship between the payout ratio and the risk shown in *Models* (*1–4*) may therefore result from the greater proportion of high growth firms. Based on our subsequent analysis, the effect of growth rates on dividend payout policies can be more accurately found when firms are separated into high growth firms and low growth firms relative to their rates of return on total assets of return on assets.

To test Hypotheses 2 and 3, we introduce an interaction term of the dummy variable and the risk. In *Model* (*5*) and *Model* (*6*), the estimated coefficients of risk are −0.23 with a *t*-statistics of −13.88 and −0.22 with a *t*-statistics of −12.69, respectively. The significantly negative coefficients support the hypothesis 2 that, because of the consideration of flexibility, the payout ratio and the risk are negatively correlated for firms with a higher growth rate relative to their rate of return on assets. In addition, significant and positive coefficients of the interaction term of the dummy variable and the risk indicate that, when the risk changes, the dividend policy for low growth firms is different from that of high growth firms. By summing the coefficient of risk and the coefficient of interaction term, we can obtain coefficients

[17]Because our sample is an unbalanced panel data, the clustering computer program cannot meaningfully estimate the variance components, variance of firm $\left(\hat{V}_{firm}\right)$, variance of time $\left(\hat{V}_{time}\right)$, and heteroskedasticity-robust OLS variance $\left(\hat{V}_{white}\right)$.

*, **, and *** indicate significance at the 10 %, 5 %, and 1 % levels, respectively

This table presents results from fixed-effects regressions of dividend payout ratios on firm characteristics for 2,645 firms during the period from 1969 to 2009. The regressions are as follows:

$$\ln\left(\frac{payout\ ratio_{i,t}}{1-\left(payout\ ratio_{i,t}\right)}\right) = \alpha + \beta_1 Risk_{i,t} + \beta_2 D\left(g_{i,t} < c \cdot ROA_{i,t}\right) \cdot Risk_i + \beta_3 Growth_{i,t} + \beta_4 Risk_{i,t} \times Growth_{i,t} + \beta_5 \ln(Size)_{i,t} + \beta_6 ROA_{i,t} + e_{i,t}$$

The dependent variable is the payout ratio with a logistic transformation. Following the theoretical model, we assume c is equal to 1. The dummy variable is equal to 1 if a firm's 5-year average growth rate is less than its 5-year average ROA and 0 otherwise. The independent variables are beta risk (total risk), dummy times beta risk (total risk), interaction between growth rate and beta risk (total risk), growth rate, log of size, and the rate of return on assets. t-statistics are presented in parentheses, and the last column presents p-values of the F-test on the null hypothesis that the restricted *Models* (*1–4*) are not different from the restricted *Models* (*5–8*) of 0.48 and 35.54 for beta and total risk, respectively, indicating the relationship between the payout ratio and the risk for low growth firms is positive. That is, when the risk increases, low growth firms will follow their optimal payout policies to increase their dividend payouts. Hypothesis 3 is thus confirmed in our empirical work. Blau and Fuller (2008) find that the flexibility hypothesis is more suitable than the free cash flow hypothesis to explain the dividend policy, but their method cannot separate the dividend policy decisions between high growth firms and low growth firms. Consequently, the model used in this paper can be regarded as a generalization of their results.

In *Model* (*7*) and *Model* (*8*) in Table 79.4, we further include the interaction term of the risk and the growth rate into the regressions. The results still support our hypotheses that the relationship between the payout ratio (Hypothesis 1) and the growth rate is negative and the relationship between the payout ratio and the risk depends on firm's growth rate with respect to its rate of return on total assets (Hypotheses 2 and 3). In addition, we find that the interaction terms of the risk and the growth rate are significantly different from zero. We also find that the adjusted R-squares for *Models* (*5–8*) are higher than those for models without dummies. F-tests also reject the null hypothesis that the regression with the interaction of the dummy variable and the risk is not different from the regression without the interaction of the dummy and the risk. We can thus conclude that the payout ratio is not linearly related to the growth rate or to the risk, and previous empirical studies on dividend policy using linear model may suffer from model misspecification.

79.7.4 Moving Estimates Process for Structural Change Model

In Eqs. 79.31 and 79.32 in Sect. 79.6, we theoretically show that the structural change breakpoint for the relationship between the payout ratio and risks is at $g_{i,t} = ROA_{i,t}$. In empirical works, we use dummy variable approach to separate the sample into a high growth ($g_{i,t} > c \,.\, ROA_{i,t}$) group and a low growth ($g_{i,t} < c \,.\, ROA_{i,t}$) group, assuming c is equal to 1, and empirically test the relationship between the payout ratio and risks for high growth firms and low growth firms. Based on the moving estimates process developed by Chow (1960), Hansen (1996, 1999, 2000), and Zeileis et al. (2002), we try to estimate the empirical breakpoint of the structural change and examine whether the empirical breakpoint is different from our theoretical breakpoint or not.

By using the moving estimates process, we can obtain an empirical estimate of $c = 0.93$ when using beta risk and $c = 0.97$ when using total risk.[18] That is, the breakpoint of the structural change is at $g_{i,t} = 0.93 \times ROA_{i,t}$ or $g_{i,t} = 0.93 \times ROA_{i,t}$. Then we redo *Model* (*5*) to *Model* (*8*) of Table 79.4 by using the empirical structural change point instead of the theoretical structural change point. In Table 79.5,

[18]Gujarati (2009) shows that this kind of problem can be regarded as piecewise regression by using moving estimates processes. Please see the Appendix 4 for the details of the moving estimates process.

Table 79.5 Fixed-effects regressions using empirical structural change point

Model	Intercept	Beta	D*beta	Growth* beta	Total risk	D*total risk	Growth* total risk	Growth	ln(Size)	ROA	Adj-R2	F-test (p-value)

*, **, and *** indicate significance at the 10 %, 5 %, and 1 % levels, respectively

This table presents results from fixed-effects regressions of dividend payout ratios on firm characteristics for 2,645 firms during the period from 1969 to 2009. The regressions are as follows:

$$\ln\left(\frac{payout\ ratio_{i,t}}{1-\left(payout\ ratio_{i,t}\right)}\right) = \alpha + \beta_1 Risk_{i,t} + \beta_2 D\left(g_{i,t} < c \cdot ROA_{i,t}\right) \cdot Risk_i + \beta_3 Growth_{i,t} + \beta_4 Risk_{i,t} \times Growth_{i,t} + \beta_5 \ln(Size)_{i,t} + \beta_6 ROA_{i,t} + e_{i,t}$$

The dependent variable is the payout ratio with a logistic transformation. Based upon results from the moving estimates process, c is equal to 0.93 when using beta risk and 0.97 when using total risk. The dummy variable is equal to 1 if a firm's 5-year average growth rate is less than its 5-year average ROA and 0 otherwise. The independent variables are beta risk (total risk), dummy times beta risk (total risk), interaction between growth rate and beta risk (total risk), growth rate, log of size, and the rate of return on assets. t-statistics are presented in parentheses, and the last column presents p-values of the F-test on the null hypothesis that the restricted *Models* (*1–4*) in Table 79.4 are not different from the restricted *Models* (*1–4*) in Table 79.5

we compare to the theoretical model and find that the estimates and significances using the empirical breakpoint of the structural change are almost the same as those using the theoretical breakpoint indicated in Table 79.4. Results obtained from the moving estimates process show the existence of an empirical breakpoint for the relationship between the payout ratio and risks and also confirm that the dummy variable used in Eq. 79.36 is both theoretically and empirically acceptable.

79.8 Summary and Concluding Remarks

In this paper, we extend the model developed in earlier studies and improve upon the results obtained in those studies on optimal dividend payout. By allowing partial dividend payout for the consideration of flexibility, we theoretically show the existence of the optimal dividend payout. The results obtained in this paper are different from those of M&M (1961) because, contrary to their model, the model developed here is dynamic, is under uncertainty, and allows the firm to retain some earnings for positive NPV projects, following DeAngelo and DeAngelo (2006) and Blau and Fuller (2008). The dynamic stochastic model developed and empirically tested here is comprehensive and for the very first time includes several variables simultaneously that have not been included in any of the earlier studies. More specifically, the optimization model developed here includes, among other things, a stochastic rate of return on assets, corporate growth rate, and total risk (broken down into its systematic and firm-specific components).

We further analyze the effects of different parameters on the optimal payout ratio. A sensitivity analysis and an approximation form show a negative but nonlinear relationship between the optimal dividend payout ratio and the growth rate. We also explicitly derive the theoretical relationship between the optimal payout ratio and risks. Results of the comparative static analyses cast a different light on the relationship between corporate dividend policy and risk. That the risk and dividend payout are negatively related is generally believed. On the contrary, the relationship between risk and dividend payout is positive when the growth rate is less than the company's rate of return on assets. Only when the growth rate exceeds the rate of return on assets does the relationship between dividend payout and risk turns negative. In sum, this paper shows for the first time that the relationship between growth and dividend payout is nonlinear. In addition, no research has ever shown that the relationship between risk rates and the dividend payout is nonlinear and influenced by other important variables, those of the company's rate of return on assets and growth rate.

Based upon our theoretical model, we develop three testable hypotheses and try to reconcile conflicts between the flexibility hypothesis and the free cash flow hypothesis in existing literature. The empirical research covers 40 years of US data from 1969 to 2009 for 28,333 dividend-paying firm-years. Our empirical results show that the optimal dividend payout ratio is negatively, but not linearly, related to the growth rate. In addition, the optimal dividend payout ratio is negatively (positively) related to both total risk and systematic risk when the growth rate is higher (lower) than the rate of return on assets. Such results also confirm the argument that high growth firms pay dividends due to flexibility considerations and low growth firms pay dividends due to the consideration of the free cash flow problem.

In sum, this paper develops a dynamic stochastic model deriving relationships between corporate dividend payout and several important financial variables. The relationships derived from the model are then tested by extensive empirical research. The relationships found between dividend payout and the growth rate and between dividend payout and risk run counter to those observed in earlier studies and also counter to generally held beliefs. Extensive empirical research validated the conclusions derived from the dynamic stochastic optimization model developed in this paper. For the first time we report here in the literature that these relationships are nonlinear and not solely negative as found in other studies. Thus, this paper extends the model developed in earlier studies and improves upon the results obtained in those studies on optimal dividend payout. We believe that this paper may contribute to an understanding dividend policy in the literature.

Appendix 1: Derivation of Eq. 79.19

This appendix presents a detailed derivation of the solution to the variable partial differential equation, Eq. 79.17, which is similar to Gould's (1968) Eq. 79.9 in investigation the adjustment cost. Following Gould's (1968) approach, we first derive a general solution for a standard variable partial differential equation. Then we apply this general equation to solve Eq. 79.17. The standard variable partial differential equation can be defined as

$$\dot{p}(t) + g(t)p(t) = q(t). \tag{79.37}$$

As a particular case of Eq. 79.37, the equation

$$\dot{p}(t) + g(t)p(t) = 0 \text{ or } \frac{\dot{p}(t)}{p(t)} = -g(t) \tag{79.38}$$

has a solution

$$p(t) = c \cdot \exp\left(-\int g(t)dt\right). \tag{79.39}$$

By substituting constant c with function $c(t)$, we have the potential solution to Eq. 79.37

$$p(t) = c(t) \cdot \exp\left(-\int g(t)dt\right). \tag{79.40}$$

Taking a differential with respect to t, we obtain

$$\begin{aligned}\dot{p}(t) &= \dot{c}(t)\cdot\exp\left(-\int g(t)dt\right) - c(t)\cdot\exp\left(-\int g(t)dt\right)g(t)\\ &= \dot{c}(t)\cdot\exp\left(-\int g(t)dt\right) - p(t)g(t).\end{aligned} \tag{79.41}$$

Therefore,

$$\dot{p}(t) + p(t)g(t) = \dot{c}(t)\cdot\exp\left(-\int g(t)dt\right). \tag{79.42}$$

From Eqs. 79.37 and 79.42, we have

$$\dot{c}(t)\cdot\exp\left(-\int g(t)dt\right) = q(t). \tag{79.43}$$

Equivalently,

$$\dot{c}(t) = q(t)\cdot\exp\left(\int g(t)dt\right). \tag{79.44}$$

Therefore,

$$c(t) = \int q(t)\cdot\exp\left(\int g(t)dt\right)dt. \tag{79.45}$$

Substituting Eq. 79.45 into Eq. 79.39, we have the general solution of Eq. 79.37

$$p(t) = \exp\left(-\int g(t)dt\right)\cdot\left[\int q(t)\exp\left(\int g(t)dt\right)dt\right]. \tag{79.46}$$

To solve Eq. 79.17, we will apply the above result. Let $g(t) = \delta\frac{\dot{m}(t)}{m(t)} - k$ and $q(t) = -G(t)$.

Because

$$\begin{aligned}&\exp\left(\int g(t)dt\right) = \exp\left(\int\left(\delta\frac{\dot{m}(t)}{m(t)} - k\right)dt\right) = \exp\left(\delta\int\frac{\dot{m}(t)}{m(t)}dt - kt\right)\\ &= \exp(\delta\mathrm{In}(m(t)) - kt + c) = c_1\cdot m(t)^{\delta}\exp(-kt), \text{where } c_1 > 0,\end{aligned} \tag{79.47}$$

then we have

$$P(t) = c_2\cdot m(t)^{-\delta}\exp(kt)\cdot\left[\int q(t)c_3\cdot m(t)^{\delta}\exp(-kt)dt\right], \tag{79.48}$$
$$\text{where } c_2 > 0, \text{and } c_3 > 0$$

or equivalently,

$$P(t) = c_4 \cdot \frac{e^{kt}}{m(t)^{\delta}} \cdot \left[\int -G(t) \frac{m(t)^{\delta}}{e^{kt}} dt \right], \tag{79.49}$$

where $c_4 > 0$.

Finally, we have

$$P(t) = c \frac{e^{kt}}{m(t)^{k}} \cdot \int G(t) m(t)^{\delta} e^{-kt} dt. \tag{79.50}$$

Changing from an indefinite integral to a definite integral, Eq. 79.49 can be shown as

$$p(t) = \frac{e^{kt}}{m(t)^{\delta}} \int_t^T G(s) m(s)^{\delta} e^{-ks} ds,$$

which is Eq. 79.19.

Appendix 2: Derivation of Eq. 79.21

This appendix presents a detailed derivation of Eq. 79.21. In Eq. 79.51, the initial value of the firm can be expressed as

$$p(0) = \frac{1}{m(0)^{\delta}} \int_0^T \left\{ \left(a + b\bar{I} - h\right) A(0) e^{th} m(t)^{\delta - 1} - \alpha' A(0)^2 \rho(t)^2 \sigma(t)^2 e^{2th} m(t)^{\delta - 2} \right\} e^{-kt} dt. \tag{79.51}$$

To maximize firm value, the number of shares outstanding at each point of time should be determined; therefore, the objective function can be written as follows:

$$\max_{\{m(t)\}_{t=0}^{T}} p(0). \tag{79.52}$$

Following the Euler-Lagrange condition (see Chiang 1984), we take first-order conditions on the objective function with respect to $m(t)$, where $t \in [0, T]$, and let such first-order conditions be equal to zero:

$$\begin{aligned} &\frac{1}{m(0)^{\delta}} \Big\{ (\delta - 1) \left(a + b\bar{I} - h\right) A(0) e^{th} m(t)^{\delta - 2} \\ &\quad - \alpha' A(0)^2 \rho(t)^2 \sigma(t)^2 e^{2th} m(t)^{\delta - 3} (\delta - 2) \Big\} e^{-kt} dt = 0, \end{aligned}$$

Where

$$t \in [0, T]. \tag{79.53}$$

To simplify Eq. 79.53,

$$(\delta-1)\left(a+b\bar{I}-h\right)A(0)e^{th}m(t)^{\delta-2}-\alpha' A(0)^2\rho(t)^2\sigma(t)^2e^{2th}m(t)^{\delta-3}(\delta-2)=0,$$

where

$$t\in[0,T], \tag{79.54}$$

which is Eq. 79.21.

Appendix 3: Derivation of Eqs. 79.28 and 79.29

This appendix presents a detailed derivation of both Eqs. 79.28 and 79.29. In Eq. 79.55, the optimal payout ratio with no changes in total risk or systematic risk is

$$\left[\overline{D}(t)/\overline{x}(t)\right]=\left(1-\frac{h}{a+b\bar{I}}\right)\left[\frac{-k+he^{(h-k)(T-t)}}{h-k}\right]. \tag{79.55}$$

Considering the finite growth case, if $(h-k)(T-t)<1$, then following Maclaurin expansion, the $e^{(h-k)(T-t)}$ can be expressed as

$$\begin{aligned}e^{(h-k)(T-t)}&=1+(h-k)(T-t)+\frac{(h-k)^2(T-t)^2}{2!}+\frac{(h-k)^3(T-t)^3}{3!}.\\&\approx 1+(h-k)(T-t)\end{aligned} \tag{79.56}$$

Therefore, Eq. 79.31 can be approximately written as

$$\left[\overline{D}(t)/\overline{x}(t)\right]\approx\left(1-\frac{h}{a+b\bar{I}}\right)(1+h(T-t)),$$

which is Eq. 79.38.

We further take the partial derivative of Eq. 79.33 with respect to the growth rate. Then the partial derivative of optimal payout ratio with respect to the growth rate can be approximately written as

$$\frac{\partial\left[\overline{D}(t)/\overline{x}(t)\right]}{\partial h}\approx\left(\frac{\left(a+b\bar{I}\right)(T-t)-2h(T-t)-1}{a+b\bar{I}}\right),$$

which is Eq. 79.29.

Table 79.6 Moving estimates process for testing the break point of structural change

1.00	622.77	545.64			

This shows the F-statistics of moving estimates processes. The nonstructural change regression and structural change regression are as follows:

$$\ln\left(\frac{payout\ ratio_{i,t}}{1-\left(payout\ ratio_{i,t}\right)}\right) = \alpha + \beta_1 Risk_{i,t} + \beta_2 Growth_{i,t} + \beta_3 \ln(Size)_{i,t} + \beta_4 ROA_{i,t} + e_{i,t}$$

$$\ln\left(\frac{payout\ ratio_{i,t}}{1-\left(payout\ ratio_{i,t}\right)}\right) = \alpha + \beta_1' Risk_{i,t} + \beta_2' D\left(g_{i,t} < c \cdot ROA_{i,t}\right) \cdot Risk_i + \beta_3' Growth_{i,t}$$
$$+ \beta_5' \ln(Size)_{i,t} + \beta_6' ROA_{i,t} + e_{i,t}$$

The dependent variable is the payout ratio with a logistic transformation. The breakpoint, c, is between 0.2 times and 1.8 times the rate of return on total assets. The dummy variable is equal to 1 if a firm's 5-year average growth rate is less than c times its 5-year average ROA and 0 otherwise. The independent variables are beta risk (total risk), dummy times beta risk (total risk), growth rate, log of size, and the rate of return on assets. F-statistics are under the null hypothesis that the relationship between the payout ratio and the risk does not depend on the growth rate of a firm

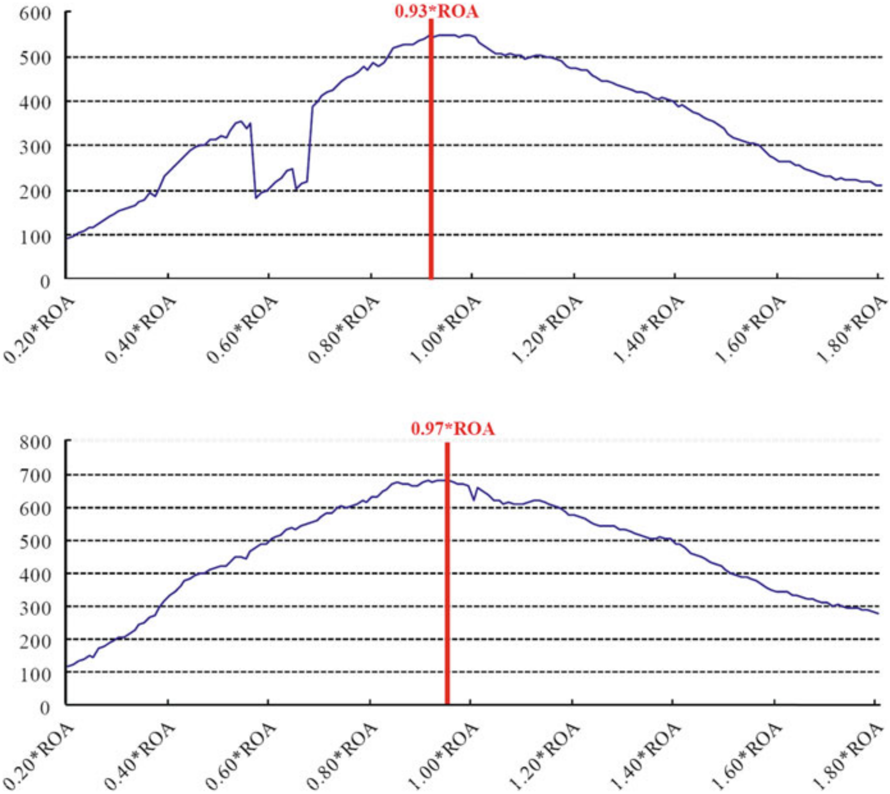

Fig. 79.2 Moving estimates process for testing the break point of structural change. The figures show the F-statistics of moving estimates processes. The nonstructural change regression and structural change regression are as follows:

$$\ln\left(\frac{payout\ ratio_{i,t}}{1-\left(payout\ ratio_{i,t}\right)}\right) = \alpha + \beta_1 Risk_{i,t} + \beta_2 Growth_{i,t} + \beta_3 \ln(Size)_{i,t} + \beta_4 ROA_{i,t} + e_{i,t}$$

$$\ln\left(\frac{payout\ ratio_{i,t}}{1-\left(payout\ ratio_{i,t}\right)}\right) = \alpha + \beta_1' Risk_{i,t} + \beta_2' D\left(g_{i,t} < c \cdot ROA_{i,t}\right) \cdot Risk_i + \beta_3' Growth_{i,t}$$
$$+ \beta_5' \ln(Size)_{i,t} + \beta_6' ROA_{i,t} + e_{i,t}.$$

The dependent variable is the payout ratio with a logistic transformation. The breakpoint, c, is between 0.2 times and 1.8 times rate of return on total assets. The dummy variable is equal to 1 if a firm's 5-year average growth rate is less than c times its 5-year average ROA and 0 otherwise. The independent variables are beta risk (total risk), dummy times beta risk (total risk), growth rate, log of size, and the rate of return on assets. F-statistics is under the null hypothesis that the relationship between the payout ratio and the risk does not depend on the growth rate of a firm. The risk used in Fig. 79. 2a is the beta, and the risk used in Fig. 79. 2b is the total risk

Appendix 4: Using Moving Estimates Process to Find the Structural Change Point in Eq. 79.36

To estimate the empirical breakpoint, we first assume the dummy variable associated with risk as $D(g_{i,t} < c\ .\ ROA_{i,t})$. We introduce a no structural change model, Eq. 79.57, and a structural change model, Eq. 79.58. In Eq. 79.58, c is a continuous constant variable, ranging from 0.2 to 1.8 ($c \in [0.2, 1.8]$). The breakpoint of structural change is at $g_{i,t} = c\ .\ ROA_{i,t}$.

$$\ln\left(\frac{payout\ ratio_{i,t}}{1-\left(payout\ ratio_{i,t}\right)}\right) = \alpha + \beta_1 Risk_{i,t} + \beta_2 Growth_{i,t} + \beta_3 \ln(\text{Size})_{i,t} + \beta_4 ROA_{i,t} + e_{i,t} \tag{79.57}$$

$$\ln\left(\frac{payout\ ratio_{i,t}}{1-\left(payout\ ratio_{i,t}\right)}\right) = \alpha + \beta_1^{'} Risk_{i,t} + \beta_2^{'} D\left(g_{i,t} < c \cdot ROA_{i,t}\right) \cdot Risk_i + \beta_3^{'} Growth_{i,t} + \beta_4^{'} \ln(Size)_{i,t} + \beta_5^{'} ROA_{i,t} + e_{i,t} \tag{79.58}$$

By using the moving estimates process, we calculate the F-statistics for all potential structural change points between $g_{i,t} = 0.2 \times ROA_{i,t}$ and $g_{i,t} = 1.8 \times ROA_{i,t}$. The F-test is under the null hypothesis that no structural change on the relationship between the payout ratio and the risk. That is, Eq. 79.57 is identical to Eq. 79.58. Finally, we can locate the breakpoint of the structural change at the point with highest value of F-statistics.

From Table 79.6, the process has a clear peak at $c = 0.93$ when using the beta risk as the independent variable and $c = 0.96$ when using the total risk as the independent variable. Figure 79.2 also graphically presents a peak F-statistics point at $c = 0.93$ (0.96) in terms of beta risk (total risk). Results from the moving estimates process indicate that a structural change on the relationship exists between the payout ratio and risks. The breakpoint of the structural change is at $g_{i,t} = 0.93 \times ROA_{i,t}$ or $g_{i,t} = 0.97 \times ROA_{i,t}$.

Modeling Asset Returns with Skewness, Kurtosis, and Outliers

80

Thomas C. Chiang and Jiandong Li

Contents

Abstract

This chapter uses an exponential generalized beta distribution of the second kind (EGB2) to model the returns on 30 Dow Jones industrial stocks. The model accounts for stock return characteristics, including fat tails, peakedness (leptokurtosis), skewness, clustered conditional variance, and leverage effect.

The evidence suggests that the error assumption based on the EGB2 distribution is capable of taking care of skewness, kurtosis, and peakedness and therefore is also capable of making good predictions on extreme values. The goodness-of-fit statistic provides supporting evidence in favor of EGB2 distribution in modeling stock returns. This chapter also finds evidence that the leverage effect is diminished when higher moments are considered.

The EGB2 distribution used in this chapter is a four-parameter distribution. It has a closed-form density function and its higher-order moments are finite and explicitly expressed by its parameters. The EGB2 distribution nests many widely used distributions such as normal distribution, log-normal distribution, Weibull distribution, and standard logistic distribution.

80.1 Introduction

Focusing on economic rationales, financial economists have identified a set of fundamental variables to predict stock returns over time, including market risk, change in interest rate, inflation rate, real activities, default risk, term premium, dividend yields, and earning yields, among other variables. In the cross-sectional analysis, Fama and French (1996) further emphasize size factor (SMB) and value factor (HML). Depending on the frequency of the data being studied, the Monday effect or the January effect is usually added to the model to highlight calendar anomalies. The empirical evidence of statistical significance to justify these variables is rather diverse. The mixed results have been attributed to variations in sample size, frequency, country, market, and/or model specification. As Avramov (2002) argues, the lack of consensus in choosing the "correct" variables may stem from model uncertainty, since the equilibrium asset pricing theories are not explicit about which variables should be included in the predictive regression.

To deal with this uncertainty, researchers occasionally resort to a missing variable. It becomes more apparent as GARCH-type models show that financial data demonstrate some sort of volatility clustering phenomenon. To incorporate the conditional variance into the mean equation is definitely helpful in tying stock returns to volatility (See French et al. 1987; Akgiray 1989; Baillie and DeGennaro 1990; and Bollerslev et al. 1992, among others). However, the GARCH-type specification based on a normal distribution is unsatisfactory for use with data that entail extreme values. Recent financial market developments show that significant daily loss occurs more frequently, and the volatility cannot reasonably be predicted from a normal distribution. The popularity of using a normal distribution assumption lies in the fact that the statistical analysis of stock returns can be simplified, allowing the analyst to focus on the first two moments. This simplification, however, misses the information contained in higher order moments.

To account for higher-order moments is important in modeling stock return series for the following reasons. First, from an econometric point of view, Hansen (1994) notes that empirical specifications of asset pricing models are incomplete unless the full conditional model is specified. Estimation and forecasting accuracy depends on the full specification of the distribution moments. Many authors have found that higher-order moments (and co-moments) can serve as explanatory variables for modeling stock returns (Harvey and Siddique 2000; Patton 2004; Ranaldo and Favre 2005; Bali et al. 2008; Boyer et al. 2010). The exclusion of higher-order moments information in the asset return model is bound to result in missing variable and misspecification problems.

Second, from the perspective of empirical finance studies, higher-order moments have particular economic meanings. Johnson and Schill (2006) suggest that Fama-French factors (SMB and HML) can be viewed as proxies for higher-order co-skewness and co-kurtosis. They show that Fama-French loadings generally become insignificant when higher-order systematic co-moments are included in cross-sectional regressions of portfolio returns.

Third, for portfolio management, higher-order moments are considered additional risk instruments in constructing the "new" portfolio theory, as argued by Jurczenko and Maillet (2002) and papers cited there. Further, the underlying theory of stochastic dominance (Vinod 2004) suggests that portfolio selection is determined not only by the conditional mean and variance but also by the skewness and kurtosis. The evidence provided by Harvey et al. (2010) and Cvitanic et al. (2008) substantiates the validity of the new portfolio theory. Moreover, in their recent studies, Andersen and Sornette (2001) and Malevergne and Sornette (2005) find that by incorporating higher-order moments risk, it is possible to increase the expected return on the portfolio while lowering its risks. Similarly, Tang (1998) finds that diversification reduces standard deviation but worsens negative skewness and fat tails in his study of the Hong Kong stock market. The evidence thus points to the fact that pricing risk based exclusively on the second moment may be very misleading. In light of this consideration, existing risk management techniques ought to be revised as well.

The significance of higher-order moments has been revealed in a series of dramatic market events, such as the market crash in 1987, the Asian crisis in 1997, the financial collapses of LTCM, the bust of internet bubble, and the subprime loan crisis in 2007. To address excess risk, both financial institutions and regulatory agencies demand risk management techniques to deal with occurrences of extreme values. Although Value at Risk (VaR) has been invented to predict a portfolio's maximum loss over a target horizon in a given confidence interval, the standard VaR models based on normal distribution often underestimate the potential risk.

Three approaches have been developed in the literature to deal with higher-order moments. The first approach is to treat higher-order moments as explanatory variables in the stock return equation. The four-moment CAPM by Jurczenko and Maillet (2002) and Ranaldo and Favre (2005) are the examples. The difficulty of this approach lies in how to generate the explanatory variables. Generating explanatory variables usually relies on higher frequency data or a rolling sample method.

The second approach is to apply the GARCH approach to higher conditional moments. Harvey and Siddique (1999) consider the conditional skewness, Brooks et al. (2005) tackle the autoregressive conditional kurtosis, and Conrad et al. (2009) find that individual securities' volatility, skewness, and kurtosis are strongly related to subsequent returns. Although these studies are capable of extracting information from the higher-order moments and use them to explain the conditional mean, they have not completely resolved the fundamental issue that the dependent variable frequently violates the assumption of a normal distribution.[1] This leads to the third approach: applying non-Gaussian distributions to model stock returns so that higher-order moments are naturally incorporated. This chapter falls into the third category.

The knowledge that stock returns are not following the Gaussian distribution dates back to the papers by Mandelbrot (1963) and Fama (1965). Subsequent research includes Officer (1972), Clark (1973), McCulloch (1985), Bollerslev (1987), Nelson (1991), Hansen (1994), Liu and Brorsen (1995), and Mittnik et al. (1999) among others. These studies propose the t distribution, skewed t distribution, general error distribution (GED, also known as exponential power distribution), and α-stable Levy distributions. Briefly speaking, the t distribution is symmetric so that it inherently fails to describe the issue of skewness. The GED is not flexible enough to allow for larger innovations. The stable distribution has theoretical appeal because of the generalized central limit theorem; however, its moments are not defined for an order greater than α. In particular, the variance is not defined except for one special case, normal distribution; the skewness and kurtosis are always not defined. Finally, the skewed t distribution used in Hansen (1994) is far from being parsimonious, and it is hard to interpret its parameters because transformations are imposed.

Recognizing the weakness of the above distributions, it is necessary to have a model that encompasses the features of asymmetry, a high peak, and fat tails. We find that an exponential generalized beta distribution of the second kind (EGB2) [2] is able to meet the diverse criteria, which forms the research foundation of this chapter.

Results emerging from this chapter show that the EGB2 distribution works very well in dealing with high-order moments of individual stock returns. The evidence indicates that AR(1)-GJR-GARCH(1,1) model based on the EGB2 distribution provides a unique specification in handling the stylized facts of stock return behaviors: autocorrelation, conditional heteroskedasticity, leverage effect, skewness, excess kurtosis, and peakedness.

---

[1]Both Harvey and Siddique (1999) and Brooks et al. (2005) use a t distribution. As shown in this paper, a t distribution has heavy tails but is not a good fit for stock return data with regard to peakedness.

[2]There are other names for the EGB2 distribution in other nonfinancial fields or in non-American journals; for example, generalized logistic distribution in Wu et al. (2000), z-distribution in Barndorff-Nielsen et al. (1982), the Burr-type distribution in actuarial science in Hogg and Klugman (1983), and four-parameter kappa distribution in geology in Hosking (1994).

This study contributes to the literature in the following aspects. We find that using EGB2 distribution is superior to models based on a normal distribution and *t* distribution in handling skewness and kurtosis, as is evident by the goodness-of-fit statistics. Second, the prevalence of the risk management method Value at Risk (VaR) can be handled and updated via the EGB2 distribution. It informs investors that omitting higher moments "...will lead to a systematic underestimate of the true riskiness of a portfolio, where risk is measured as the likelihood of achieving a loss greater than some threshold" (Brooks et al. 2005, p. 400). Third, this chapter systematically examines all 30 stocks in the Dow Jones industrial index. The individual stocks cover a broad range of assets and reveal a variety of fat tail characteristics. The model encompasses a rich spectrum of asset features that help in guiding portfolio decisions. Fourth, we find that the asymmetric effect (leverage effect) has been diminished when the EGB2 distribution is applied. It implies that the so-called leverage effect is, at least, partially attributable to the model's misspecification due to the imposition of a normal distribution of return series.

The remainder of the chapter is organized as follows. Section 80.2 describes the methodology of the EGB2-GARCH model. Section 80.3 discusses the data. Section 80.4 presents the empirical results on the stock returns by applying different distributions; Sect. 80.5 reports the goodness-of-fit tests; Sect. 80.6 contains the probability evaluation using the EGB2 distribution. Section 80.7 contains conclusions.

80.2 The GARCH-Type Model Based on the EGB2 Distribution

80.2.1 General Specification

The AR(1)-GARCH(1,1)-GJR-EGB2 stock return model can be represented by a system given below:

$$R_t = \phi_0 + \phi_1 R_{m,t} + \phi_2 R_{t-1} + \delta D_{87} + \varepsilon_{it} \tag{80.1a}$$

$$\varepsilon_t = \sqrt{h_t} u_t \tag{80.1b}$$

$$h_t = w + \alpha \varepsilon_{t-1}^2 + \beta h_{t-1} + \gamma I(\varepsilon_{t-1} < 0)\varepsilon_{t-1}^2 \tag{80.1c}$$

$$\varepsilon_t | \Im_{t-1} \sim D(0, h_t, z) \tag{80.1d}$$

Equation 80.1a is the mean equation, where R_t is an individual stock's excess return (stock return minus the risk-free rate) at time t; ε_t is an error term. The inclusion of an AR(1) term in the mean equation accounts for the autocorrelation arising from nonsynchronous trading or slow price adjustments

(Lo and MacKinlay 1990; Amihud and Mendelson 1987).[3] The market's equity premium (stock market return minus the risk-free rate), R_{mt}, at time t is included in the equation to capture the market risk as suggested by the CAPM. The dummy variable, D_{87}, takes a value of unity in the week of October 19, 1987, and 0 otherwise. The series, u_t, in Eq. 80.1b is a standardized error by conditional variance.

The conditional variance, h_t, is assumed to follow GARCH(1,1); w,α, and $\beta > 0$ to ensure a strictly positive conditional variance; and I is an indicative function that takes a value of 1 only when the error term has a negative value. The γ is used to capture the asymmetric effect of the extraordinary shock to the variance: bad news usually results in a bigger effect than good news does. In this study, we adopt the asymmetric GARCH approach suggested by Glosten et al. (1993) for its simplicity and effectiveness. The distribution of ε_t is assumed to be a general specification conditional on the distribution captured by the parameter z. For the normal distribution, the error follows that $\varepsilon_t|\Im_{t-1} \sim N(0, h_t)$. As a variant of a normal distribution, in this chapter, we consider two alternatives: t- and EGB2 distributions.

80.2.2 Modeling Financial Time Series Based on Non-Normal Distributions

Student's t distribution is well known for its capacity to capture the fat tail phenomenon. Bollerslev (1987), Bollerslev et al. (1994), and Hueng and McDonald (2005) incorporated t distribution into the GARCH model specification. The pdf of a normalized Student's t distribution takes the form of

$$t(x;\delta,\sigma,v) = \frac{\Gamma\left(\frac{v+1}{2}\right)}{\Gamma\left(\frac{v}{2}\right)\sigma\sqrt{\pi(v-2)}}\left[1+\frac{1}{v-2}\left(\frac{x-\delta}{\sigma}\right)^2\right]^{-\frac{v+1}{2}} \tag{80.2}$$

where x is a random variable, v is the degree of freedom of the t distribution ($v > 2$), and Γ is the gamma function. The excess kurtosis coefficient of the t distribution is given by $\frac{6}{v-4}$ for $v > 4$. In light of system (80.1a–80.1d), the only change is in the error distribution, which is given by $\varepsilon_t|\Im_{t-1} \sim t(0, h_t, v)$. From this perspective,

[3]Dependent on the significance test of the AR(1) coefficient in the AR(1)-GARCH(1,1) model, the AR(1) term is then dropped for some stocks. The following stocks do not have an AR(1) variable: MSFT, HON, DD, GM, IBM, MO, CAT, BA, PFE, AA, DIS, MCD, JPM, and INTC. Stock PG, which is the only one that shows Q(30) any significance, adds an AR(4) variable to ensure that the autocorrelation is removed. The rest of this paper follows this pattern. Recent literature suggests that the sign of the AR(1) coefficient, ϕ_2, can be used to detect feedback trading behavior (Sentana and Wadhwani 1992; Antoniou et al. 2005). Our results show that the coefficient of AR(1) is negative.

both the coefficients and the degree of freedom of the t distribution are estimated simultaneously by maximizing the following log-likelihood function:

$$\log L = T\left[\log\left(\Gamma\left(\frac{v+1}{2}\right) - \log\left(\Gamma\left(\frac{v}{2}\right) - 0.5\log(\pi(v-2))\right]\right.\right. \\ - 0.5\sum\left[\log(h_t) + (v+1)\log\left(1 + \frac{\varepsilon_t{}^2}{h_t(v-2)}\right)\right] \tag{80.3}$$

Although the t distribution is good at modeling fat tails for time data, its shortcoming is the built-in symmetrical nature. The distribution, however, is unable to take care of the skewness characteristic present in the financial time series. Thus, we turn to an exponential generalized beta distribution of the second kind (EGB2) developed by McDonald (1984, 1991) and McDonald and Xu (1995).

EGB2 is attractive because of its simplicity and ease in estimating the parameters.[4] There is a closed-form density function for the EGB2 distribution; its higher-order moments are finite and explicitly expressed by its parameters. Moreover, it is flexible and able to accommodate a wider range of data characteristics, such as thick tails and skewness, than the more commonly used normal and log-normal distributions.

The EGB2 distribution has the probability density function (pdf) given by

$$EGB2(x;\delta,\sigma,p,q) = \frac{\left[e^{\left(\frac{x-\delta}{\sigma}\right)}\right]^p}{|\sigma|B(p,q)\left[1+e^{\left(\frac{x-\delta}{\sigma}\right)}\right]^{p+q}} \tag{80.4}$$

where x is a random variable; δ is a location parameter that affects the mean of the distribution; σ reflects the scale of the density function; p and q ($p > 0$ and $q > 0$) are shape parameters that together determine the skewness and kurtosis of the distribution of the excess return series; $B(p, q)$ is the beta function.[5] As suggested by McDonald

[4]It is not our intention to exhaust all the non-Gaussian models in our study, which is infeasible. Rather, our strategy is to adopt a distribution that is rich enough to accommodate the features of financial data. To our knowledge, there are different types of flexible parametric distributions parallel to the EGB2 distribution to model both third and fourth moments in the literature. One family of such distributions is a skewed generalized t distribution (SGT) (Theodossiou 1998; Hueng and Brooks 2003). Special cases of SGT include generalized t distribution (McDonald and Newey 1988), skewed t distribution (Hansen 1994), and skewed generalized error distribution (SGED) (Nelson 1991). The skewness and excess kurtosis of SGT are in the range $(-\infty, \infty)$ and $(1.8, \infty)$, respectively. Another family is inverse hyperbolic sin distribution (IHS) (Johnson 1949 and Johnson et al. 1994). The skewness and excess kurtosis of IHS is in the range $(3, \infty)$ and $(-\infty, \infty)$. EGB2 has less coverage for skewness and excess kurtosis than SGT and IHS. However, it covers many skewness-kurtosis combinations encountered in practice and performs "impressively" in estimating the slope coefficient in a simulation (Theodossiou et al. 2007). Other families of flexible distributions are also available in the literature. But there isn't any comparison with the EGB2 distribution.

[5]It should be noted that beta function here has nothing to do with the stock's beta.

(1991), the EGB2 is suitable for coefficient of skewness values between −2 and 2 and coefficient of excess kurtosis values up to 6. The distribution is capable of accommodating fat-tailed and skewed error distributions pertinent to stock return modeling.[6]

For the standardized EGB2 distribution with shape parameters p and q, the univariate GARCH-EGB2 log-likelihood function is[7]

$$\log L = T\left[\log\left(\sqrt{\Omega}\right) - \log(B(p,q)) + p\Delta\right] + \sum\left[p\left(\frac{\sqrt{\Omega}\varepsilon_t}{\sqrt{h_t}}\right) - 0.5\log(h_t)\right.$$
$$\left. -(p+q)\log\left(1+\exp\left(\frac{\sqrt{\Omega}\varepsilon_t}{\sqrt{h_t}}+\Delta\right)\right)\right] \tag{80.5}$$

where $\Delta = \psi(p) - \psi(q)$, $\Omega = \psi'(p) + \psi'(q)$, and ψ and ψ' represent digamma and trigamma functions, respectively.[8] The BFGS algorithm is used in RATS to conduct a maximum likelihood estimation. The skewness and excess kurtosis for the EGB2 distribution are given respectively by

$$\text{Skewness} = g(p,q) = \frac{\psi''(p) - \psi''(q)}{\left(\psi'(p) + \psi'(q)\right)^{1.5}} \tag{80.6}$$

$$\text{Kurtosis} = h(p,q) = \frac{\psi'''(p) + \psi'''(q)}{\left(\psi'(p) + \psi'(q)\right)^{2}} \tag{80.7}$$

and ψ'' and ψ''' represent tetragamma and pentagamma functions.

Since the skewness and kurtosis coefficients are based on parameters p and q, the standard deviation of skewness and kurtosis coefficients can be drawn by using a standard delta method (see the appendix for details). By using these measures, we can judge if the EGB2 distribution correctly handles skewness and kurtosis.

80.3 Data and Summary Statistics

When asset returns are analyzed, movements in the Dow Jones Industrial Average (DJIA) are often considered one of the most important pieces of news that indicate

[6]Many distributions are nested in the EGB2 distribution. Wang et al. (2001) show that the EGB2 distribution is very powerful in modeling exchange rates that have fat tails and leptokurtosis features. The EGB2 converges to normal distribution as $p = q$ approaches infinity, to log-normal distribution when only p approaches infinity, to the Weibull distribution when $p = 1$ and q approaches infinity, and to the standard logistic distribution when $p = q = 1$. It is symmetric (called a Gumbel distribution) for $p = q$. The EGB2 is positively (negatively) skewed as $p > q$ ($p < q$) for $\sigma > 0$.

[7]This can be obtained in the appendix of Wang et al. (2001).

[8]The digamma function is the logarithmic derivative of the gamma function; the trigamma function is the derivative of the digamma function.

the health of financial markets and investment performance. This chapter uses the DJIA's 30 stocks as the sample, which represents a group of well-established and diverse companies. The sample covers the period from October 29, 1986, through December 31, 2005. One of the reasons for using this period is its completeness, so we can employ and assess information on all 30 stocks in the sample period.[9] This time period also captures the most vigorous recent stock market advancements while covering several major market crashes and financial crises.

Following the conventional approach, returns from the Standard & Poor's 500 (SP 500) index are used to measure the market return. Both daily returns on the S&P 500 index and data on the 30 Dow Jones firms are compounding and including dividend payments. These data are taken from the CRSP database. The short-term interest rate is measured by the 3-month Treasury bill rate, which is taken from the Federal Reserve's website.[10] The daily risk-free rate is measured by using the annual rate divided by 360. The excess stock return is the difference between actual stock returns and the short-term interest rate.

Weekly data are used in order to be consistent with industrial practice. For example, Value Line, Bloomberg, and Baseline all use weekly data on stocks to calculate the stocks' beta. Daily stock returns are seldom used in industry. It also helps to smooth out the volatility for single date outliers. An additional advantage of using weekly observations is that some calendar effects, such as the Monday effect, can be avoided. The excess returns are measured on a weekly basis. Table 80.1 reports summarized statistics for the weekly excess returns.

Looking at Table 80.1, we find that six stocks have a positive value for the skewness coefficient and two are significant at the 1 % level, while the remaining 24 stocks show negative values and 13 of them are significant at the 1 % level.[11] A negative skewness coefficient means that there are more negative extreme values

[9]Stock C (CitiGroup) in Table 80.1 began its trading data on Oct 29, 1986. Within this period, only one stock has one missing value. Stock MO (Philips Morris Co.) was not traded on May 25, 1994, because of "pending news which could affect the stock price." Philip Morris' board was meeting to announce whether the company would split its food and tobacco units on May 25, 1994. In this sample period, the most striking event is the market crash on October 19, 1987. This paper considers the 1987 market crash as an outlier in the later part. The week of the 9–11 terrorist attacks has only 1 day of trading information and is incorporated into the next week.

[10]http://www.federalreserve.gov/releases/H15/data.htm#top, Treasury bill secondary market rates (serial: tbsm3m) are the averages of the bid rates quoted on a bank discount basis by a sample of primary dealers who report to the Federal Reserve Bank of New York. The rates reported are based on quotes at the official close of the US government securities market for each business day.

[11]The sign of the skewness coefficient is related to data frequency. The skewness of the weekly return has nothing to do with the skewness of the daily return. For example, the stock HON (index = 2) shows significant positive skewness in its daily return but significant negative skewness in its weekly return.

[12]The skewness coefficient is the relation between the second order moment and the third order moment. It is calculated by $\frac{T}{(T-1)(T-2)\sigma^3}\sum(x_i-\mu)^3$ where μ is the mean of the sample. The literature about the positive and negative values of the distribution skewness is confusing. The skewness in our study is based on the distribution's moments (Kenney and Keeping 1962).

The 30 stocks are sorted by permanent CRSP number. nobs are the number of observations. The last row market is measured by the S&P 500. Numbers below coefficients are t-values (with bracket). Numbers below tests are p-values. ***Indicates 1 % significance, **5 %, and *10 %. The standard deviations of skewness and excess kurtosis coefficients are given approximately by $(6/T)^{0.5}$ and $(24/T)^{0.5}$, respectively. The peakedness is measured by $f_{0.75}$-$f_{0.25}$, the distance between the values of standardized variables at which the cumulative distribution function equals 0.75 and the value at which the cumulative distribution function equals 0.25. The reference value of the standard normal distribution is 1.35. A number of peakedness less than 1.35 means there is a high peak in the probability density function. The normality test is conducted using a Jarque-Bera statistic. The independence test is conducted using a Ljung-Box Q test up to the order of 30. The Q^2 test up to the order of 30 is to show volatility clustering than positive extreme values in the sample period.[12] With respect to the excess kurtosis (kurtosis coefficient minus 3), all of the estimated values are statistically significant at the 1 % level, suggesting a serious fat-tailed problem. The range of the excess kurtosis coefficient is between 1.08 and 24.13. By checking the range of peakedness measured by the inter-quartile range (i.e., 0.75 fractile minus 0.25 fractile), we found that it lies between 1.01 and 1.26. This range is much lower than the referenced figure, 1.35, indicating the presence of a high peak in the probability density function for all of the stocks under investigation. While testing for dependency, Ljung-Box Q statistics show that ten stocks are serially autocorrelated, and 27 of the 30 stocks are autocorrelated in the squared term as shown by a Q^2 test. The latter suggests a volatility clustering phenomenon and is consistent with a GARCH-type specification. By inspecting the Jarque-Bera statistics, the normality for all 30 stocks is uniformly rejected.[13]

The preliminary statistical results from Table 80.1 clearly indicate that the popular normality assumption does not conform to the weekly returns. The individual stock returns often show positive excess kurtosis (fat tails), accompanied by skewness. The evidence of peakedness is not in agreement with the normal distribution either. Besides the non-Gaussian features, some weekly stock returns present autocorrelation and almost all of them feature volatility clustering.

80.4 Empirical Evidence

In this section, we estimate the system of equations from Eq. 80.1a through 80.1d and present evidence of the GARCH(1,1) model based on different distributions. We analyze the impact of outliers on the EGB2 distribution.

80.4.1 GARCH(1,1) Model Based on the Normal Distribution

Table 80.2 reports the estimates of the GARCH(1,1) model based on the assumption that the error series follows a normal distribution, $\varepsilon_t|\Im_{t-1} \sim N(0, h_t)$.[14] Looking at the t-statistics, the null hypothesis of the absence of skewness is rejected at the 1 % level for 11 out of 30 cases (four positive and seven negative), while the null hypothesis of the absence of excess kurtosis is rejected in all of the cases. Moreover, the Jarque-Bera tests show that all of the return residuals are rejected by assuming

[13]All the non-normality features are more remarkable in daily data but less so in monthly data. This is consistent with Brown and Warner's (1985) report that the non-normal features tend to vanish in low-frequency data, such as monthly observations. Even so, subject to individual monthly stock returns, the Jarque-Bera test rejects the normality for 23 of the 30 stocks at the 1 % level.

[14]The standardized residuals are obtained by dividing the estimated regression residuals by its conditional standard deviation. Standardizing the error term makes the distribution comparison feasible. Mean and variance are not reported in the table due to the use of normalization.

Table 80.2 Estimates of the GARCH(1,1) normal distribution: weekly data, 1986–2005

The 30 stocks are sorted by permanent CRSP number. Numbers below coefficients are t-values (with bracket). Numbers below tests are p-values. ***Indicates 1 % significance, **5 %, and *10 %. The standard deviations of skewness and excess kurtosis coefficients are given approximately by $(6/T)^{0.5}$ and $(24/T)^{0.5}$, respectively. The peakedness is measured by $f_{0.75} - f_{0.25}$, the distance between the values of standardized variables at which the cumulative distribution function equals 0.75 and the value at which the cumulative distribution function equals 0.25. The reference value of the standard normal distribution is 1.35. A number of peakedness less than 1.35 means there is a high peak in the probability density function. The normality test is conducted using Jarque-Bera (JB) statistics. The independence test is conducted using a Ljung-Box Q test up to the order of 30. The Q^2 test up to the order of 30 is to show volatility clustering. The model is

(1.a) $R_t = \phi_0 + \phi_1 R_{m,t} + \phi_2 R_{t-1} + \delta D_{87} + \varepsilon_{it}$

(1.b) $\varepsilon_t = \sqrt{h_t} z_t$

(1.c) $h_t = w + \alpha\varepsilon_{t-1}^2 + \beta h_{t-1} + \gamma\, I(\varepsilon_{t-1} < 0)\varepsilon_{t-1}^2$

(1.d) $\varepsilon_t | \Im t{-}1 \sim N(0, h_t)$. The following stocks do not have AR(1) variable: MSFT, HON, DD, GM, IBM, MO, CAT, BA, PFE, AA, DIS, MCD, JPM, and INTC. Stock PG is the only one to have an AR(4) variable in the mean equation, which ensures that autocorrelation has been removed

Gaussian distribution. If we check further into the measure of peakedness, the estimate values range from 1.06 to 1.30. All of these figures are lower than the reference point of a standard normal distribution, 1.35, indicating that all of the returns are leptokurtic. It is apparent that assuming that residuals for the estimated financial data are normally distributed is invalid.

80.4.2 GARCH(1,1) Model Based on the Student's *t* Distribution

Estimating the model by using a *t* distribution indicates that the excess kurtosis has mostly been removed from the estimated residuals. As shown in Table 80.3, 29 stocks show that the coefficients of excess kurtosis are insignificant. This demonstrates the effectiveness of *t* distribution in modeling the excess kurtosis. However, the problem of skewness has not been resolved at all. The evidence shows that 18 out of 30 are significant at the 5 % level or higher. There are four significant positive and eight significant negative skewness coefficients in the standardized residuals at the 1 % level.[15]

Another problem emerging from this model is insufficient peakedness of the distribution. The range of the estimated degree of freedom is (3.9 ~ 11.1), which corresponds to the range of peakedness (1.53 ~ 1.39). Note that the actual peakedness measurement from Table 80.3 is in the range of (1.02 ~ 1.29), indicating the presence of leptokurtosis. The evidence shows that the *t* distribution is worse than the normal distribution in modeling peakedness (see Fig. 80.1).

80.4.3 GARCH(1,1) Model Based on the EGB2 Distribution

To advance our study, we reestimate the GARCH(1,1) model by employing the EGB2 distribution. Table 80.4 reports the comparable statistics based on the standardized residuals from GARCH(1,1) cum EGB2 distribution: $\varepsilon_t | \Im_{t-1} \sim EGB2(0, h_t, p, q)$. The results show that the skewness problem for most cases has been alleviated by using the EGB2 distribution. The evidence indicates that only five stocks show the presence of skewness. Turning to the statistics of excess kurtosis, we find that the EGB2 distribution works well on some stocks' kurtosis but not all of them. The evidence in Table 80.4 indicates that nine stocks still show excess kurtosis.

Table 80.4 also contains the range of p (0.334 ~ 1.776) and of q (0.348 ~ 1.669). The reported p- and q-values suggest that the residuals' distributions are far from

[15] To deal with the skewness, a number of skewed *t* distributions have been proposed (Theodossiou 1998; Hueng and Brooks 2003). One obvious drawback of a skewed *t* distribution in our study is the outcome of its peakedness measurement, which displays platykurtosis (flat topped in density). This appears to be the opposite of the leptokurtic stock returns. For this reason, we do not report results from the GARCH model based on a skewed *t* distribution in order to focus on the EGB2 distribution. However, the results are available upon request.

Table 80.3 Statistics of the standardized errors on the GARCH(1,1)-*t* distribution: weekly data, 1986–2005

The 30 stocks are sorted by permanent CRSP number. Numbers below coefficients are t-values (with bracket). Numbers below tests are p-values. ***Indicates 1 % significance, **5 %, and *10 %. The standard deviations of skewness coefficients are given approximately by $(6/T)^{0.5}$. The excess kurtosis coefficient of t distribution is given by $\frac{6}{v-4}$ for $v > 4$. Its standard deviation is obtained using the delta method. The peakedness is measured by $f_{0.75} - f_{0.25}$, the distance between the values of standardized variable at which the cumulative distribution function equals 0.75 and the value at which the cumulative distribution function equals 0.25. The reference value of the standard normal distribution is 1.35. The reference value for the estimated t distribution is reported below actual peakedness (in parenthesis), which is in the range (1.39, 1.53). A number of peakedness less than the reference value means there is a high peak in the probability density function. The normality test is omitted, since the assumption is a Student's t distribution. The independence test is conducted using a Ljung-Box Q test up to the order of 30. The Q^2 test up to the order of 30 is to show volatility clustering. The model is

(1.a) $R_t = \phi_0 + \phi_1 R_{m,t} + \phi_2 R_{t-1} + \delta D_{87} + \varepsilon_{it}$

(1.b) $\varepsilon_t = \sqrt{h_t} z_t$

(1.c) $h_t = w + \alpha\varepsilon_{t-1}^2 + \beta h_{t-1} + \gamma\, I(\varepsilon_{t-1} < 0)\varepsilon_{t-1}^2$

(1.d) $\varepsilon_t | \Im_{t-1} \sim t(0, h_t, v)$

The following stocks do not have an AR(1) variable: MSFT, HON, DD, GM, IBM, MO, CAT, BA, PFE, AA, DIS, MCD, JPM, and INTC. Stock PG is the only one to have an AR(4) variable in the mean equation, which ensures that autocorrelation has been removed

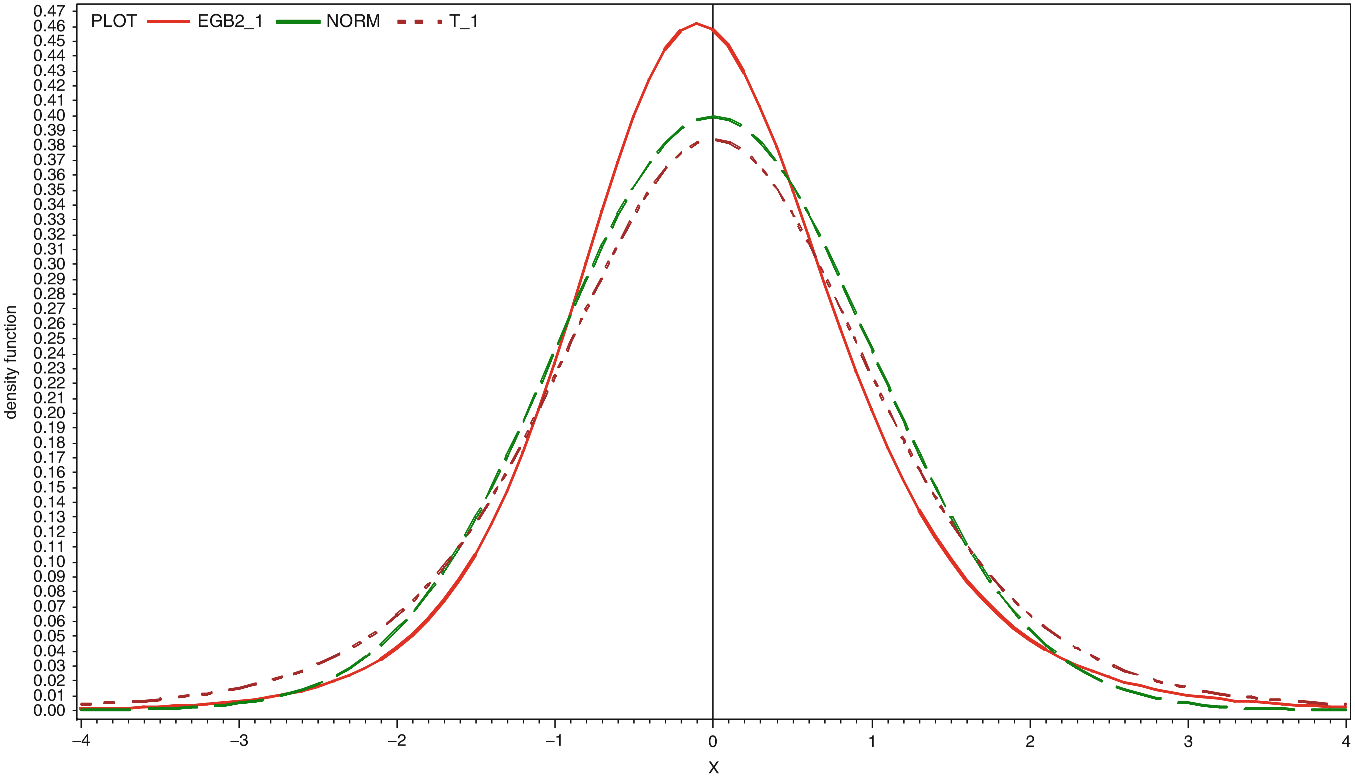

Fig. 80.1 Comparisons of probability density function of three distributions. Note: This chart compares the probability density function (pdf) of three distributions. The *solid line* is for the EGB2 distribution, *dashed line* for the normal distribution, and *dash-dot line* is for the Student's t distribution. Distribution-estimated parameters are from stock MSFT (index = 1): $p = 1.0233$; $q = 0.7971$; $v = 6.4635$

The 30 stocks are sorted by permanent CRSP number. Numbers below coefficients are t-values (with bracket). Numbers below Q test and Q^2 test are p-values. ***Indicates 1 % significance, **5 %, and *10 %. The predicted higher moments are given by the formula: Skewness $= \frac{\psi''(p)-\psi''(q)}{(\psi'(p)+\psi'(q))^{1.5}}$, Kurtosis $= \frac{\psi'''(p)+\psi'''(q)}{(\psi'(p)+\psi'(q))^{2}}$. Their standard deviations are obtained using the delta method. The peakedness is measured by $f_{0.75}$-$f_{0.25}$, the distance between the values of standardized variable at which the cumulative distribution function equals 0.75 and the value at which the cumulative distribution function equals 0.25. The reference value of the standard normal distribution is 1.35. A number of peakedness less than 1.35 means there is a high peak in the probability density function. The reference value of the EGB2 distribution is reported below peakedness with parenthesis and is in the range of (1.07, 1.26). The normality test is omitted, since the assumption is the EGB2 distribution. The independence test is conducted using a Ljung-Box Q test up to the order of 30. The Q^2 test up to the order of 30 is to show volatility clustering. The estimated model is

(1.a) $R_t = \phi_0 + \phi_1 R_{m,t} + \phi_2 R_{t-1} + \delta D_{87} + \varepsilon_{it}$
(1.b) $\varepsilon_t = \sqrt{h_t} z_t$
(1.c) $h_t = w + \alpha\varepsilon_{t-1}^2 + \beta h_{t-1} + \gamma\, I(\varepsilon_{t-1} < 0)\varepsilon_{t-1}^2$
(1.d) $\varepsilon_t | \Im_{t-1} \sim EGB2(0, h_t, p, q)$

An AR(1) variable is excluded from the following stocks in the estimated equation: MSFT, HON, DD, GM, IBM, MO, CAT, BA, PFE, AA, DIS, MCD, JPM, and INTC. Stock PG contains the only AR(4) variable in the mean equation the normal distribution that requires that both p- and q-values approach infinity. Based on the estimated shape parameters, the expected peakedness for the 30 stocks is in the range of (1.07 ∼ 1.26). The peakedness obtained from residuals of the mean equation is in the range of (1.06 ∼ 1.30), conforming to the existence of high peak implied by the EGB2 distribution.

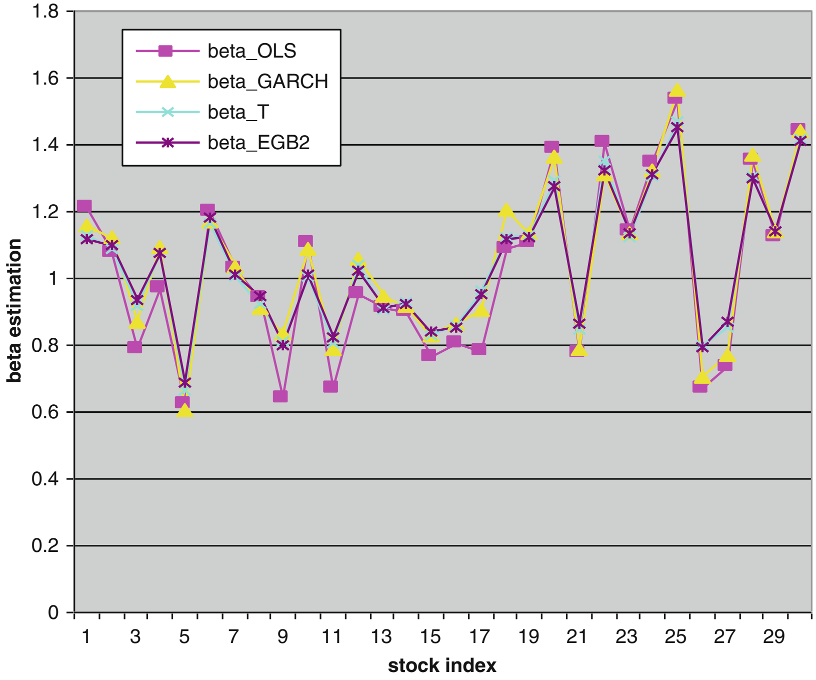
With respect to the beta coefficients, we find that the estimated values are highly significant, ranging from 0.69 to 1.32. The evidence suggests that the market risk is still one of the most influential factors for predicting individual stocks. It is of interest to compare the beta values and the associated standard errors across different distributions. As may be seen from Fig. 80.2, where the figures are mainly reproduced from Tables 80.2, 80.3 and 80.4, we find no significant difference among them for the estimated betas. This is not surprising, since the estimations of the betas are obtained from the average effect based on the whole probability space. Our finding is consistent with the results form Nelson (1991) and Hansen (1994).

While inspecting the lagged individual stock return variable, about half of them present negative signs and are statistically significant, indicating that a mean reversion process is present in the weekly data. Turning to the 1987 market crash dummy, the testing results show that 20 out of 30 stocks are significant at the 5 % level, although the signs are mixed. The diverse movements signify the profound impact due to an influential observation. Consistent with most financial data, with a few exceptions, the coefficients of the GARCH equation for each stock are found to be highly significant.

One of the most striking results emerging from the estimations is that while testing the leverage effect, only four stocks are found to be statistically significant at the 5 % level. The number of stocks that present asymmetric effects has been reduced dramatically, as compared with the statistics reported in Table 80.2, where 15 stocks show a significant asymmetric effect. It can be argued that the so-called asymmetric effect may result from the fact that empirical analysis was built on a misleading assumption by imposing a normal distribution on the financial data.

One fact in Table 80.4 is a bit disturbing: three stocks show their kurtosis coefficient being greater than 6, which is beyond the scope of EGB2 distribution. Despite this shortcoming and the abovementioned nine stocks that have significant kurtosis, we find a significant improvement compared with the model by assuming the normal distribution or the t distribution. The predicted skewness and excess kurtosis of the EGB2 distribution are much closer to the observed skewness and kurtosis. Thus, the EGB2 distribution has a good fit, although the results are not perfect.[16] Finally, we test the independence of the correlation on statistics for both return level and return squares, and we find that in only three cases in each Q and Q^2 test can the null hypothesis be rejected at the 5 % level but none at the 1 % level. In general, the models are adequate.

[16] Some refinement of the model is contained in the following section.



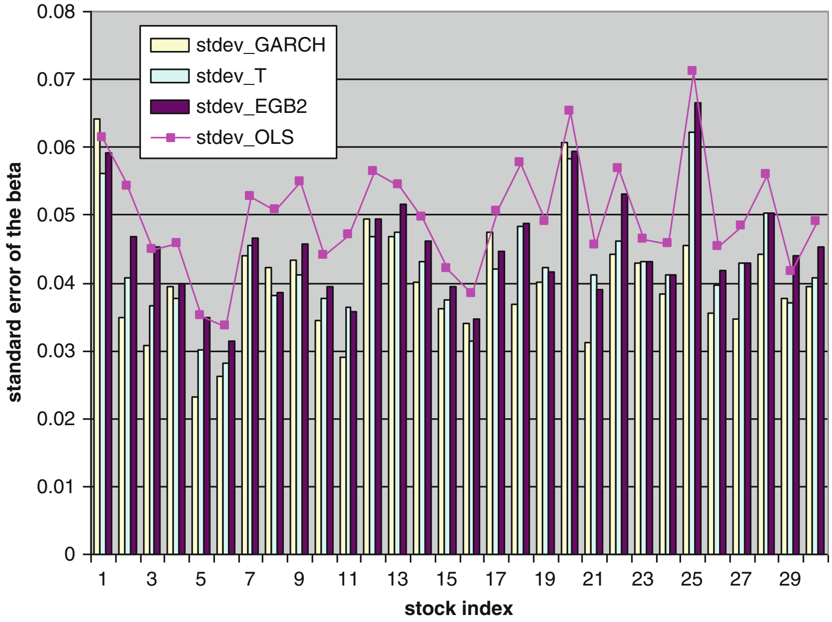


Fig. 80.2 Comparisons of the beta estimation in different models. Note: The *upper* figure contains the plots of beta coefficients. The *lower* figure presents the corresponding standard deviations of the beta coefficients

80.4.4 The Impact of Outliers

Theoretically, the EGB2 distribution is feasible for coefficients of skewness in a range of (−2, 2) and the coefficients of excess kurtosis in (0, 6). However, the statistics in Table 80.4 are not completed in these desired ranges. Two possible reasons might contribute to these problems. First, the residual series was contaminated by the presence of outliers. As pointed out by Peña et al. (2001), an outlier can have very serious effects on the properties of the observed time series and affect the estimated residuals and the parameter values. Second, the mean equation and/or the variance equation may be misspecified, although an asymmetric effect has been considered.[17] To address this issue, we further investigate the stock return series on which the outliers might more seriously impinge.

By investigating the microstructure of the nine stocks with excess kurtosis, we find a common phenomenon: multiple outliers are present. This means that a 1987 market crash dummy is incapable of accommodating multiple extreme values in the data series. For instance, stock UTX (index = 10) has an extreme value of −38 % during the week of the 9–11 terrorist attacks in 2001. To address this issue, we identify the outliers and patch the outliers by using intervention analysis as in Box and Tiao (1975) and the extension by Tsay et al. (2000) and Peña et al. (2001). Table 80.5 reports the statistics of the residual analysis for these nine stocks by adding different dummies in the mean equation. This result is rather encouraging, as evidenced by the reduction of the significance of the kurtosis coefficient. It reveals that the kurtosis problem is somehow related to a failure to account for extraordinary events that disturb the data structure, rather than the failure of the EGB2 distribution. It is evident that after removing the effect of the outliers in a given time series, the EGB2 distribution is capable of addressing the financial data with skewness and kurtosis in an appropriate range.[18]

80.5 Distributional Fit Test

Previous sections emphasized estimates of parameters pertinent to modeling the skewness and kurtosis of the standardized residuals by applying non-Gaussian distributions. As part of the modeling process, model checking in terms of goodness of fit is also important. Table 80.6 and Fig. 80.3 compare a GARCH(1,1) model based on three distributions: normal, Student's *t*, and EGB2. The reported log-likelihood function values (negative) clearly show that the EGB2 distribution outperforms the

[17]Engle et al. (1987) suggest putting a conditional volatility variable in the mean equation, which is called the GARCH-M model. However, the expected sign of the conditional variance variable is uncertain, according to literature surveys. Since we do not find its statistical significance in our empirical experiment (not reported), the conditional mean term is excluded from our test equation.

[18]Longin (1996) proposes the use of a Frechet distribution, which is able to highlight those extreme price movements. However, his model does not cover whole return distributions but only extreme values.

Table 80.5 Statistics of the nine stocks' standardized errors on the GARCH(1,1)-EGB2 estimates: weekly data, 1986–2005

The nine stocks have significant excess coefficients in Table 80.4. Numbers below coefficients are t-values (with bracket). Numbers below tests are *p*-values. ***Indicates 1 % significance, **5 %, and *10 %. The predicted higher moments are given by the formula: Skewness $= \frac{\psi''(p)-\psi''(q)}{(\psi'(p)+\psi'(q))^{1.5}}$, Kurtosis $= \frac{\psi'''(p)+\psi'''(q)}{(\psi'(p)+\psi'(q))^{2}}$. Their standard deviations are obtained using the delta method. The peakedness is measured by $f_{0.75}$-$f_{0.25}$, the distance between the values of standardized variable at which the cumulative distribution function equals 0.75 and the value at which the cumulative distribution function equals 0.25. The reference value of the standard normal distribution is 1.35. A number of peakedness less than 1.35 means there is a high peak in the probability density function. The reference value of the EGB2 distribution is reported below peakedness in parenthesis and is in the range of (1.12, 1.22). The normality test is omitted, since the assumption is the EGB2 distribution. The independence test is conducted using a Ljung-Box Q test up to order 30. The Q^2 test of order of 30 is to show volatility clustering. The model is

(1.a) $R_t = \phi_0 + \phi_1 R_{m,t} + \phi_2 R_{t-1} + \Delta_n D_{extreme} + \varepsilon_{it}$

(1.b) $\varepsilon_t = \sqrt{h_t} z_t$

(1.c) $h_t = w + \alpha\varepsilon_{t-1}^2 + \beta h_{t-1} + \gamma\, I(\varepsilon_{t-1} < 0)\varepsilon_{t-1}^2$

(1.d) $\varepsilon_t|\Im_{t-1} \sim EGB2(0, h_t, p, q)$. N in the table represents the number of dummies in the mean equation (at most 10). Those dummies represent the extreme values in the individual stocks' return series. The following stocks do not have an AR(1) variable: MSFT, HON, DD, GM, IBM, MO, CAT, BA, PFE, AA, DIS, MCD, JPM, and INTC. Stock PG is the only one to have an AR(4) variable in the mean equation, which ensures that autocorrelation has been removed

This table compares the GARCH(1,1) model based on three distributions: normal, Student's *t*(T), and EGB2 based on a negative logarithm of the likelihood function value (Left) and the χ^2 goodness-of-fit test statistic value (Right). The quantiles are computed via 40 intervals. The degree of freedom (d.f.) is 37 for the EGB2, 38 for the *t* distribution and 39 for the normal distribution. The chi-square critical values at the 1 %, 5 %, and 10 % levels are 59.89, 52.19, and 48.36, respectively, with d.f. being 37; 61.16, 53.39, and 49.51 with d.f. being 38; and 62.43, 54.57, and 50.66 with d.f. being 39. ***Indicates 1 % significance, **5 %, and *10 %

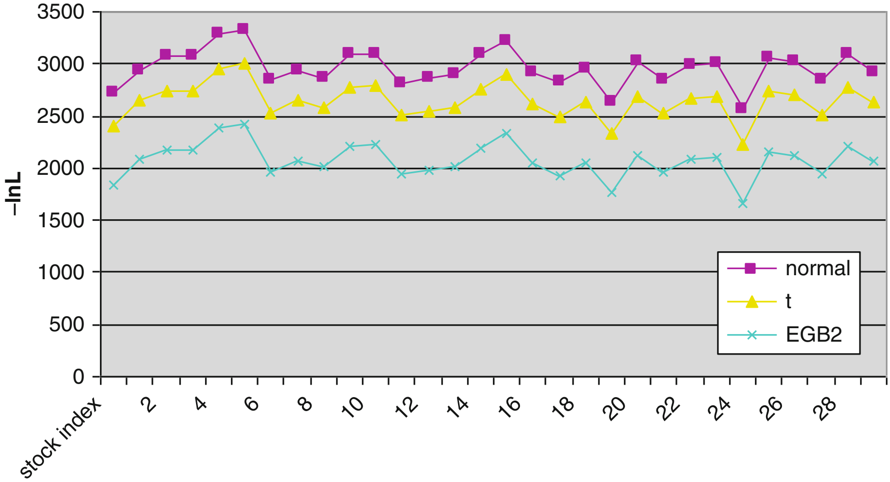

Fig. 80.3 Comparisons of log-likelihood function values in different models. The greater the function value the better of the fit the model is. The figure plots the negative logarithm value of the likelihood function

rival distributions: the normal distribution and the t distribution. However, as noted by Boothe and Glassman (1987), making non-nested distribution comparisons based on log-likelihood values can lead to spurious conclusions.[19] Consequently, we calculate the goodness-of-fit (GoF) statistics[20] to compare differences between observed distribution of standardized residuals and theoretical distribution based on estimated shape parameters following Snedecor and Cochran (1989).

The null hypothesis tested by the GoF statistics is that the observed and predicted distribution functions are identical. The statistic is calculated by

$$GoF = \sum_{i=1}^{k} \frac{(f_i - F_i)^2}{F_i} \tag{80.8}$$

where f_i is the observed count of actual standardized residuals in the i th data class (interval), F_i is the predicted count derived from the estimated values for the distribution parameters, and k is the number of data intervals used in distributional comparisons. GoF has an asymptotic chi-square distribution with degrees of freedom equal to the number of intervals minus the number of estimated distribution

[19] Normal distribution is a special case of the EGB2 distribution. A likelihood ratio rest suggests that there is significant improvement in the fit of the EGB2 distribution over that of the normal distribution.

[20] The chi-square test is an alternative to the Anderson-Darling and Kolmogorov-Smirnov goodness-of-fit tests. The chi-square test and Anderson-Darling test make use of the specific distribution in calculating critical values. This has the advantage of allowing a more sensitive test and the disadvantage that critical values must be calculated for each distribution.

parameters minus one. For EGB2 distribution, two parameters are estimated; for Student's t distribution, one parameter is estimated; for the normal distribution, no parameter is required, since the error term has been standardized.

Table 80.6 reports the results of the χ^2 test for three distributions used in the GARCH(1,1) model. The test power is maximized by choosing a data class equiprobably (equal probability). The rule of thumb of the chi-square test is to choose the number of groups starting at 2 $T^{0.4}$.[21] The test results show that the null hypothesis is rejected by 12 stocks on the normal distribution at the 1 % level, 28 stocks on the t distribution and only three stocks on the EGB2 distribution. Furthermore, the χ^2 statistic also shows that the EGB2 distribution yields lower absolute values. We can conclude that the model based on the EGB2 distribution has the least deviation of the residuals from the theoretical distribution. The evidence suggests that the Student's t distribution is able to solve the kurtosis problem, but it could not fit the whole error distributions due to peakedness. Putting the evidence together, it is clear that the EGB2 distribution is superior to the t distribution and the normal distribution in our empirical analysis.

80.6 Implication of EGB2 Distribution

One of the main objectives of analyzing financial data for risk management purposes is to provide an answer to the question: how should we evaluate the probability of the extreme values by using statistical distributions? According to the normal distribution, the 1987 market crash with more than -17σ (daily data) would have never happened. However, recent market crashes indicate that big market swings or significant declines in asset prices happen more frequently than we expect. Although VaR is one of the most prevalent risk measures under normal conditions, it cannot deal with those extreme values, since extreme values are *not* normal. From this perspective, the EGB2 distribution provides a management tool for calculating risk.

Table 80.7 reports the probability of the semivolatility of shocks. Here, we concentrate on the probability of the error term having negative shocks. From this table, we see that the predicted probability for extreme values (beyond -2σ) is greater than that of the normal distribution. For instance, probabilities of a -5σ and -7σ shock for MSFT (index = 1) are 4.9E-5 and 8.4E-7, much greater than 2.8E-7 and 1.3E-12 based on the normal distribution.

Yet, the probabilities for the EGB2 distribution under a moderate range (within $\pm 2\sigma$) are less than that of the normal distribution. This is an alternative way to determine the peakedness and fat tails of portfolio returns. Notice that the crossing point between the EGB2 distribution and the normal distribution is in

[21] Our sample contains 999 observations; 40 intervals are used. Each group (data class) has theoretically 25 observations. The degrees of freedom are 37, 38, and 39 for the EGB2 distribution, the t distribution and the normal distribution, respectively. (The chi-squared critical values are given in the note in Table 80.6.)

The probability is calculated based on estimated p- and q-values of the EGB2 distribution. It tells how often the error terms have negative extreme values. The probability values based on the normal distribution are the same for all 30 stocks

the neighborhood of $\pm 2\sigma$, where the probabilities of both distributions are about the same value. This feature implies that VaR at the 95 % confidence level based on the normal distribution is by chance consistent with reality. However, beyond this critical level, the VaR method based on the normal distribution leads an underestimation in forecasts of losses. Nevertheless, the EGB2 distribution in this regard provides a broader spectrum of risk information for guiding risk management.

80.7 Conclusions

In this chapter, we present empirical evidence on the stock return equation based on market risk, time series pattern, and asymmetric conditional variance for the 30 Dow Jones stocks. Special attention is placed on the issue of presenting skewness, kurtosis, and outlier effects. Although we find no significant difference over the estimated betas and the corresponding standard errors of the distributions, the evidence shows that the exponential generalized beta distribution of the second kind (EGB2) is superior to the Student's *t* distribution and the normal distribution in dealing with data that demonstrate skewness and excess kurtosis simultaneously. The superiority of the EBG2 distribution in modeling financial data is not only due to its flexibility but also to its closed-form density function for the distribution. Its higher-order moments are finite and explicitly expressed by its parameters. Thus, the EGB2 model provides a useful tool for forecasting variances involving extreme values. As a result, this model can have practical use for risk management.

Consistent with the finding in the literature, the asymmetric effects are highly significant in the standard GJR-GARCH specification by assuming normal distributions. However, by incorporating the heavy tail information into the distributions, we can reduce the asymmetric effects. Our study confirms that the EBG2 distribution has the capacity to deal with the asymmetric effects. Since excess kurtosis is often caused by outliers, our finding suggests that removing the contamination of outliers from the residuals enhances the performance of EGB2 distributions. In short, the GJR-GARCH-type model based on the EGB2 distribution provides a richer framework for modeling stock return volatility. It accommodates several special stock return features, including fat tails, skewness, peakedness, autocorrelation, volatility clustering, and leverage effect. As a result, this model is effective for empirical estimation and suitable for risk management.

Appendix 1

Delta Method and Standard Errors of the Skewness and Kurtosis Coefficients of the EGB2 Distribution

The delta method, in its essence, expands a function of a random variable about its mean, usually with a one-step Taylor approximation, and then takes the variance. For example, if we want to approximate the variance of $G(x)$ where x is a random variable with mean μ and $G(x)$ is differentiable, we can try

$$G(x) \approx G(\mu) + (x - \mu)G'(\mu) \tag{80.9}$$

so that

$$\mathrm{Var}(G(x)) \approx G'(\mu)^2 \mathrm{Var}(x) \tag{80.10}$$

where $G'() = dG/dX$. This is a good approximation only if x has a high probability of being close enough to its mean so that the Taylor approximation is still good.

The nth central moments of the EGB2 distribution is given by

$$\text{The nth moment} = \sigma^n \left(\psi^{n-1}(p) + (-1)^n \psi^{n-1}(q)\right) \tag{80.11}$$

where ψ^n is nth order a polygamma function. Correspondingly, the skewness coefficient is given by

$$\text{Skewness} = g(p,q) = \frac{\psi''(p) - \psi''(q)}{(\psi'(p) + \psi'(q))^{1.5}} \tag{80.12}$$

The variance of the skewness coefficient by the delta method is given by

$$\begin{aligned}\mathrm{Var}(\text{Skewness}) = {} & g_p^{'}(p,q)^2 \mathrm{var}(p) + g_q^{'}(p,q)^2 \mathrm{var}(q) \\ & + 2g_p^{'}(p,q) g_q^{'}(p,q) \mathrm{cov}(p,q)\end{aligned} \tag{80.13}$$

where

$$g_p^{'}(p,q) = \frac{\psi'''(p)(\psi'(p) + \psi'(q)) - 1.5\psi''(p)(\psi''(p) - \psi''(q))}{(\psi'(p) + \psi'(q))^{2.5}} \tag{80.14}$$

$$g_q^{'}(p,q) = \frac{-\psi'''(q)(\psi'(p) + \psi'(q)) - 1.5\psi''(q)(\psi''(p) - \psi''(q))}{(\psi'(p) + \psi'(q))^{2.5}} \tag{80.15}$$

Similarly, the excess kurtosis coefficient is given by

$$\text{Kurtosis} = h(p,q) = \frac{\psi'''(p) + \psi'''(q)}{(\psi'(p) + \psi'(q))^2} \tag{80.16}$$

The variance of the kurtosis coefficient by the delta method is given by

$$\begin{aligned}\mathrm{Var}(\text{Kurtosis}) = {} & h_p^{'}(p,q)^2 \mathrm{var}(p) + h_q^{'}(p,q)^2 \mathrm{var}(q) \\ & + 2h_p^{'}(p,q) h_q^{'}(p,q) \mathrm{cov}(p,q)\end{aligned} \tag{80.17}$$

where

$$h_p'(p,q) = \frac{\psi''''(p)(\psi'(p)+\psi'(q)) - 2\psi''(p)(\psi'''(p)+\psi'''(q))}{(\psi'(p)+\psi'(q))^3} \tag{80.18}$$

$$h_q'(p,q) = \frac{\psi''''(q)(\psi'(p)+\psi'(q)) - 2\psi''(q)(\psi'''(p)+\psi'''(q))}{(\psi'(p)+\psi'(q))^3} \tag{80.19}$$

In the equations above, high-order polygamma functions are involved. A polygamma function is the nth normal derivative of the logarithmic derivative of $\Gamma(z)$:

$$\psi^n(z) = \frac{d^{n+1}}{dz^{n+1}} \ln(\Gamma(z)) \tag{80.20}$$

which, for $n > 0$, can be written as

$$\psi^n(z) = (-1)^{n+1} n! \sum_{k=0}^{\infty} \frac{1}{(z+k)^{n+1}} \tag{80.21}$$

which is used to calculate polygamma functions in this chapter.

Note: This appendix is based on the paper by Wang et al. (2001). However, there are typos and errors in that paper. The standard deviation formula for skewness used by Wang et al. (2001) is incorrect (see g′q(p,q) equation in the paper at http://www.econ.queensu.ca/jae/2001-v16.4/wang-fawson-barrett-mcdonald/Appendix4_delta_derivations.pdf). We therefore provide this appendix. Accordingly, as we reviewed and replicated that paper by using the data supplied by the *Journal of Applied Econometrics*, the EGB2 distribution doesn't remove the skewness problem completely as shown in their Table 3. In addition, there is a computational error in the JPY series, so that its kurtosis has not been resolved either.

Abstract

This study examines the profits of revenue, earnings, and price momentum strategies in an attempt to understand investor reactions when facing multiple information of firm performance in various scenarios. We first offer evidence that there is no dominating momentum strategy among the revenue, earnings, and price momentums, suggesting that revenue surprises, earnings surprises, and prior returns each carry some exclusive unpriced information content. We next show that the profits of momentum driven by firm fundamental performance information (revenue or earnings) depend upon the accompanying firm market performance information (price), and vice versa. The robust monotonicity in multivariate momentum returns is consistent with the argument that the market does not only underestimate the individual information but also the joint implications of multiple information on firm performance, particularly when they point in the same direction. A three-way combined momentum strategy may offer monthly return as high as 1.44 %. The information conveyed by revenue surprises and earnings surprises combined account for about 19 % of price momentum effects, which finding adds to the large literature on tracing the sources of price momentum.

Keywords

Revenue surprises • Earnings surprises • Post-earnings-announcement drift • Momentum strategies

81.1 Introduction

Financial economists have long been puzzled by two robust and persistent anomalies in the stock market: price momentum (see Jegadeesh and Titman 1993, 2001; Rouwenhorst 1998), and post-earnings-announcement drift (see Ball and Brown 1968; Foster et al. 1984; Bernard and Thomas 1989; Chan et al. 1996). More recently, Jegadeesh and Livnat (2006b) also find that price reactions to revenue surprises on announcement dates only partially reflect the incremental information conveyed by the surprises. The information contents carried by revenue, earnings and stock prices are intrinsically linked through firm operations and investor evaluation, and there is evidence of mutual predictability for respective future values (e.g., see Jegadeesh and Livnat 2006b). Nonetheless, investors, aware of the linkages among the information content conveyed by revenue, earnings and prices (see Ertimur et al. 2003; Raedy et al. 2006; and Heston and Sadka 2008), may still fail to take full account of their joint implications when pricing the stocks.

This study investigates how investors price securities when facing multiple information contents of a firm, particularly those firm performance information that are most accessible for investors – price, earnings, and revenue.[1] The long-short strategy of momentums, widely used in the literature, provides a venue to detect market reactions toward individual and multiple information contents. Accordingly, this study will start with documenting the revenue momentum profits and re-confirming the earnings and price momentums profits. Explorations with momentum strategies expect to yield implications that answer our two research questions. First, among the performance information of revenue surprises, earnings surprises, and prior returns, does each carry some exclusive information content that is not priced by the market? Second, do investors mis-react toward the joint implications as well as individual information of firm revenue, earnings, and price?

Our first research question is explored by testing momentum dominance. One momentum strategy is said to be dominated if its payoffs can be fully captured by the information measure serving as the sorting criterion of another momentum strategy. Note that our emphasis here is not asset pricing tests; instead, as in Chan et al. (1996) and Heston and Sadka (2008), we focus on the return anomalies based on revenue surprises, earnings surprises, and prior returns. Results from both a pairwise nested comparison and a regression analysis indicate that revenue surprises, earnings surprises, and prior returns each lead to significant momentum returns that cannot be explained away by one another. That is, revenue momentum neither drives nor rides earnings or price momentum. Following the information diffusion hypothesis of Hong and Stein (1999), our evidence then suggests that revenue surprises, earnings surprises, and prior returns each contribute to the phenomenon of gradual information flow, or that each have some exclusive information content that is not priced by the market.[2] Further regression tests indicate

[1]Researches in the literature offer some evidence on the information linkage among revenue, earnings and prices. For example, Lee and Zumwalt (1981) find that revenue information is complementary to earnings information in security rate of return determination. Bagnoli et al. (2001) find that revenue surprises but not earnings surprises can explain stock prices both during and after the internet bubble. Swaminathan and Weintrop (1991) and Ertimur et al. (2003) suggest that the market reacts significantly more strongly to revenue surprises than to expenses surprises. Rees and Sivaramakrishnan (2001) and Jegadeesh and Livnat (2006b) also find that, conditional on earnings surprises, there is still a certain extent of market reaction to the information conveyed by revenue surprises. Ghosh et al. (2005) find that sustained increases in earnings are supported by sustained increases in revenues rather than by cost reductions.

[2]The asset pricing tests of Chordia and Shivakumar (2006) support that price momentum is subsumed by the systematic component of earnings momentum, even though they also find earnings surprises and past returns have independent explanatory power for future returns. This latter finding is consistent with the results of Chan et al. (1996) and our results, as is reported later. In comparison, Chan et al. (1996), Jegadeesh and Livnat (2006b), and we focus on whether and

that earnings surprise and revenue surprise information each accounts for about 14 % and 10 % of price momentum returns, and that these two fundamental performance information combined account for just about 19 % of price momentum effects. These results provide additional evidence in the literature on the sources of price momentum (e.g., see Moskowitz and Grinblatt 1999; Lee and Swaminathan 2000; Piotroski 2000; Grundy and Martin 2001; Chordia and Shivakumar 2002, 2005; Ahn et al. 2003; Griffin et al. 2003; Bulkley and Nawosah 2009; Chui et al. 2010; Novy-Marx 2012).

Our second research question inquires how the market reacts to the joint implications of multiple information measures. The three measures under our study all carry important messages on innovations in firm performance, and therefore expect to trigger investor reactions. They become ideal target to be studied to entail implications on how investors process multiple information interactively in pricing stocks. The results from two-way sorted portfolios find that the market anomalies vary monotonically with the joint condition of revenue surprises, earnings surprises, and prior returns, and anomalies tend to be strongest when stocks show the strongest signals in the same direction. The cross-contingencies of momentums are observed in that the momentum returns driven by *fundamental performance information* (revenue surprises or earnings surprises) change with the accompanying *market performance information* (prior returns), and vice versa. Such finding, as interpreted by the gradual-information-diffusion model, is consistent with the suggestion that the market not only underreacts to individual firm information but also underestimates the significance of the joint implications of revenue, earnings, and price information.[3] These results also have interesting implications for investment strategies that the fundamental performance information plays an important role in differentiating future returns among price winners, while the market performance information is particularly helpful in predicting future returns for stock with high surprises in revenue or earnings. Specifically, price winners, compared to price losers, yield higher returns from revenue/earnings momentum strategies; stock with greater surprises in fundamentals yield greater returns from price momentums.

The results of our dominance tests and multivariate momentum suggest that a combined momentum strategy should yield better results over single-criterion momentum strategies. A combined momentum strategy using all three performance measures is found to yield monthly returns as high as 1.44 %, which amounts to an annual return of 17.28 %. Such a combined momentum strategy outperforms single-criterion momentum strategies by at least 0.72 percentage points in monthly return.

how firm characteristics, such as revenue surprises, earnings surprises, and prior returns, are related to future cross-sectional returns, while Chordia and Shivakumar (2006) also conduct asset pricing tests.

[3]The firm performance measures, revenue, earnings, and stock price, do not only share common origins endogenously but also have added implications for future values of one another. Jegadeesh and Livnat (2006b) have documented evidence on the temporal linkages among these variables. In this study, we focus on the further inquiry that whether investors fully exploit such temporal linkages among these firm performance information in pricing stocks.

Our conclusions remain robust whether we use raw returns or risk-adjusted returns, whether we include January results or not, and whether we use dependent or independent sorts. Chan et al. (1996), Piotroski (2000), Griffin et al. (2005), Mohanram (2005), Sagi and Seasholes (2007), Asem (2009), and Asness et al. (2013) conduct similar tests on combined momentum strategies using alternative sorting criteria.[4] In comparison, our study is the first to document results considering these three firm performance information, revenue surprises, earnings surprises, and prior returns altogether.

In terms of persistency, the earnings momentum strategy is found to exhibit the strongest persistence, while the revenue momentum strategy is relatively short-lived. All the same, the short-lived revenue momentum effect is prolonged when the strategy is executed using stocks with the best prior price performance and more positive earnings surprises. In fact, the general conclusion supports our claim of cross-contingencies of momentum as applied to momentum persistence.

This study contributes to the finance literature in several respects. First, we specifically identify the profitability of revenue momentum and its relation with earnings surprises and prior returns in terms of momentum strength and persistence. A revenue momentum strategy executed with a 6-month formation period and 6-month holding-period strategy yields an average monthly return of 0.61 % for the period between 1974 and 2009. Second, this study identifies empirical interrelations of anomalies arising from three firm performance information – revenue, earnings and price. To the best of our knowledge, we are the first to offer evidence that there is no dominating momentum strategy among the three, and that the profits of momentum driven by firm fundamental performance information (revenue or earnings) depend upon the accompanying firm market performance information (price), and vice versa.[5] Third, aside from academic interest, the aforementioned findings may well serve as useful guidance for asset managers seeking profitable investment strategies. Fourth, this study also adds to the large literature attempting to trace the sources of price momentum. Our numbers indicate that the information conveyed by revenue surprises and earnings surprises combined account for about 19 % of price momentum effects. Last, our results offer additional evidence to the literature using the behavioral explanation for momentums.[6] Our empirical results

[4]Chan et al. (1996) and Griffin et al. (2005) find that when sorting prior price performance and earnings surprises together, the profits of a zero-investment portfolio are higher than those of single sorting. Piotroski (2000) and Mohanram (2005) develop fundamental indicators, FSCORE and GSCORE, to separate winners from losers. Sagi and Seasholes (2007) find that price momentum strategy becomes even more profitable when applied to stocks with high revenue growth volatility, low costs, or valuable growth options. Asness et al. (2013) find that the combination of value strategy and momentum strategy can perform better than either one alone. Asem (2009) find the momentum profits can be enhanced combining prior price returns and dividend behaviors.

[5]Heston and Sadka (2008) and Novy-Marx (2012) also provide evidence that earnings surprises are unable to explain price momentum. However, this study is the first to consider earnings surprises and revenue surprises at the same time in explaining price momentum.

[6]Barberis et al. (1998), Daniel et al. (1998), Hong and Stein (1999), Jackson and Johnson (2006), Verardo (2009), and Moskowitz et al. (2012) provide evidence in support of behavioral

are consistent with the suggestion that revenue surprises, earnings surprises, and prior returns each carry some exclusive unpriced information content. Moreover, the monotonicity of abnormal returns found in multivariate momentums suggests that the market does not only underestimate the individual information but also the joint implications of multiple information on firm performance. Such suggestion is new to the literature, and may also present a venue to track the sources of price momentum.

The study is organized as follows. In Sect. 81.2, we develop our models and describe the methodologies. In Sect. 81.3, we describe the data. In Sect. 81.4, we report the results on momentum strategies based on a single criterion. In Sect. 81.5, we discuss the empirical results of exploration of inter-relations among revenue, earnings, and price momentums using strategies built on multiple sorting criteria. In Sect. 81.6, we test the persistency and seasonality of momentum strategies. Section 81.7 concludes.

81.2 Revenue, Earnings, and Price Momentum Strategies

81.2.1 Measures for Earnings Surprises and Revenue Surprises

We follow Jegadeesh and Livnat (2006a, b) and measure revenue surprises and earnings surprises based on historical revenues and earnings.[7] Assuming that both quarterly revenue and quarterly earnings per share follow a seasonal random walk with a drift, we define the measure of revenue surprises for firm i in quarter t, standardized unexpected revenue growth (SURGE), as

$$SURGE_{i,t} = \frac{Q_{i,t}^{R} - E\left(Q_{i,t}^{R}\right)}{\sigma_{i,t}^{R}}, \tag{81.1}$$

where $Q_{i,t}^{R}$ is the quarterly revenue of firm i in quarter t, $E(Q_{i,t}^{R})$ is the expected quarterly revenue prior to earnings announcement, and $\sigma_{i,t}^{R}$ is the standard deviation of quarterly revenue growth.

The same method is applied to measure earnings surprises, specifically standardized unexpected earnings (SUE), defined as

$$SUE_{i,t} = \frac{Q_{i,t}^{E} - E\left(Q_{i,t}^{E}\right)}{\sigma_{i,t}^{E}}, \tag{81.2}$$

explanation to momentum effect, while Grundy and Martin (2001), Johnson (2002), Ahn et al. (2003), Sagi and Seasholes (2007), Li et al. (2008), Liu and Zhang (2008), and Wang and Wu (2011) attribute momentum effect to missing risk factors. In addition, Korajczyk and Sadka (2004) and Lesmond et al. (2004) re-examine the profitability of momentum strategies after taking the transaction cost into account and get mixed results.

[7]See Appendix for a detailed discussion of measures to estimate revenue and earnings surprises.

where $Q_{i,t}^{E}$ is the quarterly earnings per share from continuing operations, $E(Q_{i,t}^{E})$ is the expected quarterly earnings per share prior to earnings announcement, and $\sigma_{i,t}^{E}$ is the standard deviation of quarterly earnings growth.

81.2.2 Measuring the Profitability of Revenue, Earnings, and Price Momentum Strategies

We construct all three momentum strategies based on the approach suggested by Jegadeesh and Titman (1993). To evaluate the information effect of earnings surprises on stock returns, we form an earnings momentum strategy analogous to the one designed by Chordia and Shivakumar (2006). At the end of each month, we sort sample firms by SUE and then group the firms into ten deciles.[8] Dec 1 includes stocks with the most negative earnings surprises, and Dec 10 includes those with the most positive earnings surprises. The SUEs used in every formation month are obtained from the most recent earnings announcements, made within three months before the formation date.

We hold a zero-investment portfolio, long the most positive earnings surprises portfolio and short the most negative earnings surprises portfolio, for K ($K = 3$, 6, 9, and 12) subsequent months, not rebalancing the portfolios during the holding period. Such positive minus negative strategy (PMN) holds K different long-positive and short-negative portfolios each month. Accordingly, we obtain a series of zero-investment portfolio returns, which are the monthly returns to this earnings momentum strategy. Similarly, we apply this positive-minus-negative method to construct a revenue momentum strategy.

In the case of price momentum, we form a zero-investment portfolio each month by taking a long position in the top decile portfolio (winner) and a short position in the bottom decile portfolio (loser), and we hold this winner minus loser portfolio (WML) for subsequent K months. We thus obtain a series of zero-investment portfolio returns, i.e., the returns to the price momentum strategy.

81.3 Data and Sample Descriptions

81.3.1 Data

We collect from Compustat the firm basic information, earnings announcement dates, and firm accounting data. Stock prices, stock returns, share codes, and

[8]Note that we sort the sample firms into five quintile portfolios on each criterion in our later construction of multivariate momentum strategies. To conform to the same sorting break points, we also test the single momentum strategies based on quintile portfolios and find the results remain similar to those based on decile portfolios.

exchange codes come retrieved from the Center for Research in Security Prices (CRSP) files. The sample period is from 1974 through 2009. Only common stocks (SHRCD = 10, 11) and firms listed on New York Stock Exchange, American Stock Exchange, or Nasdaq (EXCE = 1, 2, 3, 31, 32, 33) are included in our sample. We exclude from the sample regulated industries (SIC = 4,000–4,999) and financial institutions (SIC = 6,000–6,999). We also exclude firms with stock prices below $5 on the formation date, considering that investors generally pay only limited attention to such stocks.

For the purpose of estimating their revenue surprises (SURGE), earnings surprises (SUE), and prior price performance, firms in the sample should have at least eight consecutive quarterly earnings announcements and six consecutive monthly returns before each formation month. To examine the return drift following the estimated SURGE, SUE, and prior price performance, firms in the sample need to have at least 12 consecutive monthly returns following each formation month. Firms in the sample should also have corresponding SURGE, SUE, size and book-to-market factors available in each formation month.

81.3.2 Sample Descriptions

Table 81.1 presents the summary statistics for firm size, estimates of revenue surprises and estimates of earnings surprises for our sample firms between year 1974 and year 2009. Panel A shows that there are 223,831 firm-quarters during the sample period. Median firm market capitalization is $235 million. Panel B and Panel C describe the distributions the revenue surprises (SURGE) and the earnings surprises (SUE) across firms of different market capitalization and different book-to-market ratio. Around 54 % of revenue surprises and 50 % of earnings surprises are positive.[9]

The values of SURGE and SUE are expected to be positively correlated. After all, a firm's income statement starts with revenue (sales) and ends with earnings; these two attributes share common firm operational information to a great extent, and their innovations, SURGE and SUE, should be correlated as well. Table 81.2 shows the time-series average of the cross-sectional correlations between 1974 and 2009. Panel A and Panel B present, respectively, the Pearson correlations and Spearman rank correlations. The average of both types of correlations between SURGE and SUE is 0.32, while prior price performance is not as significantly correlated with SURGE or SUE, with average correlations equal to about 0.15 and 0.19, respectively.

We then partition the sample by book-to-market ratio (B/M) and size. Value firms and small firms are found to exhibit slightly higher correlations among

[9]To ensure that firm accounting information is available to public investors at the time the stock returns are recorded, we follow the approach of Fama and French (1992) and match the accounting data for all fiscal years ending in calendar year $t-1$ with the returns for July of year t through June of $t+1$. The market capitalization is calculated by the closing price on the last trading day of June of a year times the number of outstanding shares at the end of June of that year.

Table 81.1 Summary statistics of sample firm characteristics

Panel A: sample size and firm market capitalization									
	Number of firm-quarters				Market cap (million dollars)

This table presents the descriptive statistics for major characteristics of our sample stocks. Our sample includes stocks listed on the NYSE, the AMEX, and Nasdaq with data available to compute book-to-market ratios, revenue surprises, and earnings surprises. All financial service operations and utility companies are excluded. Firms with prices below $5 as of the earnings announcement date are also excluded. Panel A lists numbers of firm-quarter observations between January 1974 and December 2009. Panel B and Panel C respectively list the mean and median values the measure of revenue surprises (SURGE) and for the measure of earnings surprises (SUE) across all firm-quarters in our sample. Statistics for positive surprises, negative surprises, and zero surprises are presented separately. Sample firms are also classified into bottom 30 %, middle 40 %, and top 30 % groups by their respective market capitalizations or book-to-market ratios. The breakpoints for the size subsamples are based on ranked values of market capitalization of NYSE firms. The breakpoints for the book-to-market subsamples are based on ranked values of book-to-market ratio of all sample firms

SURGE, SUE, and prior price performance than growth firms and large firms, although the differences in correlations across B/M and size groups are not significant. Table 81.2 also shows the fractions of months where non-zero correlations are significant at the 1 % level. These numbers again confirm that the correlations between SURGE and SUE tend to be strongest across various classifications of firms, followed by correlations between SURGE and prior returns, and then those between SUE and prior returns.

This table presents the correlations among SURGE, SUE and prior returns of our sample firms. At the end of each month, each sample firm should have its corresponding most current SUE, most current SURGE, and previous 6-month return. SURGE and SUE are winsorized at 5 % and 95 %, setting all SURGE and SUE values greater than the 95th percentile to the value of the 95th percentile and all SURGE and SUE values smaller than the 5th percentile to the value of the 5th percentile. Panel A lists the average Pearson correlations among SUE, SURGE, and prior returns between 1974 and 2009. Panel B lists the average Spearman rank correlations, where all sample firms are grouped into ten portfolios based on SURGE, SUE, and prior-6-month-returns independently at the end of each month. Decile 1 portfolio consists of firms with the lowest value of the attribute (SURGE, SUE, or prior 6-month returns), and Decile 10 consists of firms with the highest value of the attribute. The correlations are calculated at the end of each month. The values reported in the table are monthly averages of those correlations. Sample firms are further classified into bottom 30 %, middle 40 %, and top 30 % groups by their respective market capitalizations or book-to-market ratios at the end of the formation months. The breakpoints for the size subsamples are based on ranked values of market capitalization of NYSE firms. The breakpoints for the book-to-market subsamples are based on ranked values of book-to-market ratio of all sample firms. The numbers in parentheses are the average t-statistics under the null hypothesis that the correlation is zero. ***, **, and * indicate statistical significance at 1 %, 5 %, and 10 %, respectively. Percentages in brackets represent the fraction of the months with non-zero correlations that are significant at the 1 % level

These preliminary results suggest that revenue surprises and earnings surprises share highly correlated information, while each still have a distinctive content, a conclusion consistent with Swaminathan and Weintrop (1991) and Jegadeesh and Livnat (2006b). The information content conveyed by market information, i.e., prior returns, differs more from that carried by the two fundamental information measures, SURGE and SUE.

81.3.3 Descriptive Statistics for Stocks Grouped by SURGE, SUE, and Prior Returns

We next compare the firm characteristics for portfolios characterized by different revenue surprises (SURGE), earnings surprises (SUE) and prior returns. All sample stocks are sorted into quintiles based on their SURGE, SUE, and prior 6-month returns independently. The characteristics of those quintile portfolios are reported in Table 81.3. Several interesting observations emerge.

The price level, as expected, is found to be lowest for the price losers (P1). Stocks with negative revenue surprises (R1) or negative earnings surprises (E1) also have lower price levels, while the trend is not as obvious as for price losers. We also find price losers (P1) and price winners (P5) tend to be smaller stocks. Another interesting observation revealed in the book-to-market ratios is that stocks with the most positive SURGE or the most winning returns tend to be growth stocks. Stocks with the most positive SUE also have lower B/M ratios, but to much less of a degree. This suggests that growth stocks are characterized by strong revenue but not necessarily strong earnings.

The last three sections of Table 81.3 list the SURGE, SUE, and prior returns for those sorted portfolios. Stocks with strong SURGE also tend to have higher SUE and higher prior returns. A similar pattern is seen for stocks with high SUE or high prior returns. Stocks with strong SURGE, strong SUE, or winning prior returns tend to excel on all three information dimensions. This relation is consistent with the positive correlations reported in Table 81.2.

81.4 Empirical Results of Univariate Momentum Strategies

Table 81.4 presents the monthly returns to momentum strategies based on firms' revenue surprises (SURGE), earnings surprises (SUE), and prior price performance, respectively termed as revenue momentum, earnings momentum, and price momentum strategies. Decile portfolio results are reported here.

We first examine the profitability of revenue momentum. We are interested in knowing whether the well-documented post-announcement revenue drift also enables a profitable investment strategy. Following a similar strategy of earnings momentum by Chordia and Shivakumar (2006), we define a revenue momentum portfolio as a zero-investment portfolio by buying stocks with the most positive revenue surprises and selling stocks with the most negative revenue surprises.

This table presents the descriptive statistics of firm characteristics for stocks sorted on SURGE, SUE, and prior returns. All sample stocks are sorted independently according to their SURGE, SUE, and prior 6-month returns. R1 (E1) represents the quintile portfolio of stocks with the most negative SURGE (SUE), and R5 (E5) represents the quintile portfolio of stocks with the most positive SURGE (SUE). Similarly, P1 denotes the quintile portfolio of stocks with the lowest prior 6-month returns while P5 denotes the portfolio of stocks with the highest prior 6-month returns. Reported characteristics include price level, market capitalization, B/M ratio, SURGE, SUE and prior 6-month returns for component stocks in each corresponding quintile portfolio. The reported mean values are the equally weighted averages for stocks in each quintile portfolio

Panel A of Table 81.4 reports significant returns to the revenue momentum strategies. These strategies yield average monthly returns of 0.94 %, 0.93 %, and 0.84 %, respectively, by holding the relative-strength portfolios for 3, 6, and 9 months. This research, to the best of our knowledge, is the first to document specific evidence on the profitability of revenue momentum.

We also test with more recent data the profitability of earnings momentum and price momentum strategies, which have both been studied in the literature. Panel B of Table 81.4 reports the results for the earnings momentum strategies. We again find that these positive-minus-negative (PMN) zero-investment portfolios yield significantly positive returns for holding periods ranging from 3 to 12 months. The profit is strongest when the PMN portfolios are held for 3 months, leading to an average monthly return of 0.99 %, significant at the 1 % level. The results are consistent with those of Bernard and Tomas (1989) and Chordia and Shivakumar (2006). Chordia and Shivakumar (2006) find a significant monthly return of 0.96 % on a 6-month holding-period earnings momentum strategy executed over

This table presents monthly returns and associated *t*-statistics from revenue, earnings, and price momentum strategies executed during the period from 1974 through 2009. For the revenue momentum strategy, firms are grouped into ten deciles based on the measure SURGE during each formation month. Decile 1 represents the most negative revenue surprises, and Decile 10 represents the most positive revenue surprises. The values of SURGE for each formation month are computed using the most recent revenue announcements made within three months before the formation date. The zero-investment portfolios—long the most positive revenue surprises portfolio and short the most negative revenue surprises portfolio (PMN) —are held for K ($K = 3$, 6, 9, and 12) subsequent months and are not rebalanced during the holding period. Panel A lists the average monthly returns earned from the portfolio of those firms with the most negative SURGE (low), from the portfolio of those with the most positive SURGE (high), and from the earnings momentum strategies (PMN). Earnings momentum strategies are developed with the same approach of revenue momentum strategies, by buying stocks with the most positive earnings surprises and selling stocks with the most negative earnings surprises. The zero investment portfolios are then held for K subsequent months. Panel B lists the average monthly returns earned from the portfolio of those firms with the most negative SUE (low), from the portfolio of those with the most positive SUE (high), and from the earnings momentum strategies (PMN). For the price momentum strategy, firms are sorted into 10 ascending deciles on the basis of previous 6 months returns. Portfolios of buying Decile 1 (winner) and selling Decile 10 (loser) are held for K subsequent months and not rebalanced during the holding period. The average monthly returns of winner, loser, and price momentum strategies are presented in Panel C. Risk-adjusted momentum returns are also provided in this table. Adj. (1) is momentum returns adjusted by CAPM, and Ad.j (2) is momentum returns adjusted by the Fama-French 3-factor model.***, **, and * indicate statistical significance at 1 %, 5 %, and 10 %, respectively

1972–1999, while we show a significant monthly return of 0.71 % for a sample period extending to 2009.

Panel C shows the performance of price momentum strategies. Similar to the results in Jegadeesh and Titman (1993), price momentum strategies yield average monthly returns of 0.94 %, 0.93 %, 0.84 %, and 0.61 %, for the 3, 6, 9, and 12 months holding-period respectively.

A comparison of the three momentum strategies indicates that the highest returns are for price momentum, followed by earnings momentum and revenue momentum. Meanwhile, the profitability for earnings momentum portfolio deteriorates faster than for price momentum as the holding period extends from 3 to 12 months.[10] The revenue momentum strategy yields the smallest and the shortest-lived profits, with returns diminishing to an insignificant level when the holding period is extended to 12 months.

Following a similar approach by Fama and French (1996) and Jegadeesh and Titman (2001), we implement the capital asset pricing model and a Fama-French three factor (FF-3) model to examine whether the momentum returns can be

[10]We show later that earnings momentum actually demonstrates stronger persistence than price momentum when the momentum portfolios are held over 2 years.

explained by pricing factors.[11] The last two columns in Panel A of Table 81.4 list the risk-adjusted returns to revenue momentum, which remain significant. The market risk premium, size factor, and book-to-market factor, while serving to capture partial effects of the revenue momentum strategy, are still unable to explain away abnormal returns entirely. The FF-3 factor adjusted return for 6 months remains strong at 0.79 % with a *t*-statistic equal to 7.32. The risk-adjusted returns to earnings momentum and price momentum in Panels B and C of Table 81.4 are similar to those in the literature (see Jegadeesh and Titman 1993; and Chordia and Shivakumar 2006) and generally confirm the conclusion of Fama (1998) that post-earnings-announcement drift and price momentum profits remain significant.

81.5 Interrelation of Revenue, Earnings, and Price Momentum

We further examine the interrelation of momentum strategies through tests of dominance, cross-contingencies, and combined strategies. The objective is to find empirical support for hypotheses for our two research questions. First, we hypothesize that revenue surprises, earnings surprises, and prior returns each have some exclusive information content that is not captured by the market. Under this hypothesis, a particular univariate momentum strategy should not be subsumed by another strategy, which we examine through dominance tests. Second, we hypothesize that the market not only underreacts to individual firm information, but also underestimates the significance of the joint implications of revenue, earnings, and price information. Under this hypothesis, return anomalies are likely to be most pronounced when the information variables all point in the same direction.

81.5.1 Testing for Dominance Among the Momentum Strategies

To tackle the interrelation of momentums, we first explore whether any of the three momentum strategies is entirely subsumed by another strategy. Stock price represents the firm value evaluated by investors in the aggregate, given their available information. The most important firm fundamental information for investors is undoubtedly firm earnings, which summarize firm performance. Jegadeesh and Livnat (2006b) point out that an important reference for investors regarding the persistence of firm earnings is offered by firm revenue information. Obviously, these three pieces of firm-specific information, revenue, earnings and stock price, share significant information content with each other. The anomalies of their corresponding momentums therefore may arise from common sources. That is, payoffs to a momentum strategy based on one measure, being revenue

[11] We obtain monthly data on market return, the risk-free rate, and SMB and HML from Kenneth French's website (http://mba.tuck.dartmouth.edu/pages/faculty/ken.french/).

surprises, earnings surprises, or prior returns, may be fully captured by another measure. The dominance tests serve to test for such a possibility.

We first apply the pairwise nested comparison model introduced by George and Hwang (2004) and test whether one particular momentum strategy dominates another. Table 81.5 reports the results in three panels. Panel A compares the revenue momentum and earnings momentum strategies. In Panel A.1, stocks are first sorted on earnings surprises, with each quintile further sorted on revenue surprises. We find that, when controlling for the level of earnings surprises, the revenue momentum strategy still yields significant profits. The zero-investment portfolio returns for 6-month holding periods range from 0.26 % to 0.36 %. In Panel A.2, stocks are first sorted on revenue surprises, and then on earnings surprises. Likewise, the returns to an earnings momentum strategy, when controlling for the level of revenue surprises, are still significantly positive. These paired results indicate that neither earnings momentum nor revenue momentum dominates one another.

We follow the same process in comparing revenue momentum and price momentum strategies. Results in Panel B indicate that all the nested revenue momentum strategies and the nested price momentum strategies are found profitable, with the exception of revenue momentum in the loser stock group. In general, we still conclude that neither revenue momentum nor price momentum is dominated by the other. Panel C of Table 81.5 presents the results of the nested momentum strategies based on two-way sorts on earnings surprises and prior returns. Returns to all these nested momentum strategies remain significantly positive.

The pairwise nested comparisons suggest that revenue surprises, earnings surprises, and prior returns each convey some unpriced information which is not shared by each other, and therefore further contributes to a momentum effect.

A second approach allows us to simultaneously isolate the returns contributed by each momentum portfolio. Taking advantage of George and Hwang's (2004) model, we implement a panel data analysis with six performance dummies.

$$\begin{aligned} R_{it} = \alpha_{jt} &+ \beta_{1jt} R_{i,t-1} + \beta_{2jt} size_{i,t-1} + \beta_{3jt} R1_{i,t-j} + \beta_{4jt} R5_{i,t-j} \\ &+ \beta_{5jt} E1_{i,t-j} + \beta_{6jt} E5_{i,t-j} + \beta_{7jt} P1_{i,t-j} + \beta_{8jt} P5_{i,t-j} + e_{it} \end{aligned} \tag{81.3}$$

where $j = 1, \ldots, 6$. We first regress firm i's return in month t on control variables and six dummies for the portfolio ranks. We include the previous month return $R_{i,t-1}$ to control for the bid-ask bounce effect and the market capitalization $size_{i,t-1}$ to control for the size effect in the cross-sectional regressions. Momentum portfolio dummies, $R1_{i,t-j}$, $R5_{i,t-j}$, $E1_{i,t-j}$, $E5_{i,t-j}$, $P1_{i,t-j}$, and $P5_{i,t-j}$, indicate whether firm i is included in one or more momentum portfolios based on their scores in month $t - j$. To obtain momentum profits corresponding to the Jegadeesh and Titman (1993) strategies, we average the estimated coefficients of the independent variable over $j = 1, \ldots, 6$, and then subtract the coefficient average for the bottom quintile portfolio from that for the top quintile portfolio. These are the returns

This table presents the results of pairwise nested comparison between momentum strategies. Panel A shows the comparison between revenue momentum and earnings momentum during the period from 1974 to 2009. In each month, stocks are first sorted into five groups by earnings surprises (revenue surprises), then further sorted by revenue surprises (earnings surprises) in each group. All portfolios are held for 6 months. The monthly returns to 10 extreme portfolios and 5 conditional earnings (revenue) momentum strategies are presented. Pair tests are provided under the hypothesis that conditional earnings (revenue) momentum profits are the same. Panel B shows the comparison between revenue and price momentum strategies, and Panel C shows the comparison between earnings and price momentum strategies

contributed by each momentum strategy when the contributions from other momentum strategies are controlled for.

Panel A of Table 81.6 reports the regression results. The returns isolated for revenue momentum, earnings momentum, and price momentum are listed in the last three rows. The results are all significant in terms of either raw returns or FF-3 factor adjusted returns when all months are included or when all non-January months are included. Note, however, that the isolated returns to revenue momentum (R5−R1) and to price momentum (P5−P1) strategies are no longer significantly positive in January. The insignificant returns in January are consistent with the tax-loss-selling hypothesis, proposing that investors sell poorly performing stocks in October through December and buy them back in January (e.g., see Keim 1989; Odean 1998; Grinblatt and Moskowitz 2004).

The overall significant profits contributed by $R5 - R1$ ($E5 - E1$ or $P5 - P1$) indicate market underreactions with respect to the information content of revenue

This table presents returns to relative strength portfolios and momentum strategies. Each month during the period from 1974 through 2009, six cross-sectional regressions are estimated for revenue, earnings, and price momentum strategies:
$R_{it} = \alpha_{jt} + \beta_{1jt}R_{i,t-1} + \beta_{2jt}size_{i,t-1} + \beta_{3jt}R1_{i,t-j} + \beta_{4jt}R5_{i,t-j} + \beta_{5jt}E1_{i,t-j} + \beta_{6jt}E5_{i,t-j} + \beta_{7jt}P1_{i,t-j} + \beta_{8jt}P5_{i,t-j} + e_{it}$,
where R_{it} and $size_{i,t}$ are the return and the market capitalization of stock i in month t; and $R1_{i,t-j}$ ($R5_{i,t-j}$) is the most negative (positive) revenue surprise dummy that takes the value of 1 if revenue surprises for stock i is ranked in the bottom (top) quintile in month $t-j$, and zero otherwise. The dummies with respect to earnings surprises ($E1_{i,t-j}$ and $E5_{i,t-j}$), and the dummies with respect to prior 6 month price returns ($P1_{i,t-j}$ and $P5_{i,t-j}$) are similar to the settings of $R1_{i,t-j}$ and $R5_{i,t-j}$. The estimated coefficients of independent variable are averaged over $j = 1, \ldots, 6$. The numbers reported for raw returns are the time-series average of these averages. The t-statistics calculated from the time series are in parentheses. The risk adjusted returns are intercepts from Fama-French 3-factor regressions on raw returns; their t-statistics are in parentheses. Panel A presents returns to relative strength portfolios and momentum strategies solely belong to each of prior price performance, earnings surprise, and revenue surprises. Panel B presents raw return and conditional returns of price momentum strategy

surprises (earnings surprises or prior price performance) unrelated to the other two information measures. The isolated returns are greatest for price momentum (0.66 %), followed by earnings momentum (0.43 %) and then revenue momentum (0.28 %). This is similar to our earlier results on single-criterion momentum. Such a finding again rejects the existence of a dominating momentum strategy among the three.

We do not find that information leading to revenue momentum or earnings momentum fully captures the price momentum returns. Similar findings are documented by Chan et al. (1996), Heston and Sadka (2008), and Novy-Marx (2012) for the relation between earnings surprises and price momentum. We would like to examine specifically how much of the price momentum can be explained by revenue surprises and/or earnings surprises information. For this reason, we perform similar regressions by including only a subset of portfolio dummies. The results are reported in Panel B of Table 81.6. In the case of raw returns, the return to price momentum without isolating other momentum sources is 0.81 %, while it is only reduced to 0.73 % after controlling for revenue momentum, to 0.70 % after controlling for earnings momentum, and to 0.66 % after controlling for both. In other words, information leading to revenue momentum and earnings momentum each accounts for about 10 % and 14 % of price momentum, and the two pieces of information combined account for just about 19 % of price momentum effects. The results for risk-adjusted returns are similar. This conclusion adds to the large literature attempting to trace the sources of price momentum. Our numbers indicate that the information conveyed by revenue surprises or earnings surprises seems to make only a limited contribution to price momentums.

Results of the pairwise nested comparisons in Table 81.5 and the regression analysis in Table 81.6 both support the hypothesis that revenue surprises, earnings surprises, and prior returns each have some unpriced information content that is exclusive to each measure itself. This conclusion also suggests the possibility that one can improve momentum strategies by using all three information measures.

81.5.2 Two-Way Sorted Portfolio Returns and Momentum Ccross-Contingencies

Here and in the next section, we examine the momentum strategies using multiple sorting criteria. These results serve to answer the research question of whether investors underestimate the implications of joint information of revenue surprises, earnings surprises, and prior returns.

Given that the market usually informs investors with not just a single piece but multiple pieces of firm information, the incremental information content of additional firm data is likely to be contingent upon other information for the stock. Jegadeesh and Livnat (2006b) suggest that the information content of SURGE has implications for the future value of SUE and such information linkage is particularly significant when both measures point in the same direction. Jegadeesh and

Livnat (2006a) further find that the market, including financial analysts, underestimates the joint implications of these measures and thus firm market value.

Our second research question extends Jegadeesh and Livnat (2006b) by additionally considering the information of prior price performance. We hypothesize that return anomalies should be most pronounced when the joint implications of multiple measures are most underestimated by the market, and this likely occurs when all information variables point in the same direction. In addition, a different but related issue is that any momentum profits driven by one measure may well depend on the accompanying alternative information, which we call the *cross-contingencies of momentum*. We use multivariate sorted portfolios to test this hypothesis.

81.5.2.1 Two-Way Sorts on Revenue Surprises and Earnings Surprises

We start by testing the performance of investment strategies based on the joint information of revenue surprises and earnings surprises. We sort stocks into quintiles on the basis of their revenue surprises and then independently into quintiles based on earnings surprises during the 6-month formation period on each portfolio formation date. Panel A of Table 81.7 presents the raw returns of these 25 two-way sorted portfolios. The intersection of R1 and E1, labeled as $R1 \times E1$, is the portfolio formed by the stocks with both the lowest SURGE and the lowest SUE, and the intersection of R5 and E5 labeled as $R5 \times E5$, represents the portfolio formed by the stocks with both the highest SURGE and the highest SUE.

We first note that the next-period returns of the 25 two-way sorted portfolios increase monotonically with SURGE as well as with SUE. The return to the portfolio with a similar level of SURGE increases with SUE (e.g., the return increases from 0.88 % for $R1 \times E1$ to 1.21 % for $R1 \times E5$). Similarly, the payoffs to the portfolio of stocks with a similar level of SUE increase with SURGE (e.g., the return increases from 1.23 % for $R1 \times E5$ to 1.70 % for $R5 \times E5$). That is, stocks that have performed well in terms of revenue and earnings continue to outperform expectations and yield higher future returns.

Panel D of Table 81.7 shows the corresponding risk-adjusted abnormal returns for each of the 5×5 double-sorted portfolios based on SURGE and SUE. The monotonicity we see in raw returns in Panel A persists for the risk-adjusted returns. The most positive abnormal returns are for the portfolio of high-SURGE and high-SUE stocks ($R5 \times E5$) while the most negative abnormal returns are for the portfolio of low-SURGE and low-SUE stocks ($R1 \times E1$). This provides direct and robust evidence that the return anomalies tend to be most pronounced when SURGE and SUE point in the same direction.

The evidence of monotonicity suggests that the market underreaction is at its extreme when different elements of stock performance information signal in the same direction, i.e., the scenarios of $R1 \times E1$ or $R5 \times E5$. These are the scenarios where the information of SURGE and SUE are expected to have the most significant joint implications for firm value, while market underestimation of their joint implications is found to be strongest, leading to the most pronounced return drifts in the next period. This observation is consistent with the suggestion by Jegadeesh and Livnat (2006a, b).

Table 81.7 (continued)

Risk-adjusted returns on portfolios sorted by earnings	0.0036	0.0027	0.0041	0.0051	0.0072		
	(3.25)	(3.64)	(5.61)	(7.07)	(7.05)		
Price-revenue combined momentum strategy: E5 × P5 – E1 × P1						**0.0133**	**(6.09)**

For each month, we form equal-weighted portfolios according to the breakpoints of two of three firm characteristics: a firm's revenue surprises (SURGE), its earnings surprises (SUE), and its prior 6-month stock performance. Panel A and Panel D present raw returns and risk-adjusted returns of the 25 portfolios independently sorted on SURGE and on SUE. The returns of a revenue-earnings combined momentum strategy are obtained by buying the portfolio of the best SURGE stocks and the stocks with the best SUE (SURGE = 5 and SUE = 5) and selling the portfolio of the poorest SURGE stocks and the stocks with the poorest SUE (SURGE = 1 and SUE = 1). Panel B and Panel E present raw returns and risk-adjusted returns of the 25 portfolios independently sorted on SURGE and on prior price performance. The returns of a revenue-price combined momentum strategy is obtained by buying stocks in the portfolio of the best SURGE and the highest price performance and selling stocks in the portfolio of the poorest SURGE and the lowest price performance. Panel C and Panel F present the raw returns and risk-adjusted of the 25 portfolios independently sorted on SUE and on prior price performance. The returns of a earnings-price combined momentum strategy is obtained by buying stocks in the portfolio of the best SUE and the highest price performance and selling stocks in the portfolio of the poorest SUE and the lowest price performance. We also present the arbitrage returns and risk-adjusted arbitrage returns of single sorted portfolios based on the quintiles of price performance, SUE or SURGE at the bottom (and on the right hand side) of each panel for the purpose of comparisons. Risk-adjusted return is the intercept of the Fama-French 3-factor regression where the dependent variable is the arbitrage return or the excess return which is the difference between the raw return and the risk-free rate

Investors may execute various long-short strategies with those 25 portfolios. Those listed in the farthest right column of Panel A indicate earnings momentum returns for stocks with a particular level of SURGE, while those listed in the last row are returns on revenue momentum for stocks with a given level of SUE.[12]

We now examine the cross-contingencies of momentum. The revenue momentum measure is 0.36 % per month in the high-SUE subsample E5 and 0.43 % per month in the low-SUE subsample E1. Meanwhile, the earnings momentum measure is 0.39 % per month in the high-SURGE subsample R5, and 0.49 % per month in the low-SURGE subsample R1. We do not observe significant variations in momentum returns across SUE or SURGE. Panel D shows similar patterns when returns to momentum portfolios are adjusted for size and B/M risk factors. All of the profits generated earnings momentum strategies or revenue momentum strategies remain significantly positive.

81.5.2.2 Two-Way Sorts on Revenue Surprises and Prior Returns

We apply similar sorting procedures based on the joint information of revenue surprises and prior price performance. The results for raw returns as shown in Panel

[12] Similar to Hong et al. (2000), one may characterize the former strategy as earnings momentum strategies that are "revenue-momentum-neutral" and the latter as revenue momentum strategies that are "earnings-momentum-neutral."

B of Table 81.7, generally exhibit a pattern similar to Panel A but with the following differences. Although the future returns still rise with SURGE among the average and winner stocks, they become insensitive to SURGE for loser stocks. A closer look at the return for portfolio $R1 \times P1$ down to the return for portfolio $R5 \times P1$ indicates that loser portfolio returns simply do not vary much with the level of SURGE.

Panel E lists risk-adjusted returns for the 5×5 portfolios sorted on prior returns and SURGE. A similar monotonic pattern, now in relation with SURGE as well as with prior returns, is observed for most of those abnormal returns. That is, stocks that have performed well in terms of revenue (firm fundamental information) and prior returns (firm market information) continue to outperform expectations and yield higher future returns, and vice versa.

As to the cross-contingencies of momentums, the results in Panel B indicate that the revenue momentum strategies executed with winner stocks yield higher returns than those executed with loser stocks. For example, the revenue momentum strategy executed with the most winning stocks yields a monthly return of 0.78 % ($R5 \times P5 - R1 \times P5$), while with the most losing stocks it yields only a monthly return of 0.01 % ($R5 \times P1 - R1 \times P1$). Likewise, the price momentum strategy executed with stocks with greater SURGE yields higher returns than with those with lower SURGE. For example, the price momentum strategy executed with the lowest SURGE stocks yields a monthly return of 0.34 % ($R1 \times P5 - R1 \times P1$), while with the highest SUE stocks it yields a monthly return as high as 1.08 % ($R5 \times P5 – R5 \times P1$). The difference of 0.74 percentage between R1 and R5 subsamples is statistically and economically significant, with price momentum profits more than 200 % higher in R5 than in R1.

These observations suggest that the revenue surprise information is least efficient among winner stocks, producing the greatest revenue drift for the next period, and that the prior return information is least efficient among stocks with the most positive SURGE producing the strongest return continuation. One noteworthy point is that revenue momentum is no longer profitable among loser stocks. Panel E shows similar patterns of momentum cross-contingencies when returns to momentum portfolios are adjusted for size and B/M risk factors.

The message for investment strategy is that prior returns are most helpful in distinguishing future returns among stocks with high SURGE, and the same is true for the implications of revenue surprises for stocks of high prior returns. On the other hand, when a stock is priced unfavorably by the market, the information of revenue surprises does not offer much help in predicting its future returns.

81.5.2.3 Two-Way Sorts on Earnings Surprises and Prior Returns

Panel C of Table 81.7 shows the raw returns for multivariate momentum strategies based on the joint information of earnings surprises and prior returns. Several findings are observed. First, as in the cases shown in Panels A and B, the next-period returns of the 25 two-way sorted portfolios increase monotonically with SUE as well as with prior returns. For example, when a firm has a highly positive earnings surprises (E5) while having had winning stock returns (P5), these two pieces of information together are likely to have particularly strong joint implications for firm value. Such condition leads to an average monthly return as high as 2.01 % in the next 6-month period, possibly attributable to even greater investor underreactions.

Panel F of Table 81.7 shows the risk-adjusted abnormal returns for each of the 5×5 double-sorted portfolios based on SUE and prior returns. The monotonicity we see in raw returns in Panel C persists for the risk-adjusted returns. The most positive abnormal returns are for the portfolio of high-SUE and high-prior-return stocks ($E5 \times P5$) while the most negative abnormal returns are for the portfolio of low-SUE and low-prior-return stocks ($E1 \times P1$).

Looking now at the cross-contingencies between earnings momentum and price momentum, the earnings momentum strategy executed with winner stocks yields higher returns (0.78 %) than that executed with loser stocks (0.30 %), and that the price momentum strategy executed with positive-SUE stocks yields higher returns (0.92 %) than that executed with negative-SUE stocks (0.45 %). Panel F shows risk-adjusted returns for these momentum strategies and reveals a similar pattern as in Panel C for raw returns. Results indicate that the market underreactions to price performance are contingent upon the accompanying earnings performance, and vice versa.

Can we reconcile our results on momentum cross-contingencies with the behavioral explanations for momentum returns? Barberis et al. (1998) observe that a conservatism bias might lead investors to underreact to information and then result in momentum profits. The conservatism bias, described by Edwards (1968), suggests that investors underweight new information in updating their prior beliefs. If we accept the conservatism bias explanation for momentum profits, one might interpret our results as follows.

Investors update their expectations of stock value using firm fundamental performance information as well as technical information, and their information updates are subject to conservatism biases. The evidence of momentum cross-contingencies suggests that the speed of adjustment to market performance information (historical price) is contingent upon the accompanying fundamental performance information (earnings and/or revenue), and vice versa. Our results in Panel B and Panel C of Table 81.7 suggest that stock prices suffer from a stronger conservatism bias from investors and thus delay more in their adjustment to firm fundamental performance information (earnings or revenue) when those stocks experience good news, instead of bad news, as to market performance (prior returns). This then leads to greater earnings or revenue momentum returns for winner stocks than for loser stocks. Similar scenario also leads to greater price momentum returns for high-SUE or high-SURGE stocks than for low-SUE or low-SURGE stocks.

This would mean that investors are subject to a conservatism bias that is asymmetric with respect to good news vis-à-vis bad news. That is, investors tend to be even more conservative in reacting to information on firm fundamental performance (market performance) for stocks issuing good news than those issuing bad news about their market performance (fundamental performance).

81.5.3 Combined Momentum Strategies

The negative results on dominance tests in Table 81.5 and Table 81.6 mean that each of the information variables, SURGE, SUE, and prior returns, at least to some extent, independently leads to abnormal returns. This then suggests that a combined momentum strategy using more than one of these information measures should offer improved momentum profits. While Chan et al. (1996), Piotroski (2000), Griffin et al. (2005), Mohanram (2005), Sagi and Seasholes (2007), Asness et al. (2013), and Asem (2009) have examined the profitability of combined momentum strategies based on other measures, to the best of our knowledge, we offer the first evidence on the profitability of combined momentum strategies using the three most accessible information on firm performance, i.e., prior returns, earnings surprises, and revenue surprises altogether.

81.5.3.1 Bivariate Combined Momentums

Table 81.8 compares and analyzes the combined momentum returns. Panel A shows raw and FF-3 factor adjusted returns to momentum strategies based on one-way, two-way, and three-way sorts. We start with bivariate combined momentums.

If we buy stocks with the highest SURGE and the highest SUE ($R5 \times E5$) while selling stocks with the lowest SURGE and the lowest SUE ($R1 \times E1$), such a *revenue-and-earnings combined momentum strategy* yields a monthly return as high as 0.81 %, which is higher than the univariate momentum return earned solely on the basis of revenue surprises (0.47 %) or earnings surprises (0.58 %) when using quintile portfolios. This result is also a consequence of our observation that the sorted portfolio returns increase monotonically with both SURGE and SUE.

Panel A of Table 81.8 also shows that investors earn an average monthly return of 1.09 % by buying stocks with the highest SURGE and the most winning prior returns ($R5 \times P5$) and selling stocks with the lowest SURGE and the most losing prior returns ($R1 \times P1$). This *revenue-and-price combined momentum strategy* again outperforms the simple revenue momentum (0.47 %) and the simple price momentum strategy (0.72 %). Similarly, an *earnings-and-price combined momentum strategy* offers an average monthly return of 1.18 %, which outperforms the univariate earnings momentum (0.58 %) and the price momentum strategy (0.72 %).

Note that the strategy using SURGE and SUE yields a return (0.81 %) poorer than that using SURGE and prior returns (1.09 %) or that using SUE and prior returns (1.18 %). This suggests that it is important to take advantage of market information (prior returns) as well as firm fundamental information (SURGE and SUE) when it comes to formulation of investment strategies.

81.5.3.2 Multivariate Combined Momentums

Next, we further sort stocks into quintiles independently and simultaneously based on SURGE, SUE, and prior price performance to obtain three-way sorted portfolios. A *revenue-earnings-price combined momentum* strategy is performed by buying the stocks with the most positive revenue surprises, the most positive

Table 81.8 Comparisons of assorted single and combined momentum strategies

This table presents the return contribution by considering additional sorting criterion, being revenue surprises, earnings surprises or prior returns. In the table, ***R***, ***E***, and ***P*** respectively refer to revenue momentum, earnings momentum, and price momentum strategy. Momentum strategies based on combined criteria are indicated with plus signs. For example, ***R* + *P*** denotes *revenue-price combined momentum strategy*, that is, $R5 \times P5 - R1 \times P1$. Panel A summarizes raw returns and risk-adjusted returns obtained from momentum strategies based on one-way sorts, two-way sorts, and three-way sorts. Risk-adjusted return is the intercept of the Fama-French 3-factor regression on raw return. Panel B lists the return contributions of each additional sorting criterion based on the return differences. The associated *t*-statistics are in parentheses. Panel C lists the incremental returns obtained by applying additional two sorting criteria. All returns are expressed as monthly returns.***, **, and * indicate statistical significance at 1 %, 5 %, and 10 %, respectively earnings surprises, and the highest prior returns ($R5 \times E5 \times P5$), and selling the stocks with the most negative revenue surprises, the most negative earnings surprises, and the lowest prior returns ($R1 \times E1 \times P1$). This leads to a monthly momentum return of 1.44 %, which provides the highest investment returns of all the paired momentum strategies discussed so far.

Panels B and C of Table 81.8 present the differences in portfolio performance, which indicate the incremental contribution to momentum portfolio returns from each additional sorting criterion. The results are straightforward. The joint consideration of each additional performance measure, whether it is revenue surprises, earnings surprises, or prior returns, helps improve the profits of momentum strategies significantly. The net contribution from price momentum is the greatest (0.62 %), followed by earnings momentum (0.33 %), and then revenue momentum (0.24 %). This result further supports the argument that revenue, earnings, and price all convey to some extent exclusive but unpriced information.

81.5.3.3 Dependent Sorts Versus Independent Sorts

With highly correlated sorting criteria, as indicated in Table 81.2, independent multiple sorts may result in portfolios with limited numbers of stocks and therefore insufficient diversification. This will then lead to results that might be confounded by factors other than the intended sorting features. More important, only dependent sorts provide a way to identify the precise conditional momentum returns.

Table 81.9 presents the returns and the associated *t*-statistics for two-way and three-way sorted combined momentum strategies using independent sorts and dependent sorts in different orders. For two-way sorted combined momentum strategies, dependent sorts are found to generate returns that are insignificantly different from those from independent sorts. For three-way sorted combined momentum strategies, however, the results are found to vary significantly with the sorting method. The three-way dependent sorts, in any order, yield investment strategies that significantly outperform those using independent sorts; independent sorts create an average monthly return of 1.44 %, while dependent sorts lead to an average monthly return ranging from 1.66 % to 1.89 %. Yet to take advantage of a more simplified presentation, we report results from only independent sorts in Tables 81.7 and 81.8. Note that the general conclusions we have drawn remain unchanged with dependent sorts.

81.6 Persistency and Seasonality

81.6.1 Persistence of Momentum Effects

We next examine the persistence of momentum effects driven by revenue surprises, earnings surprises, and prior price performance. Stock prices tend to adjust slowly to information, and abnormal returns will not continue once information is fully incorporated into prices. Following the argument of conservatism bias (see Edwards 1968; and Barberis et al. 1998), an examination of the persistence of

Table 81.9 Returns of combined momentum strategies – a comparison between dependent sorts and independent sorts

This table presents returns and the associated *t*-statistics from two-way and three-way sorted combined momentum strategies, which are formed using independent sorts or dependent sorts. A momentum strategy formed on the basis of multiple criteria, which we call combined momentum strategy, is said to apply independent sorts if portfolios are independently sorted into quintiles according to their SURGE, SUE, and prior price performance, with the partition points being independent across these criteria. A combined momentum strategy is said to apply dependent sorts if portfolios are sorted into quintiles according to their SURGE, SUE, and prior price performance, with a particular sorting order. For example, a two-way sorted momentum strategy based on SURGE and SUE using dependent sorts could be formed by first sorting on SURGE then on SUE (*SUE*/*SURGE*) or first sorting on SUE then on SURGE (*SURGE*/*SUE*). We present here the returns of momentum strategies following all possible sequences of two-way dependent sorts and three-way dependent sorts.***, **, and * indicate statistical significance at 1 %, 5 %, and 10 %, respectively momentum returns will reveal the speed of adjustment in reaction to revenue surprises, earnings surprises, and prior returns. More interestingly, the variations of persistence in conditional momentums will demonstrate how one element of information (e.g., revenue surprises) affects the speed of adjustment to another (e.g., prior returns).

Table 81.10 presents the cumulative returns from revenue, earnings, and price momentum strategies. The formation period is kept at 6 months, and the cumulative returns are calculated up to 36 months after the event time. Panel A shows that the zero-investment portfolios built upon revenue surprises maintain their return momentum for 6 months. The buy-and-hold returns drop to insignificance 21 months after the portfolio formation. In Panel B, the profits of earnings momentum portfolios, although are not as high as on price momentum in the short term, demonstrate greater persistence than price momentum, with the cumulative returns continuing to drift upward for 25 months after portfolio formation. The cumulative returns still remain significant at 4.65 % 3 years after portfolio formation. Panel C shows that the profits to price momentum portfolio drift upward for 11 months after portfolio formation and start to reverse thereafter. The cumulative returns remain significant at 3.22 % on monthly terms 36 months after portfolio formation.

Figure 81.1 compares the cumulative returns to those three univariate momentum strategies. Price momentum generates the highest cumulative returns in the short term (for a 1 year holding period), while earnings momentum demonstrates the most persistent performance, as cumulative returns continue to grow up to 2 years after portfolio formation. On the other hand, the payoffs to revenue momentum seem to be neither as persistent nor as strong as the other two strategies.

Figure 81.2 presents the cumulative returns for momentum strategies conditional on alternative performance measures. Figure 81.2a, b present the cumulative returns of revenue momentum conditional on high-low SUEs and prior returns. They show that the revenue momentums remain short-lived, regardless of the level of SUE or the level of prior returns. The portfolio returns to a revenue momentum strategy with loser stocks not only quickly dissipate in the short term and actually reverse to negative returns starting 7 months after portfolio formation.

Figure 81.2c, d demonstrate the cumulative returns for earnings momentums conditional on high-low SURGE and prior returns. Figure 81.2c shows that the earnings momentum returns remain similar for the low-SURGE and the high-SURGE stocks during the first 20 months after portfolio formation. Such finding of momentum contingencies in fact conforms to our results in Panel A of Table 81.8. More interesting, as we hold the portfolio for over 20 months, the earnings momentum strategy with low-SURGE stocks starts deteriorating while the strategy with high-SURGE stocks still maintain significantly positive returns up to 36 months after the portfolio formation. Figure 81.2d, on the other hand, shows that earnings momentum effects are both greater and longer-lasting for winner stocks than for loser stocks. The caveat on investment strategy is that earnings momentum returns are higher and more longer-lived when applied over stocks with superior price history in the past 6 months.

This table reports the cumulative returns of zero-cost momentum portfolio in each month following the formation period. *t* is the month after portfolio formation. Three different momentum strategies are tested. The sample period is from 1974 through 2009. Panel A reports the results from the revenue momentum strategy, where sample firms are grouped into five groups based on the measure SURGE during each formation month. The revenue momentum portfolios are formed by buying stocks with the most positive SURGE and selling stocks with the most negative SURGE. Listed are the cumulative portfolio returns for the portfolio with the most negative SURGE, the portfolio with the most positive SURGE, and the revenue momentum portfolio. Panel B reports the results from the earnings momentum strategy, where firms are grouped into five groups based on the measure SUE during each formation month. The earnings momentum portfolios are formed by buying stocks with the most positive SUE and selling stocks with the most negative SUE. Listed are the cumulative portfolio returns for the portfolio with the most negative SUE, the portfolio with the most positive SUE, and the earnings momentum portfolio. Panel C reports the results from the price momentum strategy. The price momentum portfolios are formed by buying Quintile 1 (winner) stocks and selling Quintile 5 (loser) stocks on the basis of previous 6 months returns. Listed are the cumulative portfolio returns for the loser portfolio, the winner portfolio, and the price momentum portfolio.***, **, and * indicate statistical significance at 1 %, 5 %, and 10 %, respectively

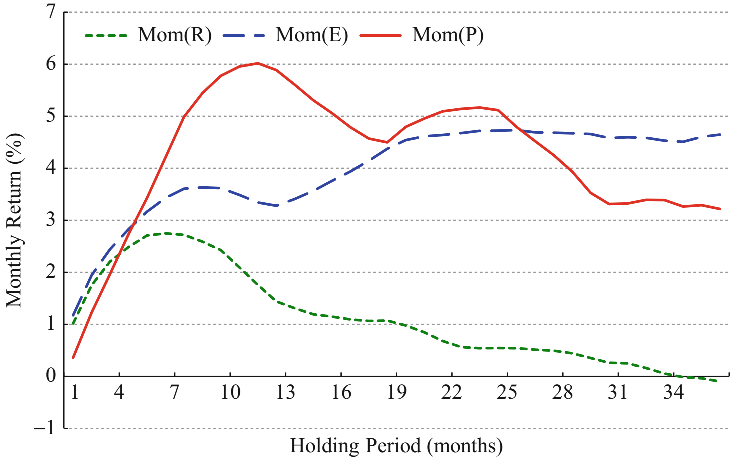

Fig. 81.1 Persistence of momentum effects. This figure shows the average cumulative returns of relative strength portfolios with respect to revenue surprises, earnings surprises, and prior price performance. The relative strength portfolio is buying stocks in highest quintile and selling stocks in lowest quintile on every formation date, and holding for 36 months. The cumulative returns are calculated by adding monthly returns from formation month t to month $t + i$

In Figure 81.2e, f, price momentum strategies yield higher and more persistent returns for stocks with positive SUE or SURGE than for stocks with negative SUE or SURGE. A comparison of Fig. 81.2e, f also finds that high-SURGE serves as a more effective driver than high-SUE for stocks to exhibit greater and more persistent price momentum.

These observations on momentum persistence provide further support for our claim on momentum cross-contingencies. We find that the persistence of a momentum, just like the magnitude of the momentum returns, depends on the accompanying condition of another firm information. Such cross-contingencies are again not as strong in the relation between revenue momentum and SUE or between earnings momentum and SURGE, as shown in Fig. 81.2a, c. Results suggest that investors update their expectations based on the joint information of revenue surprises, earnings surprises, and prior price performance, and the speed of adjustment to firm fundamental information (SURGE or SUE) depends on the prevailing content of firm market information (prior returns), and vice versa.

81.6.2 Seasonality

Jegadeesh and Titman (1993), Heston and Sadka (2008), Asness et al. (2013), Novy-Marx (2012), and Yao (2012) find that prior return winners outperform losers in all months except January, leading to positive profits for a price momentum

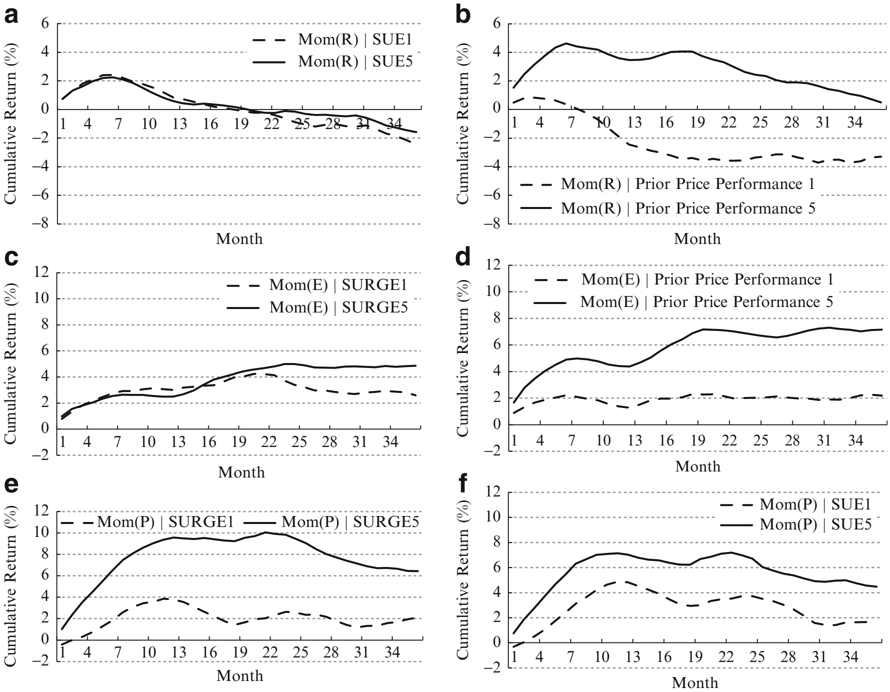

Fig. 81.2 **Cumulative returns of momentum effect conditional on performance measure**. These figures show the average cumulative returns of relative strength portfolio with respect to revenue surprises, earnings surprises, and prior price performance conditional on one another. The holding period is up to 36 months. The cumulative profits are calculated by adding monthly returns from formation month t to month $t + i$. (**a**) Cumulative returns of revenue momentum conditional on SUE. (**b**) Cumulative returns of revenue momentum conditional on prior price performance. (**c**) Cumulative returns of earnings momentum conditional on SURGE. (**d**) Cumulative returns of earnings momentum conditional on prior price performance

strategy in all months except January but negative profits for that strategy in January. Chordia and Shivakumar (2006) also find significant seasonality effects in returns to the earnings momentum strategy. Do a revenue momentum strategy and combined momentum strategies exhibit similar seasonalities?

Table 81.11 presents results for tests of seasonal patterns in returns to univariate momentum strategies and combined momentum strategies. For all types of momentum strategies, momentum profits in January are either negative or insignificantly different from zero. F-tests reject the hypothesis that the returns to momentum strategies are equal in January and non-January months. We therefore conclude that, as in finding elsewhere, there is seasonality in momentum strategies, and revenue surprises, earnings, surprises, and prior returns all yield significantly positive returns only in non-January months.

Table 81.11 Returns of momentum strategies in january and non-january months

Momentum Strategies	All months	Jan.	Feb.–Dec.	F-Statistic	p-Value
***Mom*(*R*)**	0.0047***	−0.0061	0.0057***	31.66	<0.01

	(6.06)	(−1.11)	(7.26)		

This table presents average monthly returns and the associated t-statistics for the returns obtained from single momentum strategies, two-way sorted combined momentum strategies, and two-way sorted combined momentum strategies for all calendar months, for January, and for non-January months. The F-statistics and p-values are computed under the hypothesis that the returns to momentum strategies are equal in January and non-January months. ***, **, and * indicate statistical significance at 1 %, 5 %, and 10 %, respectively

81.7 Conclusions

This study focuses on the three firm performance information that receive most attentions from investors – revenue, earnings and price. We attempt to understand how investors incorporate those information variables altogether in stock prices. Multivariate momentums are therefore used as a venue in the exploration. We provide new evidence that a revenue momentum strategy yields an average monthly return of 0.61 %, and remain significant after adjustment for market factor and FF-3 factors. Compared to the results of price momentum and earnings momentum, revenue momentum is less profitable and relatively short-lived.

Dominance tests show that none of the three momentum strategies generate returns that can be fully captured by the information driving an alternative strategy. This finding answers our first research question, and suggests that revenue surprises, earnings surprises, and prior returns each carry some unpriced information that is exclusive to itself. In particular, the information conveyed by revenue surprises and/or earnings surprises only makes a limited contribution to price momentum. The overall evidence indicates that while revenue serves as a base for a firm's earnings and stock valuation, revenue momentum neither drives nor rides earnings or price momentum.

Our second research question inquires how investors process the joint implications of multiple firm performance information. The results from double sorted portfolios find that next-period returns increase monotonically with each information variable, and the highest (lowest) abnormal return occurs for stocks receiving the best (worst) news in both variables. We further observe cross-contingencies of momentum profits in that momentum returns driven by fundamental performance information (SUE or SURGE) are positively associated with the accompanying market performance information (prior returns), and the reverse holds as well. For example, earnings/revenue momentum strategies with winner stocks yield higher returns than with loser stocks; a price momentum strategy with stocks with higher SURGE/SUE yields higher returns than with lower SURGE/SUE stocks. This pattern would mean that investors are subject to a conservatism bias that is asymmetric with respect to good news vis-à-vis bad news. The above findings are consistent with the claim that investors underestimate the joint implications of revenue surprises, earnings surprises, and prior returns, particularly when they point in the same direction. The speed of adjustment to firm fundamental information also depends on the accompanying market information, and vice versa.

The persistence of profitability also varies amongst the three momentums and exhibits inter-dependency. An earnings momentum strategy is found to present the strongest persistence, while the revenue momentum strategy is the shortest-lived among the three, except when the strategy is executed over price winner stocks. In general, the speed of adjustment to firm fundamental information also depends on the accompanying market information, and vice versa. Exploiting sources of momentums from three information variables altogether, a combined momentum strategy using independent sorts yields a monthly return of 1.44 %, amounting to an annual return as high as 17.28 %. The net contribution from prior return information is the greatest, followed by earnings surprises, and then revenue surprises.

Revenue, earnings, and historical prices are the most readily available firm performance information that investors use for stock evaluation. The pricing effect from investors' joint consideration of revenue, earnings, and prior returns is yet well explored in the finance literature. Our results are serving as useful guidance for asset managers identifying profitable investment strategies and for financial economists understanding the source of momentums in future research.

Appendix: A Measures of Earnings and Revenue Surprises

The literature provides a variety of measures to estimate earnings and revenue surprises. There are generally two approaches to building the measures; one is based on historical earnings/revenue data and the other on analysts' forecasts.

The empirical literature demonstrates consistent post-earnings-announcement drift, whichever method is used to measure the earnings surprises. For example, Foster et al. (1984) and Bernard and Thomas (1989) assume that the differences in quarterly earnings per share follow an AR(1) process, and find that firms with highly unexpected earnings outperform firms with poor unexpected earnings. Chan et al. (1996) analyze earnings momentum effects by applying three different earnings surprise measures built upon a seasonal random walk model, cumulative abnormal stock returns around the announcement date, and changes in analyst earnings forecasts. Jegadeesh and Livnat (2006a) use a seasonal random walk model with a drift and an analysts' forecast model to estimate earnings surprises, and find both approaches can capture the drift following earnings surprises.

Empirical research however finds inconsistent results as to whether revenues or expenses provide added information content over earnings, mostly thanks to the different measures being applied (e.g., see Hopwood and McKeown 1985; Swaminathan and Weintrop 1991; Ertimur et al. 2003; Rees and Sivamakrishnan 2001; Jegadeesh and Livnat 2006b). There are particular advantages and disadvantages when it comes to estimating expected earnings/revenues according to historical data or analyst forecast data. Considering that Compustat reports only restated accounting data, historical data on earnings/revenues might suffer a look-ahead bias to the extent that some input data are not available at the time we calculate earnings and revenue surprises. The analyst forecast approach has the advantage that it does not suffer from a potential look-ahead bias problem, and allows us to include in our sample young firms that do not have the accounting data required by the historical data approach. Its major disadvantage is that a sample will be limited to firms with analyst forecast data available.

Our study requires not only earnings forecast data but also revenue forecast data, which are not available from IBES until 1996, although even after 1996 many IBES sample firms still lack revenue forecasts. With such a restriction, the empirical results might be biased and lose their generality. Weighing the pros and cons, we elect to borrow the approach of Jegadeesh and Livnat (2006a, b) and measure earnings surprises and revenue surprises on the basis of historical earnings and revenues.

Specifically, we follow Jegadeesh and Livnat (2006b) and assume that quarterly earnings per share follow a seasonal random walk with a drift. We use the earnings per share in the same quarter of the previous year, instead of earnings per share in the previous quarter, to proxy for the earnings expectation; this approach takes into account the seasonality of earnings. We also accommodate a possible trend in earnings growth by including a drift term in the expected earnings. The drift term, $\delta^E_{i,t}$, is calculated from the average growth of previous eight quarters. Expected quarterly earnings per share for firm i and quarter t are estimated by

$$E\left(Q^E_{i,t}\right) = Q^E_{i,t-4} + \delta^E_{i,t} \tag{81.4}$$

and

$$\delta^E_{i,t} = \frac{\sum_{j=1}^{8}\left(Q^E_{i,t-j} - Q^E_{i,t-j-4}\right)}{8}. \tag{81.2}$$

The estimator for the standard deviation of quarterly earnings growth, $\sigma^E_{i,t}$, for computing earnings surprises is

$$\sigma^E_{i,t} = \frac{1}{7}\sqrt{\sum_{j=1}^{8}\left[Q^E_{i,t-j} - E\left(Q^E_{i,t-j}\right)\right]^2}. \tag{81.6}$$

We therefore define our measure of SUE for i in quarter t as Eq. 81.1 in the text:

$$SUE_{i,t} = \frac{Q^E_{i,t} - E\left(Q^E_{i,t}\right)}{\sigma^E_{i,t}}. \tag{81.1}$$

The same method is applied to measure revenue surprises. To deal with possible seasonal effects and trend effects in quarterly revenues, we again assume the quarterly revenue follows a seasonal random walk with a drift. That is, the expected quarterly revenue per share and the drift term are estimated as:

$$E\left(Q^R_{i,t}\right) = Q^R_{i,t-4} + \delta^R_{i,t} \tag{81.7}$$

and

$$\delta^R_{i,t} = \frac{\sum_{t=1}^{8}\left(Q^R_{i,t-j} - Q^R_{i,t-j-4}\right)}{8}. \tag{81.8}$$

For computing revenue surprises, the standard deviation of quarterly revenue growth is estimated by the year-to-year growth of revenue for the prior eight quarters:

$$\sigma^R_{i,t} = \frac{1}{7}\sqrt{\sum_{j=1}^{8}\left[Q^R_{i,t-j} - E\left(Q^R_{i,t-j}\right)\right]^2}. \tag{81.9}$$

Therefore the measure of revenue surprises is defined as Eq. 81.2 in the text:

$$SURGE_{i,t} = \frac{Q^R_{i,t} - E\left(Q^R_{i,t}\right)}{\sigma^R_{i,t}}. \tag{81.2}$$

are irregular substantial price fluctuations. The VG-NGARCH model imposes a nonlinear asymmetric structure on the conditional shape parameters in a variance-gamma process, which describes the arrival rates for news with different degrees of influence on price movements and provides an ex ante probability for the occurrence of large price movements. On the other hand, the GARJI model, a mixed GARCH-jump model proposed by Chan and Maheu (Journal of Business & Economic Statistics 20:377–389, 2002), adopts two independent autoregressive processes to model the variances corresponding to moderate and large price movements, respectively. An empirical study using daily stock prices of four major banks, namely, Bank of America, J.P. Morgan Chase, Citigroup, and Wells Fargo, from 2006 to 2009 is performed to compare the two models. The goodness of fit of the VG-NGARCH model vs. the GARJI model is demonstrated.

Keywords
VG-NGARCH model • GARCH-jump model • Autoregressive conditional jump intensity • GARJI model • Substantial price fluctuations • Shape parameter • Variance-gamma process • Ex ante probability • Daily stock price • Goodness of fit

82.1 Introduction

To model asset returns, the following two frequently observed circumstances must be recognized: the volatility clustering and the leverage effect (Nelson 1991; Campbell and Hentschel 1992; Engle and Ng 1993). The two phenomena have led to the development of the family of nonlinear asymmetric GARCH models in financial forecasting and derivatives pricing (Nelson 1991; Engle and Ng 1993; Glosten et al. 1993; Ding et al. 1993). Nevertheless, Gaussian distributed return innovations in conventional ARCH-/GARCH-type models are unable to capture irregular substantial price fluctuations resulting from extreme news reports, even when the heteroskedasticity in the conventional ARCH-/GARCH-type models has been taken care.

To account for both normal and large price movements, a mixed GARCH-jump model that combines a GARCH-type model with a Poisson jump process for the dynamics of log-returns was first proposed by Jorion (1988). Later, complicated mixed GARCH-jump models that consider jumps in both log-returns and volatilities were developed by Duffie et al. (2000), Pan (2002), Eraker et al. (2003), and Eraker (2004). The mixed GARCH-jump model with autoregressive jump intensity (GARJI), proposed by Chan and Maheu (2002), is a more advanced mixed GARCH-jump model, of which the conditional variance of asset returns is divided into two parts corresponding to moderate and large price movements resulting from normal and extreme news events, respectively. The dynamics of the two variances in a discrete-time setting are sketched by two conditionally independent autoregressive processes (Chan and Maheu 2002; Maheu and McCurdy 2004).

Instead of a jump-diffusion process in the mixed GARCH-jump model with a continuous sample path for the asset price dynamics, the VG-NGARCH model is a GARCH-type model that uses a variance-gamma (VG) process, a pure jump process having finite sum of absolute price movements during a defined time frame, to model the price dynamics to avoid the problem that the sum of absolute price movements during a finite time period is infinite. As pointed by Madan et al. (1998), the VG process is a purely jump Levy process of infinite activities characterizing a “high” arrival rate of jumps of different sizes and will adequately allow us to dispense with the need to consider the variant influences of news reports on the magnitude of price movements (Andersen 1996; Clark 1973; Ross 1989). With the VG process, the VG-NGARCH model captures the volatility clustering and the leverage effect by modeling the VG process’s shape parameter in a nonlinear asymmetric autoregressive process. For this reason, the VG-NGARCH model is more informative and parsimonious compared to the GARJI model. The specification of a VG process is given in Appendix 1.

The goodness of fit of the VG-NGARCH and the GARJI model to the log of stock price returns of four major banks listed in the S&P 500 are given. Since latent random business times are introduced into the VG framework, to find parameter estimates, Monte Carlo expectation-maximization (MCEM) algorithm together with the Metropolis algorithm are implemented. The two estimation approaches are given in Appendix 2.

The structure of this article continues as follows. In Sect. 82.2, the two GARCH-type models, namely, the VG-NGARCH and the GARJI models, are introduced. In Sect. 82.3, results of the empirical study and the performance of the two types of GARCH models are presented and compared. Finally, a concluding remark is made on Sect. 82.4.

82.2 Model Specifications

This section gives introduction and specifications for the GARJI model and the VG-NGARCH model.

82.2.1 GARJI Model

Chan and Maheu (2002) proposed a GARCH-jump model with autoregressive conditional jump intensity, i.e., the GARJI model, in which the conditional variance of return innovations is divided into two distinct modules that define smooth and steep fluctuations in price driven by normal and extreme news events, respectively. The GARJI model employs two conditionally independent autoregressive processes for the two components in a discrete-time economy in which the trading period

$[0, T]$ is partitioned into T subintervals $(0, 1], (1, 2], \ldots, (T-1, T]$. The dynamics of the log-return $Y_t = \ln(S_t/S_{t-1})$ are as follows:

$$Y_t = \mu + \varepsilon_t, \quad t = 1, \ldots, T. \tag{82.1}$$

Here the return innovation ε_t is partitioned into two independent components $\varepsilon_{1,t}$ and $\varepsilon_{2,t}$ corresponding to normal and unusual price movements, respectively. Let $\mathcal{F}_{t-1}$ be the information set available at time $t-1$. Conditional on $\mathcal{F}_{t-1}$, the innovation from normal price movement

$$\varepsilon_{1,t}|\mathcal{F}_{t-1} \sim N\left(0, \sigma_t^2\right) \tag{82.2}$$

is normally distributed with the conditional variance, $\sigma_t{}^2$, being parameterized by a GARCH function of the previous return innovation ε_{t-1} as

$$\sigma_t^2 = a_0 + a_1(\varepsilon_{t-1} - c)^2 + a_2\sigma_{t-1}^2. \tag{82.3}$$

The parameters employed for the GARCH function are based on the work of Chan and Maheu (2002) and Maheu and McCurdy (2004), albeit in a more simplified range that accommodates the asymmetric feedback from positive through negative news while allowing for the ex post evaluation of the expected number of jumps through the interval $(t-2, t-1]$ as a result of the information set $\mathcal{F}_{t-1}$ at time $t-1$. The second component, $\varepsilon_{2,t}$, represents the jump innovation and is the discrepancy between the total jump size and the expected total jump size of the n_t jumps during $(t-1, t]$, i.e.,

$$\varepsilon_{2,t} = \sum_{j=1}^{n_t} U_{t,j} - \theta\lambda_t,$$

where $U_{t,j}$ is the jth jump size being normally distributed with mean θ and standard deviation δ and n_t denotes the number of jumps distributed according to Poisson with an autoregressive conditional jump intensity (ARJI)

$$\lambda_t = \lambda_0 + \rho\lambda_{t-1} + \gamma\xi_{t-1}. \tag{82.4}$$

The intensity residual, $\xi_{t-1} = \mathrm{E}(n_{t-1}|\mathcal{F}_{t-1}) - \lambda_{t-1}$, is defined as the difference between the filter expected number of jumps given $\mathcal{F}_{t-1}$, $\mathrm{E}(n_{t-1}|\mathcal{F}_{t-1})$ and the previous intensity λ_{t-1}. The probabilities of jumps to fluctuate periodically and cluster with a persistence parameter of $0 < \rho < 1$ are afforded by specifying the conditional intensity. The conditional density of the log-return Y_t given the information set $\mathcal{F}_{t-1}$ is

$$f(Y_t|\mathcal{F}_{t-1}) = \sum_{n_t=0}^{\infty} f(Y_t|n_t, \mathcal{F}_{t-1}) \frac{e^{-\lambda_t}\lambda_t^{n_t}}{n_t!}, \tag{82.5}$$

where the conditional probability density $f(Y_t|n_t, \mathcal{F}_{t-1})$ is

$$\frac{1}{\sqrt{2\pi\left(\sigma_t^2 + n_t\delta^2\right)}}\exp\left(-\frac{(Y_t - \mu + \theta\lambda_t - \theta n_t)^2}{2\left(\sigma_t^2 + n_t\delta^2\right)}\right).$$

From Eqs. 82.1 to 82.5, it is clear that the main feature of GARJI model is the inclusion of both normal and extreme return innovations. Because these two types of innovations certainly affect future volatility differently. Nevertheless, it is impossible to identify the cutoff point between normal and extreme price movements by observing the log-returns. Consequently, only an ex post probability for the number of jumps, n_t, from the information set $\mathcal{F}_{t-1}$ at time t can be acquired, as n_t is non-observable. The ex post probability for n_t jumps given $\mathcal{F}_{t-1}$ is

$$P(n_t|\mathcal{F}_t) = \frac{f(Y_t|n_t, \mathcal{F}_{t-1})}{f(Y_t|\mathcal{F}_{t-1})} \times \frac{e^{-\lambda_t}\lambda_t^{n_t}}{n_t!}. \tag{82.6}$$

82.2.2 VG-NGARCH Model

To model stock price dynamics, Madan and Seneta (1990), Madan and Milne (1991), Madan et al. (1998), Carr et al. (2003), and Geman et al. (2001) considered the use of a VG process. In the following the specification of log-returns in terms of a VG process is given in a discrete-time setting. For $t = 1,\ldots, T$, the time-t log-return $Y_t = \ln(S_t/S_{t-1})$ can be formulated as

$$Y_t = m + \phi_t + \theta g_t + \varepsilon_t \tag{82.7}$$

where m denotes the mean of instantaneous return rate, g_t denotes a gamma-distributed random time change during the interval $(t - 1, t]$, and ϕ_t denotes a time-varying parameter. The specification of a VG process is given in Appendix 1. Because of the characteristics of the VG process, the return innovation ε_t is conditionally Gaussian distributed as

$$\varepsilon_t|\mathcal{F}_{t-1} \sim N\left(0, \sigma^2 g_t\right). \tag{82.8}$$

It is worth noting that the conditional variance of the innovation ε_t depends on g_t during the interval $(t - 1, t]$. To accommodate the volatility clustering effect, the random time change g_t is considered to be gamma-distributed with a time-varying shape parameter v_t, specifically

$$g_t|\mathcal{F}_{t-1} \sim \text{gamma}(v_t, 1). \tag{82.9}$$

It is further assumed that the shape parameter v_t follows a nonlinear asymmetric NGARCH (1,1) process that depends on the previous return innovation ε_{t-1} and shape parameter v_{t-1}, respectively. The relation among them is as follows:

$$v_t = a_0 + a_1\left(\varepsilon_{t-1} - c\sqrt{v_{t-1}}\right)^2 + a_2 v_{t-1}, t \geq 1 \tag{82.10}$$

where $c>0$. The time-varying parameter ϕ_t in Eq. 82.7 is defined to be

$$\phi_t = v_t \ln\left(1 - \theta - \frac{1}{2}\sigma^2\right). \tag{82.11}$$

The skewness and kurtosis of log-return at time t are functions of the drift parameter θ, volatility σ, and the first four moments of the shape parameter v_t, which depend on the NGARCH parameters $\boldsymbol{\alpha} = (a_0, a_1, a_2, c)$. The skewness and kurtosis functions are given in Appendix 3. According to the skewness and kurtosis functions, the sign of the skewness relies on the sign of the drift parameter θ. Moreover, if $a_0 > 0$ and $a_1(\sigma^2 + c^2) + a_2 < 1$, then shape parameter becomes stationary, and

$$v_\infty = \lim_{t\to\infty} E(v_{t+1}) = a_0\left[1 - \left(\sigma^2 + c^2\right)a_1 - a_2\right]^{-1}. \tag{82.12}$$

From Eq. 82.18, the proposal transition density $\boldsymbol{f}$ of the target distribution, i.e., the posterior distribution $p(\boldsymbol{g}|\boldsymbol{Y};\boldsymbol{\Theta})$, is chosen to be the distribution of T independent gamma random variables with shape parameters $v_1 - 0.5, \ldots, v_T - 0.5$, respectively, and scale parameter $1/\kappa$. Specifically,

$$\boldsymbol{f} \propto \prod_{t=1}^{T} \exp(-\kappa g_t + (v_t - 1.5)\log(g_t)).$$

At the lth iteration of the independent Metropolis chain algorithm, a random sample of time changes $\boldsymbol{g} = (g_1, \ldots, g_T)'$ is drawn from the proposed transition density $\boldsymbol{f}$. The random sample $\boldsymbol{g}$ is accepted and $\boldsymbol{g}^{(l)} = \boldsymbol{g}$ with probability

$$\min\left\{\exp\left[-\sum_{t=1}^{T}\left(\frac{\delta_t}{g_t} - \frac{\delta_t}{g_t^{(l-1)}}\right)\right], 1\right\}; \tag{82.13}$$

otherwise, $\boldsymbol{g}^{(l)} = \boldsymbol{g}^{(l-1)}$.

82.3 Empirical Study

Due to the extended periods of market instability experienced by banks as a consequence of the extreme news reports associated with the 2008 financial crisis, this study selects four big commercial banks listed in the S&P 500, namely,

Table 82.1 Correlations of daily log-returns

Bank	Bank of America	J.P. Morgan	Citigroup	Wells Fargo
Bank of America	1	0.81168	0.80231	0.84943
J.P. Morgan Chase		1	0.71070	0.84059
Citigroup			1	0.71889
Wells Fargo				1

the Bank of America (BAC), J.P. Morgan Chase (JPM), Citigroup (Citi), and Wells Fargo (WF), to study their stock price dynamics. Daily price data including intraday highs and lows, and adjusted close prices, are collected from January 3, 2006 to December 31, 2009. Table 82.1 lists the correlation coefficients among them. Since all correlation coefficients exceed 0.7, their price movements are highly correlated. Table 82.2 lists the mean, standard deviation, skewness, and kurtosis for log-returns of the four banks.

82.3.1 Estimation and Validation

Parameter estimates and log-likelihood of the VG-NGARCH model for each bank are given in Table 82.3. Besides model fitting, two testing procedures were conducted and the results are also contained in Table 82.3.

The first one with the null hypothesis, H_0: $a_1 = a_2 = c = 0$, helps us to determine whether the VG-NGARCH model can be reduced to a simpler model, i.e., the VG model by Madan et al. (1998). Based on the likelihood ratio test, the autoregressive shape dynamics are strongly favored for all banks over the VG model with constant shape parameter. The second testing procedure is the Ljung-Box test, with H_0 describing the randomness of residuals. To compute Ljung-Box Q statistic, the lag is set to be 25, and the large p-values for all banks, as shown in Table 82.3, indicate that there is no significant serial correlation remaining among the residuals for all banks after their log-returns were fitted by the VG-NGARCH model.

Parameter estimates and log-likelihood of GARJI for each bank are given in Tables 82.4. After fitting GARJI model for each bank, residuals are diagnosed by the Ljung-Box test, with the lag being 25. From Table 82.4, the p-values of the Ljung-Box Q statistic for all banks under GARJI model are much smaller than those under the VG-NGARCH model. To be more specific, p-values for Bank of America and Wells Fargo are too small to provide strong evidence that there is significant serial correlation among the residuals for Bank of America and Wells Fargo after fitting the GARJI model to their log-returns.

Table 82.5 Information criteria

	Bank of America	J.P. Morgan	Citigroup	Wells Fargo
VG-NGARCH model				
AIC	−5.1610	−4.9083	−4.8662	−5.0278
SC	−5.1181	−4.8654	−4.8233	−5.0056
HQ	−5.1445	−4.8918	−4.8497	−5.0106
GARJI model				
AIC	−4.9579	−4.8426	−4.6474	−4.9465
SC	4.8904	−4.7752	−4.5799	−4.8801
HQ	−4.9319	−4.8167	−4.6214	−4.9209

82.3.2 Model Selection Based on Information Criteria

Since the two models are not nested, their goodness of fit is measured by the following three criteria based on log of the maximum likelihood and the number of parameters: Akaike information criterion (AIC), Schwarz criterion (SC), and Hannan-Quinn criterion (HQ). The formulas for the three criteria are as follows:

$$\begin{aligned} \text{AIC} &= -2(\mathcal{L}/T) + 2(k/T) \\ \text{SC} &= -2(\mathcal{L}/T) + k\log(T)/T \\ \text{HQ} &= -2(\mathcal{L}/T) + 2k\log(\log(T))/T \end{aligned}$$

where $\mathcal{L}$ is log of the maximum likelihood, k is the number of parameters, and T is the sample size. The model minimizing these information criteria is preferred.

Comparing log-likelihoods and the three information criteria for the VG-NGARCH and GARJI models listed on Tables 82.3, 82.4, and 82.5, the VG-NGARCH model not only has higher log-likelihood values but also has smaller values on AIC, SC, and HQ for all banks, suggesting that it provides not only better fitting but also more parsimonious model specification for these bank data.

82.3.3 Evaluation of Volatility Forecasts

This subsection evaluates the performance of each model on variance forecasts through comparing the out-of-sample volatility forecasts of the VG-NGARCH model with those of the benchmark GARJI. To assess out-of-sample forecasts, a range-based estimate of ex post volatility was calculated in compliance with the method of Parkinson (1980) and Maheu and McCurdy (2004) as follows:

$$\text{Range}_t = \sqrt{\eta}\,\log\left(P_{t,h}/P_{t,l}\right),$$

where $P_{t,h}$ and $P_{t,l}$ represent the intraday high prices and low prices, respectively. The parameter η in the above formula is the calibration parameter to make the range

Table 82.6 Out-of-sample variance forecasts

	Bank of America	J.P. Morgan	Citigroup	Wells Fargo
VG-NGARCH				
β_0	0.0000	0.0023	0.0049	0.0098
β_1	1.1626	1.1666	1.2582	1.0759
R^2	0.6575	0.6407	0.6482	0.6148
F	963.8306	895.3023	924.9720	801.2075
p-value	0	0	0	0
GARJI				
β_0	−0.0392	−0.0221	−0.0333	−0.0206
β_1	1.3681	1.3284	1.4201	1.2472
R^2	0.6500	0.6317	0.6470	0.5727
F	932.1904	861.0316	919.9395	672.7951
p-value	0	0	0	0

estimate of the unconditional variance equal the unconditional variance of daily returns. To conduct out-of-sample analyses, all models were reestimated using observations from January 2, 2008 to December 31, 2009. These out-of-sample estimates were kept to derive the out-of-sample forecast for the date-t conditional variance given $\mathcal{F}_{t-1}$, denoted as $\widetilde{\mathrm{V}}\mathrm{ar}(Y_t|\mathcal{F}_{t-1})$. Following the approach of Maheu and McCurdy (2004), the range-based ex post volatilities were regressed on the out-of-sample forecasts of the conditional variances as

$$\mathrm{Range}_t = \beta_0 + \beta_1\sqrt{\widetilde{\mathrm{V}}\mathrm{ar}(Y_t|\mathcal{F}_{t-}1) + \mathrm{error}_t}. \tag{82.14}$$

The coefficient of determination, R^2, of the regression tells us the proportion of the total variation for the range-based volatilities explained by the out-of-sample conditional variance forecasts. Hence, the model with higher R^2 is considered to be superior in forecasting volatilities. The R^2s of the regression models given in Eq. 82.14 are displayed on Table 82.6 for all banks under the VG-NGARCH and GARJI models, respectively. Since R^2s under the VG-NGARCH model are all larger than those under the GARJI model for all banks, the VG-NGARCH outperforms the GARJI model on out-of-sample volatility forecasts.

82.3.4 Prediction of Large Price Movements or Jumps

In this subsection, the VG-NGARCH model is examined for its performance on predicting the probability of large price movements due to extreme events. Here, large price movement is defined to occur when the absolute log-return exceeds 0.05. From Eqs. 82.7, 82.8, and 82.9, the ex ante probability of large price movements is given by

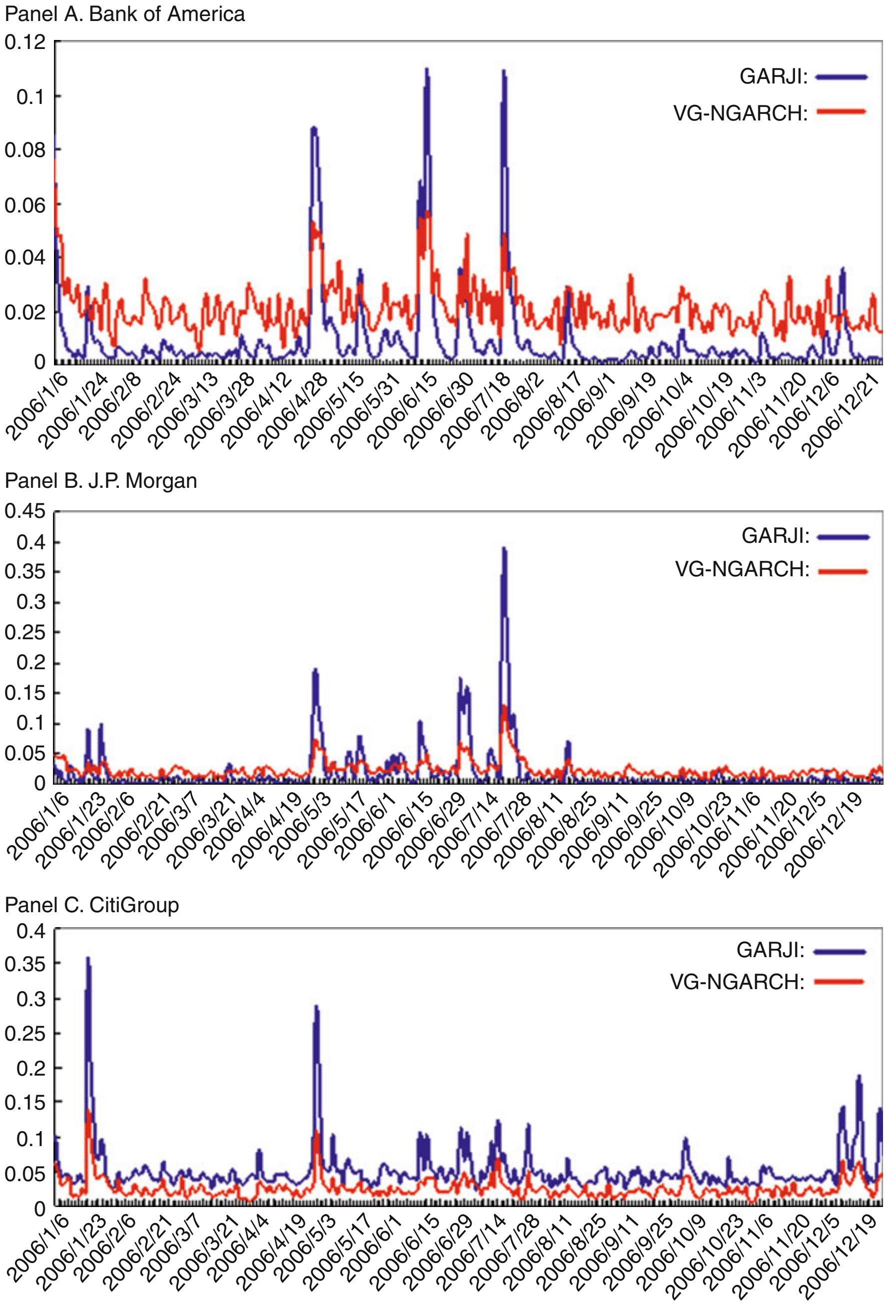

Fig. 82.1 (continued)

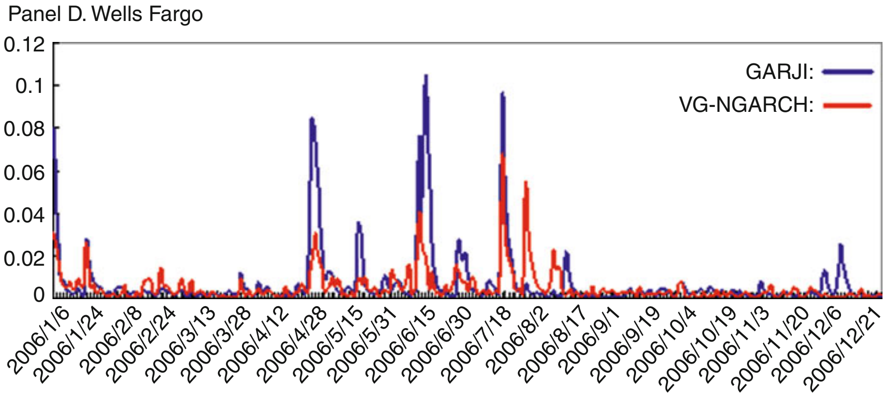

Fig. 82.1 Probabilities of large price movements or dumps during the year 2006

$$P(|Y_t| > 0.05|\mathcal{F}_{t-1}) = \int_0^\infty \left[1 - \Phi\left(\frac{0.05 - (m + \phi_t + \theta g_t)}{\sigma\sqrt{g_t}}\right)\right] h(g_t) dg_t + \int_0^\infty \Phi\left(\frac{-0.05 - (m + \phi_t + \theta g_t)}{\sigma\sqrt{g_t}}\right) h(g_t) dg_t \tag{82.15}$$

where $h(g_t)$ denotes the probability density function of a gamma distribution with shape and scale parameters v_t and 1, respectively.

For the GARJI model, the performance of prediction on jumps is based on the ex post probability of at least one jump occurring, which is expressed as

$$P(n_t \geq 1|\mathcal{F}_t) = 1 - P(n_t = 0|\mathcal{F}_t), \tag{82.16}$$

where, following Eq. 82.6,

$$P(n_t = 0|\mathcal{F}_t) = e^{-\lambda_t} \frac{f(Y_t|0, \mathcal{F}_{t-1})}{f(Y_t|\mathcal{F}_{t-1}).}$$

After the parameters in Eqs. 82.15 and 82.16 are replaced by their estimates, $P(|Y_t| > 0.05|\mathcal{F}_{t-1})$ and $P(|n_t \geq 1|\mathcal{F}_{t-1})$ are estimated for the whole study period for each bank. In order to compare their performances, the probabilities belonging to Years 2006 and 2008 are plotted on Figs. 82.1 and 82.2, respectively. From Fig. 82.1, the ex ante probabilities for large price movements under the VG-NGARCH model are smoother than those resulting from the GARJI model over the same period, where no noteworthy extreme events occurred during 2006.

Thus, the ex post probabilities of jumps from the GARJI model tend to over predict the chance of jumps when price movements are moderate.

On the other hand, as Year 2008 has been well recognized by the occurrences of financial turbulence and crisis, Fig. 82.2 does demonstrate that much higher

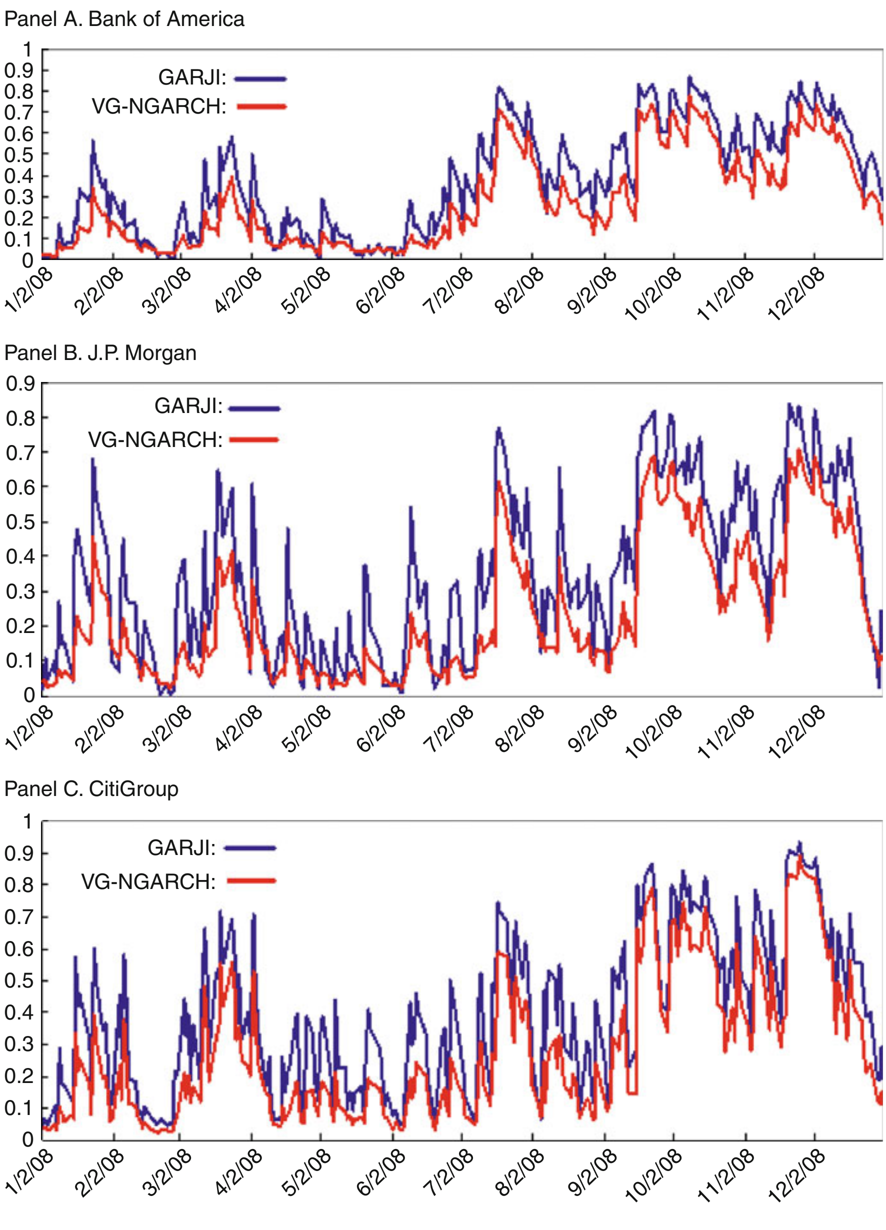

Fig. 82.2 (continued)

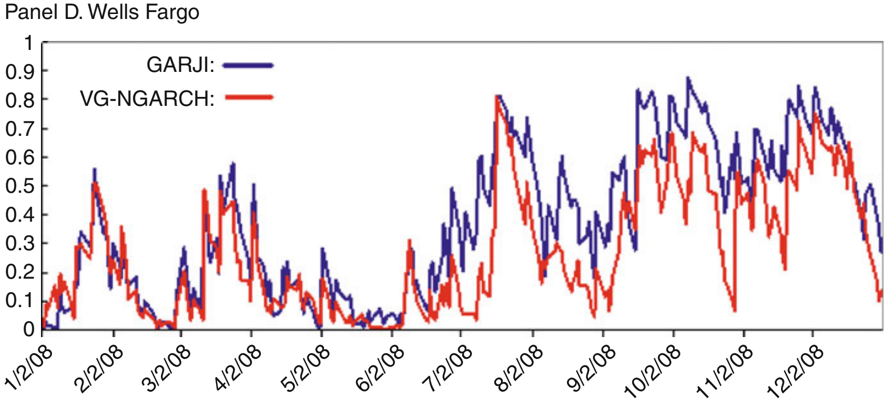

Fig. 82.2 Probabilities of large price movements or jumps during year 2008

probabilities of large price movements and jumps are predicted compared to those of Year 2006. Specifically, on September 16, 2008, the log-returns for Bank of America, J.P. Morgan, Citigroup, and Wells Fargo were −0.2398, −0.1066, −0.1642, and −0.1007, respectively. The corresponding ex ante probabilities of large price movements using the VG-NGARCH model were 0.7114, 0.4544, 0.6621, and 0.5368, respectively, while the ex post probabilities of jumps using the GARJI model were 0.8308, 0.6806, 0.7980, and 0.8348, respectively. Though both models show the ability to catch up large price movements or jumps, the VG-NGARCH model provides smoother and thus more reliable predictions than the GARJI model.

82.4 Conclusion

Differing from the GARJI model, for the VG-NGARCH model, based on a purely jump VG process, no cutoff point is required between normal and extreme price movements. In addition, instead of two independent autoregressive processes, a nonlinear asymmetric autoregressive process is used to model the shape parameter of the VG process. This makes the VG-NGARCH model more informative and parsimonious compared to the GARJI model. Furthermore, the empirical study demonstrates that through diagnosing the randomness of residuals, computing three information criteria (AIC, SC, and HQ), forecasting out-of-sample conditional volatility, and predicting the likelihood of large price movements or jumps, the VG-NGARCH model consistently outperforms the GARJI model. The superiority of the VG-NGARCH model relative to the benchmark GARJI model should improve the prediction ability of the occurrences of extreme events and hence is a better modeling approach to make financial management.

Appendix 1: Variance-Gamma Process

A VG process is a Brownian motion evaluated at a random business time modulated by a stochastic gamma process, to replace the role of Brownian motion. Specifically, at time s, a VG process X is given by

$$X(s) = \theta g(\mathrm{s}; 1, \gamma) + \sigma W(g(\mathrm{s}; 1, \gamma)), \tag{82.17}$$

where $g(\mathrm{s}; 1, \gamma)$ is the gamma process with unit mean rate and variance γ, W represents a standard Brownian motion, and θ and σ are the drift and volatility parameters, respectively. The extent of random time change $\Delta g = g(s;v,\gamma) - g(0;v,\gamma)$ is the increment of the gamma process during the interval (0, s]. Therefore, Δg follows gamma distribution with shape and scale parameters being vs and γ, respectively. Since the scale parameter γ can be transformed into one, it is set to one in our study.

Appendix 2: Parameter Estimation: Monte Carlo EM and Metropolis Algorithm

Method of maximum likelihood is adopted for the VG-NGARCH model. However, since the random time changes $g_1, \ldots, g_T$ are unobservable, the parameters of the VG-NGARCH model are unidentifiable. To resolve this problem, the mean of instantaneous return rate m is set to the mean of the log-returns $Y_1, \ldots, Y_T$, namely, $\hat{m} = \overline{Y}$, and the Monte Carlo EM (MCEM) algorithm (Wei and Tanner 1990; McCulloch 1997) is employed to estimate the parameters $\boldsymbol{\Theta} = (\theta, \sigma, v_1, \boldsymbol{\alpha})'$, where $\boldsymbol{\alpha} = (a_0, a_1, a_2, c)$ is the NGARCH parameter.

To perform the MCEM algorithm, at each iteration a set of K samples of the unobservable random time changes, $\boldsymbol{g}^{(1)}, \ldots, \boldsymbol{g}^{(K)}$, where $\boldsymbol{g}^{(l)} = (g_1{}^{(l)}, \ldots, g_T{}^{(l)})$, $1 \leqq l \leqq K$, are drawn from the posterior distribution $p(\boldsymbol{g}|\boldsymbol{Y};\boldsymbol{\Theta})$, which is

$$p(\boldsymbol{g}|\,\boldsymbol{Y}; \Theta) \propto \prod_{t=1}^{T} \exp\{-\kappa g_t - \delta_t/g_t + (v_t - 1.5)\log(g_t)\}, \tag{82.18}$$

where $v_t = a_0 + a_1\left(\varepsilon_{t-1} - c\sqrt{v_{t-1}}\right)^2 + a_2 v_{t-1}$ is the time-t shape parameter, and the coefficients κ and δ_t are

$$\kappa = \frac{\theta^2}{2\sigma^2} + 1 \ \text{ and } \ \delta_t = \frac{\left(Y_t - \overline{Y} - \phi_t\right)^2}{2\sigma^2}.$$

Since Eq. 82.18 is not proportional to any density function of well-known distributions, it is not possible to directly sample the time changes, $\boldsymbol{g}^{(1)}, \ldots, \boldsymbol{g}^{(K)}$, from the posterior distribution $p(\boldsymbol{g}|\boldsymbol{Y};\boldsymbol{\Theta})$ at each iteration of the EM algorithm. Consequently, the Metropolis chain strategy is carried out here

(Metropolis et al. 1953; Hastings 1970). In the independent Metropolis chain algorithm, a random outcome is sampled from its target distribution π by generating a chain of size L as follows: at the nth step of the chain, if the chain is at a point $X_n = \boldsymbol{x}$, a candidate value $\boldsymbol{y}$ is sampled from a proposal transition density $f(\boldsymbol{y})$ for the next location X_{n+1}. The candidate $X_{n+1} = \boldsymbol{y}$ is accepted with probability

$$p(x, y) = \min\left\{\frac{\pi(\boldsymbol{y})f(\boldsymbol{x})}{\pi(\boldsymbol{x})f(\boldsymbol{y})}, 1\right\}.$$

An independent uniform random variate U is generated; if $U < p(\boldsymbol{x}, \boldsymbol{y})$, then $X_{n+1} = \boldsymbol{y}$; otherwise the step is rejected and the chain remains at $X_{n+1} = \boldsymbol{x}$. After L such steps, where L is sufficiently large, a realization is obtained from the target distribution π.

Appendix 3: Skewness and Kurtosis of Log-returns

The unconditional skewness and kurtosis of log-return at time t are expressed in terms of the model parameters and the first four moments of the shape parameter v_t, which are

$$\text{Skewness}(Y_t) = \frac{\left(2\theta^3 + 3\theta\sigma^2\right)E(v_t) + 3(\tau+\theta)\left(\theta^2+\sigma^2\right)V(v_t) + (\tau+\theta)^3 E^3(v_t - E(v_t))}{\left[\left(\theta^2+\sigma^2\right)E(v_t) + (\tau+\theta)^2 V(v_t)\right]^{3/2}}; \tag{82.19}$$

$$\text{Kurtosis}(Y_t) = \frac{3\left(\theta^2+\sigma^2\right)^2 E\left(v_t^2\right) + \left(3\sigma^4 + 6\theta^4 + 12\theta^2\sigma^2\right)E(v_t) + Q}{\left[\left(\theta^2+\sigma^2\right)E(v_t) + (\tau+\theta)^2 V(v_t)\right]^2}, \tag{82.20}$$

where $\tau = \ln(1 - \theta - \sigma^2/2)$; and

$$\begin{aligned} Q = {} & 6(\tau+\theta)^2\left(\theta^2+\sigma^2\right)\left[E\left(v_t^3\right) + E^3(v_t) - 2E(v_t)E\left(v_t^2\right)\right] \\ & + 4(\tau+\theta)\left(2\theta^4 + 3\theta^2\sigma^2\right)V(v_t) + (\tau+\theta)^4 E^4(v_t - E(v_t)). \end{aligned}$$

Risk-Averse Portfolio Optimization via Stochastic Dominance Constraints

83

Darinka Dentcheva and Andrzej Ruszczynski

Contents

Abstract

We consider the problem of constructing a portfolio of finitely many assets whose return rates are described by a discrete joint distribution. We present a new approach to portfolio selection based on stochastic dominance.

The portfolio return rate in the new model is required to stochastically dominate a random benchmark. We formulate optimality conditions and duality relations for these models and construct equivalent optimization models with

utility functions. Two different formulations of the stochastic dominance constraint, primal and inverse, lead to two dual problems which involve von Neumann–Morgenstern utility functions for the primal formulation and rank-dependent (or dual) utility functions for the inverse formulation. We also discuss the relations of our approach to value at risk and conditional value at risk. Numerical illustration is provided.

Keywords

Portfolio optimization • Stochastic dominance • Stochastic order • Risk • Expected utility • Duality • Rank-dependent utility • Yaari's dual utility • Value at risk • Conditional value at risk

83.1 Introduction

The problem of optimal portfolio selection is subject of major theoretical and computational studies in finance. A fundamental issue while dealing with uncertain outcomes is a theoretically sound approach to their comparison.

The theory of stochastic orders plays a fundamental role in economics (see Mosler and Scarsini 1991; Whitmore and Findlay 1978). These are relations which induce partial order in the space of real random variables in the following way. A random variable R dominates the random variable Y if $\mathbb{E}[u(R)] \geq \mathbb{E}[u(Y)]$ for all functions $u(\cdot)$ from certain set of functions, called the generator of the order. The concept of *stochastic dominance* is very popular and widely used in economics and finance because of its relation to models of risk-averse preferences (Fishburn 1964). It originated from the theory of majorization (Hardy et al. 1934; Marshall and Olkin 1979) for the discrete case and was later extended to general distributions (Quirk and Saposnik 1962; Hadar and Russell 1969; Rothschild and Stiglitz 1969). Stochastic dominance of second order is defined by the set of nondecreasing concave functions: a random variable R dominates another random variable Y in the second order if $\mathbb{E}[u(R)] \geq \mathbb{E}[u(Y)]$ for all nondecreasing concave functions $u(\cdot)$ for which these expected values are finite. Thus, no risk-averse decision maker will prefer a portfolio with return rate Y over a portfolio with return rate R.

A popular approach is the utility optimization approach. Von Neumann and Morgenstern in their book (von Neumann and Morgenstern 1944) developed the *expected utility theory*: for every rational decision maker there exists a utility function $u(\cdot)$ such that the decision maker prefers outcome R over outcome Y if and only if $\mathbb{E}[u(R)] \geq \mathbb{E}[u(Y)]$. This approach can be implemented also very efficiently; however, it is almost impossible to elicit the utility function of a decision maker explicitly. More difficulties arise when a group of decision makers with different utility functions who have to reach a consensus. Recently, the *dual utility theory* (or *rank-dependent expected utility theory*) has attracted much attention in economics. This approach was first presented in (Quiggin 1982) and later rediscovered in a special case in (Yaari 1987). From a different system of axioms, than those of von Neumann and Morgenstern, one derives that every decision maker has a certain *rank-dependent utility function* w: $[0, 1] \to \mathbb{R}$. Then a nonnegative outcome R is preferred over a nonnegative outcome Y, if and only if

$$-\int_0^1 w(p) dF_{(-1)}(R;p) \geq -\int_0^1 w(p) dF_{(-1)}(Y;p), \tag{83.1}$$

where $F_{(-1)}(R;\cdot)$ is the inverse distribution function of R. For a comprehensive treatment of the rank-dependent utility theory, we refer to (Quiggin 1993), and for its application in actuarial mathematics, see (Wang et al. 1997; Wang and Yong 1998).

Another classical approach, pioneered by (Markowitz 1952, 1959, 1987), is the mean–risk approach, which compares the portfolios with respect to two characteristics. One is the expected return rate (*the mean*) and another one is *the risk*, which is given by some scalar measure of the uncertainty of the portfolio return rate. The mean–risk approach recommends the selection of Pareto-efficient portfolios with respect to these two criteria. In a mean–risk portfolio model, we combine these criteria by specifying some parameter as a trade-off between them. As a parametric optimization problem, the mean–risk model can be solved numerically very efficiently, which makes this approach very attractive (Konno and Yamazaki 1991; Ruszczynski and Vanderbei 2003).

In this chapter we formulate a model for risk-averse portfolio optimization and demonstrate its relation to the expected utility approach and to rank-dependent utility approach. We optimize the portfolio performance under an additional constraint that the portfolio return rate stochastically dominates a benchmark return rate, for example, the return rate of an index. The model is based on our earlier publications (Dentcheva and Ruszczynski 2003a, b, c, 2004a, c) where we have introduced a new model for risk-averse optimization. This approach has a fundamental advantage over mean–risk models and utility function models. All data for our model are readily available. In mean–risk models the choice of the risk measure has an arbitrary character, and it is difficult to argue for one measure against another. Similarly, optimization of expected utility requires the form of the utility function to be specified. Our analysis, departing from the benchmark outcome, generates implied utility function of the decision maker. It is implicitly defined by the benchmark used and by the problem under consideration. We provide two problem formulations in which the stochastic dominance has a primal or inverse form: a Lorenz curve. The primal form has a dual problem in terms of expected utility functions, and the inverse form has a dual problem in terms of rank-dependent utility functions. In this way our model provides also a link between this two competing economic approaches. Duality relations with coherent measures of risk are explored in (Dentcheva and Ruszczynski 2008).

83.2 The Portfolio Problem

Let $R_1, R_2, \ldots, R_n$ be random return rates of assets $1, 2, \ldots, n$. We assume that $\mathbb{E}[|R_j|] < \infty$ for all $j = 1, \ldots, n$.

Our aim is to invest our capital in these assets in order to obtain some desirable characteristics of the total return rate on the investment. Denoting by $x_1, x_2, \ldots, x_n$ the fractions of the initial capital invested in assets $1, 2, \ldots, n$, we can easily derive the formula for the total return rate:

$$R(x) = R_1x_1 + R_2x_2 + \cdots + R_nx_n. \tag{83.2}$$

Clearly, the set of possible asset allocations can be defined as follows:

$$X = \left\{x \in \mathbb{R}^n : x_1 + x_2 + \cdots + x_n = 1, x_j \geq 0, j = 1, 2, \ldots, n\right\}.$$

In some applications one may introduce the possibility of *short positions*, i.e., allow some x_j's to become negative. Other restrictions may limit the exposure to particular assets or their groups, by imposing upper bounds on the x_j's or on their partial sums. One can also limit the absolute differences between the x_j's and some reference investments $\bar{x}_j$, which may represent the existing portfolio, etc. Our analysis does not depend on the detailed way this set is defined; we only use the fact that it is a convex polyhedron. All modifications discussed above define some convex polyhedral feasible sets and are, therefore, covered by our approach.

The main difficulty in formulating a meaningful portfolio optimization problem is the definition of the preference structure among feasible portfolios. If we use only the mean return rate $\mathbb{E}[R(x)]$, then the resulting optimization problem has a trivial and meaningless solution: invest everything in assets that have the maximum expected return rate. For these reasons the practice of portfolio optimization resorts usually to two approaches.

In the first approach we associate with portfolio x some dispersion measure $\rho(R(x))$ representing the variability of the return rate $R(x)$. In the classical Markowitz model (Markowitz 1952, 1959, 1987), the function $\rho(R(x))$ is the variance of the return rate,

$$\rho(R(x)) = \mathbb{V}[R(x)],$$

but many other measures are possible here as well.

The mean–risk portfolio optimization problem is formulated as follows:

$$\max_{x \in X} \mathbb{E}[R(x)] - \lambda\rho(R(x)). \tag{83.3}$$

Here, λ is a nonnegative parameter representing our desirable exchange rate of mean for risk. If $\lambda = 0$, the risk has no value, and the problem reduces to the problem of maximizing the mean. If $\lambda > 0$ we look for a compromise between the mean and the risk. Alternatively, one can minimize the risk function $\rho(x)$, while fixing the expected return rate $\mathbb{E}[R(x)]$ at some value m, and consider a family of problems parametrized by m. The reader is referred to the book (Elton et al. 2006) for the modern perspective on mean–risk analysis in portfolio theory.

The general question of constructing mean–risk models which are in harmony with the stochastic dominance relations has been the subject of the analysis of the recent papers (Ogryczak and Ruszczynski 1999, 2001, 2002). We have identified there several primal risk measures, most notably central semideviations, and dual risk measures, based on the Lorenz curve, which are consistent with the stochastic dominance relations.

The second approach is to select a certain *utility function* $u : \mathbb{R} \to \mathbb{R}$ and to formulate the following optimization problem

$$\max_{x \in X} \mathbb{E}[u(R(x))]. \tag{83.4}$$

It is usually required that the function $u(\cdot)$ is concave and nondecreasing, thus representing preferences of a risk-averse decision maker (Fishburn 1964, 1970).

Recently, a *dual* (*rank-dependent*) *utility* model attracts much attention. It is based on distorting the cumulative probability distribution of the random variable $R(x)$ rather than applying a nonlinear function $u(\cdot)$ to the realizations of $R(x)$. The corresponding problem has the following form

$$\max_{x \in X} \int_0^1 F_{(-1)}(R(x), p)\,dw(p). \tag{83.5}$$

Here $F_{(-1)}(R(x),p)$ is the p-quantile of the random variable $R(x)$, and $w(\cdot)$ is the *rank-dependent utility function*, which distorts the probability distribution. We discuss this in Sect. 83.3.2.

The challenge in both utility approaches is to select the appropriate utility function or rank-dependent utility function that represents our preferences and whose application leads to nontrivial and meaningful solutions of Eqs. 83.4 and 83.5.

In this chapter we propose an alternative approach, by introducing a comparison to a benchmark return rate into our optimization problem. The comparison is based on the stochastic dominance relation. More specifically, we consider only portfolios whose return rates stochastically dominates a certain benchmark return rate.

83.3 Stochastic Dominance

83.3.1 Direct Forms

In the stochastic dominance approach, random return rates are compared by a point-wise comparison of some performance functions constructed from their distribution functions. For a real random variable V, its first performance function is defined as the right-continuous cumulative distribution function of V:

$$F_1(V;\eta) = \mathbb{P}\{V \le \eta\} \quad \text{for } \eta \in \mathbb{R}.$$

A random return V is said (Lehmann 1955; Quirk and Saposnik 1962) to *stochastically dominate* another random return S in the first order, denoted $V \succeq_{(1)} S$, if

$$F_1(V;\eta) \leq F_2(S;\eta) \quad \text{for all } \eta \in \mathbb{R}.$$

We can say that V is "stochastically larger" than S, because it takes values lower than η with smaller (or equal) probabilities than S, no matter what the target η is.

The second performance function F_2 is given by areas below the distribution function F,

$$F_2(V;\eta) = \int_{-\infty}^{\eta} F_1(V;\xi)\,d\xi \quad \text{for } \eta \in \mathbb{R},$$

and defines the weak relation of the *second-order stochastic dominance* (SSD). That is, random return V stochastically dominates S in the second order, denoted $V \succeq_{(2)} S$, if

$$F_2(V;\eta) \leq F_2(S;\eta) \quad \text{for all } \eta \in \mathbb{R}$$

(see Hadar and Russell 1969; Rothschild and Stiglitz 1969).

We can express the function $F_2(V;\cdot)$ as the expected shortfall (see, e.g., Levy 2006; Ogryczak and Ruszczynski 1999): for each target value η, we have

$$F_2(V;\eta) = \mathbb{E}\big[(\eta - V)_+\big], \tag{83.6}$$

where $(\eta - V)_+ = \max(\eta - V, 0)$. The function $F_{(2)}(V;\cdot)$ is continuous, convex, nonnegative, and nondecreasing. It is well defined for all random variables V with finite expected value. Due to this representation, the second-order stochastic dominance relation $V \succeq_{(2)} S$ can be equivalently characterized by the system of inequalities on the expected shortfall below any target η:

$$\mathbb{E}\big[(\eta - V)_+\big] \leq \mathbb{E}\big[(\eta - S)_+\big] \quad \text{for all } \eta \in \mathbb{R}. \tag{83.7}$$

Also, we obtain an equivalent characterization in terms of the expected utility theory of von Neumann and Morgenstern (see, e.g., Hanoch and Levy 1969; Levy 2006; Müller and Stoyan 2002):

(i) For any two random variables V, S, the relation $V \succeq_{(1)} S$ holds true if and only if for all nondecreasing functions $u(\cdot)$ defined on $\mathbb{R}$, we have

$$\mathbb{E}[u(V)] \geq \mathbb{E}[u(S)]. \tag{83.8}$$

(ii) For any two random variables V, S with finite expectations, the relation $V \succeq_{(2)} S$ holds true if and only if Eq. 83.8 is satisfied for all nondecreasing concave functions $u(\cdot)$.

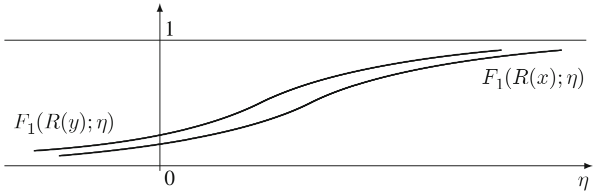

Fig. 83.1 First-order stochastic dominance $R(x) \succ_{(1)} R(y)$

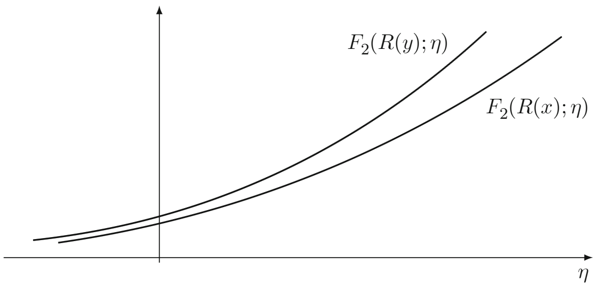

Fig. 83.2 Second-order dominance $R(x) \succ_{(2)} R(y)$

In the context of portfolio optimization, we consider stochastic dominance relations between random return rates defined by Eq. 83.2. Thus, we say that portfolio x *dominates* portfolio y *in the first order*, if

$$F_1(R(x);\eta) \leq F_1(R(y);\eta) \quad \text{for all } \eta \in \mathbb{R}.$$

This is illustrated in Fig. 83.1.

Similarly, we say that x *dominates* y *in the second-order* ($R(x) \succ_{(2)} R(y)$) if

$$F_2(R(x);\eta) \leq F_2(R(y);\eta) \quad \text{for all } \eta \in \mathbb{R}.$$

Recall that the individual return rates R_j have finite expected values, and thus the function $F_2(R(x);\cdot)$ is well defined. The second-order relation is illustrated in Fig. 83.2.

83.3.2 Inverse Forms

Let us consider the inverse model of stochastic dominance, frequently referred to as *Lorenz dominance*. For a real random variable V (e.g., a random return rate), we define the left-continuous inverse of the cumulative distribution function $F_1(V;\cdot)$ as follows:

$$F_{(-1)}(V;p) = \inf\{\eta : F_1(V;\eta) \geq p\} \quad \text{for} \quad 0 < p < 1.$$

Given $p \in (0.1)$, the number $q = q(V;p)$ is called a *p-quantile* of the random variable V if

$$\mathbb{P}\{V < q\} \leq p \leq \mathbb{P}\{V < q\}.$$

For $p \in (0.1)$ the set of p-quantiles is a closed interval, and $F_{(-1)}(V;p)$ represents its left end.

Directly from the definition of the first-order dominance, we see that

$$V \succ_{(1)} S \Leftrightarrow F_{(-1)}(V;p) \geq F_{(-1)}(S;p) \quad \text{for all} \quad 0 < p < 1. \tag{83.9}$$

The first-order dominance constraint can be interpreted as a continuum of probabilistic (chance) constraints, studied in stochastic optimization (see, Prekopa 2003; Dentcheva 2005).

Our analysis uses the *absolute Lorenz function* $F_{(-2)}(V;\cdot) : [0,1] \to \mathbb{R}$, introduced in (Lorenz 1905). It is defined as the cumulative quantile:

$$F_{(-2)}(V;p) = \int_0^p F_{(-1)}(V;t)dt \quad \text{for} \quad 0 < p < 1, \tag{83.10}$$

$F_{(-2)}(V;0) = 0$.

Similarly to $F_2(V;\cdot)$ the function $F_{(-2)}(V;\cdot)$ is well defined for any random variable V, which has a finite expected value. We notice that

$$F_{(-2)}(V;1) = \int_0^1 F_{(-1)}(V;t)dt = \mathbb{E}[V].$$

By construction, the Lorenz function is convex. Lorenz functions are commonly used for inequality ordering of positive random variables, relative to their (positive) expectations (see Arnold 1980; Gastwirth 1971; Muliere and Scarsini 1989). Such a Lorenz function, $p \mapsto F_{(-2)}(V;p)/\mathbb{E}[V]$, is convex and nondecreasing. The absolute Lorenz function, though, is not monotone when negative outcomes occur.

It is well known (see, e.g., Ogryczak and Ruszczynski 2002) that we may fully characterize the second-order dominance relation by using the function $F_{(-2)}(V;\cdot)$:

$$V \succ_{(2)} S \Leftrightarrow F_{(-2)}(V;p) \geq F_{(-2)}(S;p) \text{ for all } 0 \leq p \leq 1. \tag{83.11}$$

This characterization of stochastic dominance by Lorenz functions is widely used in economics and statistics.

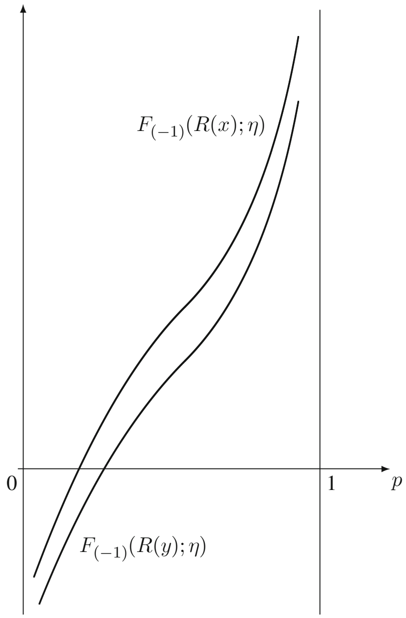
We now provide an equivalent characterization by rank-dependent utility functions. It is analogous to the characterization by expected utility functions.

In the chapter (Dentcheva and Ruszczynski 2006b) the following characterization has been shown:

(i) For any two random variables V, S, the relation $V \succ_{(1)} S$ holds true if and only if for all nondecreasing functions $w(\cdot)$ defined on [0,1], we have

$$\int_0^1 F_{(-1)}(V;p)dw(p) \geq \int_0^1 F_{(-1)}(S;p)dw(p). \tag{83.12}$$

Fig. 83.3 First-order stochastic dominance $R(x) \succ_{(1)} R(y)$ in the inverse form



(ii) For any two random variables V, S with finite expectations, the relation $V \succ_{(2)} S$ holds true if and only if Eq. 83.12 is satisfied for all nondecreasing concave functions $w(\cdot)$.

The functions $w(\cdot)$ appearing in this characterization are rank-dependent (dual) utility functions.

In the context of portfolio optimization, we consider stochastic dominance relations between random return rates defined by Eq. 83.2. Thus, we say that portfolio x *dominates* portfolio y *in the first order*, if

$$F_{(-1)}(R(x)); \mathrm{p}) \geq F_{(-1)}(R(y); p) \quad \text{for all } p \in (0, 1).$$

This is illustrated in Fig. 83.3.

Similarly, we say that x *dominates* y *in the second-order* ($R(x) \succ_{(2)} R(y)$), if

$$F_{(-2)}(R(x); p) \geq F_{(-2)}(R(y); p) \quad \text{for all } p \in [0, 1]. \tag{83.13}$$

Recall that the individual return rates R_j have finite expected values, and thus the function $F_{(-2)}(R(x); \cdot)$ is well defined. The second-order relation is illustrated in Fig. 83.4.

Second-order dominance $R(x) \succ_{(2)} R(y)$ in the inverse form.

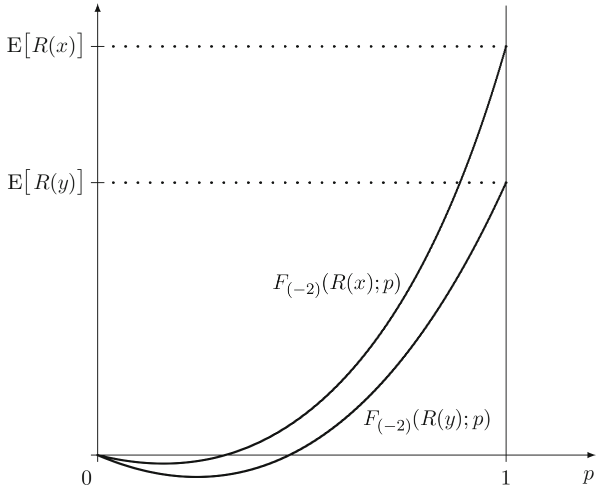


Fig. 83.4 Second order dominance in the inverse form

83.3.3 Relations to Value at Risk and Conditional Value at Risk

There are fundamental relations between the concepts of value at risk (VaR) and conditional value at risk (CVaR) and the stochastic dominance constraints. The VaR constraint in the portfolio context is formulated as follows. We define the loss rate $L(x) = - R(x)$. We specify the maximum fraction ω_p of the initial capital allowed for risk exposure at risk level $p \in (0,1)$, and we require that

$$\mathbb{P}\big[L(x) \leq \omega_p\big] \geq 1 - p.$$

Denoting by $\mathrm{VaR}_p(L(x))$ the left $(1 - p)$-quantile of the random variable $L(x)$, we can equivalently formulate the VaR constraint as

$$\mathrm{VaR}_p(L(x)) \leq \omega_p.$$

The first-order stochastic dominance relation between two portfolios is equivalent to the continuum of VaR constraints. Portfolio x dominates portfolio y in the first order, if

$$\mathrm{VaR}_p(L(x)) \leq \mathrm{VaR}_p(L(y)) \text{ for all } p \in (0, 1).$$

The CVaR at level p, roughly speaking, has the following form:

$$\mathrm{CVaR}_p(L(x)) = \mathbb{E}\big[L(x) | L(x) \geq \mathrm{VaR}_p(L(x))\big].$$

This formula is precise if $\mathrm{VaR}_p(L(x))$ is not an atom of the distribution of $L(x)$. More precisely we express it as follows:

$$\mathrm{CVaR}_p(L(x)) = \frac{1}{p}\int_0^p \mathrm{VaR}_t(L(x))dt.$$

We note that

$$\mathrm{CVaR}_p(L(x)) = -\frac{1}{p}F_{(-2)}(R(x), p). \tag{83.14}$$

Another description uses extremal properties of quantiles and equivalently represents CVaR as follows (see Rockafellar and Uryasev 2000):

$$\mathrm{CVaR}_p(L(x)) = \inf_\eta \left\{ \frac{1}{p}\mathbb{E}\left[(\eta - R(x))_+\right] - \eta \right\}. \tag{83.15}$$

A CVaR constraint on the portfolio x can be formulated as follows:

$$\mathrm{CVaR}_p(L(x)) \le \omega_p. \tag{83.16}$$

Using Eqs. 83.14 and 83.13, we conclude that the second-order stochastic dominance relation for two portfolios x and y is equivalent to the continuum of CVaR constraints:

$$R(x) \succ_{(2)} R(y) \Leftrightarrow \mathrm{CVaR}_p(L(x)) \le \mathrm{CVaR}_p(L(y)) \text{ for all } p \in (0, 1). \tag{83.17}$$

Assume that we compare the performance of a portfolio x with a random benchmark Y (e.g., an index return rate or another portfolio return rate) requiring $R(x) \succ_{(2)} Y$. Then the fraction ω_p of the initial capital allowed for risk exposure at level p is given by the benchmark Y:

$$\omega_p = \mathrm{CVaR}_p(-Y), \quad p \in (0, 1).$$

Assume that Y has a discrete distribution with realizations y_i, $i = 1, \ldots, m$. Then relation (83.7) is equivalent to

$$\mathbb{E}\left[(y_i - R(x))_+\right] \le \mathbb{E}\left[(y_i - Y)_+\right], \quad \mathrm{i} = 1, \ldots, m. \tag{83.18}$$

This result *does not* imply that the continuum of CVaR constraints (83.17) can be replaced by finitely many constraints of form

$$\mathrm{CVaR}_{pi}(R(x)) \ge \mathrm{CVaR}_{pi}(Y), \quad i = 1, \ldots, m.$$

with some fixed probabilities p_i, $i = 1, \ldots, m$. The reason is that we do not know at which probability levels the CVaR constraints have to be imposed.

83.4 The Dominance-Constrained Portfolio Problem

83.4.1 Direct Formulation

The starting point for our model is the assumption that a benchmark random return rate Y having a finite expected value is available. It may have the form of $Y = R(\bar{z})$, for some benchmark portfolio $\bar{z}$. It may be an index or our current portfolio. Our intention is to have the return rate of the new portfolio, $R(x)$, preferable over Y. Therefore, we introduce the following extension of the optimization problem (83.3):

$$\begin{array}{c}\max \mathbb{E}\left[R(x)\right] - \lambda\rho(R(x)) \\ \text{subject to}\end{array} \tag{83.19}$$

$$R(x) \succ_{(2)} Y, \tag{83.20}$$

$$x \in X. \tag{83.21}$$

Similarly to Eq. 83.3, we optimize a mean–risk objective function, but we introduce a constraint that the portfolio return dominates a benchmark. Even when $\lambda = 0$ and we maximize just the expected value of the return rate, our model will still lead to nontrivial solutions, due to the presence of the dominance constraint (83.20).

To increase flexibility of model (83.19–83.21), we may also allow a uniform shift of $R(x)$ by a constant c, as in the following model:

$$\begin{array}{l}\max \mathbb{E}[R(x)] - \lambda\rho(R(x)) - \delta c \\ \quad\text{subject to} \\ \quad R(x) + c \succ_{(2)} Y, \\ \quad x \in X.\end{array}$$

Here $\delta > 0$ can be interpreted a cost of the shift c. Observe that the shift c may also become negative, in which case we are rewarded for uniformity of dominating Y. The shift c may be interpreted as an additional cash added to the return, and δ is the interest to be paid when the loan is paid back.

To simplify the derivations, from now on we focus on the simplest formulation of the dominance-constrained problem:

$$\begin{array}{c}\max \mathbb{E}[R(x)] \\ \text{subject to}\end{array} \tag{83.22}$$

$$R(x) \succ_{(2)} Y, \tag{83.23}$$

$$x \in X. \tag{83.24}$$

We can observe the first advantage of our problem formulation: all data in it are readily available. Moreover, the set defined by Eq. 83.23 is convex (see Dentcheva and Ruszczynski 2003c, 2004a, b).

Let us assume now that Y has a discrete distribution with realizations y_i attained with probabilities π_i, $i = 1, \ldots, m$. We also assume that the return rates have a discrete joint distribution with realizations r_{jt}, $t = 1, \ldots, T$, $j = 1, \ldots, n$, attained with probabilities p_t, $t = 1, 2, \ldots, T$. Then the formulation of the stochastic dominance relation (83.23) resp. (83.18) simplifies even further. Introducing variables s_{it} representing the shortfall of $R(x)$ below y_i in realization t, $i = 1, \ldots, m$, $t = 1, \ldots, T$, we can formulate problem (83.22–83.24) as follows:

$$\max \sum_{t=1}^{T} pt \sum_{j=1}^{n} x_j r_{jt} \tag{83.25}$$

subject to

$$\sum_{j=1}^{n} x_j r_{jt} + s_{it} \geq y_i, \quad i = 1, \ldots, m, \quad t = 1, \ldots, T, \tag{83.26}$$

$$\sum_{t=1}^{T} p_t s_{it} \leq \sum_{k=1}^{m} \pi_k (y_i - y_k)_+, \quad i = 1, \ldots, m, \tag{83.27}$$

$$s_{it} \geq 0, \quad i = 1, \ldots, m, \quad t = 1, \ldots, T. \tag{83.28}$$

$$x \in X. \tag{83.29}$$

Indeed, or every feasible point x of Eqs. 83.22, 83.23, and 83.24, setting

$$s_{it} = \max\left(0, y_i - \sum_{j=1}^{n} x_j r_{jt}\right), \quad i = 1, \ldots, m, \quad t = 1, \ldots, T,$$

we obtain a feasible pair (x, s) for Eqs. 83.26, 83.27, 83.28, and 83.29. Conversely, for any feasible pair (x, s) for Eqs. 83.26, 83.27, 83.28, and 83.29, inequalities Eqs. 83.26 and 83.28 imply that

$$s_{it} \geq \max\left(0, y_i - \sum_{j=1}^{n} x_j r_{jt}\right), \quad i = 1, \ldots, m, \quad t = 1, \ldots, T.$$

Taking the expected value of both sides and using Eq. 83.27, we obtain

$$F_2(R(x); y_i) \leq F_2(Y; y_i), \quad i = 1, \ldots, m.$$

Therefore, problem (83.22–83.24) is equivalent to problem (83.25–83.29).

If the set X is a convex polyhedron, problem (83.25–83.29) becomes a large-scale linear programming problem. It may be solved by general-purpose linear programming solvers. However, the size of the problem increases dramatically with the number of assets n, their return realizations T, and benchmark realizations m, which makes it impractical for even moderate dimensions (in thousands). For the purpose of solving these problems, we developed a specialized decomposition method presented in (Dentcheva and Ruszczynski 2006a).

83.4.2 Inverse Formulation

Assume that the return rates have a joint discrete distribution realizations r_{jt}, $t = 1$, T, $j = 1,\ldots,n$, attained with probabilities p_t, $t = 1, 2,\ldots,T$. Moreover, we assume that *all probabilities* p_t are equal, that is, $p_t = 1/T$, $t = 1,\ldots,T$. This is the case of empirical distributions. Correspondingly, we assume that Y has a discrete distribution with $m = T$ equally probable realizations y_t, $t = 1,\ldots,T$. We use the symbol $R_{[t]}(x)$ to denote the ordered realizations of $R(x)$, that is,

$$R_{[1]}(x) \leq R_{[2]}(x) \leq \cdots \leq R_{[T]}(x).$$

Since $R(x)$ has a discrete distribution, the functions $F_2(R(x);\cdot)$ and $F_{(-2)}(R(x);\cdot)$ are piecewise linear. Owing to the fact that all probabilities p_t are equal, the break points of $F_{(-2)}(R(x);\cdot)$ occur at t/T, for $t = 0,1,\ldots,m$. The same applies to $F_{(-2)}(Y;\cdot)$. It follows from Eq. 83.13 that the stochastic dominance constraint (83.23) can be equivalently expressed as

$$F_{(-2)}\left(R(x);\frac{t}{T}\right) \geq F_{(-2)}\left(Y;\frac{t}{T}\right), \quad t = 1, \ldots, T.$$

Note that $F_{(-2)}(R(x);0) = F_{(-2)}(Y;0) = 0$. We have

$$F_{(-2)}(R(x);\frac{t}{T}) = \frac{1}{T}\sum_{k=1}^{t} R_{[k]}(x), \quad t = 1, \ldots, T.$$

Therefore problem (83.22–83.24) can be written with an equivalent inverse form of the dominance constraint:

$$\begin{array}{c} \max\ \mathbb{E}[R(x)] \\ \text{subject to} \end{array} \tag{83.30}$$

$$\sum_{k=1}^{t} R_{[k]}(x) \geq \sum_{k=1}^{t} y_{[k]}, \quad t = 1, \ldots, T, \tag{83.31}$$

$$x \in X. \tag{83.32}$$

It was shown in (Ogryczak and Ruszczynski 2002) that the function $x \mapsto \sum_{k=1}^{t} R_{[k]}(x)$ is concave and positively homogeneous. It is also polyhedral. Therefore, Eq. 83.31 are convex polyhedral constraints. If the set X is a convex polyhedron, problem (83.30–83.32) has an equivalent linear programming formulation.

All these transformations are possible due to the crucial assumption that the probabilities of all elementary events are equal. If they are not equal, the break points of the function $F_{(-2)}(R(x);\cdot)$ depend on x, and therefore inequality (83.13) cannot be reduced to finitely many convex inequalities. This is in contrast to the primal formulation, where the discreteness of Y alone was sufficient to reduce the stochastic dominance constraint to finitely many convex inequalities.

We have to observe that the quantile formulation (83.31) of stochastic dominance constraints is more involved than the primal formulation and requires more sophisticated computational methods. Using Eq. 83.31 directly would require employing nonsmooth optimization methods to solve problem (83.30–83.32). Equivalent formulation with linear constraints has very many constraints, because of the large number of pieces of the function $x \mapsto \sum_{k=1}^{t} R_{[k]}(x)$. Still, in (Dentcheva and Ruszczynski 2010) we have developed a highly efficient cutting plane method, which significantly outperforms direct approaches.

83.5 Optimality and Duality

83.5.1 Primal Form

From now on we assume that the probability distributions of the return rates are discrete with finitely many realizations r_{jt}, $t = 1, \ldots, T$, $j = 1, \ldots, n$, attained with probabilities p_t, $t = 1, 2, \ldots, T$. We also assume that there are finitely many ordered realizations of the benchmark outcome $Y : y_1 < y_2 < \cdots < y_m$. The probabilities of these realizations are denoted by π_i, $i = 1,\ldots,m$. We also assume that the set X is compact.

We define the set U of functions $u{:}\mathbb{R} \to \mathbb{R}$ satisfying the following conditions:

- $u(\cdot)$ is concave and nondecreasing.
- $u(\cdot)$ is piecewise linear with break points y_i, $i = 1, \ldots, m$.
- $u(t) = 0$ for all $t \geq y_m$.

It is evident that U is a convex cone.

Let us define the function $L{:}\mathbb{R}^n \times \mathrm{U} \to \mathbb{R}$ as follows:

$$L(x, u) = \mathbb{E}[R(x) + u(R(x)) - u(Y)]. \tag{83.33}$$

It will play for problem (83.22–83.24) a similar role to that of a Lagrangian. It is well defined, because for every $u \in \mathrm{U}$ and every $x \in \mathbb{R}^n$, the expected value $\mathbb{E}[u(R(x))]$ exists and is finite.

The following theorem has been proved in a more general version in (Dentcheva and Ruszczynski 2003c) (see also Dentcheva and Ruszczynski 2006a).

Theorem 1 *If $\hat{x}$ is an optimal solution of* Eqs. 83.22, 83.23, *and* 83.24, *then there exists a function $\hat{u} \in \mathrm{U}$ such that*

$$L(\hat{x}, \hat{u}) = \max_{x \in X} L(x\hat{u}) \tag{83.34}$$

$$\mathbb{E}[\hat{u}(R(\hat{x}))] = \mathbb{E}[\hat{u}(Y)]. \tag{83.35}$$

Conversely, if for some function $\hat{u} \in \mathrm{U}$ an optimal solution $\hat{x}$ of Eq. 83.34 satisfies Eqs. 83.23 and 83.35, then $\hat{x}$ is an optimal solution of Eqs. 83.22, 83.23, and 83.24.

We can also develop duality relations for our problem. With the function (83.33) we can associate the dual function

$$D(u) = \max_{x \in X} L(x, u).$$

We are allowed to write the maximization operation here, because the set X is compact and $L(\cdot,u)$ is continuous.

The dual problem has the following form:

$$\min_{u \in \mathcal{U}} D(u). \tag{83.36}$$

The set U is a closed convex cone and $D(\cdot)$ is a convex function, so Eq. 83.36 is a convex optimization problem.

Theorem 2 *Assume that* Eqs. 83.22, 83.23, *and* 83.24 *has an optimal solution. Then problem* (83.36) *has an optimal solution, and the optimal values of both problems coincide. Furthermore, the set of optimal solutions of* Eq. 83.36 *is the set of functions* $\hat{u} \in \mathcal{U}$ *satisfying* Eqs. 83.34 *and* 83.35 *for an optimal solution* $\hat{x}$ *of* Eqs. 83.22, 83.23, *and* 83.24.

Note that all constraints of our problem are linear or convex polyhedral, and therefore we do not need any constraint qualification conditions here.

The "Lagrange multiplier" u is directly related to the expected utility theory of von Neumann and Morgenstern. We have established earlier that the second-order stochastic dominance relation is equivalent to Eq. 83.8 for *all* utility functions in U. Our result shows that one of them, $\hat{u}(\cdot)$, assumes the role of a Lagrange multiplier associated with Eq. 83.23. A point $\hat{x}$ is a solution to Eqs. 83.22, 83.23, and 83.24 if there exists a utility function $\hat{u}(\cdot)$ such that $\hat{x}$ maximizes over X the objective function E[$R(x)$] augmented with this dual utility. We see that the optimization problem in Eq. 83.34 is equivalent to

$$\max_{x \in X} \mathbb{E}[v(R(x))], \tag{83.37}$$

where $v(\eta) = \eta + u(\eta)$. At the optimal solution the function $\hat{v}(\eta) = \eta + \hat{u}(\eta)$ is the implied utility function. It attaches higher penalty to smaller realizations of $R(x)$ (bigger realizations of $L(x)$). By maximizing $L(R(x),u)$ we look for x such that the left tail of the distribution of $R(x)$ is thin.

It is important to stress that the optimal function $\hat{u}(\cdot)$ is piecewise linear, with break points at the realizations $y_1, \ldots, y_m$ of the benchmark Y. Therefore, the dual problem has also an equivalent linear programming formulation.

83.5.2 Inverse Form

In addition to the assumption that all involved distributions are discrete, we also assume that all probabilities p_t are equal and that $m = T$.

We introduce the set W of concave nondecreasing functions w:[0,1] $\to \mathbb{R}$. It is evident that W is a convex cone.

Recall the identity

$$\mathbb{E}[R(x)] = \int_0^1 F_{(-1)}(R(x); p)dp.$$

Let us define the function $\Phi : X \times \mathcal{W} \to \mathbb{R}$ as follows:

$$\Phi(x, w) = \int_0^1 F_{(-1)}(R(x); p)dp + \int_0^1 F_{(-1)}(R(x); p)dw(p) - \int_0^1 F_{(-1)}(Y; p)dw(p). \tag{83.38}$$

It plays a role similar to that of a Lagrangian of Eqs. 83.30, 83.31, and 83.32.

Theorem 3 *If* $\hat{x}$ *is an optimal solution of* Eqs. 83.30, 83.31*, and* 83.32, *then there exists a function* $\hat{w} \in \mathcal{W}$ *such that*

$$\Phi(\hat{x}, \hat{w}) = \max_{x \in X} \Phi(x, \hat{w}) \tag{83.39}$$

$$\int_0^1 F_{(-1)}(R(\hat{x}); p)d\hat{w}(p) = \int_0^1 F_{(-1)}(Y; p)d\hat{w}(p). \tag{83.40}$$

Conversely, if for some function $\hat{w} \in \mathcal{W}$ an optimal solution $\hat{x}$ of Eq. 83.39 satisfies Eqs. 83.31 and 83.40, then $\hat{x}$ is an optimal solution of Eqs. 83.30, 83.31, and 83.32.

We can also develop a duality theory based on Lagrangian Eq. 83.38. For every function $w \in$ W the problem

$$\max_{x \in X} \Phi(x, w) \tag{83.41}$$

is a Lagrangian relaxation of problem (83.30–83.32). Its optimal value, $\psi(w)$, is always greater than or equal to the optimal value of Eqs. 83.30, 83.31, and 83.32.

We define the dual problem as

$$\min_{w \in \mathcal{W}} \psi(w). \tag{83.42}$$

The set W is a closed convex cone, and $\psi(\cdot)$ is a convex function, so problem (83.42) is a convex optimization problem. Duality relations in convex programming yield the following result.

Theorem 4 *Assume that problem* (83.30–83.32) *has an optimal solution. Then problem* (83.42) *has an optimal solution, and the optimal values of both problems coincide. Furthermore, the set of optimal solutions of* Eq. 83.42 *is the set of functions* $\hat{w} \in \mathcal{W}$ *satisfying* Eqs. 83.39 *and* 83.40 *for an optimal solution* $\hat{x}$ *of* Eqs. 83.30, 83.31, *and* 83.32.

The “Lagrange multiplier” w in this case is related to rank-dependent expected utility theory. We have established earlier that the second-order stochastic dominance relation is equivalent to Eq. 83.12 for *all* dual utility functions in W. Our result shows that one of them, $\hat{w}(\cdot)$, assumes the role of a Lagrange multiplier associated with Eq. 83.31. A point $\hat{x}$ is a solution to Eqs. 83.30, 83.31, and 83.32 if there exists a dual utility function $\hat{w}(\cdot)$ such that $\hat{x}$ maximizes over X the objective function E[$R(x)$] augmented with this dual utility. We can transform the Lagrangian Eq. 83.38 in the following way:

$$\begin{aligned}\Phi(X, w) &= \int_0^1 F_{(-1)}(R(x); p)dp + \int_0^1 F_{(-1)}(R(x); p)dw(p) - \int_0^1 F_{(-1)}(Y; p)dw(p)\\ &= \int_0^1 F_{(-1)}(R(x); p)dv(p) - \int_0^1 F_{(-1)}(Y; p)dw(p),\end{aligned}$$

where $v(p) = p + w(p)$. At the optimal solution the function $\hat{v}(p) = p + \hat{w}(p)$ is the quantile utility function implied by the benchmark Y. Since $\int_0^1 F_{(-1)}(Y; p)dw(p)$ is fixed, the problem at the right-hand side of Eq. 83.39 becomes a problem of maximizing the implied rank-dependent expected utility in X. It attaches higher weights to quantiles corresponding to smaller probabilities p. By maximizing $\Phi(R(x), w)$ we look for x such that the left tail of the distribution of $R(x)$ is thin.

Similarly to von Neumann–Morgenstern utility function, it is very difficult to elicit the dual utility function in advance. Our model derives it from a random benchmark.

The optimal function $\hat{w}(\cdot)$ is piecewise linear, with break points at $\frac{t}{T}$, $t = 1,\ldots, T$. Therefore, the dual problem has also an equivalent linear programming formulation. This property, though, is conditioned on the assumption of equal probabilities.

83.6 Numerical Illustration

We have tested our approach on a basket of 719 real-world assets, using 616 possible realizations of their joint return rates (Ruszczynski and Vanderbei 2003). Historical data on weekly return rates in the 12 years from Spring 1990 to Spring 2002 were used as equally likely realizations.

Implied utility functions corresponding to dominance constraints for four benchmark portfolios.

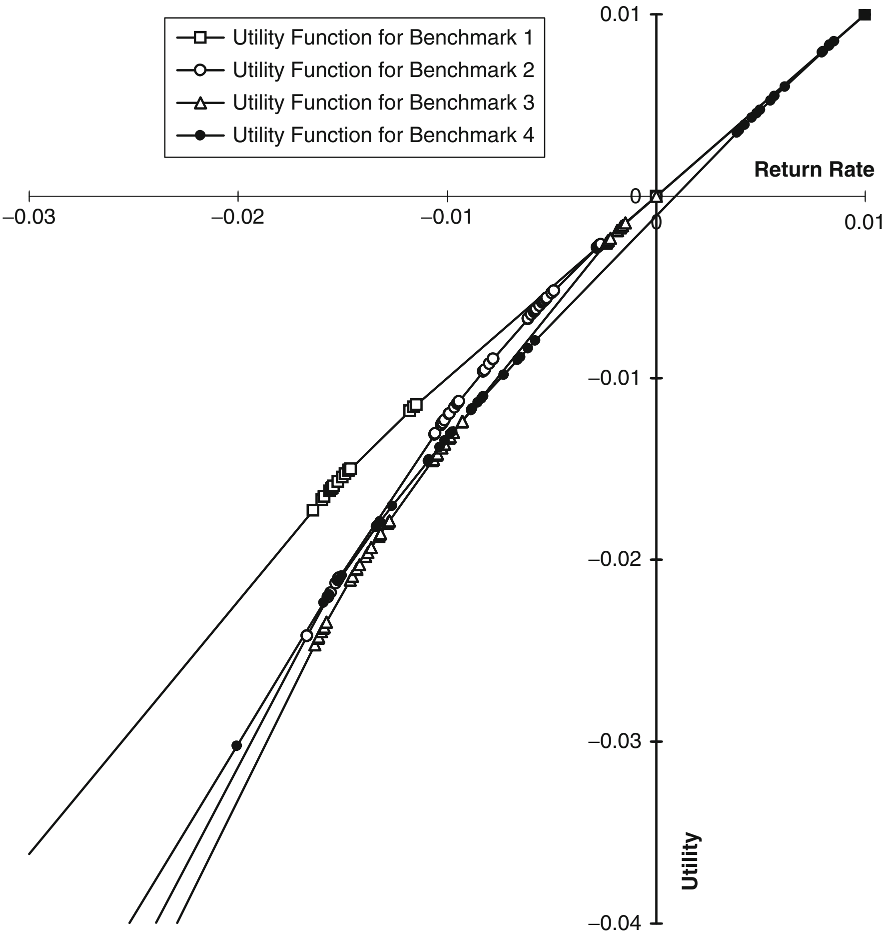

Fig. 83.5 Implied utility functions corresponding to dominance constraints for four benchmark portfolios

We have used four benchmark return rates Y. Each of them was constructed as a return rate of a certain index composed of our assets. Since we actually know the past return rates, for the purpose of comparison, we have selected equally weighted indexes composed of the N assets having the highest average return rates in this period. Benchmark 1 corresponds to $N = 26$, Benchmark 2 corresponds to $N = 54$, Benchmark 3 corresponds to $N = 82$, and Benchmark 4 corresponds to $N = 200$. Our problem was to maximize the expected return rate, under the condition that the return rate of the benchmark portfolio is dominated. Since the benchmark point was a return rate of a portfolio composed from the same basket, we have $m = T = 616$ in this case.

We have solved the problem by our method of minimizing the dual problem which was presented in (Dentcheva and Ruszczynski 2006a).

The implied utility functions from Eq. 83.37 obtained by solving the optimization problem (83.34) in the optimality conditions are illustrated in Fig. 83.5. We see that for Benchmark Portfolio 1, which contains only a small number of fast growing assets, the utility function is linear on almost the entire range of return rates. Only very negative return rates are penalized.

If the benchmark portfolio contains more assets and is therefore more diversified and less risky, in order to dominate it, we have to use a utility function which introduces penalty for a broader range of return rates and is steeper. For the broadly based index in Benchmark Portfolio 4, the optimal utility function is smoother and is nonlinear even for positive return rates. It is worth mentioning that all these utility functions, although nondecreasing and concave, have rather complicated shapes. It would be a very hard task to guess the utility function that should be used to obtain a solution which dominates our benchmark portfolio.

Obviously, the shape of the utility function is determined by the benchmark within the context of the optimization problem considered. If we change the optimization problem, the utility function will change.

Finally, we may remark that our model (83.22–83.24) can be used for testing the statistical hypothesis that the return rate Y of the benchmark portfolio is nondominated.

Implementation Problems and Solutions in Stochastic Volatility Models of the Heston Type

84

Jia-Hau Guo and Mao-Wei Hung

Contents

Abstract

In Heston stochastic volatility framework, the main problem for implementing Heston semi-analytic formulae for European-style financial claims is the inverse Fourier integration. Without good implementation procedures, the numerical results obtained from Heston formulae cannot be robust, even for customarily used Heston parameters, as the time to maturity is increased. We compare three major approaches to solve the numerical instability problem inherent in the fundamental solution of the Heston model and show that the simple adjusted-formula method is much simpler than the rotation-corrected angle method of

Kahl and Jäckel and also greatly superior to the direct integration method of Shaw if taking computing time into consideration.

In this chapter, we used the fundamental transform method proposed by Lewis to reduce the number of variables from two to one and separate the payoff function from the calculation of the Green function for option pricing. Furthermore, the simple adjusted formula is shown to be a robust option pricer as no complex discontinuities arise in this formulation even without the rotation-corrected angle.

Keywords

Heston • Stochastic volatility • Fourier inversion • Fundamental transform • Complex logarithm • Rotation-corrected angle • Simple adjusted formula • Green function

84.1 Introduction

Since the initial breakthrough by Heston (1993), the literature on asset pricing using stochastic volatility models has expanded dramatically over the last decade to capture the volatility smiles and skews appeared in market quotes. Within this class, the Heston stochastic volatility model famous for its closed-form characteristic function has spread widely in financial products. For example, Fang and Oosterlee (2011) used Heston model to price Bermudan and barrier options. However, the implementations of Heston formulae are not as straightforward as they may appear, and most numerical procedures are not reported in detail (see Lee 2005).

Recently, the robustness of Heston formula has become one of the main issues on option pricing (see the discussion of Albrecher et al. (2007)). The complex logarithm contained in the formula of the Heston model is the primary problem. As the claim of Lord and Kahl (2010), the characteristic function of Heston stochastic volatility model and all of its extensions can be discontinuous, leading to completely wrong option prices if the complex logarithm is restricted to its principal branch. This chapter compares three main approaches to this problem: rotation-corrected angle, direct integration, and simple adjusted formula.

It is a well-known fact that the logarithm of a complex variable $z = re^{i\theta}$ is multivalued, i.e., $\ln z = \ln |z| + i(\arg(z) + 2\pi n)$ where $\arg(z) \in [-\pi, \pi)$ and $n \in \mathrm{Z}$. If one restricts the logarithm to its principal branch by setting $n = 0$ (similar to most software packages, such as C++, Gauss, and Mathematica), it is necessarily discontinuous at the cut (see Fig. 84.1).

The Heston model is represented in Lewis' illustration, in which the type of financial claim is entirely decoupled from the calculation of the Green function. Different payoffs are then managed through elementary contour integration over functions and contours that depend on the payoff. In this way, one can see that the issue is fundamentally related to the Green function component of the solution. Once the implementation problems in the Green function component of the solution have been solved, the robustness of the formulae for all European-style financial claims in Heston model can be assured.

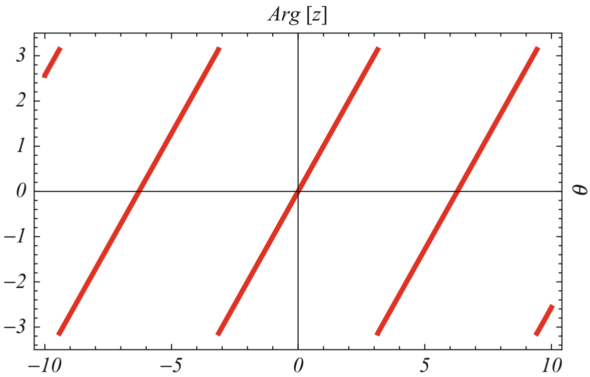

Fig. 84.1 Discontinuities occur at the cut by restricting the logarithm of a complex variable $z = e^{i\theta}$ to the principal branch

The rest of this chapter proceeds as follows: Sect. 84.2 gives the derivation of the transformed-based solution for Heston stochastic volatility model and introduces the discontinuity problem arising from the derived formula. Section 84.3 compares three main solutions to the discontinuity problem and gives some numerical examples to illustrate their usefulness. Section 84.4 summarizes the chapter.

84.2 The Transform-Based Solution for Heston Stochastic Volatility Model

Heston stochastic volatility model is based on the system of stochastic differential equations, which represent the dynamics of the stock price and variance processes under the risk-neutral measure

$$dS_t = rS_t dt + S_t\sqrt{V_t}dW_S(t) \tag{84.1}$$

$$dV_t = \kappa(\theta - V_t)dt + \sigma_V\sqrt{V_t}dW_V(t). \tag{84.2}$$

S_t and V_t denote the stock price and its variance at time t, respectively; r is the risk-free interest rate. The variance evolves according to a square-root process: θ is the long-run mean variance, κ is the speed of mean reversion, and σ_V is the parameter which controls the volatility of the variance process. W_S and W_V are two standard processes of Brownian motion having the correlation ρ. The Heston partial differential equation for a European-style claim $C(S,V,t)$ with expiration T is

$$\frac{\partial C}{\partial t} + \frac{VS^2}{2}\frac{\partial^2 C}{\partial S^2} + \sigma_V\rho SV\frac{\partial^2 C}{\partial S\partial V} + \frac{\sigma_V^2 V}{2}\frac{\partial^2 C}{\partial V^2} + rS\frac{\partial C}{\partial S} + \kappa(\theta - V)\frac{\partial C}{\partial V} - rC = 0. \tag{84.3}$$

The fundamental transform method proposed by Lewis (2000) can reduce Eq. 84.3 from two variables to one and entirely separate every (volatility independent) payoff function from the calculation of the Green function. After substituting the following, $\tau = T - t$, $x = \log(S) + r(T - t)$, $C(S,V,t) = W(x,V,\tau)e^{-r(T-t)}$ into Eq. 84.3, we have

$$\frac{\partial W}{\partial \tau} = \frac{1}{2}V\left(\frac{\partial^2 W}{\partial x^2} - \frac{\partial W}{\partial x}\right) + \rho\sigma_V V\frac{\partial^2 W}{\partial x \partial V} + \frac{1}{2}\sigma_V^2 V\frac{\partial^2 W}{\partial V^2} + \kappa(\theta - V)\frac{\partial W}{\partial V}. \quad (84.4)$$

Let $G(\phi,V,\tau)$ denote the Fourier transform of $W(x,V,\tau)$:

$$G(\phi, V, \tau) \equiv \int_{-\infty}^{\infty} e^{i\phi x} W(x, V, \tau)dx. \quad (84.5)$$

Given the transform $G(\phi,V,\tau)$, the inversion formula is

$$W(x, V, \tau) = \frac{1}{2\pi}\int_{i\mathrm{Im}[\phi]-\infty}^{i\mathrm{Im}[\phi]+\infty} e^{-i\phi x} G(\phi, V, \tau)d\phi. \quad (84.6)$$

so that differentiation w.r.t. x becomes multiplication by $-i\phi$ in the transform. By taking the τ derivative of both sides of Eq. 84.5 and then replacing $\partial W/\partial\tau$ inside the integral by the right-hand side of Eq. 84.4, we translate Eq. 84.4 into a PDE for $G(\phi,V,\tau)$:

$$\frac{\partial G}{\partial \tau} = \frac{1}{2}\sigma_V^2 V\frac{\partial^2 G}{\partial V^2} - \frac{1}{2}V\left(\phi^2 - i\phi\right)G + \left(\kappa(\theta - V) - i\phi\sigma_V\rho V\right)\frac{\partial G}{\partial V}. \quad (84.7)$$

Hence, a solution $G(\phi,V,\tau)$ to Eq. 84.7, which satisfies $G(\phi,V,0) = 1$, is called a fundamental transform. Given the fundamental transform, a solution for a particular payoff can be obtained by

$$C(S, V, t) = \frac{1}{2\pi}e^{-r(T-t)}\int_{i\mathrm{Im}[\phi]-\infty}^{i\mathrm{Im}[\phi]+\infty} e^{-i\phi x}\,\widetilde{W}(\phi, V, 0)G(\phi, V, \tau)d\phi, \quad (84.8)$$

where $\widetilde{W}(\phi, V, 0)$ is the Fourier transform of the payoff function at maturity.

We will deal with a few common types of payoff functions and see what restrictions are necessary for their Fourier transforms to exist.

84.2.1 Call Option

At maturity, the payoff of a vanilla call option with strike K is $\mathrm{Max}[S_T - K, 0]$ in terms of our original variables. In terms of the logarithmic variables, we have $W(x,V,0) = \mathrm{Max}[e^x - K, 0]$, so the Fourier transform of the payoff is of the form

$$\widetilde{W}(\phi, V, 0) = \int_{-\infty}^{\infty} e^{i\phi x} W(x, V, 0) dx = \int_{\log[K]}^{\infty} e^{i\phi x}(e^x - K) dx$$
$$= K^{1+i\phi} / \left(i\phi - \phi^2\right), \tag{84.9}$$

which does not exist unless $\mathrm{Im}[\phi] > 1$.

84.2.2 Put Option

The payoff of a vanilla put option with strike K is $\mathrm{Max}[K - S_T, 0]$. Its transformed payoff is also $K^{1+i\phi}/(i\phi - \phi^2)$, but the restriction is $\mathrm{Im}[\phi] < 0$.

84.2.3 Digital Call

The payoff of a digital call with strike K is $H[S_T - K]$ where H is a Heaviside function. Its transformed payoff is $-K^{i\phi}/(i\phi)$, subject to $\mathrm{Im}[\phi] > 0$.

84.2.4 Cash-Secured Put

The payoff of a cash-secured put with strike K is $\mathrm{Min}[S_T, K]$. Its transformed payoff is $K^{1+i\phi}/(\phi^2 - i\phi)$, subject to $0 < \mathrm{Im}[\phi] < 1$.

The fundamental solution of Eq. 84.7 is in the form

$$G(\phi, V, \tau) = e^{A(\tau,\phi)+B(\tau,\phi)V}. \tag{84.10}$$

After substituting Eq. 84.10 into Eq. 84.7, a pair of ordinary differential equations for $A(\tau,\phi)$ and $B(\tau,\phi)$ is obtained

$$\dot{A} = \theta\kappa B. \tag{84.11}$$

$$\dot{B} = \frac{1}{2}B^2\sigma_V^2 - B(\kappa + i\phi\sigma_V\rho) - \frac{1}{2}\left(\phi^2 - i\phi\right). \tag{84.12}$$

The solutions can be expressed by

$$B(\tau, \phi) = \frac{(\kappa + i\rho\sigma_V\phi + d(\phi))}{\sigma_V^2} \frac{\left(1 - e^{d(\phi)\tau}\right)}{\left(1 - g(\phi)e^{d(\phi)\tau}\right)} \tag{84.13}$$

$$A(\tau, \phi) = \frac{\kappa\theta}{\sigma_V^2}\left((\kappa + i\rho\sigma_V\phi + d(\phi))\tau - 2\log\left[\frac{g(\phi)e^{d(\phi)\tau} - 1}{g(\phi) - 1}\right]\right) \tag{84.14}$$

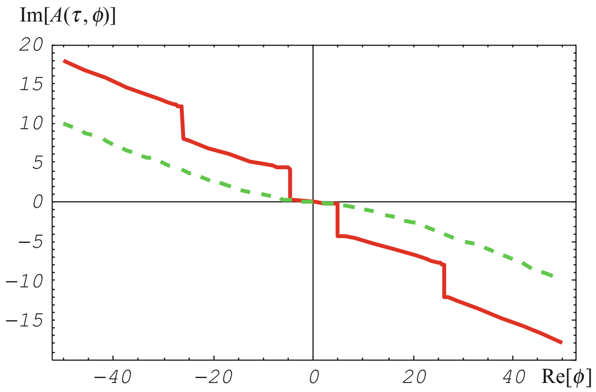

Fig. 84.2 The discontinuity occurs in the fundamental solution of the Heston model if the logarithm with complex arguments is restricted to the principal branch. Underlying: $dS_t = r S_t dt + \sqrt{V_t} S_t dW_S(t)$ with $S_0 = 100$ and $r = 0.0319$. Variance: $dV_t = \kappa(\theta - V_t)dt + \sigma_V \sqrt{V_t} dW_V(t)$ with $V_0 = 0.010201$, $\kappa = 6.21$, $\theta = 0.019$, $\sigma_V = 0.61$, and $\rho = -0.70$. Time to maturity: $T = 2.00$. The *red line* was obtained by evaluating $A(\tau,\phi)$ with the unfixed form given in Eq. 84.14. The *green dashed line* was obtained by evaluating $A(\tau,\phi)$ with the adjusted formula given in Eq. 84.31 and is the correct curve. The logarithmic function for both cases is restricted to using only the principal branch

using the auxiliary functions

$$g(\phi) = \frac{\kappa + i\rho\sigma_V\phi + d(\phi)}{\kappa + i\rho\sigma_V\phi - d(\phi)}, d(\phi) = \sqrt{\left(\phi^2 - i\phi\right)\sigma_V^2 + \left(\kappa + i\rho\sigma_V\phi\right)^2}. \quad (84.15)$$

If the complex, multivalued logarithm is restricted to the principal branch only, discontinuities are necessarily incurred at the cut of the complex logarithm along the integration path, resulting in an incorrect value for Heston formula. Figure 84.2 illustrates the discontinuity problem in the implementation of the fundamental solution. In this example, depicted in Fig. 84.2, $S_0 = 100$, $r = 0.0319$, $V_0 = 0.010201$, $\rho = -0.70$, $\kappa = 6.21$, $\theta = 0.019$, $\sigma_V = 0.61$, and $\text{Im}[\phi] = 2$.

Reasonable parameters in practice may incur the numerically induced discontinuity such that the correct treatment of the phase jump is very crucial. In fact, in examples with long maturity periods, discontinuities are certain to arise from the formula presented in Eq. 84.14 for $A(\tau,\phi)$, if the complex logarithm uses the principal branch only and $2\kappa\theta/\sigma_V^2$ is not an integer (see Fig. 84.3).

One may shift the problem from the complex logarithm to the evaluation of

$$G(\phi, V, \tau) = \left(\frac{g(\phi)e^{d(\phi)\tau} - 1}{g(\phi) - 1}\right)^{-2\alpha} e^{\alpha(\kappa + i\rho\sigma_V\phi + d(\phi))\tau + B(\tau,\phi)V}, \quad (84.16)$$

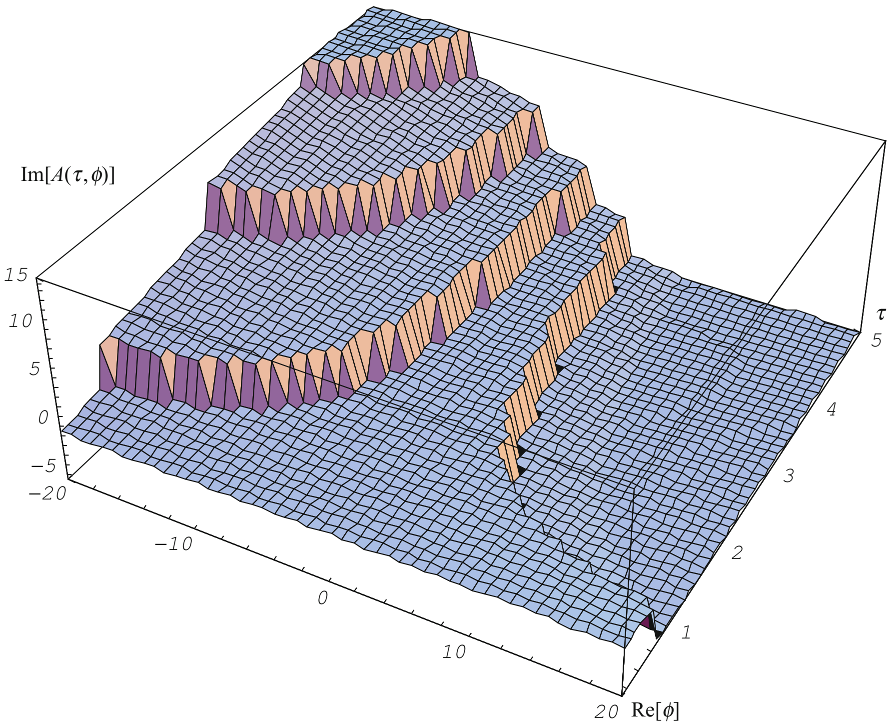

Fig. 84.3 Discontinuities arise quite naturally for customarily used Heston parameters, typically occurring in practice as time to maturity is increased. The other parameters are the same as those specified in Fig. 84.2

where $\alpha = \kappa\theta/\sigma_V^2$. However, this formula comes with the related branch-switching problem of the complex power function, and discontinuities do not diminish in its implementation. Note that taking a complex variable z to the power α gives

$$z^{\alpha} = r^{\alpha} e^{i\alpha\theta}. \tag{84.17}$$

After restricting $\arg(z) \in [-\pi, \pi)$, the complex plane is cut along the negative real axis. Whenever z crosses the negative real axis, the sign of its phase changes from π to $-\pi$. Therefore, the phase of z^{α} changes from $\alpha\pi$ to $-\alpha\pi$. This may lead to a jump because

$$e^{i\pi} = e^{-i\pi} \Rightarrow \begin{cases} e^{i\alpha\pi} \neq e^{-i\alpha\pi} & \text{if } \alpha \notin \mathrm{Z} \\ e^{i\alpha\pi} = e^{-i\alpha\pi} & \text{if } \alpha \in \mathrm{Z} \end{cases}. \tag{84.18}$$

To demonstrate this, Fig. 84.4 gives the scenario that $\alpha \in \mathrm{Z}$ and there is no jump at all. Figure 84.5 gives another scenario that $\alpha \notin \mathrm{Z}$ and the complex power function indeed incurs jumps.

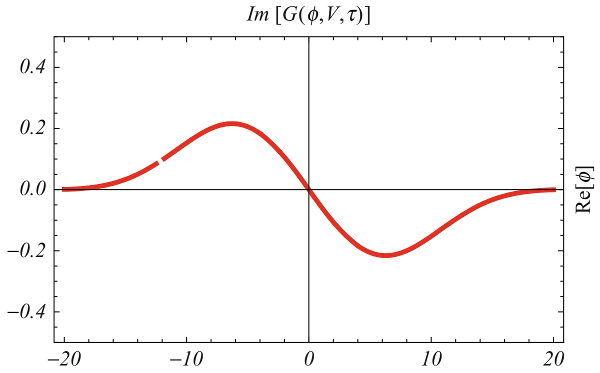

Fig. 84.4 If the power of a complex variable z^{α} is restricted to the principal branch, $\alpha \in \mathrm{Z}$ makes discontinuities diminish at the cut. The fundamental function $G(\phi,V,\tau)$ in Eq. 84.16 is evaluated with the same parameters specified in Fig. 84.2 except for $\kappa = 19.58421$. In this scenario, $\alpha = \kappa\theta/\sigma_V^2 = 1$

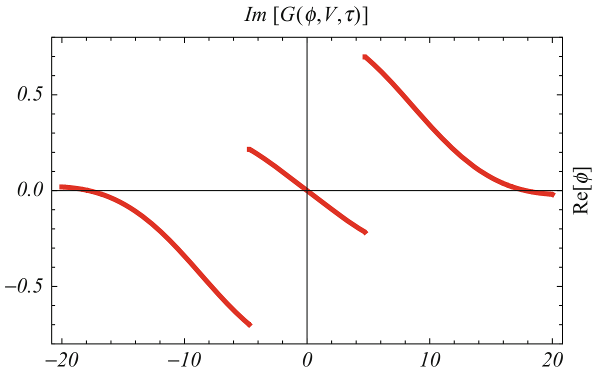

Fig. 84.5 If the power of a complex variable z^{α} is restricted to the principal branch, $\alpha \notin \mathrm{Z}$ makes discontinuities occur at the cut. The fundamental function $G(\phi,V,\tau)$ in Eq. 84.16 is evaluated with the same parameters specified in Fig. 84.2. In this scenario, $\alpha = \kappa\theta/\sigma_V^2 = 0.3170921$

84.3 Solutions to the Discontinuity Problem of Heston Formula

In the literature, various authors propose the idea of carefully keeping track of the branch by monitoring the complex logarithm function for each step along a discretized integral path to remedy phase jumps. As described in Kruse and Nögel (2005), if the imaginary value of the complex logarithm for one step differs from the previous one by more than 2π, the jump of 2π is added or subtracted to recover the continuity of phase. However, using this approach, the already complex integrals of Heston formula may become too complicated in practice. Therefore, simulation is also considered as a practical alternative for finding option prices (see Broadie and Kaya 2006).

To make matters worse, discontinuities arise quite naturally for customarily used Heston parameters simply as time to maturity is increased, thereby illustrating the importance of the correct treatment of phase jumps for Heston formula. Kahl and

Jäckel (2005) remedied these discontinuities using the rotation-corrected angle of the phase of a complex variable. Shaw (2006) dealt with this problem by replacing the call to the complex logarithm by direct integration of the differential equation. In addition, Guo and Hung (2007) also proposed a simple adjusted formula to solve this discontinuity problem. From a computational and convenience point of view, the solution of Guo and Hung (2007) can be implemented easily and is thereby suitable for practical application. These solutions are presented by the following statements.

84.3.1 Rotation-Corrected Angle

In order to guarantee the continuity of $A(\tau,\phi)$, a rotation-corrected term must be additionally calculated in advance. First, we introduce the notation

$$g(\phi) = r_g(\phi)e^{i\theta_g(\phi)}, \tag{84.19}$$

$$d(\phi) = a_d(\phi) + ib_d(\phi). \tag{84.20}$$

The next step is to have a closer look at the denominator of $(g(\phi)e^{d(\phi)\tau} - 1)/(g(\phi) - 1)$:

$$g(\phi) - 1 = r_g(\phi)e^{i\theta_g(\phi)} - 1 = r_g^*(\phi)e^{i\left(\chi_g^*(\phi)+2\pi m\right)} \tag{84.21}$$

where

$$m = \mathrm{int}\left[\frac{\theta_g(\phi) + \pi}{2\pi}\right], \tag{84.22}$$

$$\chi_g^*(\phi) = \arg(g(\phi) - 1), \tag{84.23}$$

$$r_g^*(\phi) = |g(\phi) - 1|, \tag{84.24}$$

and with int[•] denoting Gauss's integer brackets. The same calculation is done with the numerator:

$$\begin{aligned} g(\phi)e^{d(\phi)\tau} - 1 &= r_g(\phi)e^{i\theta_g(\phi)}e^{(a_d(\phi)+ib_d(\phi))\tau} - 1 = r_g(\phi)e^{a_d(\phi)\tau}e^{i\left(\theta_g(\phi)+b_d(\phi)\tau\right)} - 1 \\ &= r_{gd}^*(\phi)e^{i\left(\chi_{gd}^*(\phi)+2\pi n\right)} \end{aligned} \tag{84.25}$$

where

$$n = \mathrm{int}\left[\frac{\theta_g(\phi) + b_d(\phi)\tau + \pi}{2\pi}\right], \tag{84.26}$$

$$\chi^*_{gd}(\phi) = \arg\left(g(\phi)e^{d(\phi)\tau} - 1\right), \tag{84.27}$$

$$r^*_{gd}(\phi) = \left|g(\phi)e^{d(\phi)\tau} - 1\right|. \tag{84.28}$$

Hence, we can compute the logarithm of $(g(\phi)e^{d(\phi)\tau} - 1)/(g(\phi) - 1)$ quite simply as

$$\log\left[\frac{g(\phi)e^{d(\phi)\tau} - 1}{g(\phi) - 1}\right] = \log\left[r^*_{gd}(\phi)/r^*_g(\phi)\right] + i\left[\chi^*_{gd}(\phi) - \chi^*_g(\phi) + 2\pi(n - m)\right], \tag{84.29}$$

where $2\pi(n - m)$ is the rotation-corrected angle.

84.3.2 Direct Integration

Another way to avoid the branch cut difficulties arising from the choice of the branch of the complex logarithm is to perform direct numerical integration of $A(\tau,\phi)$ w.r.t. τ according to Eq. 84.11. Given $B(\tau,\phi)$, $A(\tau,\phi)$ can be obtained by

$$A(\tau, \phi) = \theta\kappa\int_0^\tau B(s, \phi)ds. \tag{84.30}$$

After replacing the call to the complex logarithm by direct integration of the differential equation, the complex logarithm cannot be a problem anymore, and the continuity of $A(\tau,\phi)$ is guaranteed.

84.3.3 Simple Adjusted Formula

Here, we briefly introduce the simple adjusted formula of Guo and Hung (2007) to the discontinuity problem in the implementation of Heston formula. The solution is to move $\exp[-d(\phi)\tau]$ into the logarithm of $A(\tau,\phi)$ by simply adjusting $A(\tau,\phi)$ as follows:

$$A(\tau, \phi) = \frac{\kappa\theta}{\sigma_V^2}\left((\kappa + i\rho\sigma_V\phi - d(\phi))\tau - 2\log\left[\frac{g(\phi)e^{d(\phi)\tau} - 1}{g(\phi) - 1}e^{-d(\phi)\tau}\right]\right). \tag{84.31}$$

The insight in formula (84.31) is that the subtraction of the number 1 from a complex variable, c, results simply in a shift parallel to the real axis. Because an imaginary component must be added to move a complex number across the negative real axis, the phases of $c - 1$ and c exist on the same phase interval.

Therefore, the logarithms of $c-1$ and c have the same rotation count number. It illuminates this simple solution to assure that the phase of $A(\tau,\phi)$ is continuous, without the necessity of a rotation-corrected term.

The logarithm presented in Eq. 84.31 is the only term possibly giving rise to discontinuity. Trivially,

$$\log\left[\frac{g(\phi)e^{d(\phi)\tau}-1}{g(\phi)-1}e^{-d(\phi)\tau}\right]=\log\left[\frac{g(\phi)}{g(\phi)-1}\right]+\log\left[\frac{g(\phi)e^{d(\phi)\tau}-1}{g(\phi)e^{d(\phi)\tau}}\right]. \tag{84.32}$$

Because the subtraction of 1 does not affect the rotation count of the phase of a complex variable, $g(\phi)$ has the same rotation count number (m) as $g(\phi)-1$, and $g(\phi)e^{d(\phi)\tau}-1$ also has the same rotation count number (n) as $g(\phi)e^{d(\phi)\tau}$. Hence, $\log[(g(\phi)e^{d(\phi)\tau}-1)/((g(\phi)-1)e^{d(\phi)\tau})]$ needs no rotation-corrected terms for all levels of Heston parameters because

$$\begin{aligned}\log\left[\frac{g(\phi)e^{d(\phi)\tau}-1}{(g(\phi)-1)e^{d(\phi)\tau}}\right] &= (\log[g(\phi)]-\log[g(\phi)-1])\\ &\quad+\left(\log\left[g(\phi)e^{d(\phi)\tau}-1\right]-\log\left[g(\phi)e^{d(\phi)\tau}\right]\right).\end{aligned} \tag{84.33}$$

Hence, the formula in Eq. 84.31, for $A(\tau,\phi)$, provides a simple solution to the discontinuity problem for Heston stochastic volatility model.

Compared to the rotation-corrected angle method, the simple adjusted-formula method needs no rotation-corrected terms in the already complex integral of Heston formula to recover its continuity for all levels of Heston parameters. Although the direct integration method neither needs the rotation-corrected terms to guarantee the continuity of Heston formula, it inevitably introduces the discretization bias into the evaluation of the Green function component of the solution. This bias may create another serious problem of computation. Many steps may be necessary to reduce the bias to an acceptable level, and, hence, more computational effort is needed to guarantee that the bias is small enough. As a consequence, the direct integration method requires more computing time than the simple adjusted-formula method to avoid the discontinuity problem arising from the complex logarithm.

Figure 84.6 illustrates a comparison of the computing time for applying the simple adjusted-formula and direct integration methods to evaluate a European call option. The direct integration method is more time-consuming than the simple adjusted-formula method. Moreover, the simple adjusted-formula method has an advantage in that its time consumption remains almost at the same level as the time to maturity increases. In contrast, the computing time via the direct integration method increases rapidly with an increase in time to maturity. These computational results were performed on a desktop PC with an Intel Pentium D 3.4 GHz processor and 1 GB of RAM, running Windows XP Professional. The codes were written using the Mathematica software.

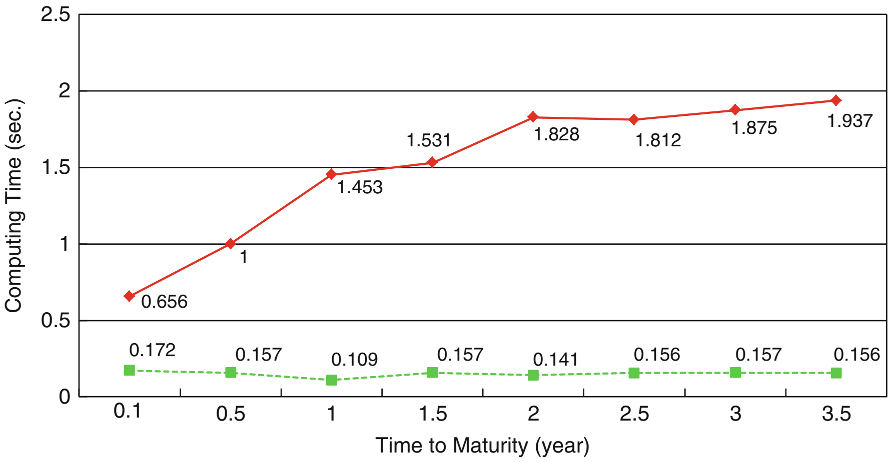

Fig. 84.6 Computing time comparison under Heston stochastic volatility model for a European call option: direct integration versus simple adjusted formula. The *red line* represents the computing time for evaluating a standard call option price using $A(\tau,\phi)$ via direct integration w.r.t. τ given in Eq. 84.30. The *green dashed line* represents the computing time for evaluating the same call option price using $A(\tau,\phi)$ via the simple adjusted formula given in Eq. 84.31. The other parameters are the same as those specified in Fig. 84.2

Table 84.1 Impact of the discontinuity problem on the evaluation of European call options in Heston model on stochastic volatility

		Fundamental solution of the Heston model	
T (year)	Monte Carlo simulation with the exact method (10,000 trials)	Adjusted formula using formula (84.31)	Unfixed formula using formula (84.14)
0.50	4.2658	4.2545	4.2555
1.00	6.7261	6.8061	6.4483
1.50	8.9510	8.9557	8.3286
2.00	10.9633	10.8830	9.7079
2.50	12.6100	12.6635	10.5542
3.00	14.2591	14.3366	10.9778

Here, $S_0 = 100.00$, $K = 100.00$, $r = 0.0319$, $V_0 = 0.010201$, $\rho = -0.70$, $\kappa = 6.21$, $\theta = 0.019$, and $\sigma_v = 0.61$. Note that the evaluation of the fundamental solution of the Heston model using formula (84.31) still yields values consistent with those of the Monte Carlo simulation for all time-to-maturity cases, although the complex logarithm is restricted to the principal branch

Table 84.1 is an illustration of the usefulness of the simple adjusted formula for evaluating European call options in Heston model using the complex logarithm restricted to the principal branch. The algorithm was verified using Monte Carlo simulation with the exact method proposed by Broadie and Kaya (2006) for the stochastic volatility process. Although the exact method of simulation has the advantage that its convergence rate is much faster than that of the conventional Euler discretization method, it is, of course, computationally more burdensome than the simple adjusted-formula method.

84.4 Summary

This chapter looks at the issue raised by branch cuts in the transform solutions for European-style financial claims in the Heston model. The multivalued nature of the complex logarithm and power functions results in numerical instability in the implementation of the fundamental transform. Compared to the work of Kahl and Jäckel (2005), neither the direct integration method of Shaw (2006) nor the simple adjusted formula of Guo and Hung (2007) requires rotation-corrected terms to assure the robustness of the evaluation of Heston formulae. After taking computing time into consideration, the evidence shows that the simple adjusted-formula method is greatly superior to the direct integration method.

Stochastic Change-Point Models of Asset Returns and Their Volatilities

85

Tze Leung Lai and Haipeng Xing

Contents

Abstract

We begin with an overview of frequentist and Bayesian approaches to incorporating change points in time series models of asset returns and their volatilities. It has been found in many empirical studies of stock returns and exchange rate that ignoring the possibilities of parameter changes yields time series models with long memory, such as unit-root nonstationarity and high volatility persistence. We therefore focus on the ARX-GARCH model and introduce two timescales, using the "short" timescale to define GARCH dynamics and the

"long" timescale to incorporate parameter jumps. This leads to a Bayesian change-point ARX-GARCH model, whose unknown parameters may undergo occasional changes at unspecified times and can be estimated by explicit recursive formulas when the hyperparameters of the Bayesian model are specified. We describe efficient estimators of the hyperparameters of the Bayesian model leading to empirical Bayes estimators of the piecewise constant parameters with relatively low computational complexity. We also show how the computationally tractable empirical Bayes approach can be applied to the frequentist problem of partitioning the time series into segments under sparsity assumptions on the change points.

Keywords

ARX-GARCH • Bounded complexity • Contemporaneous jumps • Change-point models • Empirical Bayes • Frequentist segmentation • Hidden Markov models • Hyperparameter estimation • Markov chain Monte Carlo • Recursive filters • Regression models • Stochastic volatility

85.1 Introduction

As we have noted in Lai and Xing (2010), portfolio theory, asset pricing, and hedging all involve volatilities, and volatility modeling is a cornerstone of empirical finance. Since the seminal works of Engle (1982) and Bollerslev (1986), generalized autoregressive conditionally heteroskedastic (GARCH) models have been widely used to model and forecast volatilities of financial time series. In many empirical studies of stock returns and exchange rates, estimation of the parameters v, a, and b in the GARCH (1,1) model

$$y_n = \sigma_n \epsilon_n, \quad \sigma_n^2 = (1 - a - b)v^2 + a y_{n-1}^2 + b\sigma_{n-1}^2$$

reveals high volatility persistence, with the maximum likelihood estimate of $a + b$ close to 1. To model such persistence, Engle and Bollerslev (1986) considered the "integrated" GARCH (IGARCH) models, and Baillie et al. (1996) introduced fractional integration in their FIGARCH models, with a slow hyperbolic rate of decay for the influence of the past innovations, to quantify the long memory of exchange rate volatilities. However, it has been pointed out that if the model parameters undergo occasional changes, then the fitted models that assume time-invariant parameters tend to exhibit long memory; see Diebold (1986), Perron (1989), Rappoport and Reichlin (1989), and Lamoureux and Lastrapes (1990). Therefore the long memory in the IGARCH and FIGARCH models may be due to the long timescale of the parameter changes that are ignored in these models.

The frequentist approach to incorporating change points in regression models assume that the change points are unknown parameters to be estimated from the data; see Quandt (1958, 1960), Andrews et al. (1996), Bai (1997, 1999), Bai et al. (1998), Bai and Perron (1998, 2003), Qu and Perron (2007); and the references therein. Finding these change points amounts to segmenting the data. Because of the computational complexity and analytic intractability, it is prohibitively difficult to extend these methods from relatively simple regression models to incorporate change points in a stochastic regression model with GARCH-type error variances. An alternative approach is Bayesian and assumes that the change points and the associated regimes are generated by some stochastic process so that the unknown regression parameters can be estimated from their posterior distribution via Bayes theorem; see Goldfeld and Quandt (1973) and Hamilton (1989, 1990). The Bayesian approach has been used to develop hidden Markov models (HMM) for asset returns, allowing contemporaneous jumps in their levels and volatilities. Markov chain Monte Carlo (MCMC) methods are used to estimate the hidden states and the unknown hyperparameters of the Bayesian method. Section 85.2 gives an overview of the literature, including the SVCJ models (stochastic volatility models with contemporaneous jumps in returns and volatilities) that have been an active area of research in finance and econometrics in the past decade.

In Sect. 85.3 we describe a much simpler class of Bayesian change-point models for asset returns and their volatility that we recently developed. This class of models yields explicit recursive filters and smoothers, thereby obviating the reliance on MCMC methods whose convergence properties and performance in change-point time series models have not been systematically studied because of their computational complexity. The optimal Bayes estimates in our change-point ARX-GARCH model involve unspecified hyperparameters, which can in principle be estimated by the EM algorithm. For regime-switching ARCH models, Cai (1994) have noted the "tremendous complication" of the normal equations of the EM algorithm, making it "extremely difficult" to implement for sample sizes exceeding 50. By using recursive representations of the summands of the log-likelihood function, we have a relatively simple algorithm to evaluate the log-likelihood function and estimate the hyperparameters of the change-point model. In Sect. 85.3, after introducing the change-point ARX-GARCH model, we first describe the associated filters for estimating the piecewise constant ARX parameter β_n and long-run volatility v_n based on the observations $y_1, \ldots, y_n$, assuming known hyperparameters that include the GARCH parameters associated with short-term volatility changes. Bounded complexity mixture (BCMIX) approximations are also developed for efficient computation of these filters and of the likelihood function to estimate the hyperparameters. We then use these closed-form recursions to develop BCMIX approximations to the Bayes estimates (smoothers) of β_t and v_t for $1 \leq t \leq n$. In contrast to our empirical Bayes approach that assumes a relatively simple stochastic model for change points, the frequentist approach which is often called "segmentation" assumes the change points and the pre- and post-change regression coefficients in regression models to be unknown parameters and uses maximum likelihood to estimate them and a model selection criterion to determine the number of change points. Section 85.3 also uses the relative simplicity of the EB smoothers to resolve difficulties in the frequentist segmentation problem. Section 85.4 gives some concluding remarks and discussion.

85.2 Overview of Bayesian Models with Jumps in Returns and Volatilities

85.2.1 Jumps in Regression Parameters, Error Variance, and ARCH Parameters

Since this chapter focuses on volatility modeling as in Lai and Xing (2010), we only review Bayesian change-point models that include changes in volatilities. Albert and Chib (1993) consider ARX models (autoregressive models with exogenous inputs) whose levels and error variances are subject to regime changes determined by a two-state Markov chain with unknown transition probabilities. Specifically, assuming the state space for the two-state Markov chain to be $\{0, 1\}$, with $s_t = 1$ representing that a change has occurred at time t, their model can be expressed as

$$y_t = \beta^T \mathbf{x}_t + \gamma s_t + \sum_{i=1}^{\kappa} \phi_i \left(y_{t-i} - \beta^T \mathbf{x}_{t-1} - \gamma s_{t-1} \right) + \left(\sigma^2 + \tau^2 s_t \right)^{1/2} \epsilon_t, \qquad (85.1)$$

in which ϵ_t are independent standard normal, σ^2, τ^2, γ, $\phi_1, \ldots, \phi_\kappa$ are unknown parameters such that $\phi(z) := 1 - \phi_1 z - \cdots - \phi_\kappa z^k$ has zeros outside the unit circle. Their abstract says, "The unobserved states, one for each time point, are treated as missing data and then analyzed via the simulation tool of Gibbs sampling. This method is expedient because the conditional posterior distribution of the parameters, given the states, and the conditional posterior distribution of the states, given the parameters, all have a form amenable to Monte Carlo sampling. The approach is straightforward and generates marginal posterior distribution for all parameters of interest. Posterior distributions of the states, future observations, and the residuals, averaged over the parameter space are also obtained." The unknown hyperparameters in their Bayesian model are estimated by maximum likelihood.

Instead of including ARX dynamics as in Eq. 85.1, Hamilton and Susmel (1994) consider regime-switching ARCH models

$$y_t = \alpha + \phi y_{t-1} + \tau(s_t) \sqrt{h_t} \epsilon_t, \qquad (85.2a)$$

$$h_t = a_0 + a_1 u_{t-1}^2 + \cdots + a_q u_{t-q}^2, \qquad (85.2b)$$

in which ϵ_t are independent standard normal, α, ϕ, $a_0, \ldots, a_q$, $\tau(1), \ldots, \tau(K)$ are unknown parameters, and s_t is an unobserved K-state Markov chain with unknown transition probabilities on state space $\{1, \ldots, K\}$. They use maximum likelihood to estimate the unknown parameters and also develop a complicated summation formula to compute the conditional density of $(s_t, s_{t-1}, \ldots, s_{t-q})$ given $y_1, \ldots, y_t$. They call (85.2) a *Markov-switching ARCH* model, denoted SWARCH(K, q), and have also extended it to include leverage effects by adding $\xi u_{t-1}^2 I_{\{u_{t-1} \leq 0\}}$ to the right-hand side of (85.2b), in which case the model is denoted SWARCH-L(K, q).

These Markov-switching ARCH (or ARCH-L) models can also use the standardized Student-t instead of standard normal errors as in the usual GARCH models; see Lai and Xing (2010, Sect. 93.2.3).

Instead of ARCH models, So et al. (1998) consider stochastic volatility models (Lai and Xing 2010, Sect. 93.2.7) and include regime-switching features in those models. Their Markov-switching stochastic volatility (MSSV) models are of the form

$$y_t = \sqrt{h_t}\epsilon_t, \quad \log h_t = \tau(s_t) + \phi \log h_{t-1} + \eta_t, \tag{85.3}$$

in which ϵ_t are independent standard normal, η_t are independent $N(0, \sigma^2)$ and ϕ, σ^2, $\tau(1), \ldots, \tau(K)$ are unknown parameters, and s_t is an unobserved K-state Markov chain with unknown transition probabilities on $\{1, \ldots, K\}$. As in Albert and Chib (1993), they use Gibbs sampling to estimate by Monte Carlo the posterior distribution of the states and also of the h_t after putting a prior distribution on the vector of unknown parameters and transition probabilities.

Assuming the number, but not the locations, of the change points to be known, Wang and Zivot (2000) consider a deterministically trending dynamic time series model in which multiple structural changes in level, trend, and error variance are modeled through specification of the prior distributions. Their model is a segmented heteroskedastic AR(k) model

$$y_t = \sum_{i=1}^{m+1} \left\{(\alpha_i + \beta_i t) I_{\{t_{i-1} \le t < t_i\}} + \sigma_i \epsilon_t\right\} + \sum_{j=1}^{k} \phi_j y_{t-j}, \tag{85.4}$$

with $t_0 = 1$, $t_{m+1} = T$, and m change points at unknown times $t_1, \ldots, t_m$ in the interval $[1, T]$. The ϵ_t in Eq. 85.4 are independent standard normal, and the α_i, β_i, σ_i, and ϕ_j are unknown parameters. Letting θ denote the vector consisting of these unknown parameters and $t_1, \ldots, t_m$, they put a prior distribution on θ and use Gibbs sampling to estimate its posterior distribution. Bayes factors, or posterior odds, or Schwarz's BIC can be used to select m, and they have found from simulation studies that Bayes factors and the BIC have satisfactory performance, while posterior odds are quite sensitive to the prior probabilities of models with different numbers of breaks.

McCulloch and Tsay (1993) consider AR(k) models with occasional level shifts

$$y_t = \mu_t + \sum_{i=1}^{k} \phi_i (y_{t-i} - \mu_{t-i}) + \eta_t, \tag{85.5}$$

in which η_t are independent $N(0, \sigma^2)$, or with occasional variance shifts

$$y_t = \mu + \sum_{i=1}^{k} \phi_i y_{t-i} + \sigma_t \epsilon_t, \tag{85.6}$$

in which ϵ_t are independent standard normal. The μ_t in Eq. 85.5 are piecewise constant so that $I_t := I_{\{\mu_t \neq \mu_{t-1}\}}$ are i.i.d. Bernoulli(p) with $P(I_t = 1) = p$. Similarly, in Eq. 85.6, $I_t := I_{\{\sigma_t \neq \sigma_{t-1}\}}$ are i.i.d. Bernoulli(p). To complete the prior specification of μ_t, McCulloch and Tsay (1993) write $\mu_t = \mu_{t-1} + z_t I_t$ and specify z_t to be a sequence of independent and identically distributed (i.i.d) normal random variables with variance τ^2 and independent of I_t. They also put conjugate priors on $\phi_1, \ldots, \phi_k$ and σ^2. Similarly, for Eq. 85.6, they write $\sigma_t = \sigma_{t-1} v_t^{I_t}$ and specify v_t^2 are i.i.d. inverted χ^2-random variables conditional on $(\mu, \phi_1, \ldots, \phi_k)$, which is assigned a conjugate prior distribution. Gibbs sampling is used to estimate the unknown parameters; after assigning "quite diffuse" prior distribution to the hyperparameters.

Lai et al. (2005) have introduced a more general change-point model than that of McCulloch and Tsay (1993). This change point has been reviewed in Sect. 93.3.3 of Lai and Xing (2010) and allows jumps in level, autoregressive parameters, and error variance, thereby incorporating both Eqs. 85.5 and 85.6. In addition, the model yields *explicit* recursive formulas for estimating the parameters and do not need Gibbs sampling or other Monte Carlo methods for its implementation. One may wonder why a more general model can be easier to implement. The key lies in the specification of the new parameter value at a change point. Specifically, McCulloch and Tsay (1993) assume $\mu_t = \mu_{t-1} + z_t I_t$ (or $\sigma_t = \sigma_{t-1} v_t^{I_t}$), while Lai et al. (2005) assume $\boldsymbol{\theta}_t = (1 - I_{t-1})\boldsymbol{\theta}_{t-1} + I_t \mathbf{z}_t$. Thus, the Bayesian model of Lai, Liu, and Xing samples a completely new value of the parameter vector at a change point while that of McCulloch and Tsay samples the *increment* $\mu_t - \mu_{t-1}$ or σ_t/σ_{t-1} at a change point. The great reduction in computational complexity by sampling a new parameter value over sampling an increment was first noticed by Yao (1984) in his simplification of the Bayesian model of Chernoff and Zacks (1964) for mean shifts in a Gaussian sequence of normal random variables with common known variance but piecewise constant means.

85.2.2 Stochastic Volatility Models with Jumps in Returns and Volatilities

To estimate the magnitude and assess the significance of stochastic volatility and jump risk premia in option pricing, contemporaneous jumps in prices and in stochastic volatilities have been incorporated in continuous-time models of asset price dynamics. Bakshi et al. (1997) have shown substantial improvement over including only jumps in prices, while Bates (2000) and others have found such improvement to be small. Further studies show unanimous support for jumps in prices but disagree on the importance of jumps in volatilities and even on how the volatility jumps should be modeled. Duffie et al. (2000) developed analytic methods for asset valuation and econometric analysis in the setting of affine jump-diffusion state processes. They pointed out that price jumps should depend on the size of volatility jumps via the jump intensities and introduced the following continuous-time stochastic volatility models that incorporate contemporaneous jumps in returns and volatilities for the asset price $S_t = e^{Y_t}$:

$$\begin{pmatrix} dY_t \\ dV_t \end{pmatrix} = \begin{pmatrix} \mu \\ \kappa(\theta - V_{t-})dt \end{pmatrix} + \sqrt{V}_{t-}\begin{pmatrix} 1 & 0 \\ \rho\sigma_v & \sqrt{1-\rho^2}\sigma_v \end{pmatrix} dW_t + \begin{pmatrix} \xi^y dN_t^y \\ \xi^v dN_t^v \end{pmatrix}, \tag{85.7}$$

where $V_{t-} = \lim_{s \uparrow t} V_s$, W_t is a standard 2-dimensional Brownian motion, N_t^y and N_t^v are Poisson processes with constant intensities λ_y and λ_v, and ξ^y and ξ^v are random jump sizes in returns and volatilities, respectively. Such specification covers most of the popular models used in portfolio allocation and option pricing. For example, the case $\lambda_y = \lambda_v = 0$ is equivalent to Heston's (1993) stochastic volatility model, and the case of $\lambda_v = 0$ and normal ξ^y is the same as Bates' (1996) model that has normally distributed jumps in returns. For the general model (85.7), Eraker et al. (2003) developed a simulation-based Bayes estimator, using Markov chain Monte Carlo (MCMC), of the jumps in returns and volatilities after discretizing Eq. 85.7 into

$$\begin{aligned} Y_{(t+1)\Delta} &= Y_{t\Delta} = \mu\Delta + \sqrt{V_{t\Delta}\Delta}\epsilon^y_{(t+1)\Delta} + \xi^y_{(t+1)\Delta}J^y_{(t+1)\Delta}, \\ V_{(t+1)\Delta} - V_{t\Delta} &= \kappa(\theta - V_{t\Delta})\Delta + \sigma_v\sqrt{V_{t\Delta}\Delta}\epsilon^v_{(t+1)\Delta} + \xi^v_{(t+1)\Delta}J^v_{(t+1)\Delta}, \end{aligned} \tag{85.8}$$

where $J^y_{(t+1)\Delta}$ (or $J^v_{(t+1)\Delta}$) is the indicator variable of a jump at $(t+1)\Delta$, $\epsilon^y_{(t+1)\Delta}$ and $\epsilon^v_{(t+1)\Delta}$ are standard normal random variables with correlation ρ, and Δ is the time-discretization interval. Letting $\Theta = (\theta_1, \ldots, \theta_k)$ denote the parameter vector and assuming $J^y = J^v$ (i.e., contemporaneous jumps), they note that the posterior density of Θ and the latent volatility, jump times, and jump sizes satisfy

$$f(\Theta, J, \xi^y, \xi^v, V|Y) \propto f(Y|\Theta, J, \xi^y, \xi^v, V) f(\Theta, J, \xi^y, , \xi^v, V)$$

and use the MCMC algorithm to generate samples by iteratively drawing from the following conditional posteriors till convergence to the stationary distribution:

$$\begin{aligned} &\textit{parameters}: f(\Theta_i|\Theta_{-i}, J, \xi^y, \xi^v, V, Y), \qquad i = 1, \ldots, k, \quad \text{with} \quad \Theta_{-i} = \Theta\backslash\{\theta_i\}, \\ &\textit{jump times}: f(J_{t\Delta} = 1|\Theta, \xi^y, \xi^v, V, Y), \qquad t = 1, \ldots, T \\ &\textit{jump sizes}: f\left(\xi^y_{t\Delta}|\Theta, J_{t\Delta} = 1, \xi^v, V, Y\right), f\left(\xi^v_{t\Delta}|\Theta, J_{t\Delta} = 1, \xi^v, V, Y\right), \quad t = 1, \ldots, T \\ &\textit{volatility}: f\left(V_{t\Delta}|V_{(t+1)\Delta}, V_{(t-1)\Delta}, \Theta, J, \xi^y, \xi^v, Y\right), \qquad t = 1, \ldots, T. \end{aligned}$$

Broadie et al. (2007) discussed the issue more thoroughly and found strong evidence in support of stochastic volatility and jumps in both price and volatility.

85.3 A Simple Stochastic Change-Point ARX-GARCH Model

The model (85.7), which is often referred to as SVCJ (stochastic volatility model with contemporaneous jumps in returns and volatilities), assumes Poisson arrivals of contemporaneous jumps in returns and volatilities with constant intensity. In discrete time, this is equivalent to $J_{t\Delta}$ being independent Bernoulli, which is assumed in the models of McCulloch and Tsay (1993) and Lai et al. (2005) discussed at the end of Sect. 85.2.1. What (85.8) adds to these models is the SV dynamics in the second equation of Eq. 85.8, in contrast to piecewise constant σ_t in Eq. 85.6 or in Lai et al. (2005). Because SV is a nonlinear state-space model, this makes the SVCJ model difficult to implement and also explains the need for MCMC algorithm. Replacing SV by a GARCH model achieves similar properties but obviates the need of filtering in a state-space model. To incorporate structural changes in the regression coefficients and the unconditional variance of the random disturbances in an autoregressive model with exogenous inputs (ARX), while allowing the conditional variances to follow a GARCH model, Lai and Xing (2013) consider the change-point ARX-GARCH model

$$y_t = \beta_t^T \mathbf{x}_t + v_t \sqrt{h_t} \epsilon_t, \tag{85.9}$$

in which the parameter vector β_t and the unconditional variance v_t^2 are piecewise constant, with jumps at times of structural change, the vector $\mathbf{x}_t$ consists of exogenous variables and the past observations $y_{t-1}, y_{t-2}, \ldots, y_{t-\kappa}$, and h_n represents short-term proportional fluctuations in variance generated by the GARCH model

$$h_n = \left(1 - \sum_{i=1}^{k} a_i - \sum_{l=1}^{k'} b_l\right) + \sum_{i=1}^{k} a_i w_{n-\mathrm{i}}^2 + \sum_{l=1}^{k'} b_l h_{n-l} \quad \text{with} \quad w_t = \sqrt{h_t}\epsilon_t. \tag{85.10}$$

The ϵ_t are assumed to be i.i.d. standard normal random variables such that ϵ_t are independent of $\mathbf{x}_t$ and the time-invariant GARCH parameters $a_1, \ldots, a_k$, $b_1, \ldots, b_{k'}$ are assumed to satisfy

$$a_i \geq 0, b_l \geq 0 \text{ and } \sum_{i=1}^{k} a_i + \sum_{l=1}^{k'} b_l \leq 1. \tag{85.11}$$

Letting $\tau_t = 1/(2v_t^2)$, we assume $\boldsymbol{\theta}_t = (\beta_t^T, \tau_t)^T$ to be piecewise constant and satisfy the following conditions:

(A1) For $t > t_0 = \max(k, k')$, the change times of $\boldsymbol{\theta}_t$ form a renewal process with i.i.d. inter-arrival times that are geometrically distributed with parameter p, or equivalently,

$$I_t := 1_{\{\boldsymbol{\theta}_t \neq \boldsymbol{\theta}_{t-1}\}} \text{ are i.i.d. } \text{Bernoulli}(p) \text{ with } P(I_t = 1) = p,$$

$I_{t_0} = 1$, and there is no change point prior to t_0.

(A2) $\boldsymbol{\theta}_t = (1 - I_t)\boldsymbol{\theta}_{t-1} + I_t(\mathbf{z}_t^T, \gamma_t)^T$, where $(\mathbf{z}_1^T, \gamma_1)^T$, $(\mathbf{z}_2^T, \gamma_2)^T$, ... are i.i.d. random vectors such that $\mathbf{z}_t|\gamma_t \sim$ Normal($\mathbf{z}$, $\mathbf{V}/(2\gamma_t)$), $\gamma_t \sim \chi_d^2/\rho$, where χ_d^2 denotes the chi-square distribution with d degrees of freedom.

(A3) The processes $\{I_t\}$, $\{\boldsymbol{\theta}_t\}$, and $\{(\mathbf{x}_t, \epsilon_t)\}$ are independent.

This model generalize the approach developed by Lai et al. (2005), who consider the special case of AR models with occasional jumps in regression parameters and error variances. The last paragraph of Sect. 93.3.3 of Lai and Xing (2010) has given a brief introduction of the model, and we provide more complete details here and also an updated account that includes some recent results.

85.3.1 Closed-Form Recursive Filters

Conditions (A1)–(A3) specify a Markov chain with unobserved states $(I_t, \boldsymbol{\theta}_t)$. The observations $(\mathbf{x}_t, y_t)$ are such that $(y_t - \beta_t^T \mathbf{x}_t)/v_t$ forms a GARCH process. This hidden Markov model (HMM) has hyperparameters p, $\mathbf{z}$, $\mathbf{V}$, ρ, d, $a_1, \ldots, a_k$, $b_1, \ldots, b_{k'}$. To estimate $\boldsymbol{\theta}_t$ assuming known hyperparameters, let $J_n = \max\{t \le n : I_n = 1\}$ and note that $n - J_n \ge k$ by

(A1). Define $\mathcal{Y}_n = (\mathbf{x}_1, y_1, \ldots, \mathbf{x}_n, y_n)$ and $\mathcal{Y}_{j,n} = \left(\mathbf{x}_j, y_j, \ldots, \mathbf{x}_n, y_n\right)$. The estimates $\hat{\beta}_n$ and $\hat{v}_n^2$ based on $\mathcal{Y}_n$ are weighted averages of $\hat{\beta}_{n,j}$ and $\hat{v}_{n,j}^2$ based on $\mathcal{Y}_{j,n}$, with the weights $p_{n,j}$ to be specified. The $\hat{\beta}_{n,j}$ and $\hat{v}_{n,j}^2$ can be computed recursively (with increasing n and fixed j). Initializing at $n = j - 1$ with $\hat{\beta}_{n,j} = \mathbf{z}$, $\hat{\mathbf{V}}_{n,j} = \mathbf{V}$, and $\hat{v}_{n,j}^2 = \rho/(2d)$, define for $n \ge j$

$$\hat{h}_{n,j} = \left(1 - \sum_{i=1}^{k} a_i - \sum_{l=1}^{k'} b_l\right) + \sum_{l=1}^{k'} b_l \hat{h}_{n-l,j} + \sum_{i=1}^{k} a_i \frac{\left(y_{n-i} - \hat{\beta}_{n-i,j}^T \mathbf{x}_{n-i}\right)^2}{\hat{v}_{n-i,j}^2} \tag{85.12a}$$

$$\mathbf{V}_{n,j} = \mathbf{V}_{n-1,j} - \left\{\mathbf{V}_{n-1,j}\mathbf{x}_n\mathbf{x}_n^T\mathbf{V}_{n-1,j} / \left(\hat{h}_{n,j} + \mathbf{x}_n^T\mathbf{V}_{n-1,j}\mathbf{x}_n\right)\right\}, \tag{85.12b}$$

$$\hat{\beta}_{n,j} = \hat{\beta}_{n-1,j} + \left\{\mathbf{V}_{n-1,j}\mathbf{x}_n\left(y_n - \hat{\beta}_{n-1,j}^T\mathbf{x}_n\right) / \left(\hat{h}_{n,j} + \mathbf{x}_n^T\mathbf{V}_{n-1,j}\mathbf{x}_n\right)\right\}, \tag{85.12c}$$

$$\hat{v}_{n,j}^2 = \frac{d+n-j-2}{d+n-j-1}\hat{v}_{n-1,j}^2 + \frac{1}{d+n-j-1} \cdot \frac{\left(y_n - \hat{\beta}_{n-1,j}^T\mathbf{x}_n\right)^2}{\hat{h}_{n,j} + \mathbf{x}_n^T\mathbf{V}_{n-1,j}\mathbf{x}_n}. \tag{85.12d}$$

The weights $p_{n,j}$ are given recursively by

$$p_{n,j} \propto p^*_{n,j} := \begin{cases} p\ f_{nn}/f_{00} & \text{if} \quad j = n, \\ (1-p)p_{n-1,j}f_{nj}/f_{n-1,j} & \text{if} \quad j \leq n-1 \end{cases} \tag{85.13}$$

where letting $\mathbf{z}_{n,j} = \mathbf{V}_{n,j}\left(\mathbf{V}^{-1}\mathbf{z} + \sum_{t=j}^{n} \mathbf{x}_t y_t/\hat{h}_{t,j}\right)$ and

$$\rho_{n,j} = \frac{1}{2}\rho + \mathbf{z}^T\mathbf{V}^{-1}\mathbf{z} - \mathbf{z}^T_{n,j}\mathbf{V}^{-1}_{n,j}\mathbf{z}_{n,j} + \sum_{t=j}^{n} y_t^2/\hat{h}_{t,j}, \tag{85.14}$$

$p_{n,j} = p^*_{n,j}/\sum_{j'=1}^{n} p^*_{n,j'}$, and the f_{nj} are given explicitly by

$$\begin{aligned} f_{nj} &= \left|\mathbf{V}_{n,j}\right|^{1/2}\Gamma((d+n-j+1)/2)\rho_{n,j}^{-(d+n-j+1)/2}, \\ f_{00} &= |\mathbf{V}|^{1/2}\Gamma(d/2)(\rho/2)^{-d/2}. \end{aligned} \tag{85.15}$$

These formulas are extensions of those for the special case $\mathbf{x}_t = (y_{t-1}, \ldots, y_{t-k})^T$ and $h_t \equiv 1$ considered by Lai et al. (2005). The extension from the case $h_t \equiv 1$ to more general known h_t basically amounts to extending ordinary least squares estimation (given the most recent change-point J_n) to generalized least squares estimation.

85.3.2 Estimation of Hyperparameters

The above Bayesian filter involves $\mathbf{z}$, $\mathbf{V}$, ρ, d, p, and $\boldsymbol{\eta} = (a_1, \ldots, a_k, b_1, \ldots, b_{k'})$. Note that $\mathbf{z}$ is the prior mean of β_t and $\rho/(d-2)$ is the prior mean of $2v^2$ at time t when parameter changes occur. As noted in Lai and Xing (2008), it is more convenient to represent the χ^2_d/ρ prior distribution for $(2v_t^2)^{-1}$ as a gamma $(d/2, \rho/2)$ distribution so that d does not need to be an integer. The recursions (85.12b) and (85.12c) are basically recursions for ridge regression which shrinks the generalized least squares estimate (using the weights $\hat{h}_{t,j}$) towards $\mathbf{z}$, with $\mathbf{V}^{-1}$ and $\sum_{t=j}^{n} \mathbf{x}_t\mathbf{x}_t^T$ being the matrix weights for the shrinkage target and the generalized least squares estimator, respectively. The shrinkage target $\mathbf{z}$ and its associated weight matrix $\mathbf{V}^{-1}$ are relevant when $n-j$ is small but become increasingly negligible with increasing $n-j$. We can estimate $\mathbf{z}$, $\mathbf{V}$, ρ, and d by applying the method of moments to the stationary distribution of the Markov chain $(I_t, \theta_t, \epsilon_t)$ that is partially observed via $(\mathbf{x}_t, y_t)$. Details are given in the next paragraph. With $\mathbf{z}$, $\mathbf{V}$, ρ, and d replaced by these estimates, we then estimate $\boldsymbol{\eta}$ and p by maximum likelihood, noting that the log-likelihood function ℓ_n based on $y_1, \ldots, y_n$ has the representation

$$\log\ \ell_n(\boldsymbol{\eta}, p) = \sum_{t=1}^{n} \log \left[\sum_{j=1}^{t} p^*_{t,j}(\boldsymbol{\eta}, p)\right], \tag{85.16}$$

where $p^*_{t,j}$ is given by Eq. 85.13.

Lai and Xing (2013) use the method-of-moments estimates of $\mathbf{z}$, $\mathbf{V}$, ρ, and d based on $(\mathbf{x}_t, y_t)$, $1 \le t \le n$. From (A2) and (A3), it follows that $E(\beta_t) = \mathbf{z}$, $\mathrm{Cov}(\beta_t) = (Ev_t^2)\mathbf{V}$, and $E(\mathbf{x}_t y_t) = \mathbf{x}_t \mathbf{x}_t^T \mathbf{z}$. From $n - L$ moving windows $\{(\mathbf{x}_t, y_t) : s \le t \le s + L\}$ of these data, compute the least squares estimates

$$\hat{\beta}^{(s)} = \left(\sum_{s \le t \le s+L} \mathbf{x}_t \mathbf{x}_t^T \right)^{-1} \sum_{s \le t \le s+L} \mathbf{x}_t y_t. \tag{85.17}$$

Each $\hat{\beta}^{(s)}$ is a method-of-moments estimate of $\mathbf{z}$, and so is $\hat{\beta} = (n - L)^{-1} \sum_{s=1}^{n-L} \hat{\beta}^{(s)}$. If an oracle would reveal the change times up to time n, then one would segment the time series accordingly and use the least squares estimate for each segment to estimate the regression parameter for that segment. The average of these least squares estimates over the segment would provide a method-of-moments estimate of $\mathbf{z}$. Similarly, the average squared residual in each segment is a method-of-moments estimate of $E(v_t^2) = \rho/[2(d - 2)]$, and so is the average of these values over the segments; see Engle and Mezrich (1996). In ignorance of the change points, the segments are replaced by moving windows of length $L + 1$ in Eq. 85.9 and estimate $\mathbf{z}$ by the average $\overline{\beta}$ of the $\hat{\beta}^{(s)}$. Likewise ρ and d can be estimated by equating the mean and variance of the inverted gamma distribution for v_t^2 to their sample counterparts for the average squared residuals:

$$\begin{aligned} \frac{\hat{\rho}}{\left[2\left(\hat{d} - 2\right)\right]} &= \overline{v} := (n - L)^{-1} \sum_{s=1}^{n-L} \left[\sum_{s \le t \le s+L} \left(y_t - \mathbf{x}_t^T \hat{\beta}^{(s)} \right)^2 / (L + 1) \right], \\ \frac{\hat{\rho}^2}{\left[\left(2\left(\hat{d} - 2\right)\right)^2 \left(\hat{d} - 4\right) \right]} &= (n - L)^{-1} \sum_{s=1}^{n-L} \left[\sum_{s \le t \le s+L} \left(y_t - \mathbf{x}_t^T \hat{\beta}^{(s)} \right)^2 / (L + 1) - \overline{v} \right]^2. \end{aligned} \tag{85.18}$$

Similarly Lai and Xing (2013) estimate $\mathbf{V}$ by

$$\hat{\mathbf{V}} = \left[2\left(\hat{d} - 2\right)/\hat{\rho}\right](n - L)^{-1} \sum_{s=1}^{n-L} \left(\hat{\beta}^{(s)} - \overline{\beta} \right) \left(\hat{\beta}^{(s)} - \overline{\beta} \right)^T. \tag{85.19}$$

85.3.3 Bounded Complexity Mixture Approximations

Although Eq. 85.13 provides closed-form recursions for updating the weights $p_{t,i}$, $1 \le i \le t$, the number of weights increases with t, resulting in rapidly increasing computational complexity and memory requirements for estimating θ_n as n increases. A natural idea to reduce the complexity and to facilitate the use of parallel algorithms for the recursions is to keep only a fixed number M of weights at every stage n (which is tantamount to setting the other weights to be 0).

Lai and Xing (2013) keep the most recent m weights $p_{n,i}$ (with $n - m < i \leq n$) and the largest $M - m$ of the remaining weights, where $1 \leq m < M$. Specifically, let $\mathcal{K}_{n-1}$ denote the set of indices i for which $p_{n-1,i}$ is kept at stage $n - 1$; thus $\mathcal{K}_{n-1} \supset \{n-1,, \ldots, n-m\}$. At stage n, define $p^*_{n,i}$ by Eq. 85.5 for $i \in \{n\} \cup \mathcal{K}_{n-1}$, and let i_n be the index not belonging to $\{n, n - 1, \ldots, n - m + 1\}$ such that

$$p^*_{n,i_n} = \min\left\{p^*_{n,i} : j \in \mathcal{K}_{n-1} \quad \text{and} \quad j \leq n - m\right\}, \tag{85.20}$$

choosing i_n to be the one farthest from n if the minimizing set in (85.12) has more than one element. Define $\mathcal{K}_n = \{n\} \cup (\mathcal{K}_{n-1} - \{i_n\})$, and let

$$p_{n,i} = \frac{p^*_{n,i}}{\sum_{j \in \mathcal{K}_n} p^*_{n,j}}. \tag{85.21}$$

Lai and Xing (2013) use these bounded complexity mixtures (BCMIX) not only to approximate the filters $(\beta_t, v_t)|\mathcal{Y}_t$ but also to approximate the likelihood function (85.8), in which we replace $\sum_{j=1}^{t}$ by $\sum_{j \in \mathcal{K}_t}$. They use a grid of the form $\{2^j/n : j_0 \leq j \leq j_1\}$, where $j_0 < 0 < j_1$ are integers, to search for the maximum $\hat{p}_n$ of $\ell_n(p; \hat{\eta}_n)$ over the grid. Letting $\lambda = (p, \boldsymbol{\eta}), \hat{\lambda}_n = (p_n, \hat{\eta}_n)$ is used to replace λ in the recursions (85.4) and (85.5). The update $\hat{\boldsymbol{\eta}}_n$ of the GARCH parameters after observing $(\mathbf{x}_n, y_n)$ uses simply a single iteration of the Newton-Raphson iteration procedure to maximize $\ell_n(\hat{p}_{n-1}, \boldsymbol{\eta})$ when $n \geq n_0$ and uses more iterations until convergence for small n. Therefore relatively fast updates of the hyperparameters estimates can be used to implement the adaptive BCMIX filters.

85.3.4 Sequential BCMIX Forecasts

The AR-GARCH model is often used to forecast future returns and their volatilities for portfolio optimization and risk management; see Sects. 6.4.1 and 12.2.3 of Lai and Xing (2008). Incorporating exogenous inputs and change points into the model improves the forecasts. For the change-point ARX-GARCH model, first assume that the hyperparameters are known. Since $\mathbf{x}_{n+1}$ consists of $y_n, \ldots, y_{n-\kappa+1}$ and other input variables up to time n and since time $n + 1$ has prior probability p of being a change point, the forecast $\hat{y}_{n+1|n}$ of y_{n+1} given $\mathcal{Y}_n$ is related to the filter $\hat{\beta}_n$ given in Sect. 85.1 by

$$\hat{y}_{n+1|n} = p\mathbf{z}^T\mathbf{x}_{n+1} + (1-p)\hat{\beta}_n^T\mathbf{x}_{n+1}, \tag{85.22}$$

noting that β_{n+1} is equal to β_n with probability $1 - p_{n,n}$. Similarly, the forecast $\hat{v}^2_{n+1|n}$ of v^2_{n+1} given $\mathcal{Y}_n$ is

$$\hat{v}^2_{n+1|n} = \frac{pp}{2(d-2)} + (1-p)\hat{v}^2_{n|n}, \tag{85.23}$$

assuming $d > 4$ in view of Eq. 85.10. Note that the conditional variance in the GARCH model involves $v_n^2 h_n$ rather than v_n^2. Lai and Xing (2013) can use Eq. 85.4a with n replaced by $n + 1$ to forecast h_{n+1}. In particular, for GARCH (1,1), they forecast h_{n+1} by $h_{n+1,j} = (1-a-b) + b\hat{h}_{n,j} + a\left(y_n - \hat{\beta}^T_{n,j}\mathrm{x}_n\right)^2/\hat{v}^2_{n,j}$ and use the weights $p_{n,j}$ in Eq. 85.13 to weight

$$\hat{v}^2_{n+1,j}\hat{h}_{n+1,j} = \left\{\frac{p\rho}{2(d-2)} + (1-p)\hat{v}^2_{n,j}\right\}\left\{(1-a-b) + b\hat{h}_{n,j} + \frac{a\left(y_n - \hat{\beta}^T_{n,j}\mathbf{x}_n\right)^2}{\hat{v}^2_{n,j}}\right\}. \tag{85.24}$$

85.3.5 BCMIX Smoothers

Lai and Xing (2013) begin by deriving the Bayes estimate (smoother) of $\boldsymbol{\theta}_t = (\beta_t^T, \tau_t)^T$ given $\mathcal{Y}_n$ for $1 \le t \le n$ in the "oracle" setting in which the h_t are specified exactly (by the oracle) so that there are explicit recursive representations of the posterior mean of $\boldsymbol{\theta}_t$ given $\mathcal{Y}_n$ for $1 \le t \le n$. To obtain the optimal smoother $E(\theta_t|\mathcal{Y}_n)$ for $1 \le t \le n$, they use Bayes theorem to combine the forward filter $\theta_t|\mathcal{Y}_t$ with the backward filter $\theta_t|\mathcal{Y}_{t+1,n}$. Because the h_t are assumed known in $\left(y_t - \beta_t^T\mathbf{x}_t\right)/\sqrt{h_t} = v_t\epsilon_t$ and the ϵ_t are i.i.d. standard normal, the backward filter has the same form as the forward filter. In fact, assumptions (A1)–(A3) define a reversible Markov chain of jump times and jump magnitudes, assuming $I_{n-t_0+1} = 1$ and no change points afterwards. Let π denote the density function of the stationary distribution. Letting $\widetilde{J}_{t+1} = \min\{s \ge t+1 : I_s = 1\}$ and $q_{t+1,j} = P\left(\widetilde{J}_{t+1} = j|\mathcal{Y}_{t+1,n}\right)$ for $j \ge t + 1$, one can reverse time and obtain a backward filter that is similar to the forward filter:

$$f\left(\boldsymbol{\theta}_t|\mathcal{Y}_{t+1,n}\right) = p\pi(\boldsymbol{\theta}_t) + (1-p) \sum_{j=t+1}^{n} q_{t+1,j} f\left(\boldsymbol{\theta}_{t+1}|\mathcal{Y}_{t+1,n}, \widetilde{J}_{t+1} = j\right),$$

in which

$$q_{t+1},j \propto q^*_{t+1,j} = \begin{cases} pf_{jj}/f_{00} & \text{if } j = t+1, \\ (1-p)q_{t+2,j} f_{t+1,j}/f_{t+2,j} & \text{if } j \ge t+2. \end{cases}$$

Application of Bayes theorem then yields

$$\begin{aligned} &f(\boldsymbol{\theta}_t|\mathcal{Y}_n) \propto f(\boldsymbol{\theta}_t|\mathcal{Y}_t) f\left(\boldsymbol{\theta}_t|\mathcal{Y}_{t+1,n}\right)/\pi(\boldsymbol{\theta}_t) \\ &\propto p\sum_{i=1}^{t} p_{i,t} f(\boldsymbol{\theta}_t|\mathcal{Y}_n, C_{it}) + (1-p) \sum_{1 \le i \le t < j \le n} p_{i,t} q_{t+1,j} \frac{f_{ij} f_{00}}{f_{it} f_{t+1,j}} f\left(\boldsymbol{\theta}_t|\mathcal{Y}_n, C_{ij}\right), \end{aligned}$$

where $C_{ij} = \{I_i = 1, I_{i+1} = \cdots = I_j = 0, I_{j+1} = 1\}$. Let $\boldsymbol{\tau}_n = (\tau_{j,i}, 1 \le i \le j \le n)$. The optimal smoother for β_t and v_t^2 are given by

$$\beta_t|\tau_n, \mathcal{Y}_n \sim \sum_{1 \le i \le t \le j \le n} \alpha_{ijt} N\left(\mathbf{z}_{j,i}, \mathbf{V}_{j,i}/\left(2\tau_{j,i}\right)\right), \quad \tau_{j,i}|\mathcal{Y}_n \sim \chi^2_{d+j-i+1}/\rho_{j,i}, \tag{85.25}$$

where $\mathbf{V}_{j,i}$, $\mathbf{z}_{j,i}$, and $\rho_{j,i}$ are same as those defined in Eqs. 85.4 and 85.6 and α_{ijt} can be determined recursively by

$$\begin{aligned} \alpha_{ijt} &= \alpha^*_{ijt}/A_t, \qquad A_t = \sum_{1 \le i \le t \le j \le n} \alpha^*_{ijt}, \\ \alpha^*_{ijt} &= \begin{cases} pp_{i,t}, & i \le t, j = t, \\ ap_{i,t} q_{t+1,j} f_{00} f_{ij}/f_{it} f_{t+1,j}, & i \le t, j > t. \end{cases} \end{aligned} \tag{85.26}$$

Moreover, the posterior probability of having a change point at time t is given by

$$P(I_{t+1} = 1|\mathcal{Y}_n) = \sum_{1 \le i \le t} P(C_{it}|\mathcal{Y}_n) = p/A_t.$$

The next step is to approximate α_{ijt} by $\hat{\alpha}_{ijt}$ that replaces the h_t, which is actually unknown, by the estimates $\hat{h}_{j,i}$ defined recursively for $j \ge i$ by Eq. 85.12a. As in Sect. 85.3.1, we assume known hyperparameters p and $\boldsymbol{\eta}$ for the time being. Using the BCMIX approximation to the forward and backward filters, we approximate the sum in Eq. 85.25 and that defining A_t in Eq. 85.26 by

$$\beta_t|\tau_n, \mathcal{Y}_n \sim \sum_{i \in \mathcal{K}_t, j \in \{t\} \cup \widetilde{\mathcal{K}}_{t+1}} \alpha_{ijt} N\left(\mathbf{z}_{j,i}, \mathbf{V}_{j,i}/\left(2\tau_{j,i}\right)\right), \tau_{j,i}|\mathcal{Y}_n \sim \chi^2_{d+j-i+1}/\rho_{j,i} \tag{85.27}$$

where $\mathcal{K}_t$ is the same as that in Sect. 85.3.3 for the forward filter and $\widetilde{\mathcal{K}}_{t+1}$ is the corresponding set for the backward filter. Assuming known $\boldsymbol{\eta}$ and p, the BCMIX estimates for β_t and v_t given $\mathcal{Y}_n$ are

$$\begin{aligned} \hat{\beta}_{t|n} &= \sum_{i \in \mathcal{K}_t, j \in \{t\} \cup \widetilde{\mathcal{K}}_{t+1}} \alpha_{ijt} \mathbf{z}_{j,i}, \qquad \hat{v}^2_{t|n} = \sum_{i \in \mathcal{K}_t, j \in \{t\} \cup \widetilde{\mathcal{K}}_{t+1}} \alpha_{ijt} \frac{\rho_{j,i}}{d + j - i - 1}, \\ \hat{\tau}_{t|n} &= \sum_{i \in \mathcal{K}_t, j\{t\} \cup \widetilde{\mathcal{K}}_{t+1}} \alpha_{ijt}(d + j - i + 1)/\left(2\rho_{j,i}\right). \end{aligned} \tag{85.28}$$

The conditional probability of a change point at time $t(\le n)$ given $\mathcal{Y}_n$ is estimated by

$$\hat{P}(I_{t+1} = 1|\mathcal{Y}_n) = p/A_t. \tag{85.29}$$

Without assuming p and $\boldsymbol{\eta}$ to be known, we can use the BCMIX approximation in the log-likelihood function (85.16) based on $\mathcal{Y}_n$ and evaluate its maximizer $(\hat{p}, \hat{\boldsymbol{\eta}})$. Replacing $(p, \boldsymbol{\eta})$ by $(\hat{p}, \hat{\boldsymbol{\eta}})$ in Eq. 85.28 yields the BCMIX empirical Bayes smoother.

85.3.6 Application to Segmentation

In principle, the frequentist approach to multiple change-point problems for regression models reviewed in Sect. 85.1 can be extended to ARX-GARCH models by maximizing the log-likelihood over the locations of the change points and the piecewise constant parameters when it is assumed that there are k change points. This optimization problem, however, is much more difficult than that for regression models and only constitutes an inner loop of an algorithm whose outer loop is another minimization, over k, of a suitably chosen model selection criterion to determine k. For computational and analytic tractability, the frequentist approach typically assumes that k is small relative to n and that adjacent change points are sufficiently far apart so that the segments are identifiable except for relatively small neighborhoods of change points; see Bai and Perron (1998). Lai and Xing (2011) formulate these assumptions for the piecewise constant parameter vectors $\boldsymbol{\theta}_t$ as follows:

(B1) The true change points occur at $t_1^{(n)} < \cdots < t_k^{(n)}$ such that $\liminf_{n \to \infty} n^{-1} (t_i^{(n)} - t_{i-1}^{(n)}) > 0$ for $1 \le i \le k+1$, with $t_0^{(n)} = 0$ and $t_{k+1}^{(n)} = n$.

(B2) There exists $\delta > 0$, which does not depend on n, such that $\min_{1 \le i \le k} \left\| \boldsymbol{\theta}_{t_i^{(n)}} - \boldsymbol{\theta}_{t_{i-1}^{(n)}} \right\| \ge \delta$ for all large n.

In the context of ARX-GARCH models, Lai and Xing (2013) also assume that the stochastic regressors satisfy the stability condition:

(B3) $\max_{1 \le t \le n} \|\mathbf{x}_t\|^2 / n \xrightarrow{P} 0$ and $\sum_{t=1}^{n} \mathbf{x}_t \mathbf{x}_t^T / n$ converge almost surely to a positive definite nonrandom matrix.

Under (B1)–(B3) and assuming that $m \sim |\log n|^{1+\epsilon}$ and $M - m = O(1)$ as $n \to \infty$, for some $\epsilon > 0$, Lai and Xing (2013) have shown that the BCMIX smoother $\hat{\boldsymbol{\theta}}_{t|n}$ satisfies

$$\max_{1 \le t \le n : \min_{1 \le i \le k} \left| t - t_i^{(n)} \right| \ge m} \left\| \hat{\boldsymbol{\theta}}_{t|n} - \boldsymbol{\theta}_t \right\| \to 0, \quad \text{as } n \to \infty \tag{85.30}$$

uniformly in $a_1/n \le p \le a_2/n$. They apply this result to estimate the change times $t_1^{(n)}, \ldots, t_k^{(n)}$ in (B1) as follows. Let

$$\Delta_t = \left\| \hat{\boldsymbol{\theta}}_{t+m} - \hat{\boldsymbol{\theta}}_{t-m} \right\|^2, \tag{85.31}$$

and let $\hat{\tau}_1$ be the maximizer of Δ_t over $m < t < n - m$. After $\hat{\tau}_1, \ldots, \hat{\tau}_{j-1}$ have been defined, define

$$\hat{\tau}_j = \arg \max_{t:m<t<n-m,\, \min_{1\le i\le j-1}|t-\hat{\tau}_i|\ge m} \Delta_t; \tag{85.32}$$

these estimates of the change times are unordered and do not depend on the number k of change points. Assuming that there are k change points, they order $\hat{\tau}_1, \ldots, \hat{\tau}_k$ as $\hat{t}_{(1),k} < \cdots < \hat{t}_{(k),k}$ to provide estimates of $t_1^{(n)} < \cdots < t_k^{(n)}$. Let $\boldsymbol{\theta}^{(j)}$ be the common value of $\boldsymbol{\theta}_t$ in the interval $t_{j-1}^{(n)} \le t < t_j^{(n)}$. Assuming $t_1^{(n)}, \ldots, t_k^{(n)}$ to be known, the parameter vectors $\boldsymbol{\theta}^{(1)}, \ldots, \boldsymbol{\theta}^{(k+1)}$ can be estimated by maximum likelihood. Replacing the $t_1^{(n)}, \ldots, t_k^{(n)}$ by the estimates $\hat{t}_{(1),k} < \cdots < \hat{t}_{(k),k}$ in these MLEs leads to the quasi-likelihood estimators $\widetilde{\boldsymbol{\theta}}^{(1)}, \ldots, \widetilde{\boldsymbol{\theta}}^{(k+1)}, \widetilde{\boldsymbol{\eta}}$, and the quasi-likelihood

$$\Lambda_n(k) = \sum_{j=1}^{k+1} \sum_{t=\hat{t}_{(j-1),k}}^{\hat{t}_{(j),k}-1} \log f\left(y_t; \boldsymbol{\theta}^{(j)}, \boldsymbol{\eta}\right) \tag{85.33}$$

in which $f(\cdot;\boldsymbol{\theta}, \boldsymbol{\eta})$ in the density function of y_t given the piecewise constant parameter values, noting that $\left(y_t - \beta_t^T \mathbf{x}_t\right)/\left(v_t\sqrt{h_t}\right)$ is standard normal. Assuming a known upper bound K on the number k of change points in (B1), Lai and Xing (2013) propose to estimate k by

$$\hat{k}_n = \arg \max_{1\le k\le K} \{\Lambda_n(k) - (k+1)C_n\},$$

where C_n is a penalty term that satisfies

$$C_n \to \infty \text{ and } C_n/n \to 0 \text{ as } n \to \infty; \tag{85.34}$$

making use of Theorem 1, they have shown that $\hat{k}_n \xrightarrow{P} k$, $\widetilde{\boldsymbol{\eta}} \xrightarrow{P} \boldsymbol{\eta}$, and $\widetilde{\boldsymbol{\theta}}^{(j)} \xrightarrow{P} \boldsymbol{\theta}^{(j)}$ for $1 \le j \le k + 1$. Their simulation studies show that this segmentation procedure performs well in frequentist and Bayesian scenarios.

85.4 Discussion

The idea of representing the GARCH model by $v_t\sqrt{h_t}\epsilon_t$, in which v_t^2 is the unconditional variance and h_t follows the GARCH dynamics in Eq. 85.10, has also been used by Engle and Rangel (2008) in their spline-GARCH model that uses a deterministic function of time and exogenous variables to model v_t by

$$\log v_t = \beta^T \mathbf{x}_t + \phi_0 t + \sum_{i=0}^{I} \phi_i (t - t_i)_+^2.$$

The change-point ARX-GARCH model uses a piecewise constant function to model v_t instead and relates the exogenous variables $\mathbf{x}_t$ to y_t via the regression model (85.9), allowing contemporaneous jumps in the regression coefficients and the unconditional variances. As in Lai et al. (2005) who consider the special case $h_t \equiv 1$ and $\mathbf{x}_t = (y_{t-1}, \ldots, y_{t-\kappa})^T$, the stochastic model (85.9) for jumps in (β_t, v_t) involves linear Bayes methods and conjugate priors, yielding BCMIX approximations to the Bayes estimate of (β_t, v_t^2). The BCMIX approximations also provide estimates of the hyperparameters in the Bayesian model with relatively low computational complexity, yielding empirical Bayes estimates of the piecewise constant parameters that are efficient from both computational and statistical viewpoints. Section 85.6.6 shows how the computationally attractive EB estimates can be used to address the challenging frequentist problem of segmentation.

The empirical study in Lai and Xing (2013) of weekly returns of SP500 index, from the week starting on January 2, 1990, to the week starting on August 24, 2009, shows that segmenting the data by the method in Sect. 85.3.6 can remove the spurious long memory in volatility exhibited by fitting the AR-GARCH model to the entire time series without incorporating possible parameter changes during the long period that has undergone several structural changes. The apparent long memory arises from the (long) timescale for parameter changes. The segments are more general than the "regimes" in regime-switching volatility models (which are HMMs) reviewed in Sect. 85.2.1, in which difficulties in estimating the hyperparameters are noted. To address these difficulties, Gray (1996, pp. 35–36) modifies the usual regime-switching GARCH model by aggregating the conditional variances from different regimes at each time step. In Lai and Xing's segmentation approach, the GARCH parameters are separately estimated for different segments. However, to determine the segments using the empirical Bayes estimates, the Bayesian model assumes changes only in the unconditional variance v_t^2 but not in the GARCH parameters $a_1, \ldots, a_k, b_1, \ldots, b_{k'}$. Not only does this model circumvent the computational difficulties of regime-switching GARCH (or even ARCH) models noted by Cai (1994) and Gray (1996), but it also captures the short-run dynamics of the conditional variance and the structural changes of the long-run volatility. Although not allowing the GARCH parameters to change over time may appear too restrictive, one can in fact estimate them and the other hyperparameter p from moving windows of current and past data, instead of from the entire past history as in Eq. 85.16, thereby implicitly allowing these hyperparameters to change slowly over time.

Unspanned Stochastic Volatilities and Interest Rate Derivatives Pricing

86

Feng Zhao

Contents

Abstract

This paper first reviews the recent literature on the unspanned stochastic volatilities (USV) documented in the interest rate derivatives markets. The USV refers to the volatility factors implied in the interest rate derivatives prices that have little correlation with the yield curve factors. We then present the result in Li and Zhao (*Journal of Finance, 62*, 345–382, 2006) that a sophisticated DTSM without USV feature can have serious difficulties in hedging caps and cap straddles, even though they capture bond yields well. Furthermore, at-the-money straddle hedging errors are highly correlated with cap implied volatilities and can explain a large fraction of hedging errors of all caps and straddles across

moneyness and maturities. These findings strongly suggest that the unmodified dynamic term structure models, assuming the same set of state variables for both bonds and derivatives, are seriously challenged in capturing the term structure volatilities. We also present a multifactor term structure model with stochastic volatility and jumps that yields a closed-form formula for cap prices from Jarrow et al. (*Journal of Finance, 61*, 341–378, 2007). The three-factor stochastic volatility model with Poisson jumps can price interest rate caps well across moneyness and maturity. Last we present the nonparametric estimation results from Li and Zhao (2009). Specifically, the forward densities depend significantly on the slope and volatility of LIBOR rates, and mortgage market activities have strong impacts on the shape of the forward densities. These results provide nonparametric evidence of unspanned stochastic volatility and suggest that the unspanned factors could be partly driven by activities in the mortgage markets. These findings reinforce the claim that term structure models need to accommodate the unspanned stochastic volatilities in pricing and hedging interest rate derivatives.

The econometric methods in this chapter include extended Kalman filtering, maximum likelihood estimation with latent variables, local polynomial method, and nonparametric density estimation.

Term structure modeling • Interest rate volatility • Heath-Jarrow-Morton model • Nonparametric density estimation • Extended Kalman filtering

86.1 Introduction

Interest rate caps and swaptions are among the most widely traded interest rate derivatives in the world. According to the Bank for International Settlements, their combined notional values are more than ten trillion dollars in recent years, which are many times bigger than that of exchange-traded options. Because of the size of these markets, accurate and efficient pricing and hedging of caps and swaptions have enormous practical importance. Pricing interest rate derivatives are more demanding than pricing bonds in that the derivatives are more sensitive to the higher-order moments of the distributions for underlying and therefore the models need to be able to capture the interest rate volatilities as well as the interest rates themselves. Under the unified framework of the dynamic term structure models (hereafter DTSMs), a benchmark in the term structure literature, the same set of risk factors are used in pricing bonds and derivatives. Consequently, the set of risk factors can be indentified with the observations of bond yields or swap rates, while the inclusion of derivative prices can help in terms of the efficiency of the estimation but not essential. The practitioners, on the other hand, generally apply the Heath-Jarrow-Morton (HJM) type of models in pricing interest rate derivatives, in which the entire yield curve is taken as given, and sometimes factors independent of yield curve, such as stochastic volatilities and jumps, are added in a piece-meal approach. This divergence foreshadows one of the key issues of the fast-growing literature on LIBOR-based interest rate derivatives, the so-called unspanned stochastic volatility (USV) puzzle.[1]

Interest rate caps and swaptions are derivatives written on LIBOR and swap rates, and the traditional view is that their prices be determined by the same set of risk factors that determine LIBOR and swap rates. However, several recent studies have shown that there seem to be risk factors that affect the prices of caps and swaptions but are not spanned by the underlying LIBOR and swap rates. Heidari and Wu (2003) show that while the three common term structure factors (i.e., the level, slope, and curvature of the yield curve) can explain 99.5 % of the variations of bond yields, they explain less than 60 % of swaption implied volatilities. After including three additional volatility factors, the explanatory power is increased to over 97 %. Similarly, Collin-Dufresne and Goldstein (2002) show that there is a very weak correlation between changes in swap rates and returns on at-the-money (ATM) cap straddles: the R^2s of regressions of straddle returns on changes of swap rates are typically less than 20 %. Furthermore, one principal component explains 80 % of regression residuals of straddles with different maturities. As straddles are approximately delta neutral and mainly exposed to volatility risk, they refer to the factor that drives straddle returns but is not affected by the term structure factors as "unspanned stochastic volatility" (hereafter USV). Jagannathan et al. (2003) find that an affine three-factor model can fit the LIBOR/swap curve rather well. However, they identify significant shortcomings when confronting the model with data on caps and swaptions, thus concluding that derivatives must be used when evaluating term structure models. On the other hand, Fan et al. (2003) provide evidence against the existence of USV and show the swaptions can be hedged using bonds alone with an HJM model and the difference from the previous studies results from the nonlinear dependence of derivative prices on the yield curve factors. Li and Zhao (2006) show the yield curve factors extracted using a quadratic term structure model can hedge the bonds perfectly, but not the interest rate caps, and the unhedged components can systematically improve hedging performance across moneyness. They argue the difference is likely due to the fact that the interest caps are more sensitive to the volatility factors than the swaptions, and also the DTSMs are suitable to address the question whether the derivatives are redundant since the HJM type of models needs using both data sets for estimation. Overall, most studies suggest that interest rate derivatives are not redundant securities and cannot be hedged using bonds alone. In other words, bonds do not span interest rate derivatives. In the following table we regress weekly cap straddle returns at different moneyness and maturity on weekly changes in the three yield factors and obtain very similar results. In general, the R^2s in Table 86.1 are very small for straddles that are close to the money. For deep ITM and OTM straddles, the R^2s

[1]Another issue is the relative pricing between caps and swaptions. Although both caps and swaptions are derivatives on LIBOR rates, existing models calibrated to one set of prices tend to significantly misprice the other set of prices. For a more detailed review of the literature, see Dai and Singleton (2003).

Table 86.1 Regression analysis of USV in cap market

	Maturity												
Moneyness (K/F)	1.5	2	2.5	3	3.5	4	4.5	5	6	7	8	9	10

1.35	0.872	**0.784**	0.827	0.785	0.796	0.756	0.553	–	–	–	–	–	–
1.40	0.888	0.821	0.879	0.832	0.845	0.851	–	–	–	–	–	–	–

This table reports the R^2s of regressions of weekly returns of cap straddles across moneyness and maturity on weekly changes of the three yield factors. Due to changes in interest rates and strike prices, we do not have the same number of observations for each moneyness/maturity group. The bold entries represent moneyness/maturity groups that have less than 10 % of missing values, and the rest are the ones with 10–50 % of missing values increase significantly. This is consistent with the fact that the ATM straddles are more sensitive to the volatility risk than others away from money.

The existence of USV has profound implications for term structure modeling, especially on the existing multifactor dynamic term structure models, a widely popular term structure model followed by a huge literature in the last decade. One of the main reasons of the popularity of these models is their tractability: they provide closed-form solutions for the prices of not only zero-coupon bonds but also a wide range of interest rate derivatives (see, e.g., Duffie et al. 2000; Chacko and Das 2002; Leippold and Wu 2002). The closed-form formulae significantly reduce the computational burden of implementing these models and simplify their applications in practice. However, almost all existing DTSMs assume that derivatives are redundant and can be perfectly hedged using solely bonds. Hence, the presence of USV in the derivatives market implies that one fundamental assumption underlying all DTSMs does not hold, and these models need to be substantially extended to incorporate the unspanned factors before they can be applied to derivatives. However, as Collin-Dufresne and Goldstein (2002) show, it is rather difficult to introduce USV in traditional DTSMs: one must impose highly restrictive assumptions on model parameters to guarantee that certain factors that affect derivative prices do not affect bond prices. In other words, the ATSMs with USV are restricted version of the existing ATSMs. Some recent papers, for example, Bikbov and Chernov (2004), have tested the USV restrictions by comparing USV models to the nesting unrestricted ATSMs and rejected the USV restrictions when both models are fitted to both bonds and derivatives data. This approach, however, gives misleading conclusions. The USV for term structure models resembles the inclusion of stochastic volatility (SV) in the stock price process, where the natural comparison is between the Black-Scholes model and the SV model. Similarly, the USV model should be nesting the traditional DTSM without USV for statistical testing. Specifically, if the unrestricted three-factor affine model is a good fit for the term structure of interest rates, one should test whether adding one more factor, i.e., a four-factor affine model with USV, will help capture the derivatives data.

Some recent studies have also provided evidence in support of the existence of USV using bonds data alone. They show the yield curve volatilities backed out from a cross section of bond yields do not agree with the time-series filtered volatilities, via GARCH or high-frequency estimates from yields data. This challenges the traditional DTSMs even more since these models cannot be expected to capture the option implied volatilities if they cannot even match the realized yield curve volatilities. Specifically, Collin-Dufresne et al. (2004, CDGJ) show that the LIBOR volatility implied by an affine multifactor specification from the swap rate curve can be negatively correlated with the time series of volatility obtained from a standard GARCH approach. In response, they argue that an affine four-factor USV model delivers both realistic volatility estimates and a good cross-sectional fit. Andersen and Benzoni (2006), through the use of high-frequency data on bond yields, construct the model-free "realized yield volatility" measure by computing empirical quadratic yield variation for a cross section of fixed maturities. They find that the yield curve fails to span yield volatility, as the systematic volatility factors are largely unrelated to the cross section of yields. They claim that a broad class of affine diffusive, Gaussian-quadratic, and affine jump-diffusive models is incapable of accommodating the observed yield volatility dynamics. An important implication is that the bond markets per se are incomplete and yield volatility risk cannot be hedged by taking positions solely in the Treasury bond market. They also advocate using the empirical realized yield volatility measures more broadly as a basis for specification testing and (parametric) model selection within the term structure literature. Thompson (2008), on the LIBOR/swap data, argues when the affine models are estimated with the time-series filtered yield volatility, they can pass on his newly proposed specification test, but not with the cross-sectional backed-out volatility. From these studies on the yields data alone, there may exist an alternative explanation for the failure of DTSMs in effectively pricing derivatives in that the bonds small convexity makes bonds not sensitive enough to identify the volatilities from measurement errors. Therefore, efficient inference requires derivatives data as well.

It can be argued in the same fashion that identification of the unspanned factors can be most efficiently accomplished by adding derivatives data to the analysis. Duarte (2008) shows mortgage-backed security (MBS) hedging activity affects interest rate volatility and proposes a model that takes these effects as a measure for the stochastic volatility of the underlying term structure. However, it is unclear whether the realized volatility is indeed different from the implied volatility due to the MBS effects.

Li and Zhao (2009) provide one of the first nonparametric estimates of probability densities of LIBOR rates under forward martingale measures using caps with a wide range of strike prices and maturities.[2] The nonparametric estimates of LIBOR forward densities are conditional on the slope and volatility factors of LIBOR rates, while the level factor is automatically incorporated in existing methods.[3] They find that the forward densities depend significantly on the slope and volatility of LIBOR rates. For example, the forward densities become more dispersed (compact) when the slope of the term structure (the volatility of LIBOR rates) increases. Further analysis reveals a nonlinear relation between the forward densities and the volatility of LIBOR rates that depends on the slope of the term structure. With a flat (steep) term structure, higher volatility tends to lead to more dispersed (compact) forward densities. This result suggests that the speed of mean reversion of the volatility process depends on the slope of the term structure, a feature that has not been explicitly

[2]The nonparametric forward densities estimated using caps, which are among the simplest and most liquid OTC interest rate derivatives, allow consistent pricing of more exotic and/or less liquid OTC interest rate derivatives based on the forward measure approach. The nonparametric forward densities can reveal potential misspecifications of most existing term structure models, which rely on strong parametric assumptions to obtain closed-form formula for interest rate derivative prices.

[3]Andersen and Benzoni (2006) show the “curvature” factor is not significantly correlated with the yield volatility and it is true in this paper as well; therefore, the volatility effect here is not due to the “curvature” factor.

accounted for by existing term structure models. Additionally, this paper documents important impacts of mortgage market activities on the LIBOR forward densities even after controlling for both the slope and volatility factors. For example, the forward densities at intermediate maturities (3, 4, and 5 years) are more negatively skewed when refinance activities, measured by the Mortgage Bankers Association of America (MBAA) refinance index, are high. Demands for out-of-the-money (OTM) floors by investors in mortgage-backed securities (MBS) to hedge potential losses from prepayments could lead to more negatively skewed forward densities. The impacts of refinance activities are most significant at intermediate maturities because the durations of most MBS are around 5 years. The forward density at 2-year maturity is more rightly skewed when ARMs origination (measured by the MBAA ARMs index) is high. Since every ARM contains an interest rate cap that caps the mortgage rate at a certain level, demands for OTM caps from ARMs lenders to hedge their exposures to rising interest rate could lead to more rightly skewed forward densities. The impacts of ARMs are most significant at 2-year maturity because most ARMs get reset within the first 2 years. These empirical results have important implications for the unspanned stochastic volatility puzzle by providing nonparametric and model-independent evidence of USV. The impacts of mortgage activities on the forward densities further suggest that the unspanned factors could be partially driven by activities in the mortgage markets.

The next question naturally is how to best incorporate USV into a term structure model so it can price wide spectrum of interest rate derivatives effectively. In contrast to the approach of adding USV restrictions to DTSMs, it is relatively easy to introduce USV in the Heath et al. (1992) (hereafter, HJM) class of models, which include the LIBOR models of Brace et al. (1997) and Miltersen et al. (1997), the random field models of Goldstein (2000), and the string models of Santa-Clara and Sornette (2001). Indeed, any HJM model in which the forward rate curve has stochastic volatility and the volatility and yield shocks are not perfectly correlated exhibits USV. Therefore, in addition to the commonly known advantages of HJM models (such as perfectly fitting the initial yield curve), they offer the additional advantage of easily accommodating USV. Of course, the trade-off here is that in an HJM model, the yield curve is an input rather than a prediction of the model.

Recently, several HJM models with USV have been developed and applied to price caps and swaptions. Collin-Dufresne and Goldstein (2003) develop a random field model with stochastic volatility and correlation in forward rates. Applying the transform analysis of Duffie et al. (2000), they obtain closed-form formulae for a wide variety of interest rate derivatives. However, they do not calibrate their models to market prices of caps and swaptions. Han (2007) extends the model of LSS (2001) by introducing stochastic volatility and correlation in forward rates. Han (2007) shows that stochastic volatility and correlation are important for reconciling the mispricing between caps and swaptions. Trolle and Schwartz (2009) develop a multifactor term structure model with unspanned stochastic volatility factors and correlation between innovations to forward rates and their volatilities.

Jarrow et al. (2007) develop a multifactor HJM model with stochastic volatility and jumps in LIBOR forward rates. The LIBOR rates follow the affine jump diffusions (hereafter, AJDs) of Duffie et al. (2000), and a closed-form solution for cap prices is provided. Given a small number of factors can explain most of the variation of bond yields, they consider low-dimensional model specifications based on the first few (up to three) principal components of historical forward rates. Their model explicitly incorporates jumps in LIBOR rates, making it possible to differentiate the importance between stochastic volatility and jumps for pricing interest rate derivatives.

In section two of this review, we will discuss how the original DTSMs have difficulty in pricing and hedging interest rate derivatives, as shown in Li and Zhao (2006). In section three, we present the HJM model as in Jarrow et al. (2007). Finally, we will provide nonparametric evidence from Li and Zhao (2009) showing both the realized and implied yield volatilities cannot be spanned by the yield curve factors.

86.2 Term Structure Models with Spanned Stochastic Volatility

We begin with a two-factor spot rate model with stochastic volatility as in Longstaff and Schwartz (1992). Under the risk-neutral measure Q, the short rate r and its volatility V follow a two-dimensional square-root process:

$$dr_t = \kappa_r(\theta_r - r_t)dt + \sqrt{V_t}dW_{1t}^Q; \tag{86.1}$$

$$dV_t = \kappa_V(\theta_V - V_t)dt + \sigma\sqrt{V_t}dW_{2t}^Q. \tag{86.2}$$

The price of the zero-coupon bond $P(t, T)$ with maturity T can be solved through the fundamental PDE for bond pricing:

$$\frac{1}{2}V\left(P_{rr} + \sigma^2 Pvv\right) + P_r\kappa_r(\theta_r - r) + P_v\kappa_v(\theta_v - V) + P_t = rP \tag{86.3}$$

for $0 \le t \le T$ with the terminal condition $P(T, T) = 1$. The price $P(t, T)$ and yield $y(t, T)$ are functions of the state variables $\{r_t, V_t\}$:

$$P(t,T) = e^{A(T-t)+B(T-t)rt+C(T-t)V_t}, \tag{86.4}$$

$$y(t,T) = -\frac{\log(P(t,T))}{T-t} = -\frac{A(T-t)}{T-t} - \frac{B(T-t)}{T-t}r_t - \frac{C(T-t)}{T-t}V_t, \tag{86.5}$$

where A, B, and C are coefficients depending on maturity. It is clear here that the state variables are linear combinations of the yield curve factors such as level and slope. In this sense, the stochastic volatility is spanned by the bond yields. Both bonds and bond derivatives can be priced through the fundamental PDE and the same set of state variables enters into their prices. We should note here that the volatility process in this model serves two roles. First, it helps to price the cross section of bonds, making the model more flexible than one-factor models in generating various shapes of the yield curve. Second, it is the volatility process of the short rate; therefore, it can be inferred using the time series of the short rate alone. One essential question to address therefore is whether the volatility process inferred cross-sectionally fits the time-series properties stipulated by the model. The potential failure in the fit can be due to the model misspecification or the fact that the volatility process cannot be identified using the yield curve factors. For illustration, we discuss the example given in Casassus et al. (2005):

$$dr_t = \kappa_r(\theta_t - r_t)dt + \sqrt{V_t}dW_{1t}^{Q}, \tag{86.6}$$

$$d\theta_t = \kappa_r\left(\gamma_\theta(t) - 2\kappa_r\theta_t + \frac{V_t}{\kappa_r}\right)dt, \tag{86.7}$$

$$dV_t = \mu_V(V_t, t)dt + \sigma(V_t, t)dW_{2t}^{Q}, \tag{86.8}$$

where the long-run mean of the short rate θ_t has a pure drift process and the short rate volatility V_t follows a stochastic process with general drift and diffusion functions that only depend on the volatility itself. It can be shown that the zero-coupon bond price $P(t, T)$ depends only on the short rate and its long-run mean, not on the volatility, i.e.,

$$P(t,T) = e^{A(t,T)+B(T-t)r_t+C(T-t)\theta_t}. \tag{86.9}$$

It can also be shown that the price of a European call option on the zero-coupon bond, however, depends on the volatility V_t. For this example, the call option cannot be hedged by using bonds alone.

Therefore, it is an important exercise to test whether a sophisticated DTSM without the USV factor can be used to hedge the interest derivatives. Dai and Singleton (2003) review many of the current dynamic term structure models, and these models include the affine term structure models (ATSMs) of Duffie and Kan (1996) and the QTSMs of ADG (2002) and many others.[4]

In a typical dynamic term structure model, the economy is represented by the filtered probability space $(\Omega, \mathcal{F}, \{\mathcal{F}_t\}_{0\le t\le T}, P)$, where $\{\mathcal{F}_t\}_{0\le t\le T}$ is the augmented filtration generated by an N-dimensional standard Brownian motion, W, on this probability space. It is usually assumed that $\{\mathcal{F}_t\}_{0\le t\le T}$ satisfies the usual hypothesis (see Protter 1990).

[4]The affine models include the completely affine models of Dai and Singleton (2000), the essentially affine models of Duffee (2002), and the semi-affine models of Duarte (2004). Other DTSMs include the hybrid models of Ahn et al. (2003), the regime-switching models of Bansal and Zhou (2003), and models with macroeconomic jump effects, such as Piazzesi (2001), and many others.

The ATSMs rely on the following assumptions:

- The instantaneous interest rate r_t is an affine or quadratic function of the N-dimensional state variables X_t,

$$r(X_t) = \beta' X_t + \alpha, \tag{86.10}$$

- The state variables follow a multivariate affine process:

$$dX_t = K[\theta - X_t]dt + \Sigma S_t dW_t, \tag{86.11}$$

where S_t is a diagonal matrix with elements being the square root of an affine function of X_t. Hence, the conditional means and variances of the state variables are affine functions of the state variables.

- The market price of risk is a function of the state variables:

$$\zeta(X_t) = \eta_0 X_t S_t^- + \eta_1 S_t^-, \tag{86.12}$$

where S_t^- is a diagonal matrix with elements being the inverse of those in S_t wherever positive zero otherwise.

The zero-coupon bond with time to maturity τ can be priced by risk-neutral pricing:

$$\begin{aligned} D(t,\tau) &= E_t^Q\left[e - \int_t^{t+\tau} r(X_e)^{ds}.1\right] \\ &= e^{-A(\tau)-B(\tau)'Xt}. \end{aligned} \tag{86.13}$$

The functions of $A(\tau)$ and $B(\tau)$ satisfy a system of ordinary differential equations. The continuously compounding yield $y(t, \tau)$ follows

$$y(t,\tau) = \frac{1}{\tau}\left[A(\tau) + B(\tau)' X_t\right]. \tag{86.14}$$

The interest rate derivatives can be priced similarly via risk-neutral pricing. Without any restrictions on the model parameters, the loadings for the state variables, $B(\tau)$, are not zero in general. Hence, the state variables can always be backed out given enough number of yields, leaving the derivative prices been redundant in identifying the state variables.

The QTSMs rely on the following assumptions:

- The instantaneous interest rate r_t is an affine or quadratic function of the N-dimensional state variables X_t:

$$r(X_t) = X_t' \Psi X_t + \beta' X_t + \alpha \tag{86.15}$$

- The state variables follow a multivariate Gaussian process:

$$dX_t = [\mu + \xi X_t]dt + \Sigma dW_t, \tag{86.16}$$

- The market price of risk is an affine function of the state variables:

$$\varsigma(X_t) = \eta_0 + \eta_1 X_t. \tag{86.17}$$

Note that in the above equations ψ, ξ, $\sum$, and η_1 are N-by-N matrices; β, μ, and η_0 are vectors of length N; and α is a scalar. The quadratic relation between r_t and X_t has the desired property that r_t is guaranteed to be positive if ψ is positive semidefinite and $\alpha - \frac{1}{4}\beta'\Psi\beta \geq 0$. Although X_t follows a Gaussian process in Eq. 86.2, interest rate r_t exhibits conditional heteroskedasticity because of the quadratic relationship between r_t and X_t. As a result, the QTSMs are more flexible in modeling volatility clustering in bond yields and correlations among the state variables than the ATSMs.

Consequently, the yield to maturity, $y(t, \tau)$, is a quadratic function of the state variables:

$$y(t,\tau) = \frac{1}{\tau}\left[X_t' A(\tau) X_t + b(\tau)' X_t + c(\tau)\right]. \tag{86.18}$$

In contrast, in the ATSMs the yields are linear in the state variables, and therefore the correlations among the yields are solely determined by the correlations of the state variables. Although the state variables in the QTSMs follow multivariate Gaussian process, the quadratic form of the yields helps to model the time-varying volatility and correlation of bond yields. Leippold and Wu (2002) show that a large class of fixed-income securities can be priced in closed form in the QTSMs using the transform analysis of Duffie et al. (2000). The details of the derivation are in the appendix.

The first test for these models is to capture both the cross-sectional and time-series properties of bond yields, which has been reviewed in Dai and Singleton (2003). Even though the most sophisticated models can fit the cross section of bond prices very well and they can capture the time-series property of the first moment of the yield curve factors, they do not perform satisfactorily in capturing the second moment. The second test is to see whether these models can be used to price and hedge a cross section of interest rate derivatives. The task to performing the second task is made somewhat easier due to one major advantage of these DTSMs in that they provide closed-form solutions for a wide range of interest rate derivatives.

The empirical results shown below are from Li and Zhao (2006), in which they study the performance of QTSMs in pricing and hedging interest rate caps. Even though the study is based on QTSMs, the empirical findings are common to ATSMs as well.[5]

[5]In the empirical analysis of Li and Zhao (2006), the QTSMs are chosen for several reasons. First, since the nominal spot interest rate is a quadratic function of the state variables, it is guaranteed to be positive in the QTSMs. On the other hand, in the ATSMs, the spot rate, an affine function of the state variables, is guaranteed to be positive only when all the state variables follow square-root processes. Second, the QTSMs do not have the limitations facing the ATSMs in simultaneously fitting interest rate volatility and correlations among the state variables. That is, in the ATSMs, increasing the number of factors that follow square-root processes improves the modeling of volatility clustering in bond yields, but reduces the flexibility in modeling correlations among the state variables. Third, the QTSMs have the potential to capture observed nonlinearity in term structure data (see, e.g., Ahn and Gao 1999). Indeed, ADG (2002) and Brandt and Chapman (2002) show that the QTSMs can capture the conditional volatility of bond yields better than the ATSMs.

To price and hedge caps in the QTSMs, both model parameters and latent state variables need to be estimated. Due to the quadratic relationship between bond yields and the state variables, the state variables are not identified by the observed yields even in the univariate case in the QTSMs. Previous studies such as ADG (2002) have used the efficient method of moments (EMM) of Gallant and Tauchen (1998) to estimate the QTSMs. Li and Zhao (2006) use the extended Kalman filter (EKF) to estimate model parameters and extract the latent state variables in one step. The details of the implementation of the EKF are in the appendix.

The pricing analysis can reveal two sources of potential model misspecification. One is on the number of factors in the model as a missing factor usually causes large pricing errors. An analogy is using Black-Scholes model, while the stock price is generated from a stochastic volatility model. The other is on the assumption of the innovation process of each factor. If the innovation of the factor has a fat-tailed distribution, the convenient assumption of Gaussian distribution is going to deliver large pricing error as well. So from a pricing study, we cannot conclude one or the other or both cause large pricing errors. On the other hand, hedging analysis focuses on the changes of the prices, so even if the marginal distribution of the prices can be highly non-Gaussian, the conditional distribution for a small time step can still be reasonably approximated with Gaussian distribution. As the result, a deficiency in hedging, especially at high frequency, reveals more about the potential missing factors than the distribution assumption in a model.

In Li and Zhao (2006), QTSMs can capture yield curve dynamics extremely well. First, given the estimated model parameters and state variables, they compute the 1-day-ahead projection of yields based on the estimated model. Figure 86.1 shows that QTSM1 model projected yields are almost indistinguishable from the corresponding observed yields. Secondly, they examine the performance of the QTSMs in hedging zero-coupon bonds, assuming that the filtered state variables are traded and use them as hedging instruments. The delta-neutral hedge is conducted for zero-coupon bonds of six maturities on a daily basis. Hedging performance is measured by variance ratio, which is defined as the percentage of the variations of an unhedged position that can be reduced by hedging. The results on the hedging performance in Table 86.2 show that in most cases the variance ratios are higher than 95 %. This should not be surprising given the excellent fit of bond yields by the QTSMs.

If the LIBOR and swap market and the cap market are well integrated, the estimated three-factor QTSMs should be able to hedge caps well. Based on the estimated model parameters, the delta-neutral hedge of weekly changes of difference cap prices is conducted using filtered state variables as hedging instruments. It is also possible to use LIBOR zero-coupon bonds as hedging instruments by matching the hedge ratios of a difference cap with that of zero-coupon bonds. Daily rebalance – adjustment of the hedge ratios everyday given changes in market conditions – is implemented to improve hedging performance. Therefore, daily changes of a hedged position are the difference between daily changes of the unhedged position and the hedging portfolio. The latter equals to the sum of the products of a difference cap's hedge ratios with respect to the state variables and changes in the corresponding state variables. Weekly changes are just the accumulation over daily positions. The hedging

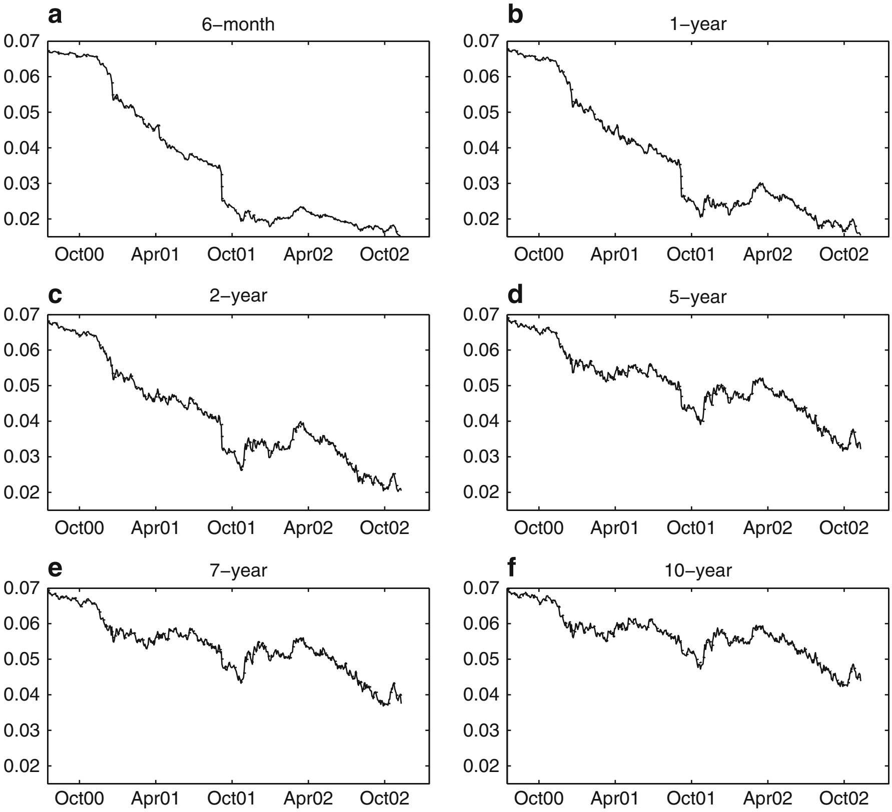

Fig. 86.1 The observed yields (*dot*) and the QTSM1 projected yields (*solid*)

effectiveness is measured by variance ratio, the percentage of the variations of an unhedged position that can be reduced by hedging. This measure is similar in spirit to R^2 in linear regression. The variance ratios of the three QTSMs in Table 86.3 show that all models have better hedging performance for ITM, short-term (maturities from 1.5 to 4 years) difference caps[6] than OTM, medium- and long-term difference caps (maturities longer than 4 years). There is a high percentage of variations in long-term and OTM difference cap prices that cannot be hedged. The maximal flexible model QTSM1 again has better hedging performance than the other two models. To control for the fact that the QTSMs may be misspecified, in Panel B of Table 86.3, the hedging errors of each moneyness/maturity group are further regressed on the changes of the three yield factors. While the three yield factors can explain some additional hedging errors, their incremental explanatory power is not very significant. Thus, even

[6]The difference cap is the difference of the caps with subsequent maturities and the same strike prices. Instead of having caplets ranging from as early as 6 months, the difference cap only has caplets of a small maturity region.

Table 86.2 The performance of QTSMs in modeling bond yields

	Maturity (year)					
	0.5	1	2	5	7	10
QTSM3	0.717	0.948	0.982	0.98	0.993	0.93
QTSM2	0.99	0.956	0.963	0.975	0.997	0.934
QTSM1	0.994	0.962	0.969	0.976	0.997	0.932

This table reports the performance of the three-factor QTSMs in capturing bond yields. Variance ratios of model-based hedging of zero-coupon bonds in QTSMs using filtered state variables as hedging instruments. Variance ratio measures the percentage of the variations of an unhedged position that can be reduced through hedging

excluding hedging errors that can be captured by the three yield factors, there is still a large fraction of difference cap prices that cannot be explained by the QTSMs. Table 86.4 reports the performance of the QTSMs in hedging cap straddles. The difference floor prices are computed from difference cap prices using the put-call parity and construct weekly straddle returns. As straddles are highly sensitive to volatility risk, both delta- and gamma-neutral hedges are needed. The variance ratios of QTSM1 are as low as the R^2s of linear regressions of straddle returns on the yield factors in Table 86.1, suggesting that neither approach can explain much variations of straddle returns. Collin-Dufresne and Goldstein (2002) show that 80 % of straddle regression residuals can be explained by one additional factor. Principal component analysis of ATM straddle hedging errors in Panel B of Table 86.4 shows that the first factor can explain about 60 % of the total variations of hedging errors. The second and third factor each explains about 10 % of hedging errors, and two additional factors combined can explain about another 10 % of hedging errors. The correlation matrix of the ATM straddle hedging errors across maturities in Panel C shows that the hedging errors of short-term (2, 2.5, 3, 3.5, and 4 years), medium-term (4.5 and 5 years), and long-term (8, 9, and 10 years) straddles are highly correlated within each group, suggesting that there could be multiple unspanned factors.

To further understand whether the unspanned factors are related to stochastic volatility, we study the relationship between ATM cap implied volatilities and straddle hedging errors. Principal component analysis in Panel A of Table 86.5 shows that the first component explains 85 % of the variations of cap implied volatilities. In Panel B, we regress straddle hedging errors on changes of the three yield factors and obtain R^2s that are close to zero. However, if we include the weekly changes of the first few principal components of cap implied volatilities, the R^2s increase significantly: for some maturities, the R^2s are above 90 %. Although the time series of implied volatilities are very persistent, their differences are not and we do not suffer from the well-known problem of spurious regression. In the extreme case in which we regress straddle hedging errors of each maturity on changes of the yield factors and cap implied volatilities with the same maturity, the R^2s in most cases are above 90 %. These results show that straddle returns are mainly affected by volatility risk but not term structure factors.

This table reports the performance of the three QTSMs in hedging difference caps. Hedging effectiveness is measured by variance ratio, the percentage of the variations of an unhedged position that can be reduced through hedging. The bold entries represent moneyness/maturity groups that have less than 10 % of missing values, and the rest are the ones with 10–50 % of missing values

This table reports the relation between straddle hedging errors and ATM cap implied volatilities

As ATM straddles are mainly exposed to volatility risk, their hedging errors can serve as a proxy of the USV. Panels A and B of Table 86.6 report the R^2s of regressions of hedging errors of difference caps and cap straddles across moneyness and maturity on changes of the three yield factors and the first five principal components of straddle hedging errors. In contrast to the regressions in Panel D of Table 86.6, which only include the three yield factors, the additional factors from straddle hedging errors significantly improve the R^2s of the regressions: for most moneyness/maturity groups, the R^2s are above 90 %. Interestingly for long-term caps, the R^2s of ATM and OTM caps are actually higher than that of ITM caps. Therefore, a combination of the yield factors and the USV factors can explain cap prices across moneyness and maturity very well.

While the above analysis is mainly based on the QTSMs, the evidence on USV is so compelling that the results should be robust to potential model misspecification. The fact that the QTSMs provide excellent fit of bond yields but can explain only a small percentage of the variations of ATM straddle returns is a strong indication that the models miss some risk factors that are important for the cap market. While we estimate the QTSMs using only bond prices, we could also include cap prices in model estimation. We do not choose the second approach for several reasons. First, the current approach is consistent with the main objective of our study: use risk factors extracted from the swap market to explain cap prices. Second, it is not clear that modifications of model parameters without changing the fundamental structure of the model could remedy the poor cross-sectional hedging performance of the QTSMs. In fact, if the QTSMs indeed miss some important factors, then no matter how they are estimated (using bonds or derivatives data), they are unlikely to have good hedging performance. Finally, Jagannathan et al. (2003) do not find significant differences between parameters of ATSMs estimated using LIBOR/swap rates and cap/swaption prices. The existence of USV strongly suggests that existing DTSMs need to relax their fundamental assumption that derivatives are redundant securities

Table 86.6 ATM straddle hedging error as a proxy of systematic USV

This table reports the contribution of USV proxied by the first few principal components of ATM straddle hedging errors in explaining the hedging errors of caps and cap straddles across moneyness and maturity. It reports the R^2s of regressions of hedging errors of caps across moneyness and maturity on changes of the three yield factors and the first five principal components of straddle hedging errors. The bold entries represent moneyness/maturity groups that have less than 10 % of missing values, and the rest are the ones with 10–50 % of missing values by explicitly incorporating USV factors. It also suggests that it might be more convenient to consider derivative pricing in the forward rate models of HJM (1992) or the random field models of Goldstein (2000) and Santa-Clara and Sornette (2001) because it is generally very difficult to introduce USV in DTSMs. For example, Collin-Dufresne and Goldstein (2002) show that highly restrictive assumptions on model parameters need to be imposed to guarantee that some state variables that are important for derivative pricing do not affect bond prices. In contrast, they show that it is much easier to introduce USV in the HJM and random field class of models: any HJM or random field model in which the forward rate has a stochastic volatility exhibits USV. While it has always been argued that HJM and random field models are more appropriate for pricing derivatives than DTSMs, the reasoning given here is quite different. That is, in addition to the commonly known advantages of these models (such as they can perfectly fit the initial yield curve while DTSMs generally cannot), another advantage of HJM and random field models is that they can easily accommodate USV (see Collin-Dufresne and Goldstein (2002) for illustration).

The existence of USV suggests that these models may not be directly applicable to derivatives because they all rely on the fundamental assumption that bonds and derivatives are driven by the same set of risk factors. In this paper, we provide probably the first empirical analysis of DTSMs in hedging interest rate derivatives and hope to resolve the controversy on USV through this exercise.

86.3 LIBOR Market Models with Stochastic Volatility and Jumps: Theory and Estimation

In this section, we develop a multifactor HJM model with stochastic volatility and jumps in LIBOR forward rates and discuss model estimation and comparison using a wide cross section of difference caps. Instead of modeling the unobservable instantaneous spot rate or forward rate, we focus on the LIBOR forward rates which are observable and widely used in the market.

86.3.1 Specification of the LIBOR Market Models

Throughout our analysis, we restrict the cap maturity T to a finite set of dates $0 = T_0 < T_1 < \cdots < T_K < T_{K+1}$ and assume that the intervals $T_{k+1} - T_k$ are equally spaced by δ, a quarter of a year. Let $L_k(t) = L(t, T_k)$ be the LIBOR forward rate for the actual period $[T_k, T_{k+1}]$, and similarly let $D_k(t) = D(t, T_k)$ be the price of a zero-coupon bond maturing on T_k: thus, we have

$$L(t, T_k) = \frac{1}{\delta}\left(\frac{D(t, T_k)}{D(t, T_{k+1})} - 1\right), \quad \text{for } k = 1, 2, \ldots K. \tag{86.19}$$

For LIBOR-based instruments, such as caps, floors, and swaptions, it is convenient to consider pricing under the forward measure. Thus, we will focus on the dynamics of the LIBOR forward rates $L_k(t)$ under the forward measure $\mathbb{Q}^{k+1}$, which is essential for pricing caplets maturing at T_{k+1}. Under this measure, the discounted price of any security using $D_{k+1}(t)$ as the numeraire is a martingale. Therefore, the time-t price of a caplet maturing at T_{k+1} with a strike price of X is

$$Caplet(t, T_{k+1}, X) = \delta D_{k+1}(t) E_t^{\mathbb{Q}^{k+1}}\left[(L_k(T_k) - X)^+\right], \tag{86.20}$$

where $E_t^{\mathbb{Q}^{k+1}}$ is taken with respect to $\mathbb{Q}^{k+1}$ given the information set at t. The key to valuation is modeling the evolution of $L_k(t)$ under $\mathbb{Q}^{k+1}$ realistically and yet parsimoniously to yield closed-form pricing formula. To achieve this goal, we rely on the flexible AJDs of Duffie et al. (2000) to model the evolution of LIBOR rates.

We assume that under the physical measure $\mathbb{P}$, the dynamics of LIBOR rates are given by the following system of SDEs, for $t \in [0, T_k)$ and $k = 1, \ldots, K$:

$$\frac{dL_k(t)}{L_k(t)} = \alpha_k(t)dt + \sigma_k(t)dZ_k(t) + dJ_k(t), \tag{86.21}$$

where $\alpha_k(t)$ is an unspecified drift term, $Z_k(t)$ is the k-th element of a K-dimensional correlated Brownian motion with a covariance matrix $\Psi(t)$, and $J_k(t)$ is the k-th element of a K-dimensional independent pure jump process assumed independent of $Z_k(t)$ for all k: to introduce stochastic volatility and correlation, we could allow the volatility of each LIBOR rate $\sigma_k(t)$ and each individual element of $\Psi(t)$ to follow a stochastic process. But such a model is unnecessarily complicated and difficult to implement. Instead, we consider a low-dimensional model based on the first few principal components of historical LIBOR forward rates. We assume that the entire LIBOR forward curve is driven by a small number of factors $N < K (N \leq 3$ in our empirical analysis). By focusing on the first N principal components of historical LIBOR rates, we can reduce the dimension of the model from K to N.

Following LSS (2001) and Han (2007), we assume that the instantaneous covariance matrix of changes in LIBOR rates shares the same eigenvectors as the historical covariance matrix. Suppose that the historical covariance matrix can be approximated as $H = U\Lambda_0 U'$, where Λ_0 is a diagonal matrix whose diagonal elements are the first N largest eigenvalues in descending order, and the N columns of U are the corresponding eigenvectors.[7] Our assumption means that the instantaneous covariance matrix of changes in LIBOR rates with fixed time to maturity, Ω_t, shares the same eigenvectors as H. That is,

$$\Omega_t = U\Lambda_t U', \tag{86.22}$$

[7]We acknowledge that with jumps in LIBOR rates, both the historical and instantaneous covariance matrices of LIBOR rates contain a component that is due to jumps. Our approach implicitly assumes that the first three principal components from the historical covariance matrix capture the variations in LIBOR rates due to continuous shocks and that the impact of jumps is only contained in the residuals.

where Λ_t is a diagonal matrix whose i-th diagonal element, denoted by $V_i(t)$, can be interpreted as the instantaneous variance of the i-th common factor driving the yield curve evolution at t. We assume that $V(t)$ follows the square-root process that has been widely used in the literature for modeling stochastic volatility (see, e.g., Heston 1993):

$$dV_i(t) = \kappa_i(\overline{v}_i - V_i(t))dt + \xi_i\sqrt{V_i(t)}d\widetilde{W}_i(t) \tag{86.23}$$

where $\widetilde{W}_i(t)$ is the i-th element of an N-dimensional independent Brownian motion assumed independent of $Z_k(t)$ and $J_k(t)$ for all k.[8]

While Eqs. 86.4 and 86.5 specify the instantaneous covariance matrix of LIBOR rates with fixed time to maturity, in applications we need the instantaneous covariance matrix of LIBOR rates with fixed maturities $\sum_t$. At $t = 0$, Σ_t coincides with Ω_t; for $t > 0$, we obtain $\sum_t$ from Ω_t through interpolation. Specifically, we assume that $U_{S,j}$ is piecewise constant,[9] i.e., for time to maturity $s \in (T_k, T_{k+1})$:

$$U_s^2 = \frac{1}{2}\left(U_k^2 + U_k^2{+}1\right). \tag{86.24}$$

We further assume that $U_{s,j}$ is constant for all caplets belonging to the same difference cap. For the family of the LIBOR rates with maturities $T = T_1, T_2, \ldots, T_K$, we denote U_{T-t} the time-t matrix that consists of rows of U_{T_k-t}, and therefore we have the time-t covariance matrix of the LIBOR rates with fixed maturities:

$$\Sigma_t = U_{T-t}\Lambda_t U_{T-t}^{'} \tag{86.25}$$

To stay within the family of AJDs, we assume that the random jump times arrive with a constant intensity λ_J, and conditional on the arrival of a jump, the jump size follows a normal distribution $N(\mu_J, \sigma^2{}_J)$. Intuitively, the conditional probability at time t of another jump within the next small time interval Δt is $\lambda_J\Delta t$, and conditional on a jump event, the mean relative jump size is $\mu = \exp\left(\mu_J + \frac{1}{2}\sigma_J^2\right) - 1$.[10] We also assume that the shocks driving LIBOR rates, volatility, and jumps (both jump time and size) are mutually independent from each other.

[8]Many empirical studies on interest rate dynamics (see, e.g., Andersen and Lund 1997; Ball and Torous 1999; Chen and Scott 2001) have shown that correlation between stochastic volatility and interest rates is close to zero. That is, there is not a strong "leverage" effect for interest rates as for stock prices. The independence assumption between stochastic volatility and LIBOR rates in our model captures this stylized fact.

[9]Our interpolation scheme is slightly different from that of Han (2002) for the convenience of deriving closed-form solution for cap prices.

[10]For simplicity, we assume that different forward rates follow the same jump process with constant jump intensity. It is not difficult to allow different jump processes for individual LIBOR rates and the jump intensity to depend on the state of the economy within the AJD framework.

Given the above assumptions, we have the following dynamics of LIBOR rates under the physical measure $\mathbb{P}$:

$$\frac{dL_k(t)}{L_k(t)} = \alpha_k(t)dt + \sum_{j=1}^{N} U_{T_k-t,j}\sqrt{V_j(t)}dW_j(t) + dJ_k(t), \quad k = 1,2,\ldots,K. \tag{86.26}$$

To price caps, we need the dynamics of LIBOR rates under the appropriate forward measure. The existence of stochastic volatility and jumps results in an incomplete market and hence the nonuniqueness of forward martingale measures. Our approach for eliminating this nonuniqueness is to specify the market prices of both the volatility and jump risks to change from the physical measure $\mathbb{P}$ to the forward measure $\mathbb{Q}^{k+1}$.[11] Following the existing literature, we model the volatility risk premium as $\eta_j^{k+1}\sqrt{V_j(t)}$, for $j = 1, \ldots, N$. For the jump risk premium, we assume that under the forward measure $\mathbb{Q}^{k+1}$, the jump process has the same distribution as that under P, except that the jump size follows a normal distribution with mean μ_J^{k+1} and variance σ_J^2. Thus, the mean relative jump size under $\mathbb{Q}^{k+1}$ is $\mu^{k+1} = \exp(\mu_J^{k+1} + \frac{1}{2}\sigma_J^2) - 1$. Our specification of the market prices of jump risks allows the mean relative jump size under $\mathbb{Q}^{k+1}$ to be different from that under $\mathbb{P}$, accommodating a premium for jump size uncertainty. This approach, which is also adopted by Pan (2002), artificially absorbs the risk premium associated with the timing of the jump by the jump size risk premium. In our empirical analysis, we make the simplifying assumption that the volatility and jump risk premiums are linear functions of time to maturity, i.e., $\eta_j^{k+1} = c_{jv}(T_k - 1)$ and $\mu_J^{k+1} = \mu_J + c_J(T_k - 1)$.[12] Due to the no arbitrage restriction, the risk premiums of shocks to LIBOR rates for different forward measures are intimately related to each other. If shocks to volatility and jumps are also correlated with shocks to LIBOR rates, then both volatility and jump risk premiums for different forward measures should also be closely related to each other. However, in our model shocks to LIBOR rates are independent of that to volatility and jumps, and as a result, the change of measure of LIBOR shocks does not affect that of volatility and jump shocks. Due to stochastic volatility and jumps, the underlying LIBOR market is no longer complete, and there is no unique forward measure. This gives us the freedom to choose the functional forms of η_j^{k+1} and μ_J^{k+1}. See Andersen and Brotherton-Ratcliffe (2001) for similar discussions.

[11]The market prices of interest rate risks are defined in such a way that the LIBOR rate is a martingale under the forward measure.

[12]In order to estimate the volatility and jump risk premiums, we need a joint analysis of the dynamics of LIBOR rates under both the physical and forward measures, as in Chernov and Ghysels (2000), Pan (2002), and Eraker (2004). In our empirical analysis, we only focus on the dynamics under the forward measure. Therefore, we can only identify the differences in the risk premiums between forward measures with different maturities. Our specifications of both risk premiums implicitly use the 1-year LIBOR rate as a reference point.

Given the above market prices of risks, we can write down the dynamics of log $(L_k(t))$ under forward measure $\mathbb{Q}^{k+1}$:

$$d\log(L_k(t)) = -\left(\lambda_{J\mu}{}^{k+1} + \frac{1}{2}\sum_{j=1}^{N} U^2_{T_k-t,j} V_j(t)\right)dt + \sum_{j=1}^{N} U_{T_k-t,j}\sqrt{V_j(t)}dW_j^{\mathbb{Q}^{k+1}}(t) + dJ_k^{\mathbb{Q}^{k+1}}(t). \tag{86.27}$$

For pricing purpose, the above process can be further simplified to the following one which has the same distribution:

$$d\log(L_k(t)) = -\left(\lambda_{J\mu}{}^{k+1} + \frac{1}{2}\sum_{j=1}^{N} U^2_{T_k-t,j} V_j(t)\right)dt + \sqrt{\sum_{j=1}^{N} U^2_{T_{k-t,j}} V_j(t)dZ_k^{\mathbb{Q}k+1}(t) + dJ_k^{\mathbb{Q}k+1}(t)}, \tag{86.28}$$

where $Z_k^{\mathbb{Q}^{k+1}}(t)$ is a standard Brownian motion under $\mathbb{Q}^{k+1}$. Now the dynamics of $V_i(t)$ under $\mathbb{Q}^{k+1}$ becomes

$$dV_i(t) = \kappa_i^{k+1}\left(v_i^{-k+1} - V_i(t)\right)dt + \xi_i\sqrt{V_i(t)}d\widetilde{W}_i^{\mathbb{Q}^{k+1}}(t) \tag{86.29}$$

where $\widetilde{W}^{\mathbb{Q}^{Qk+1}}$ is independent of $Z^{\mathbb{Q}^{k+1}}$, $\kappa_j^{k+1} = \kappa_j - \xi_j\eta_j^{k+1}$, and $v_j^{-k+1} = \frac{\kappa_j\overline{v}_j}{\kappa_j - \xi_j\eta_j^{k+1}}$, $j = 1, \ldots N$. The dynamics of $L_k(t)$ under the forward measure $\mathbb{Q}^{k+1}$ are completely captured by Eqs. 86.28 and 86.29.

Given that LIBOR rates follow AJDs under both the physical and forward measures, we can directly apply the transform analysis of Duffie et al. (2000) to derive closed-form formula for cap prices. Denote the state variables at t as $Y_t = (\log(L_k(t)), V_t)'$ and the time-t expectation of $e^{u\ YT}{}_k$ under the forward measure $\mathbb{Q}^{k+1}$ as $\psi(u, Y_t, t, T_k) \triangleq E_t^{\mathbb{Q}^{k+1}}[e^{u \cdot YT}\mathrm{k}]$. Let $u = (u_0, 0_{1xN})'$, and then the time-t expectation of LIBOR rate at T_k equals

$$\begin{aligned} E_t^{\mathbb{Q}^{k+1}}\{\exp[u_0\log(L_k(T_k))]\} &= \psi\left(u_0, Y_t, t, T_k\right) \\ &= \exp\left[a(s) + u_0\log(L_k(t)) + B(s)'V_t\right], \end{aligned} \tag{86.30}$$

where $s = T_k - t$ and closed-form solutions of $a(s)$ and $B(s)$ (an N-by-1 vector) are obtained by solving a system of Riccati equations in the appendix.

Following Duffie et al. (2000), we define

$$G_{a,b}\left(y; Y_t, T_k, \mathbb{Q}^{k+1}\right) = E_t^{\mathbb{Q}^{k+1}}\left[e^{a\cdot\log(L_k(T_k))}1_{\{b\cdot\log(L_k(T_k))\le y\}}\right], \tag{86.31}$$

and its Fourier transform

$$\begin{aligned}\mathcal{G}_{a,b}\left(v;Y_t,T_k,\mathbb{Q}^{k+1}\right) &= \int_R^{e^{ivy}dGa,b(y)} \\ &= E_t^{\mathbb{Q}k+1}\left[e^{(a+ivb)\cdot\log(L_k(T_k))}\right] \\ &= \psi(a+ivb,Y_t,t,T_k).\end{aligned} \tag{86.32}$$

Levy's inversion formula gives

$$G_{a,b}\left(y;Y_t,T_k,\mathbb{Q}^{k+1}\right) = \frac{\psi(a+ivb,Y_t,t,T_k)}{2} - \frac{1}{\pi}\int_0^\infty \frac{\mathrm{Im}[\psi(a+ivb,Y_t,t,T_k)e^{-ivy}]}{v}dv. \tag{86.33}$$

The time-0 price of a caplet that matures at T_{k+1} with a strike price of X equals

$$Caplet(0,T_{k+1},X) = \delta D_{k+1}(0)E_0^{\mathbb{Q}^{k+1}}\left[(L_k(T_k)-X)^+\right], \tag{86.34}$$

where the expectation is given by the inversion formula

$$\begin{aligned}E_0^{\mathbb{Q}^{k+1}}[L_k(T_k)-X]^+ &= G_{1,-1}\left(-\ln X;Y_0,T_k,\mathbb{Q}^{k+1}\right) \\ &\quad - XG_{0,-1}\left(-\ln X;Y_0,T_k,\mathbb{Q}^{k+1}\right).\end{aligned} \tag{86.35}$$

The new models developed in this section nest some of the most important models in the literature, such as LSS (2001) (with constant volatility and no jumps) and Han (2007) (with stochastic volatility and no jumps). The closed-form formula for cap prices makes an empirical implementation of our model very convenient and provides some advantages over existing methods. For example, Han (2007) develops approximations of ATM cap and swaption prices using the techniques of Hull and White (1987). However, such an approach might not work well for away-from-the-money options. In contrast, our method would work well for all options, which is important for explaining the volatility smile.

In addition to introducing stochastic volatility and jumps, our multifactor HJM models also have advantages over the standard LIBOR market models of Brace et al. (1997) and Miltersen et al. (1997) and their extensions often applied to caps in practice.[13] While our models provide a unified multifactor framework to characterize the evolution of the whole yield curve, the LIBOR market models typically make separate specifications of the dynamics of LIBOR rates with different maturities.

[13] Andersen and Brotherton-Ratcliffe (2001) and Glasserman and Kou (2003) develop LIBOR models with stochastic volatility and jumps, respectively.

As suggested by LSS (2001), the standard LIBOR models are "more appropriately viewed as a collection of different univariate models, where the relationship between the underlying factors is left unspecified." In contrast, the dynamics of LIBOR rates with different maturities under their related forward measures are internally consistent with each other given their dynamics under the physical measure and the market prices of risks. Once our models are estimated using one set of prices, they can be used to price and hedge other fixed-income securities.

86.3.2 Estimation Method and Results

We estimate our new market model using prices from a wide cross section of difference caps with different strikes and maturities. Every week we observe prices of difference caps with 10 moneyness and 13 maturities. However, due to changing interest rates, we do not have enough observations in all moneyness/maturity categories throughout the sample. Thus, we focus on the 53 moneyness/maturity categories that have less than 10 % of missing values over the sample estimation period. The moneyness and maturity of all difference caps belong to the following sets {0.7, 0.8, 0.9, 1.0, 1.1} and {1.5, 2.0, 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, 6.0, 7.0, 8.0, 9.0, 10.0} (unit in years), respectively. The difference caps with time to maturity less than or equal to 5 years represent portfolios of two caplets, while those with time to maturity longer than 5 years represent portfolios of four caplets.

We estimate the model parameters by minimizing the sum of squared percentage pricing errors (SSEs) of all relevant difference caps.[14] Consider the time-series observations $t = 1, \ldots, \mathcal{T}$, of the prices of 53 difference caps with moneyness m_i and time to maturities τ_i, $i = 1, \ldots, M = 53$. Let θ represent the model parameters which remain constant over the sample period. Let $C(t, m_i, \tau_i)$ be the observed price of a difference cap with moneyness m_i and time to maturity τ_i and let $\hat{C}(t, \tau_i, m_i, V_t(\theta), \theta)$ denote the corresponding theoretical price under a given model, where $V_t(\theta)$ is the model implied instantaneous volatility at t given model parameters θ. For each i and t, denote the percentage pricing error as

$$u_{i,t}(\theta) = \frac{C(t, m_i, \tau_i) - \hat{C}(t, m_i, \tau_i, V_t(\theta), \theta)}{C(t, m_i, \tau i)}, \tag{86.36}$$

where $V_t(\theta)$ is defined as

$$V_t(\theta) = \arg\min_{\{V_t\}} \sum_{i=1}^{M} \left[\frac{C(t, m_i, \tau_i) - \hat{C}(t, m_i, \tau_i, V_t, \theta)}{C(t, m_i, \tau_i)} \right]^2. \tag{86.37}$$

[14] Due to the wide range of moneyness and maturities of the difference caps involved, there could be significant differences in the prices of difference caps. Using percentage pricing errors helps to mitigate this problem.

We provide empirical evidence on the performance of six different models in capturing the cap volatility smile. The first three models, denoted as SV1, SV2, and SV3, allow one, two, and three principal components to drive the forward rate curve, respectively, each with its own stochastic volatility. The next three models, denoted as SVJ1, SVJ2, and SVJ3, introduce jumps in LIBOR rates in each of the previous SV models. SVJ3 is the most comprehensive model and nests all the others as special cases. We first examine the separate performance of each of the SV and SVJ models, and then we compare performance across the two classes of models. The estimation of all models is based on the principal components extracted from historical LIBOR forward rates between June 1997 and July 2000.[15]

The SV models contribute to cap pricing in four important ways. First, the three principal components capture variations in the levels of LIBOR rates caused by innovations in the "level," "slope," and "curvature" factors. Second, the stochastic volatility factors capture the fluctuations in the volatilities of LIBOR rates reflected in the Black implied volatilities of ATM caps.[16] Third, the stochastic volatility factors also introduce fatter tails in LIBOR rate distributions than implied by the lognormal model, which helps capture the volatility smile. Finally, given our model structure, innovations of stochastic volatility factors also affect the covariances between LIBOR rates with different maturities. The first three factors, however, are more important for our applications, because difference caps are much less sensitive to time-varying correlations than swaptions.[17] Our discussion of the performance of the SV models focuses on the estimates of the model parameters and the latent volatility variables and the time-series and cross-sectional pricing errors of difference caps.

A comparison of the parameter estimates of the three SV models in Table 86.7 shows that the "level" factor has the most volatile stochastic volatility, followed, in decreasing order, by the "curvature" and "slope" factor. The long-run mean $(\overline{v}_1)$ and volatility of volatility (ξ_1) of the first volatility factor are much bigger than that of the other two factors. This suggests that the fluctuations in the volatilities of LIBOR rates are mainly due to the time-varying volatility of the "level" factor. The estimates of the volatility risk premium of the three models are significantly negative, suggesting that the stochastic volatility factors of longer maturity LIBOR rates under the forward measure are less volatile with lower long-run mean and faster speed of mean reversion. This is consistent with the fact that the Black implied volatilities of longer maturity *difference caps* are less volatile than that of short-term *difference caps*.

[15]The LIBOR forward curve is constructed from weekly LIBOR and swap rates from Datastream following the bootstrapping procedure of LSS (2001).

[16]Throughout our discussion, volatilities of LIBOR rates refer to market implied volatilities from cap prices and are different from volatilities estimated from historical data.

[17]See Han (2002) for more detailed discussions on the impact of time-varying correlations for pricing swaptions.

Table 86.7 Parameter estimates of stochastic volatility models

	SV1		SV2		SV3

This table reports parameter estimates and standard errors of the one-, two-, and three-factor stochastic volatility models. The estimates are obtained by minimizing the sum of squared percentage pricing errors (SSEs) of difference caps in 53 moneyness and maturity categories observed on a weekly frequency from August 1, 2000, to September 23, 2003. The objective functions reported in the table are rescaled SSEs over the entire sample at the estimated model parameters and are equal to RMSE of difference caps. The volatility risk premium of the ith stochastic volatility factor for forward measure Q^{k+1} is defined as $\eta_i^{k+1} = c_{iv}(T_k - 1)$

Our parameter estimates are consistent with the volatility variables inferred from the prices of *difference caps*. The volatility of the "level" factor is the highest among the three (although at lower absolute levels in the more sophisticated models). It starts at a low level and steadily increases and stabilizes at a high level in the later part of the sample period. The volatility of the "slope" factor is much lower and relatively stable during the whole sample period. The volatility of the "curvature" factor is generally between that of the first and second factors. The steady increase of the volatility of the "level" factor is consistent with the increase of Black implied volatilities of ATM difference caps throughout our sample period. In fact, the correlation between the Black implied volatilities of most difference caps and the implied volatility of the "level" factor is higher than 0.8. The correlation between Black implied volatilities and the other two volatility factors is much weaker. The importance of stochastic volatility is obvious: the fluctuations in Black implied volatilities show that a model with constant volatility simply would not be able to capture even the general level of cap prices.

The other aspects of model performance are the time-series and cross-sectional pricing errors of *difference caps*. The likelihood ratio tests in Panel A of Table 86.8 overwhelmingly reject SV1 and SV2 in favor of SV2 and SV3, respectively. The Diebold-Mariano statistics in Panel A of Table 86.8 also show that SV2 and SV3 have significantly smaller SSEs than SV1 and SV2, respectively, suggesting that the

This table reports model comparison based on likelihood ratio and Diebold-Mariano statistics. The total number of observations (both cross sectional and time series), which equals 8,545 over the entire sample, times the difference between the logarithms of the SSEs between two models follows a χ^2 distribution asymptotically. We treat implied volatility variables as parameters. Thus, the degree of freedom of the χ^2 distribution is 168 for the pairs of SV2/SV1 and SV3/SV2, because SV2 and SV3 have four more parameters and 164 additional implied volatility variables than SV1 and SV2, respectively. The 1 % critical value of $\chi^2(168)$ is 214. The Diebold-Mariano statistics are calculated according to Eq. 86.14 with a lag order q of 40 and follow an asymptotic standard normal distribution under the null hypothesis of equal pricing errors. A negative statistic means that the more sophisticated model has smaller pricing errors. Bold entries mean that the statistics are significant at the 5 % level more sophisticated SV models improve the pricing of all caps. The time series of RMSEs of the three SV models over our sample period[18] suggest that except for two special periods where all models have extremely large pricing errors, the RMSEs of all models are rather uniform with the best model (SV3) having RMSEs slightly above 5 %. The two special periods with high pricing errors cover the period between the second half of December 2000 and the first half of January 2001, and the first half of October 2001, and coincide with high prepayments in mortgage-backed securities (MBS). Indeed, the MBAA refinancing index and prepayment speed (see Fig. 3 of Duarte 2004) show that after a long period of low prepayments between the middle of 1999 and late 2000, prepayments dramatically increased at the end of 2000 and the beginning of 2001. There is also a dramatic increase of prepayments at the beginning of October 2001. As widely recognized in the fixed-income market,[19] excessive hedging demands for prepayment risk using interest rate derivatives may push derivative prices away from their equilibrium values, which could explain the failure of our models during these two special periods.[20]

In addition to overall model performance as measured by SSEs, we also examine the cross-sectional pricing errors of difference caps with different moneyness and maturities. We first look at the squared percentage pricing errors, which measure both the bias and variability of the pricing errors. Then we look at the average percentage pricing errors (the difference between market and model prices divided by the market price) to see whether SV models can on average capture the volatility smile in the cap market.

The Diebold-Mariano statistics of squared percentage pricing errors of individual *difference caps* between SV2 and SV1 in Panel B of Table 86.8 show that SV2 reduces the pricing errors of SV1 for some but not all *difference caps*. SV2 has the most significant reductions in pricing errors of SV1 for mid- and short-term around-the-money difference caps. On the other hand, SV2 has larger pricing errors for deep ITM *difference caps*. The Diebold-Mariano statistics between SV3 and SV2 in Panel C of Table 86.8 show that SV3 significantly reduces the pricing errors of many short- (2–3 years) and midterm around-the-money and long-term (6–10 years) ITM *difference caps*.

Table 86.9 reports the average percentage pricing errors of all *difference caps* under the three SV models. Panel A of Table 86.9 shows that, on average, SV1 underprices short-term and overprices mid- and long-term ATM *difference caps* and underprices ITM and overprices OTM difference caps. This suggests that SV1 cannot generate enough skewness in the implied volatilities to be consistent with

---

[18]RMSE of a model at t is calculated as $\sqrt{u_t'\left(\hat{\theta}\right)u_t\left(\hat{\theta}\right)/M}$. We plot RMSEs instead of SSEs because the former provides a more direct measure of average percentage pricing errors of difference caps.

[19]We would like to thank Pierre Grellet Aumont from Deutsche Bank for his helpful discussions on the influence of MBS markets on OTC interest rate derivatives.

[20]While the prepayment rates were also high in later part of 2002 and for most of 2003, they might not have come as surprises to participants in the MBS markets given the two previous special periods.

This table reports average percentage pricing errors of difference caps with different moneyness and maturities of the three stochastic volatility models. Average percentage pricing errors are defined as the difference between market price and model price divided by the market price the data. Panel B shows that SV2 has some improvements over SV1, mainly for some short-term (less than 3.5 years) ATM and midterm (3.5–5 years) slightly OTM *difference caps*. But SV2 has worse performance for most deep ITM ($m = 0.7$ and 0.8) difference caps: it actually worsens the underpricing of ITM caps. Panel C of Table 86.9 shows that relative to SV1 and SV2, SV3 has smaller average percentage pricing errors for most long-term (7–10 years) ITM, midterm (3.5–5 years) OTM, and short-term (2–2.5 years) ATM *difference caps* and bigger average percentage pricing errors for midterm (3.5–6 years) ITM difference caps. There is still significant underpricing of ITM and overpricing of OTM difference caps under SV3.

Overall, the results show that stochastic volatility factors are essential for capturing the time-varying volatilities of LIBOR rates. The Diebold-Mariano statistics in Table 86.8 shows that in general more sophisticated SV models have smaller pricing errors than simpler models, although the improvements are more important for close-to-the-money difference caps. The average percentage pricing errors in Table 86.9 show that, however, even the most sophisticated SV model cannot generate enough volatility skew to be consistent with the data. While previous studies, such as Han (2007), have shown that a three-factor stochastic volatility model similar to ours performs well in pricing ATM caps and swaptions, our analysis shows that the model fails to completely capture the volatility smile in the cap markets. Our findings highlight the importance of studying the relative pricing of caps with different moneyness to reveal the inadequacies of existing term structure models; the same inadequacies cannot be obtained from studying only ATM options.

One important reason for the failure of SV models is that the stochastic volatility factors are independent of LIBOR rates. As a result, the SV models can only generate a symmetric volatility smile, but not the asymmetric smile or skew observed in the data. The pattern of the smile in the cap market is rather similar to that of index options: ITM calls (and OTM puts) are overpriced, and OTM calls (and ITM puts) are underpriced relative to the Black model. Similarly, the smile in the cap market could be due to a market expectation of dramatically declining LIBOR rates. In this section, we examine the contribution of jumps in LIBOR rates in capturing the volatility smile. Our discussion of the performance of the SVJ models parallels that of the SV models.

Parameter estimates in Table 86.10 show that the three stochastic volatility factors of the SVJ models resemble that of the SV models closely. The “level” factor still has the most volatile stochastic volatility, followed by the “curvature” and the “slope” factor. With the inclusion of jumps, the stochastic volatility factors in the SVJ models, especially that of the “level” factor, tend to be less volatile than that of the SV models (lower long-run mean and volatility of volatility). Negative estimates of the volatility risk premium show that the volatility of the longer maturity LIBOR rates under the forward measure has lower long-run mean and faster speed of mean reversion.

Most importantly, we find overwhelming evidence of strong negative jumps in LIBOR rates under the forward measure. To the extent that cap prices reflect market expectations of future evolutions of LIBOR rates, the evidence suggests that the market expects a dramatic decline in LIBOR rates over our sample

This table reports parameter estimates and standard errors of the one-, two-, and three-factor stochastic volatility and jump models. The estimates are obtained by minimizing the sum of squared percentage pricing errors (SSEs) of difference caps in 53 moneyness and maturity categories observed on a weekly frequency from August 1, 2000, to September 23, 2003. The objective functions reported in the table are rescaled SSEs over the entire sample at the estimated model parameters and are equal to RMSE of difference caps. The volatility risk premium of the ith stochastic volatility factor and the jump risk premium for forward measure Q^{k+1} are defined as $\eta_i^{k+1} = c_{iv}(T_k - 1)$ and $\mu_J{}^{k+1} = \mu_J + c_J(T_k - 1)$, respectively

period. Such an expectation might be justifiable given that the economy has been in recession during a major part of our sample period. This is similar to the volatility skew in the index equity option market, which reflects investors' fear of the stock market crash such as that of 1987. Compared to the estimates from index options (see, e.g., Pan 2002), we see lower estimates of jump intensity (about 1.5 % per annual), but much higher estimates of jump size. The positive estimates of a jump risk premium suggest that the jump magnitude of longer maturity forward rates tends to be smaller. Under SVJ3, the mean relative jump sizes, exp $(\mu_J + c_J(T_k - 1) + \sigma_J^2/2) - 1$, for 1-, 5-, and 10-year LIBOR rates are −97 %, −94 %, and −80 %, respectively. However, we do not find any incidents of negative moves in LIBOR rates under the physical measure with a size close to that under the forward measure. This big discrepancy between jump sizes under the physical and forward measures resembles that between the physical and risk-neutral measures for index options (see, e.g., Pan 2002). This could be a result of a huge jump risk premium.

The likelihood ratio tests in Panel A of Table 86.11 again overwhelmingly reject SVJ1 and SVJ2 in favor of SVJ2 and SVJ3, respectively. The Diebold-Mariano

This table reports model comparison based on likelihood ratio and Diebold-Mariano statistics. The total number of observations (both cross sectional and time series), which equals 8,545 over the entire sample, times the difference between the logarithms of the SSEs between two models follows a χ^2 distribution asymptotically. We treat implied volatility variables as parameters. Thus, the degree of freedom of the χ^2 distribution is 168 for the pairs of SVJ2/SVJ1 and SVJ3/SVJ2, because SVJ2 and SVJ3 have four more parameters and 164 additional implied volatility variables than SVJ1 and SVJ2, respectively. The 1 % critical value of χ^2 (168) is 214. The Diebold-Mariano statistics are calculated according to Eq. 86.14 with a lag order q of 40 and follow an asymptotic standard normal distribution under the null hypothesis of equal pricing errors. A negative statistic means that the more sophisticated model has smaller pricing errors. Bold entries mean that the statistics are significant at the 5 % level statistics in Panel A of Table 86.11 show that SVJ2 and SVJ3 have significantly smaller SSEs than SVJ1 and SVJ2, respectively, suggesting that the more sophisticated SVJ models significantly improve the pricing of all *difference caps*. The Diebold-Mariano statistics of squared percentage pricing errors of individual *difference caps* in Panel B of Table 86.11 show that SVJ2 significantly improves the performance of SVJ1 for long-, mid-, and short-term around-the-money *difference caps*. The Diebold-Mariano statistics in Panel C of Table 86.11 show that SVJ3 significantly reduces the pricing errors of SVJ2 for long-term ITM and some mid- and short-term around-the-money *difference caps*. Table 86.12 shows the average percentage pricing errors also improve over the SV models.

Table 86.13 compares the performance of the SVJ and SV models. During the first 20 weeks of our sample, the SVJ models have much higher RMSEs than the SV models. As a result, the likelihood ratio and Diebold-Mariano statistics between the three pairs of SVJ and SV models over the entire sample are somewhat smaller than that of the sample period without the first 20 weeks. Nonetheless, all the SV models are overwhelmingly rejected in favor of their corresponding SVJ models by both tests. The Diebold-Mariano statistics of individual *difference caps* in Panels B, C, and D show that the SVJ models significantly improve the performance of the SV models for most *difference caps* across moneyness and maturity. The most interesting results are in Panel D, which show that SVJ3 significantly reduces the pricing errors of most ITM *difference caps* of SV3, strongly suggesting that the negative jumps are essential for capturing the asymmetric smile in the cap market.

Our analysis shows that a low-dimensional model with three principal components driving the forward rate curve, stochastic volatility of each component, and strong negative jumps captures the volatility smile in the cap markets reasonably well. The three yield factors capture the variations of the levels of LIBOR rates, while the stochastic volatility factors are essential to capture the time-varying volatilities of LIBOR rates. Even though the SV models can price ATM caps reasonably well, they fail to capture the volatility smile in the cap market. Instead, significant negative jumps in LIBOR rates are needed to capture the smile. These results highlight the importance of studying the pricing of caps across moneyness: the importance of negative jumps is revealed only through the pricing of away-from-the-money caps. Excluding the first 20 weeks and the two special periods, SVJ3 has a reasonably good pricing performance with an average RMSE of 4.5 %. Given that the bid-ask spread is about 2–5 % in our sample for ATM caps, and because ITM and OTM caps tend to have even higher percentage spreads,[21] this can be interpreted as a good performance.

Despite its good performance, there are strong indications that SVJ3 is misspecified and the inadequacies of the model seem to be related to MBS markets. For example, while SVJ3 works reasonably well for most of the sample period, it has large pricing errors in several special periods coinciding with high prepayment activities in the MBS markets. Moreover, even though we assume that the

[21]See, for example, Deuskar et al. (2003).

This table reports model comparison based on likelihood ratio and Diebold-Mariano statistics. The total number of observations (both cross sectional and time series), which equals 8,545 over the entire sample and 7,485 without the first 20 weeks, times the difference between the logarithms of the SSEs between two models follows a χ^2 distribution asymptotically. We treat implied volatility variables as parameters. Thus, the degree of freedom of the χ^2 distribution is 4 for the pairs of SVJ/SV1, SVJ2/SV2, and SVJ3/SV3, because SVJ models have four more parameters and equal number of additional implied volatility variables as the corresponding SV models. The 1 % critical value of χ^2 (4) is 13. The Diebold-Mariano statistics are calculated according to Eq. 86.14 with a lag order q of 40 and follow an asymptotic standard normal distribution under the null hypothesis of equal pricing errors. A negative statistic means that the more sophisticated model has smaller pricing errors. Bold entries mean that the statistics are significant at the 5 % level

Table 86.14 Correlations between LIBOR rates and implied volatility variables

	L(t, 1)	L(t, 3)	L(t, 5)	L(t, 7)	L(t, 9)	V1(t)	V2(t)	V3(t)
V1(t)	−0.8883	−0.8772	−0.8361	−0.7964	−0.7470	1	−0.4163	0.3842
V2(t)	0.1759	0.235	0.2071	0.1545	0.08278	−0.4163	1	−0.0372
V3(t)	−0.5951	−0.485	−0.4139	−0.3541	−0.3262	0.3842	−0.0372	1

This table reports the correlations between LIBOR rates and implied volatility variables from SVJ3. Given the parameter estimates of SVJ3 in Table 86.4, the implied volatility variables are estimated at t by minimizing the SSEs of all difference caps at t

stochastic volatility factors are independent of LIBOR rates, Table 86.14 shows strong negative correlations between the implied volatility variables of the first factor and the LIBOR rates. This result suggests that when interest rate is low, cap prices become too high for the model to capture and the implied volatilities have to become abnormally high to fit the observed cap prices. One possible explanation of the "leverage" effect is that higher demands for caps to hedge prepayments from MBS markets in low interest rate environments could artificially push up cap prices and implied volatilities. Therefore, extending our models to incorporate factors from MBS markets seems to be a promising direction of future research.

86.4 Nonparametric Estimation of the Forward Density

For LIBOR-based instruments such as caps, floors, and swaptions, it is convenient to consider pricing using the forward measure approach. We will therefore focus on the dynamics of LIBOR forward rate $L_k(t)$ under the forward measure $\mathbb{Q}^{k+1}$, which is essential for pricing caplets maturing at T_{k+1}. Under this measure, the discounted price of any security using $D_{k+1}(t)$ as the numeraire is a martingale. Thus, the time-t price of a caplet maturing at T_{k+1} with a strike price of X is

$$C(L_k(t), X, t, T_k) = \delta D_{k+1}(t) \int_X^{\infty} (y - X) p^{\mathbb{Q}^{k+1}}(L_k(T_k) = y | L_k(t)) dy, \qquad (86.38)$$

where $p^{\mathbb{Q}^{k+1}}(L_k(T_k) = y | L_k(t))$ is the conditional density of $L_k(T_k)$ under forward measure $\mathbb{Q}^{k+1}$. Once we know the forward density, we can price any security whose payoff on T_{k+1} depends only on $L_k(t)$ by discounting its expected payoff under $\mathbb{Q}^{k+1}$ using $D_{k+1}(t)$.

Existing term structure models rely on parametric assumptions on the distribution of $L_k(t)$ to obtain closed-form pricing formulae for caplets. For example, the standard LIBOR market models of Brace et al. (1997) and Miltersen et al. (1997) assume that $L_k(t)$ follows a lognormal distribution and price caplet using the Black formula. The models of Jarrow et al. (2007) assume that $L_k(t)$ follows affine jump diffusions of Duffie et al. (2000).

86.4.1 Nonparametric Method

We estimate the distribution of $L_k(t)$ under $\mathbb{Q}^{k+1}$ using the prices of a cross section of caplets that mature at T_{k+1} and have different strike prices. Following Breeden and Litzenberger (1979), we know that the density of $L_k(t)$ under $\mathbb{Q}^{k+1}$ is proportional to the second derivative of $C(L_k(t), t, T_k, X)$ with respect to X:

$$p^{\mathbb{Q}^{k+1}}(L_k(T_k)|L_k(t)) = \frac{1}{\delta D_{k+1}(t)} \frac{\partial^2 C(L_k(t), t, T_k, X)}{\partial X^2} |X = L_k(T_k). \tag{86.39}$$

In standard LIBOR market models, it is assumed that the conditional density of $L_k(T_k)$ depends only on the current LIBOR rate. This assumption, however, can be overly restrictive given the multifactor nature of term structure dynamics. For example, while the level factor can explain a large fraction (between 80 % and 90 %) of the variations of LIBOR rates, the slope factor still has significant explanatory power of interest rate variations. Moreover, there is overwhelming evidence that interest rate volatility is stochastic,[22] and it has been suggested that interest rate volatility is unspanned in the sense that it cannot be fully explained by the yield curve factors such as the level and slope factors.

One important innovation of our study is that we allow the volatility of $L_k(t)$ to be stochastic and the conditional density of $L_k(T_k)$ to depend on not only the level but also the slope and volatility factors of LIBOR rates. Denote the conditioning variables as $Z(t) = \{s(t), v(t)\}$, where $s(t)$ (the slope factor) is the difference between the 10- and 2-year LIBOR forward rates and $v(t)$ (the volatility factor) is the first principal component of EGARCH-filtered spot volatilities of LIBOR rates across all maturities. Under this generalization, the conditional density of $L_k(T_k)$ under the forward measure $\mathbb{Q}^{k+1}$ is given by

$$p^{\mathbb{Q}^{k+1}}(L_k(T_k)|L_k(t), Z(t)) = \frac{1}{\delta D_{k+1}(t)} \frac{\partial^2 C(L_k(t), X, t, T_k, Z(t))}{\partial X^2} |X = L_k(T_k). \tag{86.40}$$

Next we discuss how to estimate the SPDs by combining the forward and physical densities of LIBOR rates. Denote an SPD function as π. In general, π depends on multiple economic factors, and it is impossible to estimate it using interest rate caps alone. Given the available data, all we can estimate is the projection of π onto the future spot rate $L_k(T_k)$:

$$\pi_k(L_k(T_k); L_k(t), Z(t)) = E_t^{\mathbb{P}}[\pi | L_k(T_k); L_k(t), Z(t)], \tag{86.41}$$

where the expectation is taken under the physical measure. Then the price of the caplet can be calculated as

[22]See Andersen and Lund (1997), Ball and Torous (1999), Brenner et al. (1996), Chen and Scott (2001), and many others.

$$C(L_k(t), X, t, T_k, Z(t)) = \delta E_t^{\mathbb{P}}\left[\pi \cdot (L_k(T_k) - X)^+\right]$$
$$= \delta \int_X^{\infty} \pi_k(y)(y - X)p^{\mathbb{P}}(L_k(T_k) = y|L_k(t), Z(t))dy, \tag{86.42}$$

where the second equality is due to iterated expectation and $p^{\mathbb{P}}(L_k(T_k) = y|L_k(t), Z(t))$ is the conditional density of $L_k(T_k)$ under the physical measure.

Comparing Eqs. 86.2 and 86.6, we have

$$\pi_k(L_k(T_k); L_k(t), Z(t)) = D_{k+1}(t)\frac{p^{\mathbb{Q}^{k+1}}(L_k(T_k)|L_k(t), Z(t))}{p^{\mathbb{P}}(L_k(T_k)|L_k(t), Z(t))}. \tag{86.43}$$

Therefore, by combining the densities of $L_k(T_k)$ under $\mathbb{Q}^{k+1}$ and $\mathbb{P}$, we can estimate the projection of π onto $L_k(T_k)$. The SPDs contain rich information on how risks are priced in financial markets. While Ait-Sahalia and Lo (1998, 2000); Jackwerth (2000), Rosenberg and Engle (2002), and others estimate the SPDs using index options (i.e., the projection of π onto index returns), our analysis based on interest rate caps documents the dependence of the SPDs on term structure factors.

Similar to many existing studies, to reduce the dimensionality of the problem, we further assume that the caplet price is homogeneous of degree 1 in the current LIBOR rate:

$$C(L_k(t), X, t, T_k, Z(t)) = \delta D_{k+1}(t)L_k(t)C_M(M_k(t), t, T_k, Z(t)), \tag{86.44}$$

where $M_k(t) = X/L_k(t)$ represents the moneyness of the caplet. Hence, for the rest of the paper, we estimate the forward density of $L_k(T_k)/L_k(t)$ as the second derivative of the price function C_M with respect to M:

$$p^{\mathbb{Q}^{k+1}}\left(\frac{L_k(T_k)}{L_k(t)}|Z(t)\right) = \frac{1}{\delta D_{k+1}(t)}\frac{\partial^2 C_M(M_k(t), t, T_k, Z(t))}{\partial M^2}|M = L_k(T_k)/L_k(t). \tag{86.45}$$

86.4.2 Empirical Results

In this section, we present nonparametric estimates of the probability densities of LIBOR rates under physical and forward martingale measures. In particular, we document the dependence of the forward densities on the slope and volatility factors of LIBOR rates.

Figure 86.2 presents nonparametric estimates of the forward densities at different levels of the slope and volatility factors at 2-, 3-, 4-, and 5-year maturities. The two levels of the slope factor correspond to a flat and a steep forward curve, while the two levels of the volatility factor represent low and high volatility of LIBOR rates. The 95 % confidence intervals are obtained through simulation. The forward densities should have a zero mean since LIBOR rates under appropriate forward measures are martingales. The expected log percentage changes of the LIBOR rates are slightly negative due to an adjustment from the Jensen's inequality. We normalize the forward densities so that they integrate to one. However, we do not have enough data at the right tail of the distribution at 4- and 5-year maturities. We do not extrapolate the data to avoid potential biases.

Figure 86.2 documents three important features of the nonparametric LIBOR forward densities. First, the lognormal assumption underlying the popular LIBOR market models is grossly violated in the data, and the forward densities across all maturities are significantly negatively skewed. Second, all the forward densities depend significantly on the slope of the term structure. For example, moving from a flat to a steep term structure, the forward densities across all maturities become much more dispersed and more negatively skewed. Third, the forward densities also depend on the volatility factor. Under both flat and steep term structures, the forward densities generally become more compact when the volatility factor increases. This is consistent with a mean-reverting volatility process: high volatility right now leads to low volatility in the future and more compact forward densities.

To better illustrate the dependence of the forward densities on the two conditioning variables, we also regress the quantiles of the forward densities on the two factors. We choose quantiles instead of moments of the forward densities in our regressions for two reasons. First, quantiles are much easier to estimate. While quantiles can be obtained from the CDF function, which is the first derivative of the price function, moments require integrations of the forward density, which is the second derivative of the price function. Second, a wide range of quantiles provide a better characterization of the forward densities than a few moments, especially for the tail behaviors of the densities.

Suppose we consider I and J levels of the transformed slope and volatility factors in our empirical analysis. For a given level of the two conditioning variables (s_i, v_j), we first obtain a nonparametric estimate of the forward density at a given maturity and its quantiles $Q_x(s_i, v_j)$, where x can range from 0 % to 100 %. Then we consider the following regression model:

$$Q_x(S_i, vj) = b_{0x} + b_{1x} \cdot s_i + b_{2x} \cdot v_j + b_{3x} \cdot s_i \cdot v_j + \varepsilon_x, \tag{86.46}$$

where $i = 1, 2, \ldots, I$, and $j = 1, 2, \ldots, J$. We include the interaction term to capture potential nonlinear dependence of the forward densities on the two conditioning variables.

Figure 86.3 reports regression coefficients of the slope and volatility factors for the most complete range of quantiles at each maturity, i.e., b_{1x} and b_{2x} as a function of x. While Fig. 86.3 includes only the slope and volatility factors as explanatory variables, Fig. 86.4 contains their interaction term as well. Though in results not reported here we also include lagged conditioning variables in our regressions, their coefficients are generally not statistically significant.

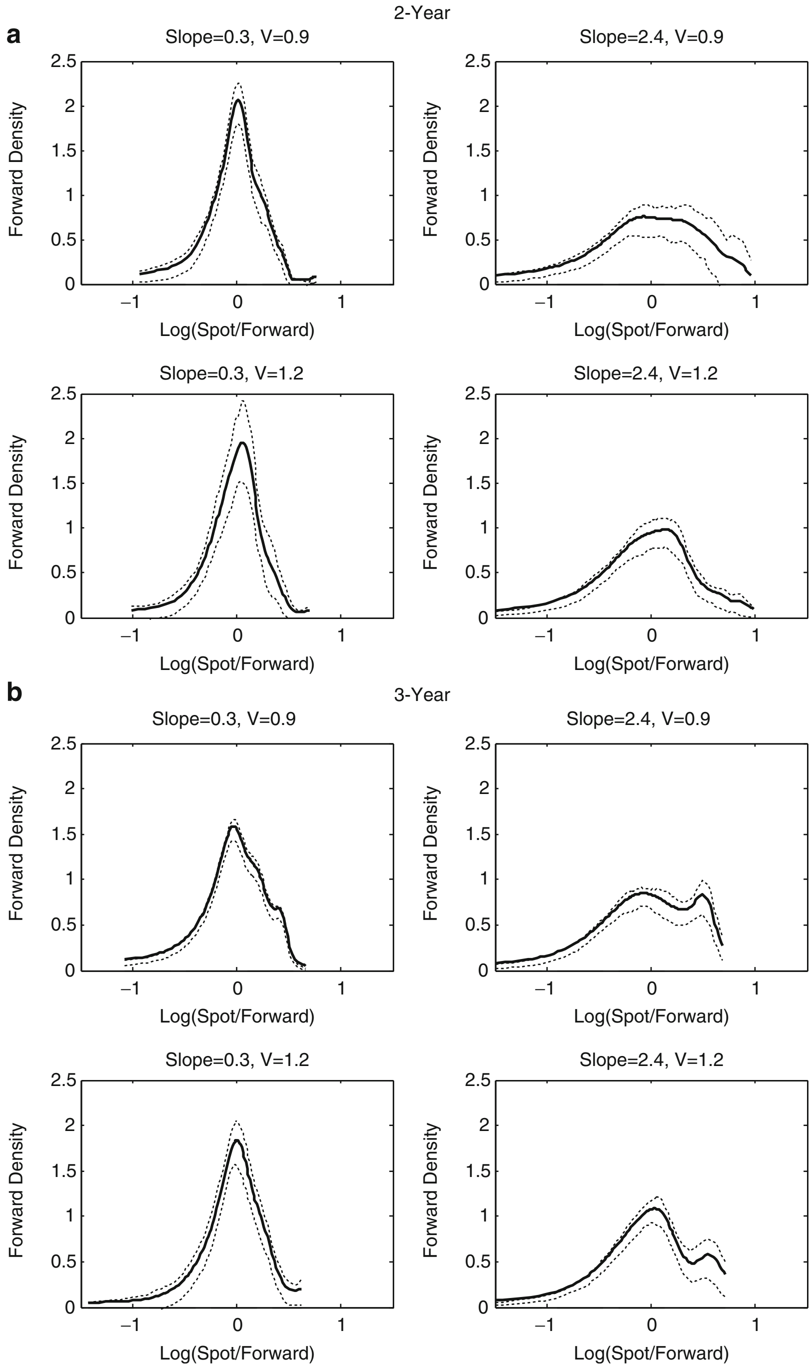

Fig. 86.2 (continued)

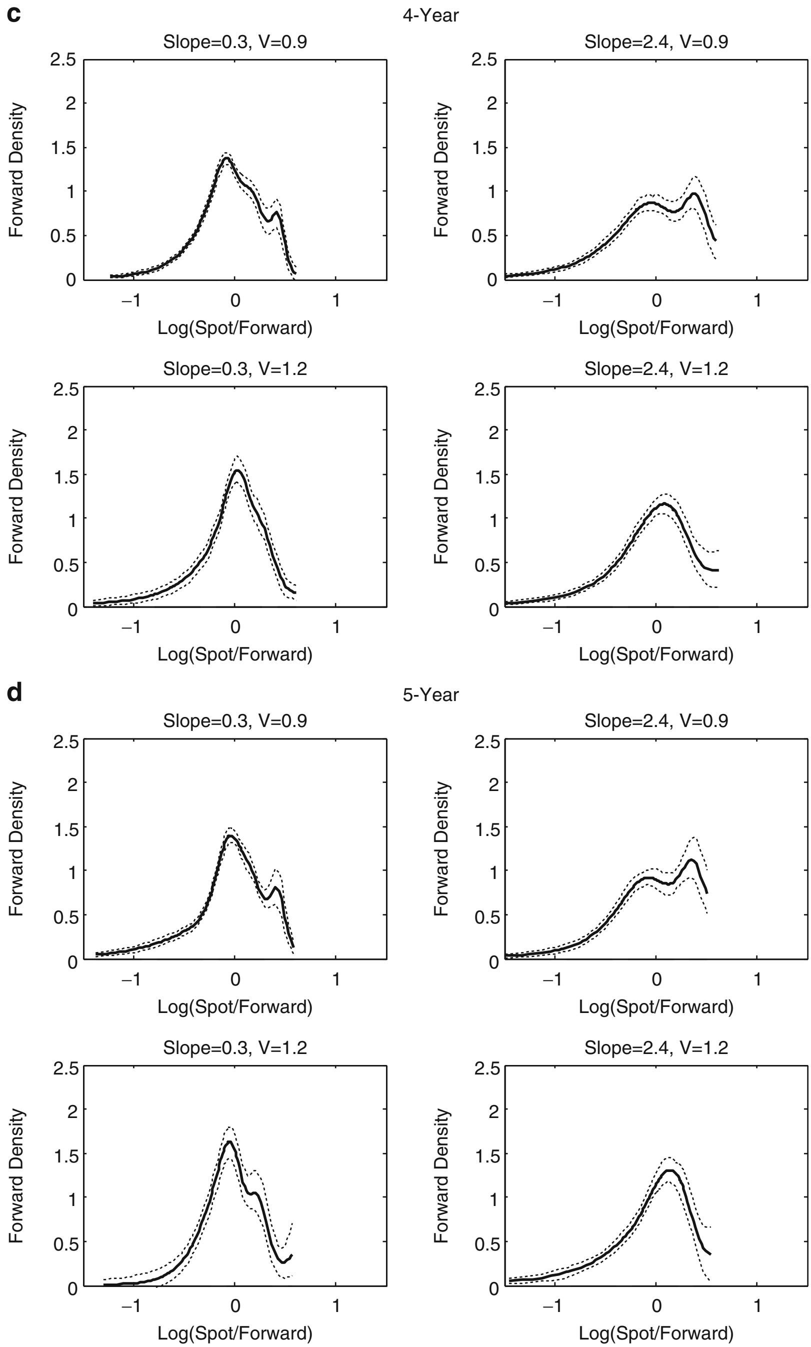

Fig. 86.2 Nonparametric estimates of the LIBOR forward densities at different levels of the slope and volatility factors. The slope factor is defined as the difference between the 10- and 2-year

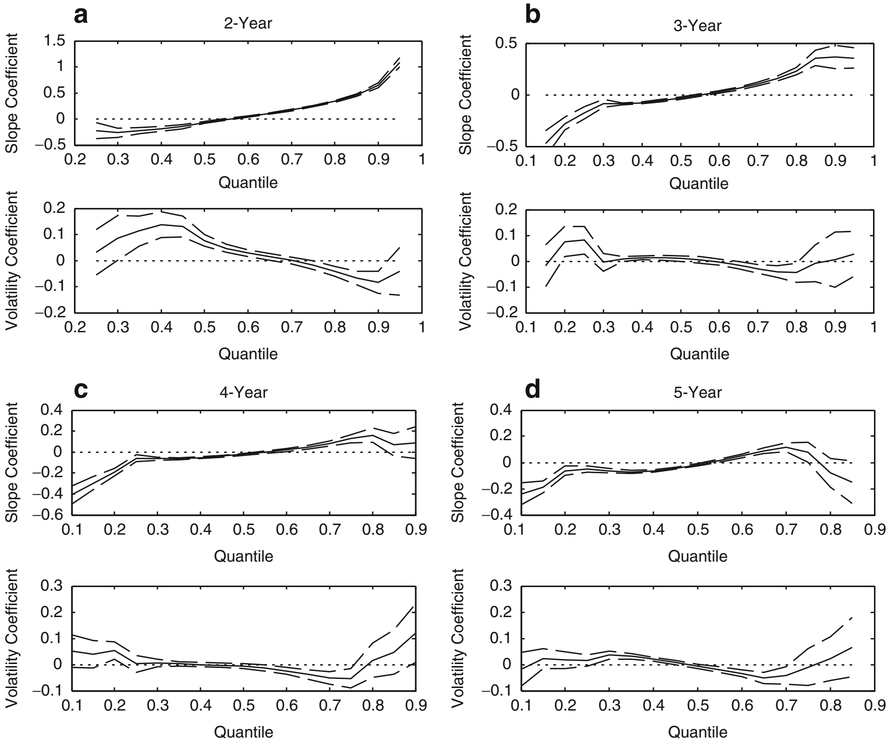

Fig. 86.3 Impacts of the slope and volatility factors on LIBOR forward densities. This figure reports regression coefficients of different quantiles of the forward densities at 2-, 3-, 4-, and 5-year maturities on the slope and volatility factors of LIBOR rates in Eq. 86.27 without the interaction term

The regression results in Fig. 86.3 are generally consistent with the main findings in Fig. 86.2. The slope coefficients are generally negative (positive) for the left (right) half of the distribution and become more negative or positive at both tails. Consistent with Fig. 86.2, this result suggests that when the term structure steepens, the forward densities become more dispersed and the effect is more pronounced at both tails. One exception to this result is that the slope coefficients become negative and statistically insignificant at the right tail at 5-year maturity. The coefficients of the volatility factor are generally positive (negative) for the left (right) half of the distribution. Although the volatility coefficients start to turn positive at the right tail of the distribution, they

Fig. 86.2 (continued) 3-month LIBOR forward rates. The volatility factor is defined as the first principal component of EGARCH-filtered spot volatilities and has been normalized to a mean that equals one. The two levels of the slope factor correspond to flat and steep term structures, while the two levels of the volatility correspond to low and high levels of volatility

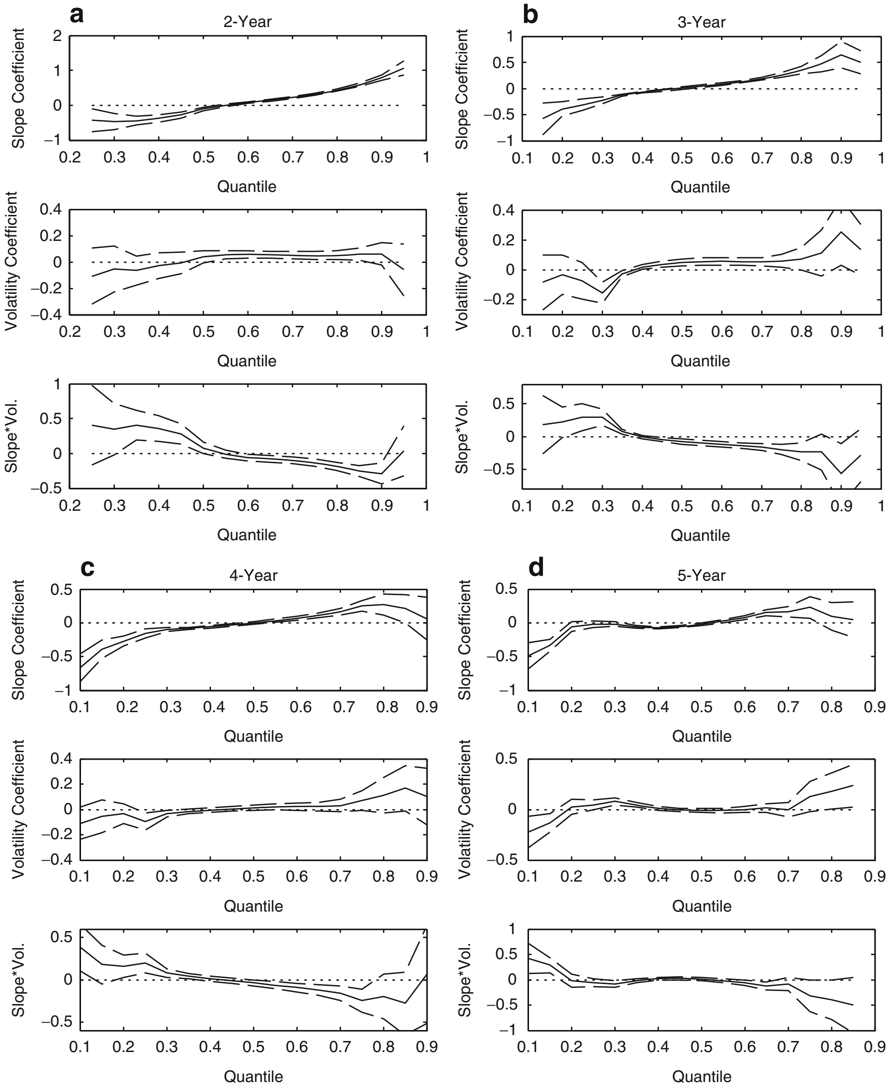

Fig. 86.4 Impacts of the slope and volatility factors (with their interaction term) on LIBOR forward densities. This figure reports regression coefficients of different quantiles of the forward densities at 2-, 3-, 4-, and 5-year maturities on the slope and volatility factors of LIBOR rates and their interaction term in Eq. 86.27

are not statistically significant. These results suggest that higher volatility leads to more compact forward densities, a result that is generally consistent with that in Fig. 86.2.

In Fig. 86.4, although the slope coefficients exhibit similar patterns as that in Fig. 86.3, the interaction term changes the volatility coefficients quite significantly.

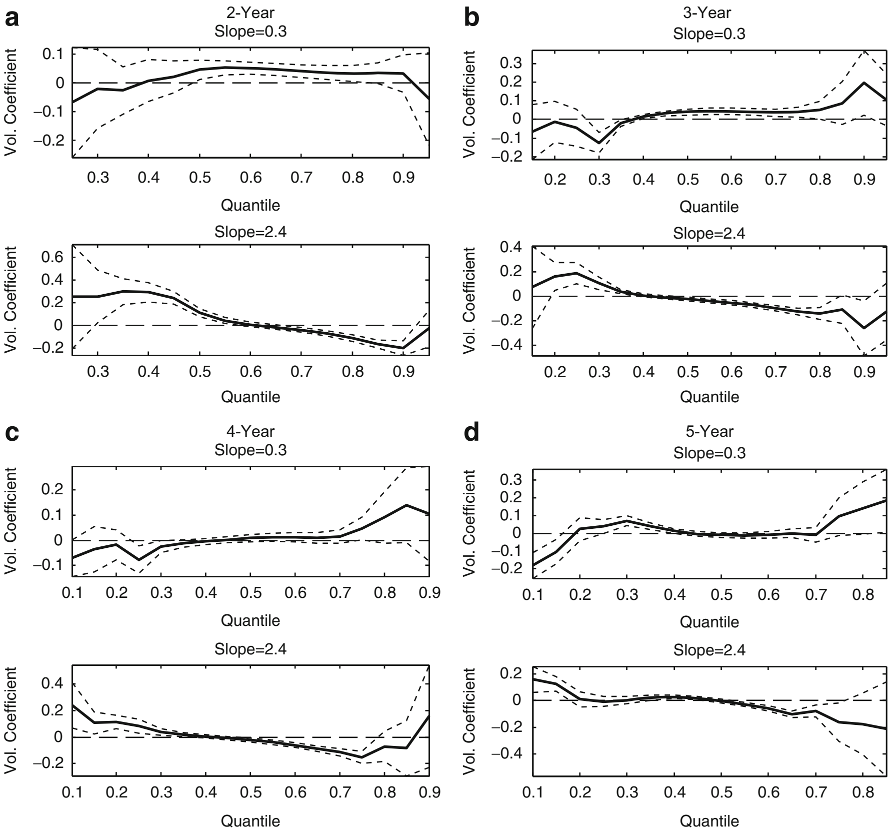

Fig. 86.5 Nonlinear dependence of LIBOR forward densities on the volatility factor of LIBOR rates. This figure presents regression coefficients of quantiles of LIBOR forward densities on the volatility factor at different levels of the slope factor. The two levels of the slope factor represent flat and steep term structures

The volatility coefficients become largely insignificant and exhibit quite different patterns than those in Fig. 86.3. For example, the volatility coefficients at 2- and 3-year maturities are largely constant across different quantiles. At 4- and 5-year maturities, they even become negative (positive) for the left (right) half of the distribution. On the other hand, the coefficients of the interaction term exhibit similar patterns as that of the volatility coefficients in Fig. 86.3. These results suggest that the impacts of volatility on the forward densities depend on the slope of the term structure.

Figure 86.5 presents the volatility coefficients at different levels of the slope factor (i.e., $\hat{b}_{2x} + \hat{b}_{3x} \cdot s_i$, where $s_i = 0.3$ or 2.4). We see clearly that the impact of volatility on the forward densities depends significantly on the slope factor. With a flat term structure, the volatility coefficients generally increase with the quantiles, especially at 3-, 4-, and 5-year maturities. The volatility coefficients are generally negative (positive) for the left (right) tail of the distribution, although not all of them are statistically significant. However, with a steep term structure, the volatility coefficients are generally positive (negative) for the left (right) half of the distribution for most maturities. Therefore, if the current volatility is high and the term structure is flat (steep), then volatility is likely to increase (decline) in the future. We observe flat term structure during early part of our sample when the Fed has raised interest rate to slow down the economy. It could be that the market was more uncertain about future state of the economy because it felt that recession was imminent. On the other hand, we observe steep term structure after the Internet bubble bursted and the Fed has aggressively cut interest rate. It could be that the market felt that the worst was over and thus was less uncertain about future state of the economy.

Our nonparametric analysis reveals important nonlinear dependence of the forward densities on both the slope and volatility factors of LIBOR rates. These results have important implications for one of the most important and controversial topics in the current term structure literature, namely, the USV puzzle. While existing studies on USV mainly rely on parametric methods, our results provide nonparametric evidence on the importance of USV: even after controlling for important bond market factors, such as level and slope, the volatility factor still significantly affects the forward densities of LIBOR rates. Even though many existing term structure models have modeled volatility as a mean-reverting process, our results show that the speed of mean reversion of volatility is nonlinear and depends on the slope of the term structure.

Some recent studies have documented interactions between activities in mortgage and interest rate derivatives markets. For example, in an interesting study, Duarte (2008) shows that ATM swaption implied volatilities are highly correlated with prepayment activities in the mortgage markets. Duarte (2008) extends the string model of Longstaff et al. (2001) by allowing the volatility of LIBOR rates to be a function of the prepayment speed in the mortgage markets. He shows that the new model has much smaller pricing errors for ATM swaptions than the original model with a constant volatility or a CEV model. Jarrow et al. (2007) also show that although their LIBOR model with stochastic volatility and jumps can price caps across moneyness reasonably well, the model pricing errors are unusually large during a few episodes with high prepayments in MBS. These findings suggest that if activities in the mortgage markets, notably the hedging activities of government-sponsored enterprises, such as Fannie Mae and Freddie Mac, affect the supply/demand of interest rate derivatives, then this source of risk may not be fully spanned by the factors driving the evolution of the term structure.[23]

In this section, we provide nonparametric evidence on the impact of mortgage activities on LIBOR forward densities. Our analysis extends Duarte (2008) in several important dimensions. First, by considering caps across moneyness, we examine the impacts of mortgage activities on the entire forward densities. Second, by explicitly allowing LIBOR forward densities to depend on the slope and volatility factors of

[23]See Jaffee (2003) and Duarte (2006) for excellent discussions on the use of interest rate derivatives by Fannie Mae and Freddie Mac in hedging interest rate risks.

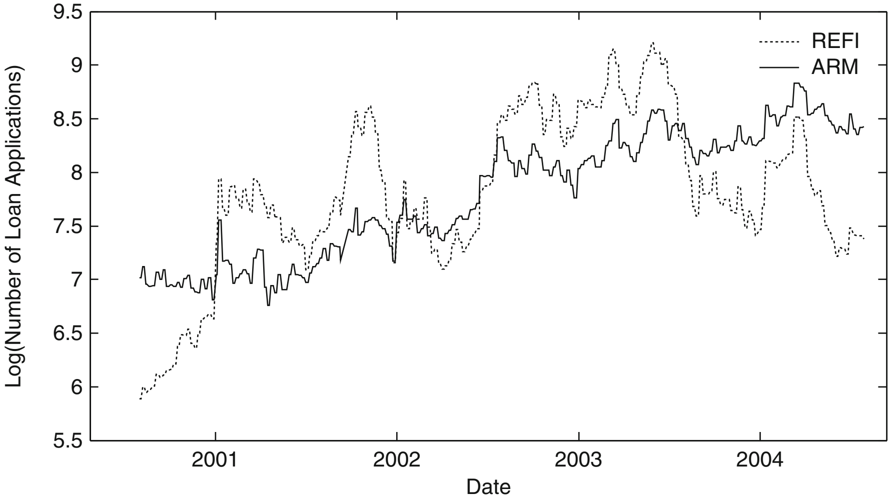

Fig. 86.6 Mortgage Bankers Association of America (MBAA) weekly refinancing and ARMs indexes. This figure reports the logs of the refinance and ARMs indexes obtained by weekly surveys at the Mortgage Bankers Association of America (MBAA)

LIBOR rates, we examine whether prepayment still has incremental contributions in explaining interest rate option prices in the presence of these two factors.[24] Finally, in addition to prepayment activities, we also examine the impacts of ARMs origination on the forward densities. Implicit in any ARM is an interest rate cap, which caps the mortgage rate at a certain level. Since lenders of ARMs implicitly sell a cap to the borrower, they might have incentives to hedge such exposures.[25]

Our measures of prepayment and ARMs activities are the weekly refinancing and ARMs indexes based on the weekly surveys conducted by MBAA, respectively. The two indexes, as plotted in Fig. 86.6, tend to be positively correlated with each other. There is an upward trend in ARMs activities during our sample period, which is consistent with what happened in the housing market in the past few years.

To examine the impacts of mortgage activities on LIBOR forward densities, we repeat the above regressions by including two additional explanatory variables that measure refinance and ARMs activities. Specifically, we refer to the top 20 % of the observations of the refinance (ARMs) index as the high prepayment (ARMs) group. After obtaining a nonparametric forward density at a particular level of the two conditioning variables, we define two new variables "Refi" and "ARMs," which

[24]While the slope factor can have nontrivial impact on prepayment behavior, the volatility factor is crucial for pricing interest rate options.

[25]We thank the referee for the suggestion of examining the effects of ARMs origination on the forward densities.

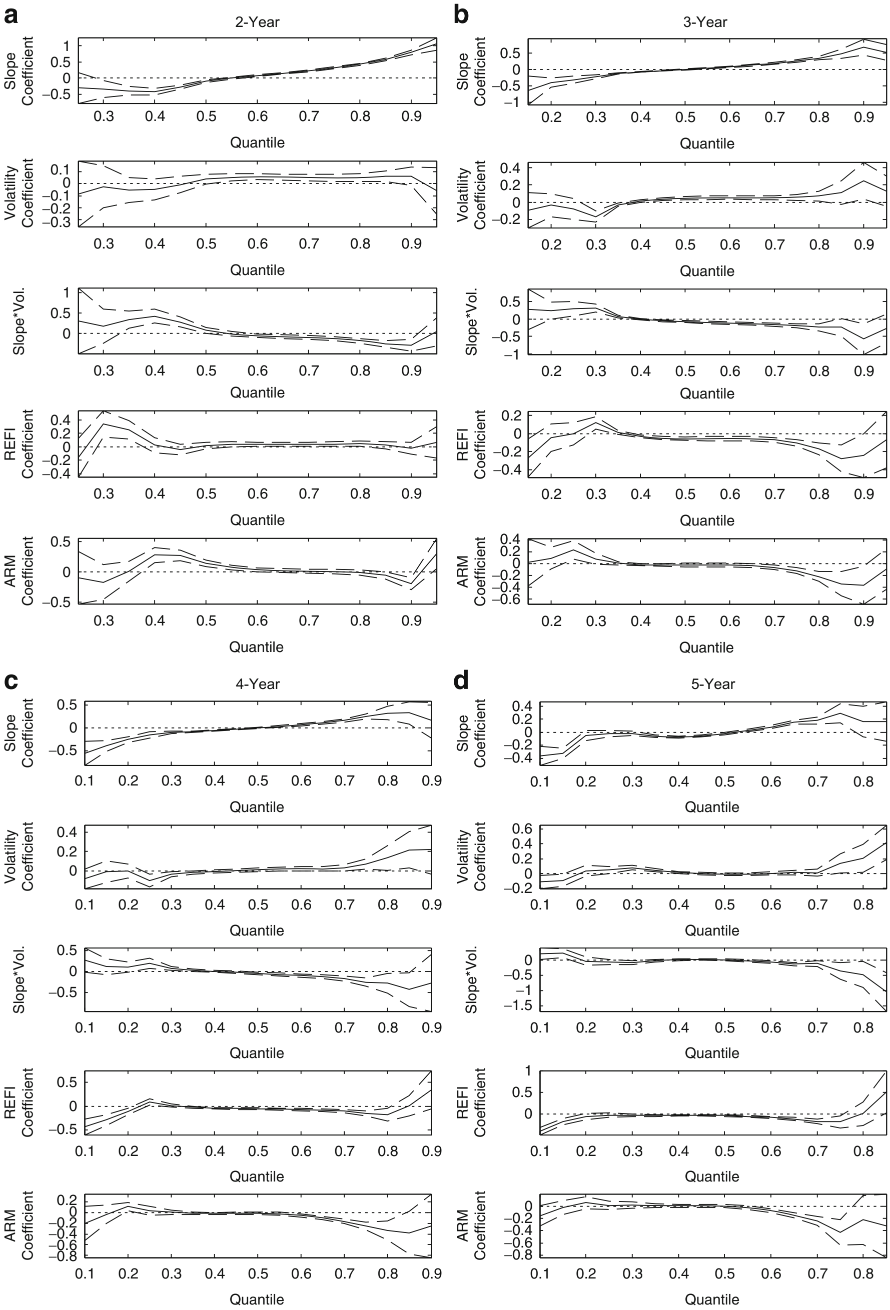

Fig. 86.7 Impacts of refinance and ARMs activities on LIBOR forward densities. In this figure, for each quantile of LIBOR forward densities at 2-, 3-, 4-, and 5-year maturities, we report regression coefficients of the quantile on (i) the slope and volatility factors and their interaction term as in Eq. 86.27 and (ii) refinance and ARMs activities

measure the percentages of observations used in estimating the forward density that belong to the high prepayment and ARMs groups, respectively. These two variables allow us to test whether the forward densities behave differently when prepayment/ARMs activities are high. To control for potential collinearity among the explanatory variables, we have orthogonalized any new explanatory variable with respect to existing ones.

Figure 86.7 contains the new regression results with "Refi" and "ARMs" for the four maturities. The coefficients of the slope, volatility, and the interaction term exhibit similar patterns as that in Fig. 86.4.[26]

The strongest impacts of ARMs on the forward densities occur at 2-year maturity, as shown in Panel A of Fig. 86.7. Therefore, high ARMs origination shifts the median and the right tail of the forward densities at 2-year maturity toward the right. This finding is consistent with the notion that hedging demands from ARMs lenders for the cap they have shorted might increase the price of OTM caps. One possible reason that the effects of ARMs are more pronounced at 2-year maturity than at 3-, 4-, and 5-year maturities is that most ARMs get reset within the first 2 years.

While high ARMs activities shift the forward density at 2-year maturity to the right, high refinance activities shift the forward densities at 3-, 4-, and 5-year maturities to the left. We see that the coefficients of Refi at the left tail are significantly negative. While the coefficients also are significantly negative for the middle of the distribution (40–70 % quantiles), the magnitude of the coefficients is much smaller. These can be seen in Panels B, C, and D of Fig. 86.7. Therefore, high prepayment activities lead to much more negatively skewed forward densities. This result is consistent with the notion that investors in MBS might demand OTM floors to hedge their potential losses from prepayments. The coefficients of Refi are more significant at 4- and 5-year maturities because the duration of most of MBS are close to 5 years.

Our results confirm and extend the findings of Duarte (2008) by showing that mortgage activities affect the entire forward density and consequently the pricing of interest rate options across moneyness. While prepayment activities affect the left tail of the forward densities at intermediate maturities, ARMs activities affect the right tail of the forward densities at short maturity. Our findings hold even after controlling for the slope and volatility factors and suggest that part of the USV factors could be driven by activities in the mortgage markets.

86.5 Conclusion

The unspanned stochastic volatility puzzle is one of the most important topics in the current term structure modeling. Similar to the stochastic volatility in the equity options literature, the existence of USV challenges the benchmark in the current

[26]In results not reported, we find that the nonlinear dependence of the forward densities on the volatility factor remains the same as well.

term structure literature, the dynamic term structure models. But it also in part explains why the practitioners generally apply the HJM type of models for interest rate derivatives, where sometimes the models are applied in an inconsistent manner across securities. Unlike the stock options models where the underlying stock price usually follows a univariate process, it is more challenging to argue that the stochastic volatilities of yields are not spanned by the existing yield curve factors. We in this paper review the current literature, which is mostly in support of the USV using either bonds data or both bonds and derivatives data. We present the results in Li and Zhao (2006) that the DTSMs have serious difficulty in hedging against the interest rate caps. We also present the results from Li and Zhao (2009) where they show nonparametrically both the actual volatility of interest rates and the liquidity component of the implied volatility affect the derivative prices after controlling for the yield curve factors. This paper also presents the model developed in Jarrow et al. (2007), which is quite rich parametrically to capture a spectrum of derivative prices. We can expect that the USV will have the similar effect on interest rate derivatives as the stochastic volatility on the equity options literature with many more issues to be addressed in the future.

Appendix 1: The Derivation for QTSMs

To guarantee the stationarity of the state variables, we assume that ξ permits the following eigenvalue decomposition:

$$\xi = U\Lambda U^{-1}$$

where Λ is the diagonal matrix of the eigenvalues that take negative values, $\Lambda \equiv \text{diag}[\lambda_i]_N$, and U is the matrix of the eigenvectors of ξ, $U \equiv [u_1 u_2 \ldots u_N]$. The conditional distribution of the state variables X_t is multivariate Gaussian with conditional mean

$$E[X_{t+\Delta t}|X_t] = U\Lambda^{-1}[\Phi - I_N]U^{-1}\mu + U\Lambda^{-1}[\Phi - I_N]U^{-1}X_t \tag{44.47}$$

and conditional variance

$$\text{var}[X_{t+\Delta t}|X_t] = U\Theta U' \tag{44.48}$$

where Φ is a diagonal matrix with elements $\exp(\lambda_i \Delta t)$ for $i = 1, \ldots, N$, Θ is an N-by-N matrix with elements

$$\left[\frac{v_{ij}}{\lambda_i + \lambda_j}\left(e^{\Delta t\left(\lambda_i + \lambda_j\right)} - 1\right)\right],$$

where $[v_{ij}]_{N \times N} = U^{-1} \sum \sum' U'^{\,-1}$.

With the specification of market price of risk, we can relate the risk-neutral measure Q to the physical one P as follows:

$$E\left[\frac{dQ}{dP}|\mathcal{F}_t\right] = \exp\left[-\int_0^t \zeta(X_s)'dW_s - \frac{1}{2}\int_0^t \zeta(X_s)'\zeta(X_s)ds\right], \quad \text{for } t \le T. \tag{44.49}$$

Applying Girsanov's theorem, we obtain the risk-neutral dynamics of the state variables

$$dX_t = [\delta + \gamma X_t]dt + \sum dW_t{}^Q$$

where $\delta = \mu - \sum \eta_0, \gamma = \xi - \sum \eta_1$, and $W_t{}^Q$ is an N-dimensional standard Brownian motion under measure Q.

Under the above assumptions, a large class of fixed-income securities can be priced in (essentially) closed form (see Leippold and Wu 2002). We discuss the pricing of zero-coupon bonds below and the pricing of caps. Let $V(t, \tau)$ be the time-t value of a zero-coupon bond that pays 1 dollar at time $T(\tau = T - t)$. In the absence of arbitrage, the discounted value process $\exp(-\int_0^t r(X_s)ds)V(t,\tau)$ is a Q-martingale. Thus, the value function must satisfy the fundamental PDE, which requires the bond's instantaneous return equals the risk-free rate:

$$\frac{1}{2}tr\left(\sum\sum{}'\frac{\partial^2 V(t,\tau)}{\partial X_t \partial X_t'}\right) + \frac{\partial V(t,\tau)}{\partial X_t'}(\delta + \gamma X_t) + \frac{\partial V(t,\tau)}{\partial t} = r_t V(t,\tau) \tag{44.50}$$

with the terminal condition $V(t, 0) = 1$. The solution takes the form

$$V(t,\tau) = \exp\left[-X_t'A(\tau)X_t - b(\tau)'X_t - c(\tau)\right],$$

where $A(\tau)$, $b(\tau)$, and $c(\tau)$ satisfy the following system of ordinary differential equations (ODEs):

$$\begin{aligned}
\frac{\partial A(\tau)}{\partial \tau} &= \psi + A(\tau)\gamma + \gamma'A(\tau) - 2A(\tau)\sum\sum{}'A(\tau);\\
\frac{\partial b(\tau)}{\partial \tau} &= \beta + 2A(\tau)\delta + \gamma'b(\tau) - 2A(\tau)\sum\sum{}'b(\tau);\\
\frac{\partial c(\tau)}{\partial \tau} &= \alpha + b(\tau)'\delta - \frac{1}{2}b(\tau)'\sum\sum{}'b(\tau) + tr\left[\sum\sum{}'A(\tau)\right];\\
&\text{with } A(0) = 0_{N\times N;b(0)} = 0_{N;c(0)} = 0.
\end{aligned}$$

Consequently, the yield to maturity, $y(t, \tau)$, is a quadratic function of the state variables:

$$y(t,\tau) = \frac{1}{\tau}\left[X_t'A(\tau)X_t + b(\tau)'X_t + c(\tau)\right].$$

In contrast, in the ATSMs the yields are linear in the state variables, and therefore the correlations among the yields are solely determined by the correlations of the state variables. Although the state variables in the QTSMs follow multivariate Gaussian process, the quadratic form of the yields helps to model the time-varying volatility and correlation of bond yields.

Leippold and Wu (2002) show that a large class of fixed-income securities can be priced in closed form in the QTSMs using the transform analysis of Duffie et al. (2000). They show that the time-t value of a contract that has an exponential quadratic payoff structure at terminal time T, i.e.,

$$\exp(-q(X_T)) = \exp\left(-X_T^{'}\overline{A}X_T - \overline{b}^{'}X_T - \overline{c}\right)$$

has the following form:

$$\begin{aligned}\Psi(q, X_t, t, T) &= E_Q\left(e^{-\int_t^T r(X_s)ds} e^{-q(X_T)}|\mathcal{F}_t\right). \\ &= \exp\left[-X_t A(T-t)X_t - b(T-t)'X_t - c(T-t)\right]. \end{aligned} \tag{44.51}$$

where $A(.)$, $b(.)$, and $c(.)$ satisfy the ODEs (86.4), (86.5), and (86.6) with the initial conditions $A(0) = \overline{A}, b(0) = \overline{b}$ and $c(0) = \overline{c}$. The time-t price a call option with payoff $\left(e^{-q(X_T)} - y\right)^+$ at $T = t + \tau$ equals

$$\begin{aligned}C(q, y, X_t, \tau) &= EQ\left(e^{-\int_t^T r(X_s)ds}\left(e^{-q(X_T)} - y\right)^+|\mathcal{F}t\right). \\ &= EQ\left(e^{-\int_t^T r(X_s)ds}\left(e^{-q(X_T)} - y\right)1\{-q(X_T) \geq \ln(y)\}|\mathcal{F}t\right). \\ &= G_{q,q}(-\ln(y), X_t, \tau) - yG_{0,q}(-\ln(y), X_t, \tau),\end{aligned}$$

where $G_{q1,q2}(y, X_t, \tau) = E_Q\left[e^{-\int_t^T r(X_s)ds} e^{-q1(X_T)}1\{q_2(X_T) \leq y\}|\mathcal{F}t\right]$ and can be computed by the inversion formula

$$\begin{aligned}G_{q1,q2}(y, X_t, \tau) = &\frac{\psi(q_1, X_t, t, T)}{2} \\ &- \frac{1}{\pi}\int_0^\infty \frac{e^{ivy}\psi(q_1 + ivq_2) - e^{-ivy}\psi(q_1 - ivq_2)}{iv}dv.\end{aligned} \tag{44.52}$$

Similarly, the price of a put option is

$$P(q, y, \tau, X_t) = yG_{0,-q}(\ln(y), X_t, \tau) - G_{q,-q}(\ln(y), X_t, \tau).$$

We are interested in pricing a cap which is portfolio of European call options on future interest rates with a fixed strike price. For simplicity, we assume the face value is 1 and the strike price is $\overline{r}$. At time 0, let τ, 2τ, . . ., $n\tau$ be the fixed dates for future interest payments. At each fixed date $k\tau$, the $\overline{r}$-capped interest payment is given by $\tau(R((k-1)\tau, k\tau) - \overline{r})^+$, where $R((k-1)\tau, k\tau)$ is the τ-year floating interest rate at time $(k-1)\tau$, defined by

$$\begin{aligned}\frac{1}{1+\tau R((k-1)\tau, k\tau)} &= q((k-1)\tau, k\tau)\\ &= E^Q\left(\exp\left(-\int_{(k-1)\tau}^{k\tau} r(X_s)ds\right)|\mathcal{F}(k-1)\tau\right).\end{aligned}$$

The market value at time 0 of the caplet paying at date $k\tau$ can be expressed as

$$\begin{aligned}Caplet(k) &= E^Q\left[\exp\left(-\int_0^{k\tau} r(X_s)ds\right)\tau(R((k-1)\tau, k\tau) - \overline{r})^+\right]\\ &= (1+\tau\overline{r})E^Q\left[\exp\left(-\int_0^{(k-1)\tau} r(X_s)ds\right)\left(\frac{1}{(1+\tau\overline{r})} - q((k-1)\tau, k\tau)\right)^+\right].\end{aligned}$$

Hence, the pricing of the k-th caplet is equivalent to the pricing of an $(k-1)\tau$ − for − τ put struck at $K = \frac{1}{(1+\tau\overline{r})}$. Therefore,

$$\begin{aligned}Caplet(k) = G_{0,-q\tau}&\left(\ln K, X_{(k-1)\tau}, (k-1)\tau\right)\\ &-\frac{1}{K}G_{q\tau,-q\tau}\left(\ln K, X_{(k-1)\tau}, (k-1)\tau\right).\end{aligned} \tag{44.53}$$

Similarly for the *k-th* floorlet,

$$\begin{aligned}Floorlet(k) = -G_{0,q\tau}&\left(-\ln K, X_{(k-1)\tau}, (k-1)\tau\right)\\ &+\frac{1}{K}G_{q\tau,q\tau}\left(-\ln K, X_{(k-1)\tau}, (k-1)\tau\right).\end{aligned} \tag{44.54}$$

Appendix 2: The Implementation of the Kalman Filter

To implement the extended Kalman filter, we first recast the QTSMs into a state-space representation. Suppose we have a time series of observations of yields of

L zero-coupon bonds with maturities $\Gamma = (\tau_1, \tau_2, \ldots, \tau_L)$. Let Ξ be the set of parameters for QTSMs and $Y_k = f(X_k, \Gamma; \Xi)$ be the vector of the L observed yields at the discrete time points $k\Delta t$, for $k = 1, 2, \ldots, K$, where Δt is the sample interval (1 day in our case). After the following change of variable,

$$Z_k = U^{-1}\left(\xi^{-1}\mu + X_k\right),$$

we have the state equation

$$Z_k = \Phi Z_{k-1} + w_k, \qquad w_k \sim N(0, \Theta)$$

where Φ and Θ are first introduced in Eqs. 86.4 and 86.5, and measurement equation

$$Y_k = d_k + H_k Z_k + v_k, \quad v_k \sim N(0, R^v)$$

where the innovations in the state and measurement equations w_k and v_k follow serially independent Gaussian processes and are independent from each other. The time-varying coefficients of the measurement equation d_k and H_k are determined at the ex ante forecast of the state variables:

$$\begin{aligned} H_k &= \frac{\partial f\left(Uz - \xi^{-1}\mu, \Gamma\right)}{\partial z} |z = Z_k|_{k-1} \\ d_k &= f\left(UZ_{k|k-1} - \xi^{-1}\mu, \Gamma\right) - H_k Z_{k|k-1} + B_k, \end{aligned}$$

where $Z_{k|k-1} = \Phi Z_{k-1}$.

In the QTSMs, the transition density of the state variables is multivariate Gaussian under the physical measure. Thus, the transition equation in the Kalman filter is exact. The only source of approximation error is due to the linearization of the quadratic measurement equation. As our estimation uses daily data, the approximation error, which is proportional to 1-day-ahead forecast error, is likely to be minor. Furthermore, we can minimize the approximation error by introducing the correction term B_k.[27] The Kalman filter starts with the initial state variable $Z_0 = E(Z_0)$ and the variance-covariance matrix P_0^Z:

$$P_0^Z = E\left[(Z_0 - E(Z_0))(Z_0 - E(Z_0))'\right].$$

These unconditional mean and variance have closed-form expressions that can be derived using Eqs. 86.4 and 86.5 by letting Δt goes to infinity. Given the set of

[27]The differences between parameter estimates with and without the correction term are very small, and we report those estimates with the correction term B_k.

filtering parameters, $\{\Xi, R^v\}$, we can write down the log-likelihood of observations based on the Kalman filter K:

$$
\begin{aligned}
\log \mathscr{L}(Y;\Xi) &= \sum_{k=1}^{K} \log f(Y_k; Y_{k-1}, \{\Xi, R^v\}) \\
&= -\frac{LK}{2}\log(2\pi) - \frac{1}{2}\sum_{k=1}^{K}\log\left|P^Y_{k|k-1}\right| \\
&\quad -\frac{1}{2}\sum_{k=1}^{K}\left[\left(Y_k - Y_{k|k-1}\right)'\left(P^Y_{k|k-1}\right)^{-1}\left(Y_k - Y_{k|k-1}\right)\right]
\end{aligned}
$$

with $\mathcal{Y}_{k-1}$ is the information set at time (k–1) Δt, and is the time $P^Y_{k|k-1}$ (k–1) Δt, conditional variance of Y_k

$$
\begin{aligned}
P^Y_{k|k-1} &= H_k P^Z_{k|k-1} H_k' + R^v; \\
P^Z_{k|k-1} &= \Phi P^Z_{k-1} \Phi' + \Theta.
\end{aligned}
$$

Appendix 3: Derivation of the Characteristic Function

The solution to the characteristic function of log ($L_k(T_k)$),

$$
\psi(u_0, Y_t, t, T_k) = \exp\left[a(s) + u_0 \log(L_k(t)) + B(s)'V_t\right],
$$

$\alpha(s)$ and $B(s)$, $0 \le s \le T_k$ satisfy the following system of Riccati equations:

$$
\begin{aligned}
\frac{dB_j(s)}{ds} &= -\kappa_j^{k+1} B_j(s) + \frac{1}{2}B_j^2(s)\xi_j^2 + \frac{1}{2}\left[u_0^2 - u_0\right]U^2_{s,j}, \qquad 1 \le j \le N, \\
\frac{da(s)}{ds} &= \sum_{j=1}^{N}\kappa_j^{k+1}\theta_j^{k+1}B_j(s) + \lambda_J[\Gamma(u_0) - 1 - u_0(\Gamma(1) - 1)],
\end{aligned}
$$

where the function Γ is

$$
\Gamma(c) = \exp\left(\mu_J^{k+1}c + \frac{1}{2}\sigma_J^2 c^2\right).
$$

The initial conditions are $B(0) = 0_{N\times 1}$, $\alpha(0) = 0$, and κ_j^{k+1} and θ_j^{k+1} are the parameters of $V_j(t)$ process under $\mathbb{Q}^{k+1}$.

For any $l < k$, given that $B(T_l) = B_0$ and $a(T_l) = a_o$, we have the closed-form solutions for $B(T_{l+1})$ and $a(T_{l+1})$. Define constants $p = \left[u_0^2 - u_0\right] U_{s,j}^2, q = \sqrt{\left(\kappa_j^{k+1}\right)^2 + p\xi_j^2}, c = \frac{p}{q-\kappa_j^{k+1}}$ and $d = \frac{p}{q+\kappa_j^{k+1}}$. Then we have

$$B_j(T_{l+1}) = c - \frac{(c+d)\left(c - B_{j0}\right)}{\left(d + B_{j0}\right)\exp(-q\delta) + \left(c - B_{j0}\right)}, \qquad 1 \leq j \leq N,$$

$$a(T_{l+1}) = \alpha_0 - \sum_{j=1}^{N} \left[\kappa_j^{k+1}\theta_j^{k+1}\left(d\delta + \frac{2}{\xi_j^2}\ln\left(\frac{\left(d + B_{j0}\right)\exp(-q\delta) + \left(c - B_{j0}\right)}{c+d}\right)\right)\right] + \lambda_J\delta[\Gamma(u_0) - 1 - u_0(\Gamma(1) - 1)],$$

if $p \neq 0$ and $B_j(T_{l+1}) = B_{j0}$, $a(T_{l+1}) = a_0$ otherwise. $B(T_k)$ and $a(T_k)$ can be computed via iteration.

Abstract

This chapter examines alternative equity valuation models and their ability to forecast future stock prices. Equity valuation models included Ohlson's (1995) Model, Feltham and Ohlson's (1995) Model, and Warren and Shelton's (1971) Model. Five research hypotheses are developed to examine whether different estimation techniques, earnings measures, and combined forecasting methods can improve the ability to predict future stock prices. We find that the simultaneous equation estimation procedure can produce more accurate future stock price forecasts than the traditional single equation estimation method in terms of smaller prediction errors. In addition, the combined forecast method can further reduce the prediction errors by using combination of individual forecasts. Empirical evidence also shows that investors can use comprehensive earnings to more accurately forecast future stock prices in these valuation models.

We use simultaneous equation estimation technique to investigate the stock price forecast ability of Ohlson's Model, Feltham and Ohlson's Model, and Warren and Shelton's (1971) Model. Moreover, we use the combined forecasting methods proposed by Granger and Newbold (1973) and Granger and Ramanathan (1984) to form combined stock price forecasts from individual models. Finally, we examine whether comprehensive earnings can provide incremental price-relevant information beyond net income.

Keywords

Ohlson Model • Feltham and Ohlson Model • Warren and Shelton Model • Equity valuation models • Simultaneous equation estimation • Fundamental analysis • Financial statement analysis • Financial planning and forecasting • Combined forecasting • Comprehensive earnings • Abnormal earnings • Operating earnings • Accounting earnings

87.1 Introduction

In this chapter, we investigate new estimation procedures and combination of forecast methods of alternative equity valuation models, namely, the Ohlson (1995) Model, the Feltham and Ohlson (1995) Model (FO Model henceforth), and the Warren and Shelton (1971) Model (WS Model henceforth). The Ohlson Model and the FO Model are valuation models based on information obtained from income statement and balance sheet, i.e., earnings and book value per share, while the WS Model accounts for the overall operating and financial environments of the firm. This chapter first uses simultaneous equation estimation procedures to estimate the information dynamics in these models and compare their forecast ability of future stock prices. Moreover, we examine the stock price forecasts ability of the Ohlson and FO Model by using other forms of earnings. Given the Ohlson Model and FO Model are derived based on the clean surplus relation (CSR), the *earnings* or *income* in CSR should include all changes in equity during a period except those resulting from investments by owners and distributions to owners. The *earnings* under this concept are closer to *comprehensive income* rather than the bottom-line net income that had been frequently used in previous empirical studies. Given its consistency with the accounting-based valuation theory, we further investigate the stock price forecast ability of the Ohlson and FO Model by using the comprehensive income in the empirical model specification. Finally, we employ forecast combination methods to integrate the individual stock price forecasts from these models and explore possible improvement in terms of producing smaller prediction errors.

Our empirical results suggest that the simultaneous equation estimation of the information dynamics improves the explanatory power of the models. Prior literature in testing the accounting-based valuation model did not consider the feedback effect between the variables of interest. In other words, the traditional linear information dynamics conjectured that the earnings dynamics is an AR(1) process which is determined by past earnings and other value-relevant information such as the analyst earnings forecasts. However, following Tsay et al. (2008), we incorporate the feedback effect between the earnings and value-relevant information variables, such as analyst earnings forecasts, and improve the predictability of future stock prices in terms of better forecast accuracy. We find that simultaneous equation estimation procedure produces smaller mean forecast errors than the single equation estimation procedure by 5.14 % (3.14 %) on average in our sample period for the Ohlson (FO) Model. Moreover, with the addition of other accounting information variables in the WS Model, we find further improvement in forecasting future stock prices. The future stock price forecasts from the WS Model are smaller than those predicted by the Ohlson (FO) Model by 5.26 % (2.23 %) annually in our sample period. By considering the firm's overall operating and financial environment, the model produces smaller prediction errors to the previous two models considering only earnings and book value per share.

Given the future stock price forecasts from these models, we employ forecast combination methods to integrate these individual forecasts in order to generate more accurate future stock price forecasts. We find that the combined future stock price forecasts based on weighted least square regression methods with the geometric weighting scheme produce smaller prediction errors than individual forecasts from the Ohlson, FO, and WS Model. The combined forecasts using the Ohlson (FO) Model with the WS Model generate smaller prediction errors than the individual forecasts by 7.16 % (4.07 %) annually. These results suggest superior accuracy of the combined forecast methods compared to the individual forecasts in terms of future stock price prediction errors. If comprehensive (operating) income is used in the Ohlson (FO) Model, we find that the prediction errors of future stock price forecast can be reduced up to 3.30 % (2.44 %) compared to using net income. Moreover, when comprehensive (operating) income-based Ohlson (FO) Model forecasts are combined with WS Model forecasts, the reduction in pricing errors can reach up to 17.85 % (15.96 %). We find that comprehensive income indeed has incremental price-relevant information beyond bottom-line net income in terms of generating more accurate stock price forecasts in these valuation models. Our results provide new evidence in the value relevance of comprehensive income and shed light on how the issuance of Statement of Financial Accounting Standard No. 130, *Reporting Comprehensive Income*, can help investors better assess the overall performance of the corporation.

The remainder of this chapter is organized as follows. Section 87.2 provides literature review in accounting-based valuation models and the financial planning and forecast models. The theoretical development and empirical implementation of these models are discussed. Section 87.3 presents the sample selection criteria, model specification of the linear information dynamics, and the research hypotheses for the empirical tests. Section 87.4 discusses the empirical results of individual forecasts and combined forecasts for future stock prices from these models. Section 87.5 provides the summary of this chapter.

87.2 Literature Review

In this section, we first review the theoretical development and the empirical assessment of the Ohlson Model and the FO Model. We then review the financial planning and forecasting model developed by Warren and Shelton (1971). We also provide the background and prior academic research on the comprehensive earnings reporting issues. Finally, we will review the combined forecasting methods proposed by Granger and Newbold (1973), Granger and Ramanathan (1984), and Diebold and Pauly (1987).

87.2.1 Ohlson Model (1995) and Feltham-Ohlson Model (1995)

The Ohlson Model provides a theoretical framework linking the valuation to the reported financial statement variables. The traditional dividend discount model states the following relations:

$$P_t = \sum_{\tau=1}^{\infty} R_f^{-\tau}\left(\widetilde{d}_{t+\tau}\right) \tag{87.1}$$

where P_t is the price of the firm's equity at time t, $\widetilde{d}_{t+\tau}$ is the dividends paid at time t, and R_f is the risk-free rate plus one. The restrictive nature of this relation is that Eq. 87.1 does not relate the reported financial statement numbers to firm value. In Eq. 87.1, the value depends on the accounting data that influences the present value of expected future dividends. Since this distribution of wealth eventually converge with the creation of wealth, the Ohlson Model considers how the current value depends on accounting measures of wealth creation process. The Ohlson Model introduced the clean surplus relations (CSR) assumption requiring that income over a period equals net dividends and the change in book value of equity. CSR ensures that all changes in shareholder equity that do not result from transactions with shareholders (such as dividends, share repurchases, or share offerings) are reflected in the income statement. In other words, CSR is an accounting system recognizing that the periodical value created is distinguished from the value distributed.

Let x_t denote the earnings for period $(t-1, t)$, y_t denote the book value at time t, and $x_t^a = x_t - (R_f - 1)y_{t-1}$ denote the abnormal earnings at time t. The clean surplus relations $y_t = y_{t-1} + x_t - d_t$ imply that

$$P_t = y_t + \sum_{\tau=1}^{\infty} R_f^{-\tau} E_t\left[\widetilde{x}_{t+\tau}^a\right] \tag{87.2}$$

the firm's value is equal to its book value adjusted for the present value of expected future abnormal earnings. The variables on the right-hand side of (87.2) are still forecasts, not past realizations. To deal with this problem, the Ohlson Model introduced the information dynamics to link the value to the contemporaneous accounting data. Assume $\left\{\widetilde{x}_t^a\right\}_{\tau \geq 1}$ follows the stochastic process

$$\begin{aligned} \widetilde{x}_{t+1}^a &= \omega x_t^a + v_t + \widetilde{\varepsilon}_{1,t+1} \\ \widetilde{v}_{t+1} &= \gamma v_t + \widetilde{\varepsilon}_{2,t+1} \end{aligned} \tag{87.3}$$

where v_t is value-relevant information other than abnormal earnings and $0 \leq \omega$, $\gamma \leq 1$. Based on Eqs. 87.2 and 87.3, the Ohlson Model demonstrated that the value of the equity is a function of contemporaneous accounting variables as follows:

$$P_t = y_t + \hat{\alpha}_1 x_t^a + \hat{\alpha}_2 v_t \tag{87.4}$$

where $\hat{\alpha}_1 = \hat{\omega}/\left(R_f - \hat{\omega}\right)$ and $\hat{\alpha}_2 = R_f/\left(R_f - \hat{\omega}\right)\left(R_f - \hat{\gamma}\right)$. Or equivalently,

$$P_t = \kappa(\varphi x_t - d_t) + (1-\kappa)y_t + \alpha_2 v_t \tag{87.5}$$

where $\kappa = \left(R_f - 1\right)\hat{\omega}/\left(R_f - \hat{\omega}\right)$ and $\varphi = R_f/(R_f - 1)$. Equations 87.4 and 87.5 imply that the market value of the equity is equal to the book value adjusted for (i) the current profitability as measured by abnormal earnings and (ii) other information that modifies the prediction of future profitability. One major limitation of the Ohlson Model is that it assumed unbiased accounting. In Eq. 87.3, since both abnormal earnings and other information follow an AR(1) process, over time their averages are zero and thus the average abnormal earnings are zero as well. If given biased (conservative) accounting, the average abnormal earnings will be nonzero. Consequently, the future growth in book value will become an important factor. This motivated Feltham and Ohlson (1995) to introduce additional dynamics to deal with this issue.

The FO Model analyzes how firm value relates to the accounting information that discloses the results from both operating and financial activities. For the financial activities, there are relatively perfect markets and the accounting measures for book value and market value of these assets are reasonably close. However for the operating assets, accrual accounting usually results in difference between the book value and the market value of these assets since they are not traded in the market. Accrual accounting for the operating assets consequently results in discrepancy between their book value and market value and thus influences the goodwill of the firm. Similar to the Ohlson Model, the information dynamics in the FO Model is

$$\begin{aligned}\widetilde{ox}^a_{t+1} &= \omega_{10} + \omega_{11} ox^a_t + \omega_{12} oa_t + \omega_{13} v_{1t} + \widetilde{\varepsilon}_{1t+1}\\ \widetilde{oa}_{t+1} &= \omega_{20} + \omega_{22} ox^a_t + \omega_{24} v_{2t} + \widetilde{\varepsilon}_{2t+1}\\ \widetilde{v}_{1t+1} &= \omega_{30} + \omega_{33} v_{1t} + \widetilde{\varepsilon}_{3t+1}\\ \widetilde{v}_{2t+1} &= \omega_{40} + \omega_{44} v_{2t} + \widetilde{\varepsilon}_{4t+1}\end{aligned} \tag{87.6}$$

where ox^a_t is the abnormal operating earnings, oa_t is the operating assets, v_{1t} and v_{2t} are the other value-relevant information variables for firm at time t, respectively. The derived implied pricing function is

$$P_t = y_t + \hat{\lambda}_0 + \hat{\lambda}_1 ox^a_t + \hat{\lambda}_2 oa_t + \hat{\lambda}_3 v_{1t} + \hat{\lambda}_4 v_{2t} \tag{87.7}$$

where

$$\begin{aligned}\hat{\lambda}_0 &= \frac{(1+r)\begin{bmatrix}\hat{\omega}_{10}(1+r-\hat{\omega}_{22})(1+r-\hat{\omega}_{33})(1+r-\hat{\omega}_{44})\\ +\hat{\omega}_{12}\hat{\omega}_{20}(1+r-\hat{\omega}_{33}) + \hat{\omega}_{13}\hat{\omega}_{30}(1+r-\hat{\omega}_{22})\\ +\hat{\omega}_{14}\hat{\omega}_{40}(1+r-\hat{\omega}_{44})\end{bmatrix}}{r(1+r-\hat{\omega}_{11})(1+r-\hat{\omega}_{22})(1+r-\hat{\omega}_{33})(1+r-\hat{\omega}_{44})}\\ \hat{\lambda}_1 &= \frac{\hat{\omega}_{11}}{r(1+r-\hat{\omega}_{11})}\\ \hat{\lambda}_2 &= \frac{(1+r)\hat{\omega}_{12}}{(1+r-\hat{\omega}_{11})(1+r-\hat{\omega}_{22})}\\ \hat{\lambda}_3 &= \frac{(1+r)\hat{\omega}_{13}}{(1+r-\hat{\omega}_{11})(1+r-\hat{\omega}_{33})}\\ \hat{\lambda}_4 &= \frac{(1+r)\hat{\omega}_{14}}{(1+r-\hat{\omega}_{11})(1+r-\hat{\omega}_{44})}\end{aligned} \tag{87.8}$$

Or equivalently,

$$P_t = k(\phi x_t - d_t) + (1-\kappa) y_t + \hat{\alpha}_2 oa_t + \hat{\lambda}_3 v_{1t} + \hat{\lambda}_4 v_{2t} \tag{87.9}$$

where $\kappa = \left(R_f - 1\right)\hat{\omega}_{11}/\left(R_f - \hat{\omega}_{11}\right)$ and $\phi = R_f/(R_f - 1)$. The implied valuation function in Eqs. 87.7 and 87.9 is a weighted average of the firm's operating earnings, the firm's book value, and the other value-relevant information with an adjustment for the understatement of the operating assets resulting from accrual accounting. The major contribution of the FO Model is that it considered the accounting conservatism in the equity valuation.

A complementary study by Lehman (1993) also examined the similar problem in the computation share value. Essentially this chapter aimed at identifying cash flows more fundamental than dividends in the computation of the present values. Specifically, the cash flows that were the focus of this chapter have the following properties: (i) Similar to dividends, current prices of the shares are the risk-adjusted present value of the cash flows. (ii) Unlike the dividends, these cash flows have to be invariant to the changes in dividend policy. Lehman (1993) provided three building blocks to identify cash flows that are more fundamental than dividends and with the property that they are invariant to the changes in the dividend policy. The first building block is to transform the present value computation using the future dividends into a relation using future values of arbitrary cash flows. The second building block is the restriction of the changes in the dividend policy to be zero net present value alteration of future dividend stream that leave the risk premium of the firm unaffected. In other words, this chapter made the assumption that only the changes in investment and financial policies would alter the riskiness of the firm but not the changes in the dividend policy. The final building block is the translation of economic earnings into accounting earnings that can be obtained from the financial statement. Essentially this assumption states that the accounting earnings used in computing the present value of the shares have to include all relevant capital gains and losses from investment associated with dividend policy.

Lehman (1993) is different from the Ohlson Model and FO Model in determining the user cost of capital. Lehman (1993) generalizes the assumption that expected earnings are linearly related to lagged earnings, dividends, and book value. Although it also imposes CSR, the earnings are not confined to accounting earnings. Moreover, Lehman (1993) also differs from the FO Model in the specification of the book value of equity. It uses an aggregate book value approach which does not separate the effects of net financial assets from the net operating assets. In the absence of conservative accounting, there will be no differences between two valuation methods given that book value of equity is equal to the market value of equity. However, given that the current GAAP is biased towards conservative accounting, the valuation implications on equity shares are different between the two models. Finally, Lehman (1993) relaxes Ohlson/FO assumption that changes in dividend payments change next period's earnings by one plus the risk-free discount rate by using a general risk-adjusted rate to discount dividends.

The line of research in empirically testing the Ohlson Model and FO Model has been growing large since its introduction. Previous empirical literature focused on either the value-relevant information variables (Abarbanell and Bushee 1997; Myers 1999; Dechow et al. 1999; Liu et al. 2002; Begley and Feltham 2002) or the dynamics of the earnings process (Morel 2001; Callen and Morel 2001). However, none of them documented empirical validity of the Ohlson Model. Callen and Segal (2005) showed that the nested Ohlson Model is rejected in favor of the FO Model but it did not improve the predictability power of the future stock prices. Based on these previous studies, we will examine whether the simultaneous equation approach in estimating the information dynamics can improve the predictability power of the Ohlson and FO Model.

The other potential cause of the lack of empirical validity of the residual income valuation models is the use of net income as the earnings measure in the linear information dynamics. Given these models are based on the clean surplus relation, the earnings measure should include all changes in equity except those resulting from investments by owners and distributions to owners. Consequently, the determination of stock price in the valuation functions of Eqs. 87.4 and 87.7 cannot be complete unless the earnings include all the value-added activities in the firm (Linsmeier et al. 1997a). Comprehensive income is defined as the change in equity (net assets) of a business enterprise during a period from transactions and other events and circumstances from nonowner sources (Statements of Financial Accounting Concepts No. 6, *Elements of Financial Statements*, 1985). Accounting standards in the USA sometimes allow nonowner changes in asset and liabilities, such as foreign currency translation adjustments, available-for-sale marketable securities adjustments, and minimum required pension liability adjustments, to bypass the income statement. The exclusion of these value-relevant items in financial reporting might mislead the users of financial statement information in assessing the value of the firm.

The debate of whether the firms should report comprehensive income or more streamlined bottom-line income can be traced back to the 1930s (Brief and Peasnell 1996). The supporters of Reporting Comprehensive Income argue that it captures all sources of value creation within a firm. Comprehensive income allows the users of the financial statement information to consider all relevant factors for earnings forecasting and firm value assessment. It also grants less leeway for the managers to engage in earnings management which could potentially distort the actual performance of the firms.[1] On the other hand, the opponents to the comprehensive income reporting point out that it includes many items that are transitory in nature which are not representative of the core operation of the firms. The inclusion of these nonrecurring and extraordinary items hinders income measure to reflect the firm's long-term cash flow prospects (Dhaliwal et al. 1999). It is also argued that these items add noises to reported earnings and make it difficult for forecasts. The users of the financial statements should be able to focus on a single measurement that summarizes all the value-relevant information without much manager's discretion in reporting this figure.[2]

The debate of whether firms in the USA should employ comprehensive income reporting led to the issuance of Statement of Financial Accounting Standard No. 130 (SFAS 130), *Reporting Comprehensive Income*, by Financial Accounting Standards Board. SFAS 130 requires firms to report comprehensive income in their primary financial statements. In the pre- and post-SFAS 130 era, there were many studies examining the value relevance of this requirement to report comprehensive income. Cheng et al. (1996) evaluate the usefulness of different earnings definition and find that the conventional income measures such as operating income and net income provide better explanatory power for residual security returns than comprehensive income. Dhaliwal et al. (1999) examine the value relevance of the major three components in comprehensive income required by SFAS 130. Their results

[1]Previous literatures in advocating comprehensive income reporting include Robinson (1991), Johnson et al. (1995), Beresford et al. (1996), and Smith and Reither (1996).

[2]Previous literatures in advocating current operating performance concepts of reporting income include Kiger and Williams (1977), Black (1993), Brief and Peasnell (1996), and Holthausen and Watts (2001).

suggest that only the marketable securities adjustment item improves the income and returns association. More importantly, they fail to find support to show comprehensive income is a better measurement for firm performance than net income and raise questions about the reporting requirement in SFAS 130. Biddle and Choi (2006) on the other hand find that comprehensive income outperforms other income measure in explaining equity returns and predicting future income and operating cash flows. Chambers et al. (2007) argue that prior studies in the pre-SFAS 130 era suffer from the measurement error problem in calculating the comprehensive earning. These authors show that the aforementioned three major components in the comprehensive income are indeed priced by the market in the post-SFAS 130 era when these items are specifically reported by requirement. In addition to the US findings, there are also many other international studies regarding the value relevance of comprehensive income.[3] The results, however, are mixed because of the different local accounting standards and time period within which the requirements are implemented.

87.2.2 Warren and Shelton Model (1971)

In addition to the accounting-based valuation model discussed above, operational financial planning models can also be used to forecast stock prices. One of such mathematical models is the Warren and Shelton (1971) Model. The WS Model uses a simultaneous equation approach to analyze important operating and financial variables. The WS Model considers the overall operational and financial environment of the firm. It is flexible so that it can be adapted and extended to meet various circumstances. The model accounts for the interrelations between investment activity, financing activity, dividend policy, and the production decision of the firm and their influences on the market value of the firm.

The critical inputs in the WS Model are the sales growth rate forecast and several operating ratios. The WS Model has four segments including 20 equations simultaneously determining 20 unknowns. The four segments are corresponding to the firm's sales, investments, financing, and return to investment concepts in the financial theory. The model first generates the sales and earnings forecasts given the historical data. Further, the model calculates the total assets required to support these sales and earnings forecasts and the venue through which these assets are to be financed. Finally, given these operation and financing decisions, the models determine the stock per share data.

Essentially the WS Model generates the price per share estimate from the assumptions about the firm's future growth in revenue, its financial and operating policies, and the overall economic environment. The model provides a valuation

[3] International evidence of the debate of comprehensive income reporting in countries such as UK and New Zealand can be found in O'Hanlon and Pope (1999), Cahan et al. (2000), Brimble and Hodgson (2007), and Lin (2006).

framework that includes many different parameter inputs which generate a wide range of estimates that can be presented statistically by a distribution with a mean and variance. The user of the model can easily examine the implication of alternative underlying firm-level and economy-wide environment changes on the equity share prices.

87.2.3 Forecast Combination

Forecast evaluation is of interest in many areas of empirical finance research, such as market efficiency (Fama 1970, 1991), volatility of the observed asset returns (Shiller 1979; LeRoy and Porter 1981; Fama and French 1988), and forward exchange rates (Hansen and Hodrick 1980). Borrowing from Diebold and Lopez (1996) and Yee (2008), we consider two groups of combining forecast methods, i.e., the variance-covariance method and the regression method. Bates and Granger (1969) first proposed the variance-covariance method for forecast combination. Denote the one-period-ahead stock price forecast at time t, $\hat{y}^i_{t,t+1}$, from model $i \in \{1,2\}$; the combined forecast can be formed as the weighted average between the two forecasts:

$$\hat{y}^c_{t,t+1} = \omega \hat{y}^1_{t,t+1} + (1-\omega)\hat{y}^2_{t,t+1}$$

which is an unbiased forecast if the weights sum up to unity. Moreover, the composite forecast error has the same relation as the combined forecast

$$\varepsilon^c_{t,t+1} = \omega \varepsilon^1_{t,t+1} + (1-\omega)\varepsilon^2_{t,t+1}$$

and the variance of the combined forecast

$$\sigma^2_c = \omega^2 + \sigma^2_{11} + (1-\omega)^2\sigma^2_{22} + 2\omega(1-\omega)\sigma_{12}$$

where σ^2_{11}, σ^2_{22}, and σ^2_{12} are the variance of the forecast from model one, model two, and their covariance. The optimal weight to minimize the forecast error ω can be derived as

$$\omega = \frac{\sigma^2_{22} - \sigma_{12}}{\sigma^2_{11} + \sigma^2_{22} - 2\sigma_{12}}$$

which is determined by the variances of each individual forecast and the covariance between them. The asymptotic properties of the optimal weights are

$$\lim_{\sigma^2_{11}\to\infty} \omega = 0 \quad \lim_{\sigma^2_{22}\to\infty} \omega = 1 \quad \lim_{\sigma^2_{11}\to 0} \omega = 1 \quad \lim_{\sigma^2_{22}\to 0} \omega = 0$$

Therefore, the variance-covariance method places larger weight on the more reliable forecast in forecast combination.

The regression method in forecast combination suggests a regression model in which the realization of y_{t+1} is regressed on the past forecasts of y_{t+1} to determine the optimal weights (Chong and Hendry 1986; Fair and Shiller 1989, 1990):

$$y_{t+1} = \alpha_0 + \alpha_1 \hat{y}^1_{t,t+1} + \alpha_2 \hat{y}^2_{t,t+1} + \varepsilon_{t,t+1} \tag{87.10}$$

Granger and Ramanathan (1984) showed that the optimal weight determined in the variance-covariance method has a regression interpretation as the coefficient vector in regression model (87.10) of a linear projection of y_{t+1} onto the forecasts y^i_{t+1} subject to the constraints that the weights α_i sum to unity and the exclusion of the intercept term. However, a number of researchers have recognized that the true but unknown variance-covariance matrix in determining the optimal weight ω is not fixed over time. Therefore, the ensuing research in this literature focused on the time-varying combining weights (Granger and Newbold 1973; Diebold and Pauly 1987) which can be achieved by using the technique of weighted least square (WLS). Diebold and Pauly (1987) proposed a WLS estimator:

$$\hat{\alpha}_{WLS} = (X'W'X)^{-1} X'WY$$

where the weighting matrix can be considered for the following schemes:

1. Equal weight (standard regression-based combining): $w_{tt} = 1$ for all t. (W1)
2. Linear weighting: $w_{tt} = t$ for all t. (W2)
3. Geometric weighting: $w_{tt} = \lambda^{T-t}$, $0 < \lambda \leq 1$, or $w_{tt} = \lambda^t$, $\lambda > 1$. (W3)
4. t^λ (t-lambda): $w_{tt} = t^\lambda$, $\lambda \geq 0$. (W4)

The geometric weighting has the appealing property that the weights increase at an increasing rate as we get closer to the present time. This yields heavy weighting on the more recent observation which might provide better accuracy for forecast values. Moreover, the geometric weighting can provide a weighting scheme that dies out fairly quickly which might be useful in modeling forecasts under an unstable environment. Similarly, the t-lambda (t^λ) specification can also produce weights that die out quickly, but it has an even more appealing fundamental characteristic that its weighting scheme can increase at an either increasing or decreasing rate as we get closer to the present time. When $\lambda = 0$, one obtains the constant weighting scheme in case (1), while when $\lambda = 1$, the linear weighting scheme in case (2) emerges.

The forecast combination equation with two primary individual forecasts can be written as

$$\underset{(T\times 1)}{\mathrm{Y}} = \underset{(T\times 3)}{\mathrm{f}} \underset{(3\times 1)}{\alpha} + \underset{(T\times 1)}{\varepsilon}$$

where

$$\alpha^i = P^i(t) = p^i_0 + p^i_1 t + \cdots + p^i_\gamma, \quad i = 0, 1, 2$$

$f_t = (1, f_t^1, f_t^2)$, $\alpha = (\alpha^0, \alpha^1, \alpha^2)$ ', and **f** is the matrix with tth row f_t. The time-varying combining weights are deterministic nonlinear polynomial functions of time. The advantage of this regression-based deterministically time-varying parameters model over the weighted least square approach is that this method can explicitly model any parameter evolution in the forecast combination equation. This approach can also project the evolution in when the forecasts are combined. The general polynomial and unrestricted regression-based combination is the following:

$$\begin{aligned} y_t &= \left(p_0^0 + p_1^0 t\right) + \left(p_0^1 + p_1^1 t\right)_{t-1} f_t^1 + \left(p_0^2 + p_1^2 t\right)_{t-1} f_t^2 \\ &= p_0^0 + p_1^0 t + p_{0\,t-1}^1 f_t^1 + p_1^1\left({}_{t-1}f_t^1\right) + p_{0\,t-1}^2 f_t^2 + p_1^2\left({}_{t-1}f_t^2\right) \end{aligned} \tag{87.11}$$

Similarly, the forecast can be obtained after estimating the parameters $\hat{p}_0^i$ and $\hat{p}_1^i$:

$$\begin{aligned} {}_t\hat{y}_{t+1} = &\left(\hat{p}_0^0 + \hat{p}_0^1(t+1)\right) + \left(\hat{p}_0^1 + \hat{p}_1^1(t+1)\right)_t f_{t+1}^1 \\ &+ \left(\hat{p}_0^2 + \hat{p}_1^2(t+1)\right)_t f_{t+1}^2 \end{aligned} \tag{87.12}$$

The weighted least square approach can be further combined with the time-varying parameters to determine the optimal weight in the forecast combination equation. For example, one can use geometric weighting scheme λ^{T-t} to construct the weighting matrix W and then estimate the parameters in Eq. 87.11. The estimated parameters $\hat{p}_0^i$ and $\hat{p}_1^i$ are then used in Eq. 87.12 to compute the forecast values. We will explore more possible combination of different weighting schemes and the time-varying parameters model to examine the combination of primary individual forecasts.

87.3 Data and Methodology

In this section, we first introduce the sample selection criteria. Then we present the research hypotheses and model specifications for the empirical tests discussed in the next section.

87.3.1 Data

The data used in this chapter is obtained from the intersection of the following three data sets between 1980 and 2007: annual Compustat for historical accounting data, monthly Center for Research in Security Prices (CRSP) for stock returns, and analyst forecast file from I/B/E/S. The following Compustat data items are used to construct the variables required in the empirical analysis in this chapter: cash and cash equivalent (# 1), total assets (# 6), long-term debt (# 9), interest expense (# 15), investments and advancements (# 32), debt in current liabilities (# 34), interest income (# 62), preferred shares (# 130), short-term investments (# 193), total liabilities (# 181), and notes payable (# 206). Moreover, the book value per share and price data are obtained from Compustat as well. For the Ohlson Model, the data required are already available from the data obtained from the aforementioned sources. However, for empirically testing the FO Model, further distinction between the net operating assets and the net financial assets, and between the operating earnings and the financial earnings, has to be conducted. As discussed previously, the FO Model assumes that the conservative accounting only applies to the operating assets while financial activities are all zero net present value investments. Consequently, only operating assets generate the differences between their book value and the market value which is the goodwill. However, neither theory nor the empirical rules demonstrate how to distinguish between the financial and operating assets. We follow the procedure outlined in Penman (2000) and Callen and Segal (2005) to calculate the operating assets and the financial assets:

$$\begin{aligned}
\text{Financial Assets} &= \text{Cash and Cash Equivalent } (\#\,1) + \text{Investments and Advancements } (\#\,32)\\
&\quad + \text{Short} - \text{Term Investments } (\#\,193)\\
\text{Financial Liabilities} &= \text{Long} - \text{Term debt } (\#\,9) + \text{Debt in Current Liabilities } (\#\,34)\\
&\quad + \text{Notes Payable } (\#\,206)\\
\text{Operating Assets} &= \text{Total Assets } (\#\,6) - \text{Financial Assets}\\
\text{Operating Liabilities} &= \text{Preferred Shares } (\#\,130) + \text{Total Liabilities } (\#\,181)\\
&\quad - \text{Financial Liabilities}\\
\text{Net Operating Assets} &= \text{Operating Assets} - \text{Operating Liabilities}\\
\text{Net Financial Assets} &= \text{Financial Assets} - \text{Financial Liabilities}
\end{aligned}$$

We also use comprehensive (operating) earnings in the linear information dynamics and examine how it affects the accuracy in forecasting future stock prices. SFAS 130 is effectively adopted in 1998 before which firms were not required to report comprehensive income. We follow Cheng et al. (1993), Dhaliwal et al. (1999), and Biddle and Choi (2006) to measure the comprehensive income. We did not use the actual reported comprehensive income given the lack of consistency in reporting of firms in our sample period.[4] The definition of comprehensive income by SFAS 130 is the net income adjusted for "other comprehensive income" items. These items include (1) the change in the balance of unrealized and losses on available-for-sale marketable securities (MSA), (2) the change in cumulative foreign currency translation adjustments (RECTA), and (3) the change in additional minimum pension liability in excess of unrecognized prior service costs (PENADJ). All these variables are scaled by the beginning-of-period market value of equity and they are calculated by using the Compustat data. *MSA* and *RECTA*

[4]In the post-SFAS 130 periods, Compustat has not yet completely disclosed all components in comprehensive income. Currently, Compustat only reports some of the items related to comprehensive income and these data are only complete after year 2001. Given that our empirical tests require sufficient time series to conduct forecasting, we employ the measurement methodology in Cheng et al. (1993) and Dhaliwal et al. (1999) to estimate comprehensive income.

are items *marketable securities adjustment* and *Retained Earnings − Cumulative Translation Adjustment* obtained directly from Compustat. *PENADJ* is calculated as *Pension-Additional Minimum Liability (PADDML) − Pension-Unrecognized Prior Service Cost (PCUPSO)*. The comprehensive income defined in SFAS 130, NI_{130}, is equal to *NI+MSA+RECTA+PENADJ*:

$$\begin{aligned}\text{Comprehensive Income } (x_{130}) = &\text{ Net Income } (\#\,172) + MSA(\#\,238)\\ &+ RECTA(\#\ \ \#\,230) + PENADJ(\#\,297 - \#\,298)\end{aligned}$$

Given the adjustments in calculating the comprehensive income, we further define the comprehensive operating income (ox_{130}) which is used in the information dynamics of the FO Model. Following Nissim and Penman (2001), we define the comprehensive operating income as follows:

$$\begin{aligned}&\text{Comprehensive Operating Income } \ (ox_{130}) = \text{Comprehensive Income } \ (x_{130})\\ &+ \text{Comprehensive Net Financial Expenses } \ (NFE) - \text{Minority Interest in Income } (\#\,49)\end{aligned}$$

where

Comprehensive Net Financial Expenses (*NFE*)
= Core Net Financial Expenses (*Core NFE*) + Unusual Financial Expenses (*UFE*)
= After-Tax Interest Expense (# 15×(1-marginal tax rate[5])) + Preferred Dividends (# 19) – After-Tax Interest Income (# 62×(1-marginal tax rate)) + Change in MSA (Lag # 238 – # 238)

Several other variables used in this chapter are discussed below. The earning used in our empirical analysis is the earnings from the continued operations obtained from I/B/E/S. We follow Callen and Segal (2005) to use the earnings reported in the I/B/E/S because of their comparability with the analyst earnings forecasts. Moreover, the interest rate on debt is computed as the interest expense (DATA 15) divided by the average financial liabilities. The cost of equity capital is calculated by the Fama-French three-factor model and the annualized 3-month treasury bill rate. Finally, we exclude the financial institution (SIC 6000) from the sample because of their minimal level of operating assets and the additional regulatory requirements. Observations with market value of equity less than $10 million, with negative operating and financial assets (liabilities), and with negative net operating and financial earnings are excluded as well. Finally, firms whose empirical variables are less than two firm years are deleted.

[5]Borrowing from Nissim and Penman (2001), the marginal tax rate is the top statutory federal tax rate plus 2 % average state tax rate. For our sample periods, the top statutory federal tax rate was 46 % in 1979–1986, 40 % in 1987, 34 % in 1988–1992, 35 % in 1993–1999, 40 % in 2000–2002, and 35 % in 2003–2008.

87.3.2 Research Hypotheses

Following Dechow et al. (1999) and Callen and Segal (2005), the empirical works in testing the Ohlson Model and FO Model employ the analyst earnings forecast to be the proxy for the other value-relevant information variable. The FO Model further supplements the Ohlson Model with the adjustment for conservative accounting towards which US GAPP is biased. By using the data in the US market, the FO Model is expected to produce better stock price forecast accuracy in terms of smaller prediction errors. As a result, we formulate our first testable hypothesis as follows:

H_{10} *The Feltham and Ohlson* (1995) *Model provides more accurate future stock price forecasts, in terms of smaller mean forecast errors, than the Ohlson* (1995) *Model.*

The use of analyst earnings forecasts is commonly used by the practitioner as well since they capture the forward-looking estimation of the performance of the firm. Should one use the analyst earnings forecasts to predict the future earnings, it is possible that there exists a relation between the two variables. Moreover, for the FO Model, it is also possible that there exist feedback relations of the operating earnings and operating assets with the short-term and long-term analyst earnings forecasts. As a result, we follow Tsay et al. (2008) to use a simultaneous equation approach to estimate the linear information dynamics in both the Ohlson Model and FO Model. By employing the simultaneous equation estimation in the linear information dynamics, we expect to capture the interaction of the future-period earnings with the current-period analyst earnings forecasts. We conjecture that the earnings forecasts influence the future-period earnings and thus the valuation of the equity. At the same time, the current-period earnings also affect the earnings forecasts produced by the analysts. It is the interrelationships between these variables that determine the fundamental value of the equity shares. Thus, we develop our second testable hypothesis as follows:

H_{20} *Simultaneous equation estimation of the linear information dynamics generates more accurate future stock price forecasts, in terms of smaller mean forecast errors, than single equation estimation in both the Ohlson* (1995) *Model and Feltham and Ohlson* (1995) *Model.*

In addition to the Ohlson Model and FO Model discussed above, we next focus on the stock price forecasts ability of the WS Model. The WS Model uses a simultaneous equation approach to forecast future stock price by considering both operating and financing decision of the firms. The WS Model is more comprehensive than the residual income valuation models because it accounts for the interrelations between investment activity, financing activity, dividend policy, and the production decision of the firm. Given its flexibility, the WS Model is expected to better predict future stock prices than the Ohlson/FO Model discussed previously. Thus, our third testable hypothesis is the following:

H_{30} *The Warren and Shelton* (1971) *Model can generate more accurate future stock price forecasts, in terms of smaller mean forecast errors, than both the Ohlson* (1995) *Model and Feltham and Ohlson* (1995) *Model.*

After considering the future stock price forecasts from these valuation models, we further investigate whether they can be combined to form more accurate forecasts. We thus employ the combined forecast methods (Granger and Newbold 1973; Granger and Ramanathan 1984; Diebold and Pauly 1987) to examine whether forecast combination is more accurate than individual forecasts in terms of mean forecast errors. Therefore, the fourth testable hypothesis in this chapter is the following:

H_{40} *The combination of individual forecasts from the Ohlson Model/Feltham-Ohlson Model and the WS Model can generate more accurate future stock price forecasts, in terms of smaller mean forecast errors, than each individual forecasts.*

Finally, we investigate whether comprehensive (operating) earnings can provide incremental price-relevant information beyond bottom-line earnings. We employ the comprehensive (operating) earnings in the linear information dynamics of the Ohlson Model/Feltham-Ohlson Model and examine its effects on the future stock price forecasts. These forecasts are further combined with the WS Model forecasts and their forecast accuracy is examined. Thus, the fifth testable hypothesis can be stated as follows:

H_{50} *Using comprehensive earnings as the earnings measure in the linear information dynamics of the Ohlson Model and Feltham-Ohlson Model can generate more accurate future stock price forecasts, in terms of mean forecast error, than bottom-line earnings as the earnings measure.*

87.3.3 The Model Specifications

In this section, we propose two sets of the linear information dynamics in the Ohlson Model and FO Model. The estimated coefficients from these information dynamics are further used in the valuation function to forecast future stock prices. The first set of specifications includes the single equation and the simultaneous equation estimation with the analyst forecast of earnings in the linear information dynamics of the Ohlson Model. The single equation approach specified in this set is essentially the model tested in Dechow et al. (1999). Moreover, as Tsay et al. (2008) stated that there are feedback relations between the other value-relevant information and the earnings, we further employ the simultaneous equation linear information dynamics. More specifically, we examine whether the feedback effect between the current earnings, analyst forecasts, and the book value improves the predictability of the model.

1. Model Set I: In the first model specification, we test the Ohlson Model with the other value-relevant information variable. This variable essentially summarizes information that is captured in a firm's stock because it can predict future abnormal earnings but is not yet reflected in the financial statements. Here we test a modified version of Dechow et al. (1999) model in which the other value-relevant information variable is the analysts' earnings forecasts. The linear information dynamic is

$$\begin{aligned} \widetilde{x}^a_{i,t+1} &= \omega_{10} + \omega_{11} x^a_{i,t} + \omega_{12} v_{i,t} + \widetilde{\varepsilon}_{i1,t+1} \\ \widetilde{v}_{i,t+1} &= \omega_{20} + \omega_{22} v_{i,t} + \widetilde{\varepsilon}_{i2,t+1} \end{aligned} \tag{87.13}$$

where $\widetilde{x}^a_{i,t+1}$ is the abnormal earnings of firm i at time t, and $v_{i,t}$ is the difference between the conditional expectation of abnormal earnings for firm i at time period t+1 based on all available information and the expectation of abnormal earnings, i.e., $v_{i,t} = E_t\left[\widetilde{x}^a_{i,t+1}\right] - \omega_{11}x^a_{i,t}$. Following Dechow et al. (1999), the period t conditional expectation of period t+1 earnings is the median consensus analyst forecast of period t+1 earnings denoted by f_t, i.e., $E_t\left[\widetilde{x}^a_{i,t+1}\right] = f^a_{i,t} = f_{i,t} - ry_{i,t}$, where $f_{i,t}$ is the median consensus analyst earnings forecasts of next year's earnings measured at the first month after the publication of the annual financial report. Consequently, the other value-relevant information can thus be written as $v_{i,t} = f^a_{i,t} - \omega_{11}x^a_{i,t}$.

The simultaneous equation specification of the linear information dynamic on the other hand is

$$\begin{aligned}\widetilde{x}^a_{i,t+1} &= \omega_{10} + \omega_{11}x^a_{i,t} + \omega_{12}v_{i,t} + \widetilde{\varepsilon}_{i1,t+1}\\ \widetilde{v}_{i,t+1} &= \omega_{20} + \omega_{21}x^a_{i,t} + \omega_{22}v_{i,t} + \widetilde{\varepsilon}_{i2,t+1}\end{aligned} \tag{87.13}$$

where the coefficient ω_{21} represents the feedback effect from current-period abnormal earnings to next-period analyst earnings forecasts. Given the specification of the information dynamics in Eqs. 87.12 and 87.13, the implied valuation function can be written as

$$P_{i,t} = y_{i,t} + \hat{\beta}_0 + \hat{\beta}_1 x^a_{i,t} + \hat{\beta}_2 v_{i,t} \tag{87.14}$$

where the estimated coefficients are

$$\begin{aligned}\hat{\beta}_0 &= \frac{\left(1+\hat{r}_{i,t}\right)\left[\hat{\omega}_{10}\left(1+\hat{r}_{i,t}-\hat{\omega}_{22}\right)+\hat{\omega}_{12}\hat{\omega}_{20}\right]}{\hat{r}_{i,t}\left(1+\hat{r}_{i,t}-\hat{\omega}_{11}\right)\left(1+\hat{r}_{i,t}-\hat{\omega}_{22}\right)}\\ \hat{\beta}_1 &= \frac{\hat{\omega}_{11}}{\left(1+\hat{r}_{i,t}-\hat{\omega}_{11}\right)}\\ \hat{\beta}_2 &= \frac{\left(1+\hat{r}_{i,t}\right)\hat{\omega}_{12}}{\left(1+\hat{r}_{i,t}-\hat{\omega}_{11}\right)\left(1+\hat{r}_{i,t}-\hat{\omega}_{22}\right)}\end{aligned}$$

and $\hat{r}_{i,t}$ is the cost of equity capital for firm i at time t. Or equivalently,

$$P_{i,t} = \kappa\left(\varphi x_{i,t} - d_{i,t}\right) + (1-\kappa)y_{i,t} + \hat{\beta}_2 v_{i,t} \tag{87.15}$$

where $\kappa = \hat{r}_{i,t}\hat{\omega}_{11}/\left(1+\hat{r}_{i,t}-\hat{\omega}_{11}\right)$ and $\varphi = \left(1+\hat{r}_{i,t}\right)/\hat{r}_{i,t}$.

In the second set of the model specification, we test the FO Model with single equation and simultaneous equation linear information dynamics. The FO Model argues that it is important to separate the financial assets and the operating assets in the valuation function since only operating assets generate goodwill.

The FO Model considers the practice of accrual accounting and how it influences the equity valuation.

2. Model Set II: The single equation linear information dynamics in the FO Model is the following:

$$\begin{aligned}
\widetilde{ox}^a_{i,t+1} &= \omega_{10} + \omega_{11} ox^a_{i,t} + \omega_{12} oa_{i,t} + \omega_{13} v_{1i,t} + \widetilde{\varepsilon}_{1i,t+1} \\
\widetilde{oa}^a_{i,t+1} &= \omega_{20} + \omega_{22} oa_{i,t} + \omega_{24} v_{2i,t} + \widetilde{\varepsilon}_{2i,t+1} \\
\widetilde{v}_{1i,t+1} &= \omega_{30} + \omega_{33} v_{1i,t} + \widetilde{\varepsilon}_{3i,t+1} \\
\widetilde{v}_{2i,t+1} &= \omega_{40} + \omega_{44} v_{2i,t} + \widetilde{\varepsilon}_{4i,t+1}
\end{aligned} \tag{87.16}$$

and the simultaneous linear information dynamics is

$$\begin{aligned}
\widetilde{ox}^a_{i,t+1} &= \omega_{10} + \omega_{11} ox^a_{i,t} + \omega_{12} oa_{i,t} + \omega_{13} v_{1i,t} + \omega_{14} v_{2i,t} + \widetilde{\varepsilon}_{1i,t+1} \\
\widetilde{oa}^a_{i,t+1} &= \omega_{20} + \omega_{21} ox^a_{i,t} + \omega_{22} oa_{i,t} + \omega_{23} v_{1i,t} + \omega_{24} v_{2i,t} + \widetilde{\varepsilon}_{2i,t+1} \\
\widetilde{v}_{1i,t+1} &= \omega_{30} + \omega_{31} ox^a_{i,t} + \omega_{32} oa_{i,t} + \omega_{33} v_{1i,t} + \omega_{34} v_{2i,t} + \widetilde{\varepsilon}_{3i,t+1} \\
\widetilde{v}_{2i,t+1} &= \omega_{40} + \omega_{41} ox^a_{i,t} + \omega_{42} oa_{i,t} + \omega_{43} v_{1i,t} + \omega_{44} v_{2i,t} + \widetilde{\varepsilon}_{4i,t+1}
\end{aligned} \tag{87.17}$$

where $ox^a_{i,t}$ is the abnormal operating earnings for firm i at time t, and $oa_{i,t}$ is the operating assets for firm i at time t. Moreover, the value-relevant information variables $v_{1i,t}$ and $v_{2i,t}$ are the growth in expected operating earnings and the expected growth in operating assets, respectively. The expected operating earnings are measured as the difference between the median consensus analyst earnings forecast for next year and the expected net interest revenue (product of end-of-current-year financial liabilities and the interest on debt). The growth in expected operating earnings is defined as the expected change in operating earnings divided by operating assets, i.e., $v_{1i,t} = E_t[\Delta\widetilde{ox}_{t+1}]/oa_t = E_t[\widetilde{ox}_{t+1} - ox_t]/oa_t$, where the current-period operating earnings ox_t are calculated as actual earnings reported by the I/B/E/S minus the interest revenue (product of beginning-of-current-year financial liabilities and the interest on debt). The expected growth in net operating asset is defined as the change in expected operating asset divided by the operating asset, i.e., $v_{2i,t} = E_t[\Delta\widetilde{oa}_{t+1}]/oa_t$. Following Liu and Ohlson (2000), we use the analyst earnings forecasts of long-term earnings growth rates as a proxy for the expected growth in net operating assets.[6]

Given the specification of the information dynamics in Eqs. 87.16 and 87.17, the implied valuation function is

$$P_{i,t} = y_{i,t} + \hat{\lambda}_0 + \hat{\lambda}_1 ox^a_{i,t} + \hat{\lambda}_2 oa_{i,t} + \hat{\lambda}_3 v_{1i,t} + \hat{\lambda}_4 v_{2i,t} \tag{87.18}$$

[6]The long-term growth forecast generally represents an expected increase in operating earnings over the company's next full business cycle. Usually, these forecasts refer to a period of between 3 and 5 years. Thomson Financial recommends the median value for long-term growth forecast rather than the mean. The median value is less affected by outlier forecasts.

where

$$\hat{\lambda}_0 = \frac{\left(1+\hat{r}_{i,t}\right)\begin{bmatrix}\hat{\omega}_{10}\left(1+\hat{r}_{i,t}-\hat{\omega}_{22}\right)\left(1+\hat{r}_{i,t}-\hat{\omega}_{33}\right)\left(1+\hat{r}_{i,t}-\hat{\omega}_{44}\right)\\ +\hat{\omega}_{12}\hat{\omega}_{20}\left(1+\hat{r}_{i,t}-\hat{\omega}_{33}\right)+\hat{\omega}_{13}\hat{\omega}_{30}\left(1+\hat{r}_{i,t}-\hat{\omega}_{22}\right)\\ +\hat{\omega}_{14}\hat{\omega}_{40}\left(1+\hat{r}_{i,t}-\hat{\omega}_{44}\right)\end{bmatrix}}{\hat{r}_{i,t}\left(1+\hat{r}_{i,t}-\hat{\omega}_{11}\right)\left(1+\hat{r}_{i,t}-\hat{\omega}_{22}\right)\left(1+\hat{r}_{i,t}-\hat{\omega}_{33}\right)\left(1+\hat{r}_{i,t}-\hat{\omega}_{44}\right)}$$

$$\hat{\lambda}_1 = \frac{\hat{\omega}_{11}}{\left(1+\hat{r}_{i,t}-\hat{\omega}_{11}\right)}$$

$$\hat{\lambda}_2 = \frac{\left(1+\hat{r}_{i,t}\right)\hat{\omega}_{12}}{\left(1+\hat{r}_{i,t}-\hat{\omega}_{11}\right)\left(1+\hat{r}_{i,t}-\hat{\omega}_{22}\right)}$$

$$\hat{\lambda}_3 = \frac{\left(1+\hat{r}_{i,t}\right)\hat{\omega}_{13}}{\left(1+\hat{r}_{i,t}-\hat{\omega}_{11}\right)\left(1+\hat{r}_{i,t}-\hat{\omega}_{33}\right)}$$

$$\hat{\lambda}_4 = \frac{\left(1+\hat{r}_{i,t}\right)\hat{\omega}_{14}}{\left(1+\hat{r}_{i,t}-\hat{\omega}_{11}\right)\left(1+\hat{r}_{i,t}-\hat{\omega}_{44}\right)}$$

Or equivalently,

$$P_{i,t} = k\left(\phi x_{i,t} - d_{i,t}\right) + (1-\kappa)y_{i,t} + \hat{\lambda}_2 oa_{i,t} + \hat{\lambda}_3 v_{1i,t} + \hat{\lambda}_4 v_{2i,t} \qquad (87.19)$$

where $\kappa = \hat{r}_{i,t}\hat{\omega}_{11}/\left(1+\hat{r}_{i,t}-\hat{\omega}_{11}\right)$ and $\phi = \left(1+\hat{r}_{i,t}\right)/\hat{r}_{i,t}$.

On the basis of these model specifications, we empirically test the research hypotheses constructed in the previous section. For the model's ability to explain the cross section of the stock prices, we first estimate the parameters ω_{ii} in the linear information dynamics under both single equation and simultaneous equation model. Given these estimated coefficients ω_{ii}, we compute the theoretical stock prices implied by the pricing equations and compare the results to the observed prices. Pricing errors of the implied valuation function will be calculated and we examine the model's ability to explain the cross section of stock prices under different model specifications. For the predictability of future stock prices on the other hand, we run the regression of each valuation function to obtain the estimated coefficients. These estimated coefficients are then used with the observation in the future periods to compute the theoretical value of the equity in the future periods. Similarly, the prediction errors of these prices calculated from the implied valuation function are calculated for the comparison between various model specifications.

87.4 Empirical Results

Based on the research hypotheses constructed in the previous section, this chapter empirically tests the Ohlson Model and the FO Model under different linear information dynamics. We conjecture that the linear information dynamic including the value-relevant information variables such as analyst earnings forecasts and the insider transaction activity improves the power of the model to explain the cross section of stock prices and to predict future price movement. Furthermore, we also expect the simultaneous linear information dynamic to exhibit superior ability in pricing the equity share than its single equation counterpart.

In the following empirical analysis, we first use single equation approach and the simultaneous equation approach to estimate the coefficient in each linear information dynamic specification. The estimated coefficients are then used to compute the theoretical price of the equity implied by the valuation function. These implied values are then compared to the prices actually being observed to examine whether the model explains the cross section of the stock prices. If the Ohlson Model and the FO Model have empirical content, then the pricing errors produced by these specifications will not be statistically significant. Furthermore, we test the model's ability to forecast the future-period stock prices. We use the panel data random effect model in each implied valuation functions to estimate the coefficients. These estimated coefficients are then used with the future-period firm-level data to compute the forecasts of the stock prices. Similarly if the models have empirical content, they should produce minimal pricing errors compared to the model tested in the previous literature.

87.4.1 Summary Statistics

Table 87.1 provides the summary statistics of the variables used in our empirical analysis. We note that the mean earnings per share in our sample period is 0.415 while the abnormal earnings per share is −0.294. This indicates that the firms on average earned less than the required cost of equity capital of 0.146 in our sample period. Moreover, the analysts are on average optimistic about future earnings performance of the firms given that the mean analyst earnings per share forecast is a positive 0.172. The two value-relevant information variables in the FO Model, expected growth in operating earnings and in operating assets, have mean values of 0.031 and 0.018, respectively, in our sample period. Finally, the mean of the book value per share and stock price per share in our sample period is 9.015 and 21.361, respectively.

87.4.2 Time Series Behavior of Linear Information Dynamics

We next examined the time series behavior of the linear information dynamics in the Ohlson Model and FO Model in Tables 87.2 and 87.3, respectively.[7] Panel A1 in Table 87.2 shows that the abnormal earnings follow a stationary process since the coefficients of the lagged variables sum up less than one. Moreover, the first lag of

[7]Since the linear information dynamics contains lagged dependent variables, the OLS estimation is inconsistent. We proceed our estimation by the IV estimation and panel GMM proposed by Anderson and Hsiao (1981) and Arellano and Bond (1991), respectively. The panel GMM is more efficient than the IV estimator because of additional lags of dependent variable as instruments. The results from the two estimation methods are similar and we reported the results from panel GMM estimator.

Table 87.1 Descriptive statistics for variables used in sample (1980–2008)

Variables	Mean	Std. dev.	Q1	Median	Q3
Beta (β)	0.9926	2.4995	0.30	0.85	1.56
Cost of equity capital (r)	0.0342	0.0436	0.01	0.02	0.04
Earnings per share (x)	0.5545	1.0330	−0.02	0.60	1.24
Abnormal earnings per share (x^a)	0.3198	1.0269	−0.24	0.37	1.00
Growth in expected operating earnings (v_1)	0.1721	0.0357	−0.09	−0.04	0.05
Expected growth of operating assets (v_2)	0.2253	0.0362	−0.09	−0.04	0.05
Book value per share (b)	8.0327	5.4195	3.74	7.13	11.41
Analyst earning forecasts of abnormal earnings per share (v)	1.3031	0.0895	0.25	0.66	1.20
Stock price per share (P)	15.5368	11.0900	6.75	13.75	23.13
Comprehensive earnings per share (x_{130})	15.6134	13.2147	5.47	14.03	24.33
Marketable securities adj. (*MSA*)	0.0743	0.2161	0.02	0.09	0.16
Foreign currency translation adj. (*RECTA*)	0.0000	0.0087	−0.01	0.01	0.04
Pension requirement adj. (*PENADJ*)	0.0765	0.1357	0.02	0.08	0.05
Comprehensive operating earnings per share (ox_{130})	16.4327	12.3154	8.11	14.54	25.67

Our sample contains all available data in Compustat, CRSP, and I/B/E/S from 1980 to 2008. The firm's beta β is calculated based on the market model using the monthly rate of returns in the past 60 months. The cost of equity r is calculated based on the CAPM. Abnormal earnings per share (x^a) are the current-period earnings per share less the previous earnings per share growing at the cost of equity capital r. v is the analyst earnings forecasts of abnormal earnings per share. v_1 is the growth in expected operating earnings per share, measured as the difference between the median consensus analyst earnings per share forecast for next year and the expected net interest revenue (product of end-of-current-year financial liabilities and the interest on debt), divided by operating asset oa. v_2 is the expected growth in operating assets which is proxied by the analyst earnings per share forecasts of long-term earnings growth rate, divided by operating asset oa. x_{130} is the comprehensive earnings per share which is calculated as earnings per share adjusted for marketable securities adjustments (*MSA*) in Compustat, cumulative foreign currency translation adjustments (*RECTA*) in Compustat, and pension requirement adjustments (*PENADJ*). *PENADJ* is calculated as Pension-Additional Minimum Liability (*PADDML*) − Pension-Unrecognized Prior Service Cost (*PCUPSO*) in Compustat. *MSA*, *RECTA*, and *PENADJ* are all scaled by the beginning-of-period total shares outstanding. Comprehensive operating income (ox_{130}) is equal to comprehensive income (x_{130}) adjusted for comprehensive net financial expenses (*NFE*) and minority interest in income

the abnormal earnings accounts for the most serial correlation in the abnormal earning process. Even though the estimated coefficients for the other lagged variables are statistically significant at 5 %, the adjusted R^2 is approximately the same after considering these lags. Therefore, we found that the AR(1) process for abnormal earnings is sufficient for the linear information dynamics in the Ohlson Model and the FO Model as documented by previous literature. Furthermore, Panel B1 in Table 87.2 showed that after accounting for the analyst forecasts in the linear information dynamics for the abnormal earnings, the adjusted R^2 increases to 69 % from 40 %. This indicates that the analyst earnings forecast serves to be an appropriate value-relevant variable that adds explanatory power to the linear information dynamics.

Panel GMM methodology proposed by Arellano and Bond (1991) is used to examine the autoregressive property of earnings and other value-relevant information variable in the Ohlson Model. The estimated coefficients ω_{ij} and the adjusted R^2 from the regression are provided in each panel. $x^a_{i,t}$ is the abnormal earnings per share for firm i at year t. $x^a_{130i,t}$ is the abnormal comprehensive earnings per share for firm i at time t. $v_{1i,t}$ is the consensus analyst earnings per share forecasts for year t+1 at year t. The p-values associated with each estimated coefficients are reported in the parenthesis below. Our sample contains all available data in Compustat, CRSP, and I/B/E/S from 1980 to 2008

Panel GMM methodology proposed by Arellano and Bond (1991) is used to examine the autoregressive property of earnings and other value-relevant information variable in the FO Model. The estimated coefficients ω_{ij} and the adjusted R^2 from the regression are provided in each panel. $ox^a_{i,t}$ is the abnormal operating earnings per share for firm i at year t. $ox^a_{130i,t}$ is the abnormal comprehensive operating earnings per share for firm i at year t. $oa_{i,t}$ is operating asset scaled by total assets for firm i at year t. $v_{1i,t}$ is the growth in expected operating earnings, measured as the difference between the median consensus analyst earnings forecast for next year and the expected net interest revenue (product of end-of-current-year financial liabilities and the interest on debt). $v_{2i,t}$ is the expected growth in operating assets, measured by the analyst earnings forecasts of long-term earnings growth rate. The p-values associated with each statistics are reported in the parenthesis below. Our sample contains all available data in Compustat, CRSP, and I/B/E/S from 1980 to 2008

Given that the Ohlson Model and FO Model are based on clean surplus relation, we also use comprehensive (operating) earnings in estimating the linear information dynamics and deriving implied valuation function. In Panel A2 of Table 87.2, we first investigate the autoregressive property of abnormal comprehensive earnings. Similar to the results found in Panel A1, we find strong statistical and economic magnitude of lag one comprehensive earnings, i.e., ranging from 0.7411 to 0.8012. The higher-ordered lags do not provide additional information given the adjusted R^2 does not improve after including additional lagged comprehensive earnings. The analyst earnings forecasts also retain its value relevance in the presence of the comprehensive earnings. Panel B2 of Table 87.2 shows that including analyst earnings forecasts improves the adjusted R^2 in the regression, from 0.4121 to 0.4363, with only lagged comprehensive earnings in Panel B1. These results confirm our previous finding that lagged one comprehensive earnings and analyst earnings forecasts are sufficient to estimate the earnings dynamics in the Ohlson Model. More interestingly, using comprehensive earning, instead of the bottom-line earnings, also seems to provide explanatory power given the high adjusted R^2 in the regression. Finally, Panel C showed the extended autoregressive process for the analyst earnings forecasts. We note that the AR(1) process again is sufficient for the linear information dynamics given that the further lagged variables do not contribute to the overall explanatory power of the model. In summary, we found that AR(1) process is sufficient for both the aerial correlation in abnormal earnings and analyst earnings forecasts. Incorporating the analyst earnings forecasts into the linear information dynamics indeed improved the ability of the model to explain the abnormal earnings process in addition to its own serial dependence.

Table 87.3 summarizes the autoregressive behavior of the abnormal operating earnings, operating assets, expected growth of operating earnings, and expected growth of operating assets in the linear information dynamics of the FO Model. We found that the AR(1) process is sufficient for all four variables given that the adjusted R^2 is approximately the same after more lagged variables are considered. In Panel A1, e.g., when the lag 2 abnormal earnings are added, the estimated coefficient for lag 1 is still statistically significant. Although the lag 2 abnormal earnings are also statistically significant, lag 1 abnormal earnings account for most of the serial dependence of the abnormal earnings process. Moreover, when additional lag 3 abnormal earnings are considered, the significance of the lag 1 abnormal earnings and adjusted R^2 is not affected. Similar results can be found for operating assets, expected growth in operating earnings, and expected growth in operating assets. Thus, we note that the AR(1) process is sufficient for the aforementioned variables in the linear information dynamics of the FO Model. In Panel A2 of Table 87.3, we investigate the dynamics of comprehensive operating earnings. Similar to the operating earnings dynamics in Panel A1, we find that lag 1 comprehensive earnings are sufficient in explaining the dynamics and additional lagged variables do not provide more information.

Panel C1 in Table 87.3 showed that incorporating more value-relevant variables in the linear information dynamics increases the ability of the model to explain the variation of abnormal operating earnings. With only lagged abnormal earnings and operating assets as the independent variables in the model, both of the variables are statistically significant with estimated coefficients of 0.2895 and 0.4023, respectively. When the expected growth of operating earnings is incorporated, lagged abnormal operating earnings and operating assets are still statistically significant and moreover the adjusted R^2 increased from 0.6433 to 0.7236. This indicates that the additional value-relevant variable, the expected growth in appearing earnings, indeed increased the explanatory power of the linear information dynamics. Moreover, the results in Panel C2 indicate that under the single equation estimation, incorporating operating assets and analyst earnings forecasts into the comprehensive operating earnings dynamics provides more information given the higher adjusted R^2 in the regression. In Panel D, we examine the addition of value-relevant variable, the expected growth in operating assets, in the autoregressive property of the operating assets. Incorporating the expected growth in operating assets as the additional value-relevant variable increased the adjusted R^2 from 0.7941 to 0.8321. Therefore, for the linear information dynamics of the operating assets, the expected growth in operating assets further improves the explanatory of the model. In summary, we find that similar to the Ohlson Model, the value-relevant variables incorporated in the FO Model provide additional information beyond the accounting variables. We next examine how different specification of these linear information dynamics affects the implied pricing function in evaluating the stock prices.

87.4.3 Estimation of Linear Information Dynamics

We start our empirical analysis by estimating the linear information dynamics using both the single equation estimation and simultaneous equation estimation in the Ohlson Model and FO Model.[8] We then use these estimated coefficients along with the observed inputs in the implied pricing functions to compute the theoretical price of the shares. Our conjecture is that given there exist feedback relations between the accounting variables and the value-relevant information variables, the simultaneous equation estimation more accurately estimates the linear information dynamics, and thus, the resulting pricing function produces smaller pricing errors than those under the single equation estimation.

Panel A1 in Table 87.4 provides the estimated coefficients from both the single equation specification and the simultaneous equation specification of the Ohlson Model information dynamics with the analyst earnings forecasts. The single

[8]The single equation estimation is conducted by the panel GMM estimator as in Table 87.2A and B. Since our system of simultaneous equation specification of information dynamics involves endogenous regressors from other equations, we use the more efficient error-component three-stage least square (3SLS) estimator proposed by Baltagi (1981) to conduct the estimation. Essentially, the 3SLS is a combination of the two-stage least square (2SLS) estimator and the seemingly unrelated regression (SUR) estimator. 3SLS considers both the simultaneous equation bias and the cross equation correlation of the errors.

In both the Ohlson and FO Model, panel GMM methodology proposed by Arellano and Bond (1991) is used to estimate the single equation estimation of the linear information dynamics. The simultaneous equation estimation of the linear information dynamics is estimated by the error-component three-stage least square (3SLS) estimator proposed by Baltagi (1981). $x^a_{i,t}$ is the abnormal earnings per share for firm i at year t. $x^a_{130i,t}$ is the abnormal comprehensive earnings per share for firm i at time t. $v_{1i,t}$ in the Ohlson Model is the consensus analyst earnings per share forecasts for year t+1 at year t. $ox^a_{i,t}$ is the abnormal operating earnings per share for firm i at year t. $ox^a_{130i,t}$ is the abnormal comprehensive operating earnings per share for firm i at year t. $oa_{i,t}$ is operating asset scaled by total assets for firm i at year t. $v_{1i,t}$ in the FO Model is the growth in expected operating earnings, measured as the difference between the median consensus analyst earnings forecast for next year and the expected net interest revenue (product of end-of-current-year financial liabilities and the interest on debt). $v_{2i,t}$ is the expected growth in operating assets, measured by the analyst earnings forecasts of long-term earnings growth rate. The p-values associated with each statistics are reported in the parenthesis to the right of the estimated coefficients. Our sample contains all available data in Compustat, CRSP, and I/B/E/S from 1980 to 2008 equation specification is essentially those shown in Panel B and C1 in Table 87.2 by using the panel GMM estimator. Following Tsay et al. (2008), we conjecture that there is a feedback relation between the current-period abnormal earnings x_{t+1}^{a} and current-period analyst forecasts for the next-period earnings $v_{i,t+1}$. Compared to the single equation specification, the simultaneous equation specification also estimates the feedback effect from the abnormal earnings to the analyst earnings forecasts. By jointly estimating the coefficient, we found that the coefficients ω_{21} are statistically significant (0.3791), indicating that the abnormal earnings indeed affect the analyst earnings forecasts for next period. In Panel A2 of Table 87.4, we estimate the linear information dynamics in the Ohlson Model by using the comprehensive earnings dynamics. The estimated ω_{21} is 0.4369 which is higher than 0.3791 in Panel A1 in which bottom-line earnings are used as the earnings measure in the information dynamics. This result suggests that abnormal comprehensive earnings provide a stronger feedback effect to the analyst earnings forecasts while the other estimated coefficients retain their statistical and economic magnitude. The statistical significant ω_{21} suggests that the single equation specification in traditional Ohlson Model linear information dynamics is not correctly identified and the simultaneous equation estimation of the linear information dynamics might yield more price-relevant information in forecasting future stock price.

Panel B1 in Table 87.4 compares the single equation and simultaneous equation specification of the linear information dynamic with bottom-line earnings in the FO Model. In the single equation specification, all the coefficients associated with the accounting variables and the value-relevant information variables are statistically significant. This indicates that the linear information dynamics in the FO Model indeed possess empirical content to capture the variation in abnormal operating earnings and operating assets. We further extended the single equation specification to simultaneous equation specification to examine whether there exist feedback relations between the accounting variables and the value-relevant information variables. For example, the coefficient ω_{31} which measures how current-period abnormal operating earnings affect the expected growth in abnormal operating earnings is statistically significant of 0.2725. Moreover, the coefficient ω_{42}, which measures how current-period operating asset affects the next-period expected growth in operating asset, is also statistically significant of 0.3895. These results suggest that there exist feedback relations of abnormal operating earnings and operating assets with their expected growth in the future periods. Estimating the linear information dynamics by the simultaneous equation approach improves the information content provided of these variables in computing the implied value of the shares. In Panel B2 of Table 87.4, we use comprehensive operating earnings to estimate the linear information dynamics in the FO Model. Compared to the results in Panel B1, we find stronger feedback effects given the larger estimated coefficients ω_{31} (0.2931) and ω_{42} (0.4873) under the estimation with abnormal comprehensive operating earnings. In the next section, we will further examine the pricing errors of the implied valuation function by employing these estimated coefficients with the observed inputs.

87.4.4 Prediction Errors of Stock Price Forecasts

Table 87.5 provides the summary of prediction errors of stock prices from the Ohlson Model and FO Model using different estimation methods for linear information dynamics (single equation vs. simultaneous equation estimation) and different earnings measures (bottom-line earnings vs. comprehensive earnings). More specifically, we estimated the coefficients in the linear information dynamics ω_{ij} and used them with the observed inputs abnormal earnings and analyst earnings forecasts to compute the theoretical price of the share at end of each year t given the implied valuation function for the Ohlson Model in Eq. 87.14 and for the FO Model in Eq. 87.18. We then measure how these implied values of the share differ from the observed current market price per share, i.e., the prediction errors for the stock prices. The prediction errors are represented by the mean forecast errors, which are calculated as the observed market price per share minus the implied price from the model divided by the market price per share at end of each period t.

In Panel A of Table 87.5, we first observe that simultaneous equation estimation of the linear information dynamics indeed improves the future stock forecast accuracy by producing significantly smaller prediction errors than those generated by the single equation estimation. The prediction error difference, $\Delta_{Simul-Single}$, is significantly negative for both abnormal earnings and abnormal comprehensive earnings at -0.0514 and -0.0305, respectively. We then discuss whether using abnormal comprehensive earnings can improve the stock price forecast ability of each individual model. Under both single equation and simultaneous equation estimation specifications, we calculate the forecast error differences between using abnormal earnings and comprehensive abnormal earnings as the earnings measures in the information dynamics, i.e., $\Delta_{x^a_{130}-x^a}$. We are expected to observe smaller forecast errors when using abnormal comprehensive earnings because of its consistency with the clean surplus relation which is used in deriving the implied valuation function in the Ohlson Model. The result in Panel A of Table 87.5 shows that the forecast error differences $\Delta_{x^a_{130}-x^a}$ are statistically significant at -0.0334 (-0.0225) under single equation (simultaneous equations) estimation. Our results suggest that under both estimation specifications of the linear information dynamics, abnormal comprehensive earnings outperform the abnormal earnings in terms of predicting future stock prices by generating smaller average forecast errors. Similar improvement in prediction accuracy can also be found in Panel B of Table 87.5 where comprehensive operating earnings are used in estimating the linear information dynamics in the FO Model. The result in Panel B of Table 87.5 suggests that the forecast error differences $\Delta_{ox^a_{130}-ox^a}$ are statistically significant at -0.0244 (-0.0186) under single equation (simultaneous equations) estimation. This indicates that abnormal comprehensive operating earnings provide more value-relevant information than abnormal operating earnings in estimating linear information dynamics and computing the 1-year-ahead model-implied stock prices. In sum, the empirical results we have shown in this chapter further demonstrate that comprehensive (operating) earnings can also produce more accurate future stock price forecasts in the residual valuation models.

In both the Ohlson and FO Model, panel GMM methodology proposed by Arellano and Bond (1991) is used for single equation estimation of the linear information dynamics. The simultaneous equation estimation of the linear information dynamics is estimated by the error-component three-stage least square (3SLS) estimator proposed by Baltagi (1981). The estimated coefficients ω_{ij} are used with the observed inputs abnormal earnings and analyst earnings forecasts to compute the estimated price of the share at end of each year t. The mean forecast errors ($M.F.E.$) are the average of the difference between observed market price and model estimated price divided by the market price per share at end of each period t. $\Delta_{FO\text{-}Ohlson}$ represents the difference of forecast errors between the Ohlson Model and FO Model. $\Delta_{Simul\text{-}Single}$ represents the difference of forecast errors between simultaneous equation estimation and single equation estimation of the linear information dynamics in a given valuation model. $\Delta_{x^a_{130}-x^a}$ represents the Ohlson Model forecast error difference between using earnings and comprehensive earnings as the earnings measure. $\Delta_{ox_{130}-ox}$ represents the FO Model forecast error difference between using operating earnings and comprehensive operating earnings as the earnings measure. The p-values associated with each estimated coefficients are reported in the parenthesis below. Our sample contains all available data in Compustat, CRSP, and I/B/E/S from 1980 to 2008

Table 87.6 summarizes the mean forecast errors (*M.F.E.*) for 1–5-year-ahead stock price forecasts of the WS Model. From 1980 to 2002, financial data of each firm are used as the base year information in the WS Model to forecast the future-period stock prices in the next 5 years. For each firm at year *t*, the sales growth rate is estimated by the linear regression model using all the past sales available in Compustat. We then calculated the mean forecast errors of the stock prices by each number-of-years-ahead forecast errors across all rolling periods. $\Delta_{WS\ -\ Ohlson}$ represents the difference of forecast errors between the WS Model and Ohlson Model with its linear information dynamics estimated by simultaneous equation method. $\Delta_{WS-Ohlson(x_{130})}$ represents the difference of forecast errors between the WS Model and Ohlson Model with comprehensive earnings as its earnings measure and its linear information dynamics estimated by simultaneous equation method. $\Delta_{WS\ -\ FO}$ represents the difference of forecast errors between the WS Model and FO Model with its linear information dynamics estimated by simultaneous equation method. $\Delta_{WS-FO(ox_{130})}$ represents the difference of forecast errors between the WS Model and FO Model with comprehensive operating earnings as its earnings measure and its linear information dynamics estimated by simultaneous equation method. The p-values associated with each estimated coefficients are reported in the parenthesis below. Our sample contains all available data in Compustat, CRSP, and I/B/E/S from 1980 to 2008

Table 87.6 summarizes the mean forecast errors for 1- to 5-year forecasts of the WS Model. At each year from 1980 to 2002, financial data of each firm are used as the base year information in the WS Model to forecast the future-period stock prices in the next 5 years. In particular, for each firm at year *t*, the sales growth rate is estimated by the linear regression model using all the past sales available in Compustat. We then calculated the mean forecast errors of future stock prices by each number-of-years-ahead forecast errors across all rolling periods. We note that the mean forecast errors mostly increase monotonically with number-of-years-ahead forecasts. We compare WS Model forecasts to Ohlson/FO Model forecasts with both bottom-line earnings and comprehensive earnings. We calculate the mean forecast error difference between the WS Model and Ohlson Model with bottom-line earnings ($\Delta_{WS\ -\ Ohlson}$) and comprehensive earnings ($\Delta_{WS-Ohlson(x_{130})}$). We also calculate the mean forecast error difference between the WS Model and FO Model with operating earnings ($\Delta_{WS\ -\ FO}$) and comprehensive operating earnings ($\Delta_{WS-FO(ox_{130})}$). Our results suggest that the WS Model produces more accurate stock prices than the Ohlson/FO Model in the shorter term. The average

1-year-ahead stock price forecast error is 0.3418 which is significantly lower than those forecasted by the Ohlson and FO Model using either bottom-line earnings or comprehensive earnings. The mean forecast error differences are all significantly negative for the 1-year forecast in Table 87.6. However, in the longer term, the model produces relatively less accurate forecasts. Our findings suggest that the WS Model considering the interrelations between investment activity, financing activity, dividend policy, and the production decision of the firm provides better forecast accuracy in terms of the stock prices than the residual income valuation models discussed in the previous sections. Nonetheless, the forecast accuracy crucially depends on the model inputs such as sales growth rate, current assets as a percent of sales, fixed asset as a percent of sales, dividend payout ratio, and the leverage ratio. Therefore, we next examined how the sensitivity of these model inputs affects the resulting forecasts.

Table 87.7 summarizes the sensitivity analysis of several model inputs in the WS Model, i.e., sales growth rate, total assets as a percent of sales, dividend payout ratio, and leverage ratio. In Panel A, we showed how sensitive the stock price forecasts are to the changes in the sales growth rate. It is expected that higher sales growth rate leads to higher stock prices because of higher future earnings. When the sales growth rate changed from its median to its third quartile, the 1-year-ahead mean forecast errors reduced from 0.4238 to 0.3954. Since the WS Model underestimates the stock prices as shown in Table 87.6, increases in sales growth rate result in higher stock prices and thus smaller pricing errors. When the sales growth rate decreases from its median to the first quartile, the implied stock prices decrease and pricing errors increase accordingly. Similar patterns of the changes of the pricing errors can be observed in longer years ahead forecasts. Furthermore, the sensitivity analysis regarding the total assets as a percent of sales is shown in Panel B. The stock prices are expected to decrease in assets as a percent of sales because more equity funds were required to support asset requirement and thus larger the pricing errors. The base case inputs for the total assets as a percent of the sales are the median value of each firm's available historical data. We examined the sensitivity of the stock price forecast to the first and third quartile value of the firm's total asset as a percent of sales. The mean forecast errors of 1-year-ahead stock prices increased (decreased) to 0.4756 (0.4048) from 0.4238 if the third (first) quartile of total assets as a percent of sales is used. Similar patterns are observed in 2- and 3-year-ahead forecasts but results for longer-year-ahead forecasts are not obvious.

Panel C summarizes the sensitivity of stock price forecasts to the firm's payout ratio. We expect the pricing errors to decrease in the dividend payout ratio because as more dividends were paid to shareholders, the firm relies more on new issues of common stocks for the financing requirement which leads to potential decline in the stock prices. The mean forecast errors increased (decreased) to 0.4451 (0.4198) if the third (first) quartile of the firm's historical dividend payout ratio is used as the model input. Panel D summarized the sensitivity of stock prices to the changes in the firm's leverage. We expect the stock prices to increase in leverage and thus smaller pricing errors. The mean forecast errors decrease (increase) to 0.4187 (0.4408) if the third (first) quartile of the historical leverage ratio is used as the

3	0.6087	0.4569	0.5841	0.4783	0.5941	0.4568
4	0.7136	0.4158	0.7136	0.4297	0.6543	0.4412
5	0.9302	0.4111	0.9362	0.3882	0.8741	0.4123

Table 87.7 summarizes the sensitivity analysis of the model inputs: sales growth rate, total assets as a percent of sales, dividend payout ratio, and leverage ratio in the WS Model. We calculate the mean forecast errors (*M.F.E.*) of stock price forecasts from WS Model by using the first quartile, median, and the third quartile of the respective model inputs. The p-values associated with each estimated coefficients are reported in the parenthesis below. Our sample contains all available data in Compustat, CRSP, and I/B/E/S from 1980 to 2008

model input in forecasting future stock prices. The longer-year-ahead forecasts are again not as apparent as the shorter-term forecasts suggesting the model's lack of ability of accurate forecast in the long run. In summary, our results suggest that the stock price forecasts are most sensitive to the changes in sales growth rate given the largest change in the mean forecast errors. This is not a surprising result since the starting point of the WS Model is the sales growth estimate. The sensitivity of the stock price forecasts to the other exogenously given variables such as the total assets as a percent of sales, dividend payout ratio, and the leverage ratio does not have a significant impact on the forecasts as the sales growth rate. Overall, the results are consistent with the model conjecture that stock price forecasts are influenced by the aforementioned inputs and sales growth rate is the most important factor in producing the accurate forecasts from the model.

87.4.5 Forecast Combination

In the previous section, the implied valuation functions of the Ohlson Model and FO Model were investigated for their ability in forecasting future stock prices. In this section, we examine how the stock price forecasts from these models can be combined with the Warren-Shelton Model to further improve their forecast ability in terms of prediction errors. More specifically, we employ the forecast combination proposed by Bates and Granger (1969), Granger and Newbold (1973), Granger and Ramanathan (1984), and Diebold and Pauly (1987) to examine the combined predictability of future stock prices from different primary individual forecasts.

We use the different weighting schemes in equations (W1) through (W4) in Sect. 87.2.3 to construct the weighting matrix W in the WLS estimation. Moreover, we employ the linear and quadratic deterministic time-varying parameters model to produce time-varying weights. Similar to the regression model in Eq. 87.12, the estimator can be written as

$$\text{Linear}:\quad {}_t\hat{y}_{t+1}=\left(\hat{p}_0^0+\hat{p}_1^0(t+1)\right)+\left(\hat{p}_0^1+\hat{p}_1^1(t+1)\right){}_tf_{t+1}^{RI}+\left(\hat{p}_0^2+\hat{p}_1^2(t+1)\right){}_tf_{t+1}^{WS}$$

$$\begin{aligned}\text{Quadratic}:\quad {}_t\hat{y}_{t+1}=&\left(\hat{p}_0^0+\hat{p}_1^0(t+1)+\hat{p}_2^0(t+1)^2\right)+\left(\hat{p}_0^1+\hat{p}_1^1(t+1)+\hat{p}_2^1(t+1)^2\right){}_tf_{t+1}^{RI}\\&+\left(\hat{p}_0^2+\hat{p}_1^2(t+1)+\hat{p}_2^2(t+1)^2\right){}_tf_{t+1}^{WS}\end{aligned}$$

where ${}_tf_{t+1}^{RI}$ and ${}_tf_{t+1}^{WS}$ are the 1-year stock price forecast from the residual income valuation models (Ohlson/FO Models) and the WS Model, respectively. We consider the following estimators for forecasting future stock prices:

M1. WLS, geometric weights, linear deterministic time-varying parameters
M2. WLS, geometric weights, quadratic deterministic time-varying parameters
M3. WLS, t^{λ} weights, linear deterministic time-varying parameters
M4. WLS, t^{λ} weights, linear quadratic time-varying parameters
M5. OLS (simple unrestricted regression-based combination)
M6. Variance-covariance combination

Panel A1 (A2) in Table 87.8 provides the prediction errors of 1-year-ahead stock prices from the forecast methods M1 through M6 combining the Ohlson Model forecasts using bottom-line (comprehensive) earnings and WS Model forecasts. We also compare the forecast errors of these combined forecasts to those individual forecasts under the Ohlson Model and WS Model alone. If the combined forecast methods indeed improve the model's ability to provide better accuracy, then the combined methods are expected to produce smaller pricing errors. Our results suggest that method M3 yields the best 1-year-ahead stock price forecast in terms of smallest mean forecast errors. Method M3 employs the t-lambda (t^{λ}) weighting specification with the linear deterministic time-varying parameters in the WLS estimator to generate optimal weights for each individual forecast from the Ohlson Model and WS Model. The M3 forecast combination method produces a mean

Table 87.8 provides the mean forecast errors (*M.F.E.*) of 1-year-ahead stock price forecast from methods (M1) through (M6) combining the Ohlson Model and WS Model (Panel A1 and A2) and FO Model and WS Model (Panel B1 and B2) forecasts. The linear (*LIN TVPM*) and quadratic (*Qd TVPM*) time-varying parameters model are

Linear: $_t\hat{y}_{t+1} = \left(\hat{p}_0^0 + \hat{p}_1^0(t+1)\right) + \left(\hat{p}_0^1 + \hat{p}_1^1(t+1)\right)_t f_{t+1}^{RI} + \left(\hat{p}_0^2 + \hat{p}_1^2(t+1)\right)_t f_{t+1}^{WS}$

Quadratic: $_t\hat{y}_{t+1} = \left(\hat{p}_0^0 + \hat{p}_1^0(t+1) + \hat{p}_2^0(t+1)^2\right) + \left(\hat{p}_0^1 + \hat{p}_1^1(t+1) + \hat{p}_2^1(t+1)^2\right)_t f_{t+1}^{RI} + \left(\hat{p}_0^2 + \hat{p}_1^2(t+1) + \hat{p}_2^2(t+1)^2\right)_t f_{t+1}^{WS}$

M7 and M8 are the individual forecasts f^{Ohlson} (f^{FO}) and f^{WS} from the Ohlson (FO) Model and WS Model, respectively. $\Delta_{M_i-M_7}$ represents the prediction error differences between the forecast combination method M_i and the individual forecast from Ohlson Model. $\Delta_{M_i-M_8}$ represents the prediction error differences between the forecast combination method M_i and the individual forecast from WS Model. The mean forecast errors (*M.F.E.*) are the average of the difference between observed market price and model estimated price divided by the market price per share at end of each period t. The p-values associated with each estimated coefficients are reported in the parenthesis below. Our sample contains all available data in Compustat, CRSP, and I/B/E/S from 1980 to 2008 forecast error of 0.2841 (0.2779) in Panel A1 (A2) which is significantly lower than the individual forecast from either the Ohlson Model or the WS Model. For the Ohlson Model using comprehensive earnings, the mean forecast error differences between the M3 method and the Ohlson Model (WS Model) $\Delta_{M_i - M_7}$ ($\Delta_{M_i - M_8}$) are significant at -0.1785 (-0.0639), suggesting that forecast combination is indeed lower that the prediction error of individual forecasts. These results show that the WLS estimator with t-lambda (t^{λ}) weighting specification and linear deterministic time-varying parameters generates the lower prediction errors for stock price forecasts than other forecast combination methods and the individual forecasts. Moreover, we find that in general, the forecast combination methods M1 through M4 generate smaller pricing errors than the individual forecasts from the Ohlson Model and WS Model. The OLS (M5) and variance-covariance method (M6) on the other hand do not improve each model's ability in forecasting future stock prices given the insignificant prediction error differences.

In a similar fashion, Panel B1 (B2) in Table 87.8 provides the prediction errors of forecast combination methods M1 through M6 by combining the FO Model forecast using (comprehensive) operating earnings and WS Model forecasts. Compared to the individual forecasts from the FO Model and WS Model, methods M1 through M4 again produce significantly lower prediction errors while M5 and M6 fail to obtain improvement in forecasting 1-year-ahead stock prices in the sample. The M4 forecast combination method produces lowest mean forecast error, i.e., 0.2284 (0.2045) in Panel B1 (B2) among all different forecast combination methods. The mean forecast error generated by M4 is also significantly lower than that produced by either the FO Model or WS Model. For example, in Panel B2, the mean forecast error differences between the M4 method forecast and the FO Model (WS Model) forecast, or $\Delta_{M_i - M_7}$ ($\Delta_{M_i - M_8}$), are significant at -0.1596 (-0.1373). This suggests that forecast combination indeed is lower than the prediction error of individual forecasts. Overall, our findings demonstrate that the appealing features of geometric weighting schemes and time-varying parameters in forecast combination provide superior accuracy in predicting future stock prices. The WLS estimator with geometric weighting schemes and time-varying parameters places more weights on the better forecast technique over time. Given the different structural designs of the residual income valuation models and the WS Model, each of them could provide superior forecast than the other under specific market condition.

87.5 Summary

This chapter investigates the stock price forecast ability of three alternative valuation models, namely, the Ohlson (1995) Model, Feltham and Ohlson (1995) Model, and the Warren and Shelton (1971) Model. In this chapter, we have developed five research hypotheses to test whether different earnings measures, estimation techniques, and combined forecast methods can improve these models' ability in predicting future stock prices. In the first hypothesis, we test whether the FO Model can produce smaller prediction errors for future stock prices than the

Ohlson Model. The second hypothesis examines whether simultaneous equation estimation of the linear information dynamics in the Ohlson and FO Model can generate smaller prediction errors for future stock prices than those produced by single equation estimation. In the third hypothesis, we investigate whether the WS Model can generate more accurate future stock price forecasts than both the Ohlson and FO Model. The fourth hypothesis examines whether combination of individual forecasts from the Ohlson Model, FO Model, and WS Model can produce more accurate future stock price forecast than each individual model. Finally, the fifth hypothesis tests whether the use of comprehensive income, instead of net income, can generate more accurate future stock price forecasts in these valuation models.

We first use simultaneous equation estimation approach to estimate the information dynamics for the Ohlson Model and FO Model and to forecast future stock prices. Our empirical results suggest that the simultaneous equation estimation of the information dynamics improves the ability of the Ohlson Model and FO Model in capturing the dynamic of the abnormal earnings process. The predictability of the 1-year-ahead stock prices is also more accurate under the simultaneous equation estimation in terms of smaller prediction errors. We then use the WS Model to predict stock price per share and find that the WS Model can generate smaller future stock price prediction errors than those predicted by the Ohlson Model and FO Model. These findings indicate a better stock price forecast ability of the WS Model in determining future stock prices. The superior accuracy compared to the Ohlson Model and FO Model is due to the incorporation of both operation and financing decisions of the firms. We also combine these different stock price forecasts by using various time-varying parameters models proposed by Granger and Newbold (1973) and Diebold and Pauly (1987) to examine whether forecast combination provides better prediction accuracy. The combined forecasting methods generally produce more accurate stock price forecasts than those made by individual models.

Previous literature found supporting evidence that comprehensive income can provide price-relevant information beyond bottom-line net income (Cheng et al. 1993; Dhaliwal et al. 1999; O'Hanlon and Pope 1999). Given that the Ohlson Model and FO Model are based on the clean surplus relation, we further investigate the price relevance of comprehensive (operating) income in these valuation models. Our results suggest that using comprehensive (operating) income in the Ohlson (FO) Model can further reduce the prediction errors of future stock price forecasts under both single equation and simultaneous equation estimation of linear information dynamics. Moreover, this superior predictability also leads to smaller prediction errors in the combined forecasting in which Ohlson (FO) Model forecasts are combined with WS Model forecasts. Evidence shown in our study demonstrates that comprehensive (operating) income indeed provides incremental price-relevant information beyond bottom-line net income.

In sum, we investigate the empirical validity in terms of stock price forecast accuracy of alternative equity valuation models. By employing the simultaneous equation estimation and combined forecasting methods, we find that these models can produce higher estimate accuracy in predicting future stock prices. We also found that using comprehensive income can further reduce the prediction errors generated by these valuation models. Our findings contribute to the literature in equity valuation models as well as the setting of accounting standard on reporting comprehensive financial performance.

Contents

Abstract

This research examines the use of various forms of time series models to predict the total NAV of an asset allocation mutual fund. In particular, the mutual fund case used is the Vanguard Wellington Fund. This fund maintains a balance between relatively conservative stocks and bonds. The period of the study on

which the prediction of the total NAV is based is the 24-month period of 2010 and 2011, and the forecasting period is the first 3 months of 2012. Forecasting the total NAV of a massive conservative allocation fund, composed of an extremely large number of investments, requires a method that produces accurate result. Achieving this accuracy has no necessary relationship to the complexity of the variety of the methods typically present in many financial forecasting studies.

Various types of methods and models were used to predict the total NAV of the Vanguard Wellington Fund. The first set of model structures included simple exponential smoothing, double exponential smoothing, and Winter's method of smoothing. The second set of predictive models used represented trend models. They were developed using regression estimation. They included linear trend model, quadratic trend model, and an exponential model. The third type of method used was a moving-average method. The fourth set of models incorporated the Box-Jenkins method, including an autoregressive model, a moving-average model, and an unbounded autoregressive and moving-average method.

Keywords
NAV of a mutual fund • Asset allocation fund • Combination of forecasts • Single exponential smoothing • Double exponential smoothing • Winter's method • Linear trend model • Quadratic trend model • Exponential trend model • Moving-average method • Autoregressive model • Moving-average model • Unbounded autoregressive moving-average model

88.1 Introduction

The purpose of this study is to develop a predictive time series model for the total NAV of a massive balanced asset allocation mutual fund during a period of time when there is not a massive decline in the economy. The historical period chosen was the 24-month period beginning January of 201 and running through December 2011. The forecasting period is the first 3 months of 2012.

The forecast of mutual funds with vast numbers of investments is certainly not the same as forecasting a single investment or a group of like investments. Forecasting net asset values of an investment structure consisting of a massive asset allocation of stocks in various industry groups, various types of bond investments, as well as both domestic and international investments presents a specialized type of financial forecasting problems.

88.1.1 NAV of a Mutual Fund

A mutual fund is an investment vehicle that operates as an investment pool. Initial investors put up prearranged amounts and issued shares of the mutual fund, with these shares representing their ownership interest. After the initial issuance, more investors can buy into the mutual fund by buying shares at the current net asset value, or total NAV. This may be more or less than the original total NAV, depending on how the investments of the mutual fund have performed.

NAV is simply the current total value of the assets of the fund minus any liabilities or management fees divided by the number of shares. For most mutual funds, NAV is constantly calculated during market hours, from the moment of the first investment is made. Thus, investors can know exactly how their mutual fund is performing at any given time, and investors can buy or sell mutual funds at any time.

NAV mutual fund investors follow NAV closely, and some even use an investment strategy of investing in mutual funds, based on the trends in NAV over time. The study of NAV history is a common practice among sophisticated investors and is considered by many to be one of the best metrics of mutual fund performance.

Mutual funds are variable. Even the best mutual funds have occasionally declined. Many sector-based mutual funds are very cyclical. The NAV managers make big savings up and down across multiyear economic cycles. Many investors study these patterns and make investment decisions on the basis of AV histories and others just look to invest in funds or managers with good track records in crating NAVs.

88.1.2 Asset Allocation Fund

On a historical basis, the performance of stocks has typically outperformed most other investments. However, stock investments carry more risk than many other investment types. Many tout the success of asset allocation in the investment process. Asset allocation investments cut across such investment classes (stocks, bonds, and cash) and across international boundaries.

The asset allocation strategy seems to balance risk and reward by apportioning portfolio assets according to individual goals, risk tolerance, and investment horizon. The three main asset classes, equities, fixed income, and cash and equivalents, all have different levels of risk and return, so each will behave differently over time.

There are no simple methods that can find the correct allocation for every individual. However, most financial experts agree that asset allocator is a key and crucial decision for investing. The selection of an individual security is secondary to how each investor allocates their investment in stocks, bonds, and case and equivalent.

The asset allocation mutual funds (life cycle or target date funds) that attempt to provide investors with portfolio structures that address the investor’s age, risk profile land investment objective, via an appropriate apportionment of asset classes.

88.1.3 Vanguard Wellington Fund (VWELX)

Vanguard Wellington Funds are one of the few funds that survived the stock market crash of 1929. Vanguard Wellington was created just months before that collapse of the stock market.

As of June 2012, VWELX has assets totaling over $30 billion. Roughly two-thirds of the portfolio consists of stocks that typically pay dividends. The fund can invest up to 25 % of its portfolio in non-US securities.

Typically the fund maintains a balance between relatively conservative stocks and bonds. Thus, it is designed to weather bear markets, but it may not perform as well as more aggressive funds during market rallies. Such a balanced fund is a middle-of-the-road investment that seeks to provide some combination of income, capital appreciation, and the conservation of capital by investing in a max of stocks and bonds. The fund invests in a mix of undervalued and dividend-paying stocks and mostly investment-grade bonds.

88.2 Computations: Models and Results

The forecasting models used in this study were implemented through the use of Minitab 16 time series procedures. The data used in the forecasting process can be viewed in Fig. 88.1. In the period of January 2010 through December 2011, the total NAV of VWELX goes from a bi less than 30 billion to a slightly more than 30 billion. The nature of these modeling structures can be detailed in the appendix of the paper (Atsulaki and Valavanis 2009; Botlen and Busse 2004; Francis and Ghijsels 1999; Frances et al. 2005; Lendasse et al. 2000; Pas and Lin 2005; Taylor and Snyder 2012; Wang et al. 2012).

The first set of models used is the regression-type model:

1. Linear growth model
2. Quadratic growth model
3. Exponential growth model
4. An S-curve model

The second type of model used was a moving-average model. The third set of models used consists of exponential smoothing models:

1. Single exponential smoothing
2. Double exponential smoothing
3. Winter's multiplicative model
4. Winter's additive model

The fourth set of models consists of an autoregressive model:

1. Autoregressive nonseasonal model

In forecasting the first 3 months of 2012, the following can be seen:

Best forecasting model for period (25):

1. Quadratic growth model
2. Autoregressive nonseasonal model
3. Winter's additive model

Best forecasting model for period (26):

1. Linear growth model
2. Exponential growth model
3. S-curve model

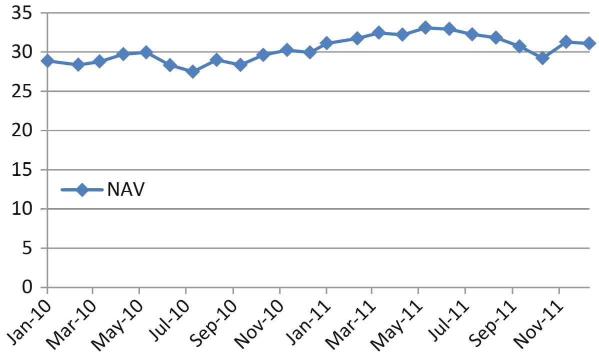

Fig. 88.1 NAV of VWELX

Best forecasting model for period (27):

1. Exponential growth model
2. Autoregressive nonseasonal model
3. S-curve model

It appears that the best model for forecasting in all three periods is the exponential growth model, followed closely by the autoregressive nonseasonal model. In evaluating the fit of the exponential growth model, the results, in terms of MAPE, MAD, and MSD, are well based.

While this model is quite simple in its performance on predicting the NAV in months 25, 26, and 27, the January–March 2012 is the best of all the models.

The forecasting period of the model structure is somewhat limited in nature. Months prior to January 2010 were a time of great economic turmoil (the worst since the Great Depression almost 70 years ago), and thus, these months were not used. In addition to further study of time series of NAV using the first 3 months of 2012 in the forecasting process of the second 3 months of 2012, we suggest using other forecasting studies to predict the total NAV of VWELX. We also suggest the development of macroeconomic econometric models to predict the total NAV of VWELX. Furthermore, the use of combination of forecasts is another topic for consideration in this forecasting process.

88.2.1 Combination of Forecasts

Besides just selecting one forecast when several sets of forecasts are available, the possibility exists to form a composite set of forecasts. This very basic idea has proven to be very effective over a wide range of management forecasting applications (see Bates and Granger 1969; Clemen 1984; Granger 1989).

If one has J forecasts over a given quantity S in a previous time period, a combined forecast is a weighted average of individual forecasts:

$$D = \sum_{I=1}^{J} w_i = 1 \text{ and } w_i = 0, j = 1, \ldots, k$$

The simplest weighting would be to consider all forecasting methods equal. If, however, a historical record of past forecasting results was available, then an appropriate combination of weights would be based upon their performance. The weights could vary over time. A possible methodology based on various historical forecasting evaluations could, also, be determined (see, e.g., Lawrence and Reeves 1981, 1982; Lawrence et al 2009). Such a process will be the topic of future research (Tables 88.1 and 88.2).

Appendix 1: A Forecasting Method Used in NAV Forecasting

Simple Exponential Smoothing

Simple exponential smoothing provides an exponentially weighted moving average of all previously observed values. The model is often appropriate for data with no predictable upward or downward trend. Exponential smoothing continually revises an estimate in the light of more recent experiences. This method is based on averaging past values of a series in an exponentially decreasing manner. The exponentially smoothing equation is

$$\hat{Y}_{t+1} = \alpha Y_t (1 - \alpha) \hat{Y}_t$$

where
$\hat{Y}_{t+1}$: new smoothed value or the forecasting value for the next period
α: smoothing constant ($0 < \alpha < 1$)
Y_t: actual value of the series in period t
$\hat{Y}_t$: old smoothed value of the forecast for period t

Simple exponential smoothing, as moving averages, uses only past values of a time series to forecast future values of the same series and is properly employed when there is no trend or seasonality present in the data. With exponential smoothing, the forecast value at any time is a weighted average of all the available previous values: the weights decline geometrically as you go back in time. Moving-average forecasting gives equal weights to the past values included in each average; exponential smoothing gives more weight in the recent observations and less to the older observations. The weights are made to decline geometrically with the age of the observation to confirm to the argument that the most recent observations contain the most relevant information so that they should be accorded proportionately more influence than older observations.

Exponential smoothing proceeds as do moving averages by smoothing past values of the series; the calculations for producing exponentially smoothed forecasts can be expressed as an equation. The weight of the most recent observation is

assigned by multiplying the observed value by α, the next most recent observation by $(1-\alpha)\alpha$, the next observation by $(1-\alpha)^2\alpha$, and so on. The number chosen for α is called the smoothing constant.

The value of the smoothing constant α must be between 0 and 1. The value of the smoothing constant cannot be equal to 0 or 1; if it is, the entire idea of exponential smoothing is negated. If a value close to 1 is chosen, recent values of the time series are weighted heavily relative to those of the distant past when the smoothed values are calculated. Likewise, if the value of α is chosen close to 0, then the values of the time series in the distant past are given weights comparable to those given the recent values. The rate at which the weights decrease can be seen from their values for an α of 0.1.

Regardless of the smoothing constant chosen, the weights will eventually sum to 1. Whether the sum of the weights converges on 1 quickly or slowly depends on the smoothing constant chosen. If a smoothing constant of 0.9 is chosen, then the sum of the weights will approach 1 much more rapidly than when the smoothing constant is 0.1.

In choosing α, select values close to 0 if the series has a great deal of random variation; select values close to 1 if the forecast values depend strongly on recent changes in the actual values. The root-mean-squared error is often used as the criterion for assigning an appropriate smoothing constant; the smoothing constant with the smallest root-mean-squared error would be selected as the model likely to produce the smallest error in generating additional forecasts. In practice, relatively small values of α generally work best when simple exponential smoothing is the most appropriate model.

Double Exponential Smoothing

A variation of simple exponential smoothing that includes trends is referred to as double exponential smoothing. This technique is appropriate only when the data vary around an average or have a step or gradual change. This double exponential model is composed of two elements:

$$\hat{Y}_{t+1} = S_t + T_t$$

where
S_t: smoothed error
T_t: current trend estimate

$S_t = Y_t + \alpha_1 \left(Y_t - \hat{Y}_e\right)$

$T_t = T_{t-1} {}_{+}\alpha_2 \left(\hat{Y}_t - \hat{Y}_{t-1-} - T_{t-1}\right)$
α_1: smoothing constant
α_2: smoothing constant

A method similar to double moving averages is double exponential smoothing. This method accounts for trend and retains the advantage of requiring less data than moving averages, an attribute of all exponential smoothing methods.

Double exponential smoothing uses a single coefficient, alpha, for both smoothing operations. As in double moving averages, this method computes the difference between single and double smoothed values as a measure of trend. It then adds this value t the single smoothed value together with adjustment for the current trend.

As is true for simple exponential smoothing, double smoothing requires starting values to initialize the formulae. The advantages of double smoothing are as follows:

1. It models the trends and level of a time series.
2. It is computationally more efficient than double moving averages.
3. It requires less data than double moving averages. Because one parameter is used, parameter optimization is simple.

Although parameter optimization is simple, there is some loss of flexibility because the best smoothing constants for the level and trend may not be equal. The exponential smoothing model is not a full model; it does not model the seasonality of a series. Often series have seasonality. Thus, it is not recommended unless the data is first deseasonalized.

Winter's Method

Winter's method is similar to those of other linear exponential smoothing methods but has the advantage of being capable of dealing with seasonal data in addition to data that have a trend. The three basic smoothing equations of Winter's method are as follows:

$$S_t = \alpha + [X_t/I_{t-L}] + (1-\alpha)(S_{t-1} + T_{t-1})$$

$$T_t = \beta(S_{t-}S_{t-1}) + (1-\beta)T_{t-1}$$

$$I_t = \tau[X_t/S_L]\tau + (1-\tau)I_{t-L}$$

where
S_t: smoothed value of deseasonalized service
T_t: smoothed value of trend
I_t: smoothed value of seasonal factor
L: length of seasonality (four quarters or a year)

Trend Models

The expected value of a series may change as time passes since the influence of factors changes. If the movement is long term and only in one direction, up or down, it is called a trend.

With trended series, one assumes that there is some functional relationship between the expected value of the series and the time variable. This function usually involves some unknown parameters β_0, β_1, ... that must be estimated from the series history.

A time series whose average value changes over time is called nonstationary. Trend is a particular kind of nonstationary in which the pattern of change has two main properties:

1. It is of long duration compared to the forecast horizon.
2. It is predominantly in one direction only, either upward or downward.

A time series y_1, y_2, ... is said to have trend if the expected value of y_i changes over time so that

$$E(y_t) = f(\beta_0, \beta_1, \ldots, t)\, t = 1, 2, \ldots$$

where f (β_0, β_1,. . ., t) is predominantly either an increasing or a decreasing function of t over the forecasting horizon (the time for which forecasts are to be constructed).

A model for trended time series is as follows:
y_t = the actual value of the series at time t
T_t = the expected value (trend) of the series at time t
= f(β_0, β_1, . . .;t)
ε_t = a random variable representing irregular fluctuations around the trend
where f(β_0, β_1,. . .; t) is an increasing or decreasing function describing the trend pattern.

The general trend model is $y_t = T_i + \varepsilon\ t = 1, 2, \ldots$. This model describes a consistently growing or declining series with variation from trend (T_t) caused by random influences (ε_t). In most cases, it is assumed that the ε_t's form a stationary random series with $E(\varepsilon_t) = 0$ for all t.

There may be some confusion about whether a trend is only a part of a very long cycle. However, practically speaking, a portion of a long cycle may be modeled as trend if the cycle has not changed direction during the time period of interest to the forecaster and if no such change is anticipated. Under these circumstances, it is probably only academic whether the movement is truly a trend of a cycle. If a cycle is modeled as trend and it happens to turn over during the forecast horizon, then large forecast errors may result.

Among the major sources of trend are the following:

1. Population changes
2. Technological changes
3. Changes in social custom
4. Inflation/deflation
5. Changing environmental conditions
6. Changing market acceptance

Linear Trend Model

These models indicate the increases or decreases like a straight line and are represented by the equation

$$\hat{Y}_t = b_0 + b_1 t$$

where

Y_t is the predicted value of the trend at time t. The values of b_0 and b_1 are found by the method of least squares.

Quadratic Trend Model

Another trend model often used is a quadratic trend model:

$$\hat{Y}_t = b_0 + b_1 t_1 + \ldots + b_2 t^2$$

where the values of b_0, b_1, and b_2 are found by the method of least squares.

Exponential Trend Model

Furthermore, when the time series starts slowly and then appears to be increasing at an increasing rate such that the percentage difference from observed is constant, an exponential trend can be fitted. The exponential trend is given by

$$\hat{Y}_t = b_0 b_1^t$$

The coefficient is related to the growth rate. If the exponential trend b_1 is fit to annual data, the annual growth rate is estimated to be 100 $(b_1 - 1)$%.

Moving-Average Method

In the method of simple averages, the mean of the data set is to forecast the future. However, if the forecaster is more concerned with more recent observations, a constant number of data points can be specified to compute the mean for the most recent set of observations. This process is referred to as a moving average. As each new data set observation becomes available, a new mean is computed by adding the newest value and dropping the oldest. This moving average is used to forecast the next period.

A moving average of adding K MA(K) is given by
$\hat{Y}_{t+1}$: the actual value at period t
Y_{e+1}: forecasted value for the next period
K: the number of terms in the moving average

Each observation in the process is given an equal weight. The rate of response to changes in the series depends on the number of period in K. The moving-average model does not handle trend or seasonality factor.

To compute the weighted average of a set of data, each first observation is multiplied by a weight representing its relative importance; then the produces are summed, and finally this sum is divided by the sum of the weights. The resulting weights then sum to 1.0 ad are called normalized weights, which are often expressed as percentages. They give quite a clear picture of the proportionate influence of each observation on the value of the average. In forecasting formulae,
w_0 = the weight given to the most recent observation
w_1 = the weight given to the one-period-old observation
w_2 = the weight given to the two-period-old observation
...
w_i = the weight given to the i-period-old observation

In smoothing schemes with normalized weights, then the one-step-ahead forecast is

$$\hat{Y}_{t+1} = \beta_0(t) = w_0 y_{t+\ wt} y_{t-1} + \ldots + w_{k-1} y_{t-k+1}\, \mathbf{k} \le \mathbf{t} = \sum_{0}^{k-1} w_i y_{t-1}$$

and the p-step-ahead forecast is

$$\hat{Y}_{t+p} = \hat{Y}_{t+1} \quad \mathbf{p} \ge \mathbf{t}$$

Because the weights move toward one step each time a new observation is obtained, the average computed is called a moving average.

With the updating procedure, the weighting scheme changes at each step. That is, the weights at time t are 1/t,1/t, 1/t,. . ., 1/t and at time t + 1 become 1/(t + 1), 1/(t + 1), . . ., 1/(t + 1). This method is referred to as updating the mean. Since all previous observations enter equally into the average, updating the mean provides a maximal amount of smoothing and, thus, a minimal amount of tracking.

Another concept used in interpreting moving averages is the center of the average. The center is that point in time which the average most represents. The center is not necessarily the idle of the interval; it depends on the weighting scheme. However, the average used in updating the mean is centered at (t + 1)/2, the middle of the interval from 1 to t, because of the symmetry of the weights.

Varying amounts of smoothing and tracking can be obtained by altering the weighting scheme. A common way to reduce the extreme smoothing of updated mean forecasts is to compute the mean of only the k most recent observations. The result is called a moving average of length k. Varying the value of k varies the amount of smoothing, with smaller values of producing less smoothing (more tracking). For any particular series, the forecaster may select k according to the amount of smoothing desired, or k may be chosen to optimized one of the standard criteria (RMSE, MAD, etc.) mentioned earlier in this section. In actually, this method discards all observations that are more than k units old, and the weight to each of the k most recent observations is equal and constant over time. There must be k observations to begin the forecasting, and to compute new forecasts we must retain all k of the most recent observations from step to step.

Box-Jenkins (ARIMA) Model

ARIMA models are a class of linear models that are capable of representing stationary as well as nonstationary time series. ARIMA models make use of information in the series itself to generate forecasts.

Box-Jenkins method is a forecasting methodology since it does not assume any particular pattern in the historical data of the series. To begin with the selection of an ARIMS model is based on the examination of the time series, and it is autocorrelated for several time lags. In specifics, the pattern of known autocorrelation is associated with a particular ARIMA model structure.

The Box-Jenkins method of forecasting is different from most methods. The technique does not assume any particular pattern in their historical data of the series to be forecast. It uses an iterative approach of identifying a possible useful model from a general class of models. The chosen model is then checked against the historical data to see whether it accurately describes the series. The model fits well if the residuals between the forecasting model and the historical data points are small, randomly distributed, and independent. If the specified model is not satisfactory, then the process is repeated by using another model designed to improve on the original one.

A general class of Box-Jenkins models for a stationary time series is the ARIMA, or autoregressive integrated moving average, models. Stationary time series is one shoes average value is not changing over time. This group of models includes the autoregressive models with only autoregressive terms with both autoregressive and moving-average terms. The Box-Jenkins methodology allows the analyst to select the model that best fits the data.

Selection of an appropriate model can be made by comparing the distributions of autocorrelation coefficients of the time series being fitted with the theoretical distributions for the various models.

There are three basic stages in the modeling process: identification, fitting, and diagnostic checking.

The objective of identification is to select the forecast model that seems most appropriate to the time series under study. The data are used to generate a series of sample autocorrelation functions. These are now compared to certain theoretical autocorrelation functions from known forecast models to seek the best match between the sample and theoretical results. With this, the forecast model is identified and selected. The principle of parsimony is applied in that the model with the smallest number of coefficients that is suitable for the item is the selected model.

Upon selecting the model, fitting is carried on where the coefficients are estimated. The estimates are found so that they yield the fit of the past demands which procedures the minimum sum of squared residual errors.

Using the fitted results, the residual errors are examined to determine the adequacy of the fit. A good fit will yield residual errors that are randomly distributed with mean zero and a common variance. The check is made via the autocorrelation function of the residual errors.

If the diagnostic check fails, then the three stages are repeated until a model is found which gives appropriate results.

Autoregressive Models

The first type of model that will be examined is an autoregressive model. A pth order autoregressive model takes the following form:

$$Y_t : a_0 + a_1 Y_{t-1} + a_2 Y_{t-2} + \ldots + a_p Y_{t-p} + e_t$$

where

$Y_{e:}$ response variable at time t

Y_{t-1}, Y_{t-2}, . . . + Y_{t-p}: response variable at various time lags

a_0, $a_{1,}$ a_2, $a_{3,\ldots}$, a_p: coefficient to be estimated

e_t: error term at time t

The given model has the form of a regression model with lagged values of the dependent variable in the independent variable. This model is referred to as an autoregressive model.

Moving-Average Model

A moving-average model is given by the gth-order moving-average model, which takes the following form:

$$Y_t = \mu + e_t - e_1 t_{t-1} - b_2 t_{t-1} - \ldots - b_g t_{t-g}$$

where

Y_t: response variable at time t

μ: constant mean of the process

$b_{1,}$ b_2, $b_{3,\ldots}$, b_g: coefficients to be estimated

e_t: error term; variables not explained by the model

e_{t-1}, t_{t-2} . . . $-e_{t-g}$: errors in previous time periods

A moving-average model provides a forecast of Yt based on a linear combination of a finite number of past errors.

Unbounded Autoregressive and Moving-Average Models

A model that has both autoregressive terms can be combined with a model having moving-average terms. It is referred to as a mixed autoregressive moving-average form.

The form of the model is

$$Y_t : a_0 + a_1 Y_{t-1} + a_2 Y_{t-2} + \ldots + a_p Y_{t-p} + \varepsilon_t + \left[-b_1 \varepsilon_{t-1} - b_2 \varepsilon_{t-2} \ldots - b_g t_{t-g}\right]$$

Contents

Abstract

Three multivariate techniques, namely, discriminant analysis, factor analysis, and principal component analysis, are discussed in detail. In addition, the stepwise discriminant analysis by Pinches and Mingo (1973) is improved using a goal

programming technique. These methodologies are applied to determine useful financial ratios and the subsequent bond ratings. The analysis shows that the stepwise discriminant analysis fails to be an efficient solution as the hybrid approach using the goal programming technique outperforms it, which is a compromised solution for the maximization of the two objectives, namely, the maximization of the explanatory power and the maximization of discriminant power.

Keywords

Multivariate technique • Discriminant analysis • Factor analysis • Principal component analysis • Stepwise discriminant analysis • Goal programming • Bond ratings • Compromised solution • Explanatory power • Discriminant power

89.1 Introduction

Financial ratios are widely used in all financial analysis and planning. Banks use a firm's current and quick ratio to determine acceptability, for commercial loans; the leverage ratio is used as a proxy for a firm's capital measure in predicting bankruptcy and to analyze the impact of leverage on the market value of a firm. In financial analysis and planning determination, lenders or managers need to measure a customer's (either an individual's or a firm's) short-term or long-term financial position. The multivariate statistical techniques of factor analysis (or principal component analysis) and discriminant analysis had been used in such instances to identify important financial ratios and to construct one or several well-known financial indicator(s), namely, the financial z-score (Altman 1968; Altman and Eisenbeis 1968; Altman et al. 1977). Although the financial *z*-scores are a compromise between theory and practice, z-scores have been used extensively by practitioners and academicians in credit analysis and bankruptcy prediction (Altman 1983). In literature, factor analysis (or principal component analysis) is often used to extract a set of variables with significant explanatory power in a high-dimensional dataset. Together with discriminant analysis, objects are classified into several homogeneous groups by the financial indicator(s) extracted from the factor analysis (or principal component analysis). The credit-scoring model by Pinches and Mingo (1973) is an example of the aforementioned stepwise principal component-discriminant analysis approach. However, when used together, due to their conflicting objectives, the performance of the stepwise principal component-discriminant analysis might not be as satisfactory as it would be when used separately.

Instead of stepwise principal component-discriminant analysis, the methodology of factor -discriminant analysis in conjunction with the minimax goal programming is explored in this chapter. In Sect. 89.2, the theory and methodology of discriminant analysis will be explored. Section 89.3 will discuss the theory and methodology of factor (or principal component) analysis.

In Sect. 89.4, the performance of a hybrid multivariate credit-scoring model that involves a compromise maximization of the two conflicting objectives associated with the principal component and discriminant analysis is presented, and its performance using Pinches and Mingo (1973) data is illustrated. Finally, the results of this chapter are summarized in Sect. 89.5.

89.2 Discriminant Analysis

The purposes of discriminant analysis are twofold: (1) to test for mean group differences among the groups and (2) to construct a classification scheme based upon a set of m variables in order to assign previously unclassified observations to appropriate groups. For example, in a study of corporate bankruptcy, Altman (1968) used data from a sample of failed firms and a sample of existing firms and developed a classification rule that uses financial ratios to determine whether bankrupt firms had significantly different financial ratios prior to failure than did solvent firms.

89.2.1 Two-Group Discriminant Analysis

A linear two-group discriminant function can be defined as

$$Y_i = a_1 x_{1i} + \dots . + a_m x_{mi} \tag{89.1}$$

where Y_i is a binary variable used to indicate two alternative options, e.g., good or bad accounts in credit analysis, bankrupt or non-bankrupt firms in corporate bankruptcy analysis, and problem or nonproblem banks in banking analysis. x_{1i},.., x_{mi} are m explanatory variables. Two different methods can be used to estimate the coefficients of Eq. 89.1; they are the dummy regression method and the eigenvalue method. The dummy regression method is given in Sect. 89.2.1.1, while the eigenvalue method is given in Sect. 89.2.1.2.

It is important for readers to understand the relationship between the logic of two-group discriminant analysis and the regression technique to estimate related discriminant function parameters. Following Tatsuoka (1988), Johnston and Dinardo (1996), and Eisenbeis and Avery (1972), the basic equation of discriminant analysis as derived in Appendix 1 can be defined as

$$\begin{aligned} &(B - EC)A = 0, \\ &D' = \left[\overline{X}_{1,1} - \overline{X}_{1,2} \dots , \overline{X}_{m,1} - \overline{X}_{m,2}\right], \end{aligned} \tag{89.2}$$

where $B = DD'$ is the between-group variance; C is the within-group variance; A is the vector representing the coefficients such that

$|A - \lambda I| = 0$, where I is the identity matrix and λ is the eigenvalue; and E is the ratio of the weighted between-group variance to the pooled within-group variance. Multiplying by C^{-1} into both sides of Eq. 89.2, the characteristic equation associated with Eq. 89.2 is

$$\left(C^{-1}B - EI\right)A = 0. \tag{89.3}$$

In order to use the linear discriminant function for empirical analysis, one must estimate the coefficients of Eq. 89.2. To illustrate the computation of two-group

Table 89.1 Roster of liquidity and leverage ratios

Group 1 ($N_1 = 6$)			Group 2 ($N_2 = 8$)		
x_{1i}	x_{2i}	Y_i	x_{1i}	x_{2i}	Y_i
2.0	0.50	1	1.8	0.35	0
1.8	0.48	1	1.9	0.34	0
2.3	0.49	1	1.7	0.42	0
3.1	0.41	1	1.5	0.49	0
1.9	0.43	1	2.2	0.36	0
2.5	0.44	1	2.8	0.38	0
			1.6	0.55	0
			1.4	0.56	0

Two groups with response variable Y and two predictors X_1 and X_2

discriminant functions as a multiple regression equation and the eigenvalue method, we shall use a numerical example illustrated in Table 89.1, which shows the number scores of two groups on two predictor variables, i.e., the liquidity ratio X_1 and the leverage ratio X_2, and the response variable Y. All members of group 1 are assigned $Y = 1$, and all members of group 2 are given $Y = 0$. There are two alternative methods, the dummy regression and the eigenvalue method, to estimate the discriminant function. The two methods are stated as below.

89.2.1.1 Dummy Regression Method

If there are two explanatory variables, i.e., $m = 2$, Eq. 89.1 can be written as

$$y_i = a_1 x_{1i} + a_2 x_{2i} \tag{89.4}$$

where $y_i = Y_i - \overline{Y}$, $x_{1i} = a_1 X_{1i} + a_2 \overline{X}_1$, and $x_{2i} = X_{2i} - \overline{X}_2$. The equation system used to solve a_1 and a_2 can be defined as

$$Var(x_{1i})a_1 + Cov(x_{1i}, x_{2i})a_2 = Cov\left(x_{1i}, y_i\right) Cov(x_{1i}, x_{2i})a_1 + Var(x_{2i})a_2 = Cov\left(x_{2i}, y_i\right).$$

Following the data listed in Table 89.1, $Var(x_{1i})$, $Var(x_{2i})$, $Cov(x_{1i}, x_{2i})$, $Cov(x_{1i}, y_i)$, and $Cov(x_{2i}, y_i)$ are calculated as follows:

$$\begin{aligned} Var(x_{1i}) &= \frac{\sum X_{1i}^2}{n} - \left(\frac{\sum X_{1i}}{n}\right)^2 \\ &= \frac{32 + 29.19}{n} - \left(\frac{13.6 + 14.9}{n}\right)^2 \\ &= \frac{61.19}{14} - \left(\frac{28.5}{14}\right)^2 = 0.2267; \end{aligned}$$

$$
\begin{aligned}
Var(x_{2i}) &= \frac{\sum X_{2i}^2}{n} - \left(\frac{\sum X_{2i}}{n}\right)^2 \\
&= \frac{1.2671 + 1.5447}{14} - \left(\frac{2.75 + 3.45}{14}\right)^2 = 0.0048;
\end{aligned}
$$

$$
\begin{aligned}
Cov(x_{1i}, x_{2i}) &= \frac{12.424}{14} - (2.0357)(0.4428) \\
&= 0.8874 - 0.9014 \\
&= -0.014;
\end{aligned}
$$

$$
\begin{aligned}
Cov(x_{1i}, y_i) &= \frac{\sum X_{1i}Y_i}{n} - \left(\overline{X}_1\right)\left(\overline{Y}\right) \\
&= \frac{13.6}{14} - (2.0357)(0.4285) \\
&= 0.9714 - 0.8722 \\
&= 0.0992;
\end{aligned}
$$

$$
\begin{aligned}
Cov(x_{2i}, y_i) &= \frac{\sum X_{2i}Y_i}{n} - \left(\overline{X}_2\right)\left(\overline{Y}\right) \\
& \frac{2.75}{14} - (0.4428)(0.4288) \\
&= 0.0.1964 - 0.1897 \\
&= 0.00668.
\end{aligned}
$$

Using Cramer's rule, a_1 and a_2 can be calculated as:

$$
\begin{aligned}
a_1 &= \frac{\begin{vmatrix} 0.0992 & -0.0140 \\ 0.0066 & 0.0048 \end{vmatrix}}{\begin{vmatrix} 0.2267 & -0.0140 \\ -0.0140 & 0.0048 \end{vmatrix}} \\
&= \frac{0.00047616 + 0.0000924}{0.0010886 - 0.000196} = 0.63697
\end{aligned}
$$

$$
\begin{aligned}
a_2 &= \frac{\begin{vmatrix} 0.2267 & 0.00992 \\ -0.0140 & 0.0066 \end{vmatrix}}{\begin{vmatrix} 0.2267 & -0.0140 \\ -0.0140 & 0.0048 \end{vmatrix}} \\
&= \frac{0.00149 + 0.00138}{0.00108 - 0.00019} = 3.2359
\end{aligned}
$$

Normalizing the regression coefficient by dividing a_2 into a_1, we obtain

$$\begin{bmatrix} a_1/a_2 \\ 1 \end{bmatrix} = \begin{bmatrix} \frac{0.63697}{3.2359} \\ 1 \end{bmatrix} = \begin{bmatrix} 0.1968 \\ 1 \end{bmatrix}. \tag{89.5}$$

89.2.1.2 Eigenvalue Method

For the eigenvalue method, the elements of the matrices C and B in Eq. 89.2 can be calculated as:

$$C_{11} = 32 - \frac{(13.6)^2}{6} + 29.19 - \frac{(14.9)^2}{8} = 2.612;$$

$$\begin{aligned} C_{22} &= 1.2671 - \frac{(2.75)^2}{6} + 1.5447 - \frac{(3.45)^2}{8} \\ &= 0.0636 \end{aligned}$$

$$\begin{aligned} C_{12} &= 6.179 - \frac{13.6 \times 2.75}{6} + 6.245 - \frac{14.9 * 3.45}{8} \\ &= -0.2350; \end{aligned}$$

$$\begin{aligned} B_{11} &= 6\left[\frac{13.6}{6} - 2.0357\right]^2 + 8\left[\frac{14.9}{8} - 2.0357\right]^2 \\ &= 0.5601; \end{aligned}$$

$$\begin{aligned} B_{22} &= 6\left[\frac{2.75}{6} - 0.4428\right]^2 + 8\left[\frac{3.45}{8} - 0.4428\right]^2 \\ &= 0.0025 \end{aligned}$$

$$\begin{aligned} B_{12} &= 6\left(\frac{13.6}{6} - 2.0357\right)\left(\frac{2.75}{6} - 0.4428\right) \\ &\quad + 8\left(\frac{14.9}{8} - 2.0357\right)\left(\frac{3.45}{8} - 0.4428\right) \\ &= 0.03753. \end{aligned}$$

The matrices C and B can now be formulated as

$$C = \begin{bmatrix} 2.612 & -0.2350 \\ -0.2350 & 0.0636 \end{bmatrix} \quad B = \begin{bmatrix} 0.5601 & 0.03753 \\ 0.03753 & 0.0025 \end{bmatrix}.$$

Therefore, we can obtain

$$C^{-1}B = \begin{bmatrix} 0.4007 & 0.0268 \\ 0.0268 & 0.1384 \end{bmatrix}.$$

Now, the characteristic equation $|C^{-1}B - EI| = 0$ can be solved as $E^2 - 0.5391E = 0$, whose single nonzero root is $E_1 = 0.5391$. Now, the adjoint of $C^{-1}B - E_1 I$ is

$$\begin{bmatrix} -0.4007 & -0.0268 \\ -0.2071 & -0.1384 \end{bmatrix}$$

Hence, the eigenvector of $C^{-1}B$, with larger elements set equal to unity, is

$$A_1 = \begin{bmatrix} -0.4007/-2.071 \\ 1 \end{bmatrix} = \begin{bmatrix} 0.1935 \\ 1 \end{bmatrix}.$$

When the vector of regression weights a_1 and a_2 obtained earlier is similarly rescaled, we arrive at the same solution as in Eq. 89.5, which was obtained by the dummy regression method in Sect. 89.2.1.1. Alternatively, the nonzero root, $E_1 = 0.5391$, can be substituted into Eq. 89.2, yielding:

$$\begin{bmatrix} -0.4007 - 0.5391 & -0.0268 \\ -2.071 & -0.1384 - 0.5391 \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \end{bmatrix} = 0.$$

Equation 89.3 implies that

$$-0.138a_1 + 0.027a_2 = 0$$

$$2.071a_1 - 0.4007a_2 = 0.$$

By normalizing $a_1^2 + a_2^2 = 1$, one has the same result in Eq. 89.5.

89.2.2 K-Group Discriminant Analysis

The two-group discriminant analysis theory can be readily generalized to the K-group case. Assume there are K samples of size N for each of the K populations with means $\boldsymbol{\mu}_1, \ldots, \boldsymbol{\mu}_K$ and weights $w_1, \ldots, w_K$, respectively, and a common variance-covariance matrix Σ. A set of r linear combinations of the p explanatory variables $X = (X_1, \ldots, X_p)'$, or discriminant functions $D_1 = \theta_1' X, \ldots, D_r = \theta_r' X$, $r \leq \min(K - 1, p)$, where the coefficient vectors $\theta_1 = \Sigma^{-1/2}\xi_1, \ldots,$

$\theta_r = \Sigma^{-1/2}\xi_r$, where ξ_j is subject to the constraints $\xi_i'\xi_i = 1$ and $\xi_i'\xi_j = 0$ for all $j < i$, are determined sequentially as follows.

Given the first i-1 coefficient vectors $\theta_1, \ldots, \theta_{i-1}$, $i \leq r$, the ith coefficient vector $\boldsymbol{\theta}_i$ is obtained by choosing ξ_i that maximizes the ratio comparing the variability between the groups to that within the groups, which can be formulated in the object function

$$g_1(\xi_i) = \xi_i' A \xi_i \tag{89.6}$$

where the $p \times p$ positive-definite matrix

$$A = \Sigma^{-\frac{1}{2}}\left(\sum_{j=1}^{K} w_j\left(\boldsymbol{\mu}_j - \overline{\boldsymbol{\mu}}\right)\left(\boldsymbol{\mu}_j - \overline{\boldsymbol{\mu}}\right)'\right)\Sigma^{-\frac{1}{2}} \tag{89.7}$$

Here, $\overline{\boldsymbol{\mu}} = \sum_{i=1}^{k} w_i \boldsymbol{\mu}_i$ is the overall mean and Σ is the common $p \times p$ variance-covariance matrix of the K populations. By maximizing the objective function g, the K population means of the r discriminant functions $D_1 = \theta_1' X, \ldots, D_r = \theta_r' X$, $r \leq \min(K-1, p)$ are separated as much as possible so that the chance of misclassification of objects is reduced and thereby the discriminant power is maximized.

89.3 Factor Analysis and Principal Component Analysis

89.3.1 Factor Analysis

Factor analysis has been applied in marketing, finance, and accounting. For example, Johnson and Dinardo (1996) used factor analysis to extract eight factors from 61 financial ratios. Anderson (2003), Tatsuoka (1988), and Churchill and Iacobucci (2004) argued that factor analysis is a popular "analyses of interdependence" technique, which is concerned with the overall relationships among the set of p explanatory variables that characterize the objects. In more specific, the model can be formulated as

$$Y = \boldsymbol{\mu} + \beta \boldsymbol{f} + U \tag{89.8}$$

Where $\boldsymbol{f}$ is the $m \times 1$ vector of unobservable factors, $\boldsymbol{\mu}$ is a fixed vector of means, and U is a vector of unobservable specific errors. The $p \times m$ matrix β consists of factor loadings ($m < p$), which are parameters to be estimated. To estimate model (89.8), it is always assumed

$$\begin{aligned}
&E(\boldsymbol{f}) = 0,\\
&E(U) = 0, E(\boldsymbol{f}'\boldsymbol{f}) = M,\\
&E\left(UU'\right) = \Sigma,\\
&E(\boldsymbol{f}U') = 0
\end{aligned}$$

where Σ is a diagonal matrix. From (89.8), the covariance matrix of the observations Y is

$$E(Y-\boldsymbol{\mu})(Y-\boldsymbol{\mu})^{'}=\beta M\beta^{'}+\Sigma. \tag{89.9}$$

Two alternative approaches exist in estimating (89.8); they are the principal component method and the maximum-likelihood method. The principal component method for extracting factors or calculating the coefficient matrix to meet the foregoing statistical assumption can be found in both Johnson and Dinardo (1996) and Tatsuoka (1988). The maximum-likelihood method can be found in Lawley (1940), Lawley and Maxwell (1963), and Joreskog (1967). In addition to model (89.8), factor scores of the latent factors $f_1, \backslash \ldots, f_{\mathrm{m}}$ are also of the primary interest and are estimated.

89.3.2 Principal Component Analysis

In many empirical studies, the number of variables under consideration is too large to handle. A way of reducing the number of variables to be treated is to discard the linear combinations that have small variances and to study only those with large variances. For example, the first principal component is the normalized linear combination (i.e., the sum of squares of the coefficients being one) with maximum variance. In essence, principal component analysis is for dimensionality reduction, i.e., for transforming a number p of possibly correlated observable variables

$$\boldsymbol{X}=\left(X_1,\ldots,X_p\right)^{'}$$

into a smaller number u, $u < p$, of uncorrelated variables $Y_1,\ldots, Y_u$ called principal components to account for as much variability, or the explanatory power, as possible. The principal components $Y_1=\boldsymbol{\varphi}_1^{'}X,\ \ldots\ ,\ Y_u=\boldsymbol{\varphi}_u^{'}X$ are determined sequentially that given the first i-1 principal components, $i\leq u$, the ith principal component Y_i is determined by choosing $\boldsymbol{\varphi}_i$ that maximizes the variance of Y_i, i.e.,

$$var(Y_i)=\boldsymbol{\varphi}_i^{'}\Xi\boldsymbol{\varphi}_i$$

subject to the constraints $\boldsymbol{\varphi}_i^{'}\boldsymbol{\varphi}_j=0$ for all $j < i$ and $\boldsymbol{\varphi}_i^{'}\boldsymbol{\varphi}_i=1$, where Ξ is the overall variance-covariance matrix

$$\Xi=\Sigma+\sum_{i=1}^{k}w_i(\boldsymbol{\mu}_i-\overline{\boldsymbol{\mu}})(\boldsymbol{\mu}_i-\overline{\boldsymbol{\mu}})^{'}.$$

To be compatible with discriminant analysis, the constraints $\boldsymbol{\varphi}_i^{'}\boldsymbol{\varphi}_j=0$ for all $j < i$ and $\boldsymbol{\varphi}_i^{'}\boldsymbol{\varphi}_j=1$ are relaxed and let $\boldsymbol{\varphi}_i=\Sigma^{-\ 1/2}\xi_i,\ i\leq u$, where the vector

ξ_i satisfies the constraints that $\xi_i'\xi_i = 1$ and $\xi_i'\xi_j = 0$ for all $j < i$. As the norm $\boldsymbol{\varphi}_i'\boldsymbol{\varphi}_i = \xi_i'\Sigma^{-1}\xi_i$ is not restricted to one, we consider an objective function $g_2$that represents the normalized explanatory power of Y_i as follows

$$g_2(\xi_i) = \frac{\xi_i'\Sigma^{-\frac{1}{2}}\Xi\Sigma^{-\frac{1}{2}}\xi_i}{\xi_i'\Sigma^{-1}\xi_i}. \tag{89.10}$$

89.4 Multivariate Analysis of Industrial Bond Ratings

Pinches and Mingo developed a credit-scoring model based on the stepwise discriminant analysis procedure, in which a set of six key financial ratios with significant variability or explanatory power is chosen first from 35 candidate financial variables using factor analysis first. After the selection process, discriminant analysis is implemented to combine and weight the six key financial variables to produce credit scores with maximal discriminatory power that discriminate obligors among different benchmark ratings ex ante as much as possible. However, the object function of the factor analysis, similar to that of the principal component analysis g_1 in (89.10), and the object function g_2 of the K-group discriminant analysis in (89.6) contradict with each other. For this reason, the extracted factors with significant explanatory power might have very low discriminatory power. Or it might occur that extracted factors with insignificant explanatory power but have very high discriminatory power. Some compromised approach needs to be developed to overcome the problem. A goal programming technique, namely, the minimax goal programming technique by Ignizio and Romero (2003), is considered to be used in conjunction with the principal component and K-group discriminant analysis to find a compromise solution between the two objectives g_1 and g_2. The description of the minimax goal programming technique is given in Appendix 2.

Here, the rating data from Pinches and Mingo (1973) in which a total of 132 industrial corporate bonds rated B, Ba, Baa, A, Aa based on Moody's ratings from January 1, 1967, to December 31, 1968, are adopted for analysis. Four different approaches are compared with one another, they are (1) principal component analysis, (2) K-group discriminant analysis, (3) stepwise discriminant analysis by Pinches and Mingo, and (4) hybrid of principal component and discriminant analysis using minimax goal programming technique. The two object functions g_1 and g_2, or the discriminant power and explanatory power, of the four approaches are listed in Tables 89.2 and 89.3.

89.5 Summary

In this chapter, method and theory of the three multivariate techniques, namely, discriminant analysis, factor analysis, and principal component analysis, are discussed in detail. In addition, the stepwise principal component-discriminant analysis by Pinches and Mingo (1973) is improved using a goal programming technique. These methodologies are applied to determine useful financial ratios and the subsequent bond ratings.

Table 89.2 Classification using hybrid of principal component and discriminant analysis

	Actual rating					
Predicted rating	Aa	A	Baa	Ba	B	Total
In-sample						
Aa	10	2	0	0	0	12
A	1	14	1	0	0	16
Baa	0	1	12	5	0	18
Ba	0	0	2	19	0	21
B	0	0	0	0	17	17
Total	11	17	15	24	17	84
Out-sample						
Aa	2	3	0	0	0	5
A	1	5	2	0	0	8
Baa	0	1	6	1	0	8
Ba	0	0	2	17	0	19
B	0	0	0	2	6	8
Total	3	9	10	20	6	48

Table 89.3 Object functions of four approaches

	Model			
Criteria	Principal component analysis	K-group discriminant	Stepwise discriminant analysis	Hybrid discriminant analysis
In-sample				
g_1	54.80 %	4.01 %	10.55 %	11.79 %
g_2	48.81 %	88.10 %	63.10 %	85.71 %
Out-sample				
g_1	46.70 %	4.82 %	10.37 %	11.65 %
g_2	58.33 %	70.83 %	70.83 %	75.00 %

The analysis shows that the stepwise discriminant analysis fails to be an efficient solution as the hybrid approach using the goal programming technique outperforms it, which is a compromised solution for the maximization of the two objectives, namely, the maximization of the explanatory power and the maximization of discriminant power.

Appendix 1: Derivation of the Discriminant Function

Data composed of two samples of size N_1 and N_2 for two-group discriminant analysis must meet the following assumptions: (1) that the groups being investigated are discrete and identifiable, (2) that each observation in each group can be described by a set of measurements on m characteristics or variables, and (3) that these m variables have a multivariate normal distribution in each population.

In vector notation, the nth observation can be represented as an $m \times 1$ column vector of the form

$$X_n^{'} = (X_{1n}, X_{2n}, \cdots, X_{mn}),$$

where $n = 1, \ldots\ldots, N_1$ or $n = 1, \ldots\ldots\ldots, N_2$. Under these assumptions, the linear discriminant function can be defined as Eq. 89.11

$$Y_i = a_1 X_{1i} + a X_{2i} + \cdots + a_m X_{mi}. \tag{89.11}$$

The a_i's were chosen to maximize the ratio of the weighted between-group variance to the pooled within-group variance. Ladd (1966) has proposed a discriminant criterion E, as defined as Eq. 89.12, to determine the coefficients $a_1, a_2, \ldots, a_m$:

$$E = \frac{A^{'}DD^{'}A}{A^{'}CA} = \frac{A^{'}BA}{A^{'}CA} \tag{89.12}$$

where
$A' = [a_1, a_2, \cdots, a_m]$;
$D^{'} = \left[\overline{X}_{1,1} - \overline{X}_{1,2}, \overline{X}_{2,1} - \overline{X}_{2,2}, \overline{X}_{m,1} - \overline{X}_{m,2}\right]$;
$C =$ within-group variance matrix and
$DD' =$ between-group variance matrix.

There are two alternative methods (a) and (b) that can be used to derive the basic equation of discriminant analysis as defined in Eq. 89.13 in the following:

(a) Subsequent vector derivation method
Symbolically, we may find the derivative of E with the respect to the column vector of A and equate the result to the $m \times 1$ vector (see Tatsuoka (1971), p. 160–161). The vector equation thus obtained is

$$\frac{\partial E}{\partial A} = \frac{2\left[BA\left(A^{'}CA\right) - \left(A^{'}BA\right)CA\right]}{\left(A^{'}CA\right)^2} = 0.$$

Dividing both numerator and denominator of the middle member by $A'CA$ and using the definition of E in Eq. 89.12, this equation reduces to

$$\frac{2[BA - ECA]}{A^{'}CA} = 0,$$

which is equivalent to

$$(B - EC)A = 0. \tag{89.13}$$

(b) Long-hand method

If $m = 2$, then Eq. 89.12 can be rewritten as

$$E = \frac{b_{11}a_1^2 + b_{22}a_2^2 + 2b_{12}a_1a_2}{c_{11}a_1^2 + c_{22}a_2^2 + 2c_{12}a_1a_2}$$

where b_{11}, b_{22}, and b_{12} are elements of B and c_{11}, c_{21}, and c_{12} are elements of C in Eq. 89.2. Taking the partial derivative of E with respect to a_1, we obtain:

$$\begin{aligned}\frac{\partial E}{\partial a_1} &= \left[(2b_{11}a_1 + 2b_{12}a_2)\left(C_{11}a_1^2 + C_{22}a_2^2 + 2C_{12}a_1a_2\right.\right.\\ &\quad - \left(b_{11}a_1^2 + b_{22}a_2^2 + 2b_{12}a_1a_2\right)\left.\left(2C_{11}\mathrm{a}_1 + 2C_{12}\mathrm{a}_2{}^2\right)\right]\\ &\quad \times \left(C_{11}\mathrm{a}_1^2 + C_{22}\mathrm{a}_2^2 + 2C_{12}\mathrm{a}_1\mathrm{a}_2\right)^{-2}\\ &= 2[b_{11}a_1 + b_{12}a_2) - E(C_{11}a_1 + C_{12}a_2)]\\ &\quad \times \left(C_{11}\mathrm{a}_1^2 + C_{22}\mathrm{a}_2^2 + 2C_{12}\mathrm{a}_1\mathrm{a}_2\right)^{-1}.\end{aligned}$$

Setting this equation equal to zero and simplifying, we get $b_{11}a_1 + b_{12}a_2 = E(C_{11}a_1 + C_{12}a_2)$. Similarly, upon equating $\partial E/\partial a_2$ to zero and simplifying, we get $b_{21}a_1 + b_{22}a_2 = E(C_{21}a_1 + C_{22}a_2)$. Using matrix notation, we have

$$\begin{bmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \end{bmatrix} A = E \begin{bmatrix} C_{11} & C_{12} \\ C_{21} & C_{22} \end{bmatrix} A.$$

Therefore, we obtain Eq. 89.13, which can be used to formulate the characteristic equation for solving A as follows. If A^* maximizes the function shown in Eq. 89.11, then so does any $A^{**} = \kappa A^*$, where κ is a scalar. Substituting A^{**} for A^* simply multiplies both the numerator and denominator by κ^2. Because the coefficients themselves are not unique, there are several methods of calculating the discriminant function. Johnston and Dinardo (1996) show that the vector A^* that maximizes the ratio E is proportional to the vector A (i.e., $A = \kappa A^*$), which maximizes $G = A'DD'A$ subject to the constraint that $L = A'CA$, where L is an arbitrary constant. Let λ be a Lagrange multiplier and define

$$F = A'DD'A - \lambda\left(A'CA - L\right).$$

Setting the derivative of F with respect to A equal to zero yields

$$\frac{\partial F}{\partial A} = 0 = 2DD'a - 2\lambda CA \tag{89.14}$$

Where $D'A$ is a scalar, say H. Hence, Eq. 89.14 can be rewritten as (λ/H) $CA = D$, and thus

$$A\left(\frac{\lambda}{H}\right) = C^{-1}D = A_1.$$

It can be seen that A_1 is a solution to Eq. 89.13 since

$$\left(DD^{'} - \lambda C\right)A_1 = \left(DD^{'} - \lambda C\right)A\left(\frac{\lambda}{H}\right) = 0.$$

Alternatively, adding the term EBA to both sides of Eq. 89.13, one has $(1 + E)BA = E(B + C)A$ or

$$\left(B - E^{'}S\right)A = 0, \tag{89.15}$$

where $E' = E/(1 + E)$ and $S = (B + C)$. Now Eq. 89.15 can be used as an alternative of Eq. 89.13, and an alternative objective function can be defined as

$$E^{'} = \frac{A'DD'A}{A^{'}SA},$$

where $S = [S_{ij}] = \textit{the}\ m \times m$ matrix of S_{ij}; here S_{ij} is the sum of the cross products of $X_i - \overline{X}$ and $X_j - \overline{X}$. Following the same procedure mentioned above, we have

$$A\left(\frac{\lambda}{H}\right) = S^{-1}D = A_2.$$

Ladd (1966) has shown that A_2 is proportional to A_1. These results imply that the parameters of a two-group discriminant function can be estimated by using the related data of S and D. Let $Y = 1$ for observations in group 1 and $Y = 0$ for those in group 2; then, using the multiple regression technique, Ladd (1966) showed that the regression coefficient vector $A = S^{-1}MD$, where $M = [N_1N_2]/[N_1 + N_2]$, and N_1 and N_2 are total observations in group 1 and group 2, respectively. It follows straightforwardly showing that the parameters obtained from the eigenvalue method differ from those of the dummy regression method only by a constant M.

Appendix 2: Minimax Goal Programming Technique

The goal programming (GP) technique is a multi-objective optimization approach. Several classes of goal programming are developed, including weighted goal programming, lexicographic goal programming, and minimax goal programming. In this study, as a balance between discriminant power as well as explanatory power is desired, the minimax goal programming technique is introduced as follows. In the standard GP formulation, each of the objectives is given aspiration levels. Unwanted deviations from this aspiration levels are minimized in an achievement function. For the minimax goal programming, the maximal deviation δ from amongst the set of goals is minimized. There are numerous forms of minimax goal programming; here we adopt the one by Ignizio and Romero (2003) as follows:

$$\begin{aligned}
&Achievement\ \ function : Min\ \ \delta \\
&\quad s.t. \\
&\qquad \frac{g_1^{max} - g_1(\xi)}{\left(g_1^{max} - g_1^{min}\right)} \le \delta \\
&\qquad \frac{g_2^{max} - g_2(\xi)}{\left(g_2^{max} - g_2^{min}\right)} \le \delta \\
&Constraints : \xi' \xi = 1 \ \text{ and } \ \delta \ge 0
\end{aligned}$$

where ξ is the decision variable and the four values $g_1^{max} = g_1(\xi_1^*)$, $g_2^{min} = g_2(\xi_1^*)$, $g_2^{max} = g_2(\xi_2^*)$, and $g_1^{min} = g_1(\xi_2^*)$ and ξ_1^* and ξ_2^* are the optimal solutions for objectives g_1 and g_2, respectively.

Abstract

The estimation of the implied volatility is the one of most important topics in option pricing research. The main purpose of this chapter is to review the different theoretical methods used to estimate implied standard deviation and to show how the implied volatility can be estimated in empirical work. The OLS method for estimating implied standard deviation is first introduced, and the formulas derived by applying a Taylor series expansion method to Black–Scholes option pricing model are also described. Three approaches of estimating

implied volatility are derived from one, two, and three options, respectively. Regarding to these formulas with the remainder terms, the accuracy of these formulas depends on how an underlying asset is close to the present value of exercise price in an option. The formula utilizing three options for estimating implied volatility is more accurate rather than other two approaches.

In empirical work, we use call options on S&P 500 index futures in 2010 and 2011 to illustrate how MATLAB can be used to deal with the issue of convergence in estimating implied volatility of future options. The results show that the time series of implied volatility significantly violates the assumption of constant volatility in Black–Scholes option pricing model. The volatility parameter in the option pricing model fluctuates over time and therefore should be estimated by the time series and cross-sectional model.

Keywords

Implied volatility • Implied standard deviation (ISD) • Option pricing model • MATLAB • Taylor series expansion • Ordinary least squares (OLS) • Black–Scholes model • Options on S&P 500 index futures

90.1 Introduction

The volatility of the return of the underlying asset is the important factor in option pricing model (see Merton 1973; Black and Scholes 1973). However, the standard deviation of the underlying asset return cannot be observed directly (See Merton 1976; Macbeth et al. 1979; Chance 1986). The estimation of the implied volatility of the underlying asset in option framework becomes the one of most important topics in option pricing research. There are two main methods developed in the finance literature to estimate the standard deviation of the underlying asset in option framework: (1) the historical standard deviation and (2) the implied standard deviation (called ISD hereafter) derived from the Black–Scholes' option pricing model framework (See Hull 2011).

Garman and Klass (1980) study the historical standard deviation by using open, high, low prices, and closed prices' data to estimate the standard deviation. To support the use of historical standard deviation for implied standard deviation in option pricing model requires that the underlying asset's rate of return is stationary over the option's life, which contradicts the time-varying standard deviation documented by Schwert (1989).

Since the Black–Scholes' option pricing model is a nonlinear equation, an explicit analytic solution for the ISD is not available in the literature (except for at-the-money call), and numerical methods are used to approximate the ISD (see Latane and Rendleman 1976; Beckers 1981; Manaster and Koehler 1982; Brenner and Subrahmanyam 1988; Lai et al. 1992; Chance 1996; Hallerback 2004; Corrado and Miller 1996, 2004; Li 2005). The derivation and use of the ISD for an option as originated by Latane and Rendleman (1976) have become a widely used methodology for variance estimation. By applying the Newton-Raphson method, Manaster and Koehler (1982) provide an iterative algorithm for the ISD. Brenner and Subrahmanyam (1988) applied Taylor series expansion at zero base to the cumulative normal function in pricing Black–Scholes option pricing model up to the first-order term and set the underlying asset price to equal the present value of exercise price to solve the ISD. Lai et al. (1992) derive a closed-form solution for the ISD in terms of the delta $\partial C/\partial S$ and $\partial C/\partial E$. Following the same approach as Brenner and Subrahmanyam, Corrado and Miller (1996, 2004) utilize the cumulative normal function at zero to the first-order term to derive a quadratic equation of the ISD. Then the ISD can be obtained by solving the quadratic equation. Hallerback (2004) also derives an improved formula, which is similar to Corrado and Miller's formula (1996), to compute the ISD. Later, Li (2005) bases on Brenner and Subrahmanyam's approach to expand the expression to third-order term and solve for the ISD with a cubic equation. Since Li includes third-order term in the Taylor expansion on the cumulative normal distribution in his derivation, Li claims that his formula of ISD provides a consistently more accurate estimate of the true ISD than that of Brenner and Subrahmanyam's formula.

However, the fact that there are as many estimated ISD of an underlying asset as the number of different exercise price in options violates the constant variance assumption used in deriving the Black–Scholes' option pricing model. Chance (1996) assumes different exercise prices result in different ISDs, which violate the constant variance assumption used in deriving the Black–Scholes' option pricing model. Under the existence of a call at-the-money assumption, Chance uses Brenner and Subrahmanyam's formula to calculate the at-the-money's ISD. Chance then applies Taylor series expansion to the difference of the call options in terms of the first and the second-order terms. The drawback of Chance's method is the constraint of the use only for at-the-money option price. In other words, if the underlying asset price deviates from the present value of the exercise price and the call option price is not available (or unobservable) in the market, then Chance's formula for the ISD may not apply. Later, Ang et al. (2009, 2012) relax the constraint in Chance's method and develop three formulas which depend on a Taylor series expansion and utilize single, two, and three options, respectively, to estimate implied volatility.

The purpose of this chapter is to review the different theoretical methods used to estimate ISD and to show how the implied volatility can be estimated in empirical work. We use the data from options on S&P 500 index futures in 2010 and 2011 to illustrate how MATLAB can be used to deal with the issue of convergence in estimating implied volatility of options on index futures. This chapter is organized as follows. In Sect. 90.2, we review the OLS method used in estimation of the ISD in Black–Scholes' option pricing model and expand this method to estimate the implied volatility of the underlying asset for options on the index futures. Then, in Sect. 90.3, we introduce the formulas of implied volatility developed by Ang et al. (2012) which apply a Taylor series expansion to the Black–Scholes option pricing model. The process and results of empirical work on estimating ISD for options on S&P 500 index futures are shown in Sect. 90.4. Finally, Sect. 90.5 represents the conclusions of this study.

90.2 Estimating the Implied Standard Deviation with OLS Method

Black and Scholes (1973) and Merton (1973) derive the European call option pricing model on a stock as follows:

$$\begin{aligned} C &= SN(d_1) - Ke^{-r\tau}N(d_2) \\ d_1 &= [1\text{n}(S/K) + (r+\sigma^2/2)\tau]/\sigma\sqrt{\tau} \\ d_2 &= d_1 - \sigma\sqrt{\tau}, \end{aligned} \tag{90.1}$$

where C is the call premium, S is the underlying stock price, K is the exercise price, r is the instantaneous risk-free rate, τ is the time to the maturity, σ is the standard deviation of the underlying asset rate of return on annual basis, and N(x) is the standard cumulative normal distribution function up to x.

The sensitivities, or first partial derivatives, of the call option formula in Eq. 90.1 with respect to the change of the volatility of the underlying stock can be derived as

$$\frac{\partial C}{\partial \sigma} = S\sqrt{\tau}N'(d_1) = \frac{S\sqrt{\tau}}{S\sqrt{2\pi}}e^{-d_1^2/2} \tag{90.2}$$

where N′(x) is the standard normal probability density function at value x. Equation 90.2 shows the positive relationship between the call option price and the volatility of the underlying stock. Since a call option has no downside risk (except for its cost), increasing risk of the underlying stock simply enlarges the probability that the option will end up in the money by expiration (hence, with a larger intrinsic value).

The OLS method for estimating implied standard deviation is first proposed by Whaley (1982). Although Whaley's original intent for this method was to improve upon the existing weighting techniques, his ordinary least squares (OLS) approach can also be used to derive the implied standard deviations (ISD) for call options. To begin the development of his method, Whaley applies a Taylor series expansion around some initial value of the standard deviation and omits higher-order terms. Mathematically, this is expressed as

$$C_{j,t}^M = C_{j,t}^T(\sigma_0) + \left(\frac{\partial C_{j,t}^T}{\partial \sigma}\bigg| \sigma = \sigma_0\right)(\sigma_s - \sigma_0) + e_{j,t}, \tag{90.3}$$

$$(j = 1, 2, \ldots, \text{J})$$

where $C_{j,t}^M$ denotes the market price for the option j at time t, $C_{j,t}^T$ is the theoretical model price estimated by Eq. 90.1 for the option j at time t based on an estimated value for the ISD (σ_0), σ_0 is the estimated ISD evaluated from some initialization value up to some minimum level of tolerance of error, σ_{s} denote the true or actual

ISD which we are looking for, and $e_{j,t}$ is the random disturbance term for option j at time t. By rearranging Eq. 90.3, we can obtain

$$\left[C^M_{j,t} - C^T_{j,t}(\sigma_0)\right] + \sigma_0\left(\frac{\partial C^T_{j,t}}{\partial\sigma}\bigg|\sigma = \sigma_0\right) = \sigma_s\left(\frac{\partial C^T_{j,t}}{\partial\sigma}\bigg|\sigma = \sigma_0\right) + e_{j,t} \qquad (90.4)$$
$$(j = 1, 2, \ldots, \mathrm{J})$$

since $C^M_{j,\,t}$ is observable in market $\left(\frac{\partial C^T_{j,t}}{\partial\sigma}\Big|\sigma = \sigma_0\right)$ and $C^T_{j,\,t}(\sigma_0)$ can be evaluated at any given value σ_0 by using Eqs. 90.1 and 90.2.

Whaley (1982) then applies OLS, which minimizes the sum of squared residuals, to achieve a single, weighted σ from the options on a particular stock. The actual estimation procedures begin from a linearization of the option pricing model around 0, and then OLS is applied to Eq. 90.4. The process thus proceeds in an iteration manner until the estimated ISD $\hat{\sigma}_s$ satisfies an acceptable tolerance of

$$\left|\frac{\hat{\sigma}_s - \sigma_0}{\sigma_0}\right| < Q, \qquad (90.5)$$

where Q is a small positive number where Whaley(1982) uses Q equal to 0.0001 as the acceptable tolerance of estimated error and $\hat{\sigma}_s$ is the estimate for the true ISD σ_s for the market option price. If the tolerance criterion is not satisfied, $\hat{\sigma}_s$ becomes the new initialization value and the OLS procedure is repeated.

The OLS method also can be applied to estimate the ISD for options on index future with the similar procedure of a Taylor series expansion (See Wolf 1982; Park et al. 1985; Ramaswamy et al. 1985; Brenner et al. 1985). The call options on index future derived by Black (1975, 1976) are given by

$$\begin{aligned} C^F_t &= e^{-r\tau}[F_t N(d_3) - KN(d_4)] \\ d_3 &= \left[1\mathrm{n}(F_t/K) + \left(\sigma_f^2/2\right)\tau\right]/\sigma_f\sqrt{\tau} \\ d_4 &= d_3 - \sigma_f\sqrt{\tau}, \end{aligned} \qquad (90.6)$$

where C^F_t is the model price for a call option on index future at time t, F_t is the underlying index future price at time t, K is the exercise price of the call option on index future, τ is the option's remaining time to maturity in terms of a year, r is the continuous annualized risk-free rate, σ_f^2 is the instantaneous variance of returns of the underlying index future contract over the remaining life of the option, and N(x) is the standard cumulative normal distribution function up to x.

There is similar procedure with Whaley's method to calculate the ISD for options on S&P 500 index futures. The ISD is obtained by first choosing an initial estimate, σ_0, and then using Eq. 90.7 to iterate towards the correct value as follows:

$$C^F{}_{t,j} - C^F{}_{t,j}(\sigma_0) = (\sigma_1 - \sigma_0)\left(\frac{\partial C^F_{j,t}}{\partial\sigma}\bigg|\sigma = \sigma_0\right), \qquad (90.7)$$

where $C^F{}_{t,j}$ denotes the market price of call option j at time t, $C^F{}_{t,j}$ (σ_0) is the theoretical price of call option j at time t given σ equal to $\sigma_{0,}$ σ_0 is the initialized estimate of the ISD, σ_1 = estimate of the true ISD from iteration, $\left(\frac{\partial C^F_{t,j}}{\partial \sigma}\middle| \sigma = \sigma_0\right)$ is the partial derivative of the call option on index future with respect to the standard deviation evaluated at a $\sigma_{0.}$ In the context of the Black (1976) option pricing model, the partial with respect to the standard deviation of the underlying index future can be expressed explicitly as

$$\frac{\partial C^F_{t,j}}{\partial \sigma} = F_t e^{-r\tau}\sqrt{\tau}N'(d_3) = F_t e^{-r\tau}\frac{\sqrt{\tau}}{\sqrt{2\pi}}e^{-d_3^2/2}, \tag{90.8}$$

where d_3 is defined as in Eq. 90.6 and N′(x) is the standard normal probability density function at value x. The partial derivative formula in Eq. 90.8 is also called Vega of a call option on index futures which is represented the rate of change of the value of a call option on index futures with respect to the volatility of the underlying index futures. The iteration proceeds by reinitializing σ_0 to equal σ_1 at each successive stage until an acceptable tolerance level in Eq. 90.5 is attained.

90.3 Estimating the Implied Standard Deviation with Taylor Series Expansion Method

In this section, we first introduce the exact closed-form solution in for the ISD under the condition that the underlying asset price equals the present value of the exercise price. Then we discuss Ang et al.'s (2012) alternative formulas to estimate the ISD by applying a Taylor series expansion to the Black–Scholes option pricing model under the relaxation of the previous restrictive condition.

When the underlying stock price equals the present value of the exercise price (i.e., $S = Ke^{-r\tau}$), the Eq. 90.1 can be reduced as follows:

$$\begin{aligned} C &= S[N(\sigma\sqrt{\tau}/2) - N(-\sigma\sqrt{\tau}/2)] \\ &= S[1 - 2N(-\sigma\sqrt{\tau}/2)] \\ &= S[2N(\sigma\sqrt{\tau}/2) - 1]. \end{aligned} \tag{90.9}$$

Based on the characteristics of existence and uniqueness of the inverse cumulative normal distribution, an exact closed-form solution for the ISD in Eq. 90.9 can be derived as

$$\sigma\sqrt{\tau} = 2N^{-1}[(S + C)/(2S)]. \tag{90.10}$$

Ang et al. (2012) apply Taylor's formula to the cumulative normal functions in Eq. 90.1 at base $\ln(S/Ke^{-r\tau})/(\sigma\sqrt{\tau})$ up to the second-order terms, then the

European call option in Eq. 90.1 can be rearranged as a quadratic equation of $\sigma\sqrt{\tau}$ plus the remainder term as follows[1]:

$$\begin{aligned}&\sigma^2\tau[4(S+Ke^{-r\tau})-(S-Ke^{-r\tau})\ln(S/Ke^{-r\tau})]-4\sigma\sqrt{\tau}\sqrt{2\pi}(2C-S+Ke^{-r\tau})\\&+8\ln(S/Ke^{-r\tau})\left[(S-Ke^{-r\tau})\left(1+(\ln(S/Ke^{-r\tau})/4)^2\right)-(S+Ke^{-r\tau})\ln(S/Ke^{-r\tau})/4\right]+\varepsilon=0.\end{aligned} \tag{90.11}$$

Dropping the remainder term ε, the ISD can be obtained by solving the root of quadratic equation function in Eq. 90.11. Since Ang et al. (2012) utilize four times of a Taylor series expansion method to derive the quadratic function of a European call option and the remainder terms are omitted, the ISD calculated by Eq. 90.11 is not an exact formula. Therefore, the effectiveness of using Eq. 90.11 to estimate the ISD depends on the deviation of the underlying stock price (S) from the present value of exercise price ($Ke^{-r\tau}$).

Moreover, Ang et al. (2012) derive the second alternative formula for estimating ISD by using two call options,C_1 and C_2, on the same underlying stock but at different exercise, K_1 and K_2, respectively (here we assume $K_1 < K_2$). By applying Taylor series expansion to Eq. 90.1 for two call options at K_2 for C_1 and at K_1 for C_2, respectively, we can obtain
