Linear programming has been applied to capital budgeting problems such as maximizing NPV with a single objective. However, the linear programming approach has limitations in handling multiple conflicting real-world goals. For instance, linear programming cannot solve the problem in which a firm ties to maximize overall profits and total market share simultaneously. This dilemma is overcome by a technique called multiple-criteria (MC) linear programming (Goicoechea et al. 1982; Steuer 1986; Yu 1985; Zeleny 1974). To extend the framework of MC linear programming, Sieford and Yu (1979) and Yu (1985) formulated a model of MC^2 linear programming. This model is based on two premises. First, from the linear system structure's perspective, the criteria and constraint levels may be interchangeable. Thus, like multiple criteria, multiple-constraint (resource availability) levels can be considered. Second, from the application's perspective, it is more realistic to consider multiple resource availability levels (discrete right-hand sides) than a single resource availability level in isolation. This recognizes that the availability of resources can fluctuate depending on the decision situation forces, such as the preferences of the different managers. The concept of multiple resource levels corresponds to the typical characteristic of capital budgeting situations where the decision-making process should reflect each manager's preference on the new project. A theoretical connection between MC linear programming and MC^2 linear programming can be found in Gyetvan and Shi (1992) and decision problems related to MC^2 linear programming have been extensively studied (see, e.g., Lee et al. (1990), Shi (1991), and Shi and Yu (1992)). Key ideas of MC^2 linear programming, as a primary theoretical foundation of this article, are described as follows.

An MC^2 linear programming problem can be formulated as

$$\max \lambda^t C_x$$

$$\text{s.t. } A_x \leq D\gamma$$

$$x \geq 0$$

where $C \in R^{qxn}$, $A \in R^{mxn}$, and $D \in R^{mxp}$ are matrices of qxn, mxn, and mxp dimensions, respectively; $x \in R^n$ are decision variables; $\lambda \in R^q$ is called the criteria parameter; and $\gamma \in R^p$ is called the constraint level parameter. Both (γ, λ) are assumed unknown.

The above MC^2 problem has q criteria (objectives) and p constraint levels. If the constraint level parameter γ is known, then the MC^2 problem reduces to an MC linear programming problem (e.g., Yu and Zeleny 1975). In addition, if the criteria parameter λ is known, it reduces to a linear programming problem (e.g., Charnes and Cooper 1961; Dantzig 1963).

Denote the index set of the basic variables $\{x_{j1}, \ldots, x_{jm}\}$ for the MC^2 problem by $J = \{j_1, \ldots, j_m\}$. Note that the basic variables may contain some slack variables. Without confusion, J is also called a basis for the MC^2 problem. Since a basic solution J depends on parameters (γ, λ), define that (1) a basic solution J is feasible for the MC^2 problem if and only if there exists a $\gamma^0 > 0$ such that J is a feasible solution for the MC^2 problem with respect to γ^0 and (2) J is potentially optimal for the MC^2 problem if and only if there exist a $\gamma^0 > 0$ and a $\lambda^0 > 0$ such that J is an optimal solution for the MC^2 problem with respect to (γ^0, λ^0). For an MC^2 problem, there may exist a number of potentially optimal solutions $\{J\}$ as parameters (γ, λ) vary depending on decision situations. Seiford and Yu (1979) derived a simplex method to systematically locate the set of all potentially optimal solutions $\{J\}$.

In summary, a model within the framework of AHP and MC^2 is proposed to formulate and solve the multiple-objective capital budgeting problems with multiple decision makers as follows. Note that because of complexity of the problem, we employed AHP to derive weights of λ and γ. This solution procedure decreases computational complexity.

29.5.1.3 A Model of MC^2 Decision-Making Capital Budgeting

The linear programming approach has limitations for solving real-world problems with multiple objectives. The goal programming or MOLP approach provides only one optimal trade-off among several objectives of the firm. None of the past mathematical models supports multiple decision makers in a capital budgeting decision-making process. As discussed before, in a real-world situation, the decision makers (DMs) can have different opinions on the same issue. These different interpretations can be represented by different constraint levels in mathematical models. Because both linear programming and goal programming presume a fixed single constraint level, they fail to mathematically describe such an organizational differentiation problem.

The MC^2 linear programming framework can resolve the above shortcomings in current capital budgeting models. The framework is flexible enough to include any objectives depending on problem situation. However, for the sake of clear presentation, we address four groups of objectives that are common in capital budgeting: (1) maximization of net present value, (2) profitability, (3) growth, and (4) flexibility of financing. Some group objectives may have multi-time periods. Net present value measures the expected net monetary gain or loss from a project by discounting all expected future cash flows to the present point in time, using the desired rate of return. If we want to incorporate risk factors, we can estimate the standard deviation of net cash flows as Hillier (1963) suggested. Profitability can be measured by return on investment (ROI). Growth can be measured by sales growth or a nonfinancial measure of market share growth, each of which focuses on the long-term success of a firm. Flexibility of financing (leverage) can be measured by the debt to equity ratio. As a firm's debt to equity ratio goes up, the firm's cost of borrowing becomes more expensive. Even though our model contains only these four specific objective groups, the flexibility of the modeling process fits in all capital budgeting problems with multiple-criteria and multiple-constraint levels.

This model integrates AHP with a mathematical model. The strengths of such an integration have been shown in several areas (e.g., advertisement media choice (Dyer and Forman 1991), R&D portfolio selection (Suh et al. 1993), and telecommunication hub design (Lee et al. 1995)). The use of both AHP and MC^2, as we will explore in this article, is the first in the decision-making literature.

In general, let i be the time period for a firm to consider capital budgeting and j be the index number of the projects that the firm can select.

Define x_j as the jth project that can be selected by the firm, $j = 1, \ldots, t$. For the coefficients of the objectives, let v_j be the net present value generated by the jth project; g_{ij} be the net sales increase generated by the jth project in the ith time period to measure sales growth, $i = 1, \ldots,$ s; r_{ij} be the ROI generated from the jth project in the ith time period; and l_{ij} be the firm's equity to debt ratio in the ith time period after jth project is selected to measure liquidity. Here, the optimum debt to equity ratio for the firm is assumed to be 1 and the inverse of debt to equity ratio is used to measure leverage. For the coefficients of the constraints, let b_{ij} be the cash outlay required by the jth project in the ith time period. For the coefficients of the constraint levels, let C_{ki} be the budget availability level believed by the kth manager (or executive) for the firm in the ith time period, $k = 1, \ldots, u$.

In this article, for illustration, if we treat $t = 10$, $i = 5$, and $u = 5$, then the model is

$$\max \sum_{j=1}^{10} v_j X_j$$

$$\max \sum_{j=1}^{10} g_{ij} X_j \ \forall i = 1, \ldots, 5$$

$$\max \sum_{j=1}^{10} r_{ij} X_j \ \forall i = 1, \ldots, 5$$

$$\max \sum_{j=1}^{10} l_{ij} X_j \ \forall i = 1, \ldots, 5$$

$$\text{subject to} \sum_{j=1}^{10} b_{ij} X_j \le (c_{li}, \ldots, c_{5i}) \ \forall i = 1, \ldots, 5$$

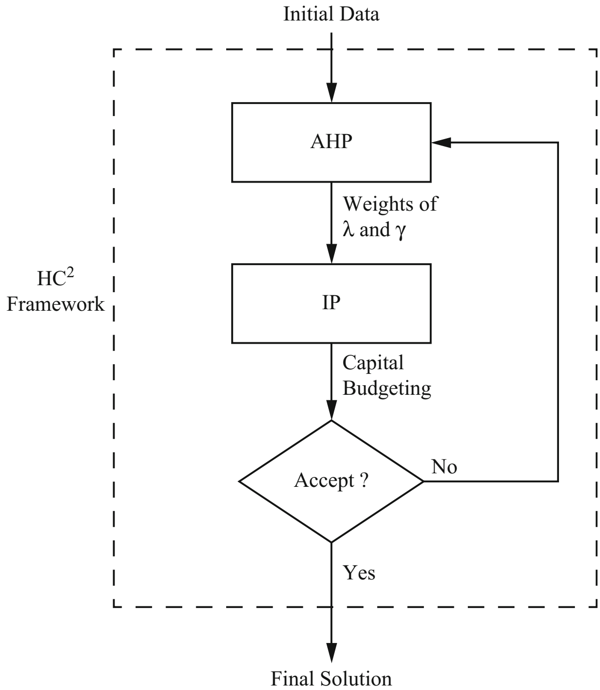
$$\text{and } X_j = \{0, 1\}$$

where $k = 1, \ldots, 5$, for c_{ki}, represents the five possible DMs (i.e., president, controller, production manager, marketing manager, and engineering manager). The weights of 16 total objectives can be expressed by $(\lambda_1, \ldots, \lambda_{16})$ with $\Sigma\lambda_q = 1$, $q = 1, \ldots, 16$, $0 < \lambda_q < 1$, and the weights of five DMs can be expressed by $(\lambda_1, \ldots, \lambda_5)$ with $\Sigma\gamma_k = 1$, $k = 1, \ldots, 5$, $0 < \gamma_k < 1$.

The above model is an integer MC^2 problem with 16 objectives and five constraint levels. Solving this problem by using a currently available solution technique (Seiford and Yu 1979) is not a trivial task because of its substantial computational complexity. To overcome this difficulty, we propose a two-phased solution procedure as depicted in Fig. 29.6.

The first phase is referred to as the AHP phase in the sense that AHP is applied to derive weights of λ and γ, which reduces the model's complexity. The computation of weights is effectively handled by Expert Choice (Forman et al. 1985), commercial software for AHP. In this phase, we first induce preferences about objectives from all five DMs involved. Note that each DM may have different preferences about the four goals. The president may think maximization of ROI is the most important goal, while the controller may think maximization of NPV is the most important goal. AHP generates relative weights for each goal. Then, multiple-constraint levels are incorporated using the MC^2 framework. For instance, DMs may estimate different budget availability levels for each time period. The controller may believe that \$40 million is available for the first year, while the production manager may believe that the company can spend \$50 million for this time period. This scenario is more realistic if we consider the characteristics of

Fig. 29.6 A two-phased capital budgeting model



a capital budgeting problem from the perspective of the different utility functions or risk factors of each DM. An example using AHP to generate relative weights for the five DMs' constraint levels (preferences) can be found in Appendix 1.

The second phase is called the integer programming (IP) phase. After applying the AHP phase to the model, the model is reduced to a linear IP problem, in which the potentially optimal projects must be selected. To solve this problem, we employ the ZOOM software (Singhal et al. 1989) that was originally introduced for solving zero-one integer linear programming problems.

29.5.2 Model Implications

29.5.2.1 Numerical Example

A prototype of our capital budgeting model demonstrates the implications for multiple criteria and multiple decision makers. We use a Lorie-Savage (1955) type of problem as follows. The Lorie-Savage Corporation has ten projects under consideration. All projects have 5-year tune periods.

The executives (president, controller, production manager, marketing manager, and engineering manager) agree on the fallowing multiple objectives:

1. Maximize net present value of each project. Net present value is computed as the sum of all the discounted, estimated future cash flows, using the desired rate of return, minus the initial investment.

Table 29.7 Net present value data for the Lorie-Savage Corporation (in millions)

		Cash outlays for each period				
Project	Net present value	Period 1	Period 2	Period 3	Period 4	Period 5
1	$20	$24	$16	$6	$6	$8
2	16	12	10	2	5	4
3	11	8	6	6	6	4
4	4	6	4	7	5	3
5	4	1	6	9	2	3
6	18	18	18	20	15	15
7	7	13	8	10	8	8
8	19	14	8	12	10	8
9	24	16	20	24	16	16
10	4	4	6	8	6	4

2. Maximize the growth of the firm due to each project. Growth can be measured by net sales increase from each project. This can measure a strategic success factor of a firm.
3. Maximize the profitability of the company. Profitability can be measured by ROI for each time period generated by each project.
4. Maximize the flexibility of financing. The flexibility of financing (leverage) can be measured by debt to equity ratio. If a firm's debt to equity ratio *is* higher than the industry average or the optimum level, the firm's cost of debt financing will become more expensive. In this example, we use the inverse of the debt to equity ratio and assume 1 as the optimum debt to equity ratio.

The data related to these objectives is given in Table 29.7. In this example, all projects are assumed to be independent. In Table 29.7, the firm's cost of capital is assumed to be known a priori and to be independent of the investment decisions. Based on these assumptions, the net present value of each project can be defined as the sum of the cash flows discounted by the cost of capital. Cash outlay is the amount of expenditure required for project $j, j = 1, 2, 3, \ldots, 10$, in each time period.

To measure growth, the net sales increase for each time period for each project is estimated. These data are provided in Table 29.8.

To measure the profitability of each project, ROI is estimated after reflecting additional income and capital expenditures from each investment for each time period. These data are provided in Table 29.9.

To measure leverage, the inverse of debt to equity ratio is used after adopting each project. Here, the optimum debt to equity ratio is assumed to be one for the Lorie-Savage Corporation. These data are provided in Table 29.10.

The five key DMs in this company (president, controller, production manager, marketing manager, and engineering manager) have different beliefs regarding resource availability. For example, for budget availability levels, each DM may have a different opinion. Of course, the president will make the final decision based on the opinions of other managers. However, the DMs' preferences of collection process should improve the quality of the final decision. Budget availability level data are provided in Table 29.11.

Table 29.8 Net sales increase data for the Lorie-Savage Corporation (in millions)

	Net sales increase for each project				
Project	Period 1	Period 2	Period 3	Period 4	Period 5
1	$120	$130	$145	$150	$170
2	100	120	140	150	160
3	80	90	95	95	100
4	40	50	50	55	60
5	40	45	50	55	60
6	110	120	140	150	165
7	60	70	65	70	80
8	110	120	100	110	120
9	150	170	180	190	200
10	35	40	40	50	50

Table 29.9 Return on investment data for the Lorie-Savage Corporation (in percentage)

	Return on investment for each project				
Project	Period 1	Period 2	Period 3	Period 4	Period 5
1	10	12	14	15	17
2	10	12	18	16	17
3	12	15	15	15	18
4	8	15	10	8	12
5	15	10	8	20	18
6	12	12	10	15	15
7	8	12	10	12	12
8	14	16	13	15	16
9	12	10	9	12	12
10	10	8	9	8	12

Table 29.10 Debt to equity data for the Lorie-Savage Corporation

	Inverse of debt to equity ratio				
Project	Period 1	Period 2	Period 3	Period 4	Period 5
1	0.85	0.90	0.98	0.95	0.95
2	0.90	0.98	0.95	0.95	0.96
3	0.96	0.97	0.98	0.92	0.92
4	0.98	0.95	0.96	0.92	0.95
5	0.90	0.95	0.95	0.98	0.95
6	0.90	0.95	0.94	0.95	0.95
7	0.96	0.98	0.98	0.98	0.98
8	0.96	0.95	0.90	0.92	0.95
9	0.90	0.88	0.85	0.95	0.95
10	0.98	0.95	0.95	0.98	0.95

Table 29.11 Budget availability level data for the Lorie-Savage Corporation (in millions)

	Estimate budget availability				
Decision maker	Period 1	Period 2	Period 3	Period 4	Period 5
President	\$50	\$30	\$30	\$35	\$30
Controller	40	45	30	30	20
Production manager	55	40	20	30	35
Marketing manager	45	30	40	45	30
Engineering	50	40	45	30	35

The parameters for budget availability levels are derived by using AHP. Here, one level of an AHP is used. The aggregated objective function also can be obtained by using AHP. The difference here is that two levels of an AHP must be used to provide preferences for the objective functions. The first level of this AHP corresponds to the four groups of objectives. The second level corresponds to time periods within each objective group. Note that the second level is not required for the objective of maximizing the net present value. Hence, four pairwise comparison matrices are required for eigenvalue computation. More detailed information about the formulation of this problem is presented in the appendix. In sum, the objective function aggregated from the 16 objectives is written as

$$\begin{aligned}\text{Maximize} \quad & 56.34x_1 + 51.74x_2 + 40.54x_3 + 25.43x_4 + 25.44x_5 \\ & + 53.63x_6 + 31.98x_7 + 50.59x_8 + 67.62x_9 + 23.17x_{10}.\end{aligned}$$

The optimum IP solution for this numerical example is selecting projects 2, 3, 4, and 8. This solution reflects the preferences of multiple DMs and satisfies budget constraints. If the DMs are not satisfied with the solution, we have to use AHP to assess and compute new values of weights γ and λ according to Fig. 29.6. This process will terminate whenever all DMs agree to the compromise solution.

29.5.2.2 Managerial Implications

The model and solution procedure proposed in this study have several managerial implications. First, the model integrates the multiple-objective capital budgeting problem with multiple decision makers. The most common problem in a capital investment decision-making situation is how to estimate cash flows and to incorporate the risk factors of decision makers (Hillier 1963; Lee 1993). In our model, we allow multiple-constraint levels to incorporate each DM's preference about budget availability. Neither linear programming nor goal programming models can handle these characteristics.

Second, our model can be applied to solve capital budgeting problems not only with the representation of a complex structure but also with motivational implications. Our method facilitates DMs' participation in order to minimize suboptimization of overall company goals (Locke et al. 1981). The model can aid coordination and synthesis of multiple objectives, some in conflict. This feature can be quite effective in a capital budgeting situation, in which many objectives are contradictory to each other and these objectives can be measured differently by a number of decision participants. This model can foster more autonomous control than any other mathematical programming models by allowing DMs to express their own priority structures and weights.

Third, adoption of the AHP reduces the solution complexity of the resulting MC^2 IP program. The MC^2 IP is a very complex problem to solve. Real-life size MC^2 IP problems are intractable by using current computational technology. Furthermore, the computing software for MC^2 IP is still under development (Shi and Lee 1992). Even though the use of AHP may lose some possible trade-offs among objectives and/or DMs' preferences, the AHP reduces MC^2 IP to a traditional zero-one IP that is much easier to be solved using currently available IF software.

Lastly, our two-phased framework (Fig. 29.6) for capital budgeting problem is highly flexible. The DMs can reach an agreement interactively. For example, alternative budgeting policy can be obtained by providing a different preference matrix of objectives and/or resource availability levels. Furthermore, the two-phased framework may be attempted iteratively until all of the DMs are satisfied with the final budgeting policy.

29.5.3 Conclusions

A decision-making process with a multiple-criteria model has been addressed to solve capital budgeting problems. This model can foster a high-quality decision in capital budgeting under multiple criteria and multiple decision makers. This decision-making strategy reflects each decision maker's preference and limits suboptimization of overall company goals. This method can also better handle real-world problems that may include uncertain factors. By incorporating information from each influential manager, our model is more likely to provide better budgeting solutions than the previous linear programming or goal programming approaches.

There are other research problems remaining to be explored. From a practical point of view, the estimation of future cash flows, determining a firm's cost of capital, measuring intangible benefits, and measuring residual value of assets are still important issues. Models like ours can reduce the chance of an ineffective decision making by incorporating multiple decision makers' preferences. This framework can be applied to other accounting problems, such as cost allocation, audit sampling objectives, and personnel planning for an audit, if the decision variables and formulation are expressed appropriately.

29.6 Conclusions

We have introduced group decision-making tools that can be applied in accounting and finance. By the nature of today's dynamic business environment, there will be more than one decision maker and business conditions keep changing. We showed

AHP and MC^2 applications in performance evaluation, banking performance evaluation, international transfer pricing, and capital budgeting. Our last paper shows the combination of AHP and MC^2 in capital budgeting to deal with multiple objectives and multiple constraints.

Our performance evaluation model shows advantages such as flexibility, feedbacks, group evaluation, and computing simplicity. A prototype was built via a personal computer so that the model can be applied to any business situations. The iterative process of getting input data in the AHP procedure helps each manager as well as employee to be aware of the importance of strategic factors of each performance measure of the bank from our second paper. Our transfer pricing model can provide a systematic and comprehensive scenario about all possible optimal transfer prices depending on multiple-criteria and multiple-constraint levels. The trade-offs of optimal transfer prices offer a broad basis for managers of a corporation to flexibly implement the optimal transfer pricing strategy and cope with various business situations. Furthermore, this method also aids global optimization, division autonomy, and performance evaluation. Our last paper shows that our capital budgeting model is more likely to provide better budgeting solutions than the previous approaches by incorporating information from each influential manager.

Appendix 1

For illustrative purposes, we show how to use AHP to induce the five DMs' preferences of budget availability and to compute the relative weights. Generally, AHP collects input judgments of DMs in the form of a matrix by pairwise comparisons of criteria (i.e., their budget availability levels). An eigenvalue method is then used to scale weights of such criteria. That is, the relative importance of each criteria is computed. The result from all of pairwise comparison is stored in an input matrix as follows:

$$\begin{array}{c} \begin{array}{ccccc} \text{President} & \text{Controller} & \begin{array}{c}\text{Production}\\ \text{Manager}\end{array} & \begin{array}{c}\text{Marketing}\\ \text{Manager}\end{array} & \begin{array}{c}\text{Engineering}\\ \text{Manager}\end{array} \end{array} \\ \begin{bmatrix} 1 & 3 & 4 & 5 & 6 \\ & 1 & 2 & 5 & 5 \\ & & 1 & 3 & 4 \\ & & & 1 & 2 \\ & & & & 1 \end{bmatrix} \end{array}$$

Applying an eigenvalue method to the above input matrix results in a vector $W_i = (0.477, 0.251, 0.154, 0.070, 0.048)$. In addition to the vector, the inconsistency ratio (γ) is obtained to estimate the degree of inconsistency in pairwise comparisons. In this example, the inconsistency ratio is 0.047. A common guideline is that if the ratio surpasses 0.1, a new input matrix must be generated. Therefore, this input matrix is acceptable.

A similar computing process can be applied for the 16 objective functions. However, two hierarchical levels are required for this case. The first level of AHP corresponds to the four groups of objectives and the second level corresponds to the time periods within each objective group.

Let x_j be the jth project that can be selected by the firm. Using data in Tables 29.7, 29.8, 29.9, and 29.10, the model for capital budgeting with multiple criteria and multiple DMs is formulated as

$$\text{maximize} \quad 20x_1 + 16x_2 + 11x_3 + 4x_4 + 4x_5 + 18x_6 + 7x_7 + 9x_8 + 24x_9 + 4x_{10}$$

$$\text{maximize} \quad 120x_1 + 100x_2 + 80x_3 + 40x_4 + 40x_5 + 110x_6 + 60x_7 + 110x_8 + 150x_9 + 35x_{10}$$

$$\text{maximize} \quad 130x_1 + 120x_2 + 90x_3 + 50x_4 + 45x_5 + 120x_6 + 70x_7 + 120x_8 + 170x_9 + 40x_{10}$$

$$\text{maximize} \quad 145x_1 + 140x_2 + 95x_3 + 50x_4 + 50x_5 + 140x_6 + 65x_7 + 100x_8 + 180x_9 + 40x_{10}$$

$$\text{maximize} \quad 150x_1 + 150x_2 + 95x_3 + 55x_4 + 55x_5 + 150x_6 + 70x_7 + 110x_8 + 190x_9 + 50x_{10}$$

$$\text{maximize} \quad 170x_1 + 160x_2 + 100x_3 + 60x_4 + 60x_5 + 165x_6 + 80x_7 + 120x_8 + 200x_9 + 50x_{10}$$

$$\text{maximize} \quad 10x_1 + 10x_2 + 12x_3 + 8x_4 + 15x_5 + 12x_6 + 8x_7 + 14x_8 + 12x_9 + 10x_{10}$$

$$\text{maximize} \quad 12x_1 + 12x_2 + 15x_3 + 15x_4 + 10x_5 + 12x_6 + 12x_7 + 16x_8 + 10x_9 + 8x_{10}$$

$$\text{maximize} \quad 14x_1 + 18x_2 + 15x_3 + 10x_4 + 8x_5 + 10x_6 + 10x_7 + 13x_8 + 9x_9 + 9x_{10}$$

$$\text{maximize} \quad 15x_1 + 16x_2 + 15x_3 + 8x_4 + 20x_5 + 15x_6 + 12x_7 + 15x_8 + 12x_9 + 8x_{10}$$

$$\text{maximize} \quad 17x_1 + 17x_2 + 8x_3 + 12x_4 + 18x_5 + 15x_6 + 12x_7 + 16x_8 + 12x_9 + 12x_{10}$$

$$\text{maximize} \quad 0.85x_1 + 0.90x_2 + 0.96x_3 + 0.98x_4 + 0.90x_5 + 0.90x_6 + 0.96x_7 + 0.96x_8 + 0.90x_9 + 0.98x_{10}$$

$$\begin{aligned}
\text{maximize}\quad & 0.90x_1 + 0.98x_2 + 0.97x_3 + 0.95x_4 + 0.95x_5 \\
& + 0.95x_6 + 0.98x_7 + 0.95x_8 + 0.88x_9 + 0.95x_{10} \\[2ex]
\text{maximize}\quad & 0.98x_1 + 0.95x_2 + 0.98x_3 + 0.96x_4 + 0.95x_5 \\
& + 0.94x_6 + 0.98x_7 + 0.90x_8 + 0.85x_9 + 0.95x_{10} \\[2ex]
\text{maximize}\quad & 0.95x_1 + 0.95x_2 + 0.92x_3 + 0.92x_4 + 0.98x_5 \\
& + 0.95x_6 + 0.98x_7 + 0.92x_8 + 0.95x_9 + 0.98x_{10} \\[2ex]
\text{maximize}\quad & 0.95x_1 + 0.96x_2 + 0.92x_3 + 0.95x_4 + 0.95x_5 \\
& + 0.95x_6 + 0.98x_7 + 0.95x_8 + 0.95x_9 + 0.95x_{10} \\[2ex]
\text{subject to}\quad & 24x_1 + 12x_2 + 8x_3 + 6x_4 + x_5 \\
& + 18x_6 + 13x_7 + 14x_8 + 16x_9 + 4x_{10} \leq 49.37 \\[2ex]
& 16x_1 + 10x_2 + 6x_3 + 4x_4 + 6x_5 \\

Abstract

This study presents model-based and compensation-based approaches to determining the price-subjective value of employee stock options (ESOs). In the model-based approach, we consider a utility-maximizing model in which the employees allocate their wealth among company stock, a market portfolio, and risk-free bonds, and then we derive the ESO formulas, which take into account illiquidity and sentiment effects. By using the method of change of measure, the derived formulas are simply like those of the market value with altered parameters. To calculate the compensation-based subjective value, we group employees by hierarchical clustering with a K-means approach and back out the option value in an equilibrium competitive employment market.

Further, we test illiquidity and sentiment effects on ESO values by running regressions that consider the problem of standard errors in the finance panel data. Using executive stock options and compensation data paid between 1992 and 2004 for firms covered by the Compustat Executive Compensation Database, we find that subjective value is positively related to sentiment and negatively related to illiquidity in all specifications, consistent with the offsetting roles of sentiment and risk aversion. Moreover, executives value ESOs at a 48 % premium to the Black-Scholes value and ESO premiums are explained by a sentiment level of 12 % in risk-adjusted, annualized excess return, suggesting a high level of executive overconfidence.

Keywords

Employee stock option • Sentiment • Subjective value • Illiquidity • Change of measure • Hierarchical clustering with K-means approach • Standard errors in finance panel data • Exercise boundary • Jump diffusion model

30.1 Introduction

Employee stock options (ESOs) are a popular method of compensation. According to the Compustat Executive Compensation database, the number of option grants increased from roughly 0.25 billion in 1992 to 1.4 billion in 2001. Specifically, in fiscal 2001, 53 % of total pay came from granted options, compared with 33 % in 1992.[1] Moreover, executives receive averagely more than ten thousand options after 1998. ESOs can help firms retain talent and reduce agency costs (Jensen and Meckling 1976). They also mitigate risk-related incentive problems (Agrawal and Mandelker 1987; Hemmer et al. 2000) and provide an alternative to cash compensation, which is especially important for firms facing

[1]The option values are estimated by the calculation in ExecuCompustat database.

financial constraints (Core and Guay 2001). In addition, ESOs attract highly motivated and able employees (Core and Guay 2001; Oyer and Schaefer 2005). All of these factors contribute to the importance of ESOs for corporate governance and finance research.

The illiquidity problem of ESOs cannot be neglected. ESOs usually have a vesting period during which they cannot be exercised, and hence they cannot be redeemed for a fixed period of time. Furthermore, ESOs are generally not publicly traded and their sale is not permitted. Standard methods for valuing options are difficult to apply to ESOs. Because of the illiquidity of ESOs, many employees hold undiversified portfolios that include large stock options of their own firms. Because of the impossibility of full diversification, the value perceived by employees (subjective value) may be quite different from the traded option. We consider the subjective value to be what a constrained agent would pay for the ESOs and the market value to be the value perceived by an unconstrained agent. Many papers address the differences between subjective and market value, each concluding that the subjective value of ESOs should be less than the market value (Lambert et al. 1991; Hall and Murphy 2002; Ingersoll 2006).

If ESOs are generally worth less than market value, why do employees continue to accept and, indeed, sometimes prefer ESO compensation? One reasonable explanation is employee sentiment. Sentiment means positive private information or behavioral overconfidence regarding the future risk-adjusted returns of the firm. Simply, the employee believes that he possesses private information and can benefit from it. Or the employee overestimates the return of the firm and believes ESOs are valuable. Some empirical evidence supports this conjecture. Oyer and Schaefer (2005) and Bergman and Jenter (2007) posit that employees attach a sentiment premium to their stock options; firms exploit this sentiment premium to attract and retain optimistic employees. Hodge et al. (2009) provide survey evidence and find that managers subjectively value the stock option greater than its Black-Scholes value.

Three statistics methods are applied in our ESO study (Chen and Fuh 2011; Chang et al. 2013), including change of measure, hierarchical clustering with a K-means approach, and estimation of standard errors in finance panel data. We derive a solution for ESO value that is a function of both illiquidity and sentiment in a world where employees balance their wealth between the company's stock, the market portfolio, and a risk-free asset. By using the method of change of measure, we find a probability measure and then the ESO formulas are derived easily. In addition, from the ESO pricing formulas, we are able to not only estimate the subjective values but also study the exercise policies. Early exercise is a pervasive phenomenon and, importantly, the early exercise effect is critical in valuation of ESOs, especially for employees who are more risk averse and when there are more restrictions on stock holding.

Applying a comprehensive set of executive options and compensation data, this study empirically determines subjective value, grouping employees by hierarchical clustering with a K-means approach and backing out the option value in an equilibrium competitive employment market. Specifically, we group executives according to position, the firm's total market value, nonoption compensation, and the immediate exercise value of the options for each industry by hierarchical clustering with a K-means approach. We then calculate the empirical value of ESO that each executive places on their ESOs in order for total compensation to be equivalent in the same cluster. Further, we model both illiquidity and sentiment effects and test them with executive options data. We regress the empirical ESO values on the proportion of total wealth held in illiquid firm-specific holdings and sentiment, which is estimated from our pricing formula or Capital Asset Pricing Model (CAPM) risk-adjusted alpha under controlling key options pricing variables such as moneyness, time to maturity, volatility, and dividend payout. As we know, when the residuals are correlated across observations, the standard errors of estimated coefficients produced by Ordinary Least Squares (OLS) may be biased and then lead to incorrect inference. Petersen (2009) compares the different methods used in the literature and gives researchers guidance for their use. The data we collected are from multiple firms over several years. Hence, we consider the problem of standard errors in finance panel data and run the regressions, including standard errors clustered by firm, year, and both firm and year.

The remainder of this chapter is organized as follows. Section 30.2 introduces some preliminary knowledge. Section 30.3 develops our model and addresses the approaches to price-subjective value of ESOs. Section 30.4 presents the simulation results. Section 30.5 shows the empirical study; Sect. 30.6 concludes the chapter.

30.2 Preliminary Knowledge

30.2.1 Change of Measure

In our ESO study, we assume stock price follows a jump-diffusion process. Here, we briefly introduce change of measure for a compound Poisson and Brownian motion. Suppose that we have a probability space $(\Omega, \mathcal{F}, \mathbb{P})$ on which is defined a Brownian motion W_t. Suppose that on this same probability space there is defined a compound Poisson process

$$Q_t = \sum_{i=0}^{N_t} Y_i$$

with intensity λ and jumps having density function $f(y)$. Assume that there is a single filtration $\mathcal{F}_t$, $t \geq 0$, for both the Brownian motion and the compound Poisson process. In this case, the Brownian motion and compound Poisson process must be independent (see Shreve 2008).

Let $\widetilde{\lambda}$ be a positive number, let $\widetilde{f}(y)$ be another density function with the property that $\widetilde{f}(y) = 0$ whenever $f(y) = 0$, and let $\Theta(t)$ be an adapted process. We define

$$Z_1(t) = \exp\left\{-\int_0^t \Theta(u)dW_u - \frac{1}{2}\int_0^t \Theta^2(u)du\right\},$$

$$Z_2(t) = e^{\left(\lambda-\widetilde{\lambda}\right)t}\prod_{i=0}^{N_t}\frac{\widetilde{\lambda}\widetilde{f}(Y_i)}{\lambda f(Y_i)},$$

$$Z(t) = Z_1(t)Z_2(t).$$

It can be verified that the process $Z(t)$ is a martingale.

Lemma 30.1 *Define* $\widetilde{\mathbb{P}}(A) = \int_A Z(T)d\mathbb{P}$ *for all* $A \in \mathcal{F}$. *Under the probability measure* $\mathbb{P}$, *the process*

$$\widetilde{W}_t = W_t + \int_0^t \Theta(s)ds$$

is a Brownian motion, Q_t *is a compound Poisson process with intensity* $\widetilde{\lambda}$ *and independent, identically distributed jump sizes having density* $\widetilde{f}(y)$, *and the processes* $\widetilde{W}_t$ *and* Q_t *are independent.*

The proof of Lemma 30.1 is presented by Shreve (2008). This lemma is useful for us to derive the ESO formula in Sect. 30.3.

30.2.2 Hierarchical Clustering with K-Means Approach

The main assumption of the compensation-based subjective value is that all executives within the same group receive the same total compensation. For each executive in the group, the implied subjective value is derived by comparing the difference between nonoption compensation and the average compensation. Grouping executives appropriately is essential in the compensation-based approach.

Clustering is an unsupervised technique for analyzing data and dividing patterns (observations, data items, or feature vectors) into groups (clusters). There are two kind of clustering algorithms: hierarchical and partitional approaches. Hierarchical methods produce a nested structure of partitions, whereas partitional methods produce only one partition (Jain et al. 1999).

Hierarchical clustering algorithms repeat the cycle of either merging smaller clusters into larger ones or dividing larger clusters to smaller ones. An agglomerative clustering strategy uses the bottom-up approach of merging clusters into larger ones, whereas divisive clustering strategy uses the top-down approach of splitting larger clusters into smaller ones. Typically, the greedy approach is used in deciding which larger/smaller clusters are used for merging/dividing. Euclidean distance, Manhattan distance, and cosine similarity are some of the most commonly used metrics of similarity for numeric data. For non-numeric data, metrics such as the Hamming distance are used. It is important to note that the actual observations (instances) are not needed for hierarchical clustering, because only the matrix of distances is sufficient. The user can obtain different clustering depending on the level that is cut.

A partitional clustering algorithm obtains a single partition of the data instead of a clustering structure. A problem accompanying the use of a partitional algorithm is the choice of the number of desired output clusters (usually called k). One of the most commonly used partitional clustering algorithms is the K-means clustering algorithm. It starts with a random initial partition and keeps reestimating cluster centers and reassigning the patterns to clusters based on the similarity between the pattern and the cluster centers. These two steps are repeated until a certain intra-cluster similarity objective function and inter-cluster dissimilarity objective function are optimized. Therefore, sensible initialization of centers is an important factor in obtaining quality results from partitional clustering algorithms.

Hierarchical and partitional approaches each have their advantages and disadvantages. Therefore, we apply a hybrid approach combining hierarchical and partitional approaches in this study.

30.2.3 Standard Errors in Finance Panel Data

In finance panel data, the residuals may be correlated across firms or across time, and OLS standard errors can be biased. Petersen (2009) compares the different methods used in the literature and provides guidance to researchers as to which method should be used.

The standard regression for a panel data is

$$Y_{it} = X_{it}\beta + \epsilon_{it} \quad i = 1, \ldots, N; \;\; t = 1, \ldots, T$$

where there are observations on firms i across years t. X and ϵ are assumed to be independent of each other and to have finite variance. OLS standard errors are unbiased when the residuals are independent and identically distributed. However, it may result in incorrect inference when the residuals are correlated across observations.

In finance study, there are two general forms of dependence: time-series dependence (firm effect), in which the residuals of a given firm may be correlated across years for a given firm, and cross-sectional dependence (time effect), in which the residuals of a given year may be correlated across different firms. Considering the firm effect, the residuals and independent variable are specified as

$$\epsilon_{it} = \gamma_i + n_{it}; \; X_{it} = \mu_i + v_{it}$$

Both the independent variable and the residual are correlated across observations of the same firm but are independent across firms. Petersen (2009) shows that OLS, Fama-MacBeth, and Newey-West standard errors are biased, and only clustered standard errors are unbiased as they account for the residual dependence created by the firm effect.

Considering the time effect, the residuals and independent variable are specified as

$$\epsilon_{it} = \delta_t + \eta_{it};\;\; X_{it} = \zeta_t + v_{it}.$$

OLS standard errors still underestimate the true standard errors. The clustered standard errors are much more accurate, but unlike the results with the firm effect, they underestimate the true standard error. However, the bias in the clustered standard error estimates declines with the number of clusters. Because the Fama-MacBeth procedure is designed to address a time effect, the Fama-MacBeth standard errors are unbiased.

In both firm and time effect, the residuals and independent variable are specified as

$$\epsilon_{it} = \gamma_i + \delta_t + \eta_{it};\;\; X_{it} = \mu_i + \zeta_t + v_{it}.$$

Standard errors clustered by only one dimension are biased downward. Clustering by two dimensions produces less biased standard errors. However, clustering by firm and time does not always yield unbiased estimates. We only introduce the method we use in this study. Readers wanting to know more methods for estimation of standard error in financial panel data should refer to Petersen (2009).

30.3 Employee Stock Options

This section introduces two methods to price the subjective value of ESOs. We call them the model-based approach and the compensation-based approach. To derive the model-based subjective value, we use the technique of change of measure and find a probability measure P^* such that the option value can be generated simply. To calculate compensation-based subjective value, we group employees by hierarchical clustering with a K-means approach and back out the option value in an equilibrium-competitive employment market.

30.3.1 Model-Based Approach to Subjective Value

From Chen and Fuh (2011), we have a three asset economy in which the employee allocates their wealth among three assets: company stock S, market portfolio M, and risk-free bond B. Because of the illiquidity of ESO, the employee is constrained to allocate a fixed fraction α of their wealth to company stock (via some form of ESO). Define the jump-diffusion processes for the three assets as follows:

$$\begin{cases} \dfrac{dS}{S} = \mu_s dt + \sigma_s dW_m + v dW_s + d\sum_{i=0}^{N_t}(Y_i - 1), \\ \dfrac{dM}{M} = (\mu_m - d_m)dt + \sigma_m dW_m, \\ \dfrac{dB}{B} = rdt, \end{cases} \tag{30.1}$$

where $\mu_s = \mu - d - \lambda k$. μ, μ_m, r are instantaneous expected rates of return for the stock, market portfolio, and risk-free bond, respectively. d and d_m are dividends for the stock and market portfolio, respectively. The Brownian motion process W_m represents the normal systematic risk of the market portfolio. The Brownian motion process W_s and jump process N_t are the idiosyncratic risk of the company stock, where N_t captures the jump risk of company stock and follows a Poisson distribution with average frequency λ. $Y_i - 1$ represents the percentage of stock variation when the ith jump occurs. Denote $E(Y_i - 1) = k$ and $E(Y_i - 1)^2 = k_2$ for all i. σ_s and σ_m are the normal systematic portions of total volatility for the stock and the market portfolio, respectively, whereas v is the normal unsystematic volatility of the stock. The two Brownian motions and the jump process are presumed independent. For simplicity, we assume that CAPM holds so that the efficient portfolio is the market.

Following the idea of Ingersoll (2006), we solve the constrained optimization problem and determine the employee's indirect utility function. The marginal utility is then used as a subjective state price density to value compensation. We assume that the employee's utility function $U(\cdot)$ is set as $U(C) = C^\gamma/\gamma$ with a coefficient of relative risk aversion, $1 - \gamma$. The process of the employee's marginal utility or the pricing kernel can be derived as[2]:

$$\begin{aligned} \frac{dJ_W}{J_W} = & -\hat{r}\, dt - \hat{\sigma}\, dW_m - (1-\gamma)\alpha v dW_s \\ & + d\sum_{i=0}^{N_t}\left\{[\alpha(Y_i - 1) + 1]^{\gamma-1} - 1\right\}, \end{aligned} \tag{30.2}$$

where $J_W = \frac{\partial J[W(t), t]}{\partial W(t)}$ is the marginal utility, $J[W(t), t]$ and $W(t)$ are the employee's total utility and wealth at time t, $\hat{r} = r - (1-\gamma)\left(\alpha^2 v^2 + \frac{1}{2}\alpha^2 \gamma \lambda + \alpha \lambda k\right)$, and $\hat{\sigma} = \frac{\mu_m - r}{\sigma_m}$.

The rational equilibrium value of the ESO at time t, $F(S_t, t)$, satisfies the Euler equation

$$F(S_t, t) = \frac{E_t\{J_W[W(T), T]F(S_T, T)\}}{J_W[W(t), t]}, \tag{30.3}$$

where $F(S_T, T)$ is the payoff at the maturity T. To easily calculate the ESO value, we find a probability measure P^* by using change of measure method and then the second equality in the following Eq. (30.4) is satisfied.

[2]Because the process can be similarly derived from Chang et al. (2008), it is omitted.

$$
\begin{aligned}
F(S_t,t) &= \frac{E_t\{J_W[W(T),T]F(S_T,T)\}}{J_W[W(t),t]} \\
&= e^{-r*(T-t)}E_t^*[F(S_T,T)],
\end{aligned}
\tag{30.4}
$$

where $\frac{dP*}{dP} = \frac{Z(T)}{Z(t)}$, $Z(t) = e^{r^*t}J_W[W(t), t]$, r^* is subjective bond yield, and E_t^* is the expectation under P^* and information at time t. Under P^*, the stock process can be expressed as

$$
\frac{dS}{S} = (r^* - d^*)dt + \sigma_N dW_t^* + d\sum_{i=0}^{N_t}(Y_i - 1),
$$

where

$$
\begin{aligned}
r^* &= r - (1-\gamma)\left(\alpha\lambda k + \frac{1}{2}\gamma\lambda k_2\alpha^2 + \alpha^2 v^2\right) \\
&\quad - \lambda(\xi - 1), \\
d^* &= d - (1-\gamma)\left[\alpha\lambda k + \frac{1}{2}\gamma\lambda k_2\alpha^2 - (1-\alpha)\alpha v^2\right] \\
&\quad - \lambda(\xi - 1) + \lambda k, \\
\sigma_N^2 &= \sigma_s^2 + v^2, \lambda^* = \lambda\xi, \xi = E[\alpha(Y_i - 1) + 1]^{\gamma-1},
\end{aligned}
$$

W_t^* is the standard Brownian motion and N_t is a Poisson process with rate λ^*. A detailed explanation is given in Appendix 1.

30.3.1.1 European ESO

First, we consider the simple ESO contract, the European ESO. The price formula is presented in Theorem 30.1.

Theorem 30.1 *The value of the European ESO with strike price K and time to maturity τ, written on the jump-diffusion process in Eq.* (30.1), *is as follows:*

$$
C_E(S_t,\tau) = \sum_{j=0}^{\infty}\frac{(\lambda*\tau)^j e^{-\lambda*\tau}}{j!}C(j) \tag{30.5}
$$

where

$$
\begin{aligned}
C(j) &= \left\{S_t e^{-d^*\tau}E^*\left[\prod_{i=0}^{j}Y_i\Phi\left(d_1^*\right)\right]\right. \\
&\quad \left. -Ke^{-r^*\tau}E^*\left[\Phi\left(d_2^*\right)\right]\right\} \\
d_1^* &= \frac{\ln\left(S_t\prod_{i=0}^{j}Y_i/K\right) + \left(r^* - d^* + \frac{1}{2}\sigma_N^2\right)\tau}{\sigma_N\sqrt{\tau}}, \\
d_2^* &= d_1^* - \sigma_N\sqrt{\tau}.
\end{aligned}
$$

The proof of Theorem 30.1 is in Appendix 2.

30.3.1.2 American ESO

Suppose that the option can be exercised at n time instants. These time instants are assumed to be regularly spaced at intervals of Δt, and denoted by t_i, $0 \leq i \leq n$, where $t_0 = 0$, $t_n = T$, and $t_{i+1} - t_i = \Delta t$ for all i. Denote C_A as the value of the American call option, C_E as the value of the European call option, K as the strike price, and $S_i = S_{t_i}$. The critical price at these time points is denoted by S_i^*, $0 \leq i \leq n$, and is the price at which the agent is indifferent between holding the option and exercising. Denote E_i^* as the expectation under P^* and information at time t_i.

Theorem 30.2 (Chen and Fuh 2011) *The value of the American ESO exercisable at n time instants, when the ESO is not exercised, written on the jump-diffusion process in Eq.* (30.1) *is as follows:*

$$\begin{aligned}
&C_A(S_0,T)\\
&= C_E(S_0,T) + \sum_{\ell=1}^{n-1} e^{-r*\ell\Delta t} E_0^*\Big\{ [S_\ell\big(1-e^{-d*\Delta t}\big)\\
&\quad - K\big(1-e^{-r*\Delta t}\big)]I_{\{S_\ell \geq S_\ell^*\}}\Big\}\\
&\quad - \sum_{j=2}^{n} e^{-r*j\Delta t} E_0^*\Big\{[C_A(S_j,(n-j)\Delta t) - \big(S_j - K\big)]I_{\{S_{j-1}\geq S_{j-1}^*\}} I_{\{S_j<S_j^*\}}\Big\}.
\end{aligned} \tag{30.6}$$

The critical price S_i^* at time t_i for $i = 1, \cdots, n$ is defined as the solution to the following equation:

$$\begin{aligned}
&S_i^* - K\\
&\quad = C_E\big(S_i^*,(n-i)\Delta t\big)\\
&\qquad + \sum_{\ell=1}^{n-i-1} e^{-r^*\ell\Delta t} E_i^*\Big\{\big[S_{i+\ell}\big(1-e^{-d^*\Delta t}\big)\\
&\qquad - K\big(1-e^{-r^*\Delta t}\big)\big]I_{\{S_{i+\ell}\geq S_{i+\ell}^*\}}\Big\}\\
&\qquad - \sum_{j=2}^{n-i} e^{-r^*j\Delta t} E_i^*\Big\{\big[C_A\big(S_{i+j},(n-i-j)\Delta t\big)\\
&\qquad - \big(S_{i+j}-K\big)\big]I_{\{S_{i+j-1}\geq S_{i+j-1}^*\}} I_{\{S_{i+j}<S_{i+j}^*\}}\Big\},
\end{aligned}$$

where $C_E(S_0, T)$ and $C_E(S_i^*, (n-i)\Delta t)$ are calculated in Theorem 30.1.

The value of the American call option, when exercise is allowed at any time before maturity, is obtained by taking the limit as Δt tends to zero in Eq. (30.6).

30.3.1.3 Sentiment Effect

Often, the manager awarded an incentive option may have different beliefs about the company's prospects than the investing public does. The manager believes that they possess private information and can benefit from it. Or they have behavioral overconfidence regarding future risk-adjusted return of their firm and believe ESOs are valuable. We consider the impact of sentiment on ESO values and the exercise decision. Now, the drift term of stock process in Eq. 30.1 becomes $\mu_s = \mu + s - d - \lambda k$, where sentiment level is denoted by s. In other words, the employee overestimates or rationally adjusts the risk-adjusted return of the company owing to inside information by s, then the same analysis in Theorem 30.1 and 30.2 are valid with a simple adjustment in parameters. The adjusted interest rate and dividend yield used in pricing are

$$r^* = r + \alpha s - (1-\gamma)\left(\alpha\lambda k + \frac{1}{2}\gamma\lambda k_2\alpha^2 + \alpha^2 v^2\right) - \lambda(\xi - 1),$$

$$d^* = d - (1-\alpha)s - (1-\gamma)\left[\alpha\lambda k + \frac{1}{2}\gamma\lambda k_2\alpha^2 - (1-\alpha)\alpha v^2\right] - \lambda(\xi - 1) + \lambda k.$$

30.3.2 Compensation-Based Approach to Subjective Value

The subjective value of ESOs implied by total compensation packages is calculated using a hierarchical clustering with K-means methodology to split executives into like groups based on industry, rank, year, the firm market value,[3] nonoption compensation, and the immediate exercise value of the options.[4] The number of groups is decided by a cubic clustering criterion and the average total compensation is calculated. Then, assuming that all executives within the same cluster receive the same total compensation, for each executive in this cluster, the implied subjective value is derived by comparing the difference between nonoption compensation and the average compensation. We then set all negative implied ESO values equal to zero and recalculate average compensation in each cluster with these subjective values, repeating until the relative sum of changes in subjective values in a given cluster is less than 0.01. This eliminates some negative subjective values such that the final number of negative or zero values is about 5.7 % of our dataset. Worth noting is the observation that, even in the first iteration of the process, after grouping, only about 7.9 % of our data has options with a negative or zero value, lending credence to the stability of our groupings.

To illustrate the intuition, presume that all executives within the same cluster receive the same compensation on average, where any differences in salaries, bonuses, and other income should be accounted for by options. If CEOs' average total annual compensation in a given year is three million, a particular CEO who receives one

[3]Gabaix and Landier (2008) finds that total market value as a proxy for firm size has the strongest predictive power on compensation. We, however, redo all tests using number of employees as the size proxy and find qualitatively identical results.

[4]The details of hierarchical clustering with a K-means approach and its performance are presented in Appendix 2.

million in nonoption compensation must then value their options at two million in order to agree to continued employment. Importantly, it may be the case that the market value of these options is only $100,000, but the CEO subjectively values them at $500,000 because they believe the market to have undervalued the options. Although this method of calculation is clearly not perfectly precise, we tried numerous robustness checks by using different grouping criteria, all of which arrived at qualitatively identical results. Some intangible sources of value, such as training, learning opportunities, and advantageous work environments, are not controlled here but may be relatively unimportant given that this is an executive database of listed firms.

30.4 Simulation Results

Section 30.3 provided a pricing formula for ESOs that includes illiquidity of the options and sentiment of the employees. Moreover, from this ESO pricing formula, we can not only estimate the subjective values but also study the exercise policies. The exercise boundary is endogenously derived by finding the minimum stock price such that the option value equals its intrinsic value for each time. In other words, the employee exercises the option when the stock price is above the exercise boundary. To illustrate our model, this section discusses factors that affect ESO values and exercise decisions including stock holding constraint, sentiment, level of risk aversion, moneyness, dividend, time to maturity, total volatility, and normal unsystematic volatility. We also empirically test these effects in next section.

According to the collected data from Compustat, the model parameters stock price S, strike price K, total volatility σ, dividend yield d, interest free rate r, and time to maturity τ are set to 25, 25, 0.3, 2 %, 5 %, 10, respectively. Normal unsystematic volatility v is two-thirds of the total volatility following calibrations applied by Compustat and the majority of papers in the area.[5] We employ the common parameterization for the coefficient of relative risk aversion $1 - \gamma = 2$ and three jump size models: double exponential, bivariate jump, and $Y = 0$ (no residual value).[6] Additionally, default intensity $\lambda = 0.01$, following Duffee (1999) and Fruhwirth and Sogner (2006), which use US and German bond data, respectively.

30.4.1 Exercise Behavior

Employees exercising their ESOs earlier is a pervasive phenomenon. Considering the exercise policies is necessary when studying American ESOs. This is an essential departure from Chang et al. (2008), which considers European-type ESOs. A number

[5]See Bettis et al. (2005), Aggarwal and Samwick (2003), Ingersoll (2006), and Bryan et al. (2000).

[6]The parameters of double exponential are estimated by daily return data from 1992 to 2004. A jump occurs if return goes beyond ± 10 %, which relates to an approximately three-standard deviation daily return during this period.

of papers link early exercise behavior to under-diversification of employees (Hemmer et al. 1996; Core and Guay 2001; Bettis et al. 2005). The problem of valuing ESOs with early exercise is often approximated in practice by simply using the expected time until exercise in place of the actual time to maturity (Hull and White 2004; Bettis et al. 2005). The expected time until exercise is estimated from past experience. However, Ingersoll (2006) mentions that even using an unbiased estimate of the expected time until exercise will not give a correct estimate of the option's value. And this method cannot be used to determine the subjective value because it will be smaller due to the extra discounting required to compensate the lack of diversification.

A proper calculation must recognize that the decision to exercise is endogenous. Liao and Lyuu (2009) incorporate the exercise pattern instead of using the expected time until exercise technique in valuation of ESOs, to which the exercise patterns are under Chi-square distribution assumption and not derived endogenously. Ingersoll (2006) derives the exercise boundaries endogenously, while the exercise policies are restricted constant in time. We extend the method developed in Gukhal (2001), with a modification to include that an agent faces a constrained portfolio problem, and derive the time varying exercise policies endogenously.

Which factors cause employees to exercise their options early? Figure 30.1 compares the exercise boundaries for some factors. Note that exercise boundaries are decreasing function of time in all cases, which are different from the constant exercise policies in Ingersoll (2006). The more restrictions on the stock holding or the more risk averse the employee, the lower the exercise boundary. In other words, because of the impossibility of full diversification, employees who are more restricted on the stock holding or more risk averse prefer early exercise of their options. Employees with high sentiment will postpone the exercise timing due to the brightening prospect of the company. The employees who receive the money-type options also tend to exercise early. In addition, larger dividends induce employees to exercise their options sooner. Options with shorter lifetime are more quickly exercised. Employees do not have much time value in these options and tend to exercise their options earlier. Employees exercise volatile options early to balance their portfolio risk, especially for idiosyncratic risk increases. Indeed, our model findings are consistent with several empirical studies. For instance, Hemmer et al. (1996), Huddart and Lang (1996), and Bettis et al. (2005) show that early exercise is a pervasive phenomenon owing to risk aversion and undiversification of employees. Huddart and Lang (1996) find that exercise is negatively related to the time to maturity and positively correlated with the market-to-strike ratio and with the stock price volatility. Hemmer et al. (1996) and Bettis et al. (2005) also find that stock price volatility has a significant effect on exercise decisions. In high-volatility firms, employees exercise options much earlier than in low-volatility firms.

30.4.2 Factors' Effects on ESOs

Understanding the factors that affect ESO values and the exercise decision is important for firms designing stock option programs. As we mentioned before,

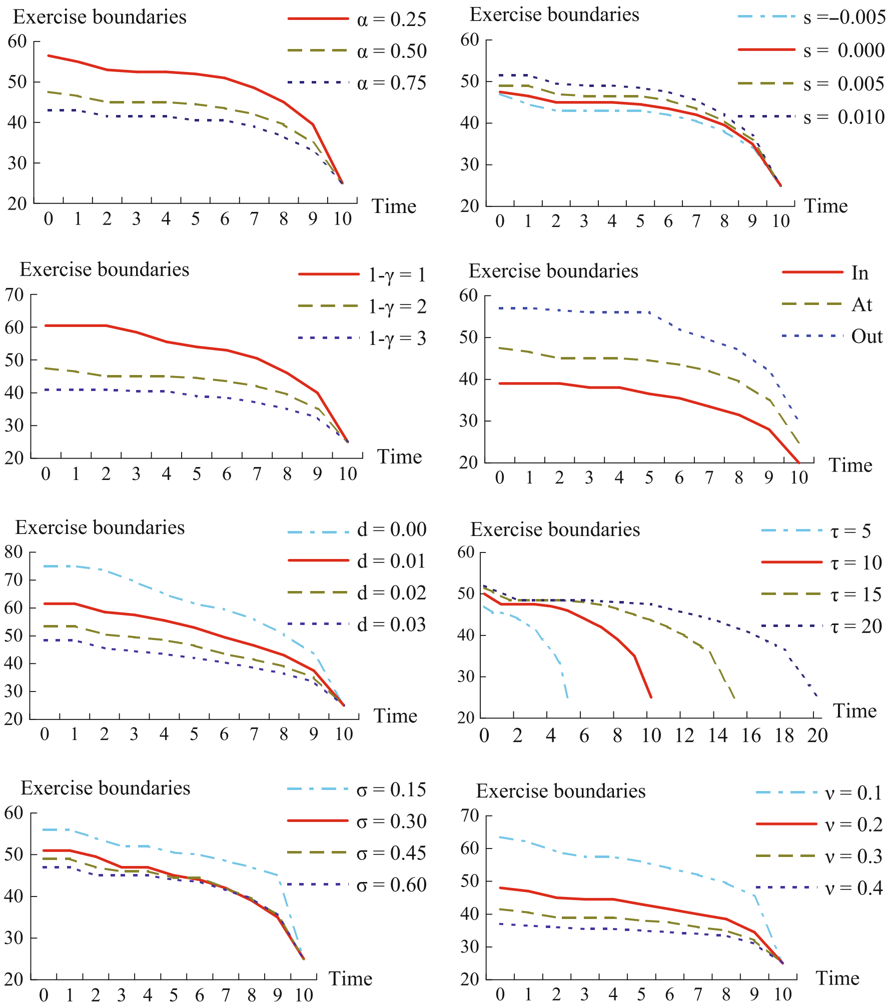

Fig. 30.1 Exercise boundaries. This figure presents the exercise boundaries according to stock holding constraint α, sentiment s, level of risk aversion $1-\gamma$, moneyness In: $K = 20$, At: $K = 25$, Out: $K = 30$, where K is exercise price, dividend yield d, time to maturity τ, total volatility σ, and idiosyncratic risk ν, respectively

ESO values and exercise decisions are closely related. Factors affecting the employees exercise policies will directly influence the valuation of ESOs. This section discusses the impact of factors on ESOs. The results are shown in Table 30.1, which presents the studied factors effect on ESO value, discount ratio, and early exercise premium, where ESO value is calculated by formula (30.6), discount ratio is defined as one minus the ratio of subjective to market value, and early exercise premium is the difference between American and European ESO value.

Table 30.1 Factors effect on employee stock options

Panel A: ESO values and discount ratios and early exercise premiums

	CA	CD	Premium		CA	CD	Premium
$\alpha = 0.00$	9.6487	0.0000	0.1839	$s = -0.005$	6.1495	0.3120	0.9385

This table presents the impact of factors on ESOs, including stock holding constraint α, sentiment s, level of risk aversion $1 - \gamma$, moneyness sok, dividend yield d, time to maturity τ, total volatility σ, idiosyncratic risk v, and vesting period VP. CA, CD and Premium are the ESO value, discount ratio (1-subjective/market) and early exercise premium, respectively

Unlike traditional options, ESOs usually have a vesting period during which they cannot be exercised and employees are not permitted to sell their ESOs. In this situation, employees receive the ESOs in a very illiquid market. Table 30.1 shows that subjective values ($\alpha \neq 0$) are uniformly smaller than the market values ($\alpha = 0$). These results are consistent with Lambert et al. (1991) and Hall and Murphy (2002), in which the subjective value is lower than market value due to the constrained fixed holding in the underlying stock. The more risk averse the employee (more positive $1 - \gamma$) and more restrictions on the stock holding (larger α), the more they lean to depreciate the option values and incur the higher early exercise premium. Note that early exercise effect on ESO values cannot be ignored in these situations. Because of the restriction of ESOs, many employees have undiversified portfolios with large stock options for their own firms. Therefore, a risk-averse employee discounts the ESO values. Discount ratios increase with stock holding constraint and the degree of risk aversion. In other words, employees who are more risk averse and more restricted on the stock holdings need to compensate more risk premium.

Employee sentiment enhances the option value and reduces the early exercise premium. One would expect for options with high sentiment having higher discount that the option value declines sharply when employees face an undiversification problem. The moneyness of each option *Sok* is the stock price at issuance divided by strike price. If the option is in (out of) the money, *Sok* is greater (less) than 1. In the money options have higher values, lower discount and higher early exercise premiums. Interestingly, even in the money options having less discount than out of the money, employees still tend more to early exercise in the money options to diversify their wealth portfolio risk. Larger dividends depreciate the option values and induce employees to exercise their options sooner, even they have lower discount ratios. More interestingly, the early exercise premium is not zero when no dividends are paid. This is a departure from traditional option theory, although it is consistent with the phenomenon that ESOs are exercised substantially before maturity date, even ESOs not paying dividends, because of the lack of diversification. Options with longer lifetime have more value; at the same time, they have higher discount ratios and early exercise premiums. Although not reported in the table, the lifetime of option may be negatively related to European ESO value. This is due to the longer one must wait and the greater risk caused by undiversification affecting the ESO value.

Whereas options may provide incentives for employees to work harder, they can also induce suboptimal risk-taking behavior. General option pricing results show that value should increase with risk while employees need to compensate more risk premium at the same time. It is not necessarily the case that subjective value is positive related to risk, as is the traditional result.[7] We have the usual finding that total volatility increases the option value; however, on the contrary, with respect to normal unsystematic volatility, the subjective value decreases with it. In the Black-Scholes framework, this risk is eliminated under a risk-neutral measure. However, in our model, the employee has an illiquid holding and full diversification is impossible. Hence, a risk-averse employee depreciates the ESO values. The discount and early exercise premium increasing with the volatility risk also can be found in Table 30.1. This is intuitive, because the more volatile the stock price, the higher the opportunity cost of not being able to exercise. Therefore, employees have more incentives to early exercise volatile options.[8]

Further we examine the effect of vesting on subjective value. Panel B compares the ESOs that vest immediately, after 2, and 4 years, respectively. Vesting obviously reduces the ESO values since it restricts the exercise timing. Discount ratio increasing with vesting period implies that market value is affected less than the subjective value. Because the constrained ESOs are usually exercised much earlier than unconstrained ESOs and more tend to fall afoul of the vesting rule. While

[7]Nohel and Todd (2005), Ryan and Wiggins (2001), and others show that option values increase with risk, however, they do not study the impact of increased idiosyncratic risk. Carpenter (2000) presents examples where convex incentive structures do not imply that the manager is more willing to take risks. The model used in Chang et al. (2008) is able to capture this result.

[8]While Panel A shows the results of options that vest immediately, we can also consider the vesting effect and there is no significant qualitative difference.

vesting has negative effect on the American ESOs, it has no effect on the European ESOs, therefore, early exercise premium decreases with vesting.

30.4.3 Offsetting Effect of Sentiment and Risk on ESO

The level of sentiment is estimated from two perspectives. First, we consider the sentiment effect on ESO value (SenV), and then the estimated sentiment level can be calculated whereby subjective value with sentiment is equal to market value. Secondly, we estimate sentiment level from the early exercise perspective (SenE), that is, what value of sentiment such that employees exercise their options at the time that unconstrained investors do. The sentiment level of European ESOs (SenVE) is also calculated. Due to the limitation of European options (they are not allowed to early exercise), the sentiment level can only be estimated from value perspective.

Estimation of sentiment is shown in Table 30.2. Here, we only list the estimated sentiment level at the money option because there is no obvious relationship between sentiment level and moneyness. Table 30.2 shows that sentiment estimated from the American and European ESO formulas have similar patterns. The more risk averse the employee and more restricted on the stock holding, the higher the sentiment level is needed. SenVE is slight higher than SenV because of more restrictions in the European contract.

30.5 Empirical Study

Applying a comprehensive set of executive options and compensation data, this study empirically prices both subjective value discount created by stock holding constraint and the risk-adjusted excess returns necessary for employees to offset the ESO risk premium, that is, the sentiment effect.

30.5.1 Data

Data for this study are collected from the Compustat Executive Compensation (Execucomp) database. From this database, all executive stock options issued between 1992 and 2004 are collected with stock price at issuance S, strike price K, maturity date T, implied volatility Vol, and dividend yield Div. While the median option is issued at the money, the mean is in the money ($Sok = 1.012$). Note that virtually all options are issued at the money ($Sok = 1$). Indeed, this is true for about 90 % of our dataset. Average values of time to maturity, implied volatility, and dividend yield are 9.3 years,[9] 0.43 % and 1.37 %, respectively.

[9]For some issues for which there is no time stamp, we assume an issuance date of July 1, inasmuch asthis would be the middle of the fiscal year for the vast majority of firms.

Table 30.2 Estimation of sentiment

	SenV			SenVE			SenE		
	$R=1$	$R=2$	$R=3$	$R=1$	$R=2$	$R=3$	$R=1$	$R=2$	$R=3$
$\alpha=0.25$	0.0100	0.0200	0.0300	0.0100	0.0200	0.0300	0.0097	0.0180	0.0291
$\alpha=0.50$	0.0199	0.0399	0.0599	0.0200	0.0400	0.0599	0.0194	0.0369	0.0585
$\alpha=0.75$	0.0298	0.0598	0.0896	0.0299	0.0598	0.0897	0.0289	0.0579	0.0866

This table presents the sentiment levels necessary to offset the ESO risk premium. Sentiment levels SenV and SenVE are calculated while the subjective value with sentiment is equal to market value for the American and European options, respectively. SenE is the value of sentiment such that an employee exercises their options at the time that unconstrained investors do. α and $R = 1 - \gamma$ represent the stock holding constraint and level of risk aversion

In addition to options data, we collect total compensation data from the Execucomp database, which includes salary, bonus, restricted stock, option, long-term incentive pay, and other income earned by executives each year. As can be seen in Table 30.3, the mean total annual compensation for executives in this dataset is a bit over \$2 million, with a median of just over \$1 million. The mean and median ESO compensation numbers are roughly \$1.2 and \$0.4 million, respectively. Not surprisingly, chief executives who were also board members received the highest compensation (\$4.2 million), but options are a substantial portion of that compensation (\$2.4 million). Indeed, options compensation generally substantially outweighs all other forms of compensation.

Following Dittmann and Maug (2007), we further define the net cash inflow (*NCash*) for each year as follows:

$$\begin{aligned}
&NCash\\
&= Fixed\ salary\ (after\ tax)\\
&\quad + \ Dividend\ income\ from\ shares\ held\ in\ own\ company\ (after\ tax)\\
&\quad + \ Value\ of\ restricted\ stock\ granted\\
&\quad - \ Personal\ taxes\ on\ restricted\ stock\ that\ vest\ during\ the\ year\\
&\quad + \ Net\ value\ realized\ from\ exercising\ options\ (after\ tax)\\
&\quad - \ Cash\ paid\ for\ purchasing\ additional\ stock
\end{aligned}$$

Fixed salary is the sum of five Compustat data types: Salary, Bonus, Other Annual, All Other Total, and long-term incentive pay (LTIP).[10] The year when the executive enters the database is denoted by t_E. The executive's cumulative wealth for year t is then

$$W(t) = NCash_t + \sum_{\ell=t_E}^{t-1} NCash_\ell \prod_{s=\ell+1}^{t} \left(1 + r_f^s\right).$$

[10] For cash paid for purchasing additional stock, where direct data is unavailable, we use the change in stock holdings times the year-end stock price to calculate this value.

Table 30.3 Compensation summary statistics

	Aggregate			Mean by title			
	Mean	Median	Std Dev	B&C	B&NC	NB&C	NB&NC
Salary	365	300	234	556	481	335	286
Bonus	336	151	816	650	479	289	222
Other annual	24	0	179	44	35	22	16
All other total	70	11	540	94	131	50	45
LTIP	77	0	442	127	128	72	48
Restricted stock	163	0	803	366	220	184	101
Options	1,178	378	3,407	2,382	1,683	1,264	748
Total	2,214	1,074	4,262	4,219	3,158	2,217	1,465

This table presents summary statistics for compensation data for four categories of executives: board & CEO (*B&C*), board & not CEO (*B&NC*), not board & CEO (*NB&C*), and not board & not CEO (*NB&NC*). Numbers are reported in 1,000s and *LTIP* represents the long-term incentive pay

In other words, assume that the executive has no wealth before entering the firm; all $NCash_t$ are realized at the end of the fiscal year and invested at the risk-free rate r_f^{t+1} during the next fiscal year. Then, α is the sum of all illiquid firm-specific holdings, including unvested restricted stocks and options, divided by total cumulative wealth. Average α is about 35 %, implying that the illiquid firm-specific holdings account for more than one-third of executive total wealth.[11] We also calculate α by an iterated approach that synchronizes α and subjective value simultaneously. Qualitative findings with respect to sentiment are identical. Several proxies of sentiment are used in an empirical study including previous year risk-adjusted CAPM alpha and *Fortune* magazine's list of top 100 firms to work for, and estimated from our ESO pricing formula.

30.5.2 Preliminary Findings

Substituting the subjective value implied by compensation data into our model along with the options variables given in our dataset, we are able to back out sentiment levels, *Sen*. Results are presented in Table 30.4. There are about 105,000 options issued by each firm (AvgIss) over the test period, with a total of nearly 2,700 firms and 82,000 total observations accounted for. Industry breakdowns, while exhibiting some fluctuations in point estimates, show that results across industries are qualitatively similar. While the mean Black-Scholes value of options, *BSOPM*, is about \$13.09, with some variation across industries, the mean subjective value, *Sub*, is more than \$19.38, reflecting a 48 % premium. That is, although virtually all of the theoretical literature implies a subjective value discount, empirical data show that executives generally value ESOs more highly than their Black-Scholes values. Though not reported in the table, t-tests show that subjective values

[11]Holland and Elder (2006) find that rank-and-file employees exhibit an α close to 10 % and concur that subjective value is decreasing in α because of risk aversion and under-diversification.

Table 30.4 Summary statistics for subjective value and sentiment by industry

Sector		*BSOPM*	*Sub*	*Sen*	AvgCom	AvgIss	Obs
10	Energy	12.589	16.239	0.089	1,774.08	78.46	4,307
15	Materials	10.822	17.613	0.076	1,399.90	61.89	6,412
20	Industrials	12.569	20.305	0.115	1,591.53	70.64	12,134
25	Con. Dis.	12.177	19.799	0.106	2,030.63	98.64	15,925
30	Con. Sta.	12.053	18.121	0.076	2,405.29	111.40	4,347
35	Health care	16.290	21.098	0.115	2,338.68	105.61	8,883
40	Financials	13.440	21.770	0.066	2,892.28	99.37	10,441
45	Inf. Tec.	15.853	18.499	0.229	2,748.47	164.53	14,614
50	Tel. Ser.	12.768	22.941	0.162	5,310.29	272.27	1,324
55	Utilities	5.475	14.633	0.063	1,370.11	67.66	3,931
	Others	9.487	9.583	0.208	1,360.34	111.24	56
	Total	13.088	19.385	0.120	2,213.73	105.13	82,374

This table presents, by industry: Black-Scholes value *BSOPM*, subjective value *Sub*, sentiment level *Sen*, average total compensation AvgCom, number of options issued AvgIss, and number of observations by individual Obs. AvgCom and AvgIss are reported in thousands. *Sen* is calculated using the European ESO formula (30.5), where the distribution of jump size follows $y = 0$. Con. Dis., Con. Sta., Inf. Tec., and Tel. Ser. refer to Consumer Discretionary, Consumer Staples, Information Technology and Telecommunication Services, respectively

are statistically significantly higher than Black-Scholes values at the 1 % level for almost all industries and in aggregate. The only exception is the others industry, where *Sen* is still significantly positive but *Sub* is about equal to *BSOPM* owing to a particularly high α in this industry.

Given the large proportion of executive income that is attributed to illiquid, firm-specific options holdings, this finding suggests substantial overconfidence or positive inside information regarding their firm's future prospects. Indeed, the data show that the average executive prices ESOs such that the firm should outperform the market's expectations by an average of 12 % per annum (*Sen*). T-tests show that these values are significantly different from zero at the 1 % level in all industries and in aggregate.

Table 30.5 shows the mean and median values of R_t and *Sub* in each subsample, where R_t is the CAPM alpha. *Top* is a dummy variable taking value 1 if the executive works for a firm listed in *Fortune* magazine's top 100 companies to work for. Results show that firms with higher previous-year return tend to have significantly higher subjective values. This is true of both the mean and median value. Interestingly, subsequent return momentum is not consistently present in this data, at least as regards mean values. Firms listed in the top 100 in fact make significantly lower risk-adjusted returns in the year in which they are so listed. However, they enjoy substantially higher subjective value. This indicates that sentiment may generally be independent of performance but does significantly affect subjective value.

Figure 30.2 shows that relative subjective values are greater than one but relatively stable over time. In contrast, the number of issuances generally increases.

Table 30.5 Difference tests for subjective value and sentiment

	$R_{t-1} > 0$	$R_{t-1} < 0$	P-value	$Top = 1$	$Top = 0$	P-value
mean(R_t)	0.00042	0.00041	0.4493	0.00038	0.00059	<.0001
median(R_t)	0.00031	0.00028	0.0176	0.00030	0.00044	<.0001
mean(Sub)	21.4131	15.6336	<.0001	24.7420	17.6169	0.0003
median(Sub)	14.1350	10.9487	<.0001	17.4147	10.9794	<.0001

This table shows the mean and median values of R_t and Sub in each subsample, where R_t is the CAPM alpha at time t. Top equals 1 if the firm is listed as a top 100 firm by *Fortune* magazine in a given year. The p-values measure the significance of difference tests

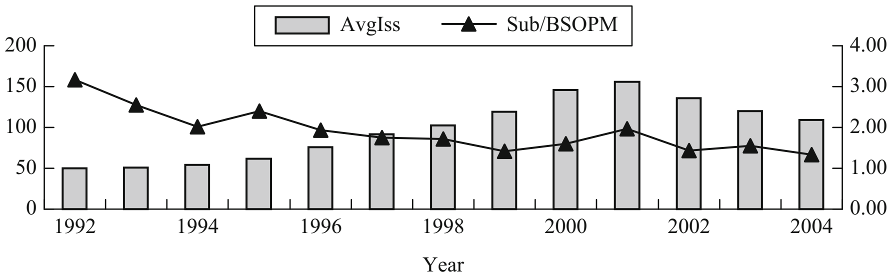

Fig. 30.2 Summary AvgIss and Sub/BSOPM by year. AvgIss and Sub/BSOPM for each year are graphed in this figure. AvgIss, BSOPM, and Sub are number of options issued, Black-Scholes value, and subjective value, respectively. The y-axis of the histogram is on the *left* and that of the line chart is on the *right*

The industry with the second highest subjective values (Financials) has a below-average number of issuances. These observations highlight the importance of looking at pricing, rather than issuance alone, as high subjective values do not imply that ESOs will be a more popular financing tool.

30.5.3 Implications of Regression Results and Variable Sensitivities

We now shift our attention to the testable implications of our model, namely confirming the relations between key options' variables and subjective value. Specifically, we apply the following regression equation:

$$\begin{aligned} Sub = Int + \beta_{\alpha}\alpha + \beta_{Sen}Sen + \beta_{Sok}Sok \\ +\beta_{\tau}\tau + \beta_{Vol}Vol + \beta_{Div}Div + \varepsilon, \end{aligned} \tag{30.7}$$

where *Int* is the intercept term and all variables are defined as before. Note that for all results presented here, the calculation of significance is via clustered standard errors by firm, though OLS results are nearly identical.

Table 30.6 Regression results for subjective value

	Int	α	*Sen*	*Sok*	τ	*Vol*	*Div*	Obs
$Sen = R_{t-1}$

This table presents the estimated coefficients from the following regressions:

$$Sub = Int + \beta_\alpha \alpha + \beta_{Sen} Sen + \beta_{Sok} Sok + \beta_\tau \tau + \beta_{Vol} Vol + \beta_{Div} Div + \varepsilon$$

where *Sub*, *Int*, α, *Sen*, *Sok*, τ, *Vol*, and *Div* refer to the subjective value, intercept term, proportion of total wealth held in illiquid firm-specific holdings, sentiment, ratio of stock price to exercise price, time to maturity, implied volatility, and dividend payout, respectively. In the first three tests, $Sen = R_{t-1}$, the CAPM alpha. We split the data into two groups according to the sign of the product of R_t and *Sen*. When *Sen* correctly forecasts the sign of the CAPM alpha for a given year, this is denoted as an "insider." When *Sen* and R_t do not match in sign, we denote this as "true sentiment." In the fourth test, *Sen* is a dummy variable that takes value 1 if the firm is in *Fortune's* top 100 and 0 otherwise. In the next three tests, *Sen* is calculated from European ESO formula (30.5), with the distribution of jump size following $y = 0$, a double exponential, and a bivariate constant jump model, respectively

First, we apply gross subjective value *Sub* as the dependent variable. The first three tests in Table 30.6 use CAPM risk-adjusted alpha from the year prior to option issuance R_{t-1} as a proxy for sentiment under the conjecture that those stocks that performed better in the previous year generate more positive sentiment prior to options being issued. Note that our model implies that only the risk-adjusted excess return should be priced because the market portion of the firm's return is eliminated via the risk-neutral measure. Bergman and Jenter (2007), in contrast, test the gross prior year return. Because a year's worth of data is required to calculate these alphas, the dataset is reduced to about 57,000 observations. We find that α is significantly negatively related to subjective value. This matches our intuition that the larger the proportion of one's portfolio held in options, the less diversified the portfolio, and the less valuable the ESO. *Sen*, on the other hand, is positively related, and significantly so. In other words, positive sentiment is associated with higher subjective value. Note that these results control for the usual options' pricing factors. Whereas *Div* is significantly negative related as expected, *Sok* and τ are not consistently significantly related, and *Vol* is negatively related. As explored more fully later, this last negative relation is quite telling and is consistent with our model as the sensitivity of subjective value to idiosyncratic risk is negative.

Further, the data are split into two groups according to the sign of the product of R_t and *Sen*. A positive (negative) sign implies that the positive sentiment measure is (not) accompanied by strong performance. The positive case (insider), then, can be explained by nonsentiment-related factors. The executive may have private inside information and hence be able to forecast future returns. They also have the ability to affect future returns so that optimism may be self-fulfilling. The negative case (true sentiment), on the other hand, has not such a concern inasmuch as it would imply that positive (negative) sentiment is followed by poor (good) performance. As it turns out, similar results are obtained in both cases: sentiment is positively related to subjective value while α is negatively related, both significantly so. As a result, it is not likely that insider information explains whole sentiment effect on subjective value.

Next, the *Top* dummy is selected as a proxy for sentiment. Once again, sentiment is significantly positively related to subjective value while α is significantly negatively related. All other relations are as above.

We also back *Sen* out of the European ESO formula (30.5) under the aforementioned three different jump size assumptions.[12] Because our model itself determines the relation between subjective value and *Sen*, the purpose of these tests is simply to observe the other variable relations as well as the stability of the model to the specification of the jump process. Results are quite consistent across the three processes tested here. All other coefficients remain qualitatively as before with the coefficient of α, importantly, remaining significantly negative in all cases.

Finally, in order to more clearly test the difference in impact of sentiment for insider versus true sentiment events, we interact the event identification dummy with our sentiment proxy as follows:

$$\begin{aligned} Sub &= Int + \beta_{\alpha}\alpha + \beta_{InSen}D_{In}Sen + \beta_{TSen}D_{T}Sen + \beta_{Sok}Sok + \beta_{\tau}\tau \\ &\quad + \beta_{Vol}Vol + \beta_{Div}Div + \varepsilon. \end{aligned} \tag{30.8}$$

All variables are defined as before and *Sen* is the previous-period CAPM alpha, also as before. D_{In} is a dummy variable that takes value 1 if the event is insider and

[12]Here, sentiment is estimated from the European option formula. It can also be calculated from the American option formula but with more exhaustive computations. As we mentioned before, sentiment estimated from the European and American ESO formulas have similar patterns. It may not affect the regression results much.

Table 30.7 Regression results for insider versus true sentiment events

	Int	α	$D_{In}Sen$	$D_T Sen$	*Sok*	τ	*Vol*	*Div*
$Sen = R_{t-1}$								
Coefficient	1.9070	−0.2214	0.0372	0.0044	0.0343	−0.2866	−0.3872	−0.0876
(p-value)	(<.0001)	(<.0001)	(<.0001)	(<.0001)	(0.3769)	(0.0876)	(<.0001)	(<.0001)

This table presents regression results for insider versus true sentiment events, where D_{In} is a dummy variable taking value 1 if the event is insider and 0 otherwise, D_T takes value 1 if it is true sentiment and 0 otherwise, and *Sen* is again defined as the CAPM alpha

0 otherwise. By analogy, D_T takes value 1 if the event is true sentiment and 0 otherwise. The results appear as in Table 30.7. Note that, while sentiment increases subjectively value significantly in both cases, the impact of sentiment when the event is likely to be an insider event is much larger. In other words, when strong prior performance reveals real information regarding future performance that may be known to managers, the impact on subjective value is strong. When prior performance proves not to be informative, the impact on subjective value is small. However, the impact is positive and significant in both cases.

30.5.4 Subjective Value and Risk

We now turn our attention to the sensitivity of subjective value to risk. While we note that our model implies a positive relation between total risk and subjective value, it further dictates that the sensitivity of subjective value to idiosyncratic risk is negative, a notion supported by our empirical findings. This indicates that increased levels of risk may negatively affect subjective value owing to the inability of executives to fully diversify their holdings. In contrast, the Black-Scholes as well as the majority of options pricing models prescribe no role to idiosyncratic risk, that is, the sensitivity should be zero, and are generally not be able to capture the empirical finding that subjective value is negatively related to risk.

In applying the empirical data to the formulae for the sensitivities of subjective value to various forms of risk, our model does indeed generate a negative relation between firm-specific risk and subjective value, a finding that is consistent also with the empirical observations of Meulbroek (2001). This finding is particularly important as managers can easily affect the firm's idiosyncratic risk level through various moral hazard-related activities.

In Table 30.8, risk sensitivities are calculated, vegas, for all options issues in our dataset assuming there are no illiquid holdings (UV), that is, $\alpha = 0$, and using our default value for α (V), with and without consideration of sentiment. The first two columns find as expected that the sensitivity with respect to total risk is positive, for both UV and V, regardless of whether sentiment is considered or not. This is true of all jump specifications. In every case, the sensitivity is higher when sentiment is not considered. Looking at the vegas with respect to jump frequency, UV(freq) can be either positive or negative depending on the jump specification, while V(freq) is always negative. Interestingly,

Table 30.8 Summary statistics for vega

Panel A: Y = 0						
	UV(total)	V(total)	UV(freq)	V(freq)	V(idio)	V(size)

This table presents test results for vega. In Panels A, B, and C, the distribution of jump sizes are zero jump, double exponential jump, and bivariate constant jump, respectively. UV(total) and UV (freq) are total risk and jump frequency risk vegas under our model when all holdings are liquid. V(total), V(idio), V(freq), and V(size) refer to total risk vega, idiosyncratic risk vega, jump frequency risk vega, and jump size risk vega, respectively

UV is positive for the constant jump model but negative for the other two models, pointing out the importance of jump specification when liquidity is not also considered. The magnitude of UV is always smaller than that of V.

Perhaps the most interesting factor affecting our subjective value in our model is idiosyncratic risk, for which the estimate is always negative and is significantly larger in magnitude than the other vegas. While the jump size vega also plays a role and is likewise always negative, the magnitude of this effect is much smaller. This finding highlights the role of idiosyncratic risk in our model and explains why the empirical sensitivity of subjective value to volatility is found to be negative, contrary to generally accepted moral hazard models that dictate that option compensation encourages risk taking. If agents are sufficiently under-diversified, the risk premium from taking on excess idiosyncratic risk offsets gains from convexity and discourages risk-taking behavior. The corresponding UVs for idiosyncratic and jump size risk are both zero as these do not play a role in determining market value when there are no under-diversified holdings. Also, the Vs are substantially more negative when sentiment is introduced, pointing out the sharply offsetting effects of positive sentiment and risk aversion in this model. Which piece dominates then depends on the risk aversion parameter and α of the employee.

30.6 Conclusion

This chapter applies three statistics methods in ESO study, including change of measure, hierarchical clustering with a K-means approach, and estimation of standard errors in finance panel data. We use a model for employee stock options that incorporates illiquidity of the options, a jump diffusion for the stock price evolution that includes various jump processes, and the potential roles of employee sentiment and insider information in a world where employees balance their wealth among the company's stock, the market portfolio, and a risk-free asset. Our option contract is American type and the optimal exercise boundary is derived endogenously. From the ESO pricing formula, we are able to not only estimate the subjective values but also study the exercise policies.

The subjective value placed on ESOs implied by compensation data is calculated by applying empirical data. Specifically, using data provided by Compustat, executives are grouped by a hierarchical clustering with a K-means approach based on a number of firm and individual criteria. By assuming that all executives in the same cluster receive the same total compensation, a notion that relies on the existence of competitive labor markets, we then back out the valuation placed by each executive on their respective ESO. These groups include consideration of nonoption compensation, rank, industry, year, firm size, and immediate exercise value. Though the extant literature predicts that employees should discount the value of their options, we find that executives in fact value their options more highly than implied by Black-Scholes, applying an average premium of 48 %. As such, the cost of issuance for the firm is vastly lower than the benefit perceived by employees, suggesting that ESO compensation should be an even larger part of executive compensation. We then relate subjective value to sentiment levels and generate the novel finding that executives must expect their firm's risk-adjusted returns to outpace that predicted by the market by 12 % in order to justify the subjective value placed on ESOs. This expectation may be the result of private information regarding the growth prospects of the firm.

Testing subjective value and its relation to pertinent variables, subjective value is negatively related to the proportion of wealth held in illiquid firm-specific holdings and positively related sentiment. In other words, the larger the illiquid ESO position is, the larger the discount risk aversion prescribed and the lower the subjective value implied in the compensation package. On the other hand, the more positive the employee's view of future risk-adjusted returns, the more valuable the ESO. Interestingly, subjective value may be negatively related to risk as the inability of executives to fully diversify their holdings may lead to risk premia that outweigh the value placed on risk by the convexity of options payouts. Note that this relation is particularly negative with regard to idiosyncratic risk and is empirically also negative for risk associated with both jump frequency and size. Because these aspects of return are precisely those that may be most directly controlled by executives, traditional moral hazard arguments relating solely to the convexity of the options payout may not hold.

Firms increasingly grant nontraditional employee stock options to link stock price performance and managerial wealth and provide greater incentives to employees. While this study focuses on the traditional employee stock option, the main intuition can be involved in nontraditional ESOs. Premium stock option, performance-vested stock option, repriceable stock option, purchased stock option, reload stock option, and index stock option are the objects of future study. We can derive the option formulas and compare the value, incentive effect, and cost per unit of subjective incentive across the nontraditional ESOs and the traditional ones. This future study provides a firm a proper compensation vehicle according to its characteristics.

Appendix 1: Derivation of Risk-Neutral Probability by Change of Measure

Here we introduce the idea for deriving the ESO formulas and define using probability measure P^* by the technique of change of measure.

The process of an employee's marginal utility or the pricing kernel is:

$$\frac{dJ_W}{J_W} = -\hat{r}dt - \hat{\sigma}dW_m + \hat{v}dW_s + \left(\hat{Y} - 1\right)dN_t,$$

where

$$\begin{aligned}
\hat{r} &= r - (1-\gamma)\left(\alpha^2 v^2 + \frac{1}{2}\alpha^2\gamma\lambda k_2 + \alpha\lambda k\right),\\
\hat{\sigma} &= \frac{\mu_m - r}{\sigma_m},\\
\hat{v} &= -(1-\gamma)\alpha v,\\
\hat{Y} &= [\alpha(Y-1)+1]^{\gamma-1},
\end{aligned}$$

then

$$J_W[W(t),t] = J_W[W(0),0]\exp\left\{\left(-\hat{r} - \frac{1}{2}\hat{\sigma}^2 - \frac{1}{2}\hat{v}^2\right)t +, \hat{\sigma}W_m(t) + \hat{v}W_s(t)\right\}\prod_{i=0}^{N_t}\hat{Y}_i.$$

Let $B(t, T)$ be the price of a zero coupon bond with maturity T, then

$$\begin{aligned}
B(t,T) &= E\left\{\frac{J_W[W(T),T]}{J_W[W(t),t]}B(T,T)|\mathcal{F}_t\right\}\\
&= E\left\{\exp\left\{\left(-\hat{r} - \frac{1}{2}\hat{\sigma}^2 - \frac{1}{2}\hat{v}^2\right)\tau + \hat{\sigma}W_m(\tau) + \hat{v}W_s(\tau)\right\}\prod_{i=0}^{N_\tau}\hat{Y}_i\right\}\\
&= \exp\{[-\hat{r} + \lambda(\xi - 1)]\tau\},
\end{aligned}$$

where

$$\tau = T - t, \;\; \xi = E\left(\hat{Y}\right) = E\left\{[\alpha(Y-1)+1]^{\gamma-1}\right\}.$$

The bond yield

$$\begin{aligned} r^* &\equiv -\frac{1}{T-t}\ln B(t,T) \\ &= r - (1-\gamma)\left(\alpha\lambda k + \frac{1}{2}\gamma\lambda k_2\alpha^2 + \alpha^2 v^2\right) - \lambda(\xi - 1). \end{aligned}$$

Let

$$Z(t) \equiv e^{r*t}J_W = \exp\left\{\left[-\frac{1}{2}\hat{\sigma}^2 - \frac{1}{2}\hat{v}^2 - \lambda(\xi-1)t + \hat{\sigma}W_m(t)\right] + \hat{v}W_s(t)\right\}\prod_{i=0}^{N_t}\hat{Y}_i,$$

then $Z(t)$ is a martingale under P, and we have

$$\frac{J_W[W(T),T]}{J_W[W(t),t]} = e^{-r*(T-t)}\frac{Z(T)}{Z(t)}.$$

The rational equilibrium value of the ESO at time t, $F(S_t, t)$, satisfies the Euler equation,

$$\begin{aligned} F(S_t,t) &= E_t\left\{\frac{J_W[W(T),T]}{J_W[W(t),t]}F(S_T,T)\right\} \\ &= e^{-r*(T-t)}E_t^*[F(S_T,T)], \end{aligned}$$

where $\frac{dP^*}{dP} = \frac{Z(t)}{Z(0)}$, and E_t^* is the expectation under P^* and information at time t. Under the probability measure P^*, the processes $W_m^* = W_m - \hat{\sigma}t$ and $W_s^* = W_s - \hat{v}t$ are Brownian motions, N_t is a Poisson process with intensity $\lambda^* = \lambda\xi$, and the jump sizes follow density $f_Y^*(y)$,

$$f_Y^*(y) = \frac{1}{\xi}[\alpha(y-1)+1]^{\gamma-1}f_Y(y).$$

Therefore,

$$\begin{aligned} \frac{dS}{S} &= \mu_s dt + \sigma_s dW_m + v dW_s + (Y-1)dN_t \\ &= \left[r - d - (1-\gamma)\alpha v^2 - \lambda k\right]dt \\ &\quad + \sigma_s dW_m^* + v dW_s^* + (Y-1)dN_t \\ &\equiv (r^* - d^*)dt + \sigma_N dW_t^* + \left(Y-1\right)dN_t, \end{aligned}$$

where

$$
\begin{aligned}
d^* &= d - (1-\gamma)\left[\alpha\lambda k + \frac{1}{2}\gamma\lambda k_2\alpha^2 - (1-\alpha)\alpha v^2\right] \\
&\quad - \lambda(\xi - 1) + \lambda k, \\
\sigma_N^2 &= \sigma_s^2 + v^2, \\
\sigma_N W_t^* &= \sigma_s W_m^* + v W_s^*.
\end{aligned}
$$

In other words,

$$
S_t = S_0 \exp\left\{\left(r^* - d^* - \frac{1}{2}\sigma_N^2\right)t + \sigma_N W_t^*\right\}\prod_{i=0}^{N_t} Y_i.
$$

Appendix 2: Valuation of European ESOs

The option price at time t is

$$
\begin{aligned}
C_E(S_t,\tau) &= e^{-r*(T-t)}E_t^*\left\{[S_T - K]^+\right\} \\
&= e^{-r*\tau}E_t^*\left\{\left\{S_t\exp\left[\left(r^* - d^* - \tfrac{1}{2}\sigma_N^2\right)\tau + \sigma_N\left(W_T^* - W_t^*\right)\right]\times\prod_{i=N_t}^{N_T} Y_i - K\right\}^+\right\} \\
&= S_t E^*\left\{\exp\left[\left(-d^* - \tfrac{1}{2}\sigma_N^2\right)\tau + \sigma_N W_\tau^*\right]\right. \\
&\quad \left.\times\prod_{i=0}^{N_\tau} Y_i I_{\left(W_\tau^* \geq a_1\right)}\right\} - Ke^{-r*\tau}E^*\left\{I_{\left(W_\tau^* \geq a_1\right)}\right\} \\
&= S_t e^{-d*\tau}E^*\left\{E^*\left\{\exp\left[-\tfrac{1}{2}\sigma_N^2\tau + \sigma_N W_\tau^*\right]\times\prod_{i=0}^{N_\tau} Y_i I_{\left(W_\tau^* \geq a_1\right)}\middle|\prod_{i=0}^{N_\tau} Y_i\right\}\right\} \\
&\quad - Ke^{-r*\tau}E^*\left\{E^*\left[I_{\left(W_\tau^* \geq a_1\right)}\middle|\prod_{i=0}^{N_\tau} Y_i\right]\right\} \\
&= S_t e^{-d^*\tau}E^*\left\{\prod_{i=0}^{N_\tau} Y_i\Phi\left(-\frac{a_1 - \sigma_N\tau}{\sqrt{\tau}}\right)\right\} - Ke^{-r*\tau}E^*\left\{\Phi\left(-\frac{a_1}{\sqrt{\tau}}\right)\right\} \\
&= \sum_{j=0}^{\infty}\frac{(\lambda\xi\tau)^j e^{-\lambda\xi\tau}}{j!}\left\{S_t e^{-d^*\tau}E^*\left[\prod_{i=0}^{j} Y_i\Phi\left(d_1^*\right)\right] - Ke^{-r*\tau}E^*\left[\Phi\left(d_2^*\right)\right]\right\}
\end{aligned}
$$

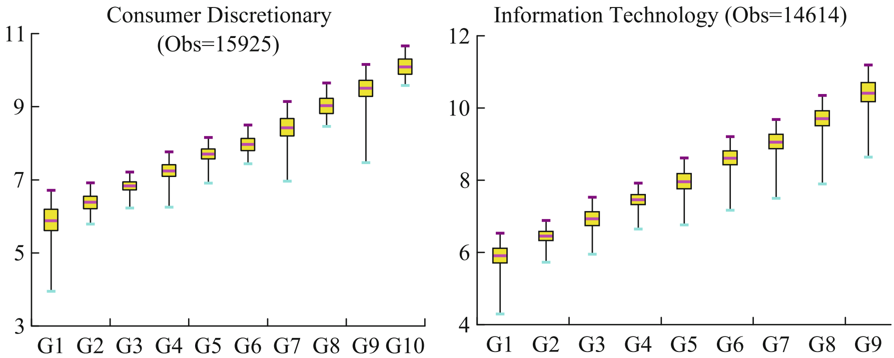

Fig. 30.3 Natural log of total compensation. The box plots show the natural log of total compensation for the two largest industries in our sample. Executives are grouped according to position, the firm's total market value, nonoption compensation, and the immediate exercise value of the options for each industry by using a hierarchical clustering with K-means approach

where

$$d_1^* = \frac{\ln\left[\left(S_t \prod_{i=0}^{j} Y_i\right)/K\right] + \left(r^* - d^* + \frac{1}{2}\sigma_N^2\right)\tau}{\sigma_N\sqrt{\tau}},$$
$$d_2^* = d_1^* - \sigma_N\sqrt{\tau}, a_1 = -d_2^*\sqrt{\tau}.$$

Appendix 3: Hierarchical Clustering with a K-Means Approach

The compensation-based subjective value is calculated by assuming that all executives within the same cluster receive the same total compensation. For each executive in this cluster, the implied subjective value is derived by comparing the difference between nonoption compensation and the average compensation. It is very important to group executives appropriately. We use cubic clustering criterion to generate number of groups and split executives according to position, the firm's total market value, nonoption compensation, and the immediate exercise value of the options for each industry by hierarchical clustering with a K-means approach. For each group, we calculate the average total compensation for all executives. If all executives receive the same compensation, on average, any differences in salaries, bonuses, and other income should be accounted for by options.

Figure 30.3 presents box plots of the natural log of total compensation for the two largest industries in our sample: Consumer Discretionary and Information Technology. With the exception of some outliers, which are subsequently removed in our main tests, the boxed areas generally do not overlap from cluster to cluster, demonstrating the relative homogeneity of firms within each cluster and generally distinctly separated from other clusters. As a result, we believe that compensation characteristics within each cluster should be quite comparable, lending a measure of credence to our method of calculating subjective value.

$I(d)$ processes and the cointegration relationship. A structural break appears a change in endogenous relationships. This break could be caused by a shift in mean, variance, or a persistent change in the data property. In general, structural change tests can be categorized into two types: one is the classical approach to testing for structural change, which employs retrospective tests using a historical data set of a given length; the other one is the fluctuation-type test in a monitoring scheme, which means for given a history period for which a regression relationship is known to be stable, we then test whether incoming data are consistent with the previously established relationship. Several structural changes such as CUSUM squared tests, the QLR test, the prediction test, the multiple break test, bubble tests, cointegration breakdown tests, and the monitoring fluctuation test are discussed in this chapter, and we further illustrate all details and usefulness of these tests.

Keywords
Cointegration breakdown test • Structural break • Long-memory process • Monitoring fluctuation test • Boundary function • CUSUM squared test • Prediction test • Bubble test • Unit root time series • Persistent change

31.1 Introduction

The structural break refers to the phenomenon illustrating the time series comes across unanticipated and significantly influential shifts. Generally, most macroeconomic and financial time series are subject to occasional structural breaks. Ignoring the presence of structural breaks can lead to seriously biased estimates and forecasts and the unreliability of models (see Clements and Hendry 1998, 1999). Since economic activities often experience rather long period, there exist plausible possibilities that structural breaks could occur. Hence, it is very important to monitor and modify the changes of the model characteristics. If those model characteristics were not corrected in *real time*, it may lead to wrong decisions on the policy making and investment plans for policy makers and practitioners. Consequently, those wrong decisions could result in the fluctuations or crises in economy and finance.

Examples in the real world are a large sum of financial crises ever since before the Industrial Revolution. For instance, ten enormous bubbles took place ahead of the twenty-first century documented by Kindleberger (2005), and the latest subprime crisis occurred in 2008. All crises crushed the wealth of the whole world again and again. After the first reported financial crisis – Dutch tulip bulb bubble in 1636 – all meltdowns in the economy systems were obviously characterized by the deviation from steadily development.

It implies that structural breaks could happen prior to the bubbles or explosions. Accordingly, an accurate approach to detecting structural breaks correctly can be treated as a measurement to notice the possible incoming financial crisis or to monitor market activities. On the other hand, developing a suitable structural break-testing mechanism is crucial to regulators and investors to modify decisions in order to avoid a potential incoming crash.

The first seminal paper of the issue regarding to the structural break tests was proposed by Chow (1960). Nowadays, structural change tests have been explored far more than the original Chow test and developed in many different dimensions. In this chapter, we survey various structural changes and monitoring tests for a class of widely used time series models in economics and finance, including $I(0)$, $I(1)$, $I(d)$ processes, the cointegration breakdown test, and bubble tests. The conventional structural change tests are categorized into three types: the mean shift, the persistent change, and the parameter change. Since the issues of break numbers and properties of the data-generating process (DGP) would be the main factors to affect the performances of the structural tests, it is essential to design the structural tests with respect to different scenarios.

The rest of this chapter is organized as follows. Section 31.2 illustrates the changes in mean and coefficients when DGP are stationary $I(0)$ and stationary long-memory $I(d)$ processes. Section 31.3 focuses on persistent change systematically. Tests of bubbles and the cointegration breakdown are discussed in Sect. 31.4. Section 31.5 provides the monitoring tests in *real time*.

31.2 Structural Breaks in Parameters

Structural break has been an intriguing issue since Chow (1960) test resolves how to detect a single structural change with known break date, and more ensuing literatures expand that in different dimensions. Break numbers can be multiple while break dates are no longer required as necessitates. Moreover, econometricians apply research closely to reality, adjusting these models from classical stationary process to nonstationary and long memory, which are found more likely to reflect economic and financial data. Now, we will offer systematical analysis of these marked developments.

31.2.1 Stationary Processes

It is the Chow (1960) test that firstly detect a potential structural break for a given break date. Suppose the model is

$$y_t = \beta_t' X_{t-1} + \varepsilon_t', \tag{31.1}$$

where our null hypothesis is $\beta_t = \beta$ for all t, ε_t is a martingale difference sequence with respect to the $\sigma-$ fields, and X_t is a $k \times 1$ vector of regressor, which are here assumed to be constant and/or I(0) with $EX_tX_t' = \Sigma_X$ and, possibly, a nonzero mean. Particularly, X_{t-1} can include lagged dependent variables as long as they are I(0) under the null. When the break date is unknown, a natural solution proposed by Quandt (1960) calculates break date, and it is extended by Davies (1977) to general models with parameters unidentified under the null. And Andrews (1993) reports asymptotic critical values of this QLR statistics. in the form of Quandt likelihood ratio (QLR) statistic.

To the contrast of the null, the alternative hypothesis of a single break in some or all of the coefficients is

$$\beta_t = \beta, \quad t \leq r \quad \text{and} \quad \beta_t = \beta + \gamma, \;\; t > r, \tag{31.2}$$

where r, $k + 1 < r < T$, is the "break date" (or "change point") and $\gamma \neq 0$.

When the potential break date is known, a natural test for change in β is the Chow (1960) test, which can be implemented in asymptotically equivalent Wald, Lagrange multiplier (LM), and LR forms. In the Wald form, the test for a break at a fraction r/T through the sample is

$$F_T(r/T) = \frac{SSR_{1,T} - \left(SSR_{1,r} + SSR_{r+1,T}\right)}{\left(SSR_{1,r} + SSR_{r+1,T}\right)/(T - 2k)}, \tag{31.3}$$

where $SSR_{1,\ r}$ is the sum of squared residuals from the estimation of Eq. 31.1 on observation 1,. . ., r, etc. For fixed r/T, $F_T(r/T)$ has an asymptotic χ_k^2 distribution under the null. However, when break date is unknown, the situation can be more complicated. An expectable idea is to estimate the break date and then compute Eq. 31.3 for that break. But since the change point is selected by virtue of an apparent break at the point, the null distribution of the resulting test is not the same as if the break date were chosen without regard to the data. Thus means of determining r/T must be further specified before the distribution of the resulting test can be obtained. Quandt (1960) and Davies (1977) come up with another F_T statistics called Quandt likelihood ratio, thus QLR statistic:

$$QLR = \underset{r=r_0,\ldots,r_1}{\text{MAX}} \quad F_T(r) \tag{31.4}$$

Intuitively, it has power against a change in β even without a known break date. Although it confuses econometricians for years to calculate its null asymptotic distribution, Andrews (1993, Table I) reports computable critical values for it. For more details, please see Stock (1994).

31.2.2 Multiple Breaks Case

This issue of detecting structural breaks becomes even richer after the possible multiple breaks are considered no matter the numbers and dates of breaks are known or not. Bai and Perron (1998) proposed a comprehensive treatment for estimating linear models with multiple structural breaks. They set the multiple linear regression with m breaks (m + 1 regimes) as follows:

$$y_t = x_t'\beta + z'\delta_j + u_t, \tag{31.5}$$

where $j = 1, \cdots, m + 1, T_0 = 0$, and $T_{m+1} = T$; y_t is the observed independent variable, $x_t(p \times 1)$, and $z_t(q \times 1)$ are vectors of covariates, and β and $\delta_j (j = 1, \cdots, m{+}1)$ are the corresponding vectors of coefficients; u_t is the disturbance. Note this is a partial structural change model in the sense that β is not subject to shifts and is effectively estimated using the entire sample. When $p = 0$, however, it is translated to a pure structural change. Now rewrite the liner regression system in Eq. 31.5 in matrix form as $Y = X\beta + \overline{Z} + U$, where $Y = (y_1, \ldots, y_T)'$, $X = (x_1, \ldots, x_T)'$, $U = (u_1, \ldots, u_T)'$, $\delta = (\delta_1', \delta_2', \ldots, \delta_{m+1}')'$, and $\overline{Z}$ is the matrix which diagonally partitions Z at the m-partition $(T_1, \ldots, T_m)$s, i.e., $\overline{Z} = \text{diag}(Z_1, \ldots, Z_{m+1})$ with $Z_i = \left(Z_{T(i-1)+1}, \ldots, Z_{T_i}\right)'$. Following this, apply associated least-squares estimates of β, and δ are obtained by minimizing the sum of squared residuals. And let $\hat{\lambda} = \left(\hat{\lambda}_1, \ldots, \hat{\lambda}_m\right) = \left(\hat{T}_1/T\hat{T}_m/T\right)$ with corresponding true value $\lambda^0 = (\lambda_1^0, \ldots, \lambda_m^0)$. Thus take the sup F type test of no structural break $(m = 0)$ versus the alternative hypothesis that there are $m = k$ breaks. Let $(T_1, \ldots, T_k)$ be a partition such that $T_i = [T\lambda_i](i = 1, \ldots, k)$. Operationally, to test a null of no break versus some fixed number of breaks, define

$$F_T(\lambda_1, \ldots, \lambda_k;\ q) = \frac{(T - (k+1)q - p)}{kq} \frac{\hat{\delta}' R' \left(R\left(\overline{Z}' M_x \overline{Z}\right)^{-1} R'\right)^{-1} R\hat{\delta}}{SSR_k} \tag{31.6}$$

where R is the conventional matrix such that $(R\delta)' = (\delta_1' - \delta_2', \ldots, \delta_k' - \delta_{k+1}')$ and $M_x = I - X(X'\ X)'\ X'$. Here SSR_k is the sum of squared residuals under the alternative hypothesis, which depends on $(T_1, \ldots, T_k)$. Define the following set for some arbitrary small positive number ϵ: $\Lambda_\epsilon = \{(\lambda_1, \ldots, \lambda_k);\ |\lambda(i+1) - \lambda_i| \geq \epsilon, \lambda_1 \geq \epsilon, \lambda_k \leq 1 - \epsilon\}$. The reason for this is to restrict each break date to be asymptotically distinct. And apparently, it is the generation of the sup F test considered by Andrews (1993) and others for the case $k = 1$.

Similarly, estimated break points by testing for l versus $l + 1$ breaks are also obtained by a global minimization of the sum of squared residuals. Comparing the difference between the sum squared residuals obtained with l breaks and that obtained with $l + 1$ breaks, it is advised to test each $(l + 1)$ segment for the presence of an additional break. This requires that the magnitude of shifts is fixed (nonshrinking). More precisely, the test is defined by

$$F_T\left(l+1|l\right) = S_T\left(\hat{T}_1, \ldots, \hat{T}_l\right) - \min_{1 \leq i \leq l+1} \inf_{\tau \in \Lambda_{i,\eta}} S_t\left(\hat{T}_1, \ldots, \hat{T}_{i-1}, \tau, \hat{T}_i, \ldots, \hat{T}_l\right)/\hat{\sigma}^2, \tag{31.7}$$

where

$$\Lambda_{i,\eta} = \left\{\tau; \hat{T}_{i-1} + \left(\hat{T}_i - \hat{T}_{i-1}\right)\eta \leq \tau \leq \hat{T}_i - \left(\hat{T}_i - \hat{T}_{i-1}\right)\eta\right\} \tag{31.8}$$

and $\hat{\sigma}^2$ is a consistent estimate of σ^2 under the null hypothesis. Note that for $i = 1$, $S_T\left(\hat{T}_1, \ldots, \hat{T}(i-1), \tau, \hat{T}_i, \ldots, \hat{T}_l\right)$ is understood as $S_T\left(\tau, \hat{T}_1, \ldots, \hat{T}_l\right)$ and for $i = l + 1$ as $S_T\left(\hat{T}_1, \ldots, \hat{T}_l, \tau\right)$.

As well, Bai and Perron (1996) also provide a valid proof for consistency of the estimated break fractions along with its limiting distributions. They also apply their model to the situations where autocorrelation could happen and compare it with sequential estimation.

31.2.3 Prediction Tests

Prediction tests which are often applied to forecast stock and exchange rate also lose power when potential structural change is incorporated without reasonable adjustment. While numerical literatures explore suitable models to fit the reality, their efforts still fail for rather long period or large forecasting sample as proven in Welch and Goyal (2008). This means tests for structural stability are equivalently vital in forecasting. For time series satisfying characters of stationarily I(0), prediction tests are operated on the difference between observed variables and predictions and only when it is before the suspected structural change could such tests be valid. Lutkepohl (1989) proposes a prediction tests for structural stability of univariate times series and compares its efficacy to the univariate time series investigated by Lutkepohl (1988).

Lutkepohl (1989) assumes a multiple time series generated by a stationary vector stochastic process $y_t = (y_{1t}, \ldots, y_{kt})$ in autoregressive (AR) representation

$$y_t = v + \sum_{i=0}^{\infty} A_i y_{t-i} + u_i \tag{31.9}$$

and moving average (MA) representation

$$y_t = \mu + \sum_{i=0}^{\infty} \Phi_i u_{t-i}, \Phi_0 = I_k, \tag{31.10}$$

Noted that I_k is the (K $\times$ K) identity matrix, v is a K-dimensional vector of constant terms, μ is the mean vector of y_t, the A_i and Φ_1 are (K $\times$ K) coefficient matrices, and $u_t = (u_{1t}, \ldots, u_{Kt})'$ is K-dimensional white noise. In other words, the $\widetilde{t}$ is i.i.d. multivariate normal, $u_t \sim N(0, \sum_u)$. Although the two present models focus on infinity, it is permitted that they can both be finite-order models. Thus the mean squared error (MSE) h-step predictor at origin is

$$y_t(h) = \mu = \sum_{i=h}^{\infty} \Phi_i u_{t+h-i},$$

and its MSE matrix is

$$\Sigma(h) = \sum_{i=0}^{h-1} \Phi_i \Sigma_u \Phi'.$$

Since y_t is Gaussian, the forecast error vector is normally distributed,

$$e(h) = y_{t+h} - y_t(h)(0, \Sigma(h)). \tag{31.11}$$

Therefore, the rest statistics

$$T(h) = e(h)^{'}\Sigma(h)^{-1}e(h) \sim \chi^2(K) \tag{31.12}$$

for $h = 1, 2, \ldots$, can be used for testing whether a structural change has occurred after period t. As usual $\chi^2(K)$ denotes the chi-squared distribution with Kdf.

Besides the univariate description of this system, another test relevant for multivariate systems is also designed by Lutkepohl (1989). Since the vector of one-step forecast errors to h-step forecast errors is also normally distributed,

$$e(h) = [e(1)(h)] \sim N(0, \Sigma(h)).$$

Here

$$\Sigma(h) = \Phi_h(I_h \otimes \Sigma_u)\Phi_h 6', \tag{31.13}$$

where $\otimes$ denotes the Kronecker product and

$$\Phi_h = \left[I_k\dot{0}\Phi_1 I_k\dot{0}\Phi_{h-1}\Phi_{h-2}\dot{I}_k\right] \tag{31.14}$$

Hence,

$$L(h) = e(h)'\Sigma(h)^{-1}e(h) \sim \chi^2(hK) \tag{31.15}$$

for $h = 1, 2, \ldots$, is another sequence of statistics that can be used for stability tests. This $L(h)$ statistics are particularly easy to compute and according to Lutkepohl (1989), while univariate time series tests can be relevant for multivariate systems, a structural change in a multivariate system will not be necessarily be reflected in the univariate models for the individual variables of the system. And Lutkepohl (1989) points that since the coefficients Φ_i, A_i, and Σ_u are usually unknown so that the statistics cannot be computed, the replacement by estimators is needed. Thus the estimated processes $\hat{T}(h) \to \chi^2(K)$ and $\hat{L}(h) \to \chi^2(hK)$ can match the null hypothesis of structural change. Generally, Lutkepohl (1989) proposes a prediction test for checking the structural stability of a system of time series. Despite the fact it lacks power in modelling the form of the change, it serves as a useful tool without imposing severe restrictions on the data. Another merit is that very few data are required after the time period or the time point at which a structural change is suspected.

31.2.4 Structural Changes in Long-Memory Processes

So far long memory has been recognized as one of most common features shared by macroeconomic and financial time series. Let X_t be a stationary process with autocovariances $r(k) = \mathrm{cov}(X_t, X_{t+k})$, then X_t is said to have long memory if as $|k| \to \infty$,

$$r(k) \sim L_1(k)|k|^{2H-2}, \ \ H \in \left(\frac{1}{2}, 1\right)$$

where $L_1(k)$ is a slowly varying function as $|k| \to \infty$. That is $L_1(ta)/L_1(t) \to 1$ as $t \to \infty$ for any $a > 0$. This property implies that the correlations are not summable, and the spectral density has a pole at zero. Under suitable conditions on $L_1(\cdot)$, the spectral density

$$f(x) = \frac{1}{2\pi} \sum_{k=-\infty}^{\infty} r(k) e^{ikx} L_2(x) |x|^{1/2H}$$

is $|x| \to 0$ for some $L_2(\cdot)$ slowly varying the origin. The explanation for this phenomenon is not elusive since these economic data always persist for a rather long period and dependence between time thus has a lasting influence. Yet traditional wisdoms usually appear stuck in analysis of long memory, and thus need for structural break detection requires econometricians to develop singular new estimations for use. Among these manufactory efforts attempt to deal with long dependence either invariant to time or matching the time future. Hereafter more methods will be discussed.

31.2.4.1 Stochastic Volatility Model with Long-Memory Property

Macroeconomic and financial data often display long-run dependence between different economic individuals. Researchers and practitioners prefer the synthesized form to describing these issues, and thus data aggregation becomes another focus in econometrics literature. Interestingly such time series often turn out distinct from the originals, for example, the singular stock price return is normally stationary I(0), while the index often displays long memory. The Standard Poor's 500 index would be a supporting evidence for it. Furthermore Hsiao and Robinson (1978) and Granger (1980) have pointed that it makes sense for contemporaneous aggregation with stationary heterogenous autoregressive-moving average processes. Portfolio arrangement in this sense also regards to connect its volatility with the long-memory feature. As discussed in Zaffaroni (2000) and Kazakevicius et al. (2004), converse results also exist in the generalized autoregressive conditional heteroskedasticity (GARCH). Thus whether a long memory can be obtained by aggregation in volatility models has attracted a lot of attentions.

Zaffaroni (2006) investigates a large class of volatility models for the memory implications. With this aim, he selects the class of square root stochastic autoregressive volatility (SR-SARV), which nests both GARCH and stochastic volatility (SV) models. So the exponential SV model of Taylor (1986) and the nonlinear moving average model (nonlinear MA) of Robinson and Zaffaroni (1998) would be the referents. The result shows long memory is ruled out for the former but is permitted for the latter. To put it more evidently, set a stationary square integrable process x_t with increasing filtration J_t if x_t is J_t-adapted, $E(x_t|J_{t-1}) = 0$, and $\mathrm{var}(x_t|J_{t-1}) =: f_{t-1}$. And the $SR - SARV(1)$ process then satisfies

$$f_t = \omega + \gamma_{t-1} + v_t, \tag{31.16}$$

where the sequence v_t is assumed as $E(v_t | J_{t-1}) = 0$. ω and γ are constant nonnegative coefficients with $\gamma < 1$. The implication means $E((x)_t^2) < \infty$. It is also assumed that ω_i, γ_i are independent identically distributed (i.i.d.), randomly drawn from a joint distribution such that $\gamma_i < 1$. At each point n heterogeneous units $x_{i,t}(1)$ are observed as SR-SARV(1).

31.2.4.2 Testing for a Change in the Long-Memory Parameters

The best known models representing long dependence are fractional Gaussian noise (Mandelbrot van and Ness 1968) and fractional ARIMA (Granger and Joyeux 1980). These models are stationary with a constant long-memory parameter H. But this assumption could not hold for some time series since the long dependence structure might change over time. It makes sense in macroeconomic data for some economic events persist over long period or has a lasting influence. Note that changes of H are relevant particularly for that the rate of convergence of confidence intervals of constants and for parameter estimates in regression with certain classes of design matrices, e.g., polynomial regression would change if H changes. More details are referred to Yajima (1988) and Beran (1991). There are huge sums of literature focused on this issue, among which Beran and Terrin (1996) offer a simple estimation by exact or approximate maximum likelihood. The method testing such structural break consists of the alternative that H is not constant. They make use of functional central limit theorem to compute the quadratic forms and offer more test statistics.

Define the spectral density by a finite dimensional parameter vector $\theta = (\tau, \eta) = (\tau, H, \eta_2, \ldots, \eta_m)$ so that

$$f(x;\theta) = \tau f\{x;\ (1,\eta)\}, \int_{-\pi}^{\pi} \log\ f\{x;\ (1,\eta)\} d_x = 0.$$

By definition, τ is the expected mean squared error of the best linear prediction of X_t given X_s, $s \le t - 1$. The long-memory behavior is characterized by H, the additional parameters $\eta_2, \ldots, \eta_m$ allow for flexible modelling of short-term features. Define

$$\alpha_k(\eta) = \int_{-\pi}^{\pi} e^{ikx} f^{-1}\{x;\ (1,\eta)\} dx.$$

Given $X_1, X_2, \ldots, X_N$, let $\hat{\eta}$ be the value of η that minimizes

$$Q(\eta) = \sum_{i,j=1}^{N} \alpha_{i-j}(\eta) \left(X_i - \overline{X}\right) \left(X_j - \overline{X}\right).$$

For Gaussian processes, the asymptotic covariance matrix is the same as for the exact maximum likelihood estimator. As proved by Beran and Terrin (1996), for $0 < t < 1$,

$$Q_1(t;\eta) = \sum_{i,j=1}^{\lfloor Nt \rfloor} \alpha_{i-j}(\eta)\left(X_i - \overline{X}\right)\left(X_j - \overline{X}\right),$$
$$Q_2(t;\eta) = \sum_{\lfloor Nt \rfloor+1}^{N} \alpha_{i-j}(\eta)\left(X_i - \overline{X}\right)\left(X_j - \overline{X}\right).$$

Let $\hat{\eta}^{(1)}(t)$ and $\hat{\eta}^{(2)}(t)\,(j=1,2)$ be defined by

$$\hat{\eta}^{(j)}(t) = \text{argmin}\ Q_j\left(t; \hat{\eta}^{(j)}\right)(j=1,2),$$

and denote by $\hat{H}^j(t) = \hat{\eta}_1^j(t)$ the corresponding estimates of H. Moreover, define $\kappa^2 = 2D_{11}^{-1}(\eta)$, where D is the $k \times k$ matrix with elements

$$D_{ij} = (2\pi)^{-1}\int_{-\pi}^{\pi} \frac{\partial}{\partial \eta_i} logf\{x;\ \ (1,\eta)\}dx.$$

Then the process

$$\widetilde{Z}_N(t) := N^{\frac{1}{2}}\kappa^{-1}\{t(1-t)\}^{\frac{1}{2}}\left\{\hat{H}^{(1)}(t) - \hat{H}^{(2)}(t)\right\}$$

converges in the Skorokhod topology on $D[0,\ 1]$ to the Gaussian process $Z(t)$ defined by

$$Z(t) = \{t(1-t)\}^{\frac{1}{2}}\left\{\frac{1}{t}B_1(t) - \frac{1}{1-t}B_2(1-t)\right\} \tag{31.17}$$

where B_1 and B_2 are two independent standard Brownian motions. Based on this distribution, the test statistics is suggested as

$$T_N = \sup_{\delta<t<1-\delta}\left|\widetilde{Z}_N(t)\right| \tag{31.18}$$

for some $0 < \delta < 1$. Also it is implied that T_N in distribution, where

$$Y = \sup_{\delta<t<1-\delta}|Z(t)| \tag{31.19}$$

and $Z(t)$ is defined by Eq. 31.17. Note that, due to the standardization by $\{t(1-t)\}^{\frac{1}{2}}$, $Z(t)$ is a standard normal random variable for each fixed t.

Comparatively, tests for a change in parameter values at a given time point are proposed in linear regression models with long-memory errors. Hidalgo and Robinson (1996) design a structural change test specially for I(d) data. They derive the new test in terms of stochastic and non-stochastic regressors. Generally, their model of form is $y_t = \beta\left(\frac{t}{n}\right)' x_t + u_t$, where x_t is a $K \times 1$ vector of observable regressors, the prime indicates transposition, and $\beta(s)$ is a $K \times 1$ vector such that

$$\beta(s) = \beta_A, 0 \le s \le \tau$$
$$= \beta_B, \tau < s < 1,$$

for a known number τ between zero and one, where the unobservable error u_t has auto-covariances featuring long memory. Thus the null hypothesis is $H_0 : \beta_A = \beta_B$ against the alternative $H_1 : \beta_A \neq \beta_B$.

For the case of non-stochastic regressors, a type of Wald testing procedure is applied. For a given τ, define $h = [\tau n]$, where $[\cdot]$ indicated integer part. Correspondingly, let $X_1 = (x_1, \ldots, x_h)'$, $X_2 = (x_{h+1}, \ldots, x_n)'$, $Y_1 = (y_1, \ldots, y_h)'$, $Y_2 = (y_{h+1}, \ldots, y_n)'$, and then estimate β_A and B by

$$\hat{\beta}_A = \left(X_1'X_1\right)^{-1}X_1'Y_1,$$
$$\hat{\beta}_B = \left(X_2'X2\right)^{-1}X_2'Y_2$$

Put

$$W = \left(\left(X_1'X_1\right)^{-1}X_1', -\left(X_2'X_2\right)^{-1}X_2'\right)',$$
$$u = (u_1, \ldots, u_n)',$$

Set w_t the tth column of W'. Then H_0 is equivalent to

$$\hat{\beta}_A - \hat{\beta}_B = W'u.$$

Assume u_t is Gaussian with zero mean, then

$$\hat{\beta}_A - \hat{\beta}_B \sim N\left(0, W'\right) \tag{31.20}$$

where Γ is the $n \times n$ Toeplitz matrix ($\gamma(s - t)$).

When x_t is stochastic but independent of u_t, however, Eq. 31.20 can be translated as

$$\left(W'\Gamma W\right)^{-1/2}\left(\hat{\beta}_A - \hat{\beta}_B\right) \sim N(0, \ I_k).$$

Hidalgo and Robinson (1996) also allowed for a degree of generality in the specification of the error structure, and the test is mainly designed for liner regression model by applying a semiparametric but a parametric model. Besides, the change point is assumed to be already known. Yet Kuan and Hsu (1998) point that such a test would incorporate size distortion that could lead to a change point while there is none. This is not peculiar since according to Kuan and Hsu (1998) when the memory parameter is in (0, 0.5), many well-known structural changes are supposed to suggest a nonexistent change. They also indicate a spurious change which might arise from stationary data with long memory while not responsible to nonstationary. They thus infer distinguishing between long-memory series with a change would not be reliable sometimes. More specifically, more and more financial literature illustrate that the realized volatility, which plays a major role in forming the portfolios, displays long-memory properties; thus, in order to avoid the loss caused by the market fluctuations, we could use those structural break tests for long-memory processes to detect the turning points of the realized volatility and further adjust the portfolio.

31.3 Persistent Change in Time Series

Permanent property shifts of the time series are characters of many key macroeconomic and financial variables in developed economies. Hence, correctly characterizing the time series whether stationary or nonstationary would be very helpful to build the accurate models. This issue has been investigated in terms of the data property change from I(0) to I(1) or the vice versa. The change might be responsible for portfolio adjustment especially for financial crises. Furthermore, recent studies indicate that other than those classical structural break types, there could also exist persistent changes in processes characterized by long memory, for example, the long-memory parameter changes from d_1 to d_2 or the vice versa, where d is the fractional differencing parameter.

31.3.1 Tests for a Change in Persistence for I(0) or I(1) Process

A normal question in testing for the persistent change is about what the process used to be and what direction it changes to. To solve that systematically, we could set the data-generating process (DGP) as following:

$$y_t = d_t + v_t, \tag{31.21}$$

$$v_t = \rho_t v_{t-1} + \varepsilon_t, t = 1, \ldots T. \tag{31.22}$$

Eq. 31.21 consists of the deterministic kernel d_t which is a constant either plus linear time trend or nothing. The error term ε_t is stationary.

Within the model (31.21), there exist four possibilities. The first is that y_t is all the time I(0) as $\rho_t = 1$ for all t, which can be defined as $H_{1,}$ and the second is denoted as $H_0 1$, reflecting Y_t changing from I(0) to I(1) at time $\lfloor \tau^* \rfloor$, where $\lfloor \cdot \rfloor$ represents the integer part. In this situation, $\rho_t = \rho$, $|\rho| < 1$ $t \leq \lfloor \tau^* \rfloor$ and $\rho_t = 1$ for $t > \lfloor \tau^* \rfloor$ in the context of (i). Noted that the change-point proportion τ^* is assumed to be unknown while set in $\Lambda = [\Lambda_L, \Lambda_U]$, which is an interval symmetric around 0.5 and between zero and one. The third denoted as $H_1 0$ is that y_t is form I(1) to I(0) at time τ^*.

Extant tests to detect the above structural changes are CUSUM of squares-based tests and regression-based tests. While the former has been improved by Leybourne et al. (2006) as displaying no tendency to spurious over-rejection, modified tests from regression angle by LKSN still lack the power for special structural change, taking large sample, for instance, where tests reject H_1 with probability one even though there is no change. Owing to these reasons, we here provide the CUSUM test according to Leybourne et al. (2006) as the ideal way in detecting this kind of persistent change.

In order to test the null hypothesis of constant I(0) behavior H_1 against a change in persistence from I(0) to I(1), H_{01}, a standardized CUSUM of squared subsample OLS residuals is needed:

$$K^f(\tau) = \frac{[\tau T]^{-2}\sum_{t=1}^{[\tau T]} \hat{v}_{t,\tau}^2}{\hat{w}_f^2(\tau)} \tag{31.23}$$

where

$$\hat{v}_{t,\tau} = y_t - \overline{y}(\tau) \quad \text{with} \quad \overline{y}(\tau) = [\tau T]^{-1}\sum_{t=1}^{[\tau T]} y_t.$$

And similarly $H(10)$ equivalent to change from $I(0)$ to $I(1)$ in the reversed series, let $x_t \equiv y(T - t + 1)$, occurring at time $(T - [\tau^* T])$ and the reversed series can be obtained as

$$K^r(\tau) = \frac{(T - [\tau T])^{-2}\sum_{t=1}^{T-[\tau T]} \widetilde{v}_{t,\tau}^2}{\hat{\omega}_r^2(\tau)} \tag{31.24}$$

where

$$\widetilde{v}_{t,\tau} = x_t - \overline{x}(1-\tau) \quad \text{with} \quad \overline{x}(1-\tau) = (T - [\tau T])^{-1}\sum_{t=1}^{T-\lfloor \tau T \rfloor} x_t.$$

Notice for both forward and reversed series, the long-run variance ω is replaced by the estimator

$$\hat{\omega}_f^2(\tau) = \hat{\gamma}_0 + 2\sum_{s=1}^{m} w_{s,m}\hat{\gamma}_s, \tag{31.25}$$

$$\hat{\gamma}_s = \lfloor \tau T \rfloor^{-1}\sum_{t=1}^{\lfloor \tau T \rfloor} \Delta\hat{v}_{t,\tau}\Delta\hat{v}_{t-s,\tau}, \tag{31.26}$$

Therefore, a test against persistent change could be based on the ratio R of the forward and reverse CUSUMs of squared statistics, i.e.,

$$R(\tau^*) = \frac{inf_{\tau \in \Lambda} K^f(\tau^*)}{inf_{\tau \in \Lambda} K^r(\tau^*)} =: \frac{N}{D}$$

where Λ is as described before and τ is assumed to be unknown. Furthermore, denote the demeaned, written as $z_t = 1$, and de-trend, $z_t = (1,t)'$, respectively. As $T \to \infty$, $l^{2/T} \to 0$,

$$R \Rightarrow \frac{inf_{\tau \in \Lambda} L_\xi^f(\tau)}{inf_{\tau \in \Lambda} L_\xi^r(\tau)}. \quad (31.27)$$

As shown in Leybourne et al. (2006), this limiting distribution of R is not dependable on the long-run variance, thus R could still hold if it is formed by the unstandardized ratio:

$$R = \frac{inf_{\tau \in \Lambda} \overline{K}^+}{inf_{\tau \in \Lambda} \overline{K}^r(\tau)} \quad (31.28)$$

where

$$\overline{K}^+(\tau) = [\tau T]^{-2} \sum_{t=1}^{[\tau T]} \hat{v}_{t,\tau}^2 \quad \text{and} \quad \overline{K}^r(\tau) = (T - [\tau T])^{-2} \sum_{t=1}^{T-[\tau T]} \widetilde{v}_{t,}^2.$$

And the large sample behavior of R, N, and D under both H_{01} and H_{10} will be provided in their Theorem 2 along with consistent estimators of τ^*. Additionally, the results of R in their Theorem 2 imply a consistent test of H_1 against H_{01} or H_{10}, respectively, by the left-tail and the right-tail distribution of R, while the unstandardized form yields a consistent estimate of break date τ^*. What's more, even the direction of the change is unknown, such a test with two tails can be appropriate against either H_{01} and H_{10}. As for the limiting distribution of R under H_0, it remains available for both the demeaned and de-trend cases. Thus, we could further know that under H_0, $R \to^p 1$.

Although Leybourne et al. (2006) rule out the size distortion when applied to process displaying constant persistence, they neglect such a test for long-memory case could cause over-rejection, which is often very serious. Sibbertsen and Kruse (2009) provide a solution based on simulation, by which they find despite that critical values may need modified, estimators for break dates still hold consistently. In this sense, the y_t generated from DGP is assumed to follow an ARFIMA(p,d,q) process, which means only the memory parameter d determine the degree of integration of y_t. Then the hypothesis should be written as

$$\begin{aligned} H_0 &: d = d_0 \quad \text{for all} \quad t, \\ H_1 &: d = d_1 \quad \text{for} \quad t = 1, \ldots, [\tau T] \\ & d = d_2 \quad \text{for} \quad t = [\tau T] + 1, \ldots, T \end{aligned}$$

Typically under H_0 the memory parameter d_0 is restricted to [0, 3/2), while $d_1 \in$ [0, 1/2) and $d_2 \in$ (1/2, 3/2]. It is equivalent to changes from stationary to nonstationary long memory at some unknown breakpoint with the vice versa also valid. Similarly, parts constituting R statistics are thus defined by

$$K^f(\tau) = [\tau T]^{-2d_0} \sum_{t=1}^{[\tau T]} \hat{v}_{t,\tau}, {}^r(\tau) = (T - [\tau T])^{-2d_0} \sum_{t=1}^{T-[\tau T]} \hat{v}_{t,\tau}.$$

However, Sibbertsen and Kruse (2009) find that asymptotic property has changed since the limiting distribution depends strongly on the memory parameter, which still leads to heavy size distortion. To deal with this problem, they simulate the adjusted critical values which are dependent on d. Although in this way practitioners benefit as such sample size will not influence critical values as significantly much as memory parameter, they have to decide the exact d for this simulation.

31.3.2 Unit Root with Persistent Change

Conventional unit root tests usually seem problematic when they are applied to nonstationary volatility, although they are proved to perform well in other situations. Breaks following a stationary Markov switching process and time-varying conditional variances are proved not to cause significant size distortion and impact on unit root and cointegration tests. Similarly, stationary time-varying conditional variances including (ARCH) are also known to have no impact on unit root and cointegration tests. Conversely, it can be different for permanent changes in volatility (so that volatility is nonstationary), since it is easy to greatly affect unit root inference. Hamori and Tokihisa (1997) show that a single abrupt increase in the innovation variance increases the size of augmented Dickey and Fuller (1979, 1981) (ADF) tests when no deterministic components are present. The similar situation happens to Kim et al. (2002) who report severe oversizing in the constant-corrected ADF tests in the presence of an early single abrupt decrease in the innovation variance. Cavaliere (2004) proposes a more general framework for investigating the effects of permanent changes in volatility by showing that the limiting null distributions of the Phillips and Perron (1988) (PP) test statistics depend on a particular function of the underlying volatility process which can lead to either oversizing or undersizing in the tests.

Cavaliere and Taylor (2006) consider both smooth volatility changes and multiple volatility shifts and construct a numerical solution to obtain approximate quantiles from the asymptotic null distributions of the standard unit root statistics. They focus on M unit root tests by Perron and Ng (1996) which is still robust when applied to autocorrelation. Set the following model to generate the time series process

$$\left(X_t - \gamma_t^{'}\right) = \alpha\left(X_{t-1} - \gamma^{'} Z_{t-1}\right) + u_t \quad t = 1, 2, \ldots, T \tag{31.29}$$

where z_t is a vector of deterministic components, thus set as $z_t = (1, t, \ldots, t^p)'$, while $\varepsilon_t = \sigma_t e_t$, $e_t \sim iid\,(0, 1)$ which is responsible for the heterogeneity. And besides X_0 is of $O_p(1)$. Furthermore, the M statistics for a given sample $\{X_t\}_0^T$ is defined as

$$MZ_\alpha := \frac{T^{-1}\hat{X}_T^2 - T^{-1}\hat{X}_0^2 - s_{AR}^2(k)}{2T^{-2}\sum_{t=1}^{T}\hat{X}_{t-1}^2}.$$

where $\hat{X}^t$ are the OLS residuals from the regression of X_t on z_t, $t = 0, \ldots, T$ and $s_{AR}^2(k)$ is an autoregressive estimator of the (non-normalized) spectral density at frequency zero of $\{u_t\}$. Specifically,

$$s_{AR}^2(k) := \hat{\sigma}^2 / \left(1 - \hat{\beta}(1)\right)^2, \quad \hat{\beta}(1) := \sum_{i=1}^{k} \hat{b}_i,$$

where $\hat{b}_i$, $i = 1, \ldots, k$, and $\hat{\sigma}^2$ are, respectively, the OLS slope and variance estimators from the regression equation $\Delta\hat{X}_t = \hat{X}_{t-1} + \sum_{i=1}^{k} b_i \Delta\hat{X}_{t-i} + \varepsilon_{t.k}$, where the lag truncation parameter satisfies the following assumption. Details about the asymptotic distribution are referred to Cavaliere and Taylor (2006). Moreover, the Cavaliere and Taylor method performs as a general way to deal with the persistent change in volatility. However, in real world it usually cannot be identified easily. In other words, it smooths off structural change and hold for any process, providing another conveniently operative way for this issue.

31.4 Tests for Special Structural Breaks

There also exist several types of structural breaks that have exclusive features distinctly from common economic phenomena. For example, a financial bubble being originated or bursting indicates a significant and catastrophical structural break, which is capable of wiping out the great wealth of people as much as possible. Additionally, the cointegration, recognized as a common relationship between economic individuals especially in international finance and macroeconomics, could be with breaks. Thus, testing a break in cointegrating relationship correctly could be a solution of financial crises.

31.4.1 Bubble Tests

31.4.1.1 Definition of the Bubble

We first present the definition of the bubble. A bubble is always characterized as an explosive asset price deviation from its fundamentals regardless of whether such a deviation is positive or negative. However, investors and regulators often ignore bubbles rather easily, because there exists no efficient methodology to monitor and detect those. In general, a bubble could be triggered by the irrational behaviors. Shiller (2000) conducts this conclusion by observing investors who switch their attentions from the specific financial asset to another and points out these behaviors take no consideration of deviations in fundamentals. More importantly, most historical events coincided with Shiller's findings; thus those opinions become more convincing. A famous example is the remark given by Greenspan, the ex-chairman of the Federal Reserve Board, which illustrates that it would be fairly difficult to know when irrational exuberance has unduly escalated asset values and thus the USA experienced the bubble collapse.

Furthermore, those claims have already been proved. Kirman and Teyssiere (2005) rebuked that the deviations from fundamental assets are not the outcome of irrational herding but the significant shifting compositions of expectations, which result from opinion diffusion processes. This view is backed up by an analysis of two types of agents in financial market, which are fundamentalists and chartists. The former denotes agents who believe asset price P_t is related to underlying fundamental $\overline{P}_t$, i.e., a constant $\overline{P}$. The latter depends on the P_t which is cumulated by historical prices. Moreover, there also exists heterogeneity between these agents. Thus for the former,

$$E^f(P_{t+1}|I_t) = \overline{P}_t + \sum_{j=1}^{M^f} v_j\left(P_{t-j+1} - \overline{P}_{t-j}\right) \tag{31.30}$$

where $v_j, j = 1, \ldots, M^f$ are positive constants and M^f is the memory of the fundamentalists. And in return for the latter

$$E^c(P_{t+1}|I_t) = \sum_{j=0}^{M^c} h_j P_{t-j} \tag{31.31}$$

where $h_j, j = 1, \ldots, M^c$ are constants, M^c is the memory of the chartists. And based on the two opinions, the market view of prices are synthetic by the weighted average of these forecast

$$E^m\left(P_{t+1}|I_t\right) = w_t E^{\mathrm{f}}(P_{t+1}|I_t) + (1 - w_t)E^c(P_{t+1}|I_t) \tag{31.32}$$

where w_t is the proportion of fundamentalists. Such a market view is dynamic since contacts or meetings happen randomly between agents and often help build their next investment plans. In this sense, consider k_t as the number of fundamentalists at time t and the remaining $N - k_t$ as chartists. Allow some fixed number M of meetings to take place at each time. Set $q_t = k_t/N$ for each agents as the observation to decide the opinion chosen by majority. And thus

$$q_{i,t} = q_t + \varepsilon_{i,t}, \varepsilon \sim N\left(0,\ \sigma_q^2\right),\ \ q_{i,t} \in [0, 1].$$

And it can be easily understood that w_t functioned in Eq. 31.32 originates from the following mechanism,

$$w_t = N^{-1} \sum_{i=1}^{N} \sharp\left\{i : q_{i,t} \geq \frac{1}{2}\right\}.$$

Apparently w_t varies with time as the q_t process, and it is believed to be dependable on k_t reciprocally. Given the two types of agents, the market price can be written as

$$P_t = cE^m(P_{t+1}|I_t) + Z_t \tag{31.33}$$

where c is a constant and Z_t is an index of a vector of fundamental variables. Obviously, the time-varying W_t decides the market view of the prices in the future and thus is determinant in the real price. As theoretically proved by Kirman and Teyssiere (2005), W_t switching from zero to one and vice versa could lead to varying prices around the fundamental level where a change-point process in the conditional mean definitely exist. It also helps explain that such process never herds on the extreme and sometimes moves gradually.

Therefore the above two given opinions are agreeable in the aspect that when prices explode there may be a change point. Accordingly, the implicit change point is another version of structural break; thus testing for bubbles efficiently could be viewed as a way to detect the explosive behavior in pricing.

31.4.1.2 Tests for Bubbles

According to the above explanation, many literatures propose suitable testing mechanism for rational bubbles. As among these tests, a basic solution is based on a unit root test. Since rational bubbles always manifest explosive characteristics in prices, these tests such as augmented Dickey-Fuller (ADF) could find this distinction with stationary process and unit root. Commonly regarded as expectations of prices and dividends in the future, the current price is determined sly by the fundamental which refers to dividends if there is no bubble. This means pricing follow the variation of dividends, and often there is cointegration relationship between them. Conversely, if a bubble occurs in the prices, explosive behaviors are expected regardless of what character dividends own. This implication motivated Diba and Grossman (1988) to firstly look for the presence of bubble behavior by applying unit root tests to $_t$. However, these tests are criticized by Evans (1991) who questions the validity of the empirical tests since none of them have much power to detect periodically collapsing bubbles. He supports this criticism by explaining that a periodically collapsing bubble process can behave much like an I(1) process or even like a stationary linear autoregressive process, as a result of which the standard unit root and cointegration tests in this context are not reliable.

Phillips et al. (2009) design a new synthetical unit root test and avoid such problem. Such a refinery ADF test against the alternative of an explosive root(the right-tailed) is conducted in an autoregressive specification as

$$x_t = \mu_x + {}_{t-1} + \sum_{j=1}^{J} \phi_{jt-j} + \varepsilon_{x,t}, \varepsilon_{x,t} \sim NID\left(0, \sigma_x^2\right) \tag{31.34}$$

where x_t stands for log stock or log dividend and the certain order of J is suggested by Campbell and Perron (1991), while NID denotes independent and normal distribution. Thus the unit root null hypothesis is $H_0 : \delta = 1$, and the right-tailed alternative is $H_1 : \delta > 1$.

After this, a series of forward recursive regressions are applied to Eq. 31.34 repeatedly with sequential subsets of the sample data incremented by one observation at each pass. Set number of observations in the first regression as $\tau_0 = [nr_0]$ and subsequent regressions employ the originating data set supplied by successive observations giving a sample of size $\tau = [nr]$ for $r_0 \le r \le 1$. And the corresponding t-statistic by ADF_r and ADF_1 corresponds to the full sample. Under the null,

$$ADF_r \Rightarrow \frac{\int_0^r WdW}{\left(\int_0^r W^2\right)^{1/2}},$$

and

$$\sup_{r\in[r_0,1]} ADF \Rightarrow \sup_{r\in[r_0,1]} \frac{\int_0^r WdW}{\left(\int_0^r W^2\right)^{1/2}}$$

where W is the standard Brownian motion. Comparing $\sup_{r\in[r_0,1]}$ ADF with the right-tailed critical values with $\sup_{r\in[r_0,1]}\left(\int_0^r WdW\right)\Big/\left(\left(\int_0^r W^2\right)^{1/2}\right)$ will lead to a unit root test for against explosiveness. And to pinpoint the structural break, the recursive test statistics ADF_r are needed against the right-tailed critical values of the asymptotic of the standard Dickey-Fuller t-statistic. In particular, if r_e denotes the origination date and r_f is the collapse date of explosive behavior in the data, estimates of these dates are as follows:

$$\hat{r}_e = \underset{s\ge r_0}{\text{INF}}\, s : ADF_s > cv_{\beta_n}^{adf}, \quad \hat{r}_f = \inf_{s\ge \hat{r}_e} \inf\left\{s : ADF_s < cv_{\beta_n}^{adf}\right\} \tag{31.35}$$

where $cv_{\beta_n}^{adf}(s)$ denotes the right-sided critical value of ADF_s corresponding to a significant level of β_n. Notice the consistent estimation of the bubble period $\hat{r}_e, \hat{r}_f$ requires the significance level β_n approaching zero asymptotically and correspondingly $cv_{\beta_n}^{adf}(s)$ diverging to infinity in order to eliminate type I error as $n \to \infty$. This can be implemented in a convenient way employing $cv_{\beta_n}^{adf}(s) = \log(\log(ns))/100$. Particularly, it replaces the explicit setting for β_n which is more complicated. This test referred by Phillips et al. (2009) is advantageous for the reason that it doesn't allow for the possibility of periodically collapsing bubbles, which are often observed in practical economic and financial applications.

What's more, there are more other attempts that could avoid potential setbacks in performance of testing for bubbles. Among them, large sums of progressing improvement are from unit root tests for explosive characters. For example, bootstrapping is applied to improve the power of tests, of which Paparoditis and Politis (2003) make use for the heavy-tail problem. For DGP in Eq. 31.34, it is assumed that

$$\hat{\varepsilon}_t = \theta \hat{\varepsilon}_{t-1} + e_t \tag{31.36}$$

For a test against $|\theta| < 1$, the residual block bootstrap method is carried as follows: for each block bootstrap series satisfying H_0, set the sample k, $k = 1, \ldots, B$, and the integer $b = b(T) < T$ is employed such that $1/b + b/\sqrt{T} \to 0$ as $T \to \infty$. Define $\kappa = [T(-1)/b]$ and draw with replacement κ integers $i_0, \ldots, i_{\kappa-1}$ from the set $1, \ldots, T - b$, and build the bootstrap samples $\varepsilon j(k)$ as follows:

$$\varepsilon_1(k) = \hat{\varepsilon}_1, \varepsilon_j(k) = \varepsilon_{j-1} + \overline{\hat{e}}_{i_m+s}, j = 2, \ldots, l, l = \kappa b + 1,$$
$$m = [(j-2)/b], s = j - mb - 1, \quad k = 1, \ldots, B.$$

Let $\hat{\theta}_T$ be the least-squares (LS) estimator of θ in Eq. 31.36 and $\widetilde{\theta}_l(k)$ be the LS estimator of the regression of $\varepsilon_j(k)$ on $\varepsilon_{j-1}(k)$. Thus H_0 would be rejected if $T\left(\hat{\theta}_T - 1\right) < q_{l,B}(\gamma)$, where $q_{l,B}(\gamma)$ is the γth quantile of the distribution of $l\left(\widetilde{\theta}\right)_l(\cdot) - 1\big)$ when the size for testing is γ. Since some financial time series might have heavy tails, the tail index α would make $Pr(|e_t| > x) \sim x^{-\alpha}$ as $x \to \infty$ for some $\alpha > 0$. Yet this modification of standard asymptotic theory for unit root tests is still valid.

Horvath and Kokoszka (2003) and Jach and Kokoszka (2004) make the mild hypothesis that the $E(e_t) = 0$ and that the e_t are in the domain of attraction of an α-stable law with $\alpha \in (1, 2)$, while Kokoszka and Parfionovas (2004) consider the more general case $\alpha \in (1, 2]$ which then includes the Gaussian case $\alpha = 2$. Chan and Tran (1989) have shown that under the null hypothesis H_0,

$$T\left(\hat{\theta}_T - 1\right) \xrightarrow{d} \xi := \frac{\int_0^1 L_\alpha(\tau-) dl_\alpha(\tau)}{\int_0^1 L_\alpha^2(\tau) d\tau}.$$

The purpose of the unit root and subsampling tests here is to approximate the distribution of the unit root statistics ξ without knowledge of the tail index *alpha* which is difficult to estimate.

Another method employing subsampling is advocated by Jach and Kokoszka (2004) consists in constructing $T - b$ processes which satisfies H_0,

$$\varepsilon_1(k) = \overline{\hat{e}}_k, \ldots, \varepsilon_b(k) = \overline{\hat{e}}_k + \cdots + \overline{\hat{e}}_{k+b-1}, k = 2, \ldots, T - b + 1,$$

where b is the size of the subsampling blocks. Let $\widetilde{\theta}_b(k)$ be the LS estimator of the regression of $\varepsilon_j(k)$ on $\varepsilon_{j-1}(k)$. Then the distribution of ξ would be estimated by $b\left(\widetilde{\theta}_b(\cdot) - 1\right)$.

Moreover Wu and Xiao (2008) have proposed a procedure similar to cointegration tests by Xiao and Phillips (2002) to help detect collapsible bubbles against which Evans (1991) pointed out that unit root tests would lose the power.

Their procedure is based on the magnitude of variation of the partial sum processes $S_k = \sum_{t=1}^{k} \hat{\varepsilon}$ of the residuals of regression (31.36). If there is no bubble, the magnitude of fluctuation of the process S_k is proportional to $k^{1/2}$, while the presence of a bubble makes the process S_k diverging to ∞. Their statistic denoted by $\underline{R}$ enjoys the advantage of no influence from serial correlation and the correlation between the residuals and the fundamentals under the null hypothesis. As showed below, $\underline{R}$ converges to the supremum of a functional of Brownian motions, i.e.,

$$\underline{R} := \max_{1\leq k\leq T} \frac{k}{\hat{\omega}_{\varepsilon,d}\sqrt{T}} \left| k^{-1} S_k^{+} - T^{-1} S_T^{+} \right| \xrightarrow{d} d\sup_{0\leq\tau\leq 1} \left| \left(\widetilde{V}\right)(\tau) \right|$$

where $\widetilde{V}(\tau) = \underline{W}_d(\tau) - \tau \underline{W}_d(1)$, $\underline{W}_d = W_1(\tau) - \left[\int_0^1 dW_1 S'\right] \left[\int_0^1 SS'\right]^{-1} \int_0$, $S(\tau)' = (1, W_2(\tau))$, $W_1(\tau)$ and $W_2(\tau)$ are Brownian motions that are independent of each other; $\hat{\omega}_{t,d}$ is a nonparametric long-run variance estimator.

31.4.2 Cointegration Breakdown Tests

In addition to detecting the structural breaks in a time series, tests for a breakdown in the cointegration relationship between two nonstationary I(1) process are also of interest. For example, correlation of global financial market becomes more obvious as a result of rapid international capital flows, which feature I(1) processes and are generally the linear combinations of nonstationary time series. As shown by most empirical evidences, the existing cointegration relationship often comes to the end prior to the finite crisis. Such a structural break is vital since it is an indicator for finance crash. Traditional wisdom formulates the cointegration breakdown tests always from the assumption that the post-breakdown period is relatively long, and this is often strong and unrealistic especially for practitioners, see Hansen (1992) and Quintos and Phillips (1993). Andrews and Kim (2003) on the contrary abandon this assumption and introduce tests for cointegration breakdown with fixed post-breakdown time length m, under the condition that the sample $T + m$ goes to infinity. Clearly, their implementation concentrating on end-of-sample could be conveniently extended to breakdown tests occurring at the beginning or in the middle of the sample.

The data-generating process is as follows:

$$y_t = \begin{cases} x'\beta_0 + u_t & \text{for} \quad t = 1, \ldots, T \\ x'\beta_t + u_t & \text{for} \quad t = T+1, \ldots, T+m \end{cases}$$

where y_t, $x_t \in R$ and x_t, β_0, $\beta_t \in R^k$ and the regressors for all time periods are I(1) processes with potential deterministic and stochastic trend or other stationary random variables. Thus the null and the alternative hypotheses are

$$H_0 : \begin{cases} \beta_t = \beta_0 \quad \text{for} \quad \text{all} \quad t = T+1, \ldots, T+m \quad \text{and} \\ u_t : t = 1, \ldots, T+m \quad \text{are stationary and ergodic} \end{cases}$$
$$H_1 : \begin{cases} \beta_t \neq \beta_0 \ \text{for some} \quad t = T+1, \ldots, T+m \quad \text{and/or} \\ \text{the distribution of} \quad u_{T+1}, \ldots, u_{T+m} \quad \text{differs from} \\ \text{the distribution of} \quad u_1, \ldots, u_m \end{cases} .$$

The alternative hypothesis H_1 represents a break in cointegrating relationship in systematical perspectives including (i) a shift in the vector β_0 to β_t and (ii) a shift in the distribution of u_t from being stationary to being a unit root random variable. They consider a test statistics in the quadratic form of the "post-breakdown" residuals $\hat{u}_t : t = T+1, \ldots, T+m$. The critical value of the test statistics is determined via a parametric subsampling method, which if the test statistics exceeds then the test rejects the null hypothesis.

For any $1 \le r \le s \le T+m$, let $Y_{r-s}\overline{(}y_r, \ldots, y_s)', X_{r-s}\overline{(}x_r, \ldots, x_s)', U_{r-s}\overline{(}u_r, \ldots, u_s)'$. And the quadratic form will be

$$P_j(\beta, \omega) = \left((Y_{j-(j+m-1)} - X_{j-(j+m-1)}\beta\right)' \omega\left((Y_{j-(j+m-1)} - X_{j-(j+m-1)}\beta\right)$$

and for $j = 1, \ldots, T + 1$. For the P tests in Andrews and Kim (2003), ω is some nonsingular m matrix and I_m denotes the m dimensional identity matrix. Naturally, an estimator of β_0 denoting as $\hat{\beta}$ is based on the least squares with observations $t = r, \ldots, s$ for $1 + m$ as following:

$$\hat{\beta}_{r-s} = \left(X'_{r-s}X_{r-s}\right)^{-1} X'_{r-s}Y_{r-s}$$

Although other estimators like the fully modified estimator of Phillips and Hansen (1990) and the ML estimator of Johansen can also be applied, the priority for explanation is given to LS estimator.

Then the first test statistics, P_a is defined as

$$P_a = P_{T+1}\left(\hat{\beta}_{1-T}\right) = \sum_{t=T+1}^{T+m} \left(y_t - x_t'\hat{\beta}_{1-T}\right)^2.$$

Referred to as a predictive statistic, P_a is the post-breakdown sum of squared residuals. The motivation for considering this is equivalent to the F statistics employed to test a single change in the regression just like Chow Test (1969). Set $P_j(\beta)$ at a "leave-m-out" estimator, $\hat{\beta}_{(j)}$ as to mirror that $\hat{\beta}_{1-T}$ is not dependent on observations after point T, then

$$\hat{\beta}_{(j)} = \begin{cases} \text{estimator of } \beta \text{ using observations indexed by } t = 1, \ldots, T \text{ with} \\ t, \ldots, j+m-1. \end{cases}$$

Clearly, $\hat{\beta}_{(j)}$ by the estimators mentioned above is consistent for β_0 under suitable assumptions. Define

$$P_{a,j} = P_j\left(\hat{\beta}_{(j)}\right) \text{ for } j = 1, \ldots, T - m + 1.$$

And the empirical df of $P_{a,j} : j = 1, \ldots, T - m + 1$ is

$$\hat{F}_{P_{(a)},T}(x) = 1 - m + 1 \sum_{t=1}^{T-m+1} l\left(P_{a,j}\right).$$

Then define the test statistic P_a to be the $1 - \alpha$ sample quantile, $\hat{q}p_a$, $1 - \alpha$ and

$$\hat{q}p_a, \;\; 1 - \alpha = \text{INF } \; x \in: \hat{F}_{P_a,T}(x) \geq 1 - \alpha.$$

Thus one can reject H_0 if $P_a > \hat{q}p_a$, $1 - \alpha$.

However, P_a test's simulation performance is not satisfying since it often over-rejects the null hypothesis. Instead, P_b test could have better finite-sample properties as defined by

$$P_b = P_{T+1}\left(\hat{\beta}_{1-(T+\lceil m/2 \rceil}\right) \text{ and } P_{b,j} = P_j\left(\hat{\beta}_{(j)}\right) \text{ for } j = 1, \ldots, T - m + 1.$$

The P_b test supersedes the P_a for it is less variable as the estimator $\hat{\beta}_{1-(T+m/2\mathrm{e})}$ depends on the observation indexed by $t = T + 1, \ldots, T + 2\rceil$.

Moreover, a naturally less variable statistic P_c is dependent on the complete sample estimator $\hat{\beta}_{1-(T+m)}$:

$$P_c = P_{T+1}\left(\hat{\beta}_{1-(T+m)}\right) P_{c,j} = P\left(\hat{\beta}_{2(j)}\right) \text{ for } j = 1, \ldots, T - m + 1.$$

where

$$\hat{\beta}_{2(j)} = \begin{cases} \text{estimator of } \beta \text{ using observations indexed by } t = 1, \ldots, T \text{ with} \\ t \neq j, \ldots, j + 2\rceil - 1 \end{cases}$$

for $j = 1, \ldots, T - m + 1$. The P tests are suitable for models where errors are uncorrelated, and including weights in the statistics based on an estimator of the error covariance matrix will be advantageous if the errors are correlated. Tests with the weights are the same as $P_a - P_c$ except that $\omega = I_m$ is replaced by

$$\hat{\omega}_{1-(T+m)} = \left(1 + 1 \sum_{j=1}^{T+1} \hat{U}_{j,j+m-1} \hat{U}'_{j,j+m-1}\right)^{-1}$$

where

$$\hat{U}_{j,j+m-1} = Y_{j,j+m-1} - X_{j,j+m-1}\hat{\beta}_{1-(T+m)},$$

The estimator $\hat{\omega}_1 - (T+m)$ is an estimator of the inverse of the m covariance matrix of the errors $\omega_0^{-1} = (EU_{1-m}U'_{1-m})^{-1}$.

As for the presence of unit root errors from $t = T + 1$ to $t = T + m$ in a linear regression model with i.i.d. normal errors, the locally best invariant (LBI) test statistic is applied. According to Andrews and Kim (2003), set $A_m(k, l) = \min\{k, l\}$ for $k, l = 1, \ldots, m$ then the R tests which are aimed to solve the breakdown will be defined as

Andrews and Kim's (2003) tests are not consistent because m is fixed as $T \to \infty$ while they are simultaneously asymptotically unbiased. The power of the tests is determined by the magnitude of the breakdown and m. The former includes the magnitude of the parameter shift and the magnitude of the unit root error variance, and the larger is m, the greater is the power. That means failure to reject the null hypothesis should not be interpreted as strong evidence in favor of stable cointegration.

31.5 Monitoring Structural Breaks

Foregoing tests almost deal with in-sample data, and it may be tempting to apply them to real-time data. Under this distinct condition, however, traditional method for detecting structural breaks mainly within a historical data set normally generates comparatively large chance of mistaken instability, which leads to variant over-rejection. Typically, such a test will signal a nonexistent break with probability one. Thus due to the law of the iterated logarithm, no matter how perfectly these methods perform as one-shot type detection, their sound performance could not be translated to monitor out-of-sample stability. Conversely, monitoring test could detect the break on time without these concerns. Focusing on monitoring structural break, this section will explain how this relatively advantageous test works better timely. Plus, it is also to provide evidence to support that the good performance still holds even in long memory, as articulated before to some degree an ideal description of economy issues.

31.5.1 Monitoring in Comparably Ideal Conditions

For a linear regression $Y_t = X'\beta_t + \varepsilon_t$, $t = 1, 2, \ldots$, usually a real-time structural break test is bounded with the assumption: $\beta_t = \beta_0$ for $t = 1, 2, \ldots, m$. And the null of the test is $\beta_t = \beta_0$ for some $t \geq m + 1$. To solve this problem, Chu et al. (1996) come up with a CUSUM monitoring procedure based on the behavior of recursive residuals and a fluctuation monitoring procedure based on recursive estimates of parameters. They use sequential testing to develop tests of structural stability for real-time economic systems and widen the class of boundary functions of previous monitoring tests, which is outstanding as it matches economic research more exactly.

Let $\{S_n\}$ be the partial sum process constructed from ε_i and assume the process ε_i follows the FCLT (functional central limiting theorem) as $\lambda \to \gamma_0^{-1} m^{-1/2} S_{[m\lambda]} \Rightarrow \lambda(\lambda)$, $\lambda \in [0, \infty)$, where $S_n = \sum_{i=1}^{n} \varepsilon_i$ and $\sigma_0^2 \to n^{-1} E(S_n^2) < \infty$. Chu et al. (1996) extend Robinson and Siegmund's (1970) limiting relation as their central mechanism

$$\lim_{m\to\infty} P\left\{S_n \geq \sqrt{m} g((n/m),\ \text{forsome}\ n \geq 1\right\} = P\{W(t) \geq g(t),\ \text{for some}\ t \geq 0\}$$

where $S_n = \sum_{t=1}^{n} \varepsilon_t$, W denotes a standard Brownian motion and g is a stopping boundary satisfying some regularity conditions. This suggests a stopping function for the monitoring test. Another limiting result similar to Eq. 31.37 is

$$\lim_{m\to\infty} P\left\{|S_n| \ \geq \sqrt{m} g((n/m),\ \text{for some}\ n \geq m\right\} = P\{|W(t)|(t), t \geq 1\} \tag{31.37}$$

Robinson and Siegmund (1970) give their proof for an i.i.d. ε_i in Eq. 31.38 could hold for a certain class of continuous functions $g(t)$ that satisfy $t^{-1/2}$ $g(t)$ is ultimately nondecreasing as $t \to \infty$ and other assumptions. Though this is useful, yet such assumption is not applicable all the time for research. Segen and Sanderson (1980) provide a partial resolution for they show that under the boundary function $t^{-1/2}$ $g(t)$ is nondecreasing, stochastic sequence S_n that satisfies the FCLT continues to hold. Yet such condition turns out more restrictive than that of Robbins and Siegmund. Chu et al. (1996) propose a new limiting similar relation without imposing these restrictions. Typically, the boundary function $g(t)$ considered to be pertinent to economy is given as

$$P\left\{|W(t)| \geq \left[t\left(a^2\right) + \ln t\right)\right]^{1/2},\ \text{for some} \quad t \geq 1\right\} = 2[1 - \Phi(a) + a\phi(a)] \tag{31.38}$$

$$P\left\{|W(t)| \geq (t+1)^{1/2}\left[a^2 + \ln(t+1)\right]^{1/2},\ \text{some}\ t > 0]\right\} = \exp\left(-a^2\right) \tag{31.39}$$

where Φ and ϕ stand for the cdf and pdf, respectively, of a standard normal random variable.

A monitoring is a stopping time, determined by a detecting statistic (detector) Γ_n and a threshold g(m,n), according to $\tau_g(\Gamma_n)n$, $\Gamma_n > g(m, n)$. Firstly consider the situation where the detector is in form of CUSUM. Let $\hat{\beta} = \left(\sum_{i=1}^{n} X_i X_i^{'}\right)^{-1} \left(\sum_{i=1}^{n} X_i Y_i\right)$ be the OLS estimator at time n. Also define recursive residuals as $w_k = 0$ and $w_n = \hat{\varepsilon}/v_n^{1/2}$, $v_n = 1 + X_n^{'}(\sum_{i=1}^{n-1} X_i X_i^{'})^{-1} X_n$, $\hat{\varepsilon}_n = Y_n - X_n^{'} \hat{\beta}_{n-1}$, $n = k + 1, \ldots m, \ldots$. Thus the nth-cumulated sum of recursive residuals is $Q_t^m = \hat{\sigma}^{-1} \sum_{i=k}^{n} \omega_i = \hat{\sigma}^{-1} \sum_{i=k}^{k+\left[\widetilde{m}\right)t]} \omega_i$, for $(n-k)/\widetilde{m} < (n-k+1)/\widetilde{m}$, where $\hat{\sigma}$ is a consistent if σ, $\widetilde{m} = (m-k)$ is the integer of $(\widetilde{m})t$. Thus under H_0,

$$t \to \widetilde{m}^{-1/2} Q_t^m, \ \ t \in [0, \infty) \Rightarrow t(t), \ \ t \in (0, \infty) \tag{31.40}$$

where "⇒" denotes the weak convergence of the associated probability measures. According to Chu et al. (1996), as the monitoring starts as $m + 1$, define $\widetilde{Q}_t^m = \hat{\sigma} \sum_{i=m+1}^{k+[\widetilde{m}(1+t)]} \omega_i$, $t \in [0, \infty)$. In particular, for $n/(m - k) < (n + 1)/(m - k)$, $\widetilde{Q}_n^m = \hat{\sigma}_{-1} \left(\sum_{i=k}^{m+n} \omega_i - \sum_{i=k}^{m} \omega_i \right)$, $n \geq 1$. It follows that $t \to \widetilde{m}^{-1/2} \widetilde{Q}_n^m \Rightarrow t \to [W(t+1) - W(t)]$, $t \in [0, \infty)$. Since this is a Brownian motion, it can be written in the form of Eq. 31.36

$$\begin{aligned} &\lim_{m\to\infty} P\left\{ |Q_n^m| \ \geq \sqrt{m-k} g\left(\frac{n}{m-k}\right), \ \text{for some} \ \ n \geq 1 \right\} \\ &= P\left\{ |W(t)| \ \geq g(t), \ \text{for some} \ t \geq 0 \right\} \end{aligned}.$$

Its mechanism can be explained as that once the path of $\left| \widetilde{Q}_n^m \right|$ crosses the boundary $(m - k)^{1/2}$ $g(n/m - k)$, it will reject the null hypothesis and imply that the model suitable for historical period is no longer reliable. Moreover, an extension of this can be applied to FL monitoring procedure as

$$\begin{aligned} &\lim_{m\to\infty} P\left\{ |Q_n^m| \geq \sqrt{m-k} g\left(\frac{n}{m-k}\right), \ \text{for some} \ n \geq m \right\} \\ &= P\left\{ |W(t)| \geq g(t), \ \text{for some} \ t \geq 1 \right\} \end{aligned} \tag{31.41}$$

It needs notice that CUSUM algorithms, except those recursive residuals, also hold for such mechanism, e.g., LR statistics for dependent sequences. Yet LR detector sometimes could be superfluously complex in general and leads to a complicated computation. According to the above statement, a CUSUM monitoring can be implemented as follows:

Suppose (i) $Y_t = X_t' \beta_0 + \varepsilon_t$, $t = 1, \ldots, m + 1, \ldots$, where X_t is a $k \times 1$ random vector such that $m^{-1} \sum_{t=1}^{m} X_t$ and $m^{-1} \sum_{t=1}^{m} X_t X_t'$ converge in probability to b, a non-stochastic $k \times 1$ vector and M, a k matrix of full rank, respectively; (ii) ε_t is a martingale difference sequence with respect to a sequence of σ-algebra F_t such that $E(\varepsilon^2) < \infty$ and $E(\varepsilon_t^2 | F_{t-1}) = \sigma_0^2$ for all t, where F_t is generated by…, (Y_{t-2}, X_{t-1}'), (Y_{-1}, X_t'); (iii) the sequence $X_t \varepsilon_t$ obeys the functional central limit theorem, then

$$\begin{aligned} &\lim_{m\to\infty} P\left\{ \left| \widetilde{Q}_n^m \right| \geq \sqrt{n+m-k} \left[a^2 + ln\left(\frac{n+m-k}{m-k} \right) \right]^{1/2}, \ \text{for some,} \ \ n \geq 1 \right\} \\ &= \exp(-a^2/2); \end{aligned} \tag{31.42}$$

$$\begin{aligned} &\lim_{m\to\infty} P\left\{ \left| \widetilde{Q}_n^m \right| \geq \sqrt{m-k} \left(\frac{n}{m-k} \right)^{1/2} \left[a^2 + ln\left(\frac{n}{m-k} \right) \right]^{1/2}, \ \text{some} \ n \right\} \\ &= 2[1 - \Phi[a] + a\phi(a)] \end{aligned} \tag{31.43}$$

Additionally, by the right-handed side of Eqs. 31.42 and 31.43, the asymptotic size control of the CUSUM monitoring is fairly effortless. For CUSUM monitoring based on $\widetilde{Q}_n^m$, the 10 % and 5 % asymptotic size correspond to a^2 = 4.6 and 6, respectively. Equally handily, we obtain the 10 % and 5 % asymptotical size of the CUSUM monitoring based on Q_m by setting $a_2 = 6.25$ and 7.78 in Eq. 31.43, respectively.

Furthermore, from Eq. 31.36 we also can construct the fluctuation monitoring of sequential parameter estimates. The key condition is that $X_t\varepsilon_t$ obeys the multivariate FCLT as

$$\lambda^{-1/2}V_0^{-1/2}\sum_{t=1}^{[m\lambda]}X_t\varepsilon_t \Rightarrow \lambda - W(\lambda),\ \ \lambda \in [0,\infty)$$

where $V_0 = lim_{m\to\infty}m^{-1}E(S_mS_m^{'})$ with $S_m = \sum_{t=1}^{m}X_t\varepsilon_t$, and $\underline{W}(\lambda)$ is a k-dimensional Wiener process. Following this, the fluctuation detector can be defined as

$$\hat{Z}_n = nD_m^{-1/2}\left(\hat{\beta}_n - \hat{\beta}_m\right), n \tag{31.44}$$

where $D_m = M_m^{-1}V_0\,M_{mp}^{-1}$ is $O_p(1)$ and uniformly positive definite such that

$$\left(\sum_{t=1}^{m}X_tX_t^{'}/m\right) - M_m \to 0.$$

The essential ingredient of this FL detector is the deviation of the updated parameter estimate $\hat{\beta}_n$ from the historical parameter estimate $\hat{\beta}_m$. Then the conclusion can be obtained as

$$(a) : \lambda^{-1/2}\hat{z}_{[m\lambda]} \Rightarrow \lambda \to \underline{W}^0(\lambda),\ \ \lambda \in [1,\infty),$$

where $\underline{W}^0(\lambda)$ is a k-dimensional Brownian bridge;

$$\begin{aligned}(b) : \lim{}_{m\to\infty}P&\left\{\left|\hat{z}^i_{[m\lambda]}\right| \geq m^{1/2}\frac{n-m}{m}\left[\frac{n}{n-m}\left[a^2 + In\left(\frac{n}{n-m}\right)\right]\right]^{1/2}\right\},\\ &(\text{for some} \geq m \quad \text{and some } i)\\ &= 1 - [1 - 2[1 - \Phi(a) + a\phi(a)]]^k,\end{aligned}$$

where $\hat{z}^i_{[m\lambda]}$ is the ith component of $\hat{Z}^i_{[m\lambda]}$. This conclusion summarizes the monitoring procedure based on the fluctuation of $\hat{\beta}_n(n > m)$ relative to $\hat{\beta}_m$. Similarly, given the number of regressors, k, and arbitrary probability of type I error, the monitoring boundary can be calculated with a derivative a^2. More details about cases of the one-time parameter shift in both FL and CUSUM monitoring are referred to Chu et al. (1996).

31.6 Concluding Remarks

In this chapter, we discuss two classes of structural breaks – the retrospective tests and the monitoring tests. From the investor's points of view, it is crucial to use suitable structural break tests to detect turning points of the financial and macroeconomics data accurately and further adjust the portfolios immediately. With the increase of the data property caused by highly frequent market fluctuations, the currently existing structural break tests could not fully detect locations of breaks without the issue of size distortion. More precisely, more and more sophisticated structural breaks tests with respect to any possible market performances would be expected to be created in the near future.

Abstract

Conditionally heteroscedastic time series models are used to describe the volatility of stock index returns. Volatility has a long memory property in the most general models and then the autocorrelations of volatility decay at a hyperbolic rate; contrasts are made with popular, short memory specifications whose autocorrelations decay more rapidly at a geometric rate.

Options are valued for ARCH volatility models by calculating the discounted expectations of option payoffs for an appropriate risk-neutral measure. Monte Carlo methods provide the expectations. The speed and accuracy of the calculations is enhanced by two variance reduction methods, which use antithetic and control variables. The economic consequences of a long memory assumption about volatility are documented, by comparing implied volatilities for option prices obtained from short and long memory volatility processes.

Results are given for options on the S & P 100-share index, with lives up to 2 years. The long memory assumption is found to have a significant impact upon the term structure of implied volatilities and a relatively minor impact upon smile shapes. These conclusions are important because evidence for long memory in volatility has been found in the prices of many assets.

Keywords

ARCH models • Implied volatility • Index options • Likelihood maximization • Long memory • Monte Carlo • Option prices • Risk-neutral pricing • Smile shapes • Term structure • Variance reduction methods

32.1 Introduction

Long memory effects in a stochastic process are effects that decay too slowly to be explained by stationary processes defined by a finite number of autoregressive and moving-average terms. Long memory is often represented by fractional integration of shocks to the process, which produces autocorrelations which decrease at a hyperbolic rate compared with the faster geometric rate of stationary ARMA processes.

Long memory in volatility occurs when the effects of volatility shocks decay slowly. This phenomenon can be identified from the autocorrelations of measures of realized volatility. Two influential examples are the study of absolute daily returns from stock indices by Ding et al. (1993) and the investigation of daily sums of squared 5-min returns from exchange rates by Andersen et al. (2001b).

Stochastic volatility causes option prices to display both smile and term structure effects. An implied volatility obtained from the Black-Scholes formula then depends on both the exercise price and the time until the option expires. Exact calculation of smile and term effects is only possible for special volatility processes, with the results of Heston (1993) being a notable example. Monte Carlo methods are usually necessary when the volatility process has a long memory and these were first applied by Bollerslev and Mikkelsen (1996, 1999).

This chapter documents the economic consequences of a long memory assumption about volatility. This is achieved by comparing implied volatilities for option prices obtained from short and long memory specifications. It is necessary to use a long history of asset prices when applying a long memory model and this chapter uses levels of the S & P 100 index from 1984 to 1998. For this data it is found that a long memory assumption has a significant economic impact upon the term structure of implied volatilities and a relatively minor impact upon smile effects. Some related empirical results are provided by Ohanissian et al. (2004).

Option traders have to make assumptions about the volatility process. The effects of some assumptions are revealed by the prices of options with long lives. Bollerslev and Mikkelsen (1999) find that the market prices of exchange traded options on the S & P 500 index, with lives between 9 months and 3 years, are described more accurately by a long memory pricing model than by the short memory alternatives. Thus these option prices reflect the long memory phenomenon in volatility, although it is found that significant biases remain unexplained.

Three explanatory sections precede the illustrative option pricing results in Sect. 32.5. Section 32.2 defines and characterizes long memory and then reviews the empirical evidence for these characteristics in volatility. The empirical evidence for the world's major markets appears compelling and explanations for the source of long memory effects in volatility are summarized.

Section 32.3 describes parsimonious volatility models which incorporate long memory, either within an ARCH or a stochastic volatility framework. The former framework is easier to use and we focus on applying the fractionally integrated extension of the exponential GARCH model, which is known by the acronym FIEGARCH. An important feature of applications is the unavoidable truncation of an autoregressive component of infinite order. Empirical results are provided for 10 years of S & P 100 returns.

Section 32.4 provides the option pricing methodology. Contingent claim prices are obtained by simulating terminal payoffs using an appropriate risk-neutral measure. Numerical methods enhance the accuracy of the simulations and these are described in Appendix 2.

Section 32.5 compares implied volatilities for European option prices obtained from short and long memory volatility specifications, for hypothetical S & P 100 options whose lives range from 1 month to 2 years. Options are valued on 10 dates, one per annum from 1989 to 1998. The major impact of the long memory assumption is seen to be the very slow convergence of implied volatilities to a limit as the option life increases. This convergence is so slow that the limit cannot be estimated precisely. Section 32.6 contains conclusions.

32.2 Long Memory

32.2.1 Definitions

Definitions which categorize stochastic processes as having either a short memory or a long memory can be found in Brockwell and Davis (1991), Baillie (1996), Granger and Ding (1996), and Taylor (2005). The fundamental characteristic of a long memory process is that dependence between variables separated by τ time units does not decrease rapidly as τ increases.

Consider a covariance stationary stochastic process $\{x_t\}$ that has variance σ^2 and autocorrelations ρ_τ, spectral density $f(\omega)$, and n-period variance ratios V_n defined by

$$\rho_\tau = \mathrm{cor}(x_t, x_{t+\tau}), \tag{32.1}$$

$$f(\omega) = \frac{\sigma^2}{2\pi} \sum_{\tau=-\infty}^{\infty} \rho_\tau \cos(\tau\omega), \quad \omega > 0, \tag{32.2}$$

$$V_n = \frac{\mathrm{var}(x_{t+1} + \ldots + x_{t+n})}{n\sigma^2} = 1 + 2\sum_{\tau=1}^{n-1} \frac{n-\tau}{n}\rho_\tau \tag{32.3}$$

Then a covariance stationary process is here said to have a short memory if $\sum_{\tau=1}^{n} \rho_\tau$ converges as $n \to \infty$; otherwise it is said to have a long memory. A short memory process then has

$$\sum_{\tau=1}^{n} \rho_\tau \to C_1, \; f(\omega) \to C_2, \; V_n \to C_3, \;\; \text{as} \;\; n \to \infty, \;\; \omega \to 0, \tag{32.4}$$

for constants C_1, C_2, C_3. Examples are provided by stationary ARMA processes. These processes have geometrically bounded autocorrelations, so that $|\rho_\tau| \le C\phi^\tau$ for some $C > 0$ and $1 > \phi > 0$, and hence Eq. 32.4 is applicable.

In contrast to the above results, all the limits given by Eq. 32.4 do not exist for a typical covariance stationary long memory process. Instead, it is typical that the autocorrelations have a hyperbolic decay, the spectral density is unbounded for low frequencies, and the variance ratio increases without limit. Appropriate limits are then provided for some positive $d < \frac{1}{2}$ by

$$\frac{\rho_\tau}{\tau^{2d-1}} \to D_1, \; \frac{f(\omega)}{\omega^{-2d}} \to D_2, \; \frac{V_n}{n^{2d}} \to D_3, \;\; \text{as} \;\; n \to \infty, \;\; \omega \to 0, \tag{32.5}$$

for positive constants D_1, D_2, D_3. The limits given by Eq. 32.5 characterize the stationary long memory processes that are commonly used to represent long memory in volatility. The fundamental parameter d can be estimated from data using a regression, either of $\ln\left(\hat{f}(\omega)\right)$ on ω or of $\ln\left(\hat{V}_n\right)$ on n as in, for example, Andersen et al. (2001a)

32.2.2 Fractionally Integrated White Noise

An important example of a long memory process is a stochastic process $\{y_t\}$ which requires fractional differencing to obtain a set of independent and identically distributed residuals $\{\varepsilon_t\}$. Following Granger and Joyeux (1980) and Hosking (1981), such a process is defined using the filter

$$(1-L)^d = 1 - dL + \frac{d(d-1)}{2!}L^2 - \frac{d(d-1)(d-2)}{3!}L^3 + \ldots \tag{32.6}$$

where L is the usual lag operator, so that $Ly_t = y_{t-1}$. Then a fractionally integrated white noise (FIWN) process $\{y_t\}$ is defined by

$$(1-L)^d y_t = \varepsilon_t \tag{32.7}$$

with the ε_t assumed to have zero mean and variance σ_ε^2. Throughout this chapter it is assumed that the differencing parameter d is constrained by $0 \le d < 1$.

The mathematical properties of FIWN are summarized in Baillie (1996). The process is covariance stationary if $d < \frac{1}{2}$ and then the following results apply. First, the autocorrelations are given by

$$\rho_1 = \frac{d}{1-d}, \quad \rho_2 = \frac{d(d+1)}{(1-d)(2-d)}, \quad \rho_3 = \frac{d(d+1)(d+2)}{(1-d)(2-d)(3-d)}, \ldots\ldots \tag{32.8}$$

or, in terms of the gamma function,

$$\rho_\tau = \frac{\Gamma(1-d)\Gamma(\tau+d)}{\Gamma(d)\Gamma(\tau+1-d)}, \tag{32.9}$$

with

$$\frac{\rho_\tau}{\tau^{2d-1}} \to \frac{\Gamma(1-d)}{\Gamma(d)} \quad \text{as} \quad \tau \to \infty. \tag{32.10}$$

Second, the spectral density is

$$f(\omega) = \frac{\sigma_\varepsilon^2}{2\pi}\left|1 - e^{-i\omega}\right|^{-2d} = \frac{\sigma_\varepsilon^2}{2\pi}\left[2\sin\left(\frac{\omega}{2}\right)\right]^{-2d}, \quad \omega > 0, \tag{32.11}$$

so that

$$f(\omega) \cong \frac{\sigma_\varepsilon^2}{2\pi}\omega^{-2d} \text{ for } \omega \text{ near } 0. \tag{32.12}$$

Also,

$$\frac{V_n}{n^{2d}} \to \frac{\Gamma(1-d)}{(1+2d)\Gamma(1+d)} \text{ as } n \to \infty. \tag{32.13}$$

When $d \geq \frac{1}{2}$, the FIWN process has infinite variance and thus the autocorrelations are not defined, although the process has some stationarity properties for $\frac{1}{2} \leq d < 1$.

32.2.3 Evidence for Long Memory in Volatility

When returns r_t can be represented as $r_t = \mu + \sigma_t u_t$, with σ_t representing volatility and independent of an i.i.d. standardized return u_t, it is often possible to make inferences about the autocorrelations of volatility from the autocorrelations of either $|r_t - \mu|$ or $(r_t - \mu)^2$; see Taylor (2005, 2008). In particular, evidence for long memory in powers of daily absolute returns is also evidence for long memory in volatility. Ding et al. (1993) observe hyperbolic decay in the autocorrelations of powers of daily absolute returns obtained from US stock indices. Dacorogna et al. (1993) observe a similar hyperbolic decay in 20-min absolute exchange rate returns. Breidt et al. (1998) find that spectral densities estimated from the logarithms of squared index returns have the shape expected from a long memory process at low frequencies. Ohanissian et al. (2008) accept the null hypothesis of long memory for exchange rate volatility, by assessing the long memory implication that d is invariant under temporal aggregation. Further evidence for long memory in volatility has been obtained by fitting appropriate fractionally integrated ARCH models and then testing the null hypothesis $d = 0$ against the alternative $d > 0$. Bollerslev and Mikkelsen (1996) use this test to support long memory models for US stock index volatility.

Direct evidence for long memory in volatility uses high-frequency data to construct accurate estimates of the volatility process. The estimated quadratic variation of the logarithm of the price process during a 24-h period denoted by t can be estimated from intraday returns $r_{t,j}$ by calculating

$$\hat{\sigma}_t^2 = \sum_{j=1}^{N} r_{t,j}^2. \tag{32.14}$$

The estimate $\hat{\sigma}_t^2$ will be very close to the integral of the latent volatility during the same 24-h period providing N is large but not so large that the bid-ask spread and other microstructure effects introduce bias into the estimate. Using 5-min returns provides conclusive evidence for long memory effects in the estimates $\hat{\sigma}_t^2$ in four studies: Andersen et al. (2001b) for 10 years of DM/$ and Yen/$ rates; Andersen et al. (2001b) for 5 years of stock prices for the 30 components of the Dow-Jones index; Ebens (1999) for 15 years of the same index; and Areal and Taylor (2002) for 8 years of FTSE-100 stock index futures prices. These papers provide striking evidence that time series of estimates $\hat{\sigma}_t^2$ display all three properties of a long memory process: hyperbolic decay in the autocorrelations, spectral densities at low frequencies that are proportional to ω^{-2d}, and variance ratios whose logarithms are very close to linear functions of the aggregation period n. It is also found that estimates of d are between 0.3 and 0.5, with most estimates close to 0.4.

32.2.4 Explanations of Long Memory in Volatility

Granger (1980) shows that long memory can be a consequence of aggregating short memory processes; specifically if AR(1) components are aggregated and if the AR(1) parameters are drawn from a beta distribution, then the aggregated process converges to a long memory process as the number of components increases. Andersen and Bollerslev (1997) develop Granger's theoretical results in more detail for the context of aggregating volatility components and also provide supporting empirical evidence obtained from only 1 year of 5-min returns. It is plausible to assert that volatility reflects several sources of news, that the persistence of shocks from these sources depends on the source, and hence that total volatility may follow a long memory process. Scheduled macroeconomic news announcements are known to create additional volatility that is very short-lived (Ederington and Lee 1993), while other sources of news that have a longer impact on volatility are required to explain volatility clustering effects that last several weeks.

Gallant et al. (1999) estimate a volatility process for daily IBM returns that is the sum of only two short memory components, yet the sum is able to mimic long memory. They also show that the sum of a particular pair of AR(1) processes has a spectral density function very close to that of fractionally integrated white noise with $d = 0.4$ for frequencies $\omega \geq 0.01\pi$. Consequently, evidence for long memory may be consistent with a short memory process that is the sum of a small number of components whose spectral density happens to resemble that of a long memory process except at extremely low frequencies. Attempts to distinguish between true long memory and short memory models which mimic long memory behavior include Ohanissian et al. (2008) and Pong et al. (2008).

Barndorff-Nielsen and Shephard (2001) model volatility in continuous time as the sum of a few short memory components. Their analysis of 10 years of 5-min DM/$ returns shows that the sum of four volatility processes is able to provide an excellent match to the autocorrelations of squared 5-min returns, which exhibit the long memory property of hyperbolic decay.

32.3 Long Memory Volatility Models

A general set of long memory stochastic processes can be defined by first applying the filter $(1 - L)^d$ and then assuming that the filtered process is a stationary ARMA (p, q) process. This defines the ARFIMA (p, d, q) models of Granger (1980), Granger and Joyeux (1980), and Hosking (1981). This approach can be used to obtain long memory models for volatility, by extending various specifications of short memory volatility processes. We consider both ARCH and stochastic volatility specifications.

32.3.1 ARCH Specifications

The conditional distributions of returns r_t are defined for ARCH models using information sets I_{t-1} which are here assumed to be previous returns $\{r_{t-i}, i \geq 1\}$, conditional mean functions $\mu_t(I_{t-1})$, conditional variance functions $h_t(I_{t-1})$, and a probability distribution D for standardized returns z_t. Then the terms

$$z_t = \frac{r_t - \mu_t}{\sqrt{h_t}} \tag{32.15}$$

are independently and identically distributed with distribution D and have zero mean and unit variance.

Baillie (1996) and Bollerslev and Mikkelsen (1996) both show how to define a long memory process for h_t by extending either the GARCH models of Bollerslev (1986) or the exponential ARCH models of Nelson (1991). The GARCH extension cannot be recommended because the returns process then has infinite variance for all positive values of d, which is incompatible with the stylized facts for asset returns. For the exponential extension, however, $\ln(h_t)$ is covariance stationary for $d < \frac{1}{2}$; it may then be conjectured that the returns process has finite variance for particular specifications of h_t.

Like Bollerslev and Mikkelsen (1996, 1999), this chapter applies the FIEGARCH(1, d, 1) specification:

$$\ln(h_t) = \alpha + (1 - \phi L)^{-1}(1 - L)^{-d}(1 + \psi L)g(z_{t-1}), \tag{32.16}$$

$$g(z_t) = \theta z_t + \gamma(|z_t| - C), \tag{32.17}$$

with α, ϕ, d, ψ respectively denoting the location, autoregressive, differencing, and moving-average parameters of $\ln(h_t)$. The i.i.d. residuals $g(z_t)$ depend on a symmetric response parameter γ and an asymmetric response parameter θ which allows the conditional variances to depend on the signs of the terms z_t; these residuals have zero mean because C is defined to be the expectation of $|z_t|$. The EGARCH(1,1) model of Nelson (1991) is given by $d = 0$. If $\phi = \psi = 0$ and $d > 0$, then $\ln(h_t) - \alpha$ is a fractionally integrated white noise process. In general, $\ln(h_t)$ is an ARFIMA(1, d, 1) process.

Calculations using Eq. 32.16 require truncation of a series expansion in the lag operator L. The relevant formulae are listed in Appendix 1. We apply the following ARMA(N, 1) approximation:

$$\ln(h_t) = \alpha + \sum_{j=1}^{N} b_j \left[\ln\left(h_{t-j}\right) - \alpha\right] + g(z_{t-1}) + \psi g(z_{t-2}), \tag{32.18}$$

with the coefficients b_j defined by Eqs. 32.31 and 32.32.

32.3.2 Estimates for the S & P 100 Index

Representative parameters are used in Sect. 32.5 to illustrate the option pricing consequences of long memory in volatility. These parameters are estimated from daily returns r_t for the S & P 100 index, excluding dividends, calculated from index levels p_t as $r_t = \ln\left(p_t/p_{t-1}\right)$.

The conditional variances are evaluated for $t \geq 1$ by setting $N = 1{,}000$ in Eq. 32.18, with $\ln\left(h_{t-j}\right)$ replaced by α and $g(z_{t-j})$ replaced by zero whenever $t - j \leq 0$. The log-likelihood function is calculated for the 2,528 trading days during the 10-year estimation period from 3 January 1989 to 31 December 1998, which corresponds to the times $1,221 \leq t \leq 3,748$ for our dataset; thus the first 1,220 returns are reserved for the calculation of conditional variances before 1989 which are needed to evaluate the subsequent conditional variances.

Results are first discussed when returns have a constant conditional mean which is estimated by the sample mean. The conditional variances are obtained recursively from Eqs. 32.15, 32.17, 32.18, and 32.32. The conditional distributions are assumed to be normal when defining the likelihood function. This assumption is known to be false but it is made to obtain consistent parameter estimates (Bollerslev and Wooldridge 1992). Preliminary maximizations of the likelihood showed that a suitable value for $C = E[|z_t|]$ is 0.737, compared with $\sqrt{2/\pi} \cong 0.798$ for the standard normal distribution. They also showed that an appropriate value of the location parameter α of $\ln\left(h_t\right)$ is -9.56; the log-likelihood is not sensitive to minor deviations from this level because α is multiplied by a term $1 - \sum_{j=1}^{N} b_j$ in Eq. 32.18 which is small for large N. Consequently, the results summarized in Table 32.1 are given by maximizing the log-likelihood function over some or all of the parameters $\theta, \gamma, \phi, \psi, d$.

The estimates of θ and γ provide the usual result for a series of US stock index returns that changes in volatility are far more sensitive to the values of negative returns than those of positive returns, as first reported by Nelson (1991). When z_t is negative, $g(z_t) = (\gamma - \theta)(-z_t) - \gamma C$, otherwise $g(z_t) = (\gamma + \theta)z_t - \gamma C$. The ratio $(\gamma - \theta)/(\gamma + \theta)$ is at least 4 and hence is substantial for the estimates presented in Table 32.1.

Table 32.1 Parameter estimates for short and long memory ARCH models

Model	Constraints	θ	γ	ϕ	ψ	d	RLL
AR(1)	$\psi = d = 0$	−0.06	0.10	0.982			0.0
ARMA(1,1)	$d = 0$	−0.09	0.15	0.988	−0.44		3.0
FI(d)	$\phi = \psi = 0$	−0.12	0.19			0.66	13.9
ARFI(1, d)	$\psi = 0$	−0.11	0.17	0.30		0.59	17.2
ARFIMA(1, d, 1)	None	−0.10	0.15	−0.16	0.98	0.57	21.7
ARFIMA(1, d, 1)	$\phi + \psi + d \leq 1$	−0.12	0.18	−0.27	0.68	0.59	19.7
ARFIMA(1, d, 1)	$d = 0.4$, $\phi + \psi \leq 0.6$	−0.11	0.18	0.64	−0.04	0.4	11.4

Parameters are estimated by maximizing the log-likelihood of daily returns from the S & P 100 index, from 3 January 1989 to 31 December 1998. Returns are modelled as
$r_t = \mu + \sqrt{h_t} z_t$,
$\ln(h_t) = \alpha + (1 - \phi L)^{-1}(1 - L)^{-d}(1 + \psi L) g(z_{t-1})$,
$g(z_t) = \theta z_t + \gamma(|z_t| - C)$
The z_t are assumed to be i.i.d., standard normal variables when defining the likelihood function. The values $C = 0.737$ and $\alpha = -9.56$ are used for all likelihood calculations. The relative log-likelihood (RLL) for a model equals the maximum log-likelihood (MLL) for that model minus the MLL for the AR(1) model. The MLL for the AR(1) model is 8561.6

The first two rows of Table 32.1 report estimates for short memory specifications of the conditional variance. The AR(1) specification has a persistence of 0.982 which is typical for this volatility model. The ARMA (1,1) specification has an additional parameter and increases the log-likelihood by 3.0. The third row shows that the fractional differencing filter alone ($d > 0$, $\phi = \psi = 0$) provides a better description of the volatility process than the ARMA(1,1) specification; with $d = 0.66$ the log-likelihood increases by 10.9. A further increase of 7.8 is then possible by optimizing over all three volatility parameters, d, ϕ, and ψ, to give the parameter estimates[1] in the fifth row of Table 32.1.

The estimates for the most general specification identify two issues of concern. First, d equals 0.57 for our daily data which is more than the typical estimate of 0.4 produced by the studies of higher frequency data mentioned in Sect. 32.2.3. The same issue arises in Bollerslev and Mikkelsen (1996) with d estimated as 0.63 (standard error 0.06) from 9,559 daily returns of the S & P 500 index, from 1953 to 1990. Second, the sum $d + \phi + \psi$ equals 1.39. As this sum equals ψ_1 in Eqs. 32.35 and 32.36, more weight is then given to the volatility shock at time $t - 2$ than to the shock at time $t - 1$ when calculating $\ln(h_t)$. This is counterintuitive. To avoid this outcome, the constraint $d + \phi + \psi \leq 1$ is applied and the results given in the penultimate row of Table 32.1 are obtained. The log-likelihood is then reduced by 2.0. Finally, if d is constrained to be 0.4, then the log-likelihood is reduced by an additional 8.3.

[1] A conservative robust standard error for our estimate of d is 0.12, using information provided by Bollerslev and Mikkelsen (1996).

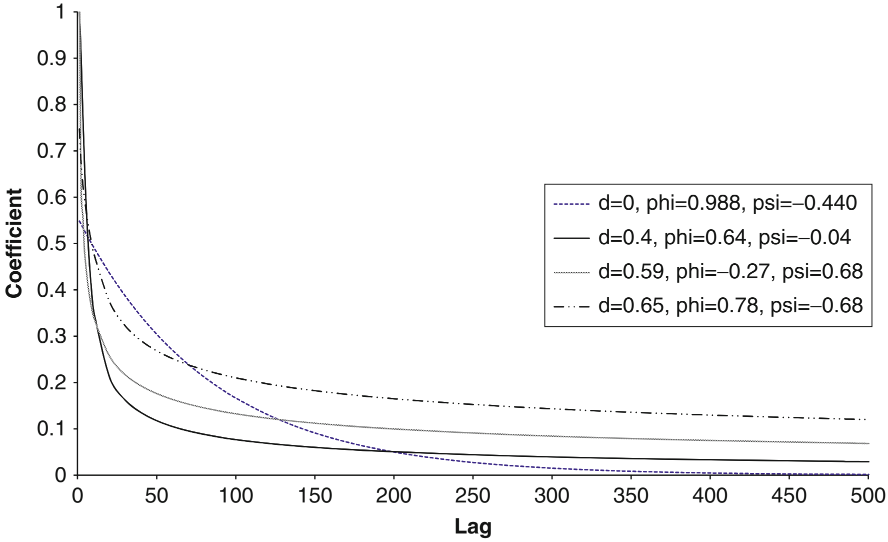

Fig. 32.1 Moving-average coefficients for four ARFIMA(1, d, 1) processes

The estimates obtained here for ϕ and ψ, namely, -0.27 and 0.68 for the most general specification, are rather different to the 0.78 and -0.68 given by Bollerslev and Mikkelsen (1999, Table 1), although the estimates of d are similar, namely, 0.59 and 0.65. However, the moving-average representations obtained from these sets of parameter estimates are qualitatively similar. This is shown on Fig. 32.1 which compares the moving-average coefficients ψ_j defined by (32.36). The coefficients are positive and monotonic decreasing for the four sets of parameter values used to produce Fig. 32.1. They show the expected hyperbolic decay when $d > 0$ and a geometric decay when $d = 0$. The values of b_j in Eqs. 32.32 and 32.38 that are used to calculate the conditional variances decay much faster. For each curve on Fig. 32.1, $\psi_{10} > 0.33$ and $\psi_{100} > 0.07$ while $0 < b_{10} < 0.02$ and $0 < b_{100} < 0.0003$.

The results reported in Table 32.1 are for a constant conditional mean, $\mu_t = \mu$. Alternative specifications such as $\mu_t = \mu + \beta r_{t-1}$, $\mu_t = \mu - \frac{1}{2}h_t$, and $\mu_t = \mu + \lambda\sqrt{h_t}$ give similar values of the log-likelihood when the volatility parameters are set to the values in the final row of Table 32.1. First, including the lagged return r_{t-1} is not necessary because the first-lag autocorrelation of the S & P 100 returns equals -0.022 and is statistically insignificant. Second, including the adjustment $-\frac{1}{2}h_t$ makes the conditional expectation of $(p_t - p_{t-1})/p_{t-1}$ constant when the conditional distribution is normal. The adjustment reduces the log-likelihood by an unimportant 0.3. Third, incorporating the ARCH-M parameter λ gives an optimal value of 0.10 and an increase in the log-likelihood of 1.5. This increase is not significant using a non-robust likelihood-ratio test at the 5 % level.

32.3.3 Stochastic Volatility Specifications

Two shocks per unit time characterize stochastic volatility (SV) models, in contrast to the single shock z_t that appears in ARCH models. A general framework for long memory stochastic volatility models is given for returns r_t by

$$r_t = \mu + \sigma_t u_t \tag{32.19}$$

with $\ln(\sigma_t)$ following an ARFIMA(p, d, q) process. For example, with $p = q = 1$,

$$\ln(\sigma_t) = \alpha + (1 - \phi L)^{-1}(1 - L)^{-d}(1 + \psi L)v_t. \tag{32.20}$$

This framework has been investigated by Breidt et al. (1998), Harvey (1998), and Bollerslev and Wright (2000), all of whom provide results for the simplifying assumption that the two i.i.d. processes $\{u_t\}$ and $\{v_t\}$ are independent. This assumption can be relaxed and has been for short memory applications (Taylor 1994; Shephard 1996).

Parameter estimation is difficult for SV models, compared with ARCH models, because SV models have twice as many random innovations as observable variables. Breidt et al. (1998) describe a spectral-likelihood estimator and provide results for a CRSP index from 1962 to 1989. For the ARFIMA(1, d, 0) specification, they estimate $d = 0.44$ and $\phi = 0.93$. Bollerslev and Wright (2000) provide detailed simulation evidence about semiparametric estimates of d, related to the frequency of the observations.

It is apparent that the ARCH specification (Eqs. 32.15–32.17) has a similar structure to the SV specification (Eqs. 32.19–32.20). Short memory special cases of these specifications, given by $d = q = 0$, have similar moments (Taylor 1994). This is a consequence of the special cases having the same bivariate diffusion limit when appropriate parameter values are defined for increasingly frequent observations (Nelson 1990; Duan 1997). It seems reasonable to conjecture that the multivariate distributions for returns defined by (32.15–17) and (32.19–20) are similar, with the special case of independent shocks $\{u_t\}$ and $\{v_t\}$ corresponding to the symmetric ARCH model that has $\theta = 0$ in Eq. 32.17.

32.4 Option Pricing Methodology

32.4.1 A Review of SV and ARCH Methods

The pricing of options when volatility is stochastic and has a short memory has been studied using a variety of methods. The most popular methods commence with separate diffusion specifications for the asset price and its volatility. These are called stochastic volatility (SV) methods. Option prices then depend on several parameters including a volatility risk premium and the correlation between the differentials of the Wiener processes in the separate diffusions.

The closed-form solution of Heston (1993) assumes that volatility follows a square-root process and permits a general correlation and a nonzero volatility risk premium; for applications see, for example, Bakshi et al. (1997) and for extensions see Duffie et al. (2000).

There has been less research into option pricing for short memory ARCH models. Duan (1995) provides a valuation framework and explicit results for the GARCH(1,1) process that can be extended to other ARCH specifications. Ritchken and Trevor (1999) provide an efficient lattice algorithm for GARCH (1,1) processes and extensions for which the conditional variance depends on the previous value and the latest return innovation. Recent innovations are provided by Christoffersen et al. (2008, 2010).

Methods for pricing options when volatility has a long memory have been described by Comte and Renault (1998) and Bollerslev and Mikkelsen (1996, 1999). The former authors provide analysis within a bivariate diffusion framework. They replace the usual Wiener process in the volatility equation by fractional Brownian motion. However, their option pricing formula appears to require independence between the Wiener process in the price equation and the volatility process which is not consistent with the empirical evidence for stock returns.

The most practical way to price options with long memory in volatility is probably based upon ARCH models, as demonstrated by Bollerslev and Mikkelsen (1999). We follow the same strategy. From the asymptotic results in Duan (1997), also discussed in Ritchken and Trevor (1999), it is anticipated that insights about options priced from a long memory ARCH model will be similar to the insights that can be obtained from a related long memory SV model.

32.4.2 The ARCH Pricing Framework

When pricing options it will be assumed that returns are calculated from prices (or index levels) as $r_t = \ln(p_t/p_{t-1})$ and hence exclude dividends. A constant risk-free interest rate and a constant dividend yield will also be assumed and, to simplify the notation and calculations, it will be assumed that interest and dividends are paid once per trading period. Conditional expectations are defined with respect to current and prior price information represented by $I_t = \{p_{t-i}, i \geq 0\}$.

To obtain fair option prices in an ARCH framework, it is necessary to make additional assumptions in order to obtain a risk-neutral measure Q. Duan (1995) and Bollerslev and Mikkelsen (1999) provide sufficient conditions to apply a risk-neutral valuation methodology. For example, it is sufficient that a representative agent has constant relative risk aversion and that returns and aggregate growth rates in consumption have conditional normal distributions. Kallsen and Taqqu (1998) derive the same solution as Duan (1995) without making assumptions about utility functions and consumption. Instead, they assume that intraday prices are determined by geometric Brownian motion with volatility determined once a day from a discrete-time ARCH model.

32.4.3 Implementation

At time t', measured in trading periods, the fair price of a European contingent claim which has value $y_{t'+n}(p_{t'+n})$ at the terminal time $t' + n$ is given by

$$y_{t'} = E^Q\left[e^{-\rho n} y_{t'+n}\left(p_{t'+n}\right) \ |I_{t'}\right] \tag{32.21}$$

with ρ the risk-free interest rate for one trading period. We now specify an appropriate way to simulate $p_{t'+n}$ under a risk-neutral measure Q. Monte Carlo methods are then used to estimate the conditional expectation in Eq. 32.21.

Following Duan (1995), it is assumed that the distribution of observed returns is defined by some probability measure P, for which

$$r_t|I_{t-1} \sim^P N(\mu_t, h_t), \tag{32.22}$$

with

$$z_t = \frac{r_t - \mu_t}{\sqrt{h_t}} \sim^P i.i.d.N(0,1) \tag{32.23}$$

It is also assumed that the distributions in a risk-neutral framework are defined by a measure Q, with

$$r_t|I_{t-1} \sim^Q N\left(\rho - \delta - \frac{1}{2}h_t, h_t\right), \tag{32.24}$$

and

$$z_t^* = \frac{r_t - \left(\rho - \delta - \frac{1}{2}h_t\right)}{\sqrt{h_t}} \sim^Q i.i.d.N(0,1). \tag{32.25}$$

Here δ is the dividend yield, which corresponds to a dividend payment of $d_t = (e^{\delta} - 1)p_t$ per share at time t. Then $E^Q[p_t|I_{t-1}] = e^{\rho-\delta}p_{t-1}$ and the expected value at time t of one share and the dividend payment is $E^Q[p_t + d_t|I_{t-1}] = e^{\rho}p_{t-1}$, as required in a risk-neutral framework. Note that the conditional means are different for measures P and Q, but the functions $h_t(p_{t-1}, p_{t-2}, \ldots.)$ that define the conditional variances for the two measures are identical.

Option prices depend on the specifications for μ_t and h_t. We again follow Duan (1995) and assume that

$$\mu_t = \rho - \delta - \frac{1}{2}h_t + \lambda\sqrt{h_t} \tag{32.26}$$

with λ representing a risk premium parameter. Then the conditional expectations of r_t for measures P and Q differ by $\lambda\sqrt{h_t}$ and

$$z_t - z_t^* = -\lambda. \tag{32.27}$$

Option prices are evaluated when the conditional variances are given by an ARMA(N, 1) approximation to the FIEGARCH(1, d, 1) specification. From Eqs. 32.18 and 32.27,

$$\left(1-\sum_{j=1}^{N} b_j L^j\right)(\ln(h_t)-\alpha) = (1+\psi L)g(z_{t-1}) = (1+\psi L)g\left(z_{t-1}^{*}-\lambda\right), \quad (32.28)$$

and

$$g(z_t) = \theta z_t + \gamma(|z_t| - C) \quad (32.29)$$

The autoregressive coefficients b_j are functions of ϕ and d, which are defined in Appendix 1. Efficient numerical methods for simulating $p_{t'+n}$ are described in Appendix 2.

32.5 Illustrative Long Memory Option Prices

32.5.1 Inputs

Many parameters and additional inputs are required to implement the FIEGARCH option pricing methodology. To apply that methodology to value European options, we specify 18 numbers, a price history, and a random number generator, as follows:

- Contractual parameters – time until exercise T measured in years, the exercise price X, and whether a call or a put option.
- The current asset price $S = p_{t'}$ and a set of previous prices $\{p_t, 1 \le t < t'\}$.
- Trading periods per annum M, such that consecutive observed prices are separated by $1/M$ years and likewise for simulated prices $\{p_t, t' < t \le t' + n\}$ with $n = MT$.
- Risk-free annual interest rate R, from which the trading period rate $\rho = R/M$ is obtained.
- Annual dividend yield D giving a constant trading period payout rate of $\delta = D/M$; both R and D are continuously compounded and applicable for the life of the option contract.
- The risk premium λ for investment in the asset during the life of the option, such that one-period conditional expected returns are $\mu_t = \rho - \delta - \frac{1}{2}h_t + \lambda\sqrt{h_t}$, for the real-world measure P.
- Parameters m and λ' that define conditional expected returns during the time period of the observed prices by $\mu_t = m - \frac{1}{2}h_t + \lambda'\sqrt{h_t}$, again for measure P.
- Eight parameters that define the one-period conditional variances h_t. The integration level d, the autoregressive parameter ϕ, and the truncation level N determine the terms b_j in the AR(N) filter in Eq. 32.28. The mean α and the moving-average parameter ψ complete the ARMA(N, 1) specification for $\ln(h_t)$ In Eq. 32.28. The values of the shocks to the ARMA(N, 1) process depend on γ

and θ, which, respectively, appear in the symmetric function $\gamma(|z_t| - C)$ and the asymmetric function θz_t whose total determines the shock term $g(z_t)$; the constant C is a parameter C' for observed prices but is $\sqrt{2/\pi}$ when returns are simulated.

- K, the number of independent simulations of the terminal asset price $S_T = p_{t'+n}$.
- A set of Kn pseudorandom numbers distributed uniformly between 0 and 1, from which pseudorandom standard normal variates can be obtained. These numbers typically depend on a seed value and a deterministic algorithm.

32.5.2 Parameter Selections

Option values are tabulated for hypothetical European options on the S & P 100 index. Options are valued for 10 dates defined by the last trading days of the 10 years from 1989 to 1998 inclusive. For valuation dates from 1992 onwards, the size of the price history is set at $t' = 2{,}000$; for previous years the price history commences on 6 March 1984 and $t' < 2{,}000$. It is assumed that there are $M = 252$ trading days in 1 year and hence exactly 21 trading days in one simulated month. Option values are tabulated when T is 1, 2, 3, 6, 12, 18, and 24 months.

Table 32.2 lists the parameter values used to obtain the main results. The annualized risk-free rate and dividend yield are set at 5 % and 2 %, respectively. The risk parameter λ is set at 0.028 to give[2] an annual equity risk premium of 6 %. The mean return parameter m is set to the historic mean of the complete set of S & P 100 returns from March 1984 to December 1998 and λ' is set to zero.

There are two sets of values for the conditional variance process because the primary objective here is to compare option values when volatility is assumed to have either a short or a long memory. The long memory parameter set takes the integration level to be $d = 0.4$, because this is an appropriate level based upon the high frequency reviewed in Sect. 32.2.3. The remaining variance parameters are then based on Table 32.1; as the moving-average parameter is small, it is set to zero and the autoregressive parameter is adjusted to retain the unit total, $d + \phi + \psi = 1$. The AR filter[3] is truncated at lag 1,000, although the results obtained will nevertheless be referred to as long memory results. The short memory parameters are similar to those for the AR(1) estimates provided in Table 32.1. The parameters γ and θ are both 6 % less in Table 32.2 than in Table 32.1 to ensure that selected moments are matched for the short and long memory specifications; the unconditional mean and variance of $\ln(h_t)$ are then matched for the historic measure P, although the unconditional means differ by approximately 0.10 for the risk-neutral measure Q as noted in Appendix 3.

[2]The conditional expectations of r_t for measures P and Q differ by $\lambda\sqrt{h_t}$ and a typical average value of $\sqrt{h_t}$ is 0.00858. Assuming 253 trading days in 1 year gives the stated value of λ.

[3]The filter coefficients sum to $b_1 + \ldots + b_{1,000} = 0.983$. After $b_1 = 1$ and $b_2 = -0.12$, all of the coefficients are near zero, with $b_{100} = 0.00017$ and $b_{1,000} = 7 \times 10^{-6}$.

Table 32.2 Parameter values for option price calculations

Trading periods per annum M	252	
Risk-free interest rate ρ	$0.05/M$	
Conditional mean		
Historic intercept m	$0.161/M$	
Historic equity risk premium term λ'	0	
Dividend yield δ	$0.02/M$	
Future equity risk premium term λ	0.028	
Conditional variance		
	Short memory	*Long memory*
Integration level d	0	0.4
Truncation limit N		1,000
Mean α of $E^P[\ln(h_t)]$	−9.56	−9.56
Autoregressive parameter ϕ	0.982	0.6
Moving-average parameter ψ	0	0
Asymmetric shock parameter θ	−0.056	−0.11
Symmetric shock parameter γ	0.094	0.18
Historical value of $E^P[\|z\|]$	0.737	0.737

Options are valued on the final trading day of ten consecutive years, from 1989 to 1998. The returns history is drawn from the set of daily returns from the S & P 100 index from 6 March 1984 to 31 December 1998. A set of $t' = 2{,}000$ historical returns is used from 1992 onwards, and as many as possible before then. The current level of the index is reset to $S = 100$ when option values are determined

Option prices are estimated from $K = 10,000$ independent simulations of prices $\{p_t, t' < t \leq t' + n\}$ with $n = 504$. Applying the antithetic and control variate methods described in Appendix 2 then produces results for a long memory process in about 12 min, when the processor speed is 2 GHz. Most of the time is spent evaluating the high-order AR filter; the computation time is about 1 min for the short memory process.

32.5.3 Comparisons of Implied Volatility Term Structures

The values of all options are reported using annualized implied volatilities rather than prices. Each implied volatility (IV) is calculated from the Black-Scholes formula, adjusted for continuous dividends. The complete set of IV outputs for one set of inputs forms a matrix with rows labelled by the exercise prices X and columns labelled by the times to expiry T; examples are given in Tables 32.5 and 32.6 and are discussed later.

Initially we only consider at-the-money options, for which the exercise price equals the forward price $F = Se^{(R-D)T}$, with IV values obtained by interpolation across two adjacent values of X. As T varies, the IV values represent the term structure of implied volatility. Tables 32.3 and 32.4, respectively, summarize these term structures for the short and long memory specifications. The same information is plotted on Figs. 32.2

Table 32.3 At-the-money implied volatilities for a short memory volatility process

The parameters of the EGARCH price process are listed in Table 32.2. The half-life of a volatility shock is 1.8 months

European option prices are estimated from 10,000 simulations of the asset prices on the dates that the options expire. The implied volatilities are for at-the-money options whose exercise prices equal the forward rates for the expiry dates. The standard errors of the implied volatilities are between 0.0001 and 0.0003

Options are valued on the final trading day of ten consecutive years. The returns history is drawn from the set of daily returns from the S & P 100 index from 6 March 1984–31 December 1998. A set of $t' = 2{,}000$ historical returns is used from 1992 onwards and as many as possible before then. The column for $T = 0$ provides the annualized volatilities on the valuation dates

and 32.3, respectively. The IV values for $T = 0$ are obtained from the conditional variances on the valuation dates. The standard errors of the tabulated implied volatilities increase with T. The maximum standard errors for at-the-money options are, respectively, 0.0003 and 0.0004 for the short and long memory specifications.

The ten IV term structures for the short memory specification commence between 9.5 % (1993) and 18.8 % (1997) and converge towards the limiting value of 14.3 %. The initial IV values are near the median level from 1989 to 1991, are low from 1992 to 1995, and are high from 1996 to 1998. Six of the term structures slope upwards, two are almost flat, and two slope downwards. The shapes of these term structures are completely determined by the initial IV values because the volatility process is Markovian.

There are three clear differences between the term structures for the short and long memory specifications that can be seen by comparing Figs. 32.2 and 32.3. First, the long memory term structures can and do intersect because the volatility process is not Markovian. Second, some of the term structures have sharp kinks for the first month. This is particularly noteworthy for 1990 and 1996 when the term structures are not monotonic. For 1990, the initial value of 14.1 % is followed by 15.6 % at 1 month and a gradual rise to 16.2 % at 6 months and a subsequent slow decline. For 1996, the term structure commences at 15.6 %,

The parameters of the FIEGARCH price process are listed in Table 32.2 and include an integration level of $d = 0.4$.

European option prices are estimated from 10,000 simulations of the asset prices on the dates that the options expire. The implied volatilities are for at-the-money options whose exercise prices equal the forward rates for the expiry dates. The standard errors of the implied volatilities are all less than 0.0004

Options are valued on the final trading day of ten consecutive years. The returns history is drawn from the set of daily returns from the S & P 100 index from 6 March 1984–31 December 1998. A set of $t' = 2{,}000$ historical returns is used from 1992 onwards, and as many as possible before then. The column for $T = 0$ provides the annualized volatilities on the valuation dates

falls to 13.6 % after 1 month, and reaches a minimum of 12.8 % after 6 months followed by a slow incline. The eight other term structures are monotonic and only those for 1997 and 1998 slope downwards. Third, the term structures approach their limiting value very slowly.[4] The 2-year IVs range from 12.1 % to 16.1 %, and it is not possible to deduce the limiting value, although 15.0–16.0 % is a plausible range.[5] It is notable that the dispersion between the ten IV values for each T decreases slowly as T increases, from 2.2 % for 1-month options to 1.4 % for 2-year options.

There are substantial differences between the two IV values that are calculated for each valuation date and each option lifetime. Figure 32.4 shows the differences between the at-the-money IVs for the long memory

[4]The results support the conjecture that $IV(T) \cong a_1 + a_2 T^{2d-1}$ for large T with a_2 determined by the history of observed returns.

[5]An estimate of the constant a_1 (defined in the previous footnote) is 16.0 %. An estimate of 15.0 % follows by supposing the long memory limit is 105 % of the short memory limit, based on the limit of $\ln(h_t)$ being higher by 0.1 for the long memory process as noted in Appendix 3. The difference in the limits is a consequence of the risk premium obtained by owning the asset; its magnitude is mainly determined by the pronounced asymmetry in the volatility shock function $g(z_t)$.

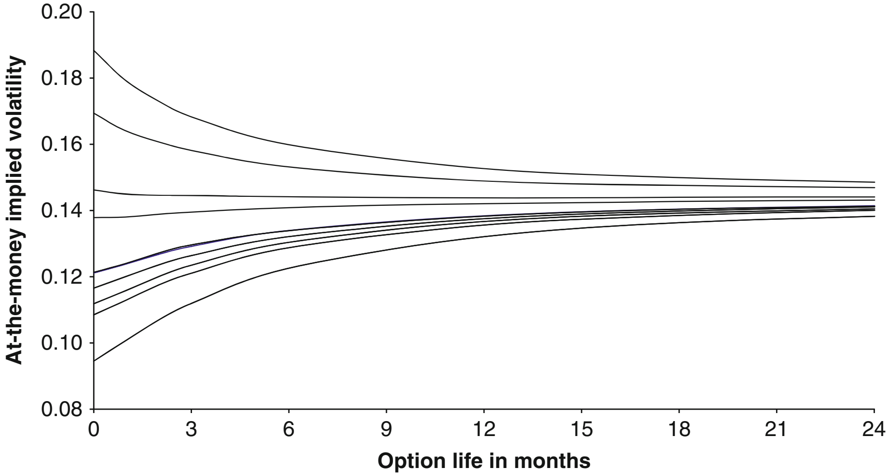

Fig. 32.2 Ten volatility term structures for a short memory process

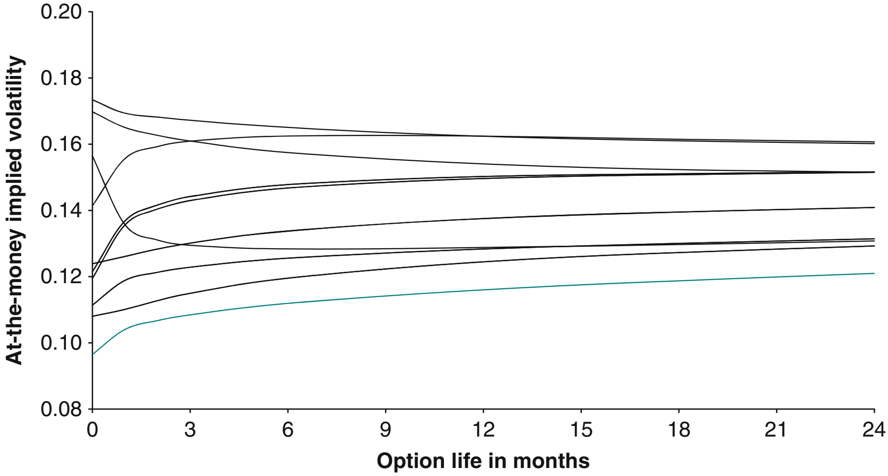

Fig. 32.3 Ten volatility term structures for a long memory process with d = 0.4

specification minus the number for the short memory specification. When $T = 0$, these differences range from -1.9 % (1997) to 1.5 % (1992), for 3 month options from -1.5 % (1995, 1996) to 2.1 % (1990), and for 2-year options from -1.9 % (1995) to 1.7 % (1990). The standard deviation of the ten differences is between 1.1 % and 1.4 % for all values of T considered so it is common for the short and long memory option prices to have IVs that differ by more than 1 %.

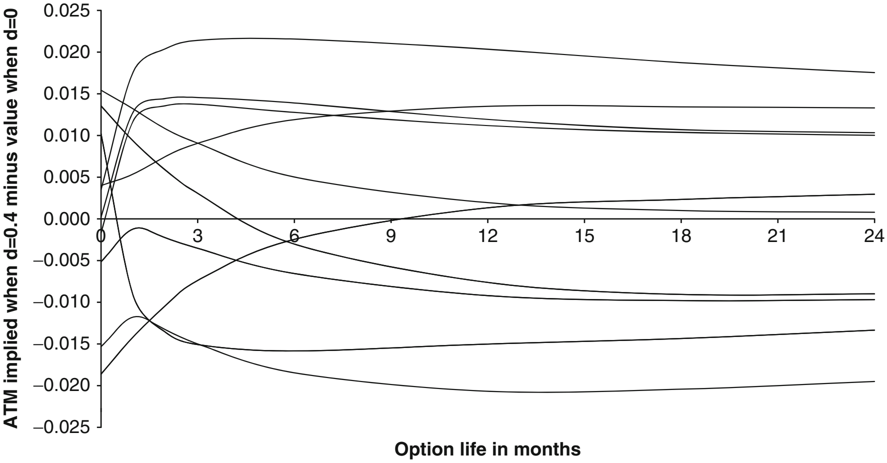

Fig. 32.4 Differences between ten pairs of term structures

32.5.4 Comparisons of Smile Effects

The columns of the IV matrix provide information about the strength of the so-called smile effect for options prices. These effects seem to be remarkably robust to the choice of valuation date and they are not very sensitive to the choice between the short and long memory specifications. This can be seen by considering the ten values of $\Delta IV = IV(T,X_1) - IV(T,X_2)$ obtained for the ten valuation dates, for various values of T, various pairs of exercise prices X_1, X_2, and a choice of volatility process. First, for 1-month options with $S = 100$, $X_1 = 92$, and $X_2 = 108$, the values of ΔIV range from 3.0 % to 3.3 % for the short memory specification and from 3.7 % to 4.0 % for the long memory specification. Second, for 2-year options with $X_1 = 80$ and $X_2 = 120$, the values of ΔIV range from 1.8 % to 2.0 % and from 1.8 % to 1.9 %, respectively, for the short and long memory specifications.

Figure 32.5 shows the smiles for 3-month options valued using the short memory model, separately for the ten valuation dates. As may be expected from the above remarks, the ten curves are approximately parallel to each other. They are almost all monotonic decreasing for the range of exercise prices considered, so that a U-shaped function (from which the idea of a smile is derived) cannot be seen. The near monotonic decline is a standard theoretical result when volatility shocks are negatively correlated with price shocks (Hull 2000). It is also a stylized empirical fact for US equity index options; see, for example, Rubinstein (1994) and Dumas et al. (1998).

Figure 32.6 shows the 3-month smiles for the long memory specification. The shapes on Figs. 32.5 and 32.6 are similar, as all the curves are for the same expiry time, but they are more dispersed on Fig. 32.6 because the long memory effect induces more dispersion in at-the-money IVs. The minima of the smiles are generally near an exercise price of 116. Figure 32.7 shows further long memory smiles, for 2-year options when the forward price is 106.2. The parallel shapes are

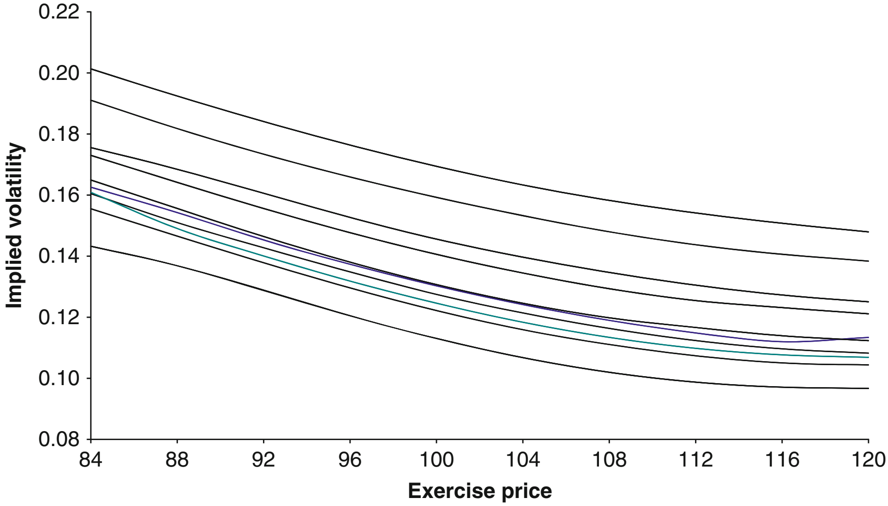

Fig. 32.5 Ten smile shapes for three-month options and a short memory process

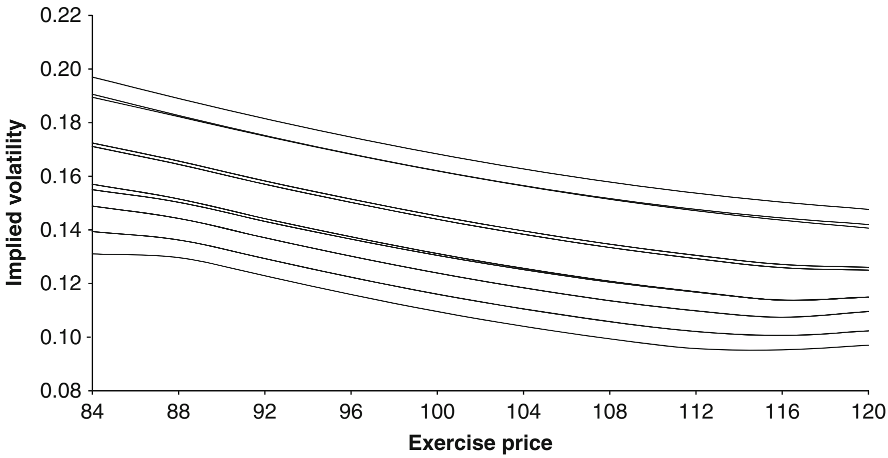

Fig. 32.6 Ten smile shapes for three-month options and a long memory process with d = 0.4

clear; the two highest curves are almost identical, and the third, fourth, and fifth highest curves are almost the same.

Tables 32.5 and 32.6 provide matrices of implied volatilities for options valued on 31 December 1998. When either the call or the put option is deep out-of-the-money, it is difficult to estimate the option price accurately because the risk-neutral probability $q(X)$ of the out-of-the-money option expiring in-the-money is small. Consequently, the IV information has not been presented when the corresponding standard errors exceed 0.002; estimates of $q(X)$ are less than 3 %.

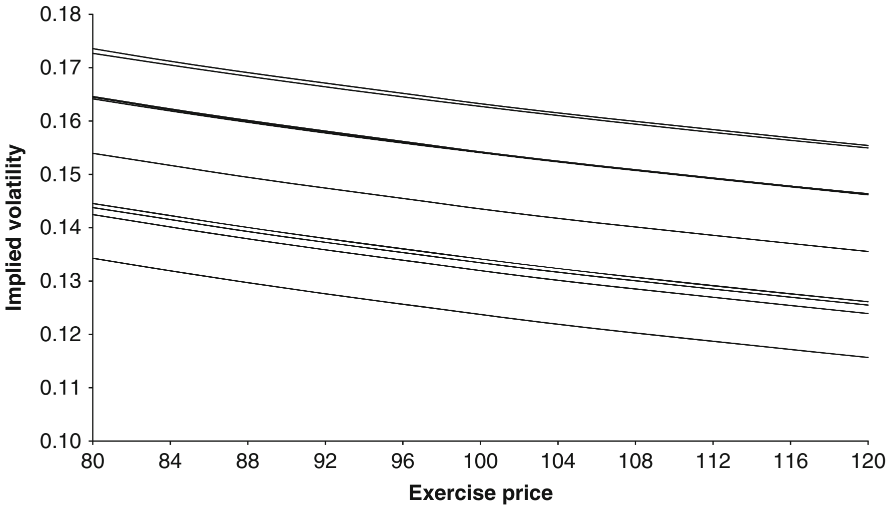

Fig. 32.7 Ten smile shapes for two-year options and a long memory process with d = 0.4

The standard errors of the IVs are least for options that are near to at-the-money and most of them are less than 0.0005 for the IVs listed in Tables 32.5 and 32.6. All the sections of the smiles summarized by Tables 32.5 and 32.6 are monotonic decreasing functions of the exercise price. The IV decreases by approximately 4–5 % for each tabulated section.

32.5.5 Sensitivity Analysis

The sensitivity of the IV matrices to three of the inputs has been assessed for options valued on 31 December 1998. First, consider a change to the risk parameter λ which corresponds to an annual risk premium of 6 % for the tabulated results. From Sect. 32.4.3, option prices should be lower for large T when λ is reduced to zero. Changing λ to zero reduces the at-the-money IV for 2-year options from 16.0 % to 15.4 % for the long memory inputs, with a similar reduction for the short memory inputs. Second, consider reducing the truncation level N in the AR(N) filter from 1,000 to 100. Although this has the advantage of a substantial reduction in the computational time, it changes the IV numbers by appreciable amounts and cannot be recommended; for example, the 2-year at-the-money IV then changes from 16.0 % to 14.7 %.

The smile shapes on Figs. 32.5, 32.6 and 32.7 are heavily influenced by the negative asymmetric shock parameter θ, which is substantial relative to the symmetric shock parameter γ. The asymmetry in the smile shapes can be expected to disappear when θ is zero, which is realistic for some assets including exchange rates. Figures 32.8 and 32.9 compare smile shapes when θ is changed from the

The parameters of the EGARCH price process are listed in Table 32.2. The half-life of a volatility shock is 1.8 months

Options are valued on 31 December 1998. The returns history is the set of 2,000 daily returns from the S & P 100 index from 4 February 1991 to 31 December 1998. European option prices are estimated from 10,000 simulations of the asset prices on the dates that the options expire

Implied volatilities shown in Roman font have standard errors (s.e.) that are at most 0.0005 and those shown in italic font have s.e. between 0.0005 and 0.0020; results are not shown when the s.e. exceeds 0.0020, when options are either deep in- or out-of-the-money

values used previously to zero, with γ scaled to ensure the variance of $\ln(h_t)$ is unchanged for measure P. Figure 32.8 shows that the 1-month smile shapes become U-shaped when θ is zero, while Fig. 32.9 shows that the IV are then almost constant for 1-year options.

32.6 Conclusions

The empirical evidence for long memory in volatility is strong, for both equity and foreign exchange markets. This evidence may more precisely be interpreted as

The parameters of the FIEGARCH price process are listed in Table 32.2 and include an integration level of $d = 0.4$

Options are valued on 31 December 1998. The returns history is the set of 2,000 daily returns from the S & P 100 index from 4 February 1991 to 31 December 1998. European option prices are estimated from 10,000 simulations of the asset prices on the dates that the options expire

Implied volatilities shown in Roman font have standard errors (s.e.) that are at most 0.0005, and those shown in italic font have s.e. between 0.0005 and 0.0020; results are not shown when the s.e. exceeds 0.0020, when options are either deep in- or out-of-the-money

evidence for long memory effects, because there are short memory processes that have similar autocorrelations and spectral densities, except at very low frequencies.

The theory of option pricing when volatility follows a discrete-time ARCH process relies on weak assumptions about the continuous-time process followed by prices and the numerical implementation of the theory is straightforward. Application of the theory when the volatility process is fractionally integrated does, however, require pragmatic approximations because the fundamental filter $(1 - L)^d$ is an infinite order polynomial that must be truncated at some power N. Option prices are sensitive to the truncation point N, so that large values and long price histories from an assumed stationary process are required.

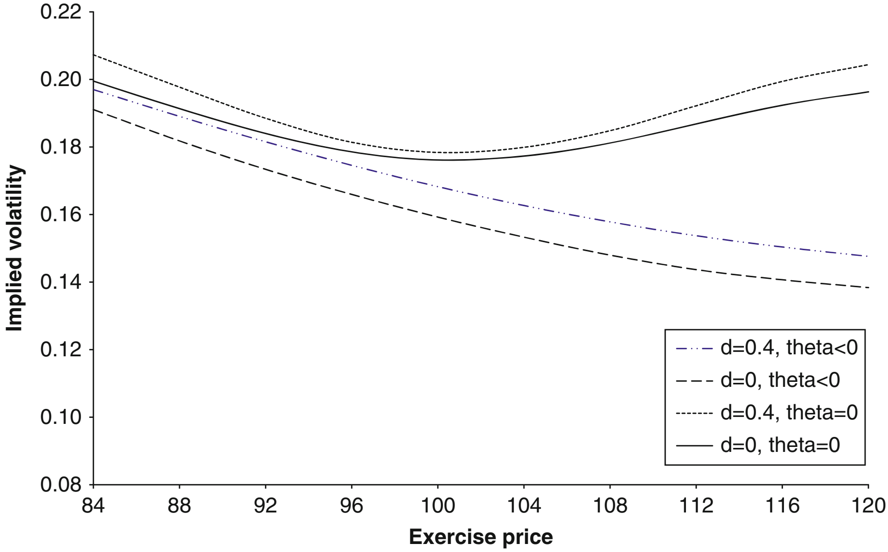

Fig. 32.8 Impact of asymmetric volatility shocks on one-month options

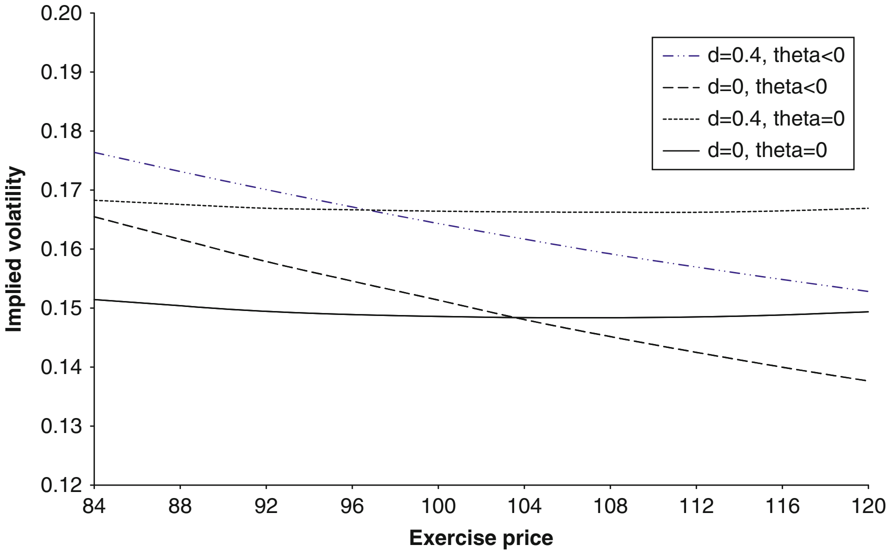

Fig. 32.9 Impact of asymmetric volatility shocks on one-year options

The term structure of implied volatility for at-the-money options can be notably different for short and long memory ARCH specifications applied to the same price history. Long memory term structures have more variety in their shapes. They may have kinks for short maturity options and they may not have a monotonic shape. Also, term structures calculated on different valuation dates sometimes intersect each other. None of these possibilities occurs for a Markovian short memory specification. Long memory term structures do not converge rapidly to a limit as the lifetime of options increases. It is difficult to estimate the limit for the typical value $d = 0.4$.

Implied volatilities as functions of exercise prices have similar shapes for short and long memory specifications. The differences in these shapes are minor in comparison to the differences in the term structure shapes.

It is common for the short and long memory implied volatilities to differ by more than 1 % for options on the S & P 100 index, regardless of the option lifetime and the exercise price; if the short memory implied is at a typical level of 14 %, then the long memory implied is often below 13 % or above 15 %. Consequently, the economic consequences of a long memory assumption are important.

Acknowledgments The support of Inquire Europe and the helpful advice of Bernard Dumas, Ton Vorst, and Granville Tunnicliffe-Wilson are gratefully acknowledged.

Appendix 1: Series Expansions and Truncation Approximations

Series expansions in the lag operator L are required to evaluate the following conditional variance:

$$\ln(h_t) = \alpha + (1 - \phi L)^{-1}(1 - L)^{-d}(1 + \psi L)g(z_{t-1}). \tag{32.30}$$

We note the results:

$$(1 - L)^d = 1 - \sum_{j=1}^{\infty} a_j L^j, a_1 = d, a_j = \frac{j - d - 1}{j} a_{j-1}, \ j \geq 2, \tag{32.31}$$

$$(1 - \phi L)(1 - L)^d = 1 - \sum_{j=1}^{\infty} b_j L^j, b_1 = d + \phi, b_j = a_j - \phi a_{j-1}, \ \ j \geq 2, \tag{32.32}$$

$$(1 - \phi L)(1 - L)^d (1 + \psi L)^{-1} = 1 - \sum_{j=1}^{\infty} \phi_j L^j,$$

$$\phi_1 = d + \phi + \psi, \phi_j = b_j - (-\psi)^j + \sum_{k=1}^{j-1} (-\psi)^{j-k} b_k, \ \ j \geq 2. \tag{32.33}$$

The autoregressive weights in Eqs. 32.33 can be denoted as $\phi_j\ (d,\phi,\psi)$. Also,

$$(1-\phi L)^{-1}(1-L)^{-d}(1+\psi L)=1+\sum_{j=1}^{\infty}\psi_j L^j, \tag{32.34}$$

$$\psi_1=d+\phi+\psi,\ \psi_j=-\phi_j(-d,-\psi,-\phi) \tag{32.35}$$

It is necessary to truncate the infinite summations when evaluating empirical conditional variances. Truncation after N terms of the summations in Eqs. 32.35, 32.33, and 32.32, respectively, gives the MA(N), AR(N), and ARMA(N, 1) approximations:

$$\ln(h_t)=\alpha+g(z_{t-1})+\sum_{j=1}^{N}\psi_j g(z_{t-j-1}), \tag{32.36}$$

$$\ln(h_t)=\alpha+\sum_{j=1}^{N}\phi_j\left[\ln(h_{t-j})-\alpha\right]+g(z_{t-1}), \tag{32.37}$$

$$\ln(h_t)=\alpha+\sum_{j=1}^{N}b_j\left[\ln(h_{t-j})-\alpha\right]+g(z_{t-1})+\psi g(z_{t-2}). \tag{32.38}$$

As $j\to\infty$, the coefficients b_j and ϕ_j converge much more rapidly to zero than the coefficients ψ_j. Consequently it is best to use either the AR or the ARMA approximation.

Appendix 2: Simulation Methods

Suppose there are returns observed at times $1\le t\le t'$, whose distributions are given by measure P, and that we then want to simulate returns for times $t>t'$ using measure Q. Then ln (h_t) is calculated for $1\le t\le t'+1$ using the observed returns, with ln $(h_t)=\alpha$ and $g(z_t)=0$ for $t<1$, followed by simulating $z_t^*\sim^Q N(0,1)$ and hence obtaining r_t and ln (h_{t+1}) for $t>t'$.

Care is required when calculating the constant C in Eq. 32.29 because the observed conditional distributions of the terms z_t are not normal while the simulations assume that they are. Consequently, we define

$$\begin{aligned} C &= C', & t&\le t',\\ &=\sqrt{2/\pi}, & t&>t', \end{aligned} \tag{32.39}$$

for a constant C' estimated from observed returns. An alternative method, described by Bollerslev and Mikkelsen (1999), is to simulate from the sample distribution of standardized observed returns.

Standard variance reduction techniques substantially enhance the accuracy of Monte Carlo estimates of contingent claim prices. Our antithetic method uses one i.i.d. $N(0, 1)$ sequence $\{z_t^*\}$ to define the further i.i.d. $N(0, 1)$ sequences, $\{-z_t^*\}$, $\{z_t^\bullet\}$, and $\{-z_t^\bullet\}$, with the terms $z_t^\bullet$ chosen so that there is negative correlation between $|z_t^*|$ and $|z_t^\bullet|$; this is achieved by defining $\Phi(z_t^\bullet) + \Phi(z_t^*) = 1 + \frac{1}{2}\text{sign}(z_t^*)$. The four sequences provide claim prices whose average, $\bar{y}$ say, is much less variable than the claim price from a single sequence. An overall average $\hat{y}$ is then obtained from a set of K values $\{\bar{y}_k, 1 \le k \le K\}$.

The control variate method makes use of an unbiased estimate $\hat{y}_{CV}$ of a known parameter y_{CV}, such that $\hat{y}$ is positively correlated with $\hat{y}_{CV}$. A suitable parameter, when pricing a call option in an ARCH framework, is the price of a call option when volatility is deterministic. The deterministic volatility process is defined by replacing all terms $\ln(h_t)$, $t > t' + 1$, by their expectations under P conditional on the history $I_{t'}$. Then y_{CV} is given by the obvious modification of the Black-Scholes formula, while $\hat{y}_{CV}$ is obtained by using the same $4K$ sequences of i.i.d. variables that define $\hat{y}$. Finally, a more accurate estimate of the option price is then given by $\tilde{y} = \hat{y} - \beta(\hat{y}_{CV} - y_{CV})$ with β chosen to minimize the variance of $\tilde{y}$.

Appendix 3: Impact of a Volatility Risk Premium

On average the term structure of implied volatilities will slope upwards for the FIEGARCH option pricing model. This occurs because the expectation of $\ln(h_t)$ depends on the measure[6] when $\lambda \neq 0$. The unconditional expectation equals α for measure P. It is different for measure Q because

$$E^Q\left[g\left(z_t^* - \lambda\right)\right] = -\lambda\theta + \gamma\left(E^Q\left[\left|z_t^* - \lambda\right|\right] - \sqrt{2/\pi}\right) \cong -\lambda\theta + \frac{\lambda^2\gamma}{\sqrt{2\pi}} \tag{32.40}$$

when λ is small, and this expectation is in general not zero.[7] For a fixed t', as $t \to \infty$,

$$E^Q[\ln(h_t)\;|I_{t'}] \to \alpha + \left(1 - \sum_{j=1}^{N} b_j\right)^{-1}(1+\psi)E^Q\left[g\left(z_t^* - \lambda\right)\right] \tag{32.41}$$

The difference between the P and Q expectations of $\ln(h_t)$ could be interpreted as a volatility risk premium. This premium is typically negative, because typically $\lambda > 0$, $\theta \le 0$ and $\gamma > 0$. Furthermore, when θ is negative, the dominant term in Eq. 32.40 is $-\lambda\theta$, because λ is always small, and then the premium reflects the degree of asymmetry in the volatility shocks $g(z_t)$.

[6]The dependence of moments of h_t on the measure is shown by Duan (1995, p. 19) for the GARCH (1,1) model.

[7]When $z \sim N(0,1)$, $E[|z - \lambda|] = \sqrt{2/\pi}\exp\left(-\frac{1}{2}\lambda^2\right) + \lambda(2\Phi(\lambda) - 1)$ with Φ the cumulative distribution function of z.

The magnitude of the volatility risk premium can be important and, indeed, the quantity defined by the limit in Eq. 32.41 becomes infinite[8] as $N \to \infty$ when d is positive. A plausible value of λ for the S & P 100 index is 0.028, obtained by assuming that the equity risk premium is 6 % per annum. For the short memory parameter values in the first row of Table 32.1, when $d = 0$ and $N = 1{,}000$, the limit of $E^Q[\ln(h_t) \,|I_t'] - \alpha$ equals 0.10. This limit increases to 0.20 for the parameter values in the final row of Table 32.1, when $d = 0.4$ and $N = 1{,}000$. The typical effect of adding 0.2 to $\ln(h_t)$ is to multiply standard deviations $\sqrt{h_t}$ by 1.1 so that far-horizon expected volatilities, under Q, are slightly higher than might be expected from historical standard deviations.

Seasonal Aspects of Australian Electricity Market

33

Vikash Ramiah, Stuart Thomas, Richard Heaney, and Heather Mitchell

Contents

Abstract

Australian electricity spot prices differ considerably from equity spot prices in that they contain an extremely rapid mean-reversion process. The electricity spot price could increase to a market cap price of AU$12,500 per megawatt hour (MWh) and revert back to a mean level (AUD$30) within a half-hour interval. This has implications for derivative pricing and risk management. For example, while the Black and Scholes option pricing model works reasonably well for equity market-based securities, it performs poorly for commodities like electricity. Understanding the dynamics of electricity spot prices and demand is also

important in order to correctly forecast electricity prices. We develop econometric models for seasonal patterns in both price returns and proportional changes in demand for electricity. We also model extreme spikes in the data. Our study identifies both seasonality effects and dramatic price reversals in the Australian electricity market. The pricing seasonality effects include time-of-day, day-of-week, monthly, and yearly effects. There is also evidence of seasonality in demand for electricity.

Keywords

Electricity • Spot price • Seasonality • Outlier • Demand • Econometric modelling

33.1 Introduction

On Monday 11th of January 2010, the temperature in the state of Victoria in Australia peaked to 42.8 °C. This led to an increase in demand for electricity as households turned on their air conditioning systems. During that half-hour interval, the wholesale price of electricity surged to over $9,000 and then reverted to the average price of around $30 in the subsequent half-hour period. Exercising a call option around that time would have been extremely profitable. What causes the spot price of electricity to exhibit such erratic behavior? We provide a partial explanation of this behavior in this study.

Unpredictable jumps in electricity spot price are usually referred to as “spikes” because jumps tend to happen very quickly, with equally quick reversion to mean levels. These events create a challenge for quantitative analysts when it comes to pricing electricity derivatives. Before one can price these derivatives, one has to be able to effectively forecast the spot price distribution. To date, this problem remains an unresolved matter. For instance, the Black and Scholes (1973) option pricing model fails to adequately price an option written on the electricity spot price because of the incidence of these pricing spikes. The Black and Scholes model works reasonably well in the equity markets whereby the equity time series takes a longer time to trend upwards or downwards. Given the rapid price reversals evident in the electricity spot prices, the Black and Scholes model does not perform particularly well. The key characteristic of non-storability of electricity partially explains why electricity spot price increases significantly during a short-term interval. As the possibility of storing large amounts of electricity does not exist, this product has to be consumed and produced simultaneously. Large price swings occur in this market mainly because supply is inelastic.

The electricity pricing literature provides clear evidence of the spikes. Thomas et al. (2011), Huisman and Huurman (2003), and Goto and Karolyi (2004) show non-normality manifested as positive skewness and extreme leptokurtosis; Johnson and Barz (1999) observe mean reversion in the long run; Kaminski (1997), Clewlow and Strickland (2000), and Eichler et al. (2012) find evidence of extreme behavior with fast-reverting spikes; and Bunn and Karakatsani (2003) demonstrate excessive volatility. Further, Escribano et al. (2002) show that electricity volatility can be time varying in a number of countries like in Argentina, New Zealand, Norway, Sweden, and Spain.[1] Other researchers devote their time to modelling the electricity time series itself. For instance, Knittel and Roberts (2001) apply mean-reversion, time-varying mean, jump-diffusion, time-dependent jump intensity, ARMAX, and exponential generalized autoregressive conditional heteroskedasticity (EGARCH) models to hourly prices in the Californian electricity market and conclude that forecasting performance is relatively poor. Kaminski (1997) addresses the spiky characteristic with a random walk jump-diffusion model, but this model ignores the persistent mean reversion, which is a feature of electricity prices, and this avenue is explored further in Clewlow and Strickland (2000). One of the limitations of the jump-diffusion approaches is the assumption that all shocks affecting the price series die out at the same rate. Escribano et al. (2002) identify two additional price components, namely, volatility clustering in the form of GARCH effects and seasonality (emphasized by Lucia and Schwartz 2002), both in the deterministic component of prices and the jump intensity.

The seasonal aspects recognized within the electricity market are also important. The results observed in one geographic region cannot be applied to other areas as the climatic conditions are different. For example, summer time occurs in different months around the globe, and for that reason, it is important to investigate the seasonal aspects within the Australian electricity market.

Seasonality in the electricity market is not limited to price series as seasonal patterns in demand or system load are well documented in the literature. Harvey and Koopman (1993) document intra-daily and intra-week effects and incorporate them into their demand model using splines. Other early studies considered longer-term load forecasting horizons several months into the future, using daily, weekly, or monthly demand data (e.g., Engle et al. 1989). Pardo et al. (2002) employ daily data in a study of Spanish electricity demand and emphasize the importance of daily and monthly seasonal structures. More recent studies consider modelling and forecasting demand over shorter periods using intraday data. In the Australian context, Smith (2000) documents intraday patterns in demand in the New South Wales electricity market and incorporates diurnal variation into a Bayesian semiparametric regression framework to model intraday electricity load data and obtain short-term load forecasts. We extend his analysis by testing whether seasonality exists in other Australian regions.

In the early 1990s, following the release of the Hilmer Report, the Australian electricity industry embarked on a progressive program of deregulation. The Hilmer reforms led to the disaggregation of vertically integrated, government-owned electricity authorities into separate generation transmission and distribution and retail sales sectors in each state. This gave rise to a wholesale market for electricity which is currently managed by the Australian Energy Market Operator (AEMO). AEMO is responsible for five regions, namely, VIC1 (Victoria), NSW1 (New South Wales), QLD1 (Queensland), SA1 (South Australia), and TAS1 (Tasmania).

[1]See Montero et al. (2011) for further evidence in the Spanish market.

Western Australia and the Northern Territory are geographically remote and to date have not been integrated into the "national" market. Physical transmission of power between regions is achieved via interconnectors that physically link the five different states. The spot electricity market in the AEMO is where all market generators and market customers settle their electricity sales and purchases based on a spot price. The market participants are generally large consumers of electricity, generators, and speculators. Large consumers of electricity like car manufacturers and supermarkets enter this market to enjoy a lower cost of production and to hedge their positions. Speculators, on the other hand, trade future contracts, forwards, options, caps, floors, and swaps for profit motives.

33.2 Australian Electricity Spot Price

The half-hourly pool price data is sourced directly from AEMO (previously known as National Electricity Market Management Company, NEMMCO) for the period from 1 January 1999 to 31 January 2006. Prices are expressed in Australian dollars per megawatt hour ($/MWh). The sample size is 124,224 observations for each region except for TAS1 that joined the pool at a later stage. Figure 33.1 shows the data series for NSW1 with evidence of considerable spiked behavior. Descriptive statistics for the price and return series which are shown in Table 33.1 tend to confirm these outliers.

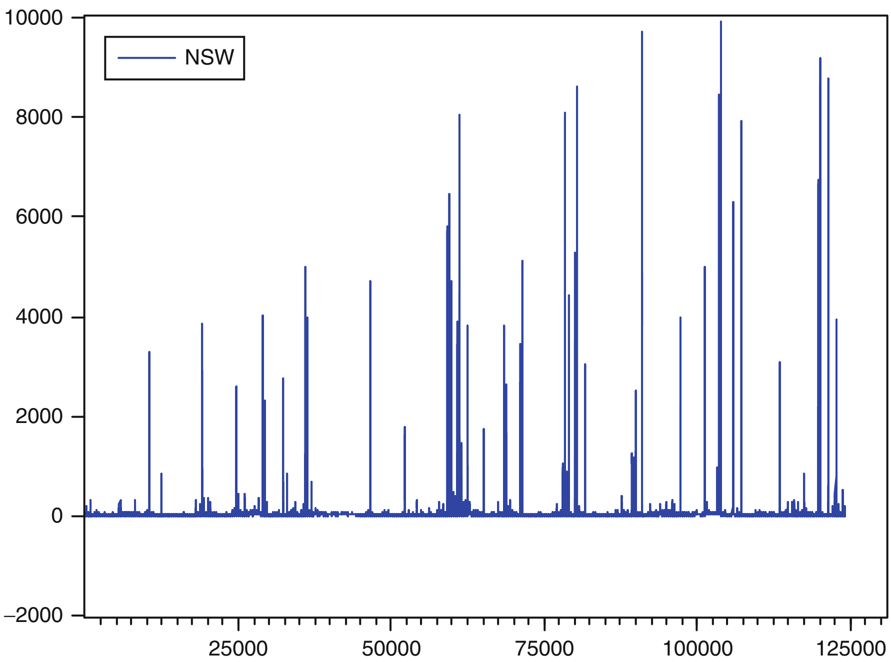

Fig. 33.1 Electricity price series for NSW1 ($/MWh) for the period 01.01.1999–31.01.2006

We report the range, minimum, maximum, mean, standard deviation, skewness, kurtosis, and Jarque-Bera statistics (JB stats) for each region's price and return series. Mean prices vary between regions from \$30.19 for VIC1 to \$41.91 for SA1 and to \$87.30 for TAS1 as the factor inputs (low-cost coal, high-cost gas and water) vary from one state to another. TAS1 was at the early stage of joining the pool, and these statistics depict and are consistent with the immature stage of the market in this region. The standard deviation of prices is generally high, is widely dispersed across the regions, and is broadly consistent with the pattern of means, ranging from \$103.26 for VIC1 to \$367.26 for TAS1. The lowest maximum price of \$7416.16 is observed in VIC1 and the highest maximum price in TAS1 at \$10,000. No prices above \$10,000 were observed as this was the market price cap during the period of the study. This amount is smaller than other international markets like the state of California in the United States, which recorded over US\$50,000 during a period when no market cap was in force. These extremely high values are the features that we are looking for and are referred to as spikes in this study. These instances are generally viewed as lucrative occurrences by arbitrageurs. The most commonly traded call options on the Australian electricity market have exercise prices of either \$100 or \$300. If we assume that market participants will exercise their rights when the option is in the money, then VIC1 traders will exercise when the spot price is above \$340 (mean price of around \$30 plus three standard deviations away) on average. To ensure that we capture a spike, we adopt a conservative approach whereby we define a spike as the mean plus four standard deviations. We observe a total of 505 spikes in NSW1, QLD1, SA1, and VIC1. QLD1 exhibits the greatest incidence of extreme price spikes by state with 173 occurrences (34 %), followed by SA1 with 159 (31 %) and VIC1 with 96 (19 %). By day of the week, Monday shows the highest incidence with 115 (23 %) tapering gradually to Sunday with 45 occurrences (9 %). June shows the highest incidence by month with 81 (16 %). The highest incidences by year occur in 2002 with 147 spikes (29 %) and 2000 with 116 spikes (23 %), both markedly higher than any other full year in the study period. It should be noted that the incidence of extreme price spikes appears to be declining from 2003 onwards as legislation on collusive behavior was passed in Queensland. There is evidence of a concentration of spikes occurring between the hours 06:30 and approximately 10:00 and between 15:30 and 19:00 h, with a marked increase in frequency concentrated at the 18:00 trading interval.

Another unique characteristic of this dataset is negative price. All five regions exhibit negative minimum prices. As shown in Table 33.1, the negative prices for NSW1, QLD1, SA1, VIC1, and TAS1 are −\$3.10, −\$156.14, −\$822.45, −\$329.91, and −\$332.00, respectively. To understand the possibility of such rare and short-lived occurrence, it is important to understand how the spot price is derived. It is a derived price per trading interval, calculated by a two-step procedure based on the offers to supply made by generators in the pool. The trading day is divided into 48 half-hour "trading intervals" which is then subdivided into 5-min. "dispatch intervals." A "dispatch price" is recorded as the marginal price of supply to meet demand for each 5-min. interval in a given half-hour period. This marginal price is typically the dispatch offer price of the last generator brought into production to meet demand at that interval. The spot price is then calculated as an arithmetic average of the six dispatch prices in a half hour. All generators who are called into production during a given half-hour trading interval receive this spot price for the quantity of electricity delivered during the trading interval. A generator may bid a negative price into the pool for its self-dispatch quantity as a tactical move to ensure that they are among the first to be called in to generate as closing down their operations due to not being called into production may be more costly than producing at negative prices. The implication of a negative price is that the standard return calculation for prices may contain this bias, and to that end, the following return formula is used:

$$RET_t = \frac{(P_t - P_{t-1})}{|P_{t-1}|}. \tag{33.1}$$

where RET_t represents the half-hourly discrete proportionate change in price ("return") at time t, P_t is half-hourly price at time t, and $|P_{t-1}|$ is the absolute value of the previous half-hourly price, i.e., at time $t-1$. The denominator is specified as the absolute value to allow for the presence of negative prices. We prefer a discrete return specification over log returns because the spot market in the AEMO trades at discrete half-hourly intervals – it is not a continuous market in the way of most conventional financial markets. Further, a log return specification will dampen the extreme spike effects we are attempting to capture and is incompatible with negative prices. Descriptive statistics for the half-hourly return series are shown in Table 33.1. Mean half-hourly returns vary widely between regions, from 2.6 % for VIC1 to 6.1 % for QLD1. High maximum returns are observed and are consistent with the spike behavior discussed above.

One of the clear patterns discussed so far is the spike behavior, and, based on the earlier discussion, it is fair to say that these spikes are more likely to occur at some specific periods like 18.00 h, Mondays, and in the year 2002. We develop a method to test if there is seasonality in the return series with half-hourly return as the dependent variable. The explanatory variables consist of seasonal dummy variables, spike behavior, and negative prices. We add lagged returns to the list of independent variables to control for serial correlation in the return series. The model employed in this study is presented as Eq. 33.2:

$$\begin{aligned} RET_{R,t} = a_0 &+ \sum_{i=1}^{5}\beta_{1,i}RET_{R,t-1} + \sum_{j-1}^{6}\beta_{2,j}DAY_j + \sum_{k=1,\neq 9}^{12}\beta_{3,k}MTH_k + \sum_{l=1999,\neq 2001}^{2006}\beta_{4,l}YR_l \\ &+ \sum_{m=1,\neq 24}^{48}\beta_{5,m}HH_m + \sum_{o=1}^{N_{R,S}}\beta_{6,o}SPIKE_{R,o} + \sum_{p=1}^{N_{R,N}}\beta_{7,p}NEG_{R,p} + \varepsilon_t \end{aligned} \tag{33.2}$$

where $RET_{R,t}$ represents the discrete return for region R at time t, α_0 represents the constant term, and DAY_j represents the dummy variable for each day of the week

(j = 1 for Monday, 2 for Tuesday, . . . , 6 for Saturday). The dummy variable for Sunday is dropped on the basis that the returns are relatively lower on that day. We use similar justification when it comes to discarding other periods. MTH_k represents the dummy variable for each month (k = 1 for January, 2 for February, . . . , 12 for December). The dummy variable for September is dropped; YR_l represents the dummy variable for each year included in the sample period (l = 1999, . . . , 2006). The dummy variable for 2001 is dropped; HH_m represents the dummy variable for each half-hourly trading interval (m = 1 for 00:00 h, 2 for 00:30 h, . . . , 48 for 23:30 h). The dummy variable for 11:30 h is dropped; $SPIKE_{R,o}$ represents a set of $N_{R,S}$ dummy variables, one for each extreme spike as previously defined, with $N_{R,S}$ representing the number of extreme returns observed in region R for the period of the study; $NEG_{R,N}$ represents the dummy variable for the return associated with an occurrence of a negative price ($p = 1, \ldots, N_{R,N}$), with $N_{R,N}$ representing the number of occurrences of a negative price for region R during for the period of the study.

The values for the trading interval at 11:30 h, Sunday, September, and the year 2001 were dropped to avoid exact collinearity and to allow comparison of these values with the remaining seasonal coefficients for HH_m, DAY_j, MTH_k, and YR_l. The equation was initially estimated for each region with 20 lagged returns ($RET_{Rt-1}, \ldots, RET_{Rt-20}$). F-tests for redundant variables were performed for all regions, and AIC and SBC values support the finding that lags 1 through 5 were significant. Lags 6 onwards were not found to be significant and were discarded. Standard tests and residual diagnostics revealed no misspecification in the above model.

Results of the regression analysis are presented in Table 33.2. Coefficients and t-statistics (t-stats) are presented for each seasonal dummy variable. The results generated from this model are consistent with Kaminski (1997), Clewlow and Strickland (2000) and De Jong and Huismann (2002) with regard to the seasonal aspects and spike behavior of the price series. Seasonal effects vary between regions, and time-of-day effects are generally more significant than other seasonalities. Positive returns are observed at times of peak population activity in the morning and early evening, and negative returns observed at most other times. In general, significant negative returns are found for the small hours of the morning between 12:30 a.m. and approximately 4:00 a.m. in all regions. NSW1 exhibits an unexplained positive return at 1:30 a.m., reverting to negative returns for the remainder of the early morning. The hours between 5:00 a.m. and 9:30 a.m. inclusively exhibit significant positive effect in all regions, reverting to generally negative returns in the late morning. Negative returns are found in SA1 during midafternoon. Significant positive effects are observed for all regions in the early evening, generally between the hours of 5:00 and 7:00 p.m., reverting to significant negative effects for the remainder of the evening, until positive effects emerge in the late evening at 10:30 p.m. and at midnight. The periods of positive return in the morning and early evening are consistent with peaks in activity in the population. The positive returns observed around 11:00 p.m. are consistent with increased demand for electricity arising from off-peak hot water systems generally switching on at 11:00 p.m.

[a]F-test was carried to exclude redundant lag returns (from lag 6 to lag 20)
[b]Akaike info criterion and Schwarz criterion were used to determine the optimal lags for the different regions

Day-of-week effects generally appeared stronger for Monday, Tuesday, and Wednesday than other days of the week. Monthly effects are not found to be consistent across regions, nor are yearly effects. There appears to be no clear pattern in monthly effect across regions, although a small but significant negative effect is noted for October in NSW1 and VIC1. Positive effects are noted for winter months in SA1, and QLD demonstrates significant positive effects in spring and summer months. As expected, there is considerable evidence of positive spikes in the return series, and the evidence shows that negative prices within the Australian electricity market cannot be ignored. Such results cast doubts on the application of lognormal prices to the Australian electricity market.

33.3 Australian Demand for Electricity

Given the instantaneous market-clearing nature of prices in the AEMO, a logical extension of this study is to investigate the prevalence of seasonal effects and spike behavior in electricity demand, with a view to examining the extent to which these effects are transmitted from demand to price and how efficiently the spot market absorbs demand-side shocks.

33.3.1 Demand Data

The demand data used in this study are half-hourly observations of total demand. The data is obtained from the same source as the price data and covers the same period and regions. The basic quantity of interest in demand modelling and forecasting is typically the periodic "total system demand" or "total demand." The total demand value reported by AEMO is a derived value, somewhat different from demand (as may be represented by traded volume), as it may be understood in conventional financial markets. Suppliers and distributors lodge schedules and bids for the sale and purchase of electricity with AEMO at 12:30 p.m. on the day prior to actual dispatch of electricity for each interval. AEMO compiles this data and mates it with a short-term forecast of system demand and grid capacity to determine an expected dispatch quantity and dispatch order of generators (Smith 2000).

This study uses AEMO's reported "total demand" values for each region, expressed in megawatts (MW) by half-hour trading interval for the sample period. Total demand is defined by AEMO as the total forecast regional demand against which a dispatch solution is performed. For any particular interval and region, this is determined as described by Eq. 33.3:

$$D_T = \sum_{i=1}^{n} G_i - \sum_{i=1}^{n} L_i + NI_i + \sum_{i=1}^{n} AIL + F(D) + ADE \tag{33.3}$$

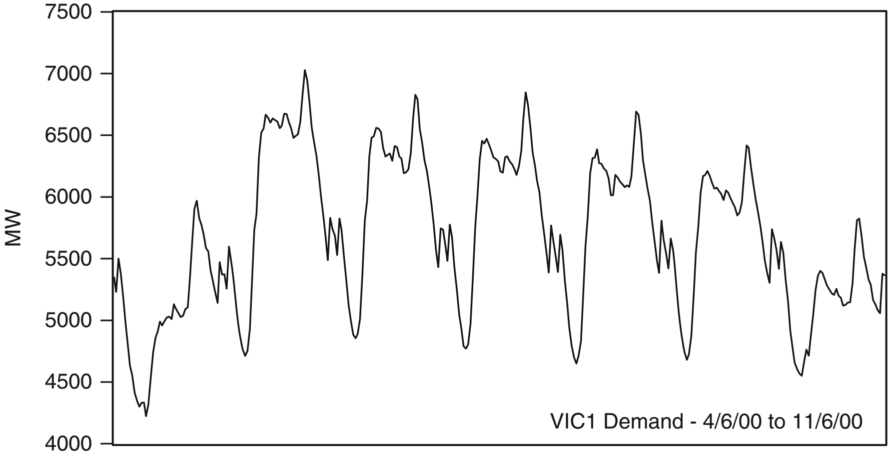

Fig. 33.2 Plot of VIC1 demand for the week commencing Monday 4/6/00, illustrating the regular intraday and daily seasonal patterns in the demand series

where:

D_T is total demand.

G_i is "generator initial MW (SCADA)," the sum of initial MW values for all scheduled generation units within the region, measured at their generator terminals and reported by SCADA.

L_i is "load initial MW (SCADA)," the scheduled base-load generation level for the interval.

NI_i is "net interconnector initial MW into region," the net of all interconnector flows into and out of the region.

AIL is "total allocated interconnector losses" represented by $\sum$(MW losses X regional loss allocation). "MW losses" represent actual power losses due to physical leakage from the transmission system. Regional loss allocation is an NEMMCO predetermined static loss factor for each interconnector.

$F(D)$ is demand forecast, a per-interval demand adjustment that relates the demand at the beginning of the interval to the target at the end of the interval.

ADE is "aggregate dispatch error," an adjustment value used by the NEM to account for disparities between scheduled and actual dispatch for all scheduled generation units in the region.

Figure 33.2 is provided to illustrate the presence of seasonal patterns in the intraday behavior of electricity demand in Victoria over a 10-day period in 2000.

Descriptive statistics for the demand series are shown in Table 33.3.

We report the mean, standard deviation, minimum, maximum, range, skewness, kurtosis, Jarque-Bera statistic, and Augmented Dickey-Fuller[2] statistics for each

[2]Additional statistics are provided for the demand series but not for the price series. This is because the original paper on the price series reports these values.

Table 33.3 Descriptive statistics for demand by region, January 1999 to January 2006

Demand	NSW1	QLD1	SA1	VIC1
Mean[a]	8123.89	5197.74	1451.56	5411.02
S.D.[a]	1306.02	864.33	264.45	757.26
Maximum[a]	12884.15	8231.95	2873.03	8545.39
Minimum[a]	4624.03	2945.96	778.00	2726.88

ADF[b]	−22.83	−17.50	−28.30	−24.77
N	124224	124224	124224	124224

[a]Mean, standard deviation, maximum, and minimum are expressed in megawatts (MW)
[b]Augmented Dickey-Fuller (ADF) statistic rejects the hypothesis of a unit root at the 1 % level of confidence

region's demand series. NSW1 has the highest mean, median, and maximum demand observations of the five regions for the period. New South Wales is Australia's most populous state so we would expect that demand for electric power to be highest in the NSW1 region. The other regions follow generally in order of state population, with VIC1 next highest, followed by QLD1, and SA1. The standard deviation and range of demand levels are generally high, widely dispersed across the regions, and broadly consistent with the pattern of means, ranging from 264 MW for SA1 to 1,306 MW for NSW1. The distributions of demand observations are slightly positively skewed for all regions. NSW1, QLD1, and VIC1 are slightly platykurtic, while SA1 is leptokurtic. Jarque-Bera (JB) statistics reject the hypothesis of normal distribution at the 1 % level of significance for all four regions, and Augmented Dickey-Fuller statistics reject the hypothesis of a unit root at the 1 % level of significance.

33.3.2 Demand Returns

In this section, we consider the proportional changes in demand over a price interval, which for convenience we refer to as "demand returns." The demand return series are of interest because there are a number of over-the-counter and exchange-traded derivative products available for hedgers and speculators in the Australian and overseas electricity markets. Pricing models for derivatives are informed by the behavior of returns on the spot price. The half-hourly pool price and its associated returns exhibit strong seasonal and outlier effects as a result of the occurrence of price spikes. Demand is widely regarded as a major influence on price (and therefore returns), and we are interested in investigating the extent to which the seasonalities observed in half-hourly returns on spot price are present in the equivalent returns on demand. Figure 33.3 shows demand and demand return over a 10-day period and indicates that demand returns appear to exhibit some time-of-day effects but also suggests the presence of sudden and fast-reverting spikes in the demand return series.

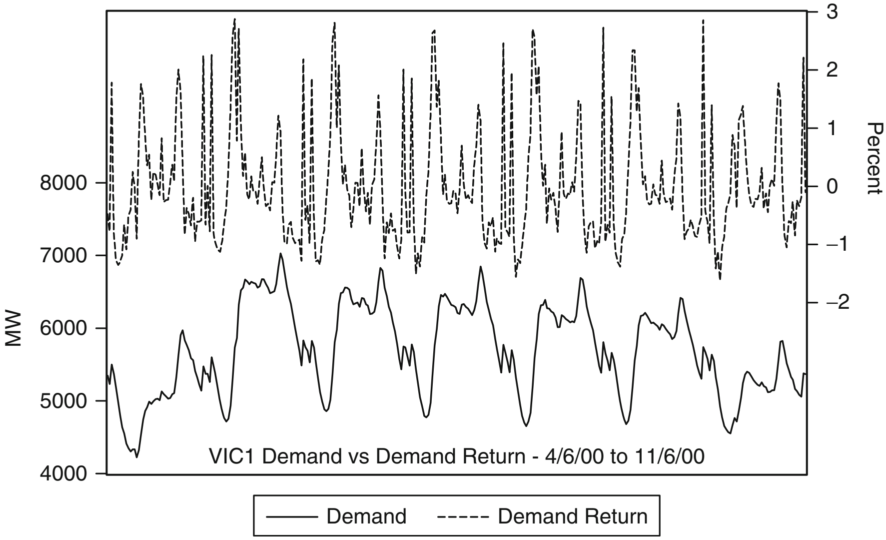

Fig. 33.3 Plot of VIC1 demand and returns on demand for the week commencing 4/6/00. Demand is in MW and returns are percentage returns

In light of the fact that AEMO's total demand is reported at half-hourly intervals in discrete time, the demand return series used in this study were generated as half-hourly discrete returns rather than log returns, according to Eq. 33.4 as follows:

$$RD_t = \frac{(D_t - D_{t-1})}{D_{t-1}} \tag{33.4}$$

where RD_t is discrete demand return at time t, D_t is half-hourly demand at time t, and D_{t-1} is the previous half-hourly total demand, i.e., at time $t-1$. The results of tests for the presence of a unit root give us confidence that the demand and return series are stationary, and we prefer this discrete return specification over log returns, as a log return specification will dampen the spike effects we are attempting to capture.

We define a spike in demand returns as any observed demand return greater than four standard deviations larger than the mean. Tables 33.4 and 33.5 collates the occurrences of spikes as defined. Panel (a) shows the occurrence of spikes by region and in aggregate for weekday, month, and year. Panels (b) and (c) show the occurrence of spikes by half-hourly trading interval.

Table 33.4 Panel (a) shows that in aggregate there are 208 spikes in demand returns observed across all regions during the sample period. VIC1 shows the highest incidence of demand spikes with 92 (44 %) of the 208 observed, followed by NSW1 with 81 (38 %), and SA1 with 22 (10 %) spikes during the sample period.

By day of the week, Monday shows the highest incidence with 67 (32 %) tapering gradually to Sunday with 15 occurrences (7 %). August shows the highest incidence by month with 42 (20 %), and of these 37 occur in NSW1. The next

highest incidences by month are March (38) and June (25), with spikes predominantly in VIC1 for March and in NSW1 in June. The highest incidence by year occurs in 1999 with 101 spikes (49 %), dropping markedly in 2000 (24) and 2001 (23). The incidence of spikes appears to have settled somewhat from 2003 onwards at around 15–16 spikes per year.[3]

Table 33.5 Panel (b) shows the incidence of extreme spikes in demand returns by half-hourly trading interval. There are concentrations of spikes occurring at the 06:30 (91 spikes, of which 78 occur in NSW1) and 23:30 (80 spikes, all of which occur in VIC1). A subperiod analysis of demand returns suggests that sharp peaks in demand

[3]Sample data for 2006 only includes the month of January and is unlikely to be representative of the full year.

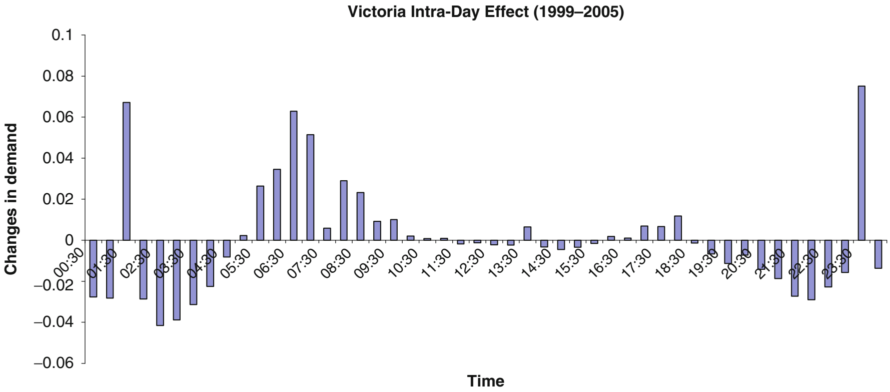

Fig. 33.4 Half-hourly demand returns for VIC1 for the period 1999–2005

returns are persistent throughout the sample period, as illustrated by Fig. 33.4. Figure 33.4 shows the pattern of demand returns for VIC1 for the period 1999–2005 and is illustrative of the pattern in NSW1. The 06:30 peak in demand appears consistent with the commencement of the morning peak in activity in the population. We believe that the 2,330 peak coincides with the activation of off-peak hot water systems set to take advantage of overnight off-peak retail electricity tariffs.

Descriptive statistics for the half-hourly demand return series are shown in Table 33.6. We report the mean, standard deviation, minimum, maximum, range, skewness, kurtosis, and Augmented Dickey-Fuller statistics for each region's demand return series.

Mean, standard deviation, maximum, and minimum are expressed in terms of half-hourly percentage return and are broadly consistent across NSW1, QLD1, SA1, and VIC1. The distributions of demand returns for all four regions demonstrate positive skewness and high positive kurtosis. Jarque-Bera (JB) statistics reject the null hypothesis of normal distribution at the 1 % level of significance for all four regions. This fat-tailed character is consistent with studies on price behavior (see Huisman and Huurman 2003; Higgs and Worthington 2005; Wolack 2000) and appears driven by the presence of spikes in demand returns. Augmented Dickey-Fuller (ADF) statistics robustly reject the hypothesis of a unit root at the 1 % level of significance for all five regions, again consistent with the findings of the earlier studies.

33.3.3 Modelling Seasonality in Demand for Electricity

In this section, we adapt and adjust Eq. 33.2 to model seasonality in demand return. The equation is as follows:

$$RD_{it} = \phi_0 + \beta_1 LR_t + \beta_2 \sum_{n=1,\, i\neq \text{Sun}}^{6} DAY_i + \beta_3 \sum_{n=1,\, i\neq \text{Sep}}^{11} MTH_i + \beta_4 \sum_{n=1999,\, i\neq 2001}^{2006} YR_i + \beta_5 \sum_{n=1,\, i\neq 1,130\ \text{hrs}}^{47} HH_i + \beta_6 \sum_{n=1}^{N_S} DDSPIKE_i + \varepsilon_t \tag{33.5}$$

where RD_{it} represents the discrete demand return for region i at time t, ϕ_0 represents the constant term, LR_{it} represents the lagged demand return for region i at time t, $DDSPIKE_i$ represents the dummy variable set for each occurrence of extreme return as previously defined, and the remaining variables are defined as in Eq. 33.2. The trading interval at 11:30 h, Sunday, September, and the year 2001 were incorporated into the constant term α in the model as the base case for each dummy series. These base cases were selected as the trading interval, day, month, and year, in which demand return activity was consistently lowest in all four regions.

33.4 Empirical Results

Results of the regression analysis are presented in Tables 33.7 and 33.8. Coefficients and t-statistics are presented for each seasonal dummy variable and for lagged returns. In view of the very large number of individual spikes in demand returns (208 spikes identified for the sample period across all regions), coefficients for individual spikes are not explicitly reported though results are discussed.

We find that coefficients are relatively small for NSW1, QLD1, SA1, and VIC1. Day-of-week effects are positive and significant for Monday in NSW1, QLD1, SA1, and VIC1. Thursday shows significant negative effect in demand returns in SA1 only. There is significant negative Friday effect in all regions. There appears to be no clear pattern evident for monthly effect across regions. There is no clear pattern evident in yearly effect, although significant negative effect is observed for 1999 in VIC1. Half-hourly time-of-day effects offer more interesting results and are broadly more consistent across regions than the seasonal effects previously discussed. In general, significant negative demand returns are found for the small hours of the morning from 12:30 a.m. until approximately 4:00–5:00 a.m. in all regions. VIC1 exhibits an unexplained highly significant positive return at 1:30 a.m., reverting to negative returns until for the remainder of the early morning. There is wide variation in the pattern of demand returns during the waking day. NSW1 and VIC1 show broadly

similar intraday patterns, with significant positive demand returns dominating between 04:30 and 18:00 and with minor variation reverting to negative demand returns for the remainder of the evening. QLD1 and SA1 are broadly similar, demonstrating significant positive effect between 04:30 and 10:30 and predominantly negative effect from 10:30 to 15:30, reverting to positive effect from 16:00 to 19:30 when we see reversion to negative effect for the remainder of the evening. The periods of positive return in the early morning and early evening are consistent with peaks in activity in the population. We would expect to observe positive demand returns arising from off-peak hot water systems generally switching on at 11:00 p.m., but curiously positive returns around that hour are evident only in NSW1.

33.5 Conclusions

The current literature establishes that electricity time series differ from traditional financial data having greater incidence of spikes than is generally observed in financial data and this results in extreme volatility. The work done overseas is of limited practical application to the Australian market as our market structure is different. The lesson learned from our study is that even within the same country, variation exists as different states reflect variation in geographic differences. The implication is that specific models must be developed for each geographic region. Our work is innovative in that we develop an econometric time series seasonal model that can be applied in areas where seasonality is suspected. For instance, the model was initially applied to price and return series and then later on to demand return series. This model has the capability to be applied in other financial time series models.

Developing models to explain and to predict electricity prices is a significant task. This is important both for the market participants who operate in the physical market and for those trading in electricity derivatives. Modelling electricity prices and trading in this market is challenging, so much so that investment banks avoid trading electricity derivatives because of the incidence of spikes. This provides a strong incentive for this research and future research into the electricity market. A better understanding of the time series nature of the electricity prices may help in the development of more efficient forecasting models which will help to lower risk management costs and thus reduce the cost of managing electricity price exposures. Electricity generators, electricity retailers, transmission and distribution network suppliers, electricity retailer companies, and electricity consumers will all benefit from development of more accurate models in this area.

Acknowledgment The authors wish to acknowledge the financial support of the Australian Centre for Financial Studies, via grant 18/2005. The research on the seasonality within the spot price has been published in 2011, "Seasonal factors and outlier effects in rate of return in Australia's National Electricity Market," *Applied Economics*, Vol. 43, Issue 3; pp. 355–369. Binesh Seetanah provided invaluable research assistance. Any remaining errors are the responsibility of the authors.

Abstract

Commercial timberland assets have attracted more attention in recent decades. One unique feature of this asset class roots in the biological growth, which is independent of traditional financial markets. Using both parametric and non-parametric approaches, we evaluate private- and public-equity timberland investments in the United States. Private-equity timberland returns are proxied by the NCREIF Timberland Index, whereas public-equity timberland returns are proxied by the value-weighted returns on a dynamic portfolio of the US publicly traded forestry firms that had or have been managing timberlands. The results from parametric analysis reveal that private-equity timberland investments outperform the market and have low systematic risk, whereas public-equity timberland investments fare similarly as the market. The nonparametric stochastic discount factor analyses reveal that both private- and public-equity timberland assets have higher excess returns.

Static estimations of the capital asset pricing model and Fama-French three-factor model are obtained by ordinary least squares, whereas dynamic estimations are by state space specifications with the Kalman filter. In estimating the stochastic discount factors, linear programming is used.

34.1 Introduction

Timberland investments have been unprecedentedly active in the United States the past 30 years. A number of factors have motivated public attention toward timberland assets. On the supply side, because of the internal subsidies from timber divisions to processing mills, timberland properties managed by traditional vertically integrated forest products firms have been undervalued by the Wall Street. To fix this mispricing, these firms began divesting their timberlands as a strategic move. For example, International Paper, a global leading forest products firm, has disposed of most of its timberlands and focused on its core business of paper and packaging products manufacturing in recent decades. Currently, almost no forest products firms in the United States still own timberlands (Harris et al. 2010). On the demand side, institutional investors, e.g., organizations with fiduciary obligations such as pension funds, university endowments, foundations, and trusts, have diversified into nonfinancial asset classes such as commercial timberlands on the passage of Employee Retirement Income Security Act (ERISA) in 1974.

There are several ways to invest in commercial timberlands. High-net-wealth families and individuals can participate in commingled (pooled) funds, or they can own and manage timberlands directly. Others can buy stocks and bonds of publicly traded forestry firms that focus on timberland business. Most institutional investors hold timberland properties via timberland investment management organizations (TIMOs). TIMOs manage their institutional assets in either separately managed accounts (individually managed accounts) or pooled funds. A separately managed account holds timberland properties of one investor in a single portfolio, whereas a pooled fund collects capital from a number of investors and allocates it to a portfolio of timberland properties. Investors tend to have more discretion with separate accounts than pooled funds (Zinkhan and Cubbage 2003). In 2008, there were about 30 TIMOs in the United States, and the total value of their timberland assets exceeded $35 billion (Zinkhan 2008).

Since the public recognition of commercial timberland as an alternative asset class, a number of studies have been conducted to assess the financial performance of timberland investments. The major findings of previous research can be summarized as follows. (1) Timberland has countercyclical returns or low (even negative in some cases) correlation with the financial assets (Binkley et al. 1996; Cascio and Clutter 2008; Redmond and Cubbage 1988; Washburn and Binkley 1990; Zinkhan 1988). (2) Timberland can be an effective hedge against unexpected inflation (Fortson 1986; Washburn and Binkley 1993). (3) If timberland investors can exploit the biological growth of timber thus time the market, they can get higher and better returns (Caulfield 1998; Conroy and Miles 1989; Haight and Holmes 1991). (4) Relative inefficiency tends to exist in timberland markets (Caulfield 1998), although this situation has been alleviated through time (Washburn 2008; Zinkhan 2008). (5) Among a variety of forestry-related investment vehicles, institutional timberland investments and timberland limited partnerships have low-risk levels but excess returns (Sun and Zhang 2001). (6) In the long run, timber and/or timberland returns are cointegrated with other nontimber financial instruments (Heikkinen 2002; Liao et al. 2009).

Almost all of the above studies are based on the single-period capital asset pricing model (CAPM). Sun and Zhang (2001) extended the literature in timberland investments by employing the arbitrage pricing theory (APT), and Heikkinen (2002) and Liao et al. (2009) expanded the literature by using cointegration analysis. Nevertheless, all those methods are parametric in nature. This study has several contributions. First, timberland assets are considered separately in private and public markets, and their returns are compared. Second, supplementary to the ordinary least squares (OLS) estimation of the CAPM and the Fama-French three-factor model, a state space model with the Kalman filter is employed to examine the time-varying risk-adjusted excess return (α) and systematic risk (β). Finally, the nonparametric stochastic discount factor (SDF) approach is introduced for pricing timberland returns.

The major results are that private-equity timberland investments have significant excess returns but low systematic risk, whereas public-equity timberland investments fare similarly as the market, and that intertemporal consumption decisions affect the intertemporal marginal rate of substitution of timberland investors and thus impact the rational pricing of timberland assets. These results can further our understanding of the financial aspects of commercial timberland assets in the United States. The next two sections describe the methodologies and the data. Section 34.4 explains the empirical results, and the last section makes some concluding remarks.

34.2 Methods

For the parametric method, an explicit model is needed. Two candidate models prevalent in the finance literature are the CAPM and the Fama-French three-factor model. The parametric method is often criticized for the "joint hypothesis tests" problem, i.e., testing the asset pricing model and the abnormal performance (market efficiency) simultaneously. The nonparametric method does not require such an explicit model specification and is therefore not subject to these critiques. The SDF approach is a general, nonparametric asset pricing approach and is complement to the parametric approaches.

34.2.1 CAPM

Built on Markowitz's (1952) groundwork of mean-variance efficient portfolio, Sharpe (1964) and Lintner (1965) developed its economy-wide implications – the CAPM. The CAPM states that the expected return on an asset or a portfolio $E[R_i]$ equals a risk-free rate R_f plus a premium that depends on the asset's β_i and the expected risk premium on the market portfolio $E[R_m] - R_f$, i.e.,

$$E[R_i] = R_f + \beta_i\left(E[R_m] - R_f\right). \tag{34.1}$$

In empirical regression analysis, the CAPM is estimated in the excess return form

$$R_i - R_f = \alpha_i + \beta_i\left(R_m - R_f\right) + \mu_i, \tag{34.2}$$

where ex post realized returns R_i and R_m rather than ex ante expected returns $E[R_i]$ and $E[R_m]$ are used. The intercept α_i is called Jensen's (1968) alpha. A positive α suggests that the individual asset outperforms the market and earns a higher than risk-adjusted return, whereas a negative α suggests that the individual asset underperforms the market and earns a lower than risk-adjusted return. Therefore, Jensen's alpha has become a commonly used measure of abnormal performance, and testing whether it is zero has been widely used in the empirical asset pricing literature.

34.2.2 Fama-French Three-Factor Model

Given the empirical evidence that small size stocks outperform large size stocks, and value (high book-to-market) stocks outperform growth (low book-to-market) stocks on average, Fama and French (1993) develop a model that includes these extra two factors to adjust for risk:

$$E[R_i] - R_f = \beta_{RMRF,i} E[R_{RMRF}] + \beta_{SMB,i} E[R_{SMB}] + \beta_{HML,i} E[R_{HML}], \tag{34.3}$$

where $R_{RMRF} = R_m - R_f$ is the same market factor as in the CAPM, representing the market risk premium; $R_{SMB} = R_{\text{small}} - R_{\text{big}}$ is the size factor, representing the return difference between a portfolio of small stocks and a portfolio of large stocks (SMB stands for "small minus big"); $R_{HML} = R_{\text{highBM}} - R_{\text{lowBM}}$ is the book-to-market factor, representing the return difference between a portfolio of high book-to-market stocks and a portfolio of low book-to-market stocks (HML stands for "high minus low"); and β's are called factor loadings, representing each asset's sensitivity to these factors. When estimating Fama-French three-factor model, ex post realized returns are used, as in the case of the CAPM, and an intercept is added to capture the abnormal performance,

$$R_i - R_f = \alpha_i + \beta_{RMRF,i} R_{RMRF} + \beta_{SMB,i} R_{SMB} + \beta_{HML,i} R_{HML} + \varepsilon_i. \tag{34.4}$$

34.2.3 CAPM and Fama-French Three-Factor Model Under the State Space Framework

The CAPM (Eq. 34.2) and the Fama-French three-factor model (Eq. 34.4) are usually estimated by OLS, possibly with some correction for the autocorrelations in the errors. One restrictive nature of the OLS method is that the coefficients in the regression are imposed to be constant. This condition may be unrealistic in real asset pricing modeling. For instance, one would suspect that both α's and β's should be time varying. To solve this problem, we can estimate the CAPM and the Fama-French three-factor model in the state space framework with the Kalman filter (Appendix 1). Using the CAPM as an example, in the state space framework, the system of equations is specified as

$$\begin{aligned} R_{i,t} - R_{f,t} &= \alpha_{i,t} + \beta_{i,t}\left(R_{m,t} - R_{f,t}\right) + \mu_{i,t} \\ \alpha_{i,t+1} &= \alpha_{i,t} + \xi_t \\ \beta_{i,t+1} &= \beta_{i,t} + \tau_t \end{aligned} \tag{34.5}$$

where $\mu_{i,t}$, ξ_t, and τ_t are normally and independently distributed mean-zero error terms. In the state space model, the first equation in (34.5) is called the observation or measurement equation, and the second and third equations are called the state equations. In this particular case, each state variable follows a random walk.

One advantage of the state space approach with time-varying parameters is that it can incorporate external shocks, such as policy and regime shifts, economic reforms, and political uncertainties, into the system, especially when the shocks are diffuse in nature (Sun 2007). This approach has been applied to a variety of issues, including demand systems (e.g., Doran and Rambaldi 1997), aggregate consumptions (e.g., Song et al. 1996), policy analysis (e.g., Sun 2007), and price modeling and forecasting (e.g., Malaty et al. 2007).

34.2.4 Stochastic Discount Factor Approach

The single-period asset pricing models ignore the consumption decisions. In effect, investors make their consumption and portfolio choices simultaneously in an intertemporal setting. In the framework of an exchange economy in which an investor maximizes the expectation of a time-separable utility function (Lucas 1978), it can be proved that (Appendix 2)

$$E_t\left[\left(1+R_{i,t+1}\right)M_{t+1}\right]=1, \tag{34.6}$$

where $R_{i,t+1}$ is the return on asset i in the economy and M_{t+1} is known as the stochastic discount factor, or intertemporal marginal rate of substitution, or pricing kernel (e.g., Campbell et al. 1997).

Hansen and Jagannathan (1991) demonstrated how to identify the SDF from a set of basis assets, i.e., the derivation of the volatility bounds. These bounds are recognized as regions of admissible mean-standard deviation pairs of the SDF. Their major assumptions are the law of one price and the absence of arbitrage opportunities. Accordingly, there are two particular solutions for the SDF: the law of one price SDF and the no-arbitrage SDF. The process of retrieving the reverse-engineered law of one price SDF is equivalent to the following constrained optimization problem:

$$\begin{aligned}
&\underset{M_t}{\text{Min}}\,\sigma_{M_t}=\left[\frac{1}{T-1}\sum_{t=1}^{T}\left(M_t-v\right)\right]^{1/2}\\
&s.t.\frac{1}{T}\sum_{t=1}^{T}M_t=v\\
&\quad\ \frac{1}{T}\sum_{t=1}^{T}M_t\left(1+R_{i,t}\right)=1
\end{aligned} \tag{34.7}$$

for a range of selected v (mean of M_t) and for all assets $i=1,2,\cdots,N$. Under the stronger condition of no arbitrage, another positivity constraint on M_t is needed. Therefore, the only difference between the law of one price SDF and the no-arbitrage SDF is whether M_t is allowed to be negative. In this study, no-arbitrage SDF is used. Following Hansen and Jagannathan (1991), nonnegativity instead of positivity restriction $M_t \geq 0$ is added to retrieve the no-arbitrage SDF. Last, sample size T should be sufficiently large such that the time-series version of law of large numbers applies; that is, the sample moments on a finite record converge to their population counterparts as the sample size becomes large (Hansen and Jagannathan 1991).

Provided the existence of a risk-free asset, it can be shown that

$$E_t\left[\left(R_{i,t+1} - R_f\right)M_{t+1}\right] = 0. \tag{34.8}$$

This equation presents the basis for testing the risk-adjusted performance of a portfolio (Chen and Knez 1996). Namely, one can test whether

$$\alpha_i = E_t\left[\alpha_{i,t}\right] = E_t\left[\left(R_{i,t+1} - R_f\right)M_{t+1}\right] = 0. \tag{34.9}$$

Ahn et al. (2003) pointed out that this measure generalizes Jensen's alpha and does not count on a specific asset pricing model. Based on this method, they reassess the profitability of momentum strategies and found that their non-parametric risk adjustment explains almost half of the anomalies.

34.3 Data

34.3.1 Timberland Returns

Returns for both private- and public-equity timberland investments are analyzed. Although TIMOs have become the major timberland investment management entities for institutional investors as well as high-net-wealth families and individuals, their financial data are rarely publicly available. To provide a performance benchmark, several TIMOs, together with National Council of Real Estate Investment Fiduciaries (NCREIF) and the Frank Russell Company, initiated the NCREIF Timberland Index in early 1992 (Binkley et al. 2003) (Appendix 3). NCREIF members can be divided into data contribution members, professional members, and academic members. Data contribution members include investment managers and plan sponsors who own or manage real estate in a fiduciary setting. Professional members include providers of accounting, appraisal, legal, consulting, or other services to the data contribution members. Academic members include full-time professors of real estate. Data contribution members submit their data on a quarterly basis for computation of the NCREIF Property Index. Regarding the NCREIF Timberland Index, it is some TIMOs that are the major data contribution members. The quarterly NCREIF Timberland Index is reported at both regional (the South, the Northeast, and the Pacific Northwest) and national levels, and extends back to 1987. In this study, the national-level NCREIF Timberland Index (1987Q1–2010Q4) is used as a return proxy for the US private-equity timberland investments.

Returns on public-equity timberland investments are proxied by the value-weighted returns on a dynamic portfolio of the US publicly traded forestry firms that had or have been managing timberlands. These firms include Deltic Timber, the Timber Co, IP Timberlands Ltd., Plum Creek, Pope Resources, Potlatch, Rayonier, and Weyerhaeuser. Deltic Timber and Pope Resources are natural resources companies focused on the ownership and management of timberland; the Timber Co and IP Timberlands Ltd. are subsidiaries of Georgia-Pacific and International Paper that track the value and performance of their timberland properties; Plum Creek, Potlatch, and Rayonier are publicly traded real estate investment trusts (REITs) that are engaged in timberland management; and Weyerhaeuser is a forest products firm that has a significant portion of its business in timberlands. The market value of each firm is calculated as the product of stock price and total shares outstanding at the end of each quarter. Financial data for these forestry firms are obtained from the Center for Research in Security Prices (CRSP). To be consistent with the NCREIF Timberland Index, the sample spans from 1987Q1 to 2010Q4.

34.3.2 Basis Assets

To mimic the complete investment opportunity set that is available to investors, a parsimonious set of basis assets needs to be specified. King (1966) proved that industry groupings maximize intragroup correlation and minimize intergroup correlation and concluded that market and industry factors capture most of the common variation in stock returns. Following Hansen and Jagannathan (1991), we construct the reference set by forming industry portfolios according to SIC code. In this study, two sets of basis assets are chosen – one is the five-industry portfolios plus long-term treasury bonds, and the other is the ten-industry portfolios plus long-term treasury bonds. The industry groups are derived from stocks listed on NYSE, AMEX, and NASDAQ based on their four-digit SIC codes. The five industries are classified as consumer goods, manufacturing, Hi-Tech, healthcare, and others, whereas the ten industries are classified as consumer nondurables, consumer durables, manufacturing, energy, Hi-Tech, telephone and television transmission, shops, healthcare, utilities, and others. Value-weighted returns on the industry portfolios are obtained from Kenneth R. French's website, and returns on the portfolio of long-term treasury bonds are obtained from CRSP. Presuming that the basis assets are rationally priced, the SDF can be retrieved.

34.3.3 Other Indices

Market returns are approximated by the value-weighted returns on all NYSE, AMEX, and NASDAQ stocks from CRSP. Risk-free rate, as approximated by the 1-month treasury bill rate from Ibbotson Associates, Inc., and Fama-French factors are available on Kenneth R. French's website.

34.4 Empirical Results

34.4.1 Estimation of the CAPM and the Fama-French Three-Factor Model

Panel A of Table 34.1 presents the OLS estimation of the CAPM and the Fama-French three-factor model using the quarterly NCREIF Timberland Index after adjustment for the seasonality. A significant positive α from the CAPM suggests that private-equity timberland investments have a risk-adjusted excess return of about 8.20 % (2.05 % $\times$ 4) per year. This excess return is slightly larger after accounting for Fama-French factors. Market β's from both models are insignificantly different from zero, but significantly less than one. This means that private-equity timberland investments are not only weakly correlated with the market but also less risky than the market. The small magnitudes with high *p*-values of the coefficients for SMB and HML signify that these two extra factors add limited explanatory power to the CAPM in pricing private-equity timberland returns.

In contrast, the CAPM and the Fama-French three-factor model fit the returns on the dynamic portfolio of forestry firms much better, as implied by the higher R^2 values (Panel A of Table 34.2). This is within our expectation since these forestry firms are publicly traded and are more exposed to the market. However, α's are insignificant albeit positive, indicating no abnormal performance. Market β's are significantly different from zero, but not from one. In addition, β's for SMB and HML in Fama-French three-factor model are significant at the 5 % level or better, meaning these factors capture some variations in the portfolio returns that are not explained by the market premium. As a result, the abnormal performance (α) has dropped by 53 %. The magnitudes of β's indicate that the dynamic portfolio is dominated by mid-large firms with middle book-to-market ratios.

34.4.2 State Space Estimation of the CAPM and the Fama-French Three-Factor Model

Panel B of Table 34.1 presents the state space estimation of the CAPM and the Fama-French three-factor model using the NCREIF Timberland Index. Those OLS coefficient estimates are used as the starting values. Only α is specified as a state variable (stochastic level) in that little time variation is observed in β, and both AIC and SBC favor the deterministic-β model. Back to the model specification in system (Eq. 34.5), this is equivalent to restrict $\tau_t = 0$. The AIC and SBC are marginally larger than those for the OLS estimation because of the relatively small sample size. Figure 34.1 depicts the evolution of the risk-adjusted excess returns of the NCREIF Timberland Index estimated from the CAPM. For most time in the last 22 years, the NCREIF Timberland Index has achieved positive abnormal returns with an average of 10.20 % per year (calculated from the estimated α series). Nevertheless, in certain years (2001–2003), the α is low and even negative,

indicating no abnormal performance. Although not reported here, the time-varying α's estimated from Fama-French three-factor model exhibit similar patterns.

For the dynamic portfolio, however, only β is specified to be stochastic since little time variation is observed in α, and both AIC and SBC favor the deterministic-α model. The time-varying β of the dynamic portfolio of forestry firms is plotted in Fig. 34.2. Overall, there is a decreasing trend in the market β. The average β over the sample period is 1.05, which is not significantly different from the market risk.

34.4.3 Abnormal Performance Measured by the SDF Approach

The mean of the no-arbitrage SDF M_t is specified in the selected range of [0.9750, 1] with an increment step of 0.0025. When the five-industry portfolios plus the long-term treasury bonds are used as the basis assets, the global minimum variance of M_t is identified at $v = 0.9800$; when the ten-industry portfolios plus

The SDF performance measures for both the NCREIF Timberland Index, and the returns on the dynamic portfolio of publicly traded timber firms are reported in Table 34.3. The α values for both return indices have increased, and the latter has become marginally significant. This indeed implies that intertemporal consumption decisions play a key role in pricing timberland assets. In a word, there is clear evidence of statistically as well as economically significant excess returns for the NCREIF Timberland Index, but only some evidence of economically significant excess returns for the portfolio of publicly traded timber firms.

34.5 Conclusion

Using both parametric and nonparametric techniques, in this study, we reexamined the financial performance of timberland investments. Private-equity timberland

Column (1) is for the NCREIF Timberland Index, and Column (2) is for the returns on a dynamic portfolio of the US publicly traded forestry firms that had or have been managing timberlands

returns are approximated by the NCREIF Timberland Index, whereas public-equity timberland returns are approximated by the value-weighted returns on a dynamic portfolio of the US publicly traded timber firms. The parametric analyses reveal that private-equity timberland assets outperform the market but have low systematic risk, whereas public-equity timberland assets perform similarly as the market. Therefore, inclusion of private-equity timberland properties can improve the efficient frontier, albeit such potential is limited for public-equity timberland properties. Unlike the parametric methods, the nonparametric SDF approach does not rely on any specific asset pricing models and hence are not subject to the "joint hypothesis test" criticisms. The results from the SDF approach suggest higher excess returns for both private- and public-equity timberland investments, which in turn signify the important role of intertemporal consumption decisions in rational pricing of timberland assets.

The positive α of private-equity timberland returns may be associated with the patience of institutional investors toward embedded strategic options for timberlands (Zinkhan 2008). If a timberland property has potential for higher and better use such as residential or commercial development opportunities, or if it is suitable for conservation easements, or if it has mineral or gas opportunities, it may have extra income sources, and the land value can be dramatically higher. The positive α may also be related to the liquidity risk that institutional investors bear since a typical TIMO has an investment time horizon of 10–15 years or even longer. In contrast, stocks of publicly traded timber firms can be easily traded on the stock exchanges. Moreover, initiation of a TIMO-type separately managed account usually requires a capital commitment of \$25–\$50 million, while participation in a TIMO-type pooled fund generally requires a minimum capital commitment of \$1–\$3 million (Zinkhan and Cubbage 2003). The large capital amount may enable the investors to achieve some degree of diversification.

The lower excess returns of the NCREIF Timberland Index around 2001–2003 may be associated with its relative weak performance during that time. In 2001Q4, the NCREIF Timberland Index fell by 6.5 %, the largest drop it ever had, which was primarily caused by the capital loss from the shrinking timberland values. In the same period, the S&P 500 index went up by 7.8 %. The overall decreasing trend in β for the dynamic portfolio of forestry firms may be related to the massive restructurings of these firms. For instance, Plum Creek, Potlatch, and Rayonier have converted themselves into timber REITs in recent years. With improved tax efficiency and increased concentration on timberland management, these timber REITs are expected to be less risky.

Another interesting fact noted in this study is that, despite the current economic downturn triggered by the subprime residential mortgage blowup, private-equity timberland returns remain relatively strong. While the CRSP market index went down 39 % in 2008, the NCREIF Timberland Index achieved a 9 % return, or on the risk-adjusted basis, an excess return of 10 % (calculated using the estimated α series in 2008). In contrast, the portfolio value of publicly traded timber firms fell 39 % just like the market. However, it should be noted that most of those forestry firms do have non-timberland business, such as paper and lumber mills, which may be more sensitive to the overall economic conditions. A close examination of the three publicly traded timber REITs reveals that they were less affected by the gloomy market. Looking ahead, global economic crisis will last for some time, multiple factors will affect timberland returns, and the net effect on timberland properties has yet to be observed (Washburn 2008).

It should be noted that there have been some concerns about the data and method consistency of the NCREIF Timberland Index. As pointed out by Binkley et al. (1996), there are no standardized appraisal and valuation practice in forestry, so heterogeneity may exist in the data. In addition, due to lack of quarterly appraisals for many properties in the NCREIF Timberland Index, quarterly return series may be less useful than the annual ones. Finally, the NCREIF Timberland Index is a composite performance measure of a very large pool of commercial forestland properties acquired in the private market for investment purposes. Hence, individual investors should use cautions when interpreting the NCREIF Timberland Index.

Appendix 1: State Space Model with the Kalman Filter

The multivariate time-series model can be represented by the following state space form:

$$y_t = Z_t\alpha_t + \varepsilon_t, \quad \varepsilon_t \sim NID(0, H_t) \tag{34.10}$$

$$\alpha_{t+1} = T_t\alpha_t + R_t\eta_t, \quad \eta_t \sim NID(0, Q_t) \tag{34.11}$$

for $t = 1, \cdots, N$, where y_t is $p \times 1$ vector of observed values at time t, Z_t is a $p \times m$ matrix of variables, α_t is $m \times 1$ state vector, T_t is called the transition matrix of order $m \times m$, and R_t is an $m \times r$ selection matrix with $m \geq r$. The first equation is called the observation or measurement equation, and the second is called state equation. The parameters α_t, H_t, and Q_t in the system of equations can be estimated jointly by the maximum likelihood method with the recursive algorithm Kalman filter. The intention of filtering is to update the information of the system each time a new observation y_t is available, and the filtering equations are

$$\begin{aligned} v_t &= y_t - Z_t a_t, \\ F_t &= Z_t P_t Z_t^{'} + H_t, \\ K_t &= T_t P_t Z_t^{'} F_t^{-1}, \\ L_t &= T_t - K_t Z_t, \\ a_{t+1} &= T_t a_t + K_t v_t, \\ P_{t+1} &= T_t P_t L_t^{'} + R_t Q_t R_t^{'}, \end{aligned} \tag{34.12}$$

For $t = 1, \cdots, N$. The mean vector a_1 and the variance matrix P_1 are known for the initial state vector α_1 (Durbin and Koopman 2001; Harvey 1989).

Appendix 2: Heuristic Proof of Equation 34.6

In a pure exchange economy with identical consumers, a typical consumer wishes to maximize the expected sum of time-separable utilities

$$\begin{aligned} &\underset{C_t}{\text{Max}}\, E_t\left[\sum_{i=0}^{\infty}\beta^i U(C_{t+i})\right] \\ &s.t. \sum_{j=1}^{N} x_t^j p_t^j + C_t = W_t + \sum_{j=1}^{N} x_{t-1}^j\left(p_t^j + d_t^j\right) \end{aligned} \tag{34.13}$$

where x_t^j is the amount of security j purchased at time t, p_t^j is the price of security j at time t, W_t is the individual's endowed wealth at time t, C_t is the individual's consumption at time t, d_t^j is the dividend paid by security j at time t, and β is time discount. Express C_t in terms of x_t^j, and differentiate the objective function with respect to x_t^j, then we can get the following first-order condition:

$$E_t\left[U'(C_t)p_t^j\right] = E_t\left[\beta U'(C_{t+1})\left(p_{t+1}^j + d_{t+1}^j\right)\right] \tag{34.14}$$

for all j. After rearranging the terms, we can reach Eq. 34.6, where

$$\begin{aligned} M_t &= \frac{\beta U'(C_{t+1})}{U'(C_t)} \\ R_{t+1} &= \frac{p_{t+1}^j + d_{t+1}^j}{p_t^j} - 1. \end{aligned} \tag{34.15}$$

Appendix 3: NCREIF Timberland Index

The NCREIF Timberland Index has two components, the income return and the capital return. The income return is also known as EBITDDA return, which represents earnings before interest expenses, income taxes, depreciation, depletion, and amortization. The capital return is derived from land appreciation. The formulas to calculate these returns are

$$IR_t = \frac{EBITDDA_t}{MV_{t-1} + 0.5(CI_t - PS_t + PP_\mathrm{t} - EBITDDA_t)} \tag{34.16}$$

$$CR_t = \frac{MV_t - MV_{t-1} - CI_t + PS_t - PP_t}{MV_{t-1} + 0.5(CI_t - PS_t + PP_t - EBITDDA_t)} \tag{34.17}$$

where IR_t and CR_t are the income return and capital return, respectively; $EBITDDA_t$ equals the net operating revenue obtained from the tree farm (primarily from timber sales); CI_t equals the capitalized expenditures on the tree farm (e.g., forest regeneration and road construction); PS_t equals the net proceeds from sales of land from the tree farm; PP_t equals the gross costs of adding land to the tree farm; and MV_t equals the market value of the tree farm (Binkley et al. 2003).

Appendix 5: Steps for the SDF Approach Using Excel Solver

First, choose minimizing the standard deviation of the SDFs as the objective function.

Second, set the mean of the SDFs equal to a predetermined value. This is constraint No.1.

Third, for each basis asset (industry group) in the industry portfolio, add one constraint according to $\frac{1}{T}\sum_{t=1}^{T} M_t\left(1 + R_{i,t}\right) = 1$. That is, add five more constraints when using the five-industry portfolio, whereas add ten more constraints when using the ten-industry portfolio. Fourth, specify the solutions to be nonnegative and solve for the SDFs. Fifth, use the SDFs to price timberland returns according to Eq. 34.9. Repeat steps 1–5 with a different value as the given mean of the SDFs.

Optimal Orthogonal Portfolios with Conditioning Information

35

Wayne E. Ferson and Andrew F. Siegel

Contents

Abstract

Optimal orthogonal portfolios are a central feature of tests of asset pricing models and are important in active portfolio management problems. The portfolios combine with a benchmark portfolio to form ex ante mean variance efficient portfolios. This paper derives and characterizes optimal orthogonal portfolios in the presence of conditioning information in the form of a set of lagged instruments. In this setting, studied by Hansen and Richard (1987), the conditioning information is used to optimize with respect to the unconditional moments. We present an

empirical illustration of the properties of the optimal orthogonal portfolios. From an asset pricing perspective, a standard stock market index is far from efficient when portfolios trade based on lagged interest rates and dividend yields. From an active portfolio management perspective, the example shows that a strong tilt toward bonds improves the efficiency of equity portfolios.

The methodology in this paper includes regression and maximum likelihood parameter estimation, as well as method of moments estimation. We form maximum likelihood estimates of nonlinear functions as the functions evaluated at the maximum likelihood parameter estimates. Our analytical results also provide economic interpretation for test statistics like the Wald test or multivariate F test used in asset pricing research.

35.1 Introduction

The optimal orthogonal portfolio, also known as the most mispriced portfolio or the active portfolio, is a central concept in asset pricing tests and in modern portfolio management. In asset pricing problems, it represents the difference between the performance of a benchmark portfolio and the maximum potential performance in a sample of assets (Jobson and Korkie 1982). In modern portfolio management, it shows how to actively tilt away from a given benchmark portfolio to achieve portfolio efficiency (Gibbons et al. 1989; Grinold and Kahn 1992).

Optimal orthogonal portfolios are studied by Roll (1980), MacKinlay (1995), Campbell et al. (1987), and others. However, these studies restrict the analysis to a setting where the portfolio weights are fixed over time. In contrast, studies in asset pricing use predetermined variables to model conditional expected returns, correlations, and volatility. Portfolio weights may be functions of the predetermined variables, and they will generally vary over time. Quantitative portfolio managers routinely use conditioning information in optimized portfolio strategies. Therefore, it is important to understand optimal orthogonal portfolios in a conditional setting.

This paper derives, characterizes, and illustrates optimal orthogonal portfolios in a conditional setting. The setting is one where the conditional means and variances of returns are time varying and optimal time-varying portfolio weights achieve unconditional mean variance efficiency with respect to the information, as described by Hansen and Richard (1987) and Ferson and Siegel (2001).[1] Ferson

[1]An alternative is to study conditional efficiency, where the weights minimize the conditional variance. This may be handled by simply reinterpreting the classical analysis.

and Siegel (2001) argue that this setting is interesting from the perspective of active portfolio management, where the client cannot observe the information that a portfolio manager may have. Ferson and Siegel (2003, 2009) show that this setting is also interesting from the perspective of testing asset pricing models, but they do not develop the optimal orthogonal portfolio.

We show that the optimal orthogonal portfolio has time-varying weights, and we derive the weights in a closed form. The portfolio weights for unconditionally efficient portfolios in the presence of conditioning information are derived by Ferson and Siegel (2001). They consider the case with no risk-free asset and the case with a fixed risk-free asset whose return is constant over time. We generalize these solutions to the case with a "conditionally" risk-free asset whose return is known at the beginning of the period and is thus included in the lagged conditioning information and may vary over time. We derive solutions for the optimal orthogonal portfolios with conditioning information, including cases where there is no risk-free asset, a constant risk-free rate, or a time-varying conditionally risk-free rate. We show that a "law of conservation of squared Sharpe ratios" holds, implying that the optimal orthogonal portfolio's squared unconditional Sharpe ratio is the difference between that of the benchmark portfolio and the maximum unconditional squared Sharpe ratio that is possible using the assets and conditioning information. Empirical examples illustrate the performance of the optimal orthogonal portfolios with conditioning information and the behavior of the portfolio weights.

Section 35.2 briefly reviews optimal orthogonal portfolios in the classical case with no conditioning information. Section 35.3 describes the setting for our analysis with conditioning information. Section 35.4 presents the main theoretical results, and Sect. 35.5 presents our empirical examples. Section 35.6 concludes. Appendix 1 includes the proofs of the main results, and Appendix 2 describes the methodology of our empirical examples in detail, including a general description of the parametric bootstrap.

35.2 Optimal Orthogonal Portfolios: The Classical Case

In the classical case, portfolio weights are fixed constants over time, and there is no conditioning information. Optimal orthogonal portfolios are tied to mean variance efficiency. Mean variance efficient portfolios maximize the expected return, given the variance of the return. Since Markowitz (1952) and Sharpe (1964), such portfolios have been at the core of financial economics.

The mean variance efficiency of a given portfolio can be described using a system of time-series regressions. If $r_t = R_t - \gamma_0$ is the vector of N *excess* returns at time t, measured in excess of a given risk-free or zero-beta return, γ_0, and $r_{pt} = R_{pt} - \gamma_0$ is the excess return on a benchmark portfolio, the regression system is

$$r_t = \alpha + \beta r_{pt} + u_t; \quad t = 1, \ldots, T, \tag{35.1}$$

where T is the number of time-series observations, β is the N-vector of regression slopes or betas, and α is the N-vector of intercepts or alphas. The tested portfolio r_{pt} is represented among the returns in r_t, so the covariance matrix of the residuals in Eq. 35.1 is singular (r_{pt} might be included explicitly or might be a fixed-weight portfolio of the assets in r_t). The portfolio r_p is minimum-variance efficient and has the given zero-beta return only if $\alpha = 0$.[2] The mean variance efficiency of a given portfolio is of normative investment interest, as an efficient portfolio maximizes a concave utility function defined solely over the mean and variance of the portfolio return, as would follow from normally distributed returns in a single-period model, for example. Equation 35.1 may be interpreted as referring to multiple factor portfolios, where r_p is a K-vector and β is an $N \times K$ matrix. Then, the benchmark portfolio is a linear combination of the K returns in the vector r_p (e.g., Shanken 1987; Gibbons et al. 1989).

Definition The *most mispriced (or optimal orthogonal) portfolio with respect to* r_p, *when there is no conditioning information, has excess return* $r_c = x'_c r$, *where the weights* x_c *satisfy.*

$$x_c = \underset{x}{\text{Arg Max}} \frac{(x'\alpha)^2}{\text{Var}(x'r)}. \tag{35.2}$$

It is clear from the definition in Eq. 35.2 why the portfolio is referred to as the most mispriced. The vector α captures the "mispricing" of the tested asset returns in Eq. 35.1 when evaluated using the benchmark r_p, and the portfolio x_c has the largest squared alpha relative to its variance. This interpretation also reveals why the portfolio is of central interest in active portfolio management. Given a benchmark portfolio r_p, an active portfolio manager places bets by deviating from the portfolio weights that define the benchmark. The manager is rewarded for bets that deliver higher returns and penalized for increasing the volatility. The portfolio in (2) describes the active bets that achieve the largest amount of extra return for the variance. Thus, the solution is also referred to as the *active* portfolio by Gibbons et al. (1989). (See Grinold and Kahn (1992) for an in-depth treatment of modern portfolio management.)

In the classical case of fixed portfolio weights, the solution to Eq. 35.2 is given by $x_c = \left(\underline{1}'V^{-1}\alpha\right)^{-1}V^{-1}\alpha$, where $\underline{1}$ is an N-vector of ones and $V = \text{Cov}(r)$, the covariance matrix of the returns. Using this solution, several well-known properties

[2]Note the distinction between *minimum variance efficient* portfolios, which minimize the variance for the given mean return, and *mean variance efficient*, which maximize the mean return given its variance. The latter set of portfolios is a subset of the former, typically depicted as the positively sloped portion of the minimum variance efficient boundary when graphed with mean return on the y-axis and standard deviation or variance of return on the x-axis. The portfolio r_p is mean variance efficient when $\alpha = 0$ and $\text{E}(r_p)$ exceeds the expected excess return of the global minimum variance portfolio.

of the optimal orthogonal portfolio follow.[3] For example, a combination of the portfolio r_c and the benchmark portfolio r_p is *optimal*, that is, minimum-variance efficient (Jobson and Korkie 1982). The portfolio is *orthogonal* to the benchmark portfolio in the sense that $\mathrm{Cov}(x_c' r, r_p) = 0$.

The optimal orthogonal portfolio is central for the interpretation of tests of portfolio efficiency. Classical test statistics for the hypothesis that $\alpha = 0$ in Eq. 35.1 can be written in terms of squared Sharpe ratios (e.g., Jobson and Korkie 1982). Consider the Wald statistic:

$$W = T\hat{\alpha}'[\mathrm{Cov}(\hat{\alpha})]^{-1}\hat{\alpha} = T\left(\frac{\hat{S}^2(R) - \hat{S}^2(R_p)}{1 + \hat{S}^2(R_p)}\right) \dot{\sim} \chi^2(N) \tag{35.3}$$

where $\hat{\alpha}$ is the OLS or maximum likelihood (ML) estimator of α (after removing r_p or another asset from the vector r to avoid singularity of the covariance matrix) and $\mathrm{Cov}(\hat{\alpha})$ is its asymptotic covariance matrix. Upper case R's refer to gross returns, and lower case r's refer to returns in excess of the zero-beta rate. The term $\hat{S}^2(R_p)$ is the sample value of the squared Sharpe ratio of R_p when the zero-beta rate is γ_0 so that $S^2(R_p) = [E(r_p)/\sigma(r_p)]^2$. The term $\hat{S}^2(R)$ is the sample value of the maximum squared Sharpe ratio that can be obtained by portfolios of the assets in R (including R_p):

$$S^2(R) = \max_x \left\{ \frac{[E(x'r)]^2}{\mathrm{Var}(x'r)} \right\}. \tag{35.4}$$

The Wald statistic has an asymptotic chi-squared distribution with N degrees of freedom, under the null hypothesis that R_p is efficient with the given zero-beta return. Scaled with a degrees of freedom adjustment, the statistic has an F distribution under normally distributed returns (Gibbons et al. 1989).

It can be shown that the squared Sharpe ratios can be decomposed using the optimal orthogonal portfolio as $S^2(R) = S^2(R_p) + S^2(R_c)$. A similar decomposition holds at the sample values. This decomposition, a "law of conservation of squared Sharpe ratios," is used by Jobson and Korkie (1982) to derive the second equality in (35.3). Since the Sharpe ratio is the slope of a line in the mean-standard deviation space, Eq. 35.3 suggests a graphical representation for the statistic in the sample mean-standard deviation space. It measures the distance between the sample mean-standard deviation frontier and the location of the tested portfolio, inside the frontier. This distance is proportional to the squared Sharpe ratio of the optimal orthogonal portfolio. Kandel (1984), Roll (1985), Gibbons et al. (1989), and Kandel and Stambaugh (1987, 1989) further develop this interpretation.

[3]See Roll (1980), Gibbons et al. (1989), MacKinlay (1995), and Campbell et al. (1987) for analyses of optimal orthogonal portfolios in the classical case with no conditioning information.

35.3 The Conditional Setting

We use conditioning information in a setting similar to that of Hansen and Richard (1987) and Ferson and Siegel (2001), where minimum-variance efficiency is defined in terms of the unconditional means and variances of the portfolios that result from the use of conditioning information. Ferson and Siegel (2009) refer to this as efficiency *with respect to the information*, Z. This setting has proven useful in asset pricing tests (Ferson and Siegel 2003, 2009; Bekaert and Liu 2004), in forming hedging portfolios (Ferson et al. 2006), and in portfolio management problems (Ahkbar et al. 2007; Chiang 2012). We study the optimal orthogonal portfolio in this setting. The distinction between mean variance efficiency and minimum-variance efficiency, as in the classical setting, applies in this setting as well.

Consider a portfolio of N assets with gross returns, R_{t+1}, where the weights that determine the portfolio at time t are functions of the information, Z_t. The gross return on such a portfolio with weight $x(Z_t)$ is $x'(Z_t)R_{t+1}$. The restrictions on the portfolio weight function are that the weights must sum to 1 (almost surely in Z_t), and that the unconditional expected value and second moments of the portfolio return are well defined. Consider now all portfolio returns that may be formed, for a given set of asset returns R_{t+1} and given conditioning information, Z_t, with well-defined first and second moments. This set determines a mean-standard deviation frontier, as shown by Hansen and Richard (1987). This frontier depicts the *unconditional* means versus the *unconditional* standard deviations of the portfolio returns. A portfolio is defined to be efficient with respect to the information Z_t if and only if it is on this mean-standard deviation frontier.

Ferson and Siegel (2001) derive solutions for efficient-with-respect-to-Z portfolios in closed form. They consider the case with no risk-free asset and the case with a fixed risk-free asset whose return is constant over time. In Theorem 1 of Appendix 1, we derive the solution for the case with a risk-free asset whose return is known at the beginning of the period and is thus included in the information Z and may vary over time. In this case the variation in the risk-free rate over time affects the unconditional variance of the portfolio return.

Ferson and Siegel (2001) argue that efficiency with respect to the information is especially relevant in a portfolio management context. It is reasonable to assume that the portfolio manager has more information about asset returns than the client. Assume that the client desires an unconditionally mean-variance efficient portfolio. The manager observes conditioning information that is relevant about future returns, and by conditioning on this information, he or she can expand the investor's opportunity set. The manager maximizes the investor's mean variance opportunity set by using his information to maximize the unconditional mean for a given unconditional variance. The efficient-with-respect-to-Z strategy is therefore the strategy that the investor would wish the portfolio manager to use.

Ferson and Siegel (2009) show how asset pricing theories make statements about portfolios that are efficient with respect to information Z and develop tests of the hypothesis that a portfolio is efficient with respect to Z. The optimal orthogonal portfolio with respect to information Z is a useful concept in these portfolio efficiency tests. We begin the analysis with a result from Hansen and Richard (1987).

Proposition 1 (Hansen and Richard 1987, Corollary 3.1.) Given N asset gross returns, R_{t+1}, a given portfolio with gross return $R_{p,t+1}$ is *minimum-variance efficient with respect to the information* Z_t if and only if Eq. 35.5 is satisfied (equivalently, there exists constants γ_0 and γ_1 such that Eq. 35.6 is satisfied) for all $x(Z_t)$ such that $x'(Z_t)\underline{1} = 1$ almost surely, where the relevant unconditional expectations exist and are finite:

$$\mathrm{Var}\left(R_{p,t+1}\right) \le \mathrm{Var}\left[x'(Z_t)R_{t+1}\right] \text{ if } E\left(R_{p,t+1}\right) = E\left[x'(Z_t)R_{t+1}\right] \tag{35.5}$$

$$E\left[x'(Z_t)R_{t+1}\right] = \gamma_0 + \gamma_1 \,\mathrm{Cov}\left[x'(Z_t)R_{t+1}, R_{p,t+1}\right]. \tag{35.6}$$

Equation 35.5 is the *definition* of efficiency with respect to Z. It states that $R_{p,\,t+1}$ is on the minimum-variance boundary formed by all possible portfolios that use the assets in R and the conditioning information. Equation 35.6 states that the familiar expected return-covariance relation from Fama (1973) and Roll (1977) must hold with respect to the efficient portfolio. In Eq. 35.6, the coefficients γ_0 and γ_1 are fixed scalars that do not depend on the functions $x(\cdot)$ or the realizations of Z_t.

35.4 The Main Results

The optimal orthogonal portfolio with conditioning information plays roles analogous to the classical setting with no conditioning information. Thus, for example, restricting the maximization in Eq. 35.4 to *fixed-weight* portfolios where x is a constant vector, we obtain efficiency in the classical case. In contrast, an efficient portfolio with respect to the information Z maximizes the squared Sharpe ratio over *all portfolio weight functions*, $x(Z)$. Maximizing over a larger set of weights expands the investment opportunity set and produces a larger maximum Sharpe ratio.

With conditioning information, the optimal orthogonal portfolio's weight function is time varying, and we derive this portfolio weight for three cases. First, with no risk-free asset in which case a fixed unconditional "zero-beta" rate γ_0 is arbitrarily chosen. By varying the zero-beta rate, the solutions can describe any point on the efficient-with-respect-to-Z frontier. Second, we consider a conditionally time-varying risk-free asset whose return $R_f = R_f(Z)$ is measureable and thus known as part of the information set Z so that $\mathrm{Var}[R_f(Z)|Z] = 0$, but which is unconditionally risky in the sense that $\mathrm{Var}[R_f(Z)] > 0$. Here, we again choose an arbitrary zero-beta rate γ_0 to describe the frontier. In the third case, there exists an unconditional risk-free asset with fixed return $R_f = \gamma_0$. In this case, the efficient-with-respect-to-Z frontier becomes a line passing through γ_0 (at risk zero) and the point representing the mean and standard deviation of a particular portfolio strategy's return.

We consider portfolios formed from the risky assets using weights $x_q = x_q(Z)$ where the weights must sum to 1 (for all Z) when there is no risk-free asset. This constraint is relaxed when there is a conditional or unconditional risk-free asset (where the implicit weight in the risk-free asset is then set at 1 minus the sum of the weights in the risky assets). When there is no risk-free asset, the portfolio return is $R_{q,t+1} = x_q'(Z_t)R_{t+1}$, and when there is a risk-free asset, the portfolio return is $R_{q,t+1} = R_f(Z_t) + x_q'(Z_t)\left[R_{t+1} - R_f(Z_t)\underline{1}\right]$ whether or not $R_f(Z)$ is constant. In either case, we denote the (unconditional) portfolio mean $\mu_q = E(R_q)$ and variance $\sigma_q^2 = \mathrm{Var}(R_q)$. When there exists a conditional time-varying risk-free asset, the portfolio takes advantage of the ability to adapt both the percentage invested in risky assets and their portfolio weights in response to the information Z. This may be interpreted as "market timing" and security selection, respectively. We define the optimal orthogonal portfolio with respect to a given benchmark portfolio P formed from the risky assets using (possibly) time-varying weights $x_p = x_p(Z)$.

Definition The *most mispriced (or optimal orthogonal) portfolio, R_c, with respect to the benchmark portfolio R_p and conditioning information Z*, with portfolio weight denoted $x_c(Z)$, uses the conditioning information to maximize α_c^2/σ_c^2 where the unconditional variance of R_c is σ_c^2, the unconditional mean is $\mu_c = E(R_c)$, the unconditional alpha of R_c with respect to R_p is $\alpha_c = \mu_c - [\gamma_0 + (\mu_p - \gamma_0)\sigma_{cp}/\sigma_p^2]$, the zero-beta rate is γ_0, and the unconditional covariance is $\sigma_{cp} = \mathrm{Cov}(R_c, R_p)$.

Proposition 2 The unique most mispriced (or optimal orthogonal) portfolio R_c with respect to a given benchmark portfolio R_p (with weights x_p and expected return μ_p), conditioning information Z and given zero-beta rate, γ_0, has the following portfolio weight in each of the following cases. If there is no risk-free rate, then the weights conditionally sum to 1 as defined by

$$x_c(Z) = A\left\{\frac{\Lambda\underline{1}}{\underline{1}'\Lambda\underline{1}} + [(c+1)\mu_s + b]\left(\Lambda - \frac{\Lambda\underline{1}\,\underline{1}'\Lambda}{\underline{1}'\Lambda\underline{1}}\right)\mu(Z)\right\} + Bx_p, \tag{35.7}$$

$R_f(Z)$ (which may be either constant or time varying, but if constant,[4] then we must choose $\gamma_0 = R_f$ along with any $\mu_s \neq R_f$), then the solution is

$$x_c(Z) = A\left[(c+1)\mu_s + b - R_f\right]Q\left[\mu(Z) - R_f\underline{1}\right] + Bx_p, \tag{35.8}$$

where

$$A = \frac{(\mu_s - \gamma_0)/\sigma_s^2}{(\mu_s - \gamma_0)/\sigma_s^2 - (\mu_p - \gamma_0)/\sigma_p^2}, \tag{35.9}$$

[4]Equation 35.11 cannot be used to determine μ_s when $R_f(Z)$ is almost surely constant due to division by zero, and, in this case, every choice $\mu_s \neq R_f$ uses the same (rescaled) portfolio of risky assets $Q\left[\mu(Z) - R_f\underline{1}\right]$ in the formation of an efficient portfolio $x_s(Z)$.

$$B = -\frac{(\mu_p - \gamma_0)/\sigma_p^2}{(\mu_s - \gamma_0)/\sigma_s^2 - (\mu_p - \gamma_0)/\sigma_p^2}, \tag{35.10}$$

$$\mu_s = -(a + b\gamma_0)/(b + c\gamma_0), \tag{35.11}$$

$$\sigma_s^2 = a + 2b\mu_s + c\mu_s^2, \tag{35.12}$$

$$\begin{aligned} Q = Q(Z) &\equiv \left\{ E\left[\left(R - R_f\underline{1}\right)\left(R - R_f\underline{1}\right)' \middle| Z \right] \right\}^{-1} \\ &= \left\{ \left[\mu(Z) - R_f\underline{1}\right]\left[\mu(Z) - R_f\underline{1}\right]' + \Sigma_\varepsilon(Z) \right\}^{-1}, \end{aligned} \tag{35.13}$$

$$\Lambda = \Lambda(Z) \equiv \left\{ E\left[RR' \middle| Z \right] \right\}^{-1} = \left[\mu(Z)\mu'(Z) + \Sigma_\varepsilon(Z) \right]^{-1}. \tag{35.14}$$

The constants a, b, and c are defined in Appendix 1 in Theorem 1 (when there exists a risk-free rate) and in Theorem 2 (when there is no risk-free rate).

Proof: See Appendix 1.

The term μ_s represents the unconditional expected return of the efficient-with-respect-to-Z portfolio, R_s, that maximizes the squared unconditional Sharpe ratio in Eq. 35.4 over all portfolio weight functions with respect to the given value of γ_0. When there exists a risk-free rate $R_f(Z)$ (that may be time varying because its value is included in the information set Z at the beginning of the period), the conditional mean variance boundary, the tangency intercept $R_f(Z)$, and thus the location of the conditionally mean variance efficient portfolio may vary over time as $R_f(Z)$ varies. When there is no risk-free rate, or when the risk-free rate is time varying, we use the parameter γ_0 to determine a fixed location on the (curved) unconditionally efficient-with-respect-to-Z boundary; however, when there is a fixed risk-free rate, this boundary is a degenerate hyperbola, and every portfolio on the upper line is efficient. We next show that the optimal orthogonal portfolio R_c can be formed by combining the benchmark portfolio R_p with the efficient-with-respect-to-Z portfolio R_s, and from this result, it then follows that R_p and R_c can be combined to produce the efficient-with-respect-to-Z portfolio R_s.

Proposition 3 The most mispriced or optimal orthogonal portfolio R_c may be found as a fixed linear combination of the benchmark portfolio R_p and the efficient-with-respect-to-Z portfolio, R_s (that maximizes the squared Sharpe ratio for the given zero-beta rate, γ_0), as follows:

$$R_c = \frac{\left[(\mu_s - \gamma_0)/\sigma_s^2\right]R_s - \left[\left(\mu_p - \gamma_0\right)/\sigma_p^2\right]R_p}{\left[(\mu_s - \gamma_0)/\sigma_s^2\right] - \left[\left(\mu_p - \gamma_0\right)/\sigma_p^2\right]} \tag{35.15}$$

Or

$$R_c = \frac{\sigma_p^2 R_s - \sigma_{ps} R_p}{\sigma_p^2 - \sigma_{ps}} = AR_s + BR_p \text{ with } A + B = 1, \tag{35.16}$$

where we assume that R_s and R_p are not perfectly correlated and that $\sigma_p^2 \neq \sigma_{sp}$.

Proof: See Appendix 1.

Propositions 2 and 3 extend the concept of the active or optimal orthogonal portfolio to the setting of efficiency with respect to conditioning information. Given a benchmark portfolio R_p, its optimal orthogonal portfolio with respect to Z shows how to tilt away from the benchmark weights to obtain efficiency with respect to Z. The portfolio R_c has weights that depend on Z. Thus, the optimal tilt away from a benchmark uses the manager's information Z in a dynamic way.

Equation 35.16 shows how the optimal orthogonal portfolio R_c can be formed by combining an efficient-with-respect-to-Z portfolio R_s with R_p. The portfolio R_c is the regression error of R_s projected on R_p, normalized so that the weights sum to 1, as can be seen by solving Eq. 35.16 for R_s. Thus, the portfolio R_c is uncorrelated with R_p.

We defined the most mispriced portfolio with conditioning information as maximizing the squared alpha relative to the unconditional variance of R_c. Since R_c is orthogonal to R_p, its residual variance in regression (Eq. 35.1) is the same as its total variance. Thus, we can think of the optimal orthogonal portfolio as maximizing alpha given its residual variance among all orthogonal portfolios.

Given a benchmark portfolio with return R_p, the optimal orthogonal portfolio with conditioning information is useful for active portfolio management. It might seem natural for a manager with information Z to simply reinterpret the classical analysis, where all the moments are the conditional moments given Z. This, in fact, is the interpretation that much of the literature on active portfolio management has used (e.g., Jorion 2003; Roll 1982). This approach produces *conditionally* mean variance efficient portfolios given Z. However, as shown by Dybvig and Ross (1985), a conditionally efficient portfolio is likely to be seen as inefficient from the (unconditional) perspective of a client without access to the information Z. The optimal orthogonal portfolio describes the active portfolio bets that deliver optimal performance from the client's perspective.

Let $S^2(R)$ be the maximum squared Sharpe ratio obtained by the efficient-with-respect-to-Z portfolio and let R_c be the optimal orthogonal portfolio with respect to R_p and information Z.

Proposition 4 *Law of conservation of squared Sharpe ratios*. For a given zero-beta or risk-free rate, if $S_s^2 = S^2(R)$ is the maximum squared Sharpe ratio obtained by portfolios $x(Z)$ and R_c is the optimal orthogonal portfolio with respect to R_p and information Z at that zero-beta rate, then $S_s^2 = S_p^2 + S_c^2$, where S_i^2 denotes the squared Sharpe ratio of portfolio i.

Proof: See Appendix 1.

Proposition 4 shows that if we test the hypothesis that a portfolio is efficient with respect to Z using versions of the test statistic in Eq. 35.3, as developed in Ferson and Siegel (2009), then the role of the optimal orthogonal portfolio with information Z is analogous to the role of the optimal orthogonal portfolio in the case of the classical test statistics. The Sharpe ratio of the optimal orthogonal portfolio with conditioning information indicates how far the tested benchmark portfolio is from the efficient-with-respect-to-Z frontier. The squared Sharpe ratio of the optimal orthogonal portfolio is the numerator of the test statistic. This numerator and thus the test statistic is zero only if the tested portfolio is efficient in the sample, and it grows larger as the tested portfolio is further from efficiency.

35.5 Empirical Examples

We present empirical examples using data on portfolios of common stocks, where the firms are grouped according to conventional criteria. We use the returns of common stocks sorted according to market capitalization and book-to-market ratios, focusing on value-weighted decile portfolios of small capitalization stocks, value stocks (high book/market), and growth stocks (low book/market), as provided on Ken French's website. We also include a long-term government bond return, splicing the Ibbotson Associates 20-year US government bond return series for 1931–1971, with the CRSP greater than 120 month US government bond return after 1971. The market portfolio, measured as the CRSP value-weighted stock return index, is the benchmark or tested portfolio, R_p. The risk-free return is the return from rolling over 1-month Treasury bills from CRSP. We use its sample average, 3.8 % per year, as the fixed zero-beta rate in all of the examples. As conditioning information in Z, its return is lagged by 1 year. All of the returns are discretely compounded annual returns, and the sample period is 1931–2007.

The lagged instruments, Z, are the lagged Treasury return and the log of the market price/dividend ratio at the end of the previous year. In calculating the price/dividend ratio, the stock price is the real price of the S & P 500 Index, and the dividend is the real dividends accruing to the index over the past year. These data are from Robert Shiller's website.

We treat the risk-free asset in three distinctly different ways to highlight the three different versions of our solutions for the optimal orthogonal portfolios. In the first case, the risk-free rate is assumed to be a fixed constant. Here, we do not include the Treasury return as a lagged instrument, and we set $\gamma_0 = 3.8$ % to be the average Treasury return during the sample. The target mean μ_s of the efficient-with-respect-to-Z portfolio is set equal to the sample mean return of the market index in this case, which determines the amount of leverage the portfolio uses at the fixed risk-free rate.

In the second case, no risk-free asset exists. Here, we again set $\gamma_0 = 3.8\ \%$ to pick a point on the mean variance boundary, and we do not allow the portfolio to take a position in a risk-free asset. We do allow the lagged Treasury return as conditioning information in Z, which highlights the information in lagged Treasury returns about the future risky asset returns. In the third case, there is a conditionally risk-free return that is contained in Z. Here, we use the lagged Treasury return in the conditioning information, and we allow the portfolio to trade the subsequent Treasury return in addition to the other risky assets. The subsequent Treasury return is not really known *ex ante* as the formula assumes, but its correlation with the lagged return is 0.92 during our sample, and this allows us to implement the time-varying risk-free rate example in a somewhat realistic way. (In reality, there is no *ex ante* risk-free asset given the importance of inflation risk.) In practical terms, this example highlights the effects of "market timing," or varying the amount of "cash" in the portfolio, in addition to varying the allocation among the risky assets.

Table 35.1 summarizes the results. The rows show results for the benchmark index (Market), three equity portfolios, and the government bond return. The CAPM α refers to the intercept in the regression (1), of the portfolio returns in excess of the Treasury bill returns, on the excess return of the market index. The small stock portfolio has the largest alpha, at 3.95 % per year, while the growth stock portfolio has a negative alpha. The symbol σ_u refers to the standard deviation of the regression residuals. The small stock portfolio has the largest σ_u or nonmarket risk, at more than 25 % per year.

The bottom four rows of Panel A summarize the optimal orthogonal portfolios when the market index is the benchmark. The fixed-weight portfolio R_c uses no conditioning information. Its alpha is larger than any of the separate assets, at 4.66 % per year, and its residual standard deviation is also relatively large, at 16.5 % per year. Since the portfolio is orthogonal to the market index, its residual standard deviation is the same as its total standard deviation, or volatility of return. The ratio of the alpha to the residual volatility is known as the appraisal ratio (Treynor and Black 1973) or the information ratio (Grinold and Kahn 1992). Optimal orthogonal portfolios try to maximize the square of this ratio. The fixed-weight portfolio R_c delivers an information ratio of 0.282, substantially larger than those of the small stock or value portfolios, at 0.155 and 0.177, respectively, and also larger than the bond portfolio, which has an information ratio of 0.183 by virtue of its relatively small volatility.

Table 35.1 summarizes performance statistics for the optimal orthogonal portfolios with conditioning information. There are three versions with (1) a fixed risk-free rate, (2) no risk-free rate, and (3) a time-varying conditional risk-free rate. The information ratios in all three cases are larger than those of the individual assets or the fixed-weight active portfolio, which illustrates the potential value of using conditioning information explicitly in a portfolio management context (see also, Chiang 2009). The improvement over fixed weights is modest for the case with no risk-free asset. However, the information ratio is about three times as large, at 0.955, in the example with a time-varying risk-free rate. This illustrates the

Table 35.1 Optimal orthogonal portfolios

Panel A: summary statistics

					Average active portfolio weights Avg $[X_c(Z)]$		
Asset	CAPM α	σ_u	Information Ratio	Fixed R_c	Fixed R_f	No R_f	Varying R_f
Market index	0	0	0.000	−1.260	0.179	−0.210	0.308
Small stocks	3.95	25.5	0.155	0.353	−0.262	0.133	0.097
Value stocks	3.14	17.8	0.177	0.345	0.137	0.079	0.142

Varying R_f	0.182	0.909	1.191

Annual returns on portfolios of common stocks and long-term US government bonds cover the 1931–2007 period. The CAPM α refers to the intercept in the regression Eq. 35.1, of the portfolio return in excess of a zero-beta parameter, on that of the broad value-weighted stock market index (market index). The symbol σ_u refers to the standard deviation of the regression residuals. The fixed portfolio, R_c, ignores the conditioning information. The alphas and residual standard deviations are annual percentage units. The information ratio is the ratio $\alpha/\ \sigma_u$

potential usefulness of interest rate information and the ability to hold "cash" as a function of market conditions, in a portfolio management context.

The averages over time of the optimal orthogonal portfolios' weights on the risky assets are shown in the right-hand columns of Panel A. The weights are normalized to sum to 1.0. The weights x_c of the optimal orthogonal portfolios combine with the benchmark (whose weights, x_p, are 100 % in the market index) to determine an efficient portfolio. The overall efficient portfolio weights x_s therefore vary over time and depend on how x_c and x_p are combined, which is determined by the coefficients A and B in Eqs. 35.9 and 35.10. The estimated weights are as follows. In the fixed risk-free rate case, $x_s = 0.60\,x_c + 0.40\,x_p$. In the no risk-free rate case, $x_s = 0.23\ x_c + 0.77\ x_p$. In the time-varying risk-free rate case, $x_s = 0.44\ x_c + 0.56\ x_p$. Thus, the efficient portfolio is formed as a convex combination of the benchmark and the active portfolio, with reasonable weights in each case.

The four right-hand columns of Panel A show that two of the active portfolios take short positions in the market benchmark, indicating an optimal tilt away from the market index. The fixed-weight portfolio R_c takes an extreme short position of -126 %, while on average the portfolio using the conditioning information but no risk-free asset takes a position of -21 % in the market index. These short positions finance large long positions in the US government bond and also long positions (in most cases) in small stocks, value stocks, and growth stocks. It is interesting that all the portfolios tilt positively, although by small amounts, into growth stocks even though growth stocks have negative CAPM alphas. This occurs because of the correlations among the asset classes.

All the versions of the optimal orthogonal portfolio suggest strong tilts into government bonds. The bond tilt is the most extreme for the fixed-weight solution, at 141 %, and is relatively modest, at 43.2 %, for the portfolio assuming a time-varying conditional risk-free rate. This makes sense, as that portfolio can hold short-term Treasuries in addition to government bonds. The large weights in bonds reflect various features of the data and the value of the zero-beta rate. With larger values for the zero-beta rate, provided that the rate remains below the mean of the global minimum-variance portfolio of risky assets, the optimal orthogonal portfolios become more aggressive as the target expected return of the efficient-with-respect-to-Z portfolio increases.

The squared Sharpe ratios in Panel B of Table 35.1 indicate how far the stock market index is from efficiency. The squared Sharpe ratio for the market is 0.189, measured relative to the fixed zero-beta rate of 3.8 %. The market portfolio's squared Sharpe ratio is slightly smaller, at 0.182, for returns measured in excess of a time-varying risk-free rate. This is because the negative covariance between the risk-free rate and stock returns increases the variance of the excess return. For the fixed-weight orthogonal portfolio R_c, the squared Sharpe ratio is 0.079, and for the portfolios using conditioning information, it varies between 0.088 and 0.909.

According to the *law of conservation of squared Sharpe ratios* in Proposition 4, the sum of the index and optimal orthogonal portfolios' squared Sharpe ratios is the squared slope of the tangency from the given zero-beta rate to the relevant

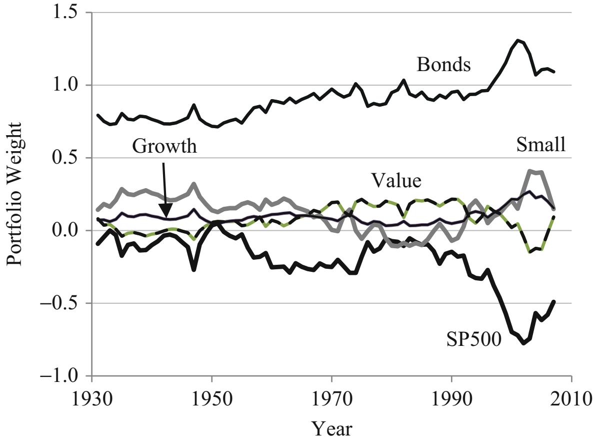

Fig. 35.1 Optimal orthogonal portfolio weights: the no risk-free rate case

mean variance frontier. The sum is 0.267 when no conditioning information is used and is 0.304–1.091 when the information is used. With a fixed risk-free rate, we condition only on the lagged dividend yield, which is a relatively weak predictor for stock returns (see Ferson et al. 2003). However, in the case with no risk-free rate, the portfolio is not allowed to hold short-term Treasuries, which substantially weakens the performance. In the time-varying risk-free rate case, the portfolio strategy is allowed to "market time" by holding short-term Treasuries. In the other two cases, we use the information in the lagged Treasury rate, which is a relatively strong predictor, and the efficient-with-respect-to-Z boundary is far above the mean variance boundary that ignores the conditioning information. (Ferson and Siegel 2009, present an analysis of the statistical significance of differences like these.)

Table 35.1 suggests that the portfolio weights of the fixed-weight R_c portfolio are extreme and would not be realistic in practical portfolio management settings. This reflects well-known issues with mean classical variance optimal solutions in practice (e.g., Michaud 1989; Siegel and Woodgate 2007). To obtain practical portfolio weights in the classical mean variance problem, it is generally necessary to constrain the weights (e.g., Frost and Savarino 1988) or shrink them toward a benchmark e.g., Jorion (2003) or Jagannathan and Ma (2003). In this context, note that the optimal orthogonal portfolios using Z take less extreme positions on average than the fixed-weight solution, yet still are able to generate larger information ratios.

Figures 35.1 and 35.2 present time-series plots of the weights for the optimal orthogonal portfolios using Z. Like the fixed-weight R_c case, the weights in the case with a fixed risk-free rate assumption appear too volatile and noisy to be of practical interest, likely reflecting the poor predictive ability based solely on the dividend yield. We do not plot them here to save space. The weights in the other two examples are shown in Figs. 35.1 and 35.2. They generally vary relatively smoothly over time, suggesting that they would not involve prohibitive trading costs in practice.

Figure 35.1 depicts the weights for the optimal orthogonal portfolio in the case with no risk-free asset. The market index weights are negative through much of the

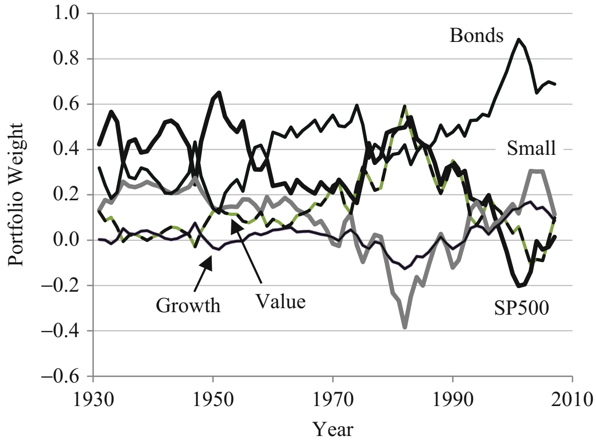

Fig. 35.2 Optimal orthogonal portfolio weights: the time-varying risk-free rate case

sample and near −25 %, indicating that the overall efficient-with-respect-to-Z portfolio keeps about 71 % of its money in the market index for much of the sample, computed as (0.23)(−0.25) + 0.77 using the estimated weights for the no risk-free rate case, $x_s = 0.23\ x_c + 0.77\ x_p$, as reported earlier. Starting in the mid-1990s, the market weights decrease to around −50 % for the optimal orthogonal portfolio weight and 66 % for the overall efficient-with-respect-to-Z portfolio. The weight of this optimal orthogonal portfolio in small stocks is positive for much of the sample, but turns slightly negative in the early 1970s, then positive again in the early 1990s. The strategy shorts value stocks in the 1930s and 1940s, but holds positive positions through most of the rest of the sample. The government bond gets the largest weight, starting near 80 % and growing sharply in the 1990s to near 100 % in the latter parts of the sample.

Figure 35.2 depicts the weights for the optimal orthogonal portfolio in the case with a time-varying, conditional risk-free rate. This strategy keeps positive weights in the market index until 1999, then it holds small short positions for most of the rest of the sample. The weight in small stocks is positive for much of the sample, turning slightly negative in the early 1970s and then positive again in the early 1990s. The strategy holds value stocks long until the early 2000s and shorts growth stocks during much of the 1980s. The government bond again gets the largest weight, starting at 32 % and growing to almost 70 % at the end of the sample.

35.6 Conclusions

This chapter derives, characterizes, and illustrates optimal orthogonal portfolios in the presence of conditioning information in the form of a set of lagged instruments. Optimal orthogonal portfolios combine with a benchmark portfolio to form mean variance efficient portfolios. We generalize previously published solutions for optimal orthogonal portfolios with information to include the case of a time-varying, but conditionally known, risk-free asset return.

In a portfolio management context, it is reasonable to assume that the portfolio manager has more information about asset returns than the client. The manager observes information about future returns and, by conditioning on this information, can expand the investor's opportunity set. Starting from a given benchmark portfolio, the optimal orthogonal portfolio with conditioning information describes the active portfolio bets that, when combined with the benchmark, deliver mean variance optimal performance from the uninformed client's perspective.

We present empirical examples using a broad stock market index as the benchmark and portfolios featuring small capitalization, value and growth stocks, and a long-term US government bond return. We examine three versions of the optimal orthogonal portfolio with (1) a fixed risk-free rate, (2) no risk-free rate, and (3) a time-varying conditional risk-free rate. The optimal orthogonal portfolios with conditioning information have larger information ratios than the orthogonal portfolio that does not use the conditioning information. At the same time, they take less extreme positions than the fixed-weight solution.

From an asset pricing perspective, a standard stock market index is far from efficient when portfolios trade based on lagged interest rates and dividend yields. From an active portfolio management perspective, the example shows that a strong tilt toward bonds improves the efficiency of equity portfolios. Our results should be useful in future asset pricing and portfolio management applications.

Appendix 1: Theorems and Proofs

Efficient Portfolio Solutions

Portfolio weights for efficient portfolios in the presence of conditioning information are derived by Ferson and Siegel (2001). They consider the case with no risk-free asset and the case with a fixed risk-free asset whose return is constant over time. In Theorem 1, we generalize to consider the case with a risk-free asset whose return is known at the beginning of the period, and thus is included in the information Z, and may vary over time. We then, in Theorem 2, reproduce the case with no risk-free asset from Ferson and Siegel (2001) for future reference.

Consider N risky assets with returns R. In $N \times 1$ column vector notation, we have

$$R = \mu(Z) + \varepsilon.$$

The noise term ε is assumed to have conditional mean zero given Z and nonsingular conditional covariance matrix $\Sigma_\varepsilon(Z)$. The conditional expected return vector is $\mu(Z) = E(R|Z)$. Let the $1 \times N$ row vector $x'(Z) = (x_1(Z), \ldots, x_N(Z))$ denote the portfolio share invested in each of the N risky assets, investing (or borrowing) at the risk-free rate the amount $1 - x'(Z)\underline{1}$, where $\underline{1} \equiv (1, \ldots, 1)'$ denotes the column vector of ones. We allow for a conditional risk-free asset returning $R_f = R_f(Z)$.

The return on the portfolio is $R_s = R_f + x'(Z)\left(R - R_f\underline{1}\right)$, with unconditional expectation and variance as follows:

$$\mu_s = E\left(R_f\right) + E\left\{x'(Z)\left[\mu(Z) - R_f\underline{1}\right]\right\},$$
$$\sigma_s^2 = E\left(R_s^2\right) - \mu_s^2 = E\left[E\left(R_s^2|Z\right)\right] - \mu_s^2,$$
$$\sigma_s^2 = E\left(R_f^2\right) + E\left[x'(Z)Q^{-1}x(Z)\right] + 2E\left\{R_f x'(Z)\left[\mu(Z) - R_f\underline{1}\right]\right\} - \mu_s^2, \tag{35.17}$$

where we have defined the $N \times N$ matrix

$$Q = Q(Z) \equiv \left\{E\left[\left(R - R_f\underline{1}\right)\left(R - R_f\underline{1}\right)'\middle|Z\right]\right\}^{-1}$$
$$= \left\{\left[\mu(Z) - R_f\underline{1}\right]\left[\mu(Z) - R_f\underline{1}\right]' + \Sigma_\varepsilon(Z)\right\}^{-1}.$$

Also, define the constants:

$$\zeta \equiv E\left\{\left[\mu(Z) - R_f\underline{1}\right]' Q\left[\mu(Z) - R_f\underline{1}\right]\right\},$$

$$\varphi \equiv E\left\{R_f\left[\mu(Z) - R_f\underline{1}\right]' Q\left[\mu(Z) - R_f\underline{1}\right]\right\},$$

and

$$\psi \equiv E\left\{R_f^2\left[\mu(Z) - R_f\underline{1}\right]' Q\left[\mu(Z) - R_f\underline{1}\right]\right\}.$$

Theorem 1 Given a target unconditional expected return μ_s, N risky assets, instruments Z, and a conditional risk-free asset with rate $R_f = R_f(Z)$ that may vary over time, the unique portfolio having minimum unconditional variance is determined by the weights

$$\begin{aligned} x_s(Z) &= \left(\frac{\mu_s - E\left(R_f\right) + \varphi}{\zeta} - R_f\right)Q\left[\mu(Z) - R_f\underline{1}\right] \\ &= \left[(c+1)\mu_s + b - R_f\right]Q\left[\mu(Z) - R_f\underline{1}\right], \end{aligned} \tag{35.18}$$

and the optimal portfolio variance is

$$\sigma_s^2 = a + 2b\mu_s + c\mu_s^2$$

where $a = E\left(R_f^2\right) + \frac{\left[E\left(R_f\right) - \varphi\right]^2}{\zeta} - \psi$, $b = \frac{\varphi - E\left(R_f\right)}{\zeta}$, and $c = \frac{1}{\zeta} - 1$. When the risk-free asset return is constant, then these formulas simplify to Theorem 2 of Ferson and Siegel (2001) with

$$x_s(Z) = \frac{\mu_s - R_f}{\zeta} Q\left[\mu(Z) - R_f \underline{1}\right]$$

and with optimal portfolio variance $\sigma_s^2 = \frac{1-\zeta}{\zeta}\left(\mu_s - R_f\right)^2$.

Proof Our objective is to minimize, over the choice of $x_s(Z)$, the portfolio variance $\mathrm{Var}(R_s)$ subject to $E(R_s) = \mu_s$, where $R_s = R_f + x'(Z)\left(R - R_f\underline{1}\right)$ and the variance is given by Eq. 35.17. We form the Lagrangian:

$$L[x(Z)] = E\left[x'(Z)Q^{-1}x(Z)\right] + 2E\left\{R_f x'(Z)\left[\mu(Z) - R_f\underline{1}\right]\right\}$$
$$+2\lambda E\left\{\mu_s - R_f - x'(Z)\left[\mu(Z) - R_f\underline{1}\right]\right\}$$

and proceed using a perturbation argument. Let $q(Z) = x(Z) + dy(Z)$, where $x(Z)$ is the conjectured optimal solution, $y(Z)$ is any regular function of Z, and d is a scalar. Optimality of $x(Z)$ follows when the partial derivative of $L[q(Z)]$ with respect to d is identically zero when evaluated at $d = 0$. Thus,

$$0 = E\left(y'(Z)\left\{Q^{-1}x(Z) + \left(R_f - \lambda\right)\left[\mu(Z) - R_f\underline{1}\right]\right\}\right)$$

for all functions $y(Z)$, which implies that $Q^{-1}x(Z) + \left(R_f - \lambda\right)\left[\mu(Z) - R_f\underline{1}\right] = 0$ almost surely in Z. Solve this expression for x(Z) to obtain Eq. 35.18, where the Lagrange multiplier λ is evaluated by solving for the target mean, μ_s. The expression for the optimal portfolio variance follows by substituting the optimal weight function into Eq. 35.17. Formulas for fixed R_f then follow directly. QED.

When the risk-free asset's return is time varying and contained in the information set Z at the beginning of the portfolio formation period, the *conditional* mean variance efficient boundary varies over time with the value of $R_f(Z)$ along with the conditional asset means and covariances . In this case, a zero-beta parameter, γ_0, may be chosen to fix a point on the *unconditionally* efficient-with-respect-to-Z boundary. The choice of the zero-beta parameter corresponds to the choice of a target unconditional expected return μ_s. For a given value of γ_0, the target mean maximizes the squared Sharpe ratio $(\mu_s - \gamma_0)^2/\sigma_s^2$ along the mean variance boundary, which implies $\mu_s = -(a + b\gamma_0)/(b + c\gamma_0)$.

When there is a risk-free asset that is constant over time, the unconditionally efficient-with-respect-to-Z boundary is linear (a degenerate hyperbola) and reaches the risk-free asset at zero risk. In this case, we use $\gamma_0 = R_f$ and can obtain any μ_s larger or smaller than R_f, levering the efficient portfolio up or down with positions in the risk-free asset.

When there is no risk-free asset, we define portfolio s by letting $x' = x'(Z) = [x_1(Z), \ldots, x_N(Z)]$ denote the shares invested in each of the N risky assets, with the constraint that the weights sum to 1.0 almost surely in Z. The return on this portfolio, $R_s = x'(Z)R$, has expectation and variance as follows:

$$\mu_s = E\left[x'(Z)\mu(Z)\right],$$

$$\sigma_s^2 = E\left\{x'(Z)\Lambda^{-1}x(Z)\right\} - \mu_s^2,$$

where we have defined the $N \times N$ matrix

$$\Lambda = \Lambda(Z) \equiv \left\{E\left[RR'|Z\right]\right\}^{-1} = \left[\mu(Z)\mu'(Z) + \Sigma_{\varepsilon}(Z)\right]^{-1}.$$

Also, define the constants:

$$\delta_1 = E\left(\frac{1}{\underline{1}'\Lambda\underline{1}}\right),$$

$$\delta_2 = E\left(\frac{\underline{1}'\Lambda\mu(Z)}{\underline{1}'\Lambda\underline{1}}\right),$$

and

$$\delta_3 = E\left[\mu'(Z)\left(\Lambda - \frac{\Lambda\underline{1}\,\underline{1}'\Lambda}{\underline{1}'\Lambda\underline{1}}\right)\mu(Z)\right].$$

Theorem 2 (Ferson and Siegel 2001, Theorem 3) Given N risky assets and no risk-free asset, the unique portfolio having minimum unconditional variance and unconditional expected return μ_s is determined by the weights:

$$\begin{aligned} x_s'(Z) &= \frac{\underline{1}'\Lambda}{\underline{1}'\Lambda\underline{1}} + \frac{\mu_s - \delta_2}{\delta_3}\mu'(Z)\left(\Lambda - \frac{\Lambda\underline{1}\,\underline{1}'\Lambda}{\underline{1}'\Lambda\underline{1}}\right) \\ &= \frac{\underline{1}'\Lambda}{\underline{1}'\Lambda\underline{1}} + [(c+1)\mu_s + b]\mu'(Z)\left(\Lambda - \frac{\Lambda\underline{1}\,\underline{1}'\Lambda}{\underline{1}'\Lambda\underline{1}}\right), \end{aligned} \tag{35.19}$$

and the optimal portfolio variance is

$$\sigma_s^2 = a + 2b\mu_s + c\mu_s^2,$$

where $a = \delta_1 + \delta_2^2/\delta_3$, $b = -\delta_2/\delta_3$, and $c = (1 - \delta_3)/\delta_3$.

The efficient-with-respect-to-Z boundary is formed by varying the value of the target mean return μ_s in Eq. 35.19. Note that the second term on the right-hand side of Eq. 35.19 is proportional to the vector of weights of an excess return, or zero net investment portfolio (post multiplying that term by a vector of ones implies that the weights sum to zero). The first term in Eq. 35.19 is the weight of the global minimum conditional second moment portfolio. Thus, Eq. 35.19 illustrates two-fund separation: any efficient-with-respect-to-Z portfolio can be found as a combination of the global minimum conditional second moment portfolio and some weight on the unconditionally efficient excess return described by the second term.

Proofs of Propositions

Proof of Propositions 2 and 3

We begin with Proposition 3. To see that Eqs. 35.15 and 35.16 are equivalent, use the fact that efficiency of R_s implies that $\mu_p = \gamma_0 + \frac{\sigma_{ps}}{\sigma_s^2}(\mu_s - \gamma_0)$ and thus $\frac{\mu_s - \gamma_0}{\sigma_s^2} = \frac{\mu_p - \gamma_0}{\sigma_{ps}}$. Next, given any portfolio $R_q \neq R_c$, we will show that $\alpha_q^2/\sigma_q^2 < \alpha_c^2/\sigma_c^2$. Beginning with Eq. 35.16, we compute:

$$\sigma_{cs} = \frac{\sigma_p^2\sigma_s^2 - \sigma_{ps}^2}{\sigma_p^2 - \sigma_{ps}}$$

and

$$\sigma_c^2 = \frac{\sigma_p^2\left(\sigma_p^2\sigma_s^2 - \sigma_{ps}^2\right)}{\left(\sigma_p^2 - \sigma_{ps}\right)^2}.$$

The efficiency of R_s implies that $\mu_c = \gamma_0 + \frac{\sigma_{cs}}{\sigma_s^2}(\mu_s - \gamma_0)$, $\mu_p = \gamma_0 + \frac{\sigma_{ps}}{\sigma_s^2}(\mu_s - \gamma_0)$, and $\mu_q = \gamma_0 + \frac{\sigma_{q\,s}}{\sigma_s^2}(\mu_s - \gamma_0)$. Substituting these expressions and using the fact that $\sigma_{cp} = 0$, which follows from (35.16), we compute:

$$\begin{aligned}
\frac{\alpha_c^2}{\sigma_c^2} - \frac{\alpha_q^2}{\sigma_q^2} &= \frac{\left(\mu_c - \left[\gamma_o + \left(\mu_p - \gamma_o\right)\sigma_{cp}/{\sigma_p}^2\right]\right)^2}{\sigma_c^2} - \frac{\left(\mu_q - \left[\gamma_o + \left(\mu_p - \gamma_o\right)\sigma_{qp}/{\sigma_p}^2\right]\right)^2}{\sigma_q^2} \\
&= (\mu_s - \gamma_0)^2\left(\frac{\sigma_{cs}^2}{\sigma_s^4\sigma_c^2} - \frac{\left(\sigma_{qs}\sigma_p^2 - \sigma_{ps}\sigma_{qp}\right)^2}{\sigma_s^4\sigma_p^4\sigma_q^2}\right) \\
&= (\mu_s - \gamma_0)^2\left(\frac{\sigma_p^2\sigma_s^2 - \sigma_{ps}^2}{\sigma_s^4\sigma_p^2} - \frac{\left(\sigma_{qs}^2\sigma_p^4 + \sigma_{ps}^2\sigma_{qp}^2 - 2\sigma_{qs}\sigma_p^2\sigma_{ps}\sigma_{qp}\right)}{\sigma_s^4\sigma_p^4\sigma_q^2}\right) \\
&= \frac{(\mu_s - \gamma_0)^2}{\sigma_s^4\sigma_p^4\sigma_q^2}\left(\sigma_p^4\sigma_s^2\sigma_q^2 - \sigma_p^2\sigma_q^2\sigma_{ps}^2 - \sigma_{qs}^2\sigma_p^4 - \sigma_{ps}^2\sigma_{qp}^2 + 2\sigma_p^2\sigma_{qs}\sigma_{ps}\sigma_{qp}\right).
\end{aligned}$$

We now use the fact that $\sigma_{sp}^2 < \sigma_s^2\sigma_p^2$ (because, by assumption, R_p and R_s are not perfectly correlated) to see that

$$\frac{\alpha_c^2}{\sigma_c^2} - \frac{\alpha_q^2}{\sigma_q^2} \geq \frac{(\mu_s - \gamma_0)^2}{\sigma_p^4 \sigma_q^2 \sigma_s^4} \left[\sigma_p^4 \sigma_q^2 \sigma_s^2 - \sigma_p^2 \sigma_q^2 \sigma_{sp}^2 - \sigma_p^4 \sigma_{qs}^2 - \sigma_{qp}^2 \left(\sigma_s^2 \sigma_p^2 \right) + 2\sigma_p^2 \sigma_{qs} \sigma_{qp} \sigma_{ps} \right]$$
$$= \frac{(\mu_s - \gamma_0)^2}{\sigma_p^2 \sigma_q^2 \sigma_s^4} \left(\sigma_p^2 \sigma_q^2 \sigma_s^2 - \sigma_q^2 \sigma_{sp}^2 - \sigma_p^2 \sigma_{qs}^2 - \sigma_{qp}^2 \sigma_s^2 + 2\sigma_{qs} \sigma_{qp} \sigma_{ps} \right) \geq 0$$

where the final inequality follows from recognizing that the variance-covariance terms in parentheses are equal to the determinant of the (necessarily nonnegative definite) covariance matrix of (R_p, R_q, R_s). This establishes the maximal property of R_c.

To show uniqueness, note further that the inequality will be strict (and we will have $\alpha_c^2/\sigma_c^2 - \alpha_q^2/\sigma_q^2 > 0$) unless we have both of the following conditions corresponding to the two inequalities in the final calculation: (1) $\sigma_{qp} = 0$ so that R_q and R_p are orthogonal, and (2) the covariance matrix of (R_p, R_q, R_s) is singular so that R_q is a linear combination of R_p and R_s. However, there is only one portfolio orthogonal to R_p that can be formed as a linear combination $\lambda R_p + (1 - \lambda) R_s$, and this solution is R_c. This establishes Proposition 3, which holds in the case of both Theorem 1 and Theorem 2, that is, whether or not there is a conditionally risk-free asset.

The expressions in Proposition 2 for the optimal weights, $x_c(Z)$, follow from substituting portfolio weights from Theorem 1 (if there exists a conditional risk-free asset that may be time varying) or Theorem 2 (otherwise) into Eq. 35.15 and noting that the constants A and B represent the combining portfolio weights implied by (35.15) as $R_c = AR_s + BR_p$. Substituting, we see that Eq. 35.15 implies that the portfolio weight function $Ax_s(Z) + Bx_p(Z)$ generates returns R_c, completing the proof of Proposition 2. QED.

Proof of Proposition 4

Let R_s denote the efficient-with-respect-to-Z portfolio corresponding to zero-beta rate γ_0. The efficiency of R_s implies that we may substitute $\mu_p - \gamma_0 = (\mu_s - \gamma_0)\frac{\sigma_{ps}}{\sigma_s^2}$ and $\mu_c - \gamma_0 = (\mu_s - \gamma_0)\frac{\sigma_{cs}}{\sigma_s^2}$ to find

$$S_p^2 + S_c^2 = \frac{(\mu_p - \gamma_0)^2}{\sigma_p^2} + \frac{(\mu_c - \gamma_0)^2}{\sigma_c^2} = \frac{(\mu_s - \gamma_0)^2}{\sigma_s^4} \left(\frac{\sigma_{ps}^2}{\sigma_p^2} + \frac{\sigma_{cs}^2}{\sigma_c^2} \right).$$

Next, substituting for σ_{cs} and σ_c^2 from the above expressions, we verify that this expression reduces to S_s^2. QED.

Appendix 2: Methodology

We estimate the conditional mean functions, $\mu(Z)$, by ordinary least squares regressions of the returns on the lagged values of the conditioning variables. On the assumption that the conditional mean returns are linear functions of Z, these are the optimal generalized method of moments (GMM, see Hansen 1982) estimators. The covariance matrix of the residuals is used as the estimate of $\Sigma_\varepsilon(Z)$, which is assumed to be constant. These are the maximum likelihood estimates (MLE) under joint normality of (R,Z). In general, the conditional covariance matrix of the returns given Z will be time varying as a function of Z, as in conditional heteroskedasticity. Ferson and Siegel (2003) model conditional heteroskedasticity in alternative ways and find using parametric bootstrap simulations that this increases the tendency of the efficient-with-respect-to-Z portfolio weights to behave conservatively in the face of extreme realizations of Z.

The optimal orthogonal portfolio weights in Table 35.1 and Fig. 35.1 are estimated from Eqs. 35.7 to 35.8 in the text where, in the time-varying risk-free rate case, the Treasury bill return is assumed to be conditionally risk-free in Eq. 35.8. The benchmark portfolio x_p is a vector with a 1.0 in the place of the market index and zeros elsewhere. The matrix Q is estimated by using the MLE estimates of $\mu(Z)$ and $\Sigma_\varepsilon(Z)$ in the function given by Eq. 35.13. The parameter μ_p is estimated as the sample excess return on the market index, and γ_0 is the sample mean of the Treasury return, 3.8 %.

The Parametric Bootstrap

The parametric bootstrap is a special case of the simple, or nonparametric, bootstrap, itself an example of a resampling scheme. Introduced by Efron (1979), the bootstrap is useful when we wish to conduct statistical inferences, but when we either don't have an analytical formula for the sampling variation of a statistic, don't wish to assume normality or some other convenient distribution that allows for an analytical formula or have a sample too small to trust asymptotic distribution theory. The basic idea is to build a sampling distribution by resampling from the data at hand. In the simplest example, we have some statistic that we have estimated from a sample, and we want to know its sampling distribution. We resample from the original data, randomly with replacement, to generate an artificial sample of the same size, and we compute the statistic on the artificial sample. Repeating this many times, the histogram of the statistics computed on the artificial samples is an estimate of the sampling distribution for the original statistic. This distribution can be used to estimate standard errors, confidence intervals, etc. We can think of the bootstrap samples as being related to the original sample as the original sample is to the population. There are many variations on the bootstrap, and a good overview is provided by Efron and Tibshirani (1993).

In the simple, or nonparametric, bootstrap, no assumptions are made about the form of the distribution. It is assumed, however, that the sample accurately reflects the underlying population distribution, and this is critical for reliable inferences. For example, suppose that the true distribution was a uniform on [0, M]. In a sample drawn from this distribution, the maximum value is likely to be smaller than M, so that the bootstrap will likely understate the true variability of the data. This problem is obviously worse if the original sample has fewer observations. If the data are contaminated with measurement errors, in contrast, the extent of the true variability can be overstated. Even with large sample sizes, the bootstrap can be unreliable. For example, if the true distribution has infinite variance, the bootstrap distribution for the sample mean is inconsistent (Athreya 1987).

With a parametric bootstrap, we can sometimes do better than with a nonparametric bootstrap, where "do better" means, for example, obtain more accurate confidence intervals (e.g., Andrews et al. 2006). The idea of the parametric bootstrap is to use some of the parametric structure of the data. This might be as simple as assuming the form of the probability distribution. For example, assuming that the data are independent and normally distributed, we can generate artificial samples from a normal distribution using the sample mean and variance as the parameters. This is not exactly the right thing to do, because we should be sampling from a population with the true parameter values, not their estimated values. But, if the estimates of the mean and variance are good enough, we should be able to obtain reliable inferences.

To illustrate and further suggest the flexibility of the parametric bootstrap, consider an example, similar to the setting in our paper, where we have a regression of stock returns on a vector of lagged instruments, Z, which are highly persistent over time. Obviously, sampling from the Z's randomly with replacement would destroy their strong time-series dependence. Time-series dependence can be accommodated in a nonparametric way by using a block bootstrap. Here, we sample randomly a block of consecutive observations, where the block length is set to capture the extent of memory in the data.

In order to capture the time-series dependence of the lagged Z in a parametric bootstrap, we can model the lagged instruments as vector AR(1), for example, retaining the estimator of the AR(1) coefficient and the model residual, which we call the shocks, U_z. Regressing the future stock returns on the lagged instruments, we retain the regression coefficient and the residuals, which we call the shocks, U_r. We generate a sample of artificial data, with the same length as the original sample, as follows. We concatenate the shocks as $v = (U_z, U_r)$. Resampling rows from v, randomly with replacement, retains the covariances between the stock return shocks and the instrument Z shocks. This can be important for capturing features like the lagged stochastic regressor bias described by Stambaugh (1999). Drawing an initial row from v, we take the U_z shock and add it to the initial value of the Z (perhaps, drawn from the unconditional sample distribution) to produce the first lagged instrument vector, Z_{t-1}. We draw another row from v and construct the first observation of the remaining data as follows. The stocks' returns are formed by adding the U_r shock to βz_{t-1}, where β is the "true" regression coefficient that defines the conditional expected return. The contemporaneous values of the Zs are formed by multiplying the VAR coefficient by Z_{t-1} and adding the shock, U_z. The next observation is generated by taking the previous contemporaneous value of the Z as Z_{t-1} and repeating the process. In this way, the Z values are built up recursively, which captures their strong serial correlation.

Contents

Abstract

This paper uses a multifactor, multi-indicator approach to test the capital asset pricing model (CAPM) and the arbitrage pricing theory (APT). This approach is able to solve the measuring problem in the market portfolio in testing CAPM; and it is also able to directly test APT by linking the common factors to the macroeconomic indicators. Our results from testing CAPM support

Stambough's (*Journal of Financial Economics*, *10*, 237–268, 1982) argument that the inference about the tests of CAPM is insensitive to alternative market indexes.

We propose a MIMIC approach to test CAPM and APT. The beta estimated from the MIMIC model by allowing measurement error on the market portfolio does not significantly improve the OLS beta, while the MLE estimator does a better job than the OLS and GLS estimators in the cross-sectional regressions because the MLE estimator takes care of the measurement error in beta. Therefore, the measurement error problem on beta is more serious than that on the market portfolio.

Capital asset pricing model, CAPM • Arbitrage pricing theory • Multifactor multi-indicator approach • MIMIC • Measurement error • LISREL approach • Ordinary least square, OLS • General least square, GLS • Maximum-likelihood estimation, MLE

36.1 Introduction

Roll (1977) has shown that the capital asset pricing model (CAPM) can never be tested unless the market portfolio is capable of being measured and identified. However, the market portfolio is actually unobservable. Stated differently, since the market portfolio is subject to measurement error, Sharpe (1964), Lintner (1965), and Mossin's (1966) type of CAPM can never be tested directly. In contrast, the test of Ross's (1976, 1977) arbitrage pricing theory (APT) does not rely upon the identifications of the market portfolio or the true factors. Nevertheless, Shanken (1982) argues that Ross's contention that APT is inherently more easily tested is questionable. If we can directly link these unobservable factors to some observable indicators, the Shanken criticism of the test of APT can be avoided or reduced.

Fortunately, a multiple indicators and multiple causes (MIMIC) model, proposed by Zellner (1970), Goldberger (1972a, b), Joreskog and Goldberger (1975), and others, is an attractive methodology in dealing with the problem of unobservable variables. Goldberger (1972b) conceptually described that structural equation model is a combination of factor analysis and econometrics model. Goldberger (1972b) and Joreskog and Goldberger (1975) develop a structural equation model with multiple indicators and multiple causes of a single latent variable, MIMIC model, and obtain maximum likelihood estimates of parameters. The MIMIC model displays a mixture of econometric and factor analysis themes. This concept has successfully been used to test economic models, such as the structure of price expectation and inflationary expectation (see Turnovsky 1970; Lahiri 1976). In addition, structural equation model has also been used in finance-related studies. Titman and Wessels (1988), Chang et al. (2009), and Yang et al. (2009) apply structural equation models (e.g., LISREL approach and MIMIC model) in determining capital structure decision. Maddala and

Nimalendran (1996) use structural equation model to examine the effect of earnings surprises on stock prices, trading volumes, and bid-ask spread. However, the structural equation model, especially MIMIC model, has not been used in capital asset pricing determination.

The purpose of this paper is twofold: (i) to use the MIMIC model to reexamine CAPM and (ii) to use the MIMIC model to investigate the relationship between the factors in APT and the macroeconomic indicators directly. APT is attractive to both academicians and practitioners, because the model allows more than one factor. However, to date the practical applications of APT are still limited since previous studies in testing the model do not directly link the factors to the indicators. If the linkage between the factors and the indicators can be derived, practical applications will be much improved.

The outline of this paper is as follows. In Sect. 36.2, the MIMIC model is reviewed and CAPM and APT in terms of the MIMIC model are demonstrated. Section 36.3 shows how MIMIC can be used to test CAPM, and Sect. 36.4 investigates the MIMIC applied to test APT. Finally, a brief summary is contained in Sect. 36.5.

36.2 The MIMIC Model and the Tests of CAPM and APT

36.2.1 The MIMC Model

Suppose that a system has k unobservable latent variables $z = (z_1, \ldots, z_k)'$, p observable exogenous indicators $x = (x_1, \ldots, x_p)'$, and m observable endogenous variables $y = (y_1, \ldots, y_m)'$.[1] The specification of this extended MIMIC model of Jöreskog and Goldberger (1975) is as follows. The latent factors z are linearly determined, subject to disturbances $e = (e_1, \ldots, e_k)'$, by observable exogenous indicators x:[2]

$$z = ax + e, \tag{36.1}$$

where

$$a = \begin{bmatrix} a_{11}, & \cdots, & a_{1p} \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ a_{k1}, & \cdots, & a_{kp} \end{bmatrix} \quad \text{is a } k \times p \text{ matrix.}$$

[1]Fogler et al. (1981) and Chen et al. (1983) indirectly link the factors extracted from the APT to economic indicators. Jöreskog and Goldberger (1975) have shown that this kind of indirect estimation method is not as efficient as the direct estimation method to be explored in this section.

[2]Here, we use different terminologies in defining the factors and indicators compared with those used in traditional MIMIC model.

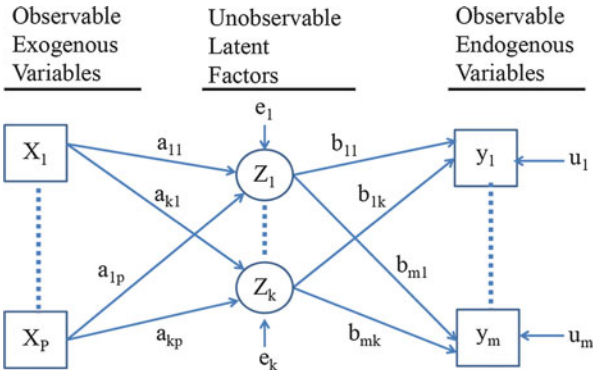

Fig. 36.1 Multiple causes and indicators of unobservable variables. This figure shows the path diagram illustrating MIMIC model of the structural equation system. In this figure, observable variables $X_1, \ldots, X_P$ are causes of the latent variables $Z_1, \ldots, Z_k$, while $Y_1, \ldots, Y_m$ are indicators of $Z_1, \ldots, Z_k$

In addition, the latent factors z linearly determine the components of endogenous variables y subject to disturbances $u = (u_1, \ldots, u_m)'$:

$$y = bz + u, \tag{36.2}$$

where

$$b = \begin{bmatrix} b_{11}, & \cdots, & b_{1k} \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ b_{m1}, & \cdots, & b_{mk} \end{bmatrix} \text{ is an } m \times k \text{ matrix.}$$

The disturbances are assumed to be mutually independent and normally disturbed with mean zero, namely, $e \sim N(0,\Sigma)$, $u \sim N(0,\theta^2)$, where $\Sigma = \text{diag}(\sigma_1^2, \ldots, \sigma_k^2)$ and $\theta^2 = \text{diag}(\theta_1^2, \ldots, \theta_m^2)$. For convenience, all variables are taken to have mean zero. The system of Eqs. 36.1 and 36.2 are shown in Fig. 36.1.

Solving the equation systems of Eqs. 36.1 and 36.2, we have the following reduced form connecting the observable variables:

$$y = bax + be + u = hx + v, \tag{36.3}$$

where the reduced-form coefficient matrix is

$$h = ba. \tag{36.4}$$

The reduced-form disturbance matrix is

$$v = be + u, \tag{36.5}$$

which has a covariance matrix of

$$\Omega = E(vv') = E\left[(be + u)(be + u)'\right] = b\Sigma b' + \theta^2, \tag{36.6}$$

where E presents expectation operator.

There are two types of restrictions on the reduced form: (i) the $m \times p$ regression coefficient matrix h has rank k, the $m \times p$ components of h being expressed in terms of $kp + mk$ elements of a and b, and (ii) the $m \times m$ residual covariance matrix Ω satisfies a factor analysis model with k common factors, the $m(m + 1)/2$ distinct elements of Ω being expressed in terms of the $k + km + m$ elements of σ^2, b, and θ^2. The first restriction, which is the same as the simultaneous equation model, is familiar to econometricians. The second restriction, which is the same as the factor analysis model, is familiar to psychometricians. In Eq. 36.5, e, b, and u are regarded as the common factors, the factor loadings, and the unique disturbances in the factor analysis model, respectively.

We observe that the reduced-form parameters remain unchanged, when any column, say j, of b is multiplied by a scalar and the j th row of a and σ_j are both divided by the same scalar. To remove this indeterminacy of the model, we can normalize the model through (i) σ^2, or (ii) b, or (iii) a. After normalization, the maximum likelihood estimation (MLE) procedure can be used to obtain consistent estimators of the elements in parameters a, b, and θ^2 (see Attfield 1983; Chen 1981; Joreskog and Goldberger 1975; and others). In the following, we demonstrate how to apply the MIMIC model to test CAPM and APT.

36.2.2 The Testing Model of CAPM by the MIMIC Approach

The CAPM can be rewritten, in terms of MIMIC model, as follows:

$$\begin{aligned} \widetilde{r}_i &= \beta_i \widetilde{r}^*_m + \widetilde{u}_i \\ \widetilde{r}^*_m &= \widetilde{r}_m + \widetilde{e}_m, \end{aligned} \qquad i = 1, \ldots, N, \tag{36.7}$$

where

$\widetilde{r}_i$ = the realized excess return (total return less risk-free rate) on security i in a deviation form

$\widetilde{r}_m$ = the realized excess return of the NYSE Composite Index

$\widetilde{r}^*_m$ = the unobservable excess return on the market portfolio

In this special one-factor case, we remove the indeterminacy by setting the coefficient on $\widetilde{r}_m$ equal to one. Equation 36.7 is a simultaneous equation model, in which there are N equations linking the individual security (or portfolio) return to the unobservable true market return and one equation linking the unobservable true market portfolio return to the realized return of the NYSE composite index. After obtaining the estimated betas from simultaneous equation system of (36.7), a cross-sectional regression of the security return against its risk (β) will be used to test CAPM or to estimate the riskless rate and the market risk premium as follows:

$$r_{it} = \hat{a}_{0t} + \hat{a}_{1t}\beta_i, \tag{36.8}$$

where
r_{it} = the excess return on security i at time t
$\hat{a}_{0t}$ = the estimate of the intercept which is supposed to be zero
$\hat{a}_{1t}$ = the estimate of the market risk premium

Four different estimation procedures will be used to estimate Eq. 36.8. They are: (i) stationary OLS, (ii) nonstationary OLS, (iii) GLS, and (iv) MLE.[3]

36.2.3 The Testing Model of APT by the MIMIC Approach

The testing model of APT, in terms of the MIMIC model, can be rewritten as follows:

$$\begin{array}{ll} \widetilde{r}_i = b_{i1}\widetilde{f}_1 + \ldots + b_{ik}\widetilde{f}_k + \widetilde{u}_i, & (i = 1, \ldots, N) \\ \widetilde{f}_j = a_{j1}\widetilde{I}_1 + \ldots + a_{jp}\widetilde{I}_p + \widetilde{e}_j, & (j = 1, \ldots, k) \end{array}, \tag{36.9}$$

where
$\widetilde{f}_j$ = the jth unobservable factor
$\widetilde{I}_h$ = the hth macroeconomic indicator, $h = 1, \cdots, p$

For convenience and easy explanation, each factor $\widetilde{f}$ is assumed to have different set of explained indicators $\widetilde{I}$'s. Note that there are N return equations plus k factor equations in the simultaneous equation system (36.9). The LISREL computer program of Jöreskog and Sörbon (1981) is used to estimate the parameters, a and b, in Eq. 36.9. A cross-sectional regression is also used to test APT and to estimate the riskless rate and the factor risk premia by regressing the security return against its risks, b's. The a's coefficients in Eq. 36.9 can be used to explain the relationship between factors and indicators.

36.3 Test of CAPM

This section tests CAPM using the market model and the MIMIC model described in Sect. 36.2. The objective is to investigate whether the MIMIC method yields a different inference from the market model. Nineteen industry common stock portfolios are formed with the same manner used by Schipper and Thompson (1981), and Stambough (1982).[4] The return on a portfolio is the arithmetic average of returns for firms on the CRSP monthly tape with the appropriate two-digit SEC code for the given month. The tests use returns from the period 1963–1982, and this total period is divided into two equal subperiods: (i) subperiod 1, 1963–1972 and

[3]The terminologies stationary OLS and nonstationary OLS have been used by Friend and Westfield (1980). The GLS and MLE methods have been discussed by Litzenberger and Ramaswamy (1979).

[4]See Chen (1981).

(ii) subperiod 2, 1973–1982. Portfolios are formed primarily because they provide a convenient way to limit the computational dimensions of the MIMIC method. As mentioned by Stambough (1982), industry portfolios also allow rejection of CAPM due to the presence of additional industry-related variables in the risk-return relation.

Table 36.1 indicates the number of securities in each portfolio, the SEC codes, and betas calculated from the market model and also from the MIMIC model. When the MIMIC model was used to estimate betas by the portfolio excess returns in subperiod 1, convergent problems were encountered during minimization so that the result is inappropriate. Consequently, raw returns in deviation form on the portfolios are used to estimate betas for subperiod 1. The betas estimated from the MIMIC model are very close to those from the market model in both periods. This evidence supports Stambough's discovery that inferences about CAPM are very insensitive to alternative market indexes.

Table 36.2 presents return-risk trade-off from the cross-sectional relationship in which the average monthly excess portfolio returns (monthly portfolio returns less monthly return on 3-month Treasury bills) is regressed on a beta estimated either from the MIMIC model or the market model from two different 120-month periods. Four different estimation procedures are used to estimate the intercepts and the market risk premia. The OLS method presents two sets of *t*-statistics shown in the parentheses under the same relevant regression coefficients. The first set (denoted *S*) assumes that the regression coefficients are constant or stationary over each 120-month period. The second set (denoted *NS*) of the OLS *t*-statistics allows the nonstationarities of the regression coefficients by computing the cross-sectional regression coefficients in each month and deriving the appropriate standard errors from the time series 120 estimates of the OLS regression coefficients. The GLS and MLE methods also permit the nonstationary coefficients. Thus, their *t*-statistics are derived from the same procedure in the OLS (NS) method. Although the OLS and the GLS estimators are biased and inconsistent due to measurement error in beta (see Litzenberger and Ramaswamy 1979), the maximum likelihood estimators are consistent simply because MLE takes care of measurement error in beta.

In Table 36.2, the coefficients in the *NS* regression of OLS, GLS, and MLE are obviously characterized by much larger standard errors so that they lose any significance shown in the stationary OLS regression.[5]

However, different estimated betas cause little changes in return-risk relationships. From the results of the OLS stationary method, there exists a significant return-risk relationship in subperiod 1, but not in subperiod 2 in both MIMIC and market models. The poor return-risk relationship in subperiod 2 may be due to the poor performance of CAPM in determining a pricing relation. In the next section, APT will be used to examine an alternative pricing relationship. Even though the null hypothesis of CAPM that $a_0 = 0$ cannot be rejected at the 5 % level in all four cases, all coefficients are positive. In addition, the intercept in subperiod 2, about

[5]The similar results were also found in the Friend and Westfield's (1980) study of co-skewness.

Table 36.1 Industry portfolio SEC codes, number of firms, and estimated betas

Portfolio description	SEC code	# of firms		Estimated betas			
				Period 1		Period 2	
		1972	1982	Market model	MIMC model	Market model	MIMC model
1. Mining	10–14	56	71	1.056	1.009	0.922	0.916

14. Railroads	40	18	11	1.294	1.229	0.899	0.895
15. Other transport.	41, 42, 44 45, 47	34	35	1.335	1.447	1.203	1.203
16. Utilities	49	138	152	0.443	0.467	0.564	0.562
17. Department stores	53	35	28	1.149	1.104	1.125	1.125
18. Other retail trades	50–52, 54–59	103	97	1.144	1.088	1.123	1.124
19. Banking, finance, real estate	60–67	184	240	0.968	1.021	1.069	1.068

This table presents the number of firms and betas in each industry portfolio. The numbers of firms are obtained in the end of 1972 and the end of 1982. The betas shown in the first column are estimated from the market model, while those in the second column are estimated from the MIMIC model. Period 1 represents the sample period from 1963 to 1972 and period 2 represents the sample period from 1973 to 1982

4.3 % annual rate, is too high. This is consistent with prior tests of the traditional version of CAPM.

All nonstationary estimates of a_0 and a_1 in OLS, GLS, and MLE in Table 36.2 are insignificant. Because of the low test power for all nonstationary procedures (the standard errors are too high), in the following, only the magnitudes of the estimated coefficients are discussed. The MLE and GLS estimates of a_0 are much lower and much closer to zero than the corresponding OLS estimates in all four cases. In addition, the MLE estimates of a_1 is greater than the corresponding GLS estimates and is closer to the realized market risk premia in all four cases. The realized market risk premia are 0.751 % and 0.636 % monthly for periods 1 and 2, respectively.

	(0.60)	(0.31)		(0.59)	(0.32)	
GLS	0.106	0.532		0.107	0.531	
	(0.24)	(0.71)		(0.24)	(0.71)	
MLE	0.081	0.556		0.081	0.556	
	(0.17)	(0.71)		(0.17)	(0.71)	

This table presents return-risk trade-off from the cross-sectional relationship in which the average monthly excess portfolio returns are regressed on a beta estimated either from the MIMC model or the market model from two different 120-month periods. For different estimation procedures, stationary OLS, nonstationary OLS, GLS, and MLE, are used to estimate the intercepts and the market risk premia. The stationary OLS version corresponds to the regression $\overline{R}_i - \overline{R}_f = a_0 + a_1\beta_i + \widetilde{e}_i$, ($i$=1,· · ·,N). The other versions correspond to the regression $\overline{R}_i - \overline{R}_f = a_0 + a_1 \beta_i + \widetilde{e}_i$, ($i = 1$,· · ·,N; and $t = 1$,· · ·T. The monthly returns are multiplied by 100 before regressing. The reported coefficients are arithmetic average of the time series, while t-statistics are in parentheses under each relevant coefficient. *represents significant at the 5 % level

This evidence proves that the MLE estimator in the return-risk cross-sectional regressions is more appropriate than OLS or GLS estimator in testing CAPM.

In sum, we have proposed an alternative estimator of betas by the MIMIC model in which measurement error in a market portfolio is allowed. Nevertheless, this reasonable alternative method does not gain much from the traditional OLS estimator. However, some interesting results have surfaced. This evidence supports Stambough's conclusion that the tests of CAPM are insensitive to different market indexes. In return-risk cross-sectional regressions, our evidence shows that the MLE estimator is more appropriate than the OLS or GLS estimator due to measurement error in beta. From these two interesting results, we conclude that measurement error on beta is more serious than measurement error on the market portfolio in testing CAPM.

36.4 Tests of APT by MIMIC Approach

This section tests APT using the MIMIC model demonstrated in Sect. 36.2. The objective is to investigate that (i) the proper number of factors is used to explain the data and (ii) the relationships between factors and indicators which are measured by macroeconomic variables. The same 19 industry portfolios described in previous section are used here. The macroeconomic variables are selected from those most likely related to common stock returns. In the following, the indicators selected in this study will be discussed.

36.4.1 Macroeconomic Variables as the Indicators

In early 1970s, several studies attempt to employ economic methods to investigate the relationship between money supply and aggregated common stock prices. Models developed by Keran (1971), Homa and Jaffee (1971), and Hamburger and Kochin (1972) appear to have met with considerable success in explaining the behavior of Standard and Poor's Composite Index. However, Pesando (1974) reexamines above models using different periods. He finds that the extraordinary success of these methods in tracking the behavior of stock prices during the sample period may be illusory. We believe that the above spurious regression phenomenon results from ignoring the autocorrelated errors in time series regression equations as pointed out by Granger and Newbold (1974). Gargett (1978) used a qualitative method to study the relationship between these two variables. He discovered that the Dow Jones Industrial Index follows changes in money supply with a lag of 3 months.

The relationship between stock returns and inflation has been extensively studied. In particular, Bodie (1976), Nelson (1976), and Fama and Schwert (1977) all present evidence that monthly returns to NYSE Composite Index are negatively related to the inflation rate as indicated by the consumer price index (CPI) since 1953. Cohn and Lessard (1981), Gultekin (1983), and Solnik (1983) also find that stock prices are negatively related to nominal interest rate and inflation in a number of countries. Fama (1981) suggests a reason why the stock market reaction to unexpected inflation is weak. He argues that unexpected inflation is contemporaneously correlated with unexpected movements in important "real" variables, such as capital expenditures or real GNP, so that the correlation between stock returns and unexpected inflation is spurious. After extensively reexamining the relationship between the stock returns and inflation, Geske and Roll (1983) conclude that only Nelson's (1979) and Fama's (1981) money demand explanation is logically consistent, but it seems unable to fully explain all of the empirical phenomena. Geske and Roll (1983) therefore propose the fiscal and monetary explanation. They argue that the basic underlying relation is between stock returns and changes in inflationary expectations.

In exploring the common stocks as hedges against the investment opportunity sets, Schipper and Thompson (1981) select two candidates for state variables.

They are price level as measured by consumer price index (CPI) and the real gross national product less corporate profit (GNP). They find that hedge portfolios offer meaningful hedging potential in portfolio-formation period. In addition, CAPM or the market model indicates that the return on a security or a portfolio most likely co-move with the return on the market portfolio.

In summary, the variables most likely correlated with a stock return would be classified as five categories: (1) money supply, (2) real production, (3) inflation, (4) interest rate, and (5) market return. Further, Brigham (1982) decomposes a risk premium into maturity risk premium and default risk premium. Thus, these two indicators are also included in our study. According to the above discussion, the following 11 variables are selected as the indicators.

1. Return on the market portfolio (RM): the return on NYSE common stock composite index.
2. Transaction volume (VL): the change rate in the transaction volume (shares) for all of the NYSE common stocks.
3. Real riskless rate (RF): the real interest rate on 3-month Treasury bills.
4. Maturity risk premium (MP): the difference between the real interest rates on long-term Treasury bonds (10 or more years) and on 3-month Treasury bills.
5. Default risk premium (DP): the difference between the real interest rates on new AA corporate bonds and on 3-month Treasury bills.
6. Consumer price index inflation rate (CPI): the change rate in urban consumer price index for all items.
7. Money supply (M2): the real change rate in money stock as measured by M2 (M1 + time deposits).
8. Velocity of money supply (PI/M2): the ratio of personal income to money supply M2. This is an alternative measure of money supply.
9. Real industrial production (IP): the change rate in real total industrial productions.
10. Real auto production (IPA): the change rate in real automotive products.
11. Real home production (IPH): the change rate in real home goods.

Since the automobile and housing industries generally lead the rest of the economy, the last two indicators, IPA and IPH, are used to catch up the first two biggest industries. The reason to select industrial production instead of GNP in this study is that all other indicators are published monthly while GNP is published quarterly. Since the industrial production is a very good proxy for GNP, we sacrifice GNP measure to gain the number of time periods.

36.4.2 Empirical Results

After carefully selecting the indicator candidates, the time lag or leading problem needs to be solved. The correlation coefficients between the market portfolio return and the other indicators with lags and leadings of zero to 5 months for both periods were examined. All indicators are contemporaneously correlated with the

Table 36.3 Eigenvalue as a percentage of the first eigenvalue for 19 industry portfolios: 1963–1982

Factor	PRC	ALP	SCF	ULS
Panel A: Period: 1963–1972				
1	100 %	100 %	100 %	100 %
2	3.8	4.4	3.9	2.9
3	3.1	1.5	2.6	1.7
4	2.1	1.0	2.3	0.8
5	1.9	0.7	2.0	0.7
6	1.6	0.6	1.9	0.6
Panel B: Period: 1973–1982				
1	100 %	100 %	100 %	100 %
2	7.9	6.9	7.1	7.2
3	2.1	2.8	2.9	1.8
4	1.3	1.0	1.9	0.9
5	1.0	0.6	1.6	0.5
6	1.0	0.4	1.4	0.4

This table shows the eigenvalues as a percentage of the first eigenvalue. Four methods are used to determine the number of factors in APT model. They are principal component analysis (PRC), alpha factor analysis (ALP), simple common factor analysis (SCF), and unweighted least squares method (ULS)

market portfolio except three real production indicators. The real production indicators follow the market portfolio return with a lag of 2 or 3 months. Therefore, in this study, all indicators are contemporaneous except three real production indicators which is a 2-month lag.

Before APT is directly tested by the MIMIC model, factor analysis is preliminarily used to determine the number of factors in both periods. Table 36.3 shows the eigenvalues as a percentage of the first eigenvalue. Clearly, it is only one factor in period 1, while it is perhaps two factors in period 2 by "scree" test described in Chapter 4 of Wei (1984).[6] Consequently, at most a two-factor model is enough to explain the historical data. Three alternative MIMIC models are proposed to test APT: (i) one-factor 11-indicator model, (ii) one-factor six-indicator model, and (iii) two-factor six-indicator model. When the two one-factor models are used to test APT in period 1, there is little difference between 11-indicator and six-indicator model. Thus, only six indicators are used in the two-factor model to save the computer time.[7]

The structural coefficients of APT in the MIMIC model for period 1 are reported in Table 36.4a. In both one-factor models, only the stock market-related variables,

[6] In his dissertation, Wei (1984) has shown that the "scree" test is a powerful test in identifying the number of relevant factors in the APT. By using simulation study, Wei has shown that Roll and Ross's (1980) ML method in estimating factors are inferior to methods listed in Table 36.3.

[7] It is very expensive to run LISREL program, especially for more than two factor models.

the market return (RM), and the transaction volume (VL) are significant at the 5 % level. From this evidence, if the pricing relation in period 1 is a one-factor APT, this common factor would be most likely related to only the stock market-related indicators, namely, the market portfolio return and the transaction volume. Other indicators may be correlated with this single common factor, but they are obviously not as important as the stock market-related indicators. Now, let us closely examine other indicators with an absolute *t*-value of greater than one for 11-indicator model. The real riskless interest rate (RF), CPI inflation rate (CPI), and the real auto production (IPA) are negatively correlated with this common factor, while the velocity of money supply (PI/M2) is positively related to this common factor. If we regard this common factor as a proxy of market portfolio because most of the weight is on the market portfolio, then, except for real auto production, this evidence supports previous studies done on the relationship between common stock returns and other indicators (Keran 1971; Homa and Jaffee 1971; Hamburger and Kochin 1972; Pesando 1974; Bodie 1976; Nelson 1976; Fama and Schwert 1977; and others). However, there is no previous study which examines the relationship between stock returns and the real auto production.

Some might argue that weak relationship between non-stock market indicators and the common factor is due to multicollinearities among the indicators. Therefore, six of the 11 indicators are selected to represent each category indicator. They are the market portfolio return (RM), the transaction volume (VL), real riskless interest rate (RF), CPI inflation rate (CPI), money supply (M2), and the real total industrial production (IP). This is the one-factor six-indicator model. The result of this model is shown in Table 36.4a column 2. The result of this one-factor six-indicator model is very close to that of the one-factor 11-indicator model. As mentioned before, only the stock market-related indicators are significantly correlated with the common factor. Real riskless interest rate, inflation, money supply, and real production are all negatively but insignificantly related to the common factor. For factor equation, the 11-indicator model has only a little high R-square than the six-indicator model. They are 0.5611 and 0.5412, respectively. Comparing the betas of these two one-factor models in Table 36.4a, they are very highly correlated with a correlation coefficient of about 1.000. In addition, the average R-square of each return equation in both one-factor models is the same with a value of 0.811. Up to this point, there is not much difference between the one-factor 11-indicator and the one-factor six-indicator models. Later on, the cross-sectional regression will be used to double check this result.

Even though we have already discussed that the appropriate model is a one-factor model for period 1 by the scree test of factor analysis, we want to use a two-factor model to double check whether the second factor is significant or not. A predetermined two-factor six-indicator model will be used to test APT. Factor analysis is employed to classify these six indicators into two groups. The first group includes the market portfolio and the transaction volume, while the second group includes other four indicators: real riskless interest rate (RF), inflation rate (CPI), money supply (M2), and real total industrial production (IP). The two-factor result shown in Table 36.4a columns 3 and 4 displays that only the first factor is significantly related to RM and VL, whereas the second factor is very insignificantly correlated with the second group indicators. This is also evident by examining from the second betas in the table. All of the second betas are insignificant. Furthermore, the first beta coefficient is very highly correlated with the betas in both one-factor models with both correlation coefficients of 0.996. This is further

This table presents the structural coefficients of the APT in the MIMIC model for period 1 and period 2. The structural model is written as

$$\tilde{r}_i = b_{i1}\tilde{f}_1 + b_{i2}\tilde{f}_2 + \tilde{u}_i, \qquad i = 1, \ldots, 19$$
$$\tilde{f}_j = a_{j1}(RM) + a_{j2}(VL) + a_{j3}(RF) + a_{j4}(MP) + a_{j5}(DP) + a_{j6}(CPI) + a_{j7}(M2) + a_{j8}(PI/M2) + a_{j9}(IP) + a_{j10}(IPA) + a_{j11}(IPH) + \tilde{e}_j, \qquad j = 1 \text{ or } 1, 2.$$

Variables used as indicators in the structural model are the market return (*RM*), transaction volume (*VL*), real risk interest rate (*RF*), maturity risk premium (*MP*), default risk premium (*DP*), CPI inflation rate (*CPI*), money supply (*M2*), velocity of money supply (*PI*/*M2*), real total industrial production (*IP*), real auto production (*IPA*), and real home production (*IPH*). *represents significant at the 5 % level supported by the R-square criteria. The average R-square of each return equation in the one-factor model is 0.811, while 0.844 in the two-factor model. If the adjusted R-square is used as the criteria, the increase in R-square will be insignificant. Thus, a one-factor APT is good enough to explain the first period data. We will reconfirm this argument by the cross-sectional regression.

Table 36.5 Panel A reports the return-risk cross-sectional relationship in period 1 for APT in the MIMIC model. Both one-factor models have a very similar result. Their adjusted R-squares are the same of 0.258. The intercepts are both insignificantly different from zero but positive (recall that the LHS variable is excess return). The factor risk premia for both one-factor models are positive and significant. This is exactly the result that should have been concluded from APT. On the other hand, the intercept in the two-factor model is much higher than those in the one-factor model, and the two factor risk premia are both insignificant.[8] The adjusted R-square is a little lower than those in the one-factor models. From the results of the MIMIC model and the cross-sectional regressions, it is probable that one-factor APT with the market portfolio and the transaction volume as the determinants of the single factor is the appropriate pricing model for period 1. Comparing the MIMIC CAPM and CAPM in Table 36.2 with this one-factor model, the MIMIC CAPM is closer to the one-factor model. In addition, the factor risk premium is closer to the realized market risk premium than that in the MIMIC CAPM model.

Now, let us examine APT in period 2. The structural coefficients of APT in the MIMIC model for period 2 are represented in Table 36.4b. Because six indicators do not make much difference from 11 indicators in the one-factor model in period 1, only the 11-indicator model is used to test APT for the one-factor model in period 2 in order to save the computer time. From the one-factor model, the result is similar to that in period 1. The stock market return and the transaction volume are the most significant indicators. However, inflation and the real auto production are also significant even just at the marginal level. This reinforces our suspicion that there may be more than one factor in period 2.

Let us closely examine the indicators with an absolute t-value greater than one. Real interest riskless rate, inflation, money supply, and real auto production are all negatively correlated with the common factor, while the velocity of money supply is positively correlated with this common factor. Overall, this result again supports previous studies. Now, let us turn to the two-factor six-indicator model. Follow the same procedures done for period 1. The result is displayed in Table 36.4b columns 2 and 3. The market portfolio (RM) and the transaction volume (LV) are significantly related to the first factor. However, the real auto production is significantly correlated with the second factor; this time even only at the marginal level. Comparing other indicators with those in period 1, real riskless interest rate is again negatively related to the second factor, but inflation rate and money supply are positively related to the second factor in the period. From the result of the relationship between the factors and the indicators, the second factor is still important even though less important than

[8]The loss of the significance of the first factor risk premium is due to the multicollinearity problem.

Table 36.5 Return-risk cross-sectional relationships of APT in the MIMIC model: 1963–1982

	$\hat{a}_0$	$\hat{a}_1$	$\hat{a}_2$	$\overline{R}^2$
Model	Panel A: Period 1, 1963–1972			
One-factor	0.159	0.543*		0.258
11-indicator	(0.710)	(2.693)		
One-factor	0.159	0.558*		0.258
6-indicator	(0.710)	(2.692)		
Two-factor	0.507	0.206	0.071	0.257
6-indicator	(1.219)	(0.529)	(1.221)	
	Panel B: Period 2, 1973–1982			
One-factor	0.370	0.285		−0.002
11-indicator	(1.328)	(0.967)		
Two-factor	0.040	0.684*	0.362*	0.215
6-indicator	(0.150)	(2.377)	(2.066)	

This table presents the return-risk cross-sectional relationship for the APT in the MIMIC model. The cross-sectional relationship between return and risk can be written as $\overline{R}_i = \hat{a}_0 + \hat{a}_1 b_1 + \hat{a}_2 b_2 + \widetilde{e}_i$, $i=1,\ldots,19$. Panel A reports the relationship in period 1 and Panel B reports the relationship in period 2. The average monthly returns are multiplied by 100 before regressing. *represents significant at the 5 % level

the first factor for period 2. This can also be checked by the significance of betas in Table 36.4b. Ten out of the 19 s factor betas are significant although the relationship is not as strong as those in the first factor betas. Because the first factor is correlated with stock market-related indicator, this factor can be regarded as a proxy of the market portfolio. The correlation coefficient between the beta in the first factor and the beta in the MIMIC CAPM is very high with a coefficient of 0.923. Further, the average R-square of each return equation in the one-factor model is 0.818, while 0.885 in the two-factor model. When the adjusted R-square is used as a criteria, the increase in R-square should not be trivial and will be significant. In addition, the R-square for the second factor equation is as high as 0.1836. All of these results indicate that the second factor should be important. We further check whether the second factor is important or not by the cross-sectional regression.

The risk-return cross-sectional relationship of APT in the MIMIC model for period 2 is shown in Table 36.5 Panel B. For the one-factor model, both the intercept and the factor risk premium are insignificant. The intercept is too high with an annual rate of 4.3 %, while the factor risk premium is far below the realized market risk premium with a monthly rate of 0.636 %. The adjusted R-square is negative. On the other hand, the intercept for the two-factor model is insignificant and very near to zero, while the two factor premia are significant with the first factor premium very close to the realized market risk premium. The adjusted R-square is as high as 0.215. The results of APT in the MIMIC model confirm the scree test of the factor analysis and the poor performance of CAPM in previous section for period 2. Furthermore, comparing the result in Table 36.5 Panel A with that in Table 36.2, we can conclude that the two-factor APT outperforms the one-factor APT, the MIMIC CAPM, and CAPM in period 2. But the one-factor APT does a better job than the two-factor APT in period 1, and there is not much difference among the one-factor APT, the MIMIC CAPM, and CAPM. This evidence supports Ross's argument that APT is more general than CAPM because APT allows more than one factor in the pricing relation.

It will be interesting to see what will happen if market variables (the market portfolio and transaction volume) are excluded from the model. Table 36.6 shows the structural coefficients of the one-factor APT without market variables.[9] The *b* coefficients (factor loadings) shown in Table 36.6 for both periods are very close to those estimated from the one-factor APT with market variables shown in Tables 36.4a and 36.4b, respectively.[10] However, the results from the factor equation have dramatically changed.

For period 1, the *R*-square is only 0.0611 which is much lower than 0.5611 from the one-factor APT with market variables. This result indicates that the market variables play the major role in the pricing behavior during period 1. When the market variables excluded from the model, among nine indicators, only the two money supply variables, M2 and PI/M2, are positively related to the unique common factor at the marginal level. For period 2, the *R*-square of the factor equation for the model without market variables is 0.3915 which is higher than the one in period 1. This evidence denotes that, in addition to the market variables, some other macroeconomic indicators play a relatively important role in the pricing behavior during period 2. Among the nine nonmarket variables, real risk-free rate (RF), default risk premium (DF), and inflation (CPI) are significantly negatively related to the common factor, while the velocity of money supply (PI/M2) and the real auto production (IPA) are significantly positively related to the common factor. All of the relationships are as we expect. The results from the model without market variables also confirm our previous evidence that the 1963–1972 data can be described by a one-factor APT with the market variables as its indicators, while the 1973–1982 data should be explained by more than one-factor APT.

36.5 Concluding Remarks

This paper bases on parts of Wei's (1984) dissertation using a MIMIC approach to test CAPM and APT. The results support the conclusion that APT outperforms CAPM, especially for the period from 1973 to 1982. The beta estimated from the MIMIC model by allowing measurement error on the market portfolio does not significantly improve the OLS beta. However, the MLE estimator does a better job than the OLS and GLS estimators in the cross-sectional regressions because the MLE estimator takes care of the measurement error in beta. Therefore, the measurement error problem

[9]Only the one-factor APT is used to investigate the difference between the models shown in Table 36.4 and in Table 36.6.

[10]If we normalize the one-factor 11-indicator model for period 2 shown in Table 36.4b by setting $b_1 = 1.00$, it is easily seen that the *b* coefficients of one-factor model shown in Tables 36.4b and 36.6 column 2 are very similar.

Table 36.6 Structural coefficients of the one-factor APT in the MIMIC model without market variables: 1963–1982

16	0.463(7.66)*	0.632(8.23)*
17	1.094(14.13)*	1.329(9.84)*
18	1.078(16.46)*	1.318(10.47)*
19	1.012(14.70)*	1.233(9.95)*

This table shows estimated coefficients of the one-factor APT in the MIMIC model without market variables. The structural model is shown as follows. *represents significant at the 5 % level

$$\widetilde{r}_i = b_{i1}\widetilde{f}_1 + b_{i2}\widetilde{f}_2 + \widetilde{u}_i, \qquad i = 1, \ldots, 19$$

$$\begin{aligned}\widetilde{f}_j = {} & a_1(RF) + a_2(MP) + a_3(DP) \\ & + a_4(CPI) + a_5(M2) + a_6(PI/M2) + a_7(IP) \\ & + a_8(IPA) + a_9(IPH) + \widetilde{e}_j,\end{aligned}$$

on beta is more serious than that on the market portfolio. This evidence supports Stambough's (1982) argument that the inference about the tests of CAPM is insensitive to alternative market indexes. When the one-factor APT with market variables is compared with the model without market variables, we found that the market variables play a major role in pricing behavior. Therefore, we conclude that it is inappropriate for the study of the relationship between the common factors extracted from APT and the macroeconomic variables without including the market variables.

John C. Lee

Contents

Abstract

This chapter will first demonstrate how Microsoft Excel can be used to create the decision trees for the binomial option pricing model. At the same time, this chapter will discuss the binomial option pricing model in a less mathematical fashion. All the mathematical calculations will be taken care by the Microsoft Excel program that is presented in this chapter. Finally, this chapter also uses the decision tree approach to demonstrate the relationship between the binomial option pricing model and the Black–Scholes option pricing model.

37.1 Introduction

The binomial option pricing model derived by Rendleman and Barter (1979) and Cox et al. (1979) is one the most famous models used to price options. Only the Black–Scholes model (1973) is more famous. One problem with learning the binomial option pricing model is that it is computationally intensive. This results in a very complicated formula to price an option.

The complexity of the binomial option pricing model makes it a challenge to learn the model. Most books teach the binomial option model by describing the formula. This is not very effective because it usually requires the learner to mentally keep track of many details, many times to the point of information overload. There is a well-known principle in psychology that the average number of things that a person can remember at one time is seven.

This chapter will first demonstrate the power of Microsoft Excel. It will do this by demonstrating that it is possible to create large decision trees for the binomial pricing model using Microsoft Excel. A ten-period decision tree would require 2,047 call calculations and 2,047 put calculations. This chapter will also show the decision tree for the price of a stock and the price of a bond, each requiring 2,047 calculations. Therefore, there would be 2,047 * 4 = 8,188 calculations for a complete set of ten-period decision trees.

Secondly, this chapter will present the binomial option model in a less mathematical matter. It will try to make it so that the reader will not have to keep track of many things at one time. It will do this by using decision trees to price call and put options.

Finally, this chapter will show the relationship between the binomial option pricing model and the Black–Scholes option pricing model.

This chapter uses a Microsoft Excel workbook called *binomialBS_OPM.xls* that contains the VBA code to create the decision trees for the binomial option pricing model. The VBA code is published in Appendix 1. The password for the workbook is *bigsky* for those who want to study the VBA code. E-mail me at JohnLeeExcelVBA@gmail.com and indicate that the password is "bigsky" to get a copy of this Microsoft Excel workbook.

Section 37.2 discusses the basic concepts of call and put options. Section 37.3 demonstrates the one-period call and put option pricing models. Section 37.4 presents the two-period option pricing model. Section 37.5 demonstrates how to use the Microsoft Excel workbook *binomialBS_OPM.xls* to create the decision trees for an *n*-period binomial option pricing model. Section 37.6 demonstrates the use

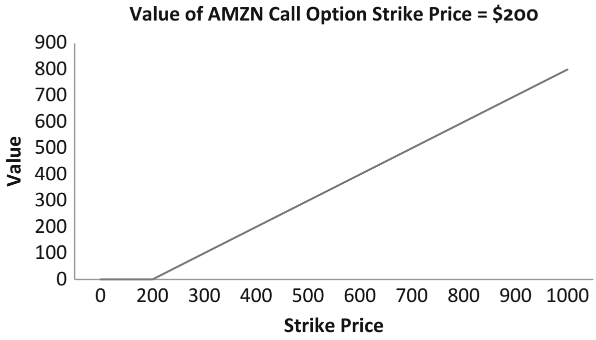

Fig. 37.1 Value of AMZN call option

of the Black–Scholes model. Section 37.7 shows the relationship between the binomial option pricing model and the Black–Scholes option pricing model. Section 37.8 demonstrates how to use the Microsoft Excel workbook *binomialBS_OPM.xls* to demonstrate the relationship between the binomial option pricing model and the Black–Scholes option pricing model.

37.2 Call and Put Options

A *call option* gives the owner the right but not the obligation to buy the underlying security at a specified price. The price in which the owner can buy the underlying price is called the *exercise price*. A call option becomes valuable when the exercise price is less than the current price of the underlying stock price.

For example, a call option on an AMZN stock with an exercise price of $200 when the stock price of an Amazon stock is $250 is worth $50. The reason it is worth $50 is because a holder of the call option can buy the AMZN stock at $200 and then sell the AMZN stock at the prevailing price of $250 for a profit of $50. Also, a call option on an AMZN stock with an exercise price of $300 when the stock price of an AMZN stock is $150 is worth $0.

A *put option* gives the owner the right but not the obligation to sell the underlying security at a specified price. A put option becomes valuable when the exercise price is more than the current price of the underlying stock price.

For example, a put option on an AMZN stock with an exercise price of $200 when the stock price of an AMZN stock is $150 is worth $50. The reason it is worth $50 is because a holder of the put option can buy the AMZN stock at the prevailing price of $150 and then sell the AMZN stock at the put price of $200 for a profit of $50. Also, a put option on an AMZN stock with an exercise price of $200 when the stock price of the AMZN stock is $250 is worth $0.

Figures 37.1 and 37.2 are charts showing the value of call and put options of the above GE stock at varying prices.

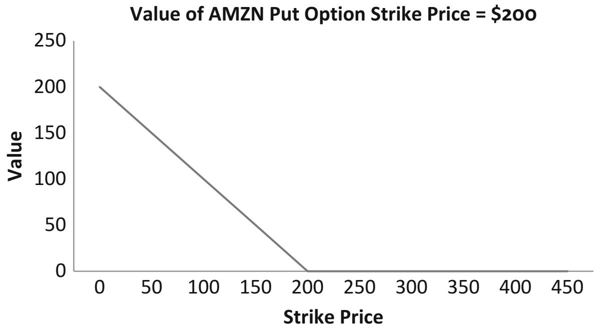

Fig. 37.2 Value of AMZN put option

37.3 One-Period Option Pricing Model

What should be the value of these options? Let's look at a case where we are only concerned with the value of options for one period. In the next period, a stock price can either go up or go down. Let's look at a case where we know for certain that an AMZN stock with a price of $200 will either go up 5 % or go down 5 % in the next period and the exercise after one period is $200. Figures 37.3, 37.4, and 37.5 show the decision tree for the AMZN stock price, the AMZN call option price, and the AMZN put option price, respectively.

Let's first consider the issue of pricing an AMZN call option. Using a one-period decision tree, we can illustrate the price of an AMZN stock if it goes up 5 % and the price of a stock AMZN if it goes down 5 %. Since we know the possible ending values of the AMZN stock, we can derive the possible ending values of a call option. If the stock price increases to $210, the price of the AMZN call option will then be $10 ($210 − $200). If the AMZ stock price decreases to $190, the value of the call option will worth $0 because it would be below the exercise price of $200. We have just discussed the possible ending value of an AMZN call option in period 1. But what we are really interested in is what the value is now of the AMZN call option knowing the two resulting values of the AMZN call option.

To help determine the value of a one-period AMZN call option, it's useful to know that it is possible to replicate the resulting two states of the value of the AMZN call option by buying a combination of stocks and bonds. Below is the formula to replicate the situation where the price increases to $210. We will assume that the interest rate for the bond is 3 %:

$$210S + 1.03B = 10$$
$$190S + 1.03B = 0$$

We can use simple algebra to solve for both S and B. The first thing that we need to do is to rearrange the second equation as follows:

$$1.03B = -190S$$

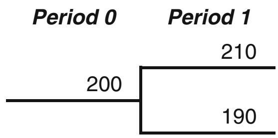

Fig. 37.3 AMZN stock price

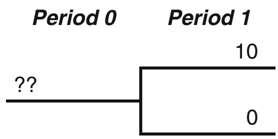

Fig. 37.4 AMZN call option price

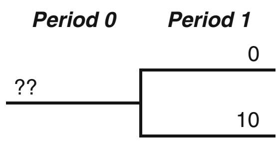

Fig. 37.5 AMZN put option price

With the above equation, we can rewrite the first equation as

$$\begin{aligned} 210\text{S} + (-190\text{S}) &= 10 \\ 20\text{S} &= 10 \\ \text{S} &= 0.5 \end{aligned}$$

We can solve for B by substituting the value 0.05 for S in the first equation:

$$\begin{aligned} 210(0.5) + 1.03\text{B} &= 10 \\ 105 + 1.03\text{B} &= 10 \\ 1.03\text{B} &= -95 \\ \text{B} &= -92.23 \end{aligned}$$

Therefore, from the above simple algebraic exercise, we should at period 0 buy 0.05 shares of AMZN stock and borrow 9.223 at 3 % to replicate the payoff of the AMZN call option. This means the value of an AMZN call option should be $0.5 * 200 - 92.23 = 7.77$.

If this were not the case, there would then be arbitrage profits. For example, if the call option were sold for \$30, there would be a profit of 22.23. This would result in the increase in the selling of the AMZN call option. The increase in the supply of AMZN call options would push the price down for the call options. If the call option were sold for \$5, there would be a saving of \$2.77. This saving would result in the increase demand for the AMZN call option. This increase demand would result in the price of the call option to increase. The equilibrium point would be \$7.77.

Using the above mentioned concept and procedure, Benninga (2000) has derived a one-period call option model as

$$C = q_u \mathrm{Max}[S(1+u)X, 0] + q_d \mathrm{Max}[S(1+d) - X, 0] \tag{37.1}$$

where

$$q_u = \frac{i-d}{(1+i)(u-d)}$$
$$q_d = \frac{u-i}{(1+i)(u-d)}$$
$$u = \text{increase factor}$$
$$d = \text{down factor}$$
$$i = \text{interest rate}$$

If we let $i = r$, $p = (r - d)/(u - d)$, $1 - p = (u - r)/(u - d)$, $R = 1/(1 + r)$, $C_u = \mathrm{Max}[S(1 + u) - X, 0]$, and $C_d = \mathrm{Max}[S(1 + d) - X, 0]$, then we have

$$C = [pC_u + (1-p)C_d]/R, \tag{37.2}$$

where
Cu = call option price after increase
Cd = call option price after decrease

Equation 37.2 is identical to Eq. 6B.6 in Lee et al. (2000, p. 234).[1]

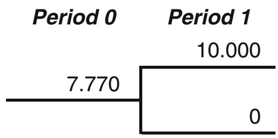
Below calculates the value of the above one-period call option where the strike price, X, is \$200 and the risk-free interest rate is 3 %. We will assume that the price of a stock for any given period will either increase or decrease by 5 %:

$$X = \$200$$
$$S = \$200$$
$$u = 1.05$$
$$d = 0.95$$
$$R = 1 + r = 1 + 0.03$$
$$p = (1.03 - 0.95)/(1.05 - 0.95)$$
$$C = [0.8(10) + 0.2(0)]/1.03 = \$7.77$$

Therefore, from the above calculations, the value of the call option is \$7.77. Figure 37.6 shows the resulting decision tree for the above call option.

[1]Please note that in Lee et al. (2000, p. 234) u = 1 + percentage of price increase and d = 1 – percentage of price increase.

Fig. 37.6 Call option price



Like the call option, it is possible to replicate the resulting two states of the value of the put option by buying a combination of stocks and bonds. Below is the formula to replicate the situation where the price decreases to \$190:

$$\begin{aligned} 210\mathrm{S} + 1.03\mathrm{B} &= 0 \\ 190\mathrm{S} + 1.03\mathrm{B} &= 10 \end{aligned}$$

We will use simple algebra to solve for both S and B. The first thing we will do is to rewrite the second equation as follows:

$$1.03\mathrm{B} = 10 - 190\mathrm{S}$$

The next thing to do is to substitute the above equation to the first put option equation. Doing this would result in the following:

$$210\mathrm{S} + 10 - 190\mathrm{S} = 0$$

The following solves for S:

$$\begin{aligned} 20\mathrm{S} &= -10 \\ \mathrm{S} &= -0.5 \end{aligned}$$

Now let us solve for B by putting the value of S into the first equation. This is shown below:

$$\begin{aligned} 210(-0.5) + 1.03\mathrm{B} &= 0 \\ 1.03\mathrm{B} &= 105 \\ \mathrm{B} &= 101.94 \end{aligned}$$

From the above simple algebra exercise, we have S = −0.5 and B = 101.94. This tells us that we should in period 0 lend \$101.94 at 3 % and sell 0.5 shares of stock to replicate the put option payoff for period 1. And the value of the AMZN put option should be 200(−0.5) + 101.94 = 1.94.

Using the same arbitrage argument that we used in the discussion of the call option, 0.194 has to be the equilibrium price of the put option.

As with the call option, Benninga (2000) has derived a one-period put option model as

$$P = q_u \mathrm{Max}[X - S(1+u), 0] + q_d \mathrm{Max}[X - S(1+d), 0] \tag{37.3}$$

where

$$q_u = \frac{i-d}{(1+i)(u-d)}$$
$$q_d = \frac{u-i}{(1+i)(u-d)}$$
$$u = \text{increase factor}$$
$$d = \text{down factor}$$
$$i = \text{interest rate}$$

If we let $i = r$, $p = (r - d)/(u - d)$, $1 - p = (u - r)/(u - d)$, $R = 1/(1 + r)$, $P_u = \text{Max}[X - S(1 + u), 0]$, and $P_d = \text{Max}[X - S(1 + d), 0]$, then we have

$$P = [pP_u + (1-p)P_d]/R, \quad (37.4)$$

where
P_u = put option price after increase
P_d = put option price after decrease

Below calculates the value of the above one-period put option where the strike price, X, is \$20 and the risk-free interest rate is 3 %:

$$P = [0.8(0) + 0.2(10)]/1.03 = \$1.94$$

From the above calculation, the put option pricing decision tree would look like the following.

Figure 37.7 shows the resulting decision tree for the above put option.

There is a relationship between the price of a put option and the price of all call option. This relationship is called the put-call parity. Equation 37.5 shows the relationship between the price of a put option and the price of a call option:

$$\mathrm{P} = \mathrm{C} + \mathrm{X}/\mathrm{R} - \mathrm{S} \quad (37.5)$$

where
C = call price
X = strike price
R = 1 + interest rate
S = stock price

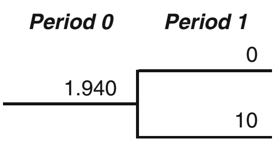


Fig. 37.7 AMZN put option price

The following uses the put-call parity to calculate the price of the AMZN put option:

$$\begin{aligned} P &= \$7.77 + \$200/(1.03) - \$200 \\ &= 7.77 + 194.17 - 200 \\ &= 1.94 \end{aligned}$$

37.4 Two-Period Option Pricing Model

We now will look at pricing options for two periods. Figure 37.8 shows the stock price decision tree based on the parameters indicated in the last section. This decision tree was created based on the assumption that a stock price will either increase by 5 % or decrease by 5 %.

How do we price the value of a call and put option for two periods?

The highest possible value for our stock based on our assumption is \$220.5. We get this value first by multiplying the stock price at period 0 by 105 % to get the resulting value of \$210 of period 1. We then again multiply the stock price in period 1 by 105 % to get the resulting value of \$220.5. In period two, the value of a call option when a stock price is \$220.5 is the stock price minus the exercise price, \$220.5 − \$200, or \$20.5. In period two, the value of a put option when a stock price is \$220.5 is the exercise price minus the stock price, \$200 − \$220.5, or −\$20.5. A negative value has no value to an investor so the value of the put option would be \$0.

The lowest possible value for our stock based on our assumptions is \$180.5. We get this value first by multiplying the stock price at period 0 by 95 % (decreasing the value of the stock by 5 %) to get the resulting value of \$190 of period 1. We then again multiply the stock price in period 1 by 95 % to get the resulting value of \$180.5. In period two, the value of a call option when a stock price is \$180.5 is the stock price minus the exercise price, \$180.5 − \$200, or −\$19.5. A negative value has no value to an investor so the value of a call option would be \$0. In period two, the value of a put option when a stock price is \$18.05 is the exercise price minus the stock price, \$200 − \$180.5, or \$19.5. We can derive the call and put option values for the other possible values of the stock in period 2 in the same fashion.

Figures 37.9 and 37.10 show the possible call and put option values for period 2.

We cannot calculate the value of the call and put options in period 1 the same way we did in period 2 because it's not the ending value of the stock. In period 1, there are two possible call values. One value is when the stock price increased, and one value is when the stock price decreased. The call option decision tree shown in Fig. 37.9 shows two possible values for a call option in period 1. If we just focus on the value of a call option when the stock price increases from period one, we will notice that it is like the decision tree for a call option for one period. This is shown in Fig. 37.11.

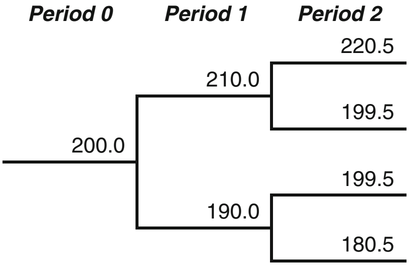

Fig. 37.8 AMZN stock price

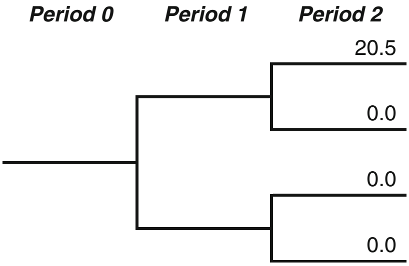

Fig. 37.9 AMZN call option

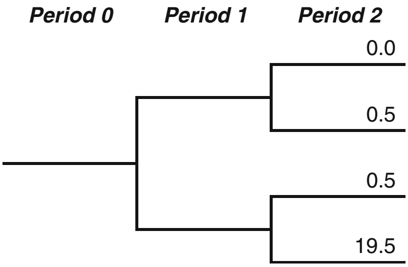

Fig. 37.10 AMZN put option

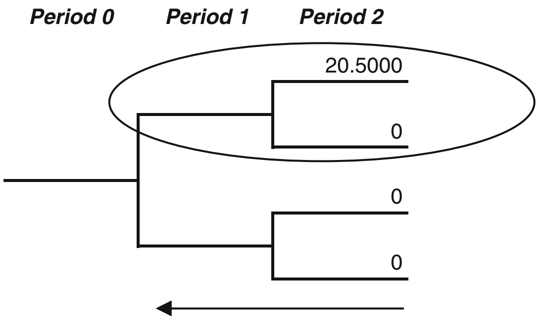

Fig. 37.11 AMZN call option

Using the same method for pricing a call option for one period, the price of a call option when stock price increases from period 0 will be \$15.922. The resulting decision tree is shown in Fig. 37.12.

In the same fashion, we can price the value of a call option when a stock price decreases. The price of a call option when a stock price decreases from period 0 is \$0. The resulting decision tree is shown in Fig. 37.13.

In the same fashion, we can price the value of a call option in period 0. The resulting decision tree is shown in Fig. 37.14.

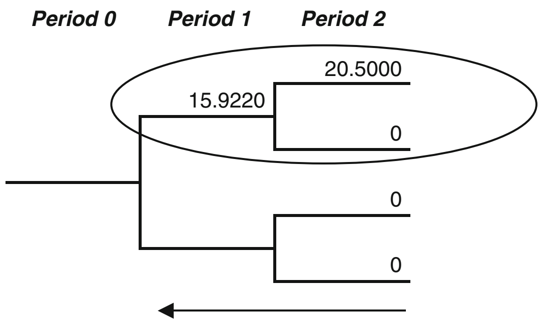

Fig. 37.12 AMZN call option

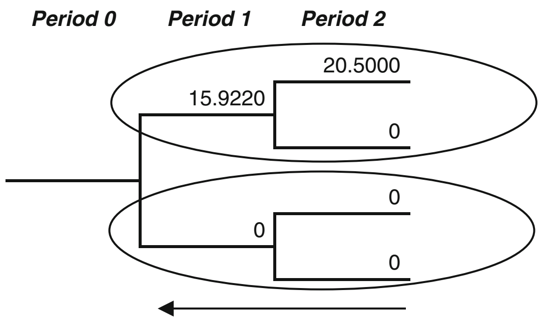

Fig. 37.13 AMZN call option

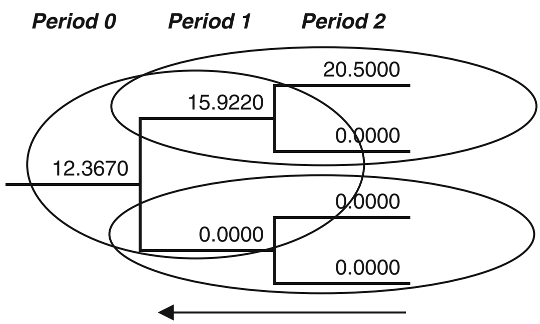

Fig. 37.14 AMZN call option

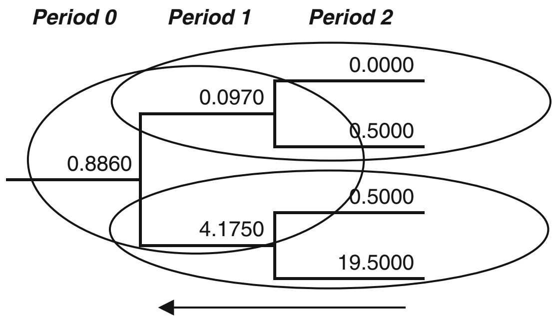

Fig. 37.15 AMZN put option

Table 37.1

Periods	Calculations
1	3
2	7
3	17
4	31
5	63
6	127
7	255
8	511
9	1,023
10	2,047
11	4,065
12	8,191

We can calculate the value of a put option in the same manner as we did in calculating the value of a call option. The decision tree for a put option is shown in Fig. 37.15.

37.5 Using Microsoft Excel to Create the Binomial Option Trees

In the previous section, we priced the value of a call and put option by pricing backwards, from the last period to the first period. This method of pricing call and put options will work for any n-period. To price the value of a call option for two periods required seven sets of calculations. The number of calculations increases dramatically as n increases. Table 37.1 lists the number of calculations for specific number of periods.

After two periods, it becomes very cumbersome to calculate and create the decision trees for a call and put option. In the previous section, we saw that calculations were very repetitive and mechanical. To solve this problem, this chapter will use Microsoft Excel to do the calculations and create the decision trees for the call and put options. We will also use Microsoft Excel to calculate and draw the related decision trees for the underlying stock and bond.

To solve this repetitive and mechanical calculation of the binomial option pricing model, we will look at a Microsoft Excel file called *binomialBS_OPM.xls*. We will use this Microsoft Excel workbook to produce four decision trees for the GE stock that was discussed in the previous sections. The four decision trees are:

1. Stock price
2. Call option price
3. Put option price
4. Bond price

This section will demonstrate how to use the *binomialBS_OPM.xls* Excel file to create the four decision trees. Figure 37.16 shows the Excel file *binomialBS_OPM.xls* after the file is opened. Pushing the button shown in Fig. 37.16 will get the dialog box shown in Fig. 37.17.

The dialog box shown in Fig. 37.17 shows the parameters for the *binomial option pricing model*. These parameters are changeable. The dialog box in Fig. 37.17 shows the default values.

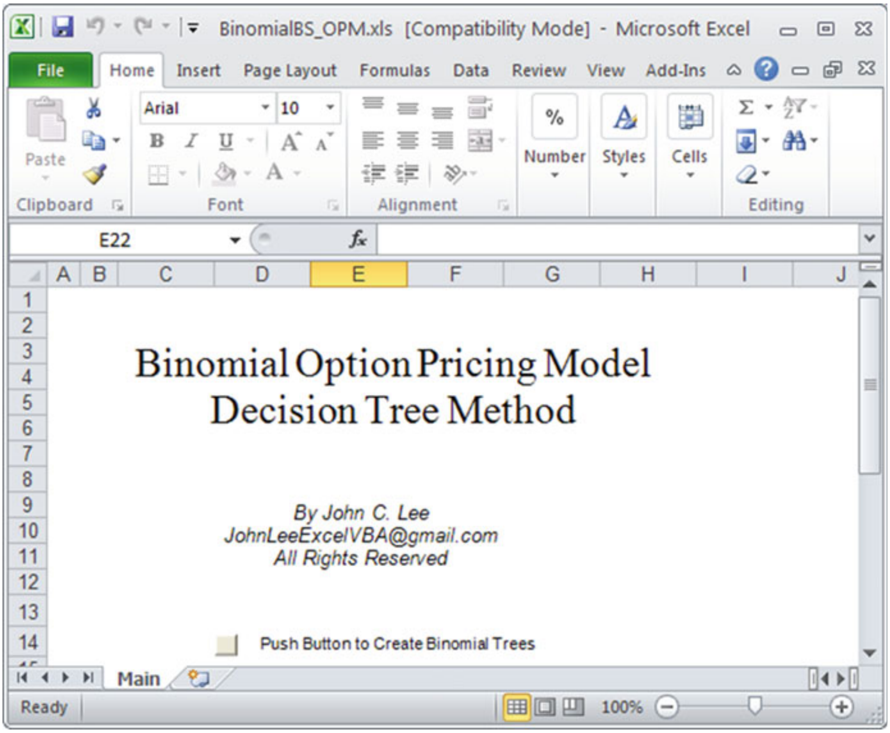

Fig. 37.16 Excel file BinomialBS_OPM.xls

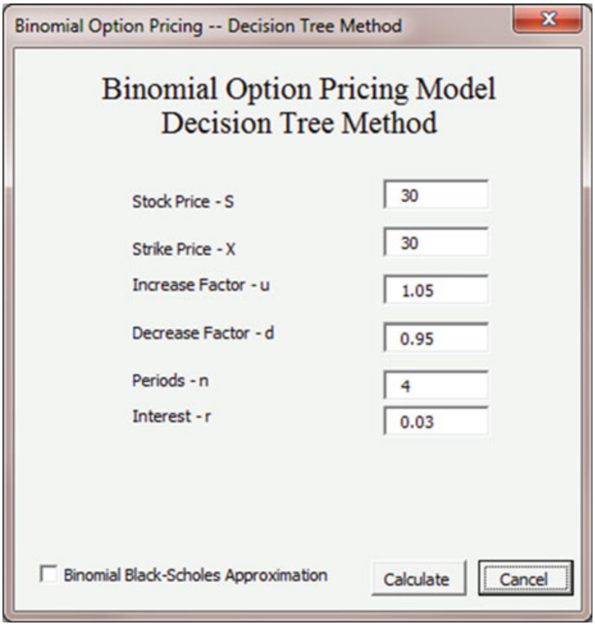

Fig. 37.17 Dialog box showing parameters for the binomial option pricing model

Pushing the *calculate* button shown in Fig. 37.17 will produce the four decision trees shown in Figs. 37.18, 37.19, 37.20, and 37.21.

The table at the beginning of this section indicated 31 calculations were required to create a decision tree that has four periods. This section showed four decision trees. Therefore, the Excel file did 31 * 4 = 121 calculations to create the four decision trees.

Benninga (2000, p. 260) has defined the price of a call option in a binomial option pricing model with n-periods as

$$C = \sum_{i=0}^{n} \binom{n}{i} q_u^i q_d^{n-i} \max\left[S(1+u)^i(1+d)^{n-i}, 0\right] \tag{37.6}$$

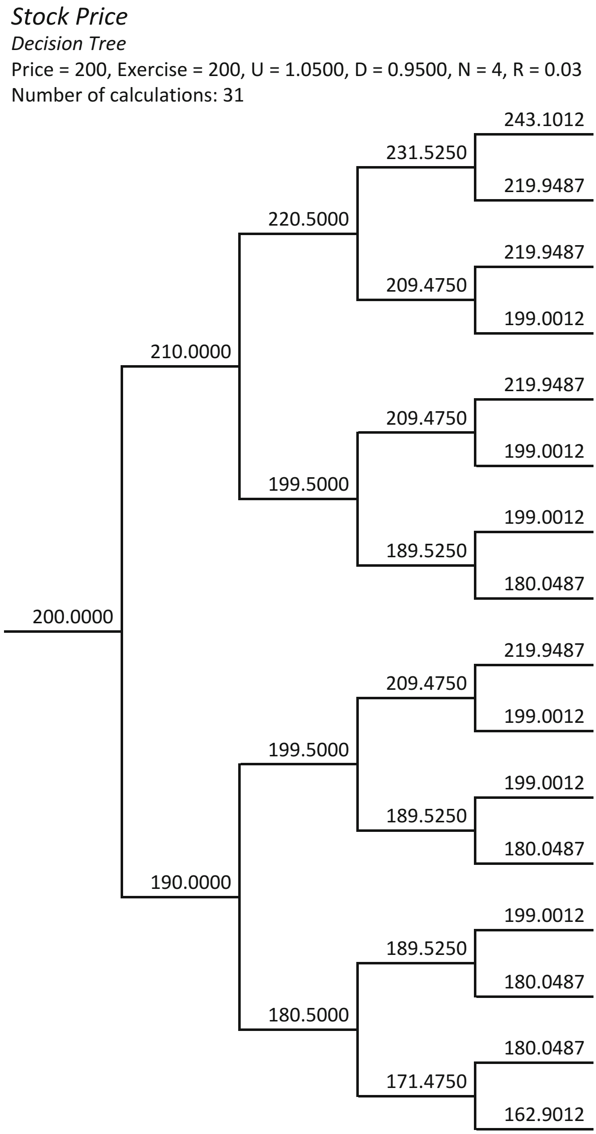
and the price of a put option in a binomial option pricing model with n-periods as

$$P = \sum_{i=0}^{n} \binom{n}{i} q_u^i q_d^{n-i} \max\left[X - S(1+u)^i(1+d)^{n-i}, 0\right] \tag{37.7}$$

Lee et al. (2000, p. 237) have defined the pricing of a call option in a binomial option pricing model with n-period as

$$C = \frac{1}{R^n} \sum_{k=0}^{n} \frac{n!}{k!(n-k!)} p^k (1-p)^{n-k} \max\left[0, (1+u)^k(1+d)^{n-k}, S - X\right] \tag{37.8}$$

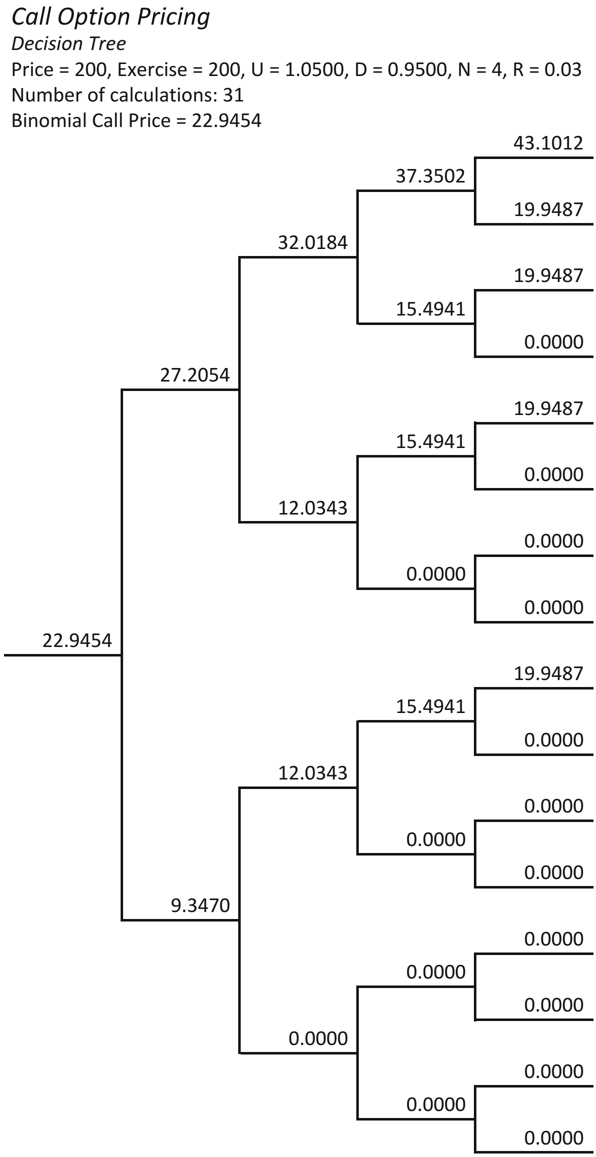
Fig. 37.18 Stock price decision tree



The definition of the pricing of a put option in a binomial option pricing model with n-period would then be defined as

$$P = \frac{1}{R^n} \sum_{k=0}^{n} \frac{n!}{k!(n-k)!} p^k (1-p)^{n-k} \max\left[0, X - (1+u)^k (1+d)^{n-k}, S\right] \quad (37.9)$$

Fig. 37.19 Call option pricing decision tree



37.6 Black–Scholes Option Pricing Model

The most famous option pricing model is the Black–Scholes option pricing model. In this section, we will demonstrate the usage of the Black–Scholes option pricing model. In latter sections, we will demonstrate the relationship between the binomial option pricing model and the Black–Scholes pricing model. The Black–Scholes

Fig. 37.20 Put option pricing decision tree

Put Option Pricing

Decision Tree

Price = 200, Exercise = 200, U = 1.0500, D = 0.9500, N = 4, R = 0.03

Number of calculations: 31

Binomial Put Price: 0.6428

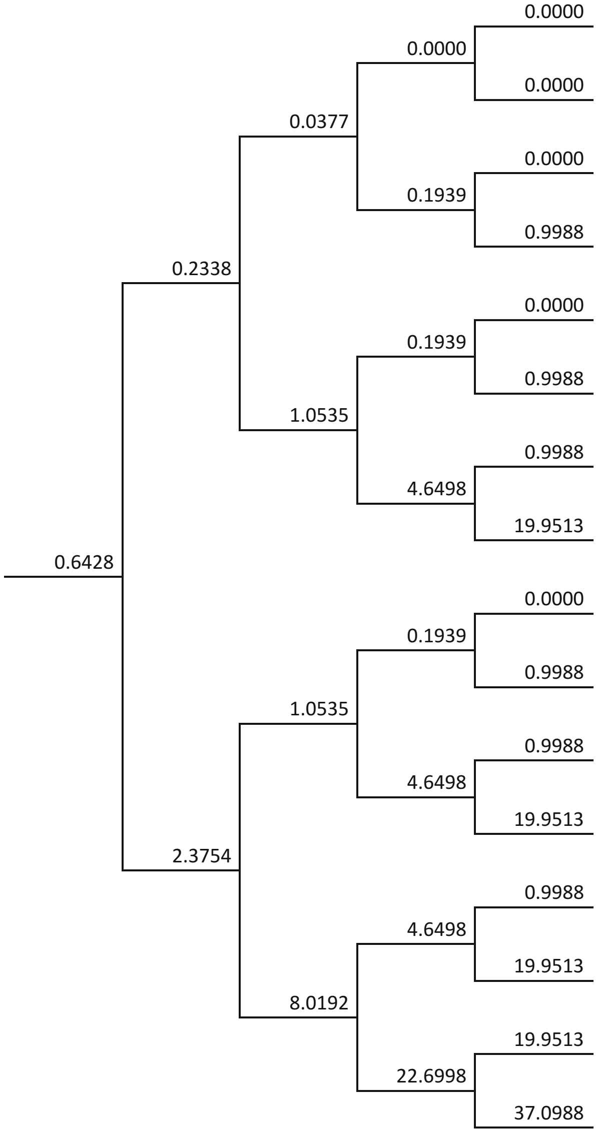


Fig. 37.21 Bond pricing decision tree

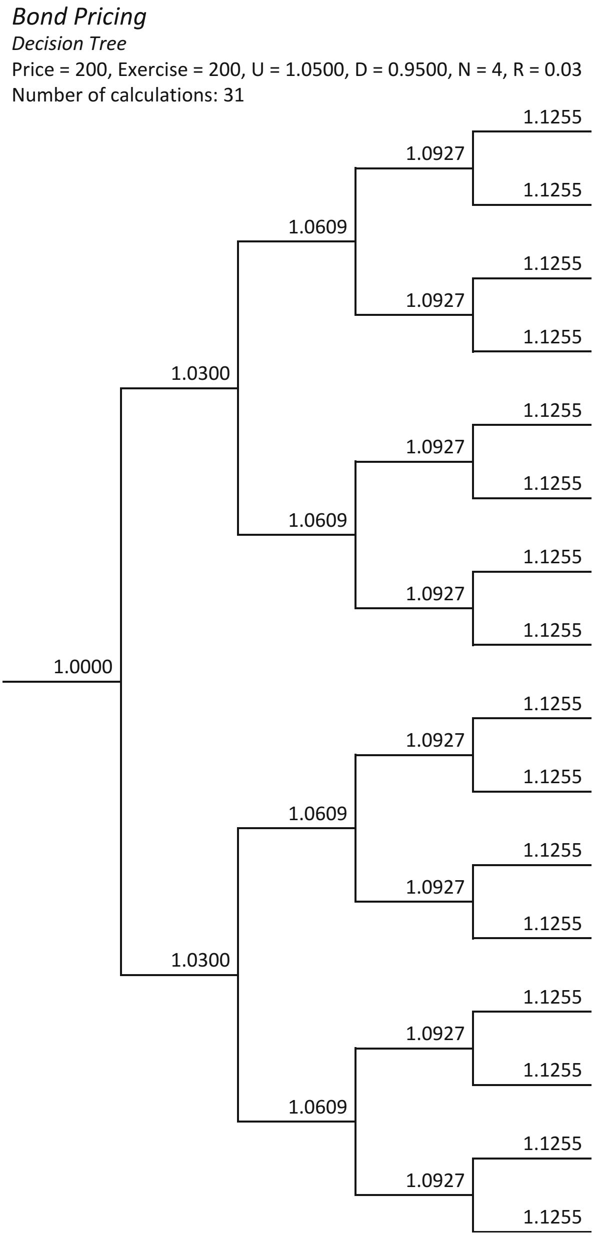

model prices European call and put options. The Black–Scholes model for a European call option is

$$C = SN(d1) - Xe^{-rT}N(d2) \tag{37.10}$$

where
C = call price
S = stock price
r = risk-free interest rate
T = time to maturity of option in years
N = standard normal distribution
σ = stock volatility

$$d1 = \frac{\ln(S/X) + \left(r + \frac{\sigma^2}{2}\right)T}{\sigma\sqrt{T}}$$
$$d2 = d1 - \sigma\sqrt{T}$$

Let's manually calculate the price of a European call option in terms of Eq. 37.10 with the following parameter values, S = 200, X = 200, r = 3 %, T = 4, and σ = 20 %.

Solution

$$d1 = \frac{\ln(S/X) + \left(r + \frac{\sigma^2}{2}\right)T}{\sigma\sqrt{T}} = \frac{\ln(200/200) + \left(.03 + \frac{.2^2}{2}\right)(4)}{.2\sqrt{4}} = \frac{(.03 + .02) * 4}{.4} = \frac{.2}{.4} = .5,$$
$$d2 = .5 - .2\sqrt{4} = .1$$

$$\begin{aligned} N(d1) &= 0.69146, N(d2) = 0.5398, e^{-rT} = 0.8869 \\ C &= (200) * (0.69146) - (200) * (0.8869) * 0.5398 \\ &= 138.292 - 95.74972 = 42.5422 \end{aligned}$$

The Black–Scholes put-call parity equation is

$$P = C - S + Xe^{-rT}$$

The put option value for the stock would be

$$\begin{aligned} P &= 42.54 - 200 + 200(0.8869) \\ &= 42.54 - 200 + 177.38 = 19.92 \end{aligned}$$

37.7 Relationship Between the Binomial OPM and the Black–Scholes OPM

We can use either the binomial model or Black–Scholes to price an option. They both should result in similar numbers. If we look at the parameters in both models, we will notice that the binomial model has an *Increase Factor* (*U*), a *Decrease Factor* (*D*), and *n*-period parameters that the Black–Scholes model does not have. We also notice that the Black–Scholes model has the σ and T parameters that the binomial model does not have. Benninga (2008) suggests the following translation between the binomial and Black–Scholes parameters:

$$\Delta t = \mathrm{T}/n \quad \mathrm{R} = e^{r\Delta t} \quad \mathrm{U} = e^{\sigma\sqrt{\Delta t}}\ \mathrm{D} = e^{-\sigma\sqrt{\Delta t}}$$

In the Excel program, shown in Appendix 1, we use Benninga's (2008) *Increase Factor* and *Decrease Factor* definitions. They are defined as follows:

$$q_U = \frac{\mathrm{R} - \mathrm{D}}{\mathrm{R}(\mathrm{U} - \mathrm{D})},\quad q_D = \frac{\mathrm{U} - \mathrm{R}}{\mathrm{R}(\mathrm{U} - \mathrm{D})}$$

where
$\mathrm{U} = 1$ + percentage of price increase
$\mathrm{D} = 1 -$ percentage of price increase
$\mathrm{R} = 1$ + interest rate

Binomial Call Price = 40.6705

Black-Scholes Call Price = 42.5356, d1 = 0.5000, d2 = 0.1000, N(d1) = 0.6915, N(d2) = 0.5398

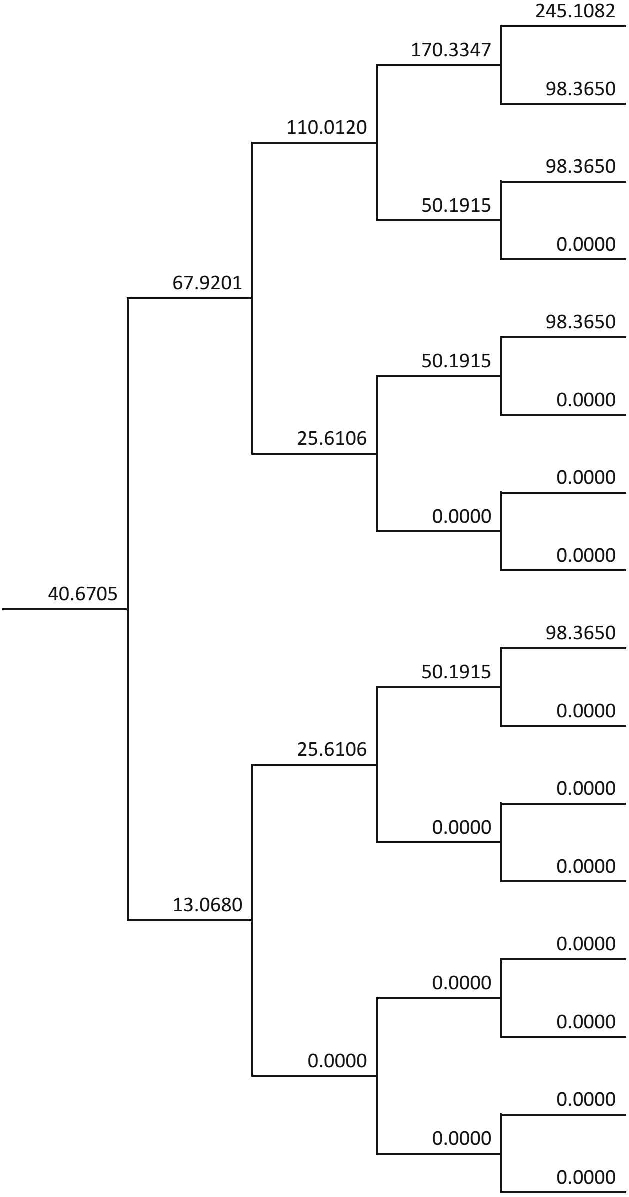

Fig. 37.23 Decision tree approximation of Black–Scholes call pricing

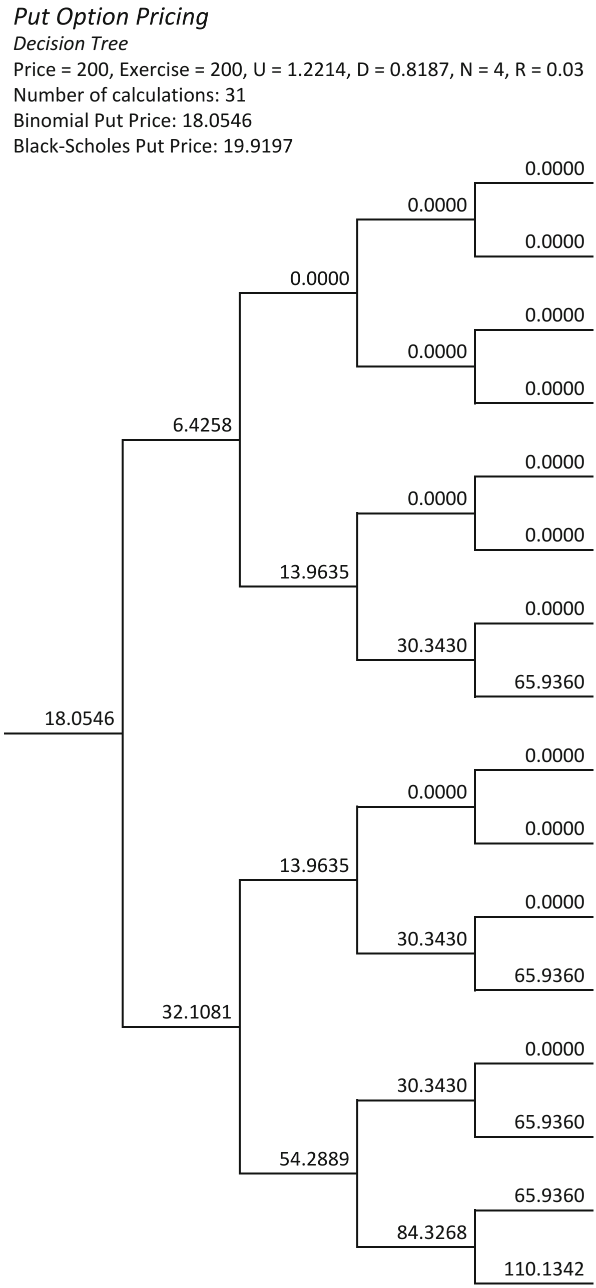

Fig. 37.24 Decision tree approximation of Black–Scholes put pricing

37.8 Decision Tree Black–Scholes Calculation

We will now use the *BinomialBS_OPM.xls* Excel file to calculate the binomial and Black–Scholes call and put values illustrated in Sect. 37.5. Notice that in Fig. 37.22 the *Binomial Black–Scholes Approximation* check box is checked. Checking this box will cause T and Sigma parameters to appear and will adjust the *Increase Factor – u and Decrease Factor – d* parameters. The adjustment was done as indicated in Sect. 37.7.

Notice in Figs. 37.23 and 37.24 that the binomial option pricing model value does not agree with the Black–Scholes option pricing model. The binomial OPM value will get very close to the Black–Scholes OPM value once the binomial parameter *n* gets very large. Benninga (2008) demonstrated that the binomial value will be close to the Black–Scholes when the binomial *n* parameter gets larger than 500.

37.9 Summary

This chapter demonstrated, with the aid of Microsoft Excel and decision trees, the binomial option model in a less mathematical fashion. This chapter allowed the reader to focus more on the concepts by studying the associated decision trees, which were created by Microsoft Excel. This chapter also demonstrates that using Microsoft Excel releases the reader from the computation burden of the binomial option model.

This chapter also published the Microsoft Excel Visual Basic for Application (VBA) code that created the binomial option decision trees. This allows for those who are interested in studying the many advance Microsoft Excel VBA programming concepts that were used to create the decision trees. One major computer science programming concept used by the Excel VBA program in this chapter is recursive programming. Recursive programming is the ideal of a procedure calling itself many times. Inside the procedure, there are statements to decide when not to call itself.

This chapter also used decision trees to demonstrate the relationship between the binomial option pricing model and the Black–Scholes option pricing model.

Appendix 1: Excel VBA Code: Binomial Option Pricing Model

It is important to note that the thing that makes Microsoft Excel powerful is that it offers a powerful professional programming language called Visual Basic for Applications (VBA). This section shows the VBA code that generated the decision trees for the binomial option pricing model. This code is in the form *frmBinomiaOption*. The procedure *cmdCalculate_Click* is the first procedure to run.

Abstract

The analyses of dividends paid by firms and decisions to repurchase their own shares require an econometric approach because of the complex dynamic interrelationships. This chapter begins by, first, highlighting the importance of developing comprehensive econometric models for these interrelationships. It is common in finance research to spell out "specific hypotheses" and conduct empirical research to investigate validity of the hypotheses. However, such an approach can be misleading in situations where variables are simultaneously determined as is often the case in financial applications. Second, financial and accounting databases such as Compustat are complex and contain useful longitudinal information on variables that display considerable heterogeneity across the firms. Empirical analyses of financial databases demand the use of econometric and computational methods in order to draw robust inferences. For example, using longitudinal data on the same US firms, it was found that dividends were neither "disappearing" nor "reappearing" but were relatively stable in the period 1992–2007 Bhargava (*Journal of the Royal Statistical Society A, 173*, 631–656, 2010). Third, the econometric methodology tackled the dynamics of relationships and investigated endogeneity of certain explanatory variables. Identification of the model parameters is achieved in such models by exploiting the cross-equations restrictions on the coefficients in different time periods. Moreover, the estimation entails using nonlinear optimization methods to compute the maximum likelihood estimates of the dynamic random effects models and for testing statistical hypotheses using likelihood ratio tests. For example, share repurchases were treated as endogenous explanatory variable in the models for dividend payments, and dividends were treated as endogenous variables in the models for share repurchases. The empirical results showed that dividends are decided quarterly at the first stage, and higher dividends payments lowered share repurchases by firms that are made at longer intervals. These findings cast some doubt on evidence for the simple "substitution" hypothesis between dividends and share repurchases. The appendix outlines some of the econometric estimation techniques and tests that are useful for research in finance.

Compustat database • Corporate policies • Dividends • Dynamic random effects models • Econometric methodology • Endogeneity • Maximum likelihood • Intangible assets • Model formulation • Nonlinear optimization • Panel data • Share repurchases

38.1 Introduction and Background

The proximate determinants of dividends payments by firms are of interest to researchers in economics and finance. From a historical perspective, Tinbergen (1939) proposed a model for predicting stock prices based on firms' earnings and dividends per share. Later, Lintner (1956) proposed a partial adjustment scheme for dividends and represented it by a first-order autoregressive ("dynamic") model where dividends per share in the current time period were a function of the previous levels. Such models were also employed in the economics literature to reflect "habit persistence" in the consumption function (Duesenberry 1949), i.e., current consumption depends on the past consumption. The work by Lintner (1956) was extended to data on US firms by Fama and Babiak (1968). However, the methods used in the early research for estimation of model parameters were rather elementary.

While data on macroeconomic variables such as consumption and income typically span for long periods and facilitate the estimation of econometric models (Koopmans 1950), the estimation of models using firm level data presents additional complications. For example, the large amount of heterogeneity across firms needs to be taken into account. Such issues are important for finance research because the neglect of unobserved between-firm differences can vitiate the consistency properties of the estimated model parameters. Moreover, financial databases such as (Compustat 2008) contain elaborate information at the firm level and several variables affecting dividend payments by firms need to be accounted for in the econometric models.

Further, shares repurchase, where firms purchase their own shares from stock holders and place them in "Treasury stock," have become popular since the 1980s in the United States and in the European Union (von Eije and Megginson 2008). Share repurchases reduce the numbers of shares held by investors ("common shares outstanding"), thereby increasing share values and hence are a form of payment to stock holders. It has also become popular for executives and employees of firms to receive part of their remuneration as options to purchase company stock at the current price in the future. The longitudinal information in financial data sets such as Compustat can facilitate the investigation of substantive issues such as the proximate determinants of dividend payments and the interrelationships between dividends and share repurchases by firms (e.g., Jagannathan et al. 2000; Fama and French 2001; Grullon and Michaely 2002; De Angelo et al. 2006; Skinner 2008; Bhargava 2010; Jones and Wu 2010).

Further, while analyses of the Compustat data can provide useful insights, methodological aspects are critical. For example, most previous analyses have not exploited the longitudinal ("panel") nature of the Compustat data. Instead, cross-sectional regressions have been estimated in different time periods for modeling firms' chances of paying dividends, i.e., dependent variables take the values 0 or 1 (Jagannathan et al. 2000; Fama and French 2001; De Angelo et al. 2006). In applications where longitudinal analyses were conducted for dividends payments (Skinner 2008), the model parameters were likely to be inconsistently estimated because the appropriate estimators for dynamic models were not employed. This chapter discusses several difficulties in the previous literature and presents findings on the interrelationships between dividends and share repurchases by over 2,000 US industrial firms (see Bhargava 2010).

First, it is essential to model the time structure of the interrelationships between dividends and share repurchases using longitudinal data on firms. While Lintner (1956) argued that firms may be reluctant to alter dividend rates, firms often adjust dividends per share to the market circumstances. Thus, classification of firms between dividend "payers" and "non-payers" is not a concrete one since a majority of firms may pay dividends during some periods. For example, using eight 2-yearly averages of dividends paid by a panel of 3,154 US industrial firms in the period 1992–2007 (i.e., for 1992–1993, 1994–1995, 1996–1997, 1998–1999, 2000–2001, 2002–2003, 2004–2005, 2006–2007), Bhargava (2010) found that 42 % of the firms never paid dividends, 33 % paid dividends in all 8 periods, and 25 % paid dividends in 1–7 periods. Moreover, dividends per share ranged from \$0.00 to \$67.61 so that it is appropriate to model the payments via continuous random variables (Fama and Babiak 1968). Similarly, firms' share repurchase are continuous variables and can be defined using the variables "Treasury stock," "purchase of common stock," and "sale of common stock." Using longitudinal data on 2,907 firms in 8 periods, 20 % of firms made no repurchases, 5 % repurchased shares in all 8 periods, and 75 % made 1–7 repurchases (Bhargava 2010). Thus, models with continuous dependent variables for dividends and share repurchases are suitable for analyses of payout decisions. Moreover, it is essential to use longitudinal data on the *same* firms for analyzing the interrelationships between dividends and share repurchases.

Second, from a methodological standpoint, the estimation of dynamic models from longitudinal data covering large number of firms observed for a few time periods requires the treatment of lagged dependent variables as "endogenous" variables that are correlated with firm-specific random effects (Anderson and Hsiao 1981; Bhargava and Sargan 1983); this issue will be discussed below and in the Appendix. Despite the popularity of Lintner (1956) type models in finance literature, such issues have seldom been addressed by researchers and critically affect consistency properties of the estimated model parameters. Moreover, it is informative to model the actual magnitudes of dividends and share repurchases, since these are likely to be related to firm characteristics such as size, earnings, and debt. It would also be useful to consider their joint determination; models for continuous dependent variables using longitudinal data can handle situations where some explanatory variables are correlated with errors affecting the models (Bhargava and Sargan 1983; Bhargava 1991).

Third, there has been a discussion in the finance literature regarding possible "substitution" between dividends payments and share repurchases by firms. While some researchers have argued that these payout methods may not be substitutes (e.g., John and Williams 1985), substitution of dividends by share repurchases (or vice versa) are consistent with certain economic formulations (Miller and Modigliani (1961). For example, Grullon and Michaely (2002) interpreted negative correlations between forecasting errors in changes in dividends and share repurchases as evidence of substitution. However, these issues demand an econometric approach for addressing the possible asymmetries and endogeneity in the relationships. For example, using the Compustat data on 2,800 industrial firms in the eight time periods noted above, bivariate correlations between dividends per share and repurchases were 0.11, 0.11, 0.08, 0.07, 0.11, 0.03, 0.05, and 0.06, respectively. These *positive* correlations were statistically significant; similar results were obtained for correlations between total dividend payments and share repurchases. Thus, investigation of possible substitution between dividends and share repurchases demands a comprehensive econometric framework (see below).

This chapter outlines a comprehensive analysis of the interrelationships between dividends and share repurchases using longitudinal Compustat data at 2-year intervals on over 2,000 US firms for the period 1992–2007 (Bhargava 2010). A brief discussion of issues arising in econometric methodology that is important for formulation of models and testing hypotheses in finance research is presented in Sect. 38.2. The analytical framework for dividends and share repurchase interrelationships is developed in Sect. 38.3, and econometric models embodying various hypotheses are outlined. In Sect. 38.4, Compustat variables are described and construction of the longitudinal data set is explained. For example, 2-yearly averages for variables are well suited for the analyses because share repurchases occur roughly at 2-year intervals (e.g., Stephens and Weisbach 1998); averaging also reduces the impact of missing values. The comprehensive econometric models for dividends and share repurchase relationships are outlined in Sect. 38.5. The econometric framework is outlined in Sect. 38.6 and it yields consistent and efficient estimates of model parameters; diagnostic tests for model adequacy and certain steps in the applications of the methods are outlined in the Appendix. The descriptive results from the Compustat data are in Sect. 38.7; results from estimating simple dynamic models for dividends and share repurchases are in Sect. 38.8. In Sect. 38.9, the results from estimating comprehensive dynamic econometric models for dividends and share repurchases are discussed. It is emphasized that one can draw robust conclusions from the estimated parameters of models that capture salient aspects of the various relationships. The conclusions are summarized in Sect. 38.10.

38.2 Specific Hypotheses, Financial Databases, and the Formulation of Econometric Models

It would be useful to discuss the role of conceptual aspects in the formulation of econometric models for finance relationships especially in the context of interrelationships between dividends and share repurchases. First, note that in biomedical sciences, randomized controlled trials are designed to investigate "specific hypotheses." The design of experiments is influenced by previous findings that are treated as assumptions in the trial (Cox 1958) and enable the investigation of specific hypotheses under consideration (Bhargava 2008). The validity of specific hypotheses is investigated using the emerging data from control and treatment groups of the trial. In contrast, finance researchers often spell out hypotheses that are influenced by economic postulates and investigate the support for the hypotheses using existing databases such as Compustat for the United States. However, the hypotheses driving the economic and finance investigation are often based on untested assumptions and/or "stylized facts" (Granger 1992). By contrast, assumptions invoked in biomedical sciences reflect the knowledge accumulated from previous experimental studies, and hypotheses are tested using the new data.

Further, in social sciences research, most phenomena being explained result from the interactions between economic and social factors. Because different dimensions of the relationships merit different emphasis depending on the context, social science researchers are forced to address several hypotheses simultaneously. Typically, this is done via formulation of comprehensive models where, for example, the systematic part of the relationships incorporates the relevant variables. The stochastic properties of the dependent variable and error terms are also tackled in the formulation of comprehensive econometric models.

The analyses of databases such as Compustat entail the modeling of accounting, finance, and economic variables so that financial research often demands econometric modeling of variables that are jointly determined. Moreover, economic theory is helpful in identifying variables and often implies restrictions on certain model parameters. Thus, investigation of hypotheses in finance applications entails the development of comprehensive econometric models within which several hypotheses can be embedded and tested using the estimated model parameters. This is in contrast with the approach in biomedical sciences where trials are designed to investigate specific hypotheses, and researchers are not concerned with interdependence between the variables. Thus, the currently popular approach in finance of spelling out a few specific hypotheses needs to be augmented by development of comprehensive econometric models reflecting the hypotheses. It is only *after* the estimation of comprehensive econometric models from databases such as Compustat that investigators can satisfactorily test the validity of specific hypotheses using statistical procedures.

As an illustration of the importance of methodological aspects for drawing inferences, it would be helpful to reappraise the work by Grullon and Michaely (2002) claiming empirical support for the "substitution" hypothesis between dividend payments and share repurchases. First, as noted in the Introduction, the correlations between dividend payments and share repurchases estimated from Compustat data were *positive* so the interrelationships are likely to be complex. Second, if dividends and share repurchases are substitutes, then they are likely to be simultaneously determined; modeling the interrelationships would require the use of econometric methods for handling endogenous explanatory variables in longitudinal analyses. Also, longitudinal data need to cover the *same* firms over time in order to shed light on the interrelationships. While such issues were not considered by Grullon and Michaely (2002), the authors explained forecasting errors in changes in dividends based on share repurchases and interpreted negative correlations as evidence for substitution hypothesis. However, dividends are announced quarterly, whereas share repurchases are made at 2–3-yearly intervals. Thus, the stochastic properties of variables cast doubt on adequacy of the models that explain a higher frequency variable such as dividends by the slowly changing share repurchases. In fact, it is likely that dividend payments that are made on a quarterly basis affect share repurchases but not vice versa. As shown below, firms' share repurchases are constrained by dividend payments and repurchases are relatively flexible (Bhargava 2010). Overall, from a methodological standpoint, it is important in financial analyses to develop comprehensive models *prior* to the testing of specific hypotheses.

38.3 Analytical Framework for Modeling the Dividends and Share Repurchases Interrelationships

38.3.1 Background Issues

The earliest dynamic model for dividends is given by Lintner (1956):

$$D_{i\,t} = a_{i\,t} + b\,P_{i\,t} + d\,D_{i\,t-1} + u_{i\,t} \quad (i = 1, 2, \ldots, H; t = 2, 3, \ldots, T) \tag{38.1}$$

For firm i in time period t, $D_{i\,t}$ is the dividend payment, $P_{i\,t}$ is profit or earnings, and $u_{i\,t}$ is a random error term; it is assumed that there are H firms in the sample that are observed in T time periods. The subsequent work by Fama and Babiak (1968) expressed dividends and earnings in per share terms. An important feature of these models is that the short-run effect of a unit increase in profit is given by b, while the long-run equilibrium impact is $[b/(1 - d)]$ with $|d| < 1$.

Explanatory variables such as firms' debt, assets, and investments can be included in Eq. 38.1. However, the estimation methods employed in previous research (Lintner 1956; Fama and Babiak 1968; Lee et al. 1987) were appropriate for time series data on a single firm rather than for a panel of firms. Because firms in Compustat and other databases are heterogeneous, it is important to include firm-specific "random" or "fixed" effects in the model. For example, treating the unobserved between-firm differences as randomly distributed variables, error terms $u_{i\,t}$ can be decomposed as:

$$u_{i\,t} = \delta_i + v_{i\,t} \tag{38.2}$$

where, δ_i are firm-specific random effects that follow some distribution (e.g., normal) with zero mean and constant variance, and $v_{i\,t}$ are distributed with zero mean and constant variance (Anderson and Hsiao 1981; Bhargava and Sargan 1983). Moreover, one can invoke the general assumption that $u_{i\,t}$'s are drawings from a multivariate distribution with a symmetric and positive definite dispersion matrix.

38.3.2 Some Conceptual Aspects of Dividends and Share Repurchase Interrelationships

From a conceptual standpoint, one would expect comprehensive models for dividends or dividends per share to resemble the dynamic model in Eq. 38.1, with additional explanatory variables such as firms' assets, debt, and investments (Bhargava 2010). Similar models can be developed for share repurchases that have become popular following the 1986 Tax Reform Act in the United States. However, there are likely to be asymmetries in the interrelationships between dividend payments and share repurchases. For example, firms regularly paying dividends may be reluctant to lower dividends in order to increase share repurchases since that might send ambiguous signals to investors. Thus, higher dividend payments are likely to lower firms' ability to make repurchases, i.e., in a model for repurchases, dividend payments are likely to be estimated with a negative coefficient. By contrast, decisions to make repurchases may be influenced by firms' unexpectedly large cash holdings (Guay and Harford 2000; Brav et al. 2005; Chen and Wang 2012) so that in a model for dividends, coefficient of share repurchases need not be statistically significant. These conceptual aspects can be embedded in a simultaneous equation model taking into account endogeneity of dividend payments and share repurchases (Sect. 38.5, below).

38.4 Processing the Compustat Database from the United States

Databases such as Compustat compile detailed information on accounting and finance variables for large numbers of firms listed on stock exchanges. However, many firms merge or exit after some years and are removed from the database. Cross-sectional studies analyzing data on firms for different years are therefore likely to include many firms that will be dropped in subsequent periods. From the standpoint of modeling the proximate determinants of dividends and share repurchases, this raises several issues. First, firms staying on the stock market for only a few time periods may typically pay small or no dividends. Also, the interrelationships between dividend payments and share repurchases require a longer time frame since dividends per share are announced on a quarterly basis, while share repurchases are made roughly at 2-year intervals. Thus, while cross-sectional analyses can provide insights, the interrelationships between dividend payments and share repurchases require that the *same* firms are observed for a certain number of years.

Second, there are trade-offs between analyzing longitudinal data that span long versus short time periods. If, for example, the data cover long periods of (say) over 30 years, then the number of firms in the sample is likely to be small and mainly the well-established firms will be included. By contrast, if one analyzes longitudinal data for only 5 years, then many firms included in the sample will be dropped from the stock exchange in later periods. In view of the fact that share repurchase decisions are made roughly at 2-year intervals, a reasonable approach would be to analyze data covering around 15 years. Moreover, one can create 2-yearly averages so that if observations were missing for a firm in one of the years, the firm could still be included in the sample. Since the data on executive compensation are available from 1992 (ExecuComp 2008), the sample period 1992–2007 is appealing (Bhargava 2011).

Third, even when the same firms are retained in the sample, there is large intra- and interfirm variation in financial variables. In the context of dividends, some problems can be tackled by expressing variables in per share terms (Fama and Babiak 1968). However, as recognized in the early statistical literature by Pearson (1897) and Neyman (1952), transforming variables into ratios can induce spurious correlations. Such practices were criticized by Kronmal (1993), Bhargava (1994) developed a likelihood ratio statistic for testing the restrictions on coefficients that enable expressing variables as ratios in empirical models. While research in finance often expresses variables in ratio forms, such transformation can affect the magnitudes and signs of estimated regression coefficients. It is important to conduct robustness check to ensure that transformation of variables do alter the conclusions.

Finally, there is often high inter- and intra-firm variation in variables such as share repurchases, assets, and debt that are measured in millions of dollars in the Compustat database. Transformations to natural logarithms can reduce internal variation in the data. For example, share repurchase can be expressed in dollars and then transformed into natural logarithms with zero dollar values set equal to one. This procedure facilitates the estimation of model parameters using numerical optimization techniques and obviates the need for arbitrarily truncating large values of variables (Bhargava 2010).

38.5 Comprehensive Empirical Models for Dividends and Share Repurchase Interrelationships

A dynamic random effects model for dividends per share adjusted for "stock splits" using cumulative adjustment factor (#27), with Compustat item numbers next to the variables, can be written as (Bhargava 2010):

$$\begin{aligned}
&(\text{Dividends per share; \#26, \#27})_{i\,t} = a_0 + a_1(\text{Earnings; \#18, \#17})_{i\,t} + a_2 \ln(\text{Total assets; \#6})_{i\,t} \\
&\quad + a_3(\text{Market-to-book value; \#199, \#25, \#60})_{i\,t} + a_4 \ln(\text{Long} - \text{term debt; \#9})_{i\,t} \\
&\quad + a_5 \ln(\text{Short-term investments; \#193})_{i\,t} + a_6(\text{Time dummy period 3})_{i\,t} \\
&\quad + a_7(\text{Time dummy period 4})_{i\,t} + a_8(\text{Time dummy period 5})_{i\,t} \\
&\quad + a_9(\text{Time dummy period 6})_{i\,t} + a_{10}(\text{Time dummy period 7})_{i\,t} \\
&\quad + a_{11}(\text{Time dummy period 8})_{i\,t} + a_{12}(\text{Dividends per share; \#26, \#27})_{i\,t-1} \\
&\quad + u_{i\,t}\ (i = 1, 2, \ldots, H;\, t = 2, 3, \ldots, 8)
\end{aligned} \tag{38.3}$$

In the empirical model in Eq. 38.3, it is recognized that firms sometimes split their shares especially if share prices are high. Earnings are defined as "income before extraordinary items" (#18) minus 0.6 times "special items" (#17), measured in million of dollars (Skinner 2008). Income before extraordinary items is the firms' incomes taking into account all expenses, while special items reflect adjustments for debts and losses. “Total assets” (#6), “long-term debt” (#9), and “short-term investments” (#193) were expressed in dollars and then converted into natural logarithms. The “market-to-book value” variable was constructed by multiplying “share price” (#199) by number of “common shares outstanding” (#25) and dividing this product by “common equity total” (#60). “Dividends per share” in period $(t-1)$ will be referred to as “lagged dependent variable.” Models of the type in Eq. 38.3 were also estimated for dividends expressed as ratios to firms’ book values, while dropping the explanatory variable market-to-book value from Eq. 38.3.

It is assumed in Eq. 38.3 that 8-time observations at 2-yearly intervals {1992–1993, 1994–1995, 1996–1997, 1998–1999, 2000–2001, 2002–2003, 2004–2005, 2006–2007} were available on H firms. Moreover, as explained in Sect. 38.6 and the Appendix, initial values of the dependent variable in time period 1 were modeled using a “reduced form” equation that includes a separate coefficient, c_0, for the constant term. Thus, the model in Eq. 38.3 includes separate coefficients of the constant term for each of the 8-time periods. This formulation allows the variables in the model to have different means in the 8-time periods and is useful if there are trends in the dependent variables in the observation period.

Further, $u_{i\,t}$’s are error terms that can be decomposed in the simple random effect fashion as in Eq. 38.2. The variance of $v_{i\,t}$ is the “within” (or intra-) firm variance, and [var (δ_i)/var (v_{it})] is the “between-to-within” variance ratio that can be estimated when errors are decomposed as in Eq. 38.2. In another version of the model in Eq. 38.3, firms’ intangible assets (Compustat item #33) were included in the model, though greater numbers of observations were missing for this variable. Also, firms’ share repurchases were introduced as potentially endogenous explanatory variables to test if they influenced dividend payments. Last, static versions of the model in Eq. 38.3 that excluded the lagged dividends were estimated to assess robustness of the results.

The model for share repurchases was similar to that in Eq. 38.3 except that dividends per share were included as a potentially endogenous explanatory variable:

$$\begin{aligned}
&\ln(\text{Share repurchases};\#226,\#115,\#108)_{i\,t} = b_0 + b_1(\text{Earnings};\#18,\#17)_{i\,t}\\
&\quad + b_2 \ln(\text{Total assets};\#6)_{i\,t} + b_3\,(\text{Market-to-book value};\#199,\#25,\#60)_{i\,t}\\
&\quad + b_4 \ln(\text{Long-term debt};\#9)_{i\,t} + b_5 \ln(\text{Short-term investments};\#193)_{i\,t}\\
&\quad + b_6\,(\text{Time dummy period 3})_{i\,t} + b_7\,(\text{Time dummy period 4})_{i\,t} + b_8(\text{Time dummy period 5})_{i\,t}\\
&\quad + b_9\,(\text{Time dummy period 6})_{i\,t} + b_{10}\,(\text{Time dummy period 7})_{i\,t} + b_{11}(\text{Time dummy period 8})_{i\,t}\\
&\quad + b_{12}\,(\text{Dividends per share};\#26,\#27)_{i\,t} + b_{13} \ln(\text{Share repurchases};\#226,\#115,\#108)_{i\,t-1}\\
&\quad + u_{2\,i\,t} \quad (i = 1,2,\ldots,H;\, t = 2,3,\ldots,8)
\end{aligned} \tag{38.4}$$

Note that share repurchases were defined as the change in “Treasury stock” (#226), and if this was less than or equal to zero for the firm, the nonnegative difference between “purchase of common stock” (#115) and “sale of common stock” (#108) was used (Fama and French 2001). This definition covered the situation where firms "retire" shares from Treasury stock so that when the change in Treasury stock was less than or equal to zero, nonnegative difference between purchase of common stock and sale of common stock was used as the measure of repurchases. Banyi et al. (2008) have advocated the use of purchase of common stock as a measure of repurchases, and this variable was also modeled to assess robustness of the results. Finally, alternative models for share repurchases were estimated with intangible assets included as an explanatory variable, and also where dividends per share was replaced by dividends expressed as ratios to firms' book values.

38.6 The Econometric Framework for Addressing Simultaneity and Between-Firm Heterogeneity

The methodology used for estimation of dynamic and static random effect models, where some explanatory variables are endogenous, was developed in Bhargava and Sargan (1983) and Bhargava (1991). Let the dynamic model be given by:

$$y_{i\,t} = \sum_{j=1}^{m} z_{i\,j}\gamma_j + \sum_{j=1}^{n_1} x_{1\,i\,j\,t}\beta_j + \sum_{j=n_1+1}^{n} x_{2\,i\,j\,t}\beta_j + \alpha\, y_{i\,t-1} + u_{i\,t} \quad (i = 1, 2, \ldots, H;\, t = 2, 3, \ldots, T) \tag{38.5}$$

where z's are time-invariant variables, x_1 and x_2 are, respectively, n_1 exogenous and n_2 endogenous time-varying variables ($n_1 + n_2 = n$). In the model for share repurchases, for example, dividends per share is potentially an endogenous time-varying variable; unobserved factors affecting share repurchases, reflected in firm-specific random effects (δ_i) in Eq. 38.2, can influence dividend payments. For exposition purposes, first assuming that all time-varying variables are exogenous so that $n_2 = 0$ and subscripts on the x variables can be dropped, the dynamic model can be written in a simultaneous equations framework by defining a "reduced form" equation for initial observations that do not include any endogenous explanatory variables, and a "triangular" system of (T-1) "structural" equations for the remaining periods (Bhargava and Sargan 1983):

$$y_{i\,1} = \sum_{j=1}^{m} z_{i\,j}\zeta_j + \sum_{j=1}^{n}\sum_{k=1}^{T} \upsilon_{j\,k} x_{i\,j\,k} + u_{i\,1} \quad (i = 1, \ldots, H) \tag{38.6}$$

And

$$\underset{(T-1)\mathrm{x}T}{B}\ \underset{T\mathrm{x}H}{Y'} + \underset{(T-1)\mathrm{x}\,m}{C_z}\ \underset{m\mathrm{x}H}{Z'} + \underset{(T-1)\mathrm{x}\,nT}{C_x}\ \underset{nT\mathrm{x}H}{X'} = \underset{(T-1)\mathrm{x}H}{U'} \tag{38.7}$$

Here, Y, Z, and X are, respectively, matrices containing observations on the dependent, time-invariant, and time-varying explanatory variables; dimensions of the matrices are written below the respective symbols. B is a (T−1) x T lower triangular matrix of coefficients:

$$B_{i\,i} = \alpha, B_{i,i+1} = -1, B_{i\,j} = 0 \text{ otherwise} \quad (i = 1, \ldots, T-1; j = 1, \ldots, T) \tag{38.8}$$

where α is the coefficient of lagged dependent variable. Matrices C_z and C_x contain coefficients of time-invariant and time-varying regressors, respectively; U contains the error terms.

Note that in the reduced form Eq. 38.6, all T realizations of the n exogenous time-varying variables appear as explanatory variables for modeling the systematic or predicted part of $y_{i\ 1}$. Because maximum likelihood or instrumental variable methods treat $\{y_{i\ 1}, y_{i\ 2}, \ldots, y_{i\ T}\}$ as jointly determined variables, it is essential to explain the reduced form Eq. 38.6 using all exogenous variables in the model. The estimation of model parameters and certain econometric tests are described in the Appendix.

38.7 Descriptive Statistics from the Annual Compustat Database

The Compustat annual data on firms for the period 1992–2007 were processed for the analyses (Bhargava 2010). As is customary in the dividends literature, financial firms with Standard Industry Classification (SIC) codes between 6,000 and 6,999 and utility firms with SIC codes between 4,900 and 4,949 were dropped since there are regulations on dividend payments by such firms (Fama and French 2001). Moreover, observations were retained on firms that were in the Compustat database for at least 14 years, and 2-yearly averages were created at 8-time points, i.e., for {1992–1993, 1994–1995, 1996–1997, 1998–1999, 2000–2001, 2002–2003, 2004–2005, 2006–2007}. An alternative data set created 3-yearly averages at 5-time points, i.e.,{1992–1994, 1995–1997, 1998–2000, 2001–2003, 2004–2006}, though the analyses of the 2-yearly averages led to more robust parameter estimation. Averaging over 2 years led to a sample of 3,290 industrial firms observed in 8-time periods. Also, estimation of dynamic models requires "balanced" panels, i.e., where firms are included at all eight time points. While it is possible to analyze "unbalanced" panels using static models in software packages such as Stata (2008), it is difficult to address endogeneity issues in the analyses.

The sample means and standard deviations of 2-year averages of variables are reported in Table 38.1 for some of the years with Compustat annual item numbers noted next to the variables. The mean dividends per share were approximately \$0.32 for the period 1992–1999, and declined slightly to \$0.27 for 2000–2003, and increased to \$0.39 in 2006–2007. While a simple paired *t*-test on the set of firms' observations showed significant ($P < 0.05$) increase in dividends per share between

Table 38.1 Sample means and standard deviations of 2-yearly averages of selected variables from the Compustat database for up to 3,290 US industrial firms in 1992–2007

Means and standard deviations of variables using 2-yearly averages at four time points for up to 3,290 US industrial firms observed for at least 14 years in 1992–2007 (Source: Bhargava 2010); specific number of firms included depends on the extent of unavailable information for each variable in each period; Compustat items and units of measurements are listed next to variables

[a]Percentages are based on firms' with nonzero payments

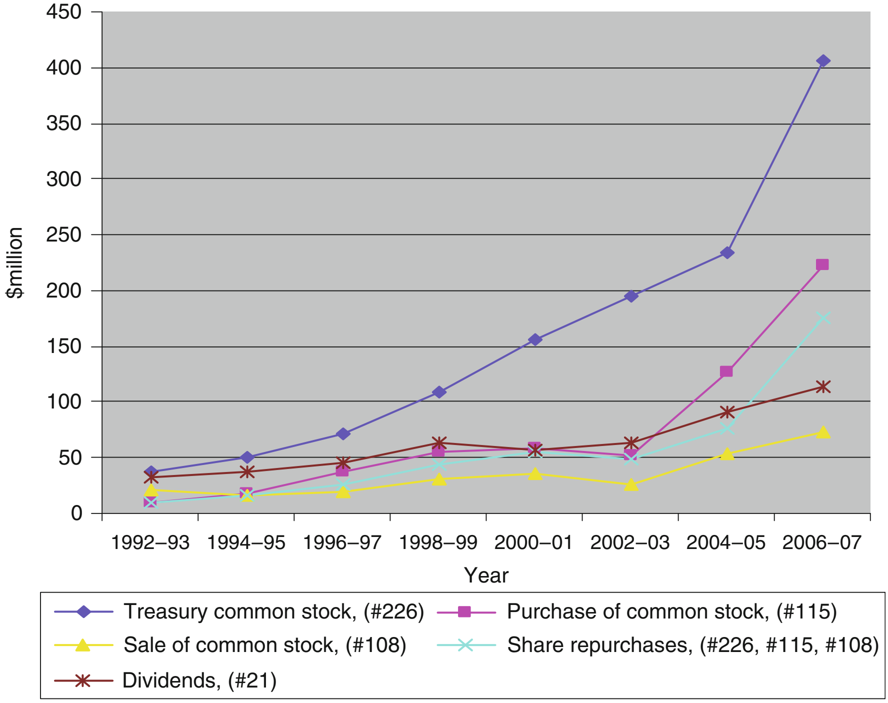

Fig. 38.1 Sample means of dividends and components of share repurchases by US industrial firms for 1992–2007. Share repurchases were calculated as the change in Treasury stock (#226), and if this was less than or equal to zero, the nonzero difference between purchase of common stock (#115) and sale of common stock (#108) was used (Source: Bhargava 2010)

1992–1993 and 2006–2007, the pattern over time was more complex partly because of tax changes in 2003. Mean share repurchases increased from \$10 million in 1992–1993 to \$175 million in 2006–2007.

Figure 38.1 plots the sample means (in \$ millions) of Treasury stock, purchase of common stock, sale of common stock, dividends, and share repurchases. There were upward trends in Treasury stock, share repurchases, and purchases of common stock. There was an increase in dividends in the period from 2002–2003 to 2006–2007, where dividends increased from \$63 million to \$113 million. This could be due to reductions in 2003 in tax rates on dividends (Julio and Ikenberry 2004).

Further, focusing on 2,880 firms with non-missing observations on dividends and share repurchases, percentages of firms paying dividends and making share repurchases in the 8-time periods, were {36.5, 39.9, 40.6, 40.8, 39.6, 39.9, 43.7, 44.0} and {26.3, 30.7, 38.2, 49.8, 48.1, 37.9, 38.1, 43.5}, respectively. While percentages of firms making share repurchases increased from 26.3 in 1992–1993 to 43.5 in 2006–2007, the peak of 49.8 % was reached in the 1998–1999 period. The mean share repurchases in 1998–1999 were 44.44 million, while they amounted to \$174.77 million in 2006–2007 so that share repurchases were significantly higher in 2006–2007 after adjusting for the price level. The other salient feature of the Compustat data was that the mean intangible assets increased from \$99.9 million in 1992–1993 to \$980.2 million in 2006–2007 constituting a tenfold increase.

38.8 Results from Simple Dynamic Models for Dividends and Share Repurchase Controlling for Between-Firm Heterogeneity

The results from estimating simple dynamic random effects models for dividends per share are in Table 38.2 for the sample of 3,113 industrial firms (Bhargava 2010). The results are presented for the cases where firms paid nonzero dividends at least in one of the eight time periods and where firms paid dividends in all 8-time periods. The results for ratios of dividends to book value of firms are presented in the last column of Table 38.2. A set of six dummy variables for time periods 3–8 was included to account for differences in dividend payments in the 8-time periods. The models were estimated by maximum likelihood and provide consistent and efficient estimates of the parameters.

For the pooled sample, coefficients of the dummy variables in the model for dividends per share were positive and significant ($P < 0.05$) in time periods 7 and 8 corresponding to 2004–2005 and 2006–2007, respectively. The positive coefficients were consistent with reported increases in dividends following reduction in tax rates in 2003. Coefficients of the dummy variables were qualitatively similar for the reduced sample of 1,827 firms that paid dividends at least in one of the eight periods and in the case where 1,035 firms paid dividends in all eight periods. Moreover, coefficients of the dummy variables for time periods 7 and 8 corresponding to 2004–2005 and 2006–2007, respectively, were approximately twice as large for firms paying dividends than for firms that never paid dividends. Thus, reduction in tax rates on dividends in 2003 appeared to have increased dividends per share. These results also show the robustness of dynamic models in situations where firms decide against paying dividends in some time periods, i.e., to zero values of the dependent variables. This is not surprising since one is modeling the deviations of dividends per share from an overall mean.

The coefficients of the lagged dependent variables for the first three cases presented in Table 38.2 were close to 0.28. Moreover, the ratios of between-to-within variances for the three cases, i.e., pooled sample, firms paying nonzero dividends at least once, and firms paying dividends in all 8 periods were, 0.38, 0.33, and 0.45, respectively. These estimates were close despite reduction in sample size from 3,113 firms in the pooled sample to 1,035 in the case of firms paying nonzero dividends in all 8 periods. The within firm variances for the three cases were 0.52, 0.88, and 1.07, respectively. Finally, in the last column, the results for the ratio of dividends to firms' book values were similar to those for the pooled sample for dividends per share. While the estimated coefficient of lagged dependent

*$P < 0.05$

variable was very close (0.29), the estimated between-to-within variance ratio was 0.016 that was lower than the corresponding estimate (0.38) in the model for dividends per share.

The results from simple dynamic models for logarithms of US firms' share repurchases are in Table 38.3 for the three cases, i.e., pooled sample, firms making at least one repurchase, and firms making repurchase in all 8-time periods. For the pooled sample of 2,907 firms, coefficients of dummy variables for five of the time periods were positive and statistically significant; coefficient of the dummy variable for time period six corresponding to 2002–2003 was not significant. The results were very similar for the case where 2,329 firms made repurchases at least once. The dummy variables were generally insignificant in the third case for firms making repurchases in all 8 periods; there were 127 firms in this group which was a small sample size for estimating dynamic models.

The coefficients of lagged dependent variables in the three cases were 0.36, 0.35, and 0.75, respectively; these estimates were significantly less than unity thereby indicating that share repurchase series were stationary. The between-to-within variance ratios for the three cases were 0.15, 0.07, and 0.18, respectively; within firm variances were quite large in these models. The higher coefficient of lagged dependent variable in the model where 127 firms made repurchases in all 8 periods may be due to the small sample size. Moreover, such firms may have been less heterogeneous in some respects and had a smooth pattern of share repurchases. Such issues can be systematically investigated by controlling for firm characteristics and are addressed below.

38.9 Results from Comprehensive Dynamic Models for Dividends and Share Repurchases

The results from empirical models for dividends per share and share repurchases, outlined in Eqs. 38.3 and 38.4, are presented in this section. Dynamic and static random effects models were estimated and the results are initially presented for the pooled samples and for the case where firms paid dividends or made repurchases at least once during 8-time periods.

38.9.1 Results from Dynamic and Static Models for Firms' Dividends per Share

Table 38.4 presents the results from dynamic and static models for dividends per share paid by US industrial firms; a set of six dummy variables for time periods was included in the models though the coefficients are not reported (Bhargava 2010). The firms' total assets, long-term debt, and short-term investments were expressed in dollars and converted to natural logarithms. Because firms' earnings were defined as the difference between income before extraordinary items and special items, this variable sometimes assumed negative values and was not transformed into logarithms.

For the dynamic model estimated using the pooled sample, coefficient of earnings was estimated with a positive coefficient that was statistically significant. The coefficients of earnings and total assets were also significant in the static model for the pooled sample and in dynamic and static models for the subsample where firms paid dividends at least once during the 8-time periods. These results provide evidence that earnings and total assets of US firms were positively and significantly associated with dividends per share. By contrast, Skinner (2008, Table 8) found these variables to be generally insignificant predictors of the ratio of dividends to total payout (dividends plus repurchases) using cross-sectional regressions and data on 345 US firms. When some of the coefficients were statistically significant, they were positive for some years and negative for others. The contradictory findings were likely to be due to combining dividends and share repurchases into a single variable and using estimation methods that are appropriate for cross-sectional analyses. The results in Table 38.4, however, were consistent with evidence from the European Union (von Eije and Megginson 2008), where static random effects models were estimated using unbalanced panel data on approximately 3,000 firms.

*$P < 0.05$

The variable market-to-book value was not statistically significant in the dynamic and static models estimated from the pooled or disaggregated samples. Because market-to-book value is a composite variable based on Compustat items price, common shares outstanding, and common equity total, it may be difficult to unscramble the effects on dividend payments. Coefficients of long-term debt were not statistically significant in the four cases reported in Table 38.4. Because firms may be reluctant to frequently alter dividend policy, it is likely that long-term debt might influence share repurchases rather than dividends. Coefficients of short-term investments were positively and significantly associated with dividends per share in the dynamic and static models estimated using the subsample of firms that paid dividends at least once.

The coefficients of lagged dependent variables from the pooled sample and the subsample of firms paying dividends at least once were 0.20 and 0.19, respectively. These coefficients implied that the long-run effects of explanatory variables were 1.25 times the respective short-run effects reported in Table 38.4. Moreover, the ratios of between-to-within variance in the two dynamic models were 0.13 and 0.11, respectively. While these ratios were smaller than those reported in Table 38.2 for simple dynamic models for dividends per share (0.38 and 0.33, respectively), the estimates suggest that some heterogeneity across firms could not be accounted for by explanatory variables in the models. The within firm variances in the two dynamic models were 0.61 and 0.98. Overall, the results in Table 38.4 supported the view that larger firms paid higher dividends per share.

38.9.2 Results from Dynamic and Static Models for Firms' Share Repurchases

The results for logarithms of share repurchases by US industrial firms are in Table 38.5 for the pooled sample and for firms making repurchases at least once in the sample period. As in the results from the model for dividends per share, firms' earnings and total assets were estimated with significant positive coefficients in dynamic and static models for the pooled sample and for the subsample of firms making repurchases at least once. Coefficients of the logarithm of total assets in dynamic models were the short-run "elasticities" of share repurchases with respect to total assets, i.e., 0.61 and 0.78, respectively, for the pooled sample and subsample of firms making repurchases. Because coefficients of lagged dependent variables were approximately 0.40 in this model, the long-run effects were about 1.67 times the respective short-run effects. For example, the long-run elasticity of share repurchases with respect to total assets was 1.02 and this was larger than the point estimate (0.70) from the static model for the pooled sample. Similarly, short- and long-run elasticities of share repurchases with respect to total assets for firms making repurchases at least once were 0.78 and 1.33, respectively. Thus, the size of the firm was an important determinant of magnitudes of share repurchases. However, there were no nonlinearities apparent with respect to firms' earnings and total assets, i.e., squared terms of these variables were not significant predictors of share repurchases.

Table 38.5 Maximum likelihood estimates from comprehensive dynamic and static random effects models for 2-yearly averages of share repurchases by US industrial firms in 1992–2007

*$P < 0.05$

In all the models in Table 38.5, firms' market-to-book value ratio was estimated with negative and significant coefficients in the dynamic and static models using the pooled and disaggregated samples. Thus, firms with higher market-to-book value ratio made lower share repurchases. Also, firms' long-term debt was estimated with negative and significant coefficients in dynamic models from the pooled sample and from the subsample of firms making repurchases at least once. The short-run elasticity from the pooled sample was −0.02, while the long-run elasticity was −0.03. Doubling of firms' long-term debt predicted a 3 % decline in long-run share repurchases. The coefficients of short-term investments were not significant in any of the models in Table 38.5.

An important aspect of the results in Table 38.5 was that the estimated coefficients of dividends per share were negative and statistically significant in the dynamic and static models for the pooled sample and for the subsample of firms that made at least one repurchase. Thus, controlling for factors such as earnings and size of the firm, firms paying higher dividends per share made significantly lower share repurchases. The short-run effects of dividends per share on share repurchases were −0.20 and −0.18, respectively, for the pooled sample and subsample of firms making repurchases; the respective long-run effects were −0.33 and −0.30. The relatively large magnitudes of these effects indicated that firms with higher dividend payments were likely to make smaller share repurchases.

Last, exogeneity hypotheses for dividends per share were accepted at the 5 % level using test statistics that were distributed as Chi-square variables with 8° of freedom (5 % critical limit of Chi-square (8) = 15.5). The values of Chi-square statistics around 12 in Table 38.5 indicated that there might be some dependence in the unobserved components of firms' decisions to pay dividends and make share repurchases though it was not significant at the 5 % level. Such hypotheses will be tested below for the effects of share repurchases on firms' dividend payments.

38.9.3 Results from Dynamic and Static Models for Dividends per Share with Share Repurchases and Intangible Assets Included as Explanatory Variables

The results from models for dividends per share and ratios of dividends to firms' book value, with share repurchases included as a potentially endogenous explanatory variable, are in Table 38.6; firms' intangible assets were included in these models. Because short-term investments were not significant predictors of share repurchases in Table 38.5, this variable was dropped from the models for dividends and share repurchases in Tables 38.6 and 38.7, respectively. There were greater number of missing observations on intangible assets and sample sizes in Table 38.6 were lower than sample sizes in Table 38.4.

The noteworthy feature of the results for dividends per share in Table 38.6 was that coefficients of share repurchases was estimated with a small negative coefficient (−0.004) in the dynamic model that reached statistical significance at the 5 % level. However, this coefficient from the static model was 0.0002 and was not

Dependent variable share repurchases were based on items #226, #115, and #108 (Source: Bhargava 2010); Specification 1 included dividends per share as explanatory variable, while Specification 2 included dividends expressed in terms of book values; 8-time observations at 2-yearly intervals on firms in 1992–2007 were used; slope coefficients and standard errors are reported; time dummies for 6 periods were included though their coefficients are not reported

*$P < 0.05$

significant. Also, coefficients of share repurchases in the model for the ratio of dividends to book value were statistically not different from zero. Exogeneity hypotheses for share repurchases could not be rejected using the Chi-square statistics in dynamic and static models for dividends per share and for the ratio of dividends to firms' book value. Because share repurchases in the comprehensive models generally did not affect dividend payments, it seems likely that firms decided their dividends payments at an earlier stage than share repurchases. By contrast, dividends per share were significant predictors of share repurchases in Table 38.5.

Another important finding in Table 38.6 was that intangible assets were estimated with negative and significant coefficients in dynamic and static models for dividends per share. The results for other explanatory variables were similar to those presented in Table 38.4, thereby showing robustness of the estimates to changes in model specification and to reductions in sample sizes due to greater number of missing observations on intangible assets.

38.9.4 Results from Dynamic and Static Models for Share Repurchases with Intangible Assets Included as Explanatory Variables

Table 38.7 presents the results for logarithms of share repurchases with intangible assets included as explanatory variables in the models; in Specification 2, dividends per share were replaced by the ratio of dividends to firms' book values. The results in Table 38.7 showed that intangible assets were positively and significantly associated with share repurchases. This was in contrast with the results in Table 38.6 where intangible assets were negatively associated with dividends per share. Thus, firms possessing higher intangible assets paid lower dividends per share and made greater share repurchases; these results indicate the inappropriateness of modeling the ratio of dividend payments to total payouts (Skinner 2008). Furthermore, while intangible assets have received attention in the literature (Lev 2001), their effects on dividends and share repurchases have not been rigorously investigated. For example, it has been suggested that information technology firms may pay low (or zero) dividends and make frequent repurchases in part because they have higher investments in research and development. A dummy variable was created using SIC codes for information technology firms in manufacturing, transportation, and communications sectors. However, the estimated coefficient was not significantly different from zero. Thus, the reported coefficients in Table 38.7 appear not to suffer from biases due to omission of such variables.

Further, dividends per share and the ratio of dividends to book value were negatively and significantly associated with share repurchases, with large magnitudes of the estimated coefficients. Thus, the models with intangible assets as an explanatory variable again showed that firms paying higher dividends made smaller share repurchases. Also, exogeneity hypothesis for dividends-to-book value ratio was close to rejection using the Chi-square statistic at 5 % level in the static model.

The rejection of the null indicated that there was some dependence in the unobserved factors affecting the firms' decisions to pay dividends and make share repurchases. For example, if firms made "unexpectedly" large share repurchases, then such decisions in turn can affect dividend payments.

Finally, in view of the literature on choice of measures for share repurchases (Banyi et al. 2008), the variable "purchase of common stock" was used as a proxy for share repurchases, and dynamic and static models were estimated. The results from modeling purchase of common stock were similar to those reported in Tables 38.5 and 38.7 using the more complex definition of share repurchases. However, greater numbers of observations were missing on purchase of common stock variable and these were reduced in the more complex definition because changes in Treasury stock were often positive so that the purchase of common stock variable was not utilized. Overall, the results indicated that these two measures for share repurchases yield similar results, perhaps because the models captured many salient features of the interrelationships.

38.10 Conclusion

This chapter presented a detailed analysis of the interrelationships between dividend payments and share repurchases by US industrial firms and modeled the proximate determinants of the payout methods (Bhargava 2010). The usefulness of analyzing longitudinal Compustat data on large number of firms and of appropriate econometric estimators was underscored. The empirical results provided several insights that can be summarized as follows. First, the magnitudes of dividends per share and dividend payments were broadly stable over the period of 1992–2007 using the data on the *same* firms. Moreover, simple dynamic models showed that dividends were higher in the period 2003–2007, following reduction in tax rates in 2003. These results were in some contrast with previous cross-sectional findings where entry and exit by firms in the Compustat database affected the numbers of firms paying dividends and magnitudes of dividend payments. For example, dividends were not seen to be "disappearing" (Fama and French 2001) and, apart from the effects of the tax cut in 2003, dividends were not "reappearing" (Julio and Ikenberry 2004). The simple dynamic models for share repurchases indicated steady increases in the period 1992–2007.

Second, the analytical and econometric frameworks led to comprehensive dynamic models for dividends per share and repurchases. The empirical results showed that variables such as firms' earnings, total assets, and investments were positively and significantly associated with dividends per share. Similar results were found for share repurchases, though firms' long-term debt was negatively and significantly associated with repurchases but was significantly associated with dividends only in a few models. Moreover, while dividends per share were negatively and significantly associated with share repurchases, coefficients of share repurchases were generally insignificant in the models for dividends. Exogeneity hypotheses for dividends per share were accepted in most models for repurchases, and exogeneity of share repurchases was also accepted in the models for dividends. These results suggest that firms' decisions to pay dividends at particular rates are taken prior to the decisions to repurchase shares that are more strongly influenced by the firms' current financial situations. For example, while firms can adjust repurchases given their debt levels, it may be more difficult to alter dividend payments. Thus, interpreting negative correlations between dividend forecasting errors and share repurchases as evidence of "substitution" between payment forms (Grullon and Michaely 2002) seems inconsistent with the elaborate two stage decision process documented by econometric analyses of the longitudinal Compustat database.

Third, the effects of firms' intangible assets on dividends per share were negative and significant, while these coefficients were positive and significant in the models for share repurchases. Such findings indicate that it is appropriate to model the two payout methods via separate models rather than combining them into a single variable. These results support the insights of Pearson (1897) and Neyman (1952) cautioning against employing ratios of variables in applied work. Such problems are exacerbated in longitudinal data analyses because stochastic properties of variables combined can evolve differently over time. It might have been useful to disaggregate intangible assets into components such as goodwill since they may differentially affect dividends and repurchase decisions. Because of missing observations on such variables in the Compustat database, further analyses were not pursued.

Finally, while econometric methods were useful for modeling the dynamic interactions between dividend payments and share repurchases, it is important in future research to investigate the role played by executive remuneration or compensation in making such allocations. Options to purchase company stock at some point in the future are regularly granted to the top executives and other employees of US firms and these may have potentially increased firms' share repurchases. If such decisions in turn reduce funds available for investment and research and development, then tax policies should discourage excessive repurchase activity. The ExecuComp (2008) database contains information on salary, bonus, and stock options granted to top executives of approximately 1,500 US firms from 1992. A recent analysis of the merged ExecuComp and Compustat databases in fact showed that beyond certain thresholds, share repurchases lower firms' expenditures on research and development and investments and should be discouraged (Bhargava 2012).

Appendix

The concentrated or "profile" log-likelihood functions of the model in Eq. 38.3 was computed by a FORTRAN program and was optimized using the numerical scheme

E04 JBF from Numerical Algorithm Group (1991). Note that the data were read firm-by-firm and several second moment matrices were created. Thus, there was no limit on the number of firms in the sample. The profile likelihood function, which depends only on the structural form parameters of interest, was computed using the second moment matrices. FORTRAN programs for the computations of the likelihood functions are available on request from the author.

The likelihood functions were separately computed for the case where the variance-covariance matrix of the errors was unrestricted and where the errors were decomposed in a random effect fashion, as in Eq. 38.2. Likelihood ratio tests were applied to discriminate between these two alternative formulations. Assuming that the number of firms (H) is large but the number of time observations is fixed, asymptotic standard errors of the parameters were obtained by approximating second derivatives of the functions at the maximum.

Further, assuming that n_1 and n_2 time-varying variables are exogenous and endogenous, respectively, as in Eq. 38.5, one can tackle the correlation between the errors u's and x_2's. It is reasonable to assume in short panels that a variable such as dividends per share in Eq. 38.5 may be correlated only with firm-specific random effects δ_i. Thus, the correlation pattern can be decomposed as:

$$x_{2ijt} = \lambda_j \delta_i + x^*_{2ijt} \tag{38.9}$$

where x^*_{2ijt} are uncorrelated with δ_i, and δ_i are randomly distributed variables with zero mean and finite variance as in Eq. 38.2. This correlation pattern was invoked by Bhargava and Sargan (1983) and has the advantage that deviations of x_{2ijt}'s from their time means:

$$x^+_{2ijt} = x_{2ijt} - x^-_{2ij} \quad (t = 2, \ldots, T; j = n_1 + 1, \ldots, n; i = 1, \ldots, H) \tag{38.10}$$

Where

$$x^-_{2ij} = \sum_{t=1}^{T} x_{2ijt}/T \quad (j = n_1 + 1, \ldots n; i = 1, \ldots, H) \tag{38.11}$$

can be used as additional $[(T-1)\,n_2]$ instrumental variables to facilitate identification and estimation of parameters. Because the T deviations from means (x^+_{2ijt}) in Eq. 38.10 will sum to zero for every firm, one time observation per variable needs to be omitted so that the (T−1) instrumental variables are linearly independent. The reduced form Eq. 38.6 for y_1 is modified in this case as:

$$y_{i1} = \sum_{j=1}^{m} z_{ij}\zeta_j + \sum_{j=1}^{n_1}\sum_{k=1}^{T} \upsilon_{jk}\, x_{1ijk} + \sum_{j=1}^{n_2}\sum_{k=2}^{T} \mu_{jk} x^+_{2ijk} + u_{i1}\,(i = 1, \ldots, H) \tag{38.12}$$

Further, likelihood ratio tests can be applied to test for exogeneity of time means of the n_2 endogenous variables (x_2) in Eq. 38.11 by testing if correlations between the T errors ($u_{i\ t}$) affecting the dependent variables and n_2 time means in Eq. 38.11 are zero. For example, given 8-time observations ($T = 8$), likelihood ratio statistic for testing zero correlation between errors affecting share repurchases in Eq. 38.4 ($n_2 = 1$) and time means of dividends per share is distributed for large H as a Chi-square variable with 8 degrees of freedom.

The identification of parameters is achieved via the n_1 time-varying exogenous variables in the model (e.g., Sargan 1958). For example, in the system representing ($T-1$) time periods in Eq. 38.7, only the exogenous explanatory variables in time period t explain the dependent variable in period t. The remaining ($T-1$) n_2 variables are excluded from the t th equation and are used in the set of instrumental variables for identifying the coefficients of endogenous variables. Sufficient conditions for identification, exploiting the time structure of longitudinal models, were developed in Bhargava and Sargan (1983). For example, each exogenous time-varying variable in the model for share repurchases in Eq. 38.4 effectively provides eight exogenous variables of which seven are excluded from the equations. The null hypothesis that dividends per share do not affect share repurchases can be tested using the estimated coefficient b_{12} of dividends per share in Eq. 38.4. Also, one can test if share repurchases affect dividends per share by including repurchases as a potentially endogenous variable in Eq. 38.3.

For static version of the models not containing lagged dependent variables, one can use stepwise estimation procedures with equality restrictions on coefficients across time periods (Bhargava 1991). Efficient instrumental variables estimators were used to estimate model parameters of Eq. 38.4, assuming the correlation patterns for $x_{2\ i\ j\ t}$ as in Eq. 38.9 and without restricting variance-covariance matrices of the errors, i.e., the T x T dispersion matrix was assumed to be symmetric and positive definite but not of the simple random effects form as in Eq. 38.2. This formulation has the advantage that the errors $v_{i\ t}$ in Eq. 38.2 may be serially correlated which was likely to be the case in static models since the lagged dependent variables were omitted. Exogeneity hypotheses can be tested in the stepwise estimation procedures via Chi-square tests that are asymptotically equivalent to likelihood ratio tests.

Finally, while one can use “fixed” effects estimators (with dummy variables for each firm) to circumvent certain endogeneity problems, increase in the number of parameters with sample size leads to the problem of “incidental parameters” (Neyman and Scott 1948). For example, coefficient of the lagged dependent variable cannot be consistently estimated due to the incidental parameters in fixed effects models unless the number of time observation is large. Moreover, from a modeling standpoint, the use of random effects models obviates the need for estimating the coefficients of large numbers of dummy variables for firms thereby enhancing the efficiency of estimates. Exogeneity hypotheses for variables such as dividends per share can be tested in the model for share repurchases. If the null were rejected, then the models were estimated under the appropriate assumption that dividends per share were correlated with errors affecting the models for share repurchases.

Term Structure Modeling and Forecasting Using the Nelson-Siegel Model 39

Jian Hua

Contents

Abstract

In this chapter, we illustrate some recent developments in the yield curve modeling by introducing a latent factor model called the dynamic Nelson-Siegel model. This model not only provides good in-sample fit, but also produces superior out-of-sample performance. Beyond Treasury yield curve, the model can also be useful for other assets such as corporate bond and volatility. Moreover, the model also suggests generalized duration components corresponding to the level, slope, and curvature risk factors.

The dynamic Nelson-Siegel model can be estimated via a one-step procedure, like the Kalman filter, which can also easily accommodate other variables of interests. Alternatively, we could estimate the model through a two-step process by fixing one parameter and estimating with ordinary least squares. The model is flexible and capable of replicating a variety of yield curve shapes: upward

sloping, downward sloping, humped, and inverted humped. Forecasting the yield curve is achieved through forecasting the factors and we can impose either a univariate autoregressive structure or a vector autoregressive structure on the factors.

Keywords
Term structure • Yield curve • Factor model • Nelson-Siegel curve • State-space model

39.1 Introduction

There have been major advances in theoretical term structure models, as well as their econometric estimation. Two popular approaches to term structure modeling are no-arbitrage models and equilibrium models. The no-arbitrage tradition focuses on eliminating arbitrage opportunities by perfectly fitting the term structure at a point in time, which is important for pricing derivatives; see Hull and White (1990) and Health et al. (1992), among others. The equilibrium tradition models the dynamics of the instantaneous rate typically through affine models so that yields at other maturities can be derived under various assumptions about the risk premium (e.g., Vasicek 1977; Cox et al. 1985; Duffie and Kan 1996).

For many finance questions, such as bond portfolio management, derivatives pricing, and risk management, it is crucial to both produce accurate estimates of the current term structure as well as forecast future interest rate dynamics. One class of models that has one potential satisfactory answer to these questions is that of the Nelson-Siegel class of models (see, Nelson and Siegel 1987). Here, we survey some recent developments of this model. This model not only provides good in-sample fit, but also produces superior out-of-sample performance. Moreover, the model also suggests generalized duration components corresponding to the level, slope, and curvature risk factors.

39.2 Modeling the Term Structure

Let $P_t(\tau)$ be the date t price of a zero-coupon riskless bond that pays \$1 in τ periods. Then,

$$P_t(\tau) = \exp(-\tau y_t(\tau)). \tag{39.1}$$

In practice, yield curves, discount curves, and forward curves are not observed. Instead, they must be estimated from observed bond prices. A popular approach is to estimate forward rates at the observed maturities, and then, construct unsmoothed yields by averaging appropriate estimated forward rates. These yields exactly price the included bonds (see Fama and Bliss 1987).

The original Nelson and Siegel (1987) framework is a convenient and parsimonious three-component exponential approximation. They work with the forward

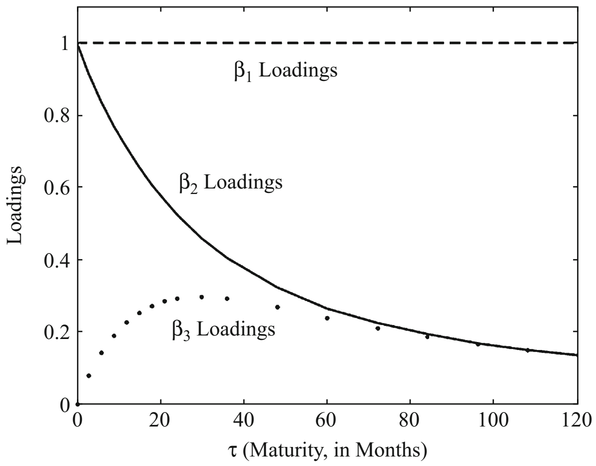

Fig. 39.1 Factor loadings. This figure plots the factor loadings when λ is prefixed at 0.0609

rate, which can be viewed as a constant plus a Laguerre function. Diebold and Li (2006) made it dynamic, and thus, the corresponding yield curve is

$$y_t(\tau) = \beta_{1t} + \beta_{2t}\left(\frac{1 - e^{-\lambda\tau}}{\lambda\tau}\right) + \beta_{3t}\left(\frac{1 - e^{-\lambda\tau}}{\lambda\tau} - e^{-\lambda\tau}\right) + \varepsilon_t, \tag{39.2}$$

and call it DNS hereafter. β_1 changes all yields uniformly, and it can be called the level factor (L_t). β_2 loads the short rate more heavily, its loading decays to zero as maturity lengthens, and it can be called the slope factor (S_t). β_3 loads the medium term more heavily, its loading starts at zero and decays back to zero as maturity increases, and it can be called the curvature factor (C_t). In Fig. 39.1, we plot the factor loadings for a specific value of λ. λ determines the maturity at which the medium-term (or the curvature factor) loading achieves its maximum, which effectively controls the location of the hump of the curve. The DNS model is different from the factor analysis, in which one estimates both the unobserved factors and factor loadings. Here, the framework imposes structure on the factor loadings.

39.3 Fitting the Yield Curve

39.3.1 Data Construction

The standard way of measuring the term structure is by means of the spot rate curve (or equivalently the yield-to-maturity) on zero-coupon bonds.[1] The problem with

[1]Zero coupon bonds are chosen to limit the "coupon effect," which implies that two bonds that are identical in every respect except for bearing different coupon rates can have a different yield-to-maturity.

zero-coupon yields is that these are not usually directly observed. For example, the US Treasury Bills do not bear coupon, but they are only available for maturities of 1-year or less, and the longer maturity zero-coupon yields need to derived from coupon bearing Treasury Notes and Bonds. A popular approach to resolve such an issue is the bootstrapping procedure by Fama and Bliss (1987), which sequentially extracts forward rates from bond prices with successively longer maturities and then takes advantages of the interchangeable nature of the spot rate curve, discount curve, and forward rate curve.

39.3.2 Estimation Procedure

Because of the structure the model imposes, estimation can be achieved with high precision. There are two popular approaches: the one-step and two-step procedures. The one-step procedure can be achieved in two ways. One method is simply to estimate the model by nonlinear least squares for each month t. The other way is to transform the system into a state-space representation and estimate λ and the factors via a Kalman filter. Alternatively, for a two-step procedure, Diebold and Li (2006) advocate prefixing the λ, and estimating the factors via ordinary least squares (OLS). The appendix provides more discussion of these two approaches.

As we can see in Fig. 39.2, the model is flexible and is capable of replicating a variety of yield curve shapes: upward sloping, downward sloping, humped, and inverted humped. Figure 39.3 displays the autocorrelations of the estimated factors and residuals. The level factor displays high persistence and is, of course, positive. In contrast, the slope and curvature factors are less persistent and assume both positive and negative values.

39.4 Forecasting the Yield Curve

Forecasting the yield curve can be achieved through forecasting the factors. We can impose either a univariate autoregressive structure or a vector autoregressive structure on the factors.

The yield forecasts based on underlying univariate AR(1) factor specifications are

$$\hat{y}_{t+h/t}(\tau) = \beta_{1,t+h/t} + \beta_{2,t+h/t}\left(\frac{1-e^{-\lambda_t \tau}}{\lambda_t \tau}\right) + \beta_{3,t+h/t}\left(\frac{1-e^{-\lambda_t \tau}}{\lambda_t \tau} - e^{-\lambda_t \tau}\right), \quad (39.3)$$

where β forecasts are made by the following:

$$\begin{aligned} \hat{\beta}_{1,t+h/t} &= \hat{c}_1 + \hat{\gamma}_1 \hat{\beta}_{1t} \\ \hat{\beta}_{2,t+h/t} &= \hat{c}_2 + \hat{\gamma}_2 \hat{\beta}_{2t} \\ \hat{\beta}_{3,t+h/t} &= \hat{c}_3 + \hat{\gamma}_3 \hat{\beta}_{3t} \end{aligned} \quad (39.4)$$

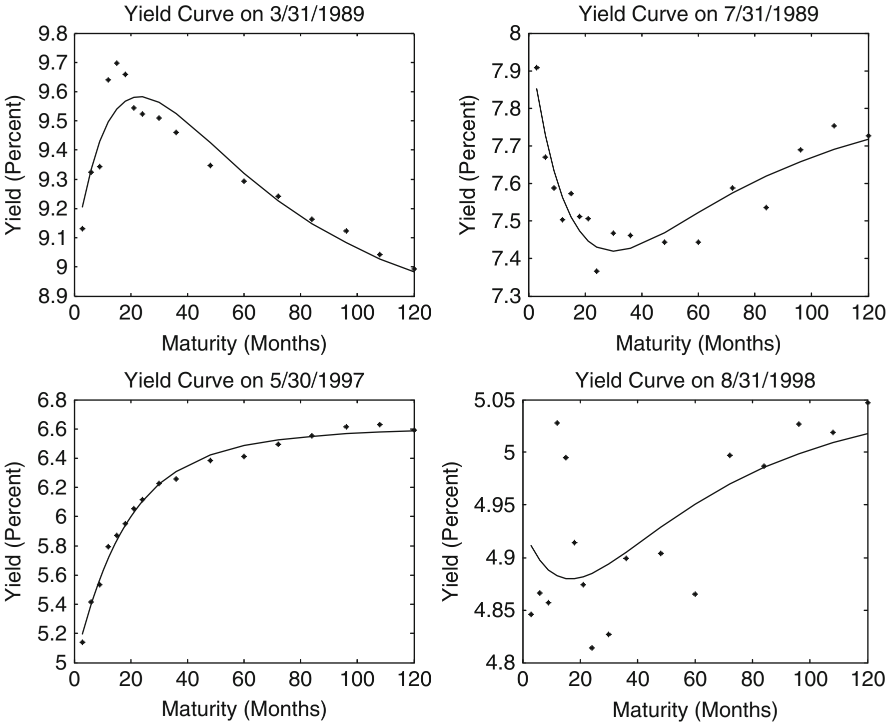

Fig. 39.2 Selected fitted yield curves. This figure presents fitted yield curve for selected dates, together with actual yields (Source: Diebold and Li 2006)

The yield forecasts based on an underlying multivariate autoregressive specification (Vector AR(1)) are

$$\hat{y}_{t+h/t}(\tau) = \beta_{1,\,t+h/t} + \beta_{2,\,t+h/t}\left(\frac{1 - e^{-\lambda_t \tau}}{\lambda_t \tau}\right) + \beta_{3,\,t+h/t}\left(\frac{1 - e^{-\lambda_t \tau}}{\lambda_t \tau} - e^{-\lambda_t \tau}\right), \quad (39.5)$$

where

$$\hat{\beta}_{t+h/t} = \hat{c} + \hat{\gamma}\hat{\beta}_t, \quad (39.6)$$

and $\beta = \{\beta_1, \beta_2, \beta_{3,}\}'$.

The random walk model,

$$\hat{y}_{t+h/t}(\tau) = y_t(\tau), \quad (39.7)$$

is a no-change forecast model, which is used as the benchmark.[2]

[2]Diebold and Li (2006) conduct a more extensive comparisons with competing models.

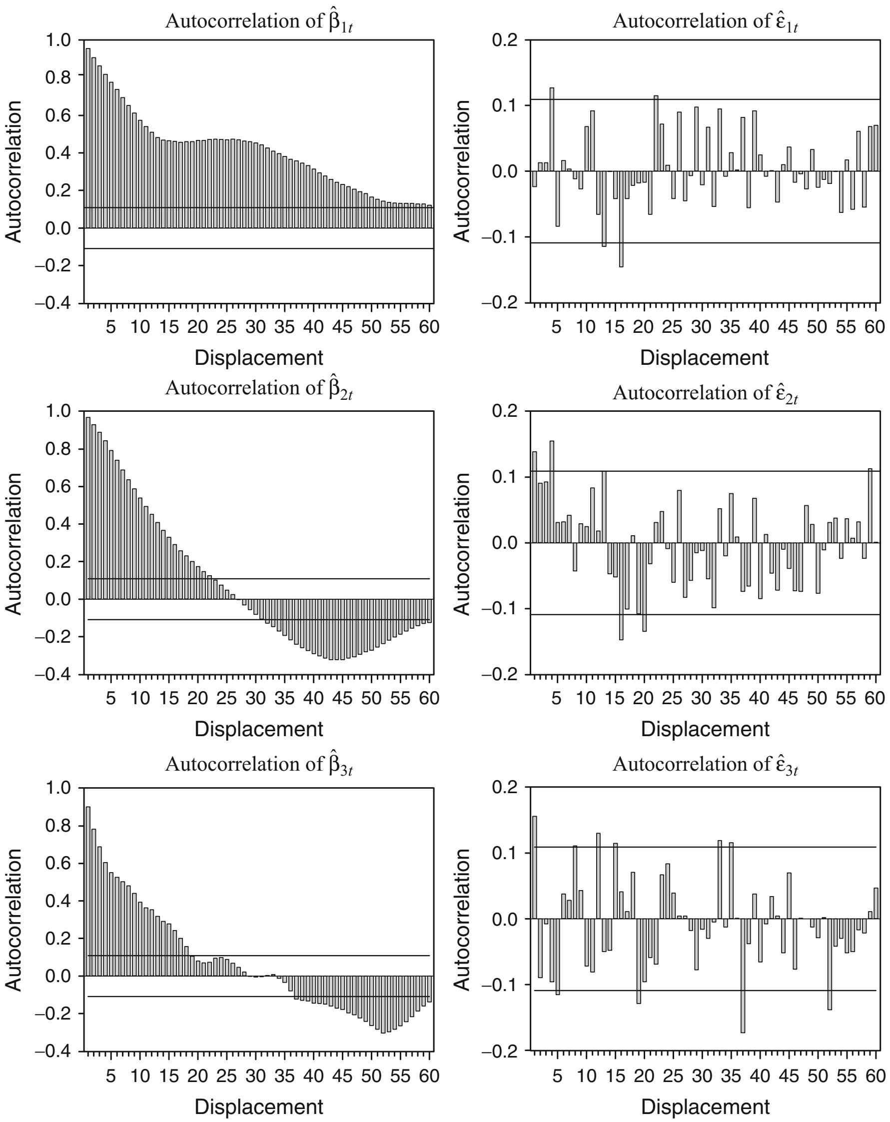

Fig. 39.3 Autocorrelation and residual autocorrelation. This figure presents sample autocorrelations of the level, slope, and curvature factors, as well as the sample autocorrelations of AR (1) models t to the three estimated factors, along with Barletts approximate 95 condence bands (Source: Diebold and Li 2006)

We define forecast errors at $t + h$ as $y_{t+h}(\tau) - \hat{y}_{t+h|t}(\tau)$. Table 39.1 reports the root mean-squared errors of the out-of-sample performance of the DNS model versus the random walk model. An error of 0.235 indicates a mean-squared error of 23.5 basis points in the yield prediction. For 1 month ahead, the random walk is

Table 39.1 Out-of-sample forecasting results

	3-month	1-year	2-year	3-year	5-year	10-year	30-year
1 *month a head*							
Random walk	0.235	**0.259**	**0.290**	0.300	**0.288**	**0.257**	**0.211**
Unrestricted VAR	**0.213**	0.261	0.307	0.302	0.310	0.314	0.419
Univariate AR	0.248	0.282	0.315	0.301	0.311	0.314	0.418
6 *months ahead*							
Random walk	0.910	0.904	0.938	**0.857**	**0.813**	0.655	0.570
Unrestricted VAR	0.909	1.050	1.078	0.999	0.949	0.796	0.717
Univariate AR	**0.694**	**0.890**	**0.908**	0.881	0.827	**0.651**	**0.486**
1 years ahead							
Random walk	1.552	1.505	1.343	1.190	1.065	0.858	0.622
DNS Unrestricted VAR	1.643	1.731	1.641	1.483	1.338	1.123	0.979
DNS Univariate AR	**1.383**	**1.445**	**1.338**	**1.182**	**1.041**	**0.819**	**0.615**

This table presents the results of out-of-sample forecasts using VAR and univariate AR specifications of the DNS factors. I estimate all models recursively from 1987:1 to the time the forecast is made, beginning in 1997:1 and extending through 2002:12. I define forecast errors at $t + h$ as $y_{t+h}(\tau) - \hat{y}_{t+h/t}(\tau)$ and report the root mean-squared errors versus random walk.

hard to beat, but matters improve dramatically. The DNS model with an AR (1) specification produces smaller errors, so it clearly has advantages (see Diebold and Li 2006 for more details). Remember here, we only illustrate the point forecast, and it can be extended easily to interval forecasting since they are useful for risk management.

39.5 Other Applications

Beyond the US Treasury yield curve, the Nelson-Siegel model has also shown success in fitting and forecasting other assets and global yield curves (see Krishnan et al. 2010; Diebold et al. 2008; Hua 2010). Since the model produces three factors that capture the information in the entire term structure, we can analyze the dynamic relationship among them. For example, Hua (2010) analyzes the dynamic interaction between the credit spread term structure and equity option implied volatility term structure.

Moreover, the DNS framework can be easily augmented with other variables of interest. We could also analyze how macroeconomic variables are linked with the interest rate term structure; see Auroba et al. (2006). This can be done easily in a state-space framework. Frequently, yield variation reacts to macrovariables, and macrovariables can also be impacted by the yields. Potentially, we can improve our forecasts of one by incorporating information from the other.

39.6 Generalized Duration Measure

Traditional interest rate risk management focuses on duration and duration management, which only considers parallel shifts of the yield curve. However, in practice, nonparallel shifts do exist and these are a significant source of risk. The DNS model presents a generalized duration component that corresponds to the level, slope, and curvature risk factors.

We can define a bond duration measure as follows. Let the cash flows from bond be $C_1, C_2, \ldots, C_I$, and define the associated maturities to be $\tau_1, \tau_2, \ldots, \tau_I$. We assume that the yield curve is linear in some arbitrary factors f_1, f_2, and f_3,

$$y_t(\tau) = B_1(\tau) f_{1t} + B_2(\tau) f_{2t} + B_3(\tau) f_{3t}. \tag{39.8}$$

This is consistent with the DNS setup. Since the price of the bond can be expressed as,

$$P = \sum_{i=1}^{I} C_i e^{-\tau_i y_t(\tau_i)}, \tag{39.9}$$

for an arbitrary change of the yield curve, the price change is

$$dP = \sum_{i=1}^{I} \frac{\partial P}{\partial y_t(\tau_i)} dy_i(\tau_i) = \sum_{i=1}^{I} \left[C_i e^{-\tau_i y_t(\tau_i)} (-\tau_i) \right] dy_t(\tau_i), \tag{39.10}$$

Where $y_t(\tau_i)$ are treated as independent variables. Rearranging terms, we can express the percentage change in bond price as a function of changes in the factors

$$-\frac{dP}{P} = \sum_{j=1}^{3} \left\{ \sum_{i=1}^{I} \left[\frac{1}{P} C_i e^{-\tau_i y_t(\tau_i)} \tau_i \right] B_j(\tau_i) \right\} df_{it} = \sum_{j=1}^{3} \left\{ \sum_{i=1}^{I} w_i \tau_i B_j(\tau_i) \right\} df_{it}, \tag{39.11}$$

where w_i is the weight associated with C_i.

Since we have decomposed the bond price changes into risk factor changes, the duration component associated with each risk factor is, for $j = 1,2,3$,

$$D_j = \sum_{i=1}^{I} w_i \tau_i B_j(\tau_i). \tag{39.12}$$

Moreover, based on the dynamic Nelson-Siegel model, the vector duration is

$$
\begin{aligned}
D_1 &= \sum_{i=1}^{I} w_i \tau_i \\
D_2 &= \sum_{i=1}^{I} w_i \frac{1 - e^{-\lambda \tau_i}}{\lambda} \\
D_3 &= \sum_{i=1}^{I} w_i \left(\frac{1 - e^{-\lambda \tau_i}}{\lambda} - \tau_i e^{-\lambda \tau_i} \right).
\end{aligned}
\tag{39.13}
$$

The vector duration measure has the following properties:

- D_1, D_2, and D_3 increase with maturity τ.
- D_1, D_2, and D_3 decrease with coupon rate.
- D_1, D_2, and D_3 decrease with yield-to-maturity.

Note that D_1 is exactly the tradition Macaulay duration.

Diebold et al. (2006) apply this vector duration measure as immunization tools in a practical bond portfolio management context. They report that hedging based on the vector duration outperforms hedging based on Macaulay duration in almost all samples and all holding periods. Moreover, it also outperforms polynomial vector duration during unusual market situations such as the monetary regime of the early 80s. Therefore, the vector duration measure seems to be an appealing risk management tool.

39.7 Summary

We have presented the DNS model as a capable and flexible model that can fit the term structure of interest rates in-sample and predict them out-of-sample. It can easily be extended to a different asset class or accommodate other variables into the specifications. Given the advantages of the dynamic Nelson-Siegel model in many dimensions, it is gaining in popularity. Recently, the Board of Governors of the Federal Reserve System has started publishing the daily estimated factors of the Treasury yield curve on their website.[3]

One potential drawback of the DNS model is that it does not rule out arbitrage opportunities. Recently, an arbitrage free version of the model has been developed; see Christensen et al. (2009, 2011).

Appendix 1: One-Step Estimation Method

We illustrate the one-step method to estimate the DNS model. If the dynamics of betas (factors) follow a vector autoregressive process of first order, the model

[3]The data can be found at http://www.federalreserve.gov/econresdata/researchdata.htm

immediately forms a state-space system since ARMA state vector dynamics of any order may be transformed into a state-space form. Thus, the transition equation is

$$\begin{pmatrix} \beta_{1,t} - \mu_{\beta 1} \\ \beta_{2,t} - \mu_{\beta 2} \\ \beta_{3,t} - \mu_{\beta 3} \end{pmatrix} = \begin{pmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{pmatrix} \begin{pmatrix} \beta_{1,t-1} - \mu_{\beta 1} \\ \beta_{2,t-1} - \mu_{\beta 2} \\ \beta_{3,t-1} - \mu_{\beta 3} \end{pmatrix} + \begin{pmatrix} \eta_{1,t} \\ \eta_{2,t} \\ \eta_{3,t} \end{pmatrix}, \tag{39.14}$$

$t = 1, \ldots, T$. The measurement equation, which relates N yields to the three unobserved factors, is

$$\begin{pmatrix} y_t(\tau_1) \\ y_t(\tau_2) \\ \vdots \\ y_t(\tau_N) \end{pmatrix} = \begin{pmatrix} 1 & \dfrac{1 - e_1^{\tau}\lambda}{\tau_1\lambda} & \dfrac{1 - e^{-\tau_1\lambda}}{\tau_1\lambda} - e^{-\tau_1\lambda} \\ 1 & \dfrac{1 - e_2^{\tau}\lambda}{\tau_2\lambda} & \dfrac{1 - e^{-\tau_2\lambda}}{\tau_2\lambda} - e^{-\tau_2\lambda} \\ \vdots & \vdots & \vdots \\ 1 & \dfrac{1 - e_1^{\tau}\lambda}{\tau_N\lambda} & \dfrac{1 - e^{-\tau_N\lambda}}{\tau_N\lambda} - e^{-\tau_N\lambda} \end{pmatrix} \begin{pmatrix} \beta_{1,t} \\ \beta_{2,t} \\ \beta_{3,t} \end{pmatrix} + \begin{pmatrix} \varepsilon_{1,t} \\ \varepsilon_{2,t} \\ \vdots \\ \varepsilon_{\mathrm{N},t} \end{pmatrix}, \tag{39.15}$$

$t = 1, \ldots, T$. In matrix notation, we rewrite the state-space system as measurement equation,

$$y_t = \Gamma f_t + \varepsilon_t; \tag{39.16}$$

state equation,

$$(f_t - \mu) = A(f_{t-1} - \mu) + \eta_t. \tag{39.17}$$

For optimality of the Kalman filter, we assume that the white noise transaction and measurement errors be orthogonal to each other.

$$\begin{pmatrix} \eta_t \\ \varepsilon_t \end{pmatrix} \sim WN\left(\begin{bmatrix} 0 \\ 0 \end{bmatrix}, \begin{bmatrix} Q & 0 \\ 0 & H \end{bmatrix} \right), \tag{39.18}$$

$$E\left(f_0 \eta_t'\right) = 0, \tag{39.19}$$

$$E\left(f_0 \varepsilon_t'\right) = 0. \tag{39.20}$$

The state-space set up with the application of the Kalman filter delivers maximum-likelihood estimates and smoothed underlying factors, where all parameters are estimated simultaneously. Such representation also allows for heteroskedasticity, missing data, or heavy-tailed measurement errors. Moreover, other useful variables, such as macroeconomic variables, can be augmented into the state equation to understand the dynamic interactions between the yield curve and the macroeconomy.

Appendix 2: Two-Step Estimation Method

The estimation for the two-step procedure requires us to choose a λ value first. Once the λ is fixed, the values of the two regressors (factor loadings) can be computed, so ordinary least squares can be applied to estimate the betas (factors) at each period t. Doing so is not only simple and convenient, but also eliminates the potential for numerical optimization challenges. The question is: What is the appropriate value of λ. Recall that λ determines the maturity at which the loading achieves its maximum. For example, for Treasury data, 2 or 3 years are commonly considered medium term, so a simple average of the two is 30-month. The λ value that maximizes the loadings on the medium-term factor at exactly 30-month is 0.0609. For a different market, the medium maturity could be different, so the corresponding λ value could be different as well.

The Intertemporal Relation Between Expected Return and Risk on Currency

40

Turan G. Bali and Kamil Yilmaz

Contents

Abstract

The literature has so far focused on the risk-return trade-off in equity markets and ignored alternative risky assets. This paper examines the presence and significance of an intertemporal relation between expected return and risk in the foreign exchange market. The paper provides new evidence on the intertemporal capital asset pricing model by using high-frequency intraday data on currency and by presenting significant time variation in the risk aversion parameter. Five-minute returns on the spot exchange rates of the US dollar vis-à-vis six major currencies (the euro, Japanese yen, British pound sterling, Swiss franc, Australian dollar, and Canadian dollar) are used to test the existence and significance of a daily risk-return trade-off in the FX market based on the

GARCH, realized, and range volatility estimators. The results indicate a positive but statistically weak relation between risk and return on currency.

Our empirical analysis relies on the maximum likelihood estimation of the GARCH-in-mean models as described in Appendix 1. We also use the seemingly unrelated (SUR) regressions and panel data estimation to investigate the significance of a time-series relation between expected return and risk on currency as described in Appendix 2.

40.1 Introduction

Merton's (1973) intertemporal capital asset pricing model (ICAPM) indicates that the conditional expected excess return on a risky market portfolio is a linear function of its conditional variance plus a hedging component that captures the investor's motive to hedge for future investment opportunities. Merton (1980) shows that the hedging demand component becomes negligible under certain conditions and the equilibrium relation between risk and return is defined as

$$E_t(R_{t+1}) = \beta \cdot E_t\left(\sigma^2_{t+1}\right) \tag{40.1}$$

where $E_t(R_{t+1})$ and $E_t(\sigma^2_{t+1})$ are, respectively, the conditional mean and variance of excess returns on a risky market portfolio and $\beta > 0$ is the risk aversion parameter of market investors. Equation 40.1 establishes the dynamic relation that investors require a larger risk premium at times when the market is riskier.

Many studies investigate the significance of an intertemporal relation between expected return and risk in the aggregate stock market. However, the existing literature has not yet reached an agreement on the existence of a positive risk-return trade-off for stock market indices.[1] Due to the fact that the conditional mean and volatility of the market portfolio are not observable, different approaches, different data sets, and different sample periods used by previous studies in estimating the conditional mean and variance are largely responsible for the contradictory empirical evidence.

The prediction of Merton (1973, 1980) that expected returns should be related to conditional risk applies not only to the stock market portfolio but also to any risky portfolio. However, earlier studies have so far focused on the risk-return trade-off in

[1]See French et al. (1987), Campbell (1987), Nelson (1991), Campbell and Hentschel (1992), Chan et al. (1992), Glosten et al. (1993), Scruggs (1998), Harvey (2001), Goyal and Santa-Clara (2003), Brandt and Kang (2004), Ghysels et al. (2005), Bali and Peng (2006), Christoffersen and Diebold (2006), Guo and Whitelaw (2006), Lundblad (2007), and Bali (2008).

equity markets and ignored other risky financial assets. Although there are a few studies testing the significance of a time-series relation between risk and return in international equity markets, the focus is generally on the US stock market. It is also important to note that earlier studies assume a constant risk-return trade-off and ignore time variation in the risk aversion parameter β.[2] This paper examines the intertemporal relation between expected return and risk in currency markets. The paper not only investigates ICAPM in the foreign exchange market but examines the significance of time-varying risk aversion as well.

The foreign exchange market includes the trading of one currency against another between large banks, central banks, currency speculators, multinational corporations, governments, and other financial markets and institutions. The FX market is an interbank or inter-dealer network first established in 1971 when many of the world's major currencies moved towards floating exchange rates. It is considered an over-the-counter (OTC) market, meaning that transactions are conducted between two counterparties that agree to trade via telephone or electronic network. Because foreign exchange is an OTC market where brokers/dealers negotiate directly with one another, there is no central exchange or clearing house.[3]

The FX market has grown rapidly since the early 1990s. According to the triennial central bank surveys conducted by the Bank for International Settlements (BIS), the April 2007 data show an unprecedented rise in activity in traditional foreign exchange markets compared to 2004. As shown in Table 40.1, average daily turnover rose to US $3.1 trillion in April 2007, an increase of 69 % (compared to April 2004) at current exchange rates and 63 % at constant exchange rates.[4] Since April 2001, average daily turnover in foreign exchange markets worldwide (adjusted for cross-border and local double-counting and evaluated at April 2007 exchange rates) increased by 58 % and 69 % between two consecutive triennial surveys. Comparing the average daily turnovers of US $500 billion in 1988 and US $3.1 trillion in 2007 indicates that trading volume in FX markets increased by more than five times over the past two decades.

The FX market has become the world's largest financial market, and it is not uncommon to see over US $3 trillion traded each day. By contrast, the New York Stock Exchange (NYSE) – the world's largest equity market with daily trading volumes in the US $60–80 billion dollar range – is positively dwarfed when compared to the FX market. Daily turnover in FX markets is now more than ten times the size of the combined daily turnover on all the world's equity markets.

---

[2]A few exceptions are Chou et al. (1992), Harvey (2001), and Lettau and Ludvigson (2010).

[3]As FX trading has evolved, several locations have emerged as market leaders. Currently, London contributes the greatest share of transactions with over 32 % of the total trades. Other trading centers – listed in order of volume – are New York, Tokyo, Zurich, Frankfurt, Hong Kong, Paris, and Sydney. Because these trading centers cover most of the major time zones, FX trading is a true 24-h market that operates 5 days a week.

[4]In addition to "traditional" turnover of US $3.1 trillion in global foreign exchange market, US $2.1 trillion was traded in currency derivatives.

Table 40.1 Reported foreign exchange market turnover by currency pair[a] (Daily averages in April, in billions of US dollars and percent)

	2001		2004		2007	
	Amount	% share	Amount	% share	Amount	% share

[a]Adjusted for local and cross-border double-counting

Even when combining the US bond and equity markets, total daily volumes still do not come close to the values traded on the currency market.

The FX market is unique because of its trading volumes; the extreme liquidity of the market; the large number of, and variety of, traders in the market; its geographical dispersion; its long trading hours (24 h a day except on weekends); the variety of factors that affect exchange rates; the low margins of profit compared with other markets of fixed income (but profits can be high due to very large trading volumes); and the use of leverage.

Earlier studies have so far focused on the US stock market when investigating the ICAPM. However, with an average daily trading volume of US $3 trillion per day, Forex is far and away the most enormous financial market in the world, dwarfing the trading volumes of other markets. We contribute to the existing literature by examining for the first time the significance of an intertemporal relation between expected return and risk on currency. We also test whether aggregate risk aversion in the FX market changes through time.

We utilize 5-min returns on the spot exchange rates of the US dollar vis-à-vis six major currencies (the euro, Japanese yen, British pound sterling, Swiss franc, Australian dollar, and Canadian dollar) to construct the daily returns, realized volatility, and range volatility estimators. Then, using the intraday data-based daily returns as well as the GARCH, realized, and range-based volatility measures, we test for the presence and significance of a risk-return trade-off in the FX market. By sampling the return process more frequently, we improve the accuracy of the conditional volatility estimate and measure the risk-return relationship at the daily level. When we assume a constant risk-return trade-off in currency markets, we find a positive but statistically weak relation between expected return and risk on currency.

We estimate the dependence of expected returns on the lagged realized variance over time using rolling regressions. This also allows us to check whether our results are driven by a particular sample period. Two different rolling regression approaches provide strong evidence on the time variation of risk aversion parameters for all currencies considered in the paper. However, the direction of a relationship between expected return and risk is not clear for the entire FX market.

The paper is organized as follows. Section 40.2 provides the descriptive statistics for the daily and 5-min returns on exchange rates as well as the daily realized and range-based volatility measures. Section 40.3 explains the estimation methodology. Section 40.4 presents the empirical results on a constant risk-return trade-off in the FX market. Section 40.5 examines the significance of time-varying risk aversion. Section 40.6 investigates whether the covariances of individual exchange rates with the FX market are priced in currency market. Section 40.7 concludes the paper.

40.2 Data

To test the significance of a risk-return trade-off in currency markets, we use daily returns on the spot exchange rates of the US dollar vis-à-vis six major currencies: the euro (EUR), Japanese yen (JPY), British pound sterling (GBP), Swiss franc (CHF), Australian dollar (AUD), and Canadian dollar (CAD). According to the BIS (2007) study, on the spot market the most heavily traded currency pairs were EUR/USD (27 %), JPY/USD (13 %), GBP/USD (12 %), AUD/USD (6 %), CHF/USD (5 %), and CAD/USD (4 %). As reported in Table 40.2, the US dollar has been the dominant currency in both the spot and the forward and the swap transactions. Specifically, the US currency was involved in 88.7 % of transactions, followed by the euro (37.2 %), the Japanese yen (20.3 %), the pound sterling (16.9 %), the Swiss franc (6.1 %), Australian dollar (5.5 %), and Canadian dollar (4.2 %). The sum of the six major currencies (EUR, JPY, GBP, CHF, AUD, CAD) accounts for a market share approximately equal to that of the US dollar (90.2 %).[5]

The raw 5-min data on six exchange rates (EUR/USD, JPY/USD, GBP/USD, CHF/USD, AUD/USD, and CAD/USD) are obtained from Olsen and Associates. The full sample covers 2,282 days, from January 1, 2002 to March 31, 2008. Following Bollerslev and Domowitz (1993) and Andersen et al. (2001b), we define the day as starting at 21:05 pm on one night and ending at 21:00 pm the next night. The total number of 5-min observations for each exchange rate is therefore equal to $2{,}282 \times 288 = 657{,}216$. However, we are not able to use all of these observations

[5]Note that volume percentages should add up to 200 %; 100 % for all the sellers and 100 % for all the buyers. As shown in Table 40.2, the market shares of seven major currencies add up to 180 %. The remaining 20 % of the total (200 %) market turnover has been accounted by other currencies from Europe and from other parts of the world.

Table 40.2 Most traded currencies: currency distribution of reported FX market turnover

Currency	Symbol	% daily share
US dollar	USD ($)	88.7 %
Euro	EUR (€)	37.2 %
Japanese yen	JPY (¥)	20.3 %
British pound sterling	GBP (£)	16.9 %
Swiss franc	CHF (Fr)	6.1 %
Australian dollar	AUD ($)	5.5 %
Canadian dollar	CAD ($)	4.2 %
Swedish krona	SEK (kr)	2.3 %
Hong Kong dollar	HKD ($)	1.9 %
Norwegian krone	NOK (kr)	1.4 %
Other		15.5 %
Total		200 %

because the trading activity in FX markets slows down substantially during the weekends and the major US official holidays. Following Andersen et al. (2001b), along with the weekends, we removed the following holidays from our sample: Christmas (December 24–26), New Year's (December 31–January 2), July 4th, Good Friday, Easter Monday, Memorial Day, Labor Day, Thanksgiving Day, and the day after. In addition to official holidays and weekends, we removed 3 days (March 4, 2002, April 14, 2003, and January 30, 2004) from our sample as these days contained the longest zero or constant 5-min return sequences that might contaminate the daily return and variance estimates. As a result, we end up with a total of 1,556 daily observations.

Panel A of Table 40.3 presents the mean, median, maximum, minimum, standard deviation, skewness, kurtosis, and autoregressive of order one, AR(1), statistics for daily returns on the six exchange rates. The standard errors of the skewness and kurtosis estimates provide evidence that the empirical distributions of returns on exchange rates are generally symmetric and fat tailed. More specifically, the skewness measures are statistically insignificant for all currencies, except for the Japanese yen. The kurtosis measures are statistically significant without any exception. The Jarque-Bera, JB $= n[(S^2/6) + (K–3)^2/24]$, is a formal statistic with the Chi-square distribution for testing whether the returns are normally distributed, where n denotes the number of observations, S is skewness, and K is kurtosis. The JB statistics indicate significant departures from normality for the empirical return distributions of six exchange rates. As expected, daily returns on exchange rates are not highly persistent, as shown by the negative AR (1) coefficients which are less than 0.10 in absolute value. Although the economic significance of the AR(1) coefficients is low, they are statistically significant at the 5 % or 1 % level for all currencies, except for the British pound and Australian dollar.

The daily intertemporal relation between expected return and risk on currency is tested using the daily realized variance of returns on exchange rates. In very early work, the daily realized variance of asset returns is measured

This table reports statistics for daily returns on US dollar exchange rates (Panel A), daily realized variance (Panel B), and daily range variance (Panel C) for six major currencies: the euro (EUR), Japanese yen (JPY), British pound sterling (GBP), Swiss franc (CHF), Australian dollar (AUD), and Canadian dollar (CAD). Mean, median, maximum, minimum, standard deviation, skewness, kurtosis, and AR(1) statistics are reported for each currency. Standard errors of skewness and kurtosis estimates, computed under the null hypothesis that the returns are normally distributed, are $\sqrt{6/n}$ and $\sqrt{24/n}$, respectively. Jarque-Bera, JB $= n[(S^2/6) + (K-3)^2/24]$, is a formal statistic for testing whether the returns are normally distributed, where n denotes the number of observations, S is skewness, and K is kurtosis. The JB statistic distributed as the Chi-square with 2° of freedom measures the difference of the skewness and kurtosis of the series with those from the normal distribution. The sample period is from January 3, 2002 to March 31, 2008, yielding a total of 1,556 daily observations

*, ** denote statistical significance at the 5 % and 1 % level, respectively

by the squared daily returns, where the asset return is defined as the natural logarithm of the ratio of consecutive daily closing prices. A series of papers by Andersen et al. (2001a, b, 2003, 2004) indicate that these traditional measures are poor estimators of day-by-day movements in volatility, as the idiosyncratic component of daily returns is large. They demonstrate that the realized volatility measures based on intraday data provide a dramatic reduction in noise and a radical improvement in temporal stability relative to realized volatility measures based on daily returns. Andersen et al. (2003) show formally that the concept of realized variance is, according to the theory of quadratic variation and under suitable conditions, an asymptotically unbiased estimator of the integrated variance, and thus it is a canonical and natural measure of daily return volatility.

Following the recent literature on integrated volatility, we use the high-frequency intraday data to construct the daily realized variance of exchange rates. To set forth notation, let P_t denote the time t ($t \geq 0$) exchange rate with the unit interval t corresponding to 1 day. The discretely observed time-series process of logarithmic exchange rate returns with q observations per day, or a return horizon of $1/q$, is then defined by

$$R_{(q),t} = \ln P_t - \ln P_{t-1/q} \tag{40.2}$$

where $t = 1/q, 2/q, \ldots$. We calculate the daily realized variance of exchange rates using the intraday high-frequency (5-min) return data as

$$VAR_t^{\text{realized}} = \sum_{i=0}^{q_i - 1} R^2_{(q),t-i/q} \tag{40.3}$$

where $q_{i,t}$ is the number of 5-min intervals on day t and $R_{i,t}$ is the logarithmic exchange rate return in 5-min interval i on date t.

On a regular trading day, there are 288 5-min intervals. The exchange rate of the most recent record in a given 5-min interval is taken to be the exchange rate of that interval. A 5-min return is then constructed using the logarithmic exchange rate difference for a 5-min interval. With 1,556 days in our full sample, we end up with using a total of $1{,}556 \times 288 = 448{,}128$ 5-min return observations to calculate daily return and variance estimates.

Panel B of Table 40.3 presents the summary statistics of the daily realized-variances of exchange rate returns. The average daily realized variance is 6×10^{-5} for AUD/USD, 4.31×10^{-5} for CHF/USD, 4.07×10^{-5} for JPY/USD, 3.60×10^{-5} for CAD/USD, 3.47×10^{-5} for EUR/USD, and 2.77×10^{-5} for GBP/USD. These measures correspond to an annualized volatility of 12.30 % for AUD/USD, 10.42 % for CHF/USD, 10.13 % for JPY/USD, 9.52 % for CAD/USD, 9.35 % for EUR/USD, and 8.35 % for GBP/USD. A notable point in Panel B is that the daily realized variances are highly persistent, as shown by the AR(1) coefficients which are in the range of 0.49–0.64. Consistent with Andersen et al. (2001a, b), the distributions of realized variances are skewed to the right and have much thicker tails than the corresponding normal distribution.

Market microstructure noises in transaction data such as the bid-ask bounce may influence our risk measures based on the realized volatility and GARCH volatility forecasts, even though the data we use contain very liquid financial time series and thus are least subject to biases created by market microstructure effects. An alternative volatility measure that utilizes information contained in the high-frequency intraday data is Parkinson's (1980) range-based estimator of the daily integrated variance:

$$VAR_t^{\text{range}} = 0.361 \left[\ln\left(P_t^{\max}\right) - \ln\left(P_t^{\min}\right)\right]^2 \tag{40.4}$$

where $P_t^{\max}$ and $P_t^{\min}$ are the maximum and minimum values of the exchange rate on day t. Alizadeh et al. (2002) and Brandt and Diebold (2006) show that the range-based volatility estimator is highly efficient, approximately Gaussian, and robust to certain types of microstructure noise such as bid-ask bounce. In addition, range data are available for many assets over a long sample period.

Panel C of Table 40.3 presents the summary statistics of the daily range variances of exchange rate returns. The average daily range variance is 4.20×10^{-5} for AUD/USD, 3.56×10^{-5} for CHF/USD, 3.15×10^{-5} for JPY/USD, 2.63×10^{-5} for CAD/USD, 2.76×10^{-5} for EUR/USD, and 2.0×10^{-5} for GBP/USD. These measures correspond to an annualized volatility of 10.29 % for AUD/USD, 9.47 % for CHF/USD, 8.91 % for JPY/USD, 8.14 % for CAD/USD, 8.34 % for EUR/USD, and 7.61 % for GBP/USD. These results indicate that the daily realized volatility estimates are somewhat higher than the daily range volatilities. Another notable point in Panel C is that the daily range variances are less persistent than the daily realized variances. Specifically, the AR(1) coefficients are in the range of 0.09–0.34 for the daily range variances. Similar to our findings for the daily realized variances, the distributions of range variances are skewed to the right and have much thicker tails than the corresponding normal distribution.

40.3 Estimation Methodology

The following GARCH-in-mean process is used with the conditional normal density to model the intertemporal relation between expected return and risk on currency:

$$R_{t+1} \equiv \alpha + \beta \cdot \sigma_{t+1|t}^2 + \varepsilon_{t+1} \tag{40.5}$$

$$\varepsilon_{t+1} = z_{t+1} \cdot \sigma_{t+1|t}, z_{t+1} \sim N(0,1), E(\varepsilon_{t+1}) = 0 \tag{40.6}$$

$$E\left(\varepsilon_{t+1}^2 | \Omega_t\right) = \sigma_{t+1|t}^2 = \gamma_0 + \gamma_1 \varepsilon_t^2 + \gamma_2 \sigma_t^2, \tag{40.7}$$

$$f\left(R_{t+1}; \mu_{t+1|t}, \sigma_{t+1|t}\right) = \frac{1}{\sqrt{2\pi\sigma_{t+1|t}^2}} \exp\left[-\frac{1}{2}\left(\frac{R_{t+1} - \mu_{t+1|t}}{\sigma_{t+1|t}}\right)^2\right] \tag{40.8}$$

where R_{t+1} is the daily return on exchange rates for period $t+1$, $\mu_{t+1|t} \equiv \alpha + \beta \cdot \sigma^2_{t+1|t}$ is the conditional mean for period $t + 1$ based on the information set up to time t, $\varepsilon_{t+1} = z_{t+1} \cdot \sigma_{t+1|t}$ is the error term with $E(\varepsilon_{t+1}) = 0$, $\sigma_{t+1|t}$, is the conditional standard deviation of daily returns on currency, and $z_{t+1} \sim N(0,1)$ is a random variable drawn from the standard normal density and can be viewed as information shocks in the FX market. $\sigma^2_{t+1|t}$ is the conditional variance of daily returns based on the information set up to time t denoted by Ω_t. The conditional variance, $\sigma^2_{t+1|t}$, follows a GARCH(1,1) process as defined by Bollerslev (1986) to be a function of the last period's unexpected news (or information shocks), z_t, and the last period's variance, $\sigma_t{}^2$. $f(R_{t+1};\mu_{t+1|t},\sigma_{t+1|t})$ is the conditional normal density function of R_{t+1} with the conditional mean of $\mu_{t+1|t}$ and conditional variance of $\sigma^2_{t+1|t}$. Our focus is to examine the magnitude and statistical significance of the risk aversion parameter β in Eq. 40.5.

Campbell (1987) and Scruggs (1998) point out that the approximate relationship in Eq. 40.1 may be misspecified if the hedging term in ICAPM is important. To make sure that our results from estimating Eq. 40.5 are not due to model misspecification, we added to the specifications a set of control variables that have been used in the literature to capture the state variables that determine changes in the investment opportunity set. Several studies find that macroeconomic variables associated with business cycle fluctuations can predict the stock market.[6] The commonly chosen variables include Treasury bill rates, federal funds rate, default spread, term spread, and dividend-price ratios. We study how variations in the fed funds rate, default spread, and term spread affect the intertemporal risk-return relation.[7] Earlier studies also control for the lagged return in the conditional mean specification.

We obtain daily data on the federal funds rate, 3-month Treasury bill, 10-year Treasury bond yields, and BAA-rated and AAA-rated corporate bond yields from the H.15 database of the Federal Reserve Board. The federal funds (*FED*) rate is the interest rate at which a depository institution lends immediately available funds (balances at the Federal Reserve) to another depository institution overnight. It is a closely watched barometer of the tightness of credit market conditions in the banking system and the stance of monetary policy. In addition to the fed funds rate, we use the term and default spreads as control variables. The term spread (*TERM*) is calculated as the difference between the yields on the 10-year Treasury bond and the 3-month Treasury bill. The default spread (*DEF*) is computed as the difference between the yields on the BAA-rated and AAA-rated corporate bonds. We test the significance of the risk aversion parameter, β, after controlling for macroeconomic variables and lagged return:

[6]See Keim and Stambaugh (1986), Chen et al. (1986), Campbell and Shiller (1988), Fama and French (1988, 1989), Campbell (1987, 1991), Ghysels et al (2005), and Guo and Whitelaw (2006).

[7]We could not include the aggregate dividend yield (or the dividend-price ratio) because the data on dividends are available only at the monthly frequency while our empirical analyses are based on the daily data.

$$R_{t+1} \equiv \alpha + \beta \cdot \sigma^2_{t+1|t} + \lambda_1 \cdot FED_t + \lambda_2 \cdot DEF_t + \lambda_3 \cdot TERM_t + \lambda_4 \cdot R_t + \varepsilon_{t+1}$$

$$R_{t+1} \equiv \alpha + \beta \cdot \sigma^2_{t+1|t} + \lambda_1 \cdot FED_t + \lambda_2 \cdot DEF + \lambda_3 \cdot TERM_t + \lambda_4 \cdot R_t + \varepsilon_{t+1} \tag{40.9}$$

$$\varepsilon_{t+1} = z_{t+1} \cdot \sigma_{t+1|t}, z_{t+1} \sim N(0,1), E(\varepsilon_{t+1}) = 0 \tag{40.10}$$

$$E\left(\varepsilon^2_{t+1}|\Omega_t\right) = \sigma^2_{t+1|t} = \gamma_0 + \gamma_1\varepsilon^2_t + \gamma_2\sigma^2_t \tag{40.11}$$

Earlier studies that investigate the daily risk-return trade-off generally rely on the GARCH-in-mean methodology. In risk-return regressions, it is not common to use the realized variance measures obtained from the intraday data. In this paper, we first generate the daily realized variance based on the 5-min returns on exchange rates and then estimate the following risk-return regression:

$$R_{t+1} = \alpha + \beta \cdot E_t\left[VAR^{\text{realized}}_{t+1}\right] + \varepsilon_{t+1} \tag{40.12}$$

where R_{t+1} is the 1-day ahead return on exchange rate and $E_t[VAR^{\text{realized}}_{t+1}]$ is proxied by the lagged realized variance measure, i.e., $E_t[VAR^{\text{realized}}_{t+1}]=VAR^{\text{realized}}_t$ defined in Eq. 40.3. As reported in Panel B of Table 40.3, VAR^{realized}_t has significant persistence measured by the first-order serial correlation that makes VAR^{realized}_t a reasonable proxy for the 1-day ahead expected realized variance. The slope coefficient β in Eq. 40.12, according to Merton's (1973) ICAPM, is the relative risk aversion coefficient which is expected to be positive and statistically significant.

To control for macroeconomic variables and lagged returns that may potentially affect the fluctuations in the FX market, we estimate the risk aversion coefficient, β, after controlling for the federal funds rate, term spread, default spread, and lagged return:

$$R_{t+1} \equiv \alpha + \beta \cdot VAR^{\text{realized}}_t + \lambda_1 \cdot FED_t + \lambda_2 \cdot DEF_t + \lambda_3 \cdot TERM_t + \lambda_4 \cdot R_t + \varepsilon_{t+1} \tag{40.13}$$

and test the statistical significance of β.

In addition to the GARCH-in-mean and realized volatility models, we use the range-based volatility estimator with and without control variables to test the significance of risk aversion β:

$$R_{t+1} = \alpha + \beta \cdot VAR^{\text{range}}_t + \varepsilon_{t+1} \tag{40.14}$$

$$R_{t+1} \equiv \alpha + \beta \cdot VAR^{\text{range}}_t + \lambda_1 \cdot FED_t + \lambda_2 \cdot DEF_t + \lambda_3 \cdot TERM_t + \lambda_4 \cdot R_t + \varepsilon_{t+1} \tag{40.15}$$

where VAR^{range}_t is the Parkinson's (1980) range-based estimator of the daily integrated variance defined in Eq. 40.4.

The uncovered interest rate parity indicates that the appreciation (or depreciation) rate of a currency is related to the interest rate differential of two countries.[8] Therefore, the hedging demand component of the ICAPM is proxied by the short-term interest rates of the two countries. Specifically, the intertemporal relation is tested based on the GARCH-in-mean, realized, and range volatility estimators along with the London Interbank Offer Rate (LIBOR) for the US and the corresponding foreign country:

$$R_{t+1} \equiv \alpha + \beta \cdot \sigma^2_{t+1|t} + \lambda_1 \cdot LIBOR_t^{\mathrm{US}} + \lambda_2 \cdot LIBOR_t^{\mathrm{foreign}} + \lambda_3 \cdot R_t + \varepsilon_{t+1} \tag{40.16}$$

$$R_{t+1} \equiv \alpha + \beta \cdot VAR_t^{\mathrm{realized}} + \lambda_1 \cdot LIBOR_t^{\mathrm{US}} + \lambda_2 \cdot LIBOR_t^{\mathrm{foreign}} + \lambda_3 \cdot R_t + \varepsilon_{t+1} \tag{40.17}$$

$$R_{t+1} \equiv \alpha + \beta \cdot VAR_t^{\mathrm{range}} + \lambda_1 \cdot LIBOR_t^{\mathrm{US}} + \lambda_2 \cdot LIBOR_t^{\mathrm{foreign}} + \lambda_3 \cdot R_t + \varepsilon_{t+1} \tag{40.18}$$

where $LIBOR_t^{\mathrm{US}}$ and $LIBOR_t^{\mathrm{foreign}}$ are the LIBOR rates for the US and the corresponding foreign country. To control for a potential first-order serial correlation in daily returns on exchange rates, we include the lagged return (R_t) to the conditional mean specifications.

40.4 Empirical Results

Table 40.4 presents the maximum likelihood parameter estimates and the t-statistics in parentheses for the GARCH-in-mean model. The risk aversion parameter (β) is estimated to be positive for all currencies considered in the paper, but the parameter estimates are not statistically significant, except for the British pound and the Canadian dollar. Specifically, β is estimated to be 5.18 for the euro, 4.42 for the Japanese yen, 29.07 for the British pound, 0.87 for the Swiss franc, 11.04 for the Australian dollar, and 22.40 for the Canadian dollar. Based on the Bollerslev-Wooldridge (1992) heteroscedasticity consistent covariance t-statistics reported in Table 40.4, the risk aversion coefficient has a t-statistic of 1.83 for the Canadian dollar and t-statistic of 1.77 for the British pound. Although we do not have a strong statistical significance, we can interpret this finding as a positive risk-return trade-off in the US/Canadian dollar and US dollar/lb exchange rate markets. Overall, these results indicate a positive but statistically weak relation between expected return and risk on currency.

[8] Assuming that the interest rate is 5 % per annum in the US and 2 % per annum in Japan, the uncovered interest rate parity predicts that the US dollar would depreciate against the Japanese yen by 3 %.

Table 40.4 Daily risk-return trade-off in foreign exchange markets based on the GARCH-in-mean model

The following GARCH-in-mean process is used with conditional normal density to model the intertemporal relation between expected return and risk on currency

$$
\begin{aligned}
R_{t+1} &\equiv \alpha + \beta \cdot \sigma^2_{t+1|t} + \varepsilon_{t+1} \\
\varepsilon_{t+1} &= z_{t+1} \cdot \sigma_{t+1|t}, z_{t+1} \sim N(0,1), E(\varepsilon_{t+1}) = 0 \\
E\left(\varepsilon^2_{t+1}|\Omega_t\right) &= \sigma^2_{t+1|t} = \gamma_0 + \gamma_1 \varepsilon^2_t + \gamma_2 \sigma^2_t
\end{aligned}
$$

where R_{t+1} is the daily return on exchange rates for period t+1, $\mu_{t+1|t} \equiv \alpha + \beta \cdot \sigma^2_{t+1|t}$ is the conditional mean for period t+1 based on the information set up to time t denoted by Ω_t, $\varepsilon_{t+1} = z_{t+1} \cdot \sigma_{t+1|t}$ is the error term with $E(\varepsilon_{t+1}) = 0$, $\sigma_{t+1|t}$ is the conditional standard deviation of daily returns on currency, and $z_{t+1} \sim N(0,1)$ is a random variable drawn from the standard normal density and can be viewed as information shocks in FX markets. $\sigma^2_{t+1|t}$ is the conditional variance of daily returns based on the information set up to time t denoted by Ω_t. The conditional variance, $\sigma^2_{t+1|t}$, follows a GARCH(1,1) process defined as a function of the last period's unexpected news (or information shocks), z_t, and the last period's variance, $\sigma_t^{\ 2}$. The table presents the maximum likelihood parameter estimates and the t-statistics in parentheses

Another notable point in Table 40.4 is the significance of volatility clustering. For all currencies, the conditional volatility parameters (γ_1, γ_2) are positive, between zero and one, and highly significant. The results indicate the presence of rather extreme conditionally heteroskedastic volatility effects in the exchange rate process because the GARCH parameters, γ_1 and γ_2, are found to be not only highly significant, but also the sum ($\gamma_1 + \gamma_2$) is close to one for all exchange rates considered in the paper. This implies the existence of substantial volatility persistence in the FX market.

Table 40.5 reports the daily risk aversion parameter estimates and their statistical significance for each currency after controlling for macroeconomic variables and lagged return. The risk-return coefficient estimates are similar to our earlier findings in Table 40.4. The relationship between expected return and conditional risk is positive but statistically weak for all exchange rates, except for the British pound and the Canadian dollar where we have a risk aversion parameter of 36.51 with t-stat. =1.89 for the British pound and 27.86 with t-stat. = 2.15 for the Canadian dollar. These results indicate that controlling for the hedging demand component of the ICAPM does not alter our findings.

Table 40.5 Daily risk-return trade-off in foreign exchange markets based on the GARCH-in-mean model with control variables

	(97.28)	(33.74)	(77.76)	(88.65)	(53.11)	(92.60)

The following GARCH-in-mean process is used with control variables to estimate the intertemporal relation between expected return and risk on currency

$$R_{t+1} \equiv \alpha + \beta \cdot \sigma^2_{t+1|t} + \lambda_1 \cdot FED_t + \lambda_2 \cdot DEF_t + \lambda_3 \cdot TERM_t + \lambda_4 \cdot R_t + \varepsilon_{t+1}$$

$$\varepsilon_{t+1} = z_{t+1} \cdot \sigma_{t+1|t}, z_{t+1} \sim N(0,1), E(\varepsilon_{t+1}) = 0$$

$$E\left(\varepsilon^2_{t+1} | \Omega_t\right) = \sigma^2_{t+1|t} = \gamma_0 + \gamma_1 \varepsilon^2_t + \gamma_2 \sigma^2_t$$

where FED_t, DEF_t, and $TERM_t$ are macroeconomic variables that proxy for the hedging demand component of ICAPM, and R_t is the lagged daily return. The federal funds rate (*FED*) is the interest rate at which a depository institution lends immediately available funds (balances at the Federal Reserve) to another depository institution overnight. The term spread (*TERM*) is calculated as the difference between the yields on the 10-year Treasury bond and the 3-month Treasury bill. The default spread (*DEF*) is computed as the difference between the yields on the BAA-rated and AAA-rated corporate bonds. The table presents the maximum likelihood parameter estimates and the t-statistics in parentheses

Table 40.5 shows that the slope coefficient (λ_4) on the lagged return is negative for all currencies, but it is statistically significant only for the euro (with t-stat. = –2.04) and the Swiss franc (with t-stat. = –2.48).[9] We find a negative but insignificant first-order serial correlation for the Japanese yen, British pound, Australian dollar, and Canadian dollar.

Table 40.6 presents the parameter estimates and their Newey and West (1987) adjusted *t*-statistics from the risk-return regressions with realized daily variance. Panel A reports results without the control variables and tests whether the realized variance obtained from the sum of squared 5-min returns can predict 1-day ahead returns on exchange rates. The risk aversion parameter (β) is estimated to be positive for five out of six currencies considered in the paper, but only two of these parameter estimates are statistically significant at the 10 % level. Specifically, β is estimated to be 11.39 for the euro, 7.91 for the Japanese yen, 7.91 for the British pound, 13.78 for the Swiss franc, –1.09 for the Australian dollar, and 11.89 for the Canadian dollar. Based on the Newey-West (1987) t-statistics reported in Table 40.6, the Swiss franc has a risk aversion parameter of 13.78 (t-stat. = 2.21) and the euro has a risk aversion coefficient of 11.39 (t-stat. = 1.77). These results indicate that the daily realized variance measures obtained from intraday data positively predict future returns on exchange rates, but the link between risk and return is generally statistically insignificant.

Panel B of Table 40.6 presents the risk aversion coefficient estimates after controlling for the federal funds rate, term spread, default spread, and lagged return. Similar to our findings in Panel A, the risk aversion parameter is estimated to be 18.76 with t-stat. = 2.42 for the euro, 8.77 with t-stat. = 1.80 for the Japanese yen, and 18.89 with t-stat. = 2.70 for the Swiss franc, indicating a positive and significant link between the realized variance and the 1-day ahead returns on the US dollar/euro, US dollar/yen, and US dollar/Swiss franc exchange rates. There is also a positive but statistically weak relation for the British pound and the Canadian dollar.

Table 40.7 reports the parameter estimates and their Newey-West t-statistics from the risk-return regressions with the daily range variance of Parkinson (1980). As shown in both panels, with and without control variables, the risk aversion parameter (β) is estimated to be positive but statistically insignificant, except for the marginal significance of β for the Canadian dollar in Panel B. These results provide evidence that the daily range volatility obtained from the intraday data positively predict future returns on exchange rates, but there is no significant relation between risk and return on currency.

The estimates in Tables 40.6 and 40.7 present a negative and significant autocorrelation for the euro, Japanese yen, Swiss franc, and Canadian dollar. The first-order autocorrelation coefficient is negative but statistically insignificant for the British pound and the Australian dollar.

[9]Jegadeesh (1990), Lehmann (1990), and Lo and MacKinlay (1990) provide evidence for the significance of short-term reversal (or negative autocorrelation) in short-term stock returns.

	(−0.99)	(−1.06)	(−0.90)	(−1.03)	(0.01)	(−0.25)
λ_2	−0.00051	−0.00112	0.00013	−0.00076	−0.00059	0.00041
	(−0.72)	(−1.33)	(0.18)	(−0.91)	(−0.63)	(0.60)
λ_3	−0.00054	−0.00054	−0.00041	0.00065	−0.00004	−0.00012
	(−1.54)	(−1.36)	(−1.19)	(1.67)	(−0.07)	(−0.37)
λ_4	−0.068	−0.048	−0.013	−0.077	−0.017	−0.071
	(−2.81)	(−1.81)	(−0.49)	(−3.00)	(−0.56)	(−2.88)

The following regression is estimated with and without control variables to test the significance of the intertemporal relation between expected return and risk on currency

$$R_{t+1} \equiv \alpha + \beta \cdot VAR_t^{\text{realized}} + \lambda_1 \cdot FED_t + \lambda_2 \cdot DEF_t + \lambda_3 \cdot TERM_t + \lambda_4 \cdot R_t + \varepsilon_{t+1}$$

where VAR_t^{realized} is the daily realized variance computed as the sum of squared 5-min returns on exchange rates. The table presents the parameter estimates and their Newey and West (1987) t-statistics in parentheses

An interesting observation in Tables 40.5, 40.6, and 40.7 is that the slope coefficients (λ_1, λ_2, λ_3) on the lagged macroeconomic variables are found to be statistically insignificant, except for some marginal significance for the term spread in the regressions with the Swiss franc. Although one would think that unexpected news in macroeconomic variables could be viewed as risks that would be rewarded in the FX market, we find that the changes in federal funds rate and term and default spreads do not affect time-series variation in daily exchange rate returns. Our interpretation is that it would be very difficult for macroeconomic variables to explain daily variations in exchange rates. If we examined the risk-return trade-off at lower frequency (such as monthly or quarterly frequency), we might observe significant impact of macroeconomics variables on monthly or quarterly variations in exchange rates.

Panel A of Table 40.8 presents the maximum likelihood parameter estimates and the t-statistics in parentheses for the GARCH-in-mean model with LIBOR rates for the US and the corresponding foreign country. The risk aversion parameter (β) is estimated to be positive for all currencies, but the parameter estimates are

	(−1.59)	(−1.25)	(−1.18)	(1.81)	(−0.40)	(−0.28)
λ_4	−0.067	−0.051	−0.012	−0.078	−0.026	−0.067
	(−2.77)	(−1.89)	(−0.45)	(−3.13)	(−0.87)	(−2.71)

The following regression is estimated with and without control variables to test the significance of the intertemporal relation between expected return and risk on currency

$$R_{t+1} \equiv \alpha + \beta \cdot VAR_t^{\text{range}} + \lambda_1 \cdot FED_t + \lambda_2 \cdot DEF_t + \lambda_3 \cdot TERM_t + \lambda_4 \cdot R_t + \varepsilon_{t+1}$$

where $VAR_t^{\text{range}} = 0.361[\ln(P_t^{\max}) - \ln(P_t^{\min})]^2$ is Parkinson's (1980) range-based estimator of the daily integrated variance. The table presents the parameter estimates and their Newey-West (1987) t-statistics in parentheses

statistically significant only for the British pound, Australian dollar, and Canadian dollar. Specifically, β is estimated to be 30.87 for the British pound, 17.75 for the Australian dollar, and 32.90 for the Canadian dollar. Based on the Bollerslev-Wooldridge heteroscedasticity consistent covariance t-statistics reported in Table 40.8, the risk aversion coefficient has a t-statistic of 1.82 for the British pound, 1.84 for the Australian dollar, and 2.36 for the Canadian dollar. Although we do not have a strong statistical significance, we can interpret this finding as a positive risk-return trade-off in the US dollar/British pound, US/Australian dollar, and US/Canadian dollar markets. Overall, the results indicate a positive but statistically weak relation between expected return and risk on currency.

Another point worth mentioning in Panel A is that the slope coefficients on the US LIBOR rate are estimated to be positive and statistically significant at the 5 % level for the euro, Japanese yen, and Swiss franc and significant at the 10 % level for the Canadian dollar. As expected, the slope coefficients on the LIBOR rates of the corresponding foreign country turn out to be negative but statistically insignificant.

	(−2.82)	(−1.87)	(−0.47)	(−3.22)	(−0.85)	(−2.71)

The following regressions with GARCH-in-mean, realized variance, and range variance are estimated to test the significance of the intertemporal relation between expected return and risk on currency

$$R_{t+1} \equiv \alpha + \beta \cdot \sigma^2_{t+1|t} + \lambda_1 \cdot LIBOR_t^{\mathrm{US}} + \lambda_2 \cdot LIBOR_t^{\mathrm{foreign}} + \lambda_3 \cdot R_t + \varepsilon_{t+1},$$
$$R_{t+1} \equiv \alpha + \beta \cdot VAR_t^{\mathrm{realized}} + \lambda_1 \cdot LIBOR_t^{\mathrm{US}} + \lambda_2 \cdot LIBOR_t^{\mathrm{foreign}} + \lambda_3 \cdot R_t + \varepsilon_{t+1},$$
$$R_{t+1} \equiv \alpha + \beta \cdot VAR_t^{\mathrm{range}} + \lambda_1 \cdot LIBOR_t^{\mathrm{US}} + \lambda_2 \cdot LIBOR_t^{\mathrm{foreign}} + \lambda_3 \cdot R_t + \varepsilon_{t+1},$$

where $LIBOR_t^{\mathrm{US}}$ and $LIBOR_t^{\mathrm{foreign}}$ are the LIBOR rates for the US and the corresponding foreign country

Panel B of Table 40.8 reports the parameter estimates and their Newey-West adjusted t-statistics from the risk-return regressions with daily realized variance after controlling for the LIBOR rates and the lagged return. The results indicate a positive and significant link between the realized variance and the 1-day ahead returns on the euro, Japanese yen, Swiss franc, and Canadian dollar. There is also a positive but statistically weak relation for the British pound.

Panel C of Table 40.8 shows the parameter estimates and their Newey-West t-statistics from the risk-return regressions with the daily range variance of Parkinson (1980). With LIBOR rates and the lagged return, the risk aversion parameter (β) is estimated to be positive for all currencies but statistically significant only for the Canadian dollar. Overall, the results provide evidence that after controlling for the interest rate differential of two countries, there is a positive but statistically weak relation between risk and return on currency.

Similar to our earlier findings from the GARCH-in-mean model, Panels B and C of Table 40.8 show that the slope coefficients on the US LIBOR rate are generally positive, whereas the slopes on the corresponding foreign LIBOR rates are negative with a few exceptions.

Many studies fail to identify a statistically significant intertemporal relation between risk and return of the stock market portfolios. French et al. (1987) find that the coefficient estimate is not significantly different from zero when they use past daily returns to estimate the monthly conditional variance.[10] Chan et al. (1992) employ a bivariate GARCH-in-mean model to estimate the conditional variance,

[10]When testing monthly risk-return trade-off, French et al. (1987) use the monthly realized variance obtained from the sum of squared daily returns within a month.

and they also fail to obtain a significant coefficient estimate for the United States. Campbell and Hentchel (1992) use the quadratic GARCH (QGARCH) model of Sentana (1995) to determine the existence of a risk-return trade-off within an asymmetric GARCH-in-mean framework. Their estimate is positive for one sample period and negative for another sample period, but neither is statistically significant. Glosten et al. (1993) use monthly data and find a negative but statistically insignificant relation from two asymmetric GARCH-in-mean models. Based on semi-nonparametric density estimation and Monte Carlo integration, Harrison and Zhang (1999) find a significantly positive risk and return relation at a 1-year horizon, but they do not find a significant relation at shorter holding periods such as 1 month. Using a sample of monthly returns and implied and realized volatilities for the S and P 500 index, Bollerslev and Zhou (2006) find an insignificant intertemporal relation between expected return and realized volatility, whereas the relation between return and implied volatility turns out to be significantly positive.

Several studies find that the intertemporal relation between risk and return is negative (e.g., Campbell 1987; Breen et al. 1989; Turner et al. 1989; Nelson 1991; Glosten et al. 1993; Harvey 2001; Brandt and Kang 2004). Some studies do provide evidence supporting a positive and significant relation between expected return and risk on stock market portfolios (e.g., Bollerslev et al. 1988; Scruggs 1998; Ghysels et al. 2005; Bali and Peng 2006; Guo and Whitelaw 2006; Lundblad 2007; Bali 2008).

Merton's (1973) ICAPM provides a theoretical model that gives a positive equilibrium relation between the conditional first and second moments of excess returns on the aggregate market portfolio. However, Abel (1988), Backus and Gregory (1993), and Gennotte and Marsh (1993) develop models in which a negative relation between expected return and volatility is consistent with equilibrium. As summarized above, there has been a lively debate on the existence and direction of a risk-return trade-off, and empirical studies are still not in agreement for the stock market portfolios. The empirical results presented in Tables 40.4, 40.5, 40.6, 40.7, and 40.8 indicate that the intertemporal relation between expected return and risk on currency is positive but in most cases statistically insignificant. Hence, our findings from the FX market are in line with some of the earlier studies that investigated the significance of a risk-return trade-off for the stock market.

40.5 Time-Varying Risk Aversion in the Foreign Exchange Market

Chou et al. (1992), Harvey (2001), and Lettau and Ludvigson (2010) suggest that the risk-return relation for the stock market may be time varying. In the existing literature, there is no study investigating the presence and significance of time-varying risk aversion in the FX market. We have so far assumed a constant risk-return trade-off in currency markets and found a positive but statistically insignificant relation between expected return and risk on exchange rates.

We now estimate the dependence of expected returns on the lagged realized variance over time using rolling regressions. This also allows us to check whether our results are driven by a particular sample period. We estimate the risk-return relation specified in Eqs. 40.12 and 40.13 for the six exchange rates with rolling samples. We used two different rolling regression approaches. The first one uses a fixed rolling window of 250 business days (i.e., approximately 1 year), whereas the second one starts with the in-sample period of 250 business days and then extends the sample by adding each daily observation to the estimation while keeping the start date constant.

Figure 40.1 plots the estimated relative risk aversion parameters (β) and their statistical significance over time from the fixed rolling window of 250 days.[11] Specifically, the first 250 daily return observations of exchange rates and their realized variances (from 1/3/2002 to 1/8/2003) are used for estimation of the relative risk aversion parameter for 1/8/2003. The sample is then rolled forward by removing the first observation of the sample and adding one to the end, and another 1-day ahead risk-return relationship is measured. This recursive estimation procedure is repeated until the sample is exhausted on March 31, 2008. The estimated relative risk aversion parameter over the fixed rolling sample period represents the average degree of risk aversion over that sample period. Computation of the relative risk aversion parameters using a rolling window of data allows us to observe the time variation in an investors' average risk aversion.

A common observation in Fig. 40.1 is that there is a strong time-series variation in the risk aversion estimates for all currencies considered in the paper. The first panel in Fig. 40.1 indicates that in the US dollar/euro FX market, the aggregate risk aversion is generally positive with some exceptions in the second half of 2006 and from May to August 2007. For the out-of-sample period of January 2003 to March 2008, only 208 out of 1,306 daily risk aversion estimates are negative. Based on the Newey-West adjusted t-statistics, all of these negative risk aversion estimates are statistically insignificant. 143 (291) out of 1,098 positive risk aversion estimates turn out to be statistically significant at least at the 5 % level (10 % level). These results indicate a positive but statistically insignificant time-varying risk aversion in the US dollar/euro market.

The second panel in Fig. 40.1 displays that in the Japanese yen market, the aggregate risk aversion is generally positive, but there are quite a lot of days in which we observe a negative relation between expected return and risk in the US dollar/yen market. 431 out of 1,306 daily risk aversion estimates are negative, but about one third is statistically significant at the 10 % level. 185 (314) out of 875 positive risk aversion estimates turn out to be statistically significant at least at the 5 % level (10 % level). These results indicate that there is a positive but not strong time-varying risk aversion in the US dollar/yen exchange rate market.

[11] Since the time-varying risk aversion coefficients from estimating Eqs. 40.12 and 40.13 with and without control variables turn out to be very similar, we only report results from the full specification of Eq. 40.13. Time-varying risk aversion estimates obtained from the parsimonious specification of Eq. 40.12 are available from the authors upon request.

Third panel in Fig. 40.1 shows that in the US dollar/lb sterling market, the risk aversion is generally positive, but there is a long period of time in which we observe a negative relation between expected return and risk in the US dollar/lb market. Specifically, 872 out of 1,306 daily risk aversion estimates are positive, but only 5 out of 872 are marginally significant. Similarly, only 46 out of 434 negative risk aversion estimates turn out to be statistically significant at the 10 % level. These results provide evidence that although there is a significant time variation in the aggregate risk aversion, it is not clear whether the currency trade generates a larger or smaller risk premium at times when the US dollar/lb FX market is riskier.

The fourth panel in Fig. 40.1 indicates that in the Swiss franc market, the risk aversion is estimated to be positive throughout the sample period (2002–2008), except for a few months in 2006. Only 71 out of 1,306 daily risk aversion estimates are negative, but none of them is statistically significant. 353 (467) out of 1,235 positive risk aversion estimates turn out to be statistically significant at least at the 5 % level (10 % level). These results indicate a positive and relatively strong time-varying risk aversion, implying that the currency trade generates a larger risk premium at times when the US dollar/Swiss franc trade becomes riskier.

The fifth panel in Fig. 40.1 indicates that in the Australian dollar market 736 out of 1,306 daily risk aversion estimates are positive, but none of them is statistically significant. Only 65 out of 570 negative risk aversion estimates turn out to be marginally significant at the 10 % level. The figure indicates a strong time-varying risk aversion, but there is no significantly positive or negative relation between risk and return in the US/Australian dollar exchange rate market.

The last panel in Fig. 40.1 demonstrates that in the US/Canadian dollar market, for slightly more than half of the sample, the risk aversion is estimated to be positive and slightly less than half of the sample it turns out to be negative. However, based on the t-statistics of these risk aversion estimates, there is no evidence for a significantly positive or negative link between expected return and risk on currency. Only 35 out of 757 positive risk aversion coefficients and only 46 out of 549 negative risk aversion parameters are found to be significant at the 10 % level. Although there is a significant time-series variation in the aggregate risk aversion, trading in the US/Canadian dollar FX market does not provide clear evidence for a larger or smaller risk premium at times when the market is riskier.

Figure 40.2 plots the estimated relative risk aversion parameters (β) and their statistical significance over time from the rolling regressions with a fixed starting date. Specifically, the first 250 daily return observations of exchange rates and their realized variances (from 1/3/2002 to 1/7/2003) are used for estimation of the relative risk aversion parameter for 1/8/2003. The sample is then extended by adding one observation to the end (from 1/3/2002 to 1/8/2003), and the 1-day ahead risk-return relation is measured for 1/9/2003. This recursive estimation procedure is repeated until March 31, 2008.

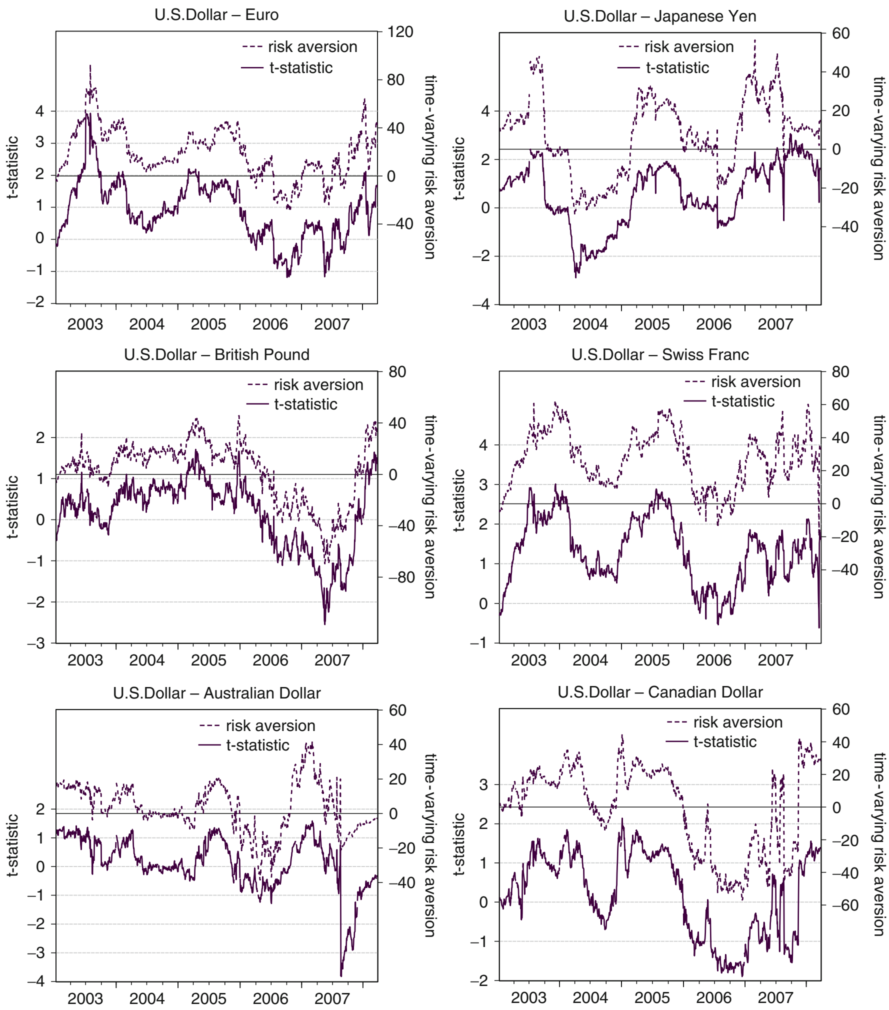

Fig. 40.1 Rolling regression estimates from the fixed length window of 250 days

Similar to our findings from the fixed rolling window regressions, Fig. 40.2 provides evidence for a significant time variation in the risk aversion estimates for all currencies considered in the paper. The first panel in Fig. 40.2 shows that in the US dollar/euro market, the aggregate risk aversion is positive with a few exceptions in January 2003. Only 16 out of 1,306 risk aversion estimates are negative, but none of these estimates is statistically significant based on the Newey-West t-statistics. 795 (870) out of 1,290 positive risk aversion estimates turn out to be statistically significant at least at the 5 % level (10 % level). These results indicate a positive and strong time-varying risk aversion in the US dollar/euro market.

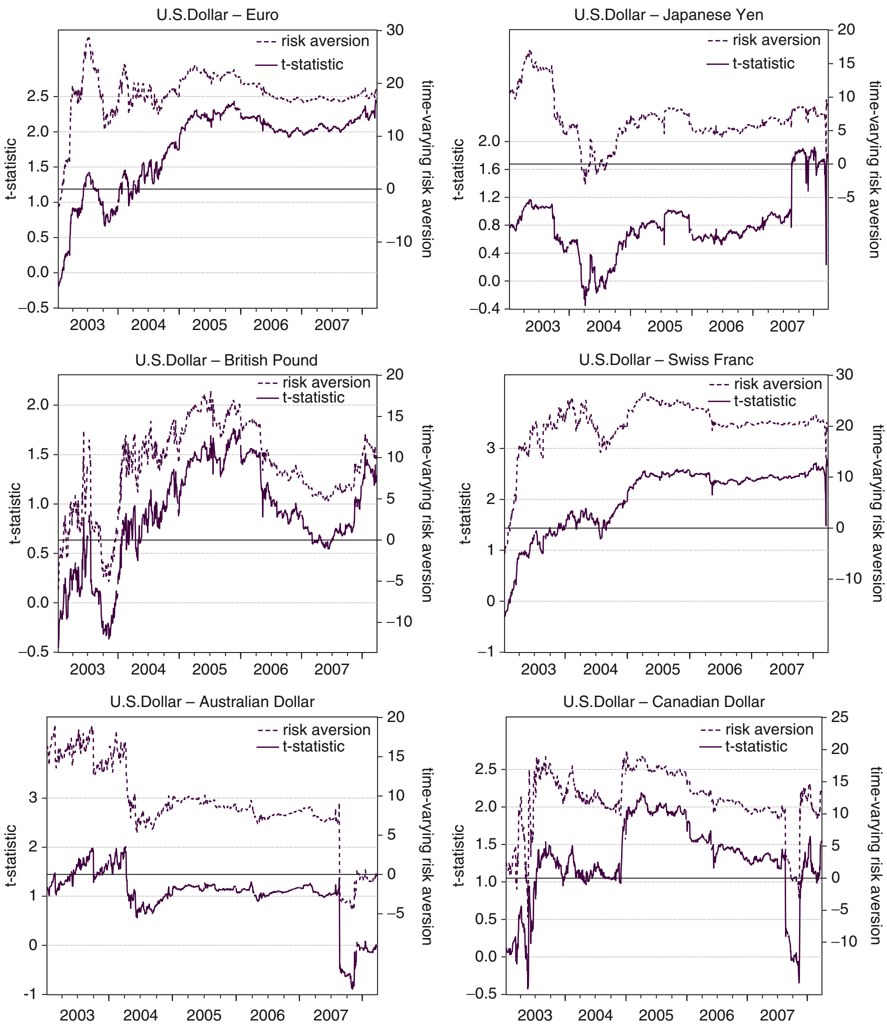

Fig. 40.2 Rolling regression estimates from the windows with fixed starting point

The second panel in Fig. 40.2 shows that in the US dollar/yen FX market, the aggregate risk aversion is positive with a few exceptions from March to June 2004. Only 68 out of 1,306 risk aversion estimates are negative and all of them are statistically insignificant. 129 out of 1,238 positive risk aversion estimates turn out to be marginally significant at the 10 % level. These results imply a positive but statistically weak time-varying risk aversion in the US dollar/yen market.

The third panel in Fig. 40.2 depicts that in the pound sterling market, the risk aversion is positive throughout the sample, except for a short period of time in 2003. Only 90 out of 1,306 risk aversion estimates are negative, but they are not statistically significant. Although there is a significant time variation in the risk aversion and most of the risk-return coefficients are positive, only 41 out of 1,216 positive risk aversion estimates turn out to be significant at the 10 % level. Therefore, it is not clear whether the currency trade generates a larger or smaller risk premium at times when the US dollar/lb market is riskier.

The fourth panel in Fig. 40.2 provides evidence that in the Swiss franc market, the risk aversion is estimated to be positive throughout the sample period (2002–2008), except for a few days in January 2003. Only 20 out of 1,306 risk aversion estimates are negative but statistically insignificant. 816 (934) out of 1,286 positive risk aversion estimates turn out to be statistically significant at least at the 5 % level (10 % level). These results suggest a positive and strong time-varying risk aversion, implying that the currency trade generates a larger risk premium at times when the US dollar/Swiss franc exchange rate market is riskier.

The fifth panel in Fig. 40.2 shows that in the Australian dollar market only 138 out of 1,306 risk aversion estimates are negative with no statistical significance even at the 10 % level. Only 106 out of 1,168 positive risk aversion coefficients are found to be marginally significant at the 10 % level. Although there is significant time variation in the aggregate risk aversion, the results do not suggest a strong positive or negative link between expected return and risk in the US/Australian dollar market.

The last panel in Fig. 40.2 demonstrates that in the US/Canadian dollar market, the risk aversion is estimated to be positive, except for a few days in May, October, and November 2003. Similar to our earlier findings, only 41 out of 1,308 risk aversion estimates are negative with very low t-statistics. However, based on the statistical significance of positive risk aversion estimates, there is no evidence for a strong positive link between expected return and risk on currency either. Only 276 out of 1,265 positive risk aversion coefficients are found to be significant at the 10 % level. Although there is a significant time-series variation in the aggregate risk aversion, trading in the US/Canadian dollar FX market does not provide clear evidence for a larger or smaller risk premium at times when the market is riskier.

40.6 Testing Merton's (1973) ICAPM in Currency Market

Merton's (1973) ICAPM implies the following equilibrium relation between risk and return for any risky asset i:

$$\mu_i - r = A \cdot \sigma_{im} + B \cdot \sigma_{ix}, \tag{40.19}$$

where r is the risk-free interest rate, $\mu_i - r$ is the expected excess return on the risky asset i, σ_{im} denotes the covariance between the returns on the risky asset i and the market portfolio m, and σ_{ix} denotes a $(1 \times k)$ row of covariances between the returns on risky asset i and the k state variables x. A denotes the average relative risk aversion of market investors, and B measures the market's aggregate reaction to shifts in a k-dimensional state vector that governs the stochastic investment opportunity. Equation 40.19 states that in equilibrium, investors are compensated in terms of expected return for bearing market risk and for bearing the risk of unfavorable shifts in the investment opportunity set.

Merton (1980) shows that the intertemporal hedging demand component ($B \cdot \sigma_{ix}$) is economically and statistically smaller than the market risk component ($A \cdot \sigma_{im}$) of ICAPM. While testing the significance of A and B at daily frequency, Bali and Engle (2010) provide supporting evidence for Merton (1980) that the conditional covariances of individual stocks with the market portfolio have positive and statistically significant loading, whereas the innovations in state variables are not priced in the stock market. That is, the conditional covariances of stock returns with the unexpected news in state variables have insignificant loadings.

We examine Merton's (1973) ICAPM based on the following system of equations:

$$\begin{aligned} R_{i,t+1} &= C_i + A \cdot \sigma_{im,t} + \varepsilon_{i,t+1} \\ R_{m,t+1} &= C_m + A \cdot \sigma^2_{m,t} + \varepsilon_{m,t+1} \end{aligned} \tag{40.20}$$

where the expected conditional covariance of individual exchange rates with the currency market, $E_t(\sigma_{im,t+1})$, is represented by the 1-day lagged realized covariance, i.e., $E_t(\sigma_{im,t+1}) = \sigma_{im,t}$. Similarly, the expected conditional variance of the currency market, $E_t(\sigma_{m,t+1}{}^2)$, is represented by the 1-day lagged realized variance, i.e., $E_t(\sigma_{m,t+1}{}^2) = \sigma_{m,t}{}^2$.[12]

The currency market portfolio is measured by the "value-weighted" average returns on EUR, JPY, GBP, CHF, AUD, and CAD. The weights are obtained from the "US Dollar Index." Just as the Dow Jones Industrial Average reflects the general state of the US stock market, the US Dollar Index (USDX) reflects the general assessment of the US dollar. USDX does it through exchange rates averaging of US dollar and six most tradable global currencies. The weights are 57.6 % for EUR, 13.6 % for JPY, 11.9 % for GBP, 9.1 % CAD, 4.2 % for AUD, and 3.6 % for CHF. In our empirical analysis, daily returns on the currency market, $R_{m,t+1}$, are calculated by multiplying daily returns on the six exchange rates by the aforementioned weights.

We estimate the system of Eq. 40.20 using an ordinary least square (OLS) as well as a weighted least square method that allows us to place constraints on coefficients across equations. We constrain the slope coefficient (A) on the lagged realized variance-covariance matrix ($\sigma_{im,t}$, $\sigma_{m,t}{}^2$) to the same value across all the currencies for cross-sectional consistency. We allow the intercepts (C_i, C_m) to differ across all the currencies. Under the null hypothesis of the ICAPM, the intercepts should be jointly zero, and the common slope coefficient (A) should be positive and statistically significant. We use insignificant estimates of A and the deviations from zero of the intercept estimates as a test against the validity and sufficiency of

[12]Daily realized covariances between the exchange rates and the currency market and daily realized variance of the currency market are computed using 5-min returns in a day.

the ICAPM. In addition to the OLS panel estimates, we compute the t-statistics of the parameter estimates accounting for heteroskedasticity and autocorrelation as well as contemporaneous cross-correlations in the error terms. This estimation methodology for the system of Eq. 40.20 can be regarded as an extension of the seemingly unrelated regression (SUR) method.

Table 40.9 presents the OLS and SUR panel regression estimates of the currency-specific intercepts, common slope coefficients on the lagged realized variance-covariance matrix, and their t-statistics. The parameters and their t-statistics are estimated using the daily returns on the currency market and the six exchange rates. The last row reports the Wald statistics with p-values from testing the joint hypothesis that all intercepts equal zero: H_0: $C_1 = C_2 = \ldots = C_6 = C_m = 0$. A notable point in Table 40.9 is that the common slope coefficient (A) is positive and statistically significant. Specifically, the risk aversion coefficient on the realized variance-covariance matrix is estimated to be 23.33 with a t-statistic of 5.40. After correcting for heteroscedasticity, autocorrelation, and contemporaneous cross-correlations, the SUR estimate of the risk aversion coefficient turns out to be 15.80 with t-stat. = 2.57. These results indicate a positive and significant relation between risk and return on the currency market. Another notable point in Table 40.9 is that for both the OLS and SUR estimates, the Wald statistics reject the hypothesis that all intercepts equal zero. This implies that the market risk alone cannot explain the entire time-series variation in exchange rates.

According to the original ICAPM of Merton (1973), the relative risk aversion coefficient (A) is restricted to the same value across all risky assets, and it is positive and statistically significant. The common slope estimates in Table 40.9 provide empirical support for the positive risk-return trade-off.

We now test whether the slopes on (σ_{im}, ${\sigma_m}^2$) are different across currencies. We examine the sign and statistical significance of different slope coefficients (A_i, A_m) on (σ_{im}, ${\sigma_m}^2$) in the following system of equations:

$$\begin{aligned} R_{i,t+1} &= C_i + A_i \cdot \sigma_{im,t} + \varepsilon_{i,t+1}, \\ R_{m,t+1} &= C_m + A_m \cdot \sigma^2_{m,t} + \varepsilon_{m,t+1} \end{aligned} \tag{40.21}$$

To determine whether there is a common slope coefficient (A) that corresponds to the average relative risk aversion, we first estimate the currency-specific slope coefficients (A_i, A_m) and then test the joint hypothesis that H_0: $A_1 = A_2 = \ldots = A_6 = A_m$.

Table 40.10 presents the OLS and SUR parameter estimates using daily returns on the six exchange rates and the value-weighted currency market index. As compared to Eq. 40.20, we have additional six-slope coefficients to estimate in Eq. 40.21. As shown in Table 40.10, all of the slope coefficients (A_i, A_m) are estimated to be positive and highly significant without any exception. These results indicate a positive and significant intertemporal relation between risk and return on the currency market. We examine the cross-sectional consistency of the intertemporal relation by testing the equality of slope coefficients based on the Wald statistics. As reported in Table 40.10, the Wald statistics, from testing

Table 40.9 Testing Merton's (1973) ICAPM with a common slope coefficient

Entries report the OLS and SUR panel regression estimates based on the following system of equations

$$R_{i,t+1} = C_i + A \cdot \sigma_{im,t} + \varepsilon_{i,t+1},$$
$$R_{m,t+1} = C_m + A \cdot \sigma^2_{m,t} + \varepsilon_{m,t+1},$$

where $\sigma_{im,t}$ is the 1-day lagged realized covariance between the exchange rate and the currency market. ${\sigma_{m,t}}^2$ is the 1-day lagged realized variance of the currency market. A is a common slope coefficient on the lagged realized variance-covariance matrix. (C_i, C_m) denotes currency-specific intercepts for AUD, EUR, GBP, CAD, CHF, JPF, and the currency market. The last row reports the Wald statistics with p-values from testing the joint hypothesis that all intercepts equal zero: H_0: $C_1 = C_2 = \ldots = C_6 = C_m = 0$

the joint hypothesis that H_0: $A_1 = A_2 = \ldots = A_6 = A_m$, is 1.41 for OLS and 5.24 for SUR, which fail to reject the null hypothesis. These results indicate the equality of positive slope coefficients across all currencies, which empirically validates the ICAPM.

40.7 Conclusion

There is an ongoing debate in the literature about the intertemporal relation between stock market risk and return and the extent to which expected stock returns are related to expected market volatility. Recently, some studies have provided evidence for a significantly positive link between risk and return in the aggregate stock market, but the risk-return trade-off is generally found to be insignificant and sometimes even negative. This paper is the first to investigate the presence and significance of an intertemporal relation between expected return and risk in the foreign exchange market. The paper provides new evidence on the ICAPM by using high-frequency intraday data on currency and by presenting significant time variation in the risk aversion parameter. We utilize daily and 5-min returns on the spot exchange rates of the US dollar vis-à-vis six major currencies (the euro, Japanese yen, British pound sterling, Swiss franc, Australian dollar, and Canadian dollar)

Entries report the OLS and SUR panel regression estimates based on the following system of equations

$$R_{i,t+1} = C_i + A_i \cdot \sigma_{im,t} + \varepsilon_{i,t+1},$$
$$R_{m,t+1} = C_m + A_m \cdot \sigma^2_{m,t} + \varepsilon_{m,t+1},$$

where $\sigma_{im,t}$ is the 1-day lagged realized covariance between the exchange rate and the currency market. $\sigma^2_{m,t}$ is the 1-day lagged realized variance of the currency market. (A_i, A_m) denotes currency-specific slope coefficients on the lagged realized variance-covariance matrix. (C_i, C_m) denotes currency-specific intercepts for AUD, EUR, GBP, CAD, CHF, JPF, and the currency market. The Wald statistics with p-values are reported from testing the joint hypothesis that all intercepts equal zero: H_0:$C_1 = C_2 = \ldots = C_6 = C_m = 0$. The last row presents the Wald statistics from testing the equality of currency-specific slope coefficients H_0: $A_1 = A_2 = \ldots = A_6 = A_m$

and test the existence and significance of a risk-return trade-off in the FX market using the GARCH, realized, and range-based volatility measures. The maximum likelihood parameter estimates of the GARCH-in-mean model and the risk-return regressions with daily realized and range volatility estimators indicate that the intertemporal relation between risk and return is generally positive but statistically weak in the FX market.

We provide strong evidence on the time variation of risk aversion parameters for all currencies considered in the paper. However, the direction of a relationship between expected return and risk is not clear. The results indicate a positive but not strong time-varying risk aversion in the US dollar/euro exchange rate market. The risk-return regressions with realized variance provide evidence for a positive but statistically weak risk aversion estimates in the US dollar/yen market. Although there is a significant time variation in risk aversion estimates for the British pound, it is not clear whether the currency trade generates a larger or smaller risk premium at times when the US dollar/lb market is riskier. The risk aversion parameter is estimated to be positive but marginally significant throughout the sample period for the Swiss franc, implying that the currency trade generally yields a larger risk premium at times when the US dollar/Swiss franc market is riskier. For most of the sample, the risk-return coefficients are estimated to be positive but statistically insignificant for the Canadian dollar, suggesting that the intertemporal relation between risk and return is flat for the US/Canadian dollar market.

Appendix 1: Maximum Likelihood Estimation of GARCH-in-Mean Models

Modeling and estimating the volatility of financial time series has been high on the agenda of financial economists since the early 1980s. Engle (1982) put forward the Autoregressive Conditional Heteroskedastic (ARCH) class of models for conditional variances which proved to be extremely useful for analyzing financial return series. Since then an extensive literature has been developed for modeling the conditional distribution of stock prices, interest rates, exchange rates, and futures prices. Following the introduction of ARCH models by Engle (1982) and their generalization by Bollerslev (1986), there have been numerous refinements of this approach to estimating conditional volatility. Most of the refinements have been driven by empirical regularities in financial data.

Engle (1982) introduces *ARCH*(*p*) model:

$$R_{t+1} \equiv \alpha + \varepsilon_{t+1} \tag{40.22}$$

$$\begin{aligned} &\varepsilon_{t+1} = z_{t+1} \cdot \sigma_{t+1|t}, z_{t+1} \sim N(0,1), \\ &E(\varepsilon_{t+1}) = 0 \end{aligned} \tag{40.23}$$

$$E\left(\varepsilon_{t+1}^2|\Omega_t\right) = \sigma_{t+1|t}^2 = \gamma_0 + \gamma_1\varepsilon_t^2 + \gamma_2\varepsilon_{t-1}^2 + \ldots + \gamma_p\varepsilon_{t-p}^2 \tag{40.24}$$

$$f\left(R_{t+1};\mu,\sigma_{t+1|t}\right)=\frac{1}{\sqrt{2\pi\sigma^2_{t+1|t}}}\exp\left[-\frac{1}{2}\left(\frac{R_{t+1}-\mu}{\sigma_{t+1|t}}\right)^2\right] \tag{40.25}$$

where R_{t+1} is the daily return for period t+1, $\mu = \alpha$ is the constant conditional mean, $\varepsilon_{t+1} = z_{t+1} \cdot \sigma_{t+1|t}$ is the error term with $E(\varepsilon_{t+1}) = 0$, $\sigma_{t+1|t}$ is the conditional standard deviation of daily returns, and $z_{t+1} \sim N(0,1)$ is a random variable drawn from the standard normal density and can be viewed as information shocks or unexpected news in the market. ${\sigma_{t+1|t}}^2$ is the conditional variance of daily returns based on the information set up to time t denoted by Ω_t. The conditional variance, ${\sigma_{t+1|t}}^2$, follows an ARCH(p) process which is a function of the last period's unexpected news (or information shocks). $f(R_{t+1};\mu,\sigma_{t+1|t})$ is the conditional normal density function of R_{t+1} with the conditional mean of μ and conditional variance of ${\sigma_{t+1|t}}^2$.

Given the initial values of ε_t and, the parameters in Eqs 40.22 and 40.24 can be estimated by maximizing the log-likelihood function over the sample period. The conditional normal density in Eq. 40.25 yields the following log-likelihood function:

$$\text{Log}L_{ARCH}=-\frac{n}{2}\ln(2\pi)-\frac{n}{2}\ln\sigma_{t+1|t}-\frac{1}{2}\sum_{t=1}^{n}\left(\frac{R_{t+1}-\mu}{\sigma_{t+1|t}}\right)^2 \tag{40.26}$$

Bollerslev (1986) extends the original work of Engle (1982) and defines the current conditional variance as a function of the last period's unexpected news as well as the last period's conditional volatility:

$$R_{t+1}\equiv\alpha+\varepsilon_{t+1} \tag{40.27}$$

$$\varepsilon_{t+1}=z_{t+1}\cdot\sigma_{t+1|t},z_{t+1}\sim N(0,1)E(\varepsilon_{t+1})=0 \tag{40.28}$$

$$E\left(\varepsilon^2_{t+1}|\Omega_t\right)=\sigma^2_{t+1|t}=\gamma_0+\gamma_1\varepsilon^2_t+\gamma_2\sigma^2_t \tag{40.29}$$

where the conditional variance, ${\sigma_{t+1|t}}^2$, in Eq. 40.29 follows a GARCH(1,1) process as defined by Bollerslev (1986) to be a function of the last period's unexpected news (or information shocks), z_t, and the last period's variance, σ_t^2. The parameters in Eqs. 40.27, 40.28, and 40.29 are estimated by maximizing the conditional log-likelihood function in Eq. 40.26.

Engle et al. (1987) introduce the ARCH-in-mean model in which the conditional mean of financial time series is defined as a function of the conditional variance. In our empirical investigation of the ICAPM for exchange rates, we use the following GARCH-in-mean process to model the intertemporal relation between expected return and risk on currency

$$R_{t+1}\equiv\alpha+\beta\cdot\sigma^2_{t+1|t}+\varepsilon_{t+1} \tag{40.30}$$

$$\begin{aligned}&\varepsilon_{t+1}=z_{t+1}\cdot\sigma_{t+1|t};z_{t+1}\sim N(0,1);\\&E(\varepsilon_{t+1})=0\end{aligned} \tag{40.31}$$

$$E\left(\varepsilon^2_{t+1}|\Omega_t\right)=\sigma^2_{t+1|t}=\gamma_0+\gamma_1\varepsilon^2_t+\gamma_2\sigma^2_t \tag{40.32}$$

$$f\left(R_{t+1};\mu_{t+1|t},\sigma_{t+1|t}\right) = \frac{1}{\sqrt{2\pi\sigma^2_{t+1|t}}}\exp\left[-\frac{1}{2}\left(\frac{R_{t+1}-\mu_{t+1|t}}{\sigma_{t+1|t}}\right)^2\right] \tag{40.33}$$

where R_{t+1} is the daily return on exchange rates for period t+1, $\mu_{t+1|t} \equiv \alpha + \beta \cdot \sigma^2_{t+1|t}$ is the conditional mean for period t+1 based on the information set up to time t, $\varepsilon_{t+1} = z_{t+1} \cdot \sigma_{t+1|t}$ is the error term with $E(\varepsilon_{t+1}) = 0$, $\sigma_{t+1|t}$ is the conditional standard deviation of daily returns on currency, and $z_{t+1} \sim N(0,1)$ is a random variable drawn from the standard normal density and can be viewed as information shocks in the FX market. $\sigma^2_{t+1|t}$ is the conditional variance of daily returns based on the information set up to time t denoted by Ω_t. The conditional variance, $\sigma^2_{t+1|t}$, follows a GARCH(1,1) process as defined by Bollerslev (1986) to be a function of the last period's unexpected news (or information shocks), z_t, and the last period's variance, σ_t^2. $f(R_{t+1};\mu_{t+1|t},\sigma_{t+1|t})$ is the conditional normal density function of R_{t+1} with the conditional mean of $\mu_{t+1|t}$ and conditional variance of $\sigma^2_{t+1|t}$.

Given the initial values of ε_t and, the parameters in Eqs. 40.30 and 40.32 can be estimated by maximizing the log-likelihood function over the sample period. The conditional normal density in Eq. 40.33 yields the following log-likelihood function

$$\begin{aligned}\text{Log}L_{ARCH} = &-\frac{n}{2}\ln(2\pi) - \frac{n}{2}\ln\sigma_{t+1|t} \\ &-\frac{1}{2}\sum_{t=1}^{n}\left(\frac{R_{t+1}-\mu_{t+1|t}}{\sigma_{t+1|t}}\right)^2\end{aligned} \tag{40.34}$$

where the conditional mean $\mu_{t+1|t} \equiv \alpha + \beta \cdot \sigma^2_{t+1|t}$ has two parameters and the conditional variance $\sigma_{t+1|t}{}^2 = \gamma_0 + \gamma_1\varepsilon_t{}^2 + \gamma_2\sigma_t^2$ has three parameters. Maximizing the log-likelihood in Eq. 40.34 yields the parameter estimates (α, β, γ_0, γ_1, γ_2).

The interested reader may wish to consult Enders (2009), Chap. 3, and Tsay (2010), Chap. 3, for comprehensive analysis of ARCH/GARCH models and their maximum likelihood estimation. Chapter 3 in Enders (2009) provides a detailed coverage of the basic ARCH and GARCH models, as well as the GARCH-in-mean processes and multivariate GARCH in some detail. Chapter 3 in Tsay (2010) provides a detailed coverage of the ARCH, GARCH, GARCH-M, the exponential GARCH, and Threshold GARCH models.

Appendix 2: Estimation of a System of Regression Equations

Consider a system of n equations, of which the typical ith equation is

$$y_i = X_i\beta_i + u_i \tag{40.35}$$

where y_i is a $N \times 1$ vector of time-series observations on the i th dependent variable, X_i is a $N \times k_i$ matrix of observations of k_i independent variables, β_i is a $k_i \times 1$ vector of unknown coefficients to be estimated, and u_i is a $N \times 1$ vector of random disturbance terms with mean zero. Parks (1967) proposes an estimation procedure that allows the error term to be both serially and cross-sectionally correlated. In particular, he assumes that the elements of the disturbance vector u follow an AR(1) process

$$u_{it} = \rho_i u_{it-1} + \varepsilon_{it}; \rho_i < 1 \tag{40.36}$$

where ε_{it} is serially independently but contemporaneously correlated:

$$\mathrm{Cov}\left(\varepsilon_{it}\varepsilon_{jt}\right) = \sigma_{ij}, \forall i, j, \text{and } \mathrm{Cov}\left(\varepsilon_{it}\varepsilon_{js}\right) = 0, \text{for } s \neq t \tag{40.37}$$

Equation 40.35 can then be written as

$$y_i = X_i\beta_i + P_i\varepsilon_i, \tag{40.38}$$

with

$$P_i = \begin{bmatrix} \left(1-\rho_i^2\right)^{-1/2} & 0 & 0 & \dots & 0 \\ \rho_i\left(1-\rho_i^2\right)^{-1/2} & 1 & 0 & \dots & 0 \\ \rho_i^2\left(1-\rho_i^2\right)^{-1/2} & \rho_i & 0 & \dots & 0 \\ \cdot & & & & \\ \cdot & & & & \\ \cdot & & & & \\ \rho_i^{N-1}\left(1-\rho_i^2\right)^{-1/2} & \rho_i^{N-2} & \rho_i^{N-3} & \dots & 1 \end{bmatrix} \tag{40.39}$$

Under this setup, Parks presents a consistent and asymptotically efficient three-step estimation technique for the regression coefficients. The first step uses single equation regressions to estimate the parameters of autoregressive model. The second step uses single equation regressions on transformed equations to estimate the contemporaneous covariances. Finally, the Aitken estimator is formed using the estimated covariance,

$$\hat{\beta} = \left(X^T\Omega^{-1}X\right)^{-1}X^T\Omega^{-1}y \tag{40.40}$$

Where $\Omega \equiv E[uu^T]$ denotes the general covariance matrix of the innovation. In my application, I use the aforementioned methodology with the slope coefficients restricted to be the same for all portfolios. In particular, we use the same three-step procedure and the same covariance assumptions as in Eqs. 40.36, 40.37, 40.38, 40.39, and 40.40 to estimate the covariances and to generate the t-statistics for the parameter estimates.

estimations based on quantile regression of the QAR models, copula models, ARCH models, GARCH models, and the CaViaR models are systematically introduced. Comparing the proposed QR method with traditional methods based on distributional assumptions, the QR method has the important property in that it is robust to non-Gaussian distributions. Quantile estimation is only influenced by the local behavior of the conditional distribution of the response near the specified quantile. As a result, the estimates are not sensitive to outlier observations. Such a property is especially attractive in financial applications since many financial data like, say, portfolio returns (or log returns) are usually not normally distributed. To highlight the importance of the QR method in estimating VaR, we apply the QR techniques to estimate VaRs in International Equity Markets. Numerical evidence indicates that QR is a robust estimation method for VaR.

Keywords

ARCH • Copula • GARCH • Non-normality • QAR • Quantile regression • Risk management • Robust estimation • Time series • Value at risk

41.1 Introduction

The Value at Risk (VaR) is the loss in market value over a given time horizon that is exceeded with probability τ, where τ is often set at 0.01 or 0.05. In recent years, VaR has become a popular tool in the measurement and management of financial risk. This popularity is spurred both by the need of various institutions for managing risk and by government regulations (see Blankley et al., 2000; Dowd 1998, 2000; Saunders 1999). VaR is an easily interpretable measure of risk that summarizes information regarding the distribution of potential losses. In requiring publicly traded firms to report risk exposure, the Securities and Exchange Commission (SEC) lists VaR as a disclosure method "expressing the potential loss in future earnings, fair values, or cash flows from market movements over a selected period of time and with a selected likelihood of occurrence."

Estimation of VaR has attracted much attention from researchers (Duffie and Pan (1997); Wu and Xiao (2002); Guo et al. (2007)). Many existing methods of VaR estimation in economics and finance are based on the assumption that financial returns have normal (or conditional normal) distributions (usually with ARCH or GARCH effects). Under the assumption of a conditionally normal return distribution, the estimation of conditional quantiles is equivalent to estimating conditional volatility of returns. The massive literature on volatility modeling offers a rich source of parametric methods of this type. However, there is accumulating evidence that financial time series and return distributions are *not* well approximated by Gaussian models. In particular, it is frequently found that market returns display negative skewness and excess kurtosis. Extreme realizations of returns can adversely affect the performance of estimation and inference designed for Gaussian conditions; this is particularly true of ARCH and GARCH models whose estimation of variances is very sensitive to large innovations. For this reason, research attention has recently shifted toward the development of more robust estimators of conditional quantiles.

There is also growing interest in nonparametric estimation of conditional quantiles. However, nearest neighbor and kernel methods are somewhat limited in their ability to cope with more than one or two covariates. Other approaches to estimating VaR include the hybrid method and methods based on extreme value theory.

Quantile regression as introduced by Koenker and Bassett (1978) is well suited to estimating VaR. Value at Risk, as mandated in many current regulatory contexts, is a conditional quantile by definition. This concept is intimately linked to quantile regression estimation.

Quantile regression has now become a popular robust approach for statistical analysis. Just as classical linear regression methods based on minimizing sums of squared residuals enable one to estimate models for conditional mean, quantile regression methods offer a mechanism for estimating models for the conditional quantiles. These methods exhibit robustness to extreme shocks and facilitate distribution-free inference. In recent years, quantile regression estimation for time-series models has gradually attracted more attention. Koenker and Zhao (1996) extended quantile regression to linear ARCH models and estimate conditional quantiles by a linear quantile regression. Engle and Manganelli (1999) have suggested a nonlinear dynamic quantile model where conditional quantiles themselves follow an autoregression, and they call this a Conditional Autoregressive Value at Risk (CaViaR) specification. Computation of the CaViaR model is challenging and grid searching is conventionally used in practice. Koenker and Xiao (2006) investigate quantile autoregressive processes that can capture systematic influences of conditioning variables on the location, scale, and shape of the conditional distribution of the response and therefore constitute a significant extension of classical time-series models in which the effect of conditioning is confined to a location shift. Xiao and Koenker (2009) recently studied quantile regression estimation of GARCH models. GARCH models have proven to be highly successful in modeling financial data and are arguably the most widely used class of models in financial applications. However, quantile regression GARCH models are highly nonlinear and thus complicated to estimate. The quantile estimation problem in GARCH models corresponds to a restricted nonlinear quantile regression, and conventional nonlinear quantile regression techniques are not directly applicable, adding an additional challenge to the already complicated estimation problem. Koenker and Xiao (2009) propose a two-step approach for quantile regression on GARCH models. The proposed method is relatively easy to implement compared to other nonlinear estimation techniques in quantile regression and has good sampling performance in our simulation experiments.

VaRs estimated by the quantile regression approach display some nice properties. For example, they track VaRs estimated from GARCH volatility models well during normal market conditions. However, during market turmoils when large market price drops are followed by either further drops or rebounds, GARCH volatility models tend to predict implausibly high VaRs. This is due to the fact that volatility and VaRs are not synonymous. While large positive and negative return shocks indicate higher volatility, only large negative return shocks indicate higher Value at Risk. GARCH models treat both large positive and negative return shocks as indications of higher volatility. VaRs estimated by the ARCH/GARCH quantile regression model, while predicting higher volatility in the ARCH/GARCH component, assign a much bigger weight to the large negative return shock than the large positive return shock. The resulting estimated VaRs seem to be closer to reality.

In this chapter, we study quantile regression estimation of VaR. Different quantile models in estimating VaR are introduced in this paper. In particular, Value at Risk analysis based on quantile regression of the QAR models, copula models, ARCH models, GARCH models, and the CaViaR models is systematically introduced. To highlight the importance of quantile regression method in estimating VaR, we apply the quantile regression techniques to estimate VaR in International Equity Markets. Numerical evidence indicates that quantile regression is a robust estimation method for VaR.

This chapter is organized as follows. We introduce the traditional VaR estimation methods and quantile regression in Sect. 41.2. The quantile autoregression (QAR) models are given in Sect. 41.3; nonlinear QAR models based on copula and the CaViaR models are also introduced. Section 41.4 introduces quantile regression estimation on ARCH and GARCH models. Section 41.5 contains an empirical application of quantile regression estimation of VaRs. Section 41.6 concludes.

41.2 Traditional Estimation Methods of VaR

For a time series of returns on an asset, $\{r_t\}_{t=1}^{n}$, the τ (or $100\tau\%$) VaR at time t, denoted by VaR_t, is defined by

$$\Pr(r_t < -VaR_t | \mathcal{F}_{t-1}) = \tau \tag{41.1}$$

where $\mathcal{F}_{t-1}$ denotes the information set at time $t-1$, including past values of returns and possibly the value of some covariates X_t.

If we assume that the time series of returns are modeled by

$$r_t = \mu_t + \sigma_t \varepsilon_t,$$

where r_t is the return of an asset at time t and $\mu_t, \sigma_t \in \mathcal{F}_{t-1}$. The random variables ε_t are martingale difference sequences. The Conditional Value at Risk of r_t given $\mathcal{F}_{t-1}$ is

$$VaR_t(\tau) = \mu_t + \sigma_t Q_\varepsilon(\tau),$$

where $Q_\varepsilon(\tau)$ denotes the Unconditional Value at Risk of the error term ε_t. Assuming conditional normality, the 5 % VaR at time t can be computed as

$$VaR_t(0.05) = \mu_t + 1.65\sigma_t$$

where μ_t and σ_t are the conditional mean and conditional volatility for r_t.

RiskMetrics takes a simple and pragmatic approach to modeling the conditional volatility. The forecast for time t variance in RiskMetrics method is a weighted average of the previous forecast, using weight λ, and of the latest squared innovation, using weight $(1-\lambda)$:

$$\sigma_t^2 = \lambda\sigma_{t-1}^2 + (1-\lambda)r_{t-1}^2 \tag{41.2}$$

where the parameter λ is called the decay factor $(1 > \lambda > 0)$. Conceptually λ should be estimated using a maximum likelihood approach. RiskMetrics simply set it optimally at 0.94 for daily data and 0.97 for monthly data. Our analysis is on weekly data and we set λ at 0.95.

There are extensive empirical evidences supporting the use of ARCH and GARCH models in conditional volatility estimation. Bollerslev et al. (1992) provide a nice overview of the issue. Sarma et al. (2000) showed that at the 5 % level, an AR(1)-GARCH(1,1) model is a preferred model under the conditional normality assumption. The AR(1)-GARCH(1,1) model is specified:

$$\begin{aligned} r_{t+1} &= a_0 + a_1 r_t + \in_{t+1} \qquad\qquad \in_{t+1}\big|I_t \sim N\left(0, \sigma_t^2\right) \\ \sigma_t^2 &= \omega_0 + \omega_1\sigma_{t-1}^2 + \omega_2\in_t^2. \end{aligned} \tag{41.3}$$

The conditional mean equation is modeled as an AR(1) process to account for the weakly autoregressive behavior of returns.

41.3 Quantile Regression

Quantile regression was introduced by Koenker and Bassett (1978) and has received a lot of attention in econometrics and statistics research in the past two decades. The *quantile function* of a scalar random variable Y is the inverse of its distribution function. Similarly, the *conditional quantile function* of Y given X is the inverse of the corresponding conditional distribution function, i.e.,

$$Q_Y\left(\tau|X\right) = F_Y^{-1}(\tau|X) = \inf\{y : F_Y(y|X) \geq \tau\},$$

where $F_Y(y|X) = P(Y \leq y|X)$. By definition, the τ VaR at time t is the τ-th conditional quantile of r_t giving information at time $t-1$.

Consider a random variable Y characterized by its distribution function $F(y)$, the τ-th quantile of Y is defined by

$$Q_Y(\tau) = \inf\{y|F(y) \geq \tau\}.$$

If we have a random sample $\{y_1, \ldots, y_n\}$ from the distribution F, the τ-th sample quantile can be defined as

$$\hat{Q}_Y(\tau) = \inf\{y | \hat{F}(y) \geq \tau\},$$

where $\hat{F}$ is the empirical distribution function of the random sample. Note that the above sample quantile may be found by solving the following minimization problem:

$$\min_{b \in \Re} \left[\sum_{t \in \{t: y_t \geq b\}} \tau |y_t - b| + \sum_{t \in \{t: y_t < b\}} (1 - \tau)|y_t - b| \right]. \tag{41.4}$$

Koenker and Bassett (1978) studied the analogue of the empirical quantile function for the linear models and generalized the concept of quantiles to the regression context.

If we consider the linear regression model

$$Y_t = \beta' X_t + u_t, \tag{41.5}$$

where u_t are iid mean zero random variables with quantile function $Q_u(\tau)$ and X_t are k-by-1 vector of regressors including an intercept term and lagged residuals, then, conditional on the regressor X_t, the τ-th quantile of Y is a linear function of X_t:

$$Q_{Y_t}(\tau | X_t) = \beta' X_t + Q_u(\tau) = \beta(\tau)' X_t$$

where $\beta(\tau)' = (\beta_1 + Q_u(\tau), \beta_2, \cdots, \beta_k)$. Koenker and Bassett (1978) show that the τ-th conditional quantile of Y can be estimated by an analogue of Eq. 41.4:

$$\hat{Q}_{Y_t}(\tau | X_t) = X_t' \hat{\beta}(\tau)$$

where

$$\hat{\beta}(\tau) = \arg\min_{\beta \in \Re^k} \left[\sum_{t \in \{t: y_t \geq x_t \beta\}} \tau |y_t - x_t' \beta| + \sum_{t \in \{t: y_t < x_t \beta\}} (1 - \tau)|y_t - x_t' \beta| \right] \tag{41.6}$$

is called as the regression quantiles. Let $\rho_\tau(u) = u(\tau - I(u < 0))$, then

$$\hat{\beta}(\tau) = \arg\min_{\beta \in \Re^k} \sum_t \rho_\tau \left(y_t - x_t' \beta \right).$$

Quantile regression method has the important property that it is robust to distributional assumptions. This property is inherited from the robustness property of the ordinary sample quantiles. Quantile estimation is only influenced by the local behavior of the conditional distribution of the response near the specified quantile. As a result, the estimated coefficient vector $\hat{y}(\tau)$ is not sensitive to outlier observations. Such a property is especially attractive in financial applications since many financial data like, say, portfolio returns (or log returns) are usually heavy tailed and thus not normally distributed.

The quantile regression model has a mathematical programming representation which facilitates the estimation. Notice that the optimization problem (Eq. 41.6) may be reformulated as a linear program by introducing "slack" variables to represent the positive and negative parts of the vector of residuals (see Koenker and Bassett (1978) for a more detailed discussion). Computation of the regression quantiles by standard linear programming techniques is very efficient. It is also straightforward to impose the nonnegativity constraints on all elements of γ. Barrodale and Roberts (1974) proposed the first efficient algorithm for L_1-estimation problems based on modified simplex method. Koenker and d'Orey (1987) modified this algorithm to solve quantile regression problems. For very large quantile regression problems, there are some important new ideas which speed up the performance of computation relative to the simplex approach underlying the original code. Portnoy and Koenker (1997) describe an approach that combines some statistical preprocessing with interior point methods and achieves faster speed over the simplex method for very large problems.

41.4 Autoregressive Quantile Regression Models

41.4.1 The QAR Models

In many finance applications, the time-series dynamics can be more complicated than the classical autoregression where past information (Y_{t-j}) influences only the location of the conditional distribution of Y_t. For example, it is well known that the correlations tend to be larger in bear than in bull markets. Recognizing that the correlation is asymmetric is important for risk management and other financial applications. Any attempt to diagnose or forecast series of this type requires that a mechanism be introduced to capture the empirical features of the series.

An important extension of the classical constant coefficient time-series model is the quantile autoregression (QAR) model (Koenker and Xiao 2006). Given a time series $\{Y_t\}$, let $\mathcal{F}_t$ be the σ-field generated by $\{Y_s, s \leq t\}$; $\{Y_t\}$ is a p-th order QAR process if

$$Q_{Y_t}(\tau|\mathcal{F}_{t-1}) = \theta_0(\tau) + \theta_1(\tau)Y_{t-1} + \cdots + \theta_p(\tau)Y_{t-p}; \tag{41.7}$$

this implies, of course, that the right-hand side of Eq. 41.7 is monotonically increasing in τ. In the above QAR model, the autoregressive coefficients may be τ-dependent and thus can vary over different quantiles of the conditional distribution. Consequently, the conditioning variables not only shift the location of the distribution of Y_t but also may alter the scale and shape of the conditional distribution. The QAR models play a useful role in expanding the modeling territory of the classical autoregressive time-series models, and the classical AR(p) model can be viewed as a special case of QAR by setting $\theta_j(\tau)$ ($j = 1, \ldots, p$) to constants.

Koenker and Xiao (2006) studied the QAR model. The QAR model can be estimated by

$$\hat{\theta}(\tau) = \min_{\theta} \sum_{t} \rho_{\tau}\left(Y_t - \theta^{\top} X_t\right), \tag{41.8}$$

where $X_t = (1, Y_{t-1}, \ldots, Y_{t-p})^{\top}$ and $\theta(\tau) = (\theta_0(\tau), \theta_1(\tau), \ldots, \theta_p(\tau))^{\top}$; they show that under regularity assumptions, the limiting distribution of the QAR estimator is given by

$$\sqrt{n}\left(\hat{\theta}(\tau) - \theta(\tau)\right) \Rightarrow \mathcal{N}\left(0, \tau(1-\tau)\Omega_1^{-1}\Omega_0\Omega_1^{-1}\right),$$

where $\Omega_0 = E(X_t X_t^{\top})$ and $\Omega_1 = \lim n^{-1} \sum_{t=1}^{n} f_{t-1}[F_{t-1}^{-1}(\tau)]X_t X_t^{\top}$.

The QAR models expand the modeling options for time series that display asymmetric dynamics and allow for local persistency. The models can capture systematic influences of conditioning variables on the location, scale, and shape of the conditional distribution of the response and therefore constitute a significant extension of classical constant coefficient linear time-series models.

Quantile varying coefficients indicate the existence of conditional heteroskedasticity. Given the QAR process (Eq. 41.7), let $\theta_0 = \mathrm{E}[\theta_0(U_t)]$, $\theta_1 = \mathrm{E}[\theta_1(U_t)], \ldots,$ $\theta_p = \mathrm{E}[\theta_p(U_t)]$, and

$$V_t = \theta_0(U_t) - \mathrm{E}\theta_0(U_t) + [\theta_1(U_t) - \mathrm{E}\theta_1(U_t)]Y_{t-1} + \cdots + \left[\theta_p(U_t) - \mathrm{E}\theta_p(U_t)\right]Y_{t-p};$$

the QAR process can be rewritten as

$$Y_t = \theta_0 + \theta_1 Y_{t-1} + \cdots + \theta_p Y_{t-p} + V_t \tag{41.9}$$

where V_t is martingale difference sequence. The QAR process is a weak sense AR process with conditional heteroskedasticity.

What's the difference between a QAR process and an AR process with ARCH (or GARCH) errors? In short, the ARCH type model only focuses on the first two moments, while the QAR model goes beyond the second moment and allows for more flexible structure in higher moments. Both models allow for conditional heteroskedasticity and they are similar in the first two moments, but they can be quite different beyond conditional variance.

41.4.2 Nonlinear QAR and Copula-Based Quantile Models

More complicated functional forms with nonlinearity can be considered for the conditional quantile function if we are interested in the global behavior of the time series. If the τ-th conditional quantile function of Y_t is given by

$$Q_{Y_t}(\tau|\mathcal{F}_{t-1}) = H(X_t;\, \theta(\tau)),$$

where X_t is the vector containing lagged Ys, we may estimate the vector of parameters $\theta(\tau)$ (and thus the conditional quantile of Y_t) by the following nonlinear quantile regression:

$$\min_\theta \sum_t \rho_\tau(Y_t - H(X_t,\, \theta)). \tag{41.10}$$

Let $\varepsilon_{t\tau} = y_t - H(x_t, \theta(\tau)), \dot{H}_\theta(x_t, \theta) = \partial H(x_t; \theta)/\partial\theta$; we assume that

$$V_n(\tau) = \frac{1}{n}\sum_t f_t\big(Q_{Y_t}(\tau|X_t)\big)\dot{H}_\theta(X_t, \theta(\tau))\dot{H}_\theta(X_t, \theta(\tau))^\top \xrightarrow{P} V(\tau),$$

$$\Omega_n(\tau) = \frac{1}{n}\sum_t \dot{H}_\theta(X_t, \theta(\tau))\dot{H}_\theta(X_t, \theta(\tau))^\top \xrightarrow{P} \Omega(\tau),$$

and

$$\frac{1}{\sqrt{n}}\sum_t \dot{H}_\theta(x_t,\, \theta(\tau))Y_\tau(\varepsilon_{t\tau}) \Rightarrow N(0,\;\; \tau(1-\tau)\Omega(\tau)),$$

where $V(\tau)$ and $\Omega(\tau)$ are non-singular; then under appropriate assumptions, the nonlinear QAR estimator $\hat{\theta}(\tau)$ defined as solution of Eq. 41.10 is root-n consistent and

$$\sqrt{n}\Big(\hat{\theta}(\tau) - \theta(\tau)\Big) \Rightarrow N\Big(0, \tau(1-\tau)V(\tau)^{-1}\Omega(\tau)V(\tau)^{-1}\Big). \tag{41.11}$$

In practice, one may employ parametric copula models to generate nonlinear-in-parameters QAR models (see, e.g., Bouyé and Salmon 2008; Chen et al. 2009). Copula-based Markov models provide a rich source of potential nonlinear dynamics describing temporal dependence and tail dependence. If we consider, for example, a first-order strictly stationary Markov process, $\{Y_t\}_{t=1}^n$, whose probabilistic properties are determined by the joint distribution of Y_{t-1} and Y_t, say, $G^*(y_{t-1}, y_t)$, and suppose that $G^*(y_{t-1}, y_t)$ has continuous marginal distribution function $F^*(\cdot)$, then by Sklar's Theorem, there exists a unique copula function $C^*(\cdot, \cdot)$ such that

$$G^*(y_{t-1}, y_t) \equiv C^*(F^*(y_{t-1}),\;\; F^*(y_t)),$$

where the copula function $C^*(\cdot,\cdot)$ is a bivariate probability distribution function with uniform marginals. Differentiating $C^*(u, v)$ with respect to u and evaluating at $u = F^*(x)$, $v = F^*(y)$, we obtain the conditional distribution of Y_t given $Y_{t-1} = x$:

$$\Pr[Y_t < y | Y_{t-1} = x] = \left.\frac{\partial C^*(u,v)}{\partial u}\right|_{u=F^*(x),\, v=F^*(y)} \equiv C_1^*(F^*(x), F^*(y)).$$

For any $\tau \in (0, 1)$, solving $\tau = \Pr[Y_t < y | Y_{t-1} = x] \equiv C_1^*(F^*(x), F^*(y))$ for y (in terms of τ), we obtain the τ-th conditional quantile function of Y_t given $Y_{t-1} = x$:

$$Q_{Y_t}(\tau|x) = F^{*-1}\left(C_1^{*-1}(\tau; F^*(x))\right),$$

where $F^{*-1}(\cdot)$ signifies the inverse of $F^*(\cdot)$ and $C_1^{*-1}(\cdot;u)$ is the partial inverse of $C_1^*(u,v)$ with respect to $v = F^*(y_t)$.

In practice, neither the true copula function $C^*(\cdot,\cdot)$ nor the true marginal distribution function $F^*(\cdot)$ of $\{Y_t\}$ is known. If we model both parametrically by $C(\cdot,\cdot;\alpha)$ and $F(y;\beta)$, then the τ-th conditional quantile function of Y_t, $Q_{Y_t}(\tau|x)$, becomes a function of the unknown parameters α and β, i.e.,

$$Q_{Y_t}(\tau|x) = F^{-1}\left(C_1^{-1}(\tau; F(x,\beta), \alpha), \beta\right).$$

Denoting $\theta = (\alpha', \beta')'$ and $h(x, \alpha, \beta) \equiv C_1^{-1}(\tau; F(x, \beta), \alpha)$, we will write

$$Q_{Y_t}(\tau|x) = F^{-1}(h(x,\alpha,\beta),\beta) \equiv H(x;\theta). \tag{41.12}$$

For example, if we consider the Clayton copula:

$$C(u,v;\alpha) = [u^{-\alpha} + v^{-\alpha} - 1]^{-1/\alpha}, \text{ where } \alpha > 0,$$

one can easily verify that the τ-th conditional quantile function of U_t given u_{t-1} is

$$Q_{U_t}\left(\tau|u_{t-1}\right) = \left[\left(\tau^{-\alpha/(1+\alpha)} - 1\right)u_{t-1}^{-\alpha} + 1\right]^{-1/\alpha}.$$

See Bouyé and Salmon (2008) for additional examples of copula-based conditional quantile functions.

Although the quantile function specification in the above representation assumes the parameters to be identical across quantiles, we may permit the estimated parameters to vary with τ, thus extending the original copula-based QAR models to capture a wide range of systematic influences of conditioning variables on the conditional distribution of the response. By varying the choice of the copula specification, we can induce a wide variety of nonlinear QAR(1) dependence, and the choice of the marginal enables us to consider a wide range of possible tail behavior as well. In many financial time-series applications, the nature of the temporal dependence varies over the quantiles of the conditional distribution. Chen et al. (2009) studied asymptotic properties of the copula-based nonlinear quantile autoregression.

41.4.3 The CaViaR Models

Quantile-based method provides a local approach to directly model the dynamics of a time series at a specified quantile. Engle and Manganelli (2004) propose the Conditional Autoregressive Value at Risk (CaViaR) specification for the τ-th conditional quantile of u_t:

$$Q_{u_t}(\tau|\mathcal{F}_{t-1}) = \beta_0 + \sum_{i=1}^{p} \beta_i Q_{u_{t-i}}(\tau|\mathcal{F}_{t-i-1}) + \sum_{j=1}^{q} \alpha_j \ell\left(X_{t-j}\right), \tag{41.13}$$

where $X_{t-j} \in \mathcal{F}_{t-j}$, $\mathcal{F}_{t-j}$ is the information set at time $t-j$. A natural choice of X_{t-j} is the lagged u. When we choose $X_{t-j} = |u_{t-j}|$, we obtain GARCH-type CaViaR models:

$$Q_{u_t}(\tau|\mathcal{F}_{t-1}) = \beta_0 + \sum_{i=1}^{p} \beta_i Q_{u_{t-i}}(\tau|\mathcal{F}_{t-i-1}) + \sum_{j=1}^{q} \alpha_j \left|u_{t-j}\right|.$$

If $X_{t-j} = 0$, we obtain an autoregressive model for the VaRs:

$$Q_{u_t}(\tau|\mathcal{F}_{t-1}) = \beta_0 + \sum_{i=1}^{p} \beta_i Q_{u_{t-i}}(\tau|\mathcal{F}_{t-i-1}).$$

Engle and Manganelli (2004) discussed many choices of $\ell(X_{t-j})$, leading to different specifications of the CaViaR model.

41.5 Quantile Regression of Conditional Heteroskedastic Models

41.5.1 ARCH Quantile Regression Models

ARCH and GARCH models have proven to be highly successful in modeling financial data. Estimators of volatilities and quantiles based on ARCH and GARCH models are now widely used in finance applications. Consider the following linear ARCH(p) process:

$$u_t = \sigma_t \cdot \varepsilon_t, \sigma_t = \gamma_0 + \gamma_1 |u_{t-1}| + \cdots + \gamma_p \left|u_{t-p}\right|, \tag{41.14}$$

where $0 < \gamma_0 < \infty$, $\gamma_1, \ldots, \gamma_p \geq 0$ and ε_t are iid(0,1) random variables with pdf $f(\cdot)$ and CDF $F(\cdot)$. Let $Z_t = (1,|u_{t-1}|, \ldots,|u_{t-q}|)^\top$ and $\gamma(\tau) = (\gamma_0 F^{-1}(\tau), \gamma_1 F^{-1}(\tau), \ldots, \gamma_q F^{-1}(\tau))^\top$; the conditional quantiles of u_t is given by

$$Q_{u_t}(\tau|\mathcal{F}_{t-1}) = \gamma_0(\tau) + \gamma_1(\tau)|u_{t-1}| + \cdots + \gamma_p(\tau)\left|u_{t-p}\right| = \gamma(\tau)^\top Z_t$$

and can be estimated by the following linear quantile regression of u_t on Z_t:

$$\min_\gamma \sum_t \rho_\tau\left(u_t - \gamma^\top Z_t\right), \tag{41.15}$$

where $\gamma = (\gamma_0, \gamma_1, \cdots, \gamma_q)^\top$. The asymptotic behavior of the above quantile regression estimator is given by Koenker and Zhao (1996). In particular, suppose that u_t is given by model (Eq. 41.14), f is bounded and continuous, and $f(F^{-1}(t)) > 0$ for any $0 < \tau < 1$. In addition, if $\mathrm{E}|u_t|^{2+\delta} < \infty$, then the regression quantile $\hat{\gamma}(\tau)$ of Eq. 41.15 has the following Bahadur representation:

$$\sqrt{n}(\hat{\gamma}(\tau) - \gamma(\tau)) = \frac{\Sigma_1^{-1}}{f\left(F^{-1}(\tau)\right)} \frac{1}{\sqrt{n}} \sum_{t=1}^n Z_t^\top y_\tau(\varepsilon_{t\tau}) + o_p(1)$$

where $\Sigma_1 = \mathrm{E}Z_t Z_t'/\sigma_t$ and $\varepsilon_{t\tau} = \varepsilon_t - F^{-1}(\tau)$. Consequently,

$$\sqrt{n}(\hat{\gamma}(\tau) - \gamma(\tau)) = N\left(0,\ \frac{\tau(1-\tau)}{f\left(F^{-1}(\tau)\right)^2} \Sigma_1^{-1}\Sigma_0\Sigma_1^{-1}\right),\ \text{with}\ \Sigma_0 = \mathrm{E}Z_t Z_t'.$$

In many applications, conditional heteroskedasticity is modeled on the residuals of a regression. For example, we may consider the following AR-ARCH model:

$$Y_t = \alpha' X_t + u_t \tag{41.16}$$

where $X_t = (1, Y_{t-1}, \ldots,Y_{t-p})^\top$, $\alpha = (\alpha_0, \alpha_1, \ldots, \alpha_p)^\top$, and u_t is a linear ARCH(p) process given by model (Eq. 41.14). The conditional quantiles of Y_t is then given by

$$Q_{Y_t}(\tau|\mathcal{F}_{t-1}) = \alpha' X_t + \gamma(\tau)^\top Z_t. \tag{41.17}$$

One way to estimate the above model is to construct a *joint* estimation of α and $\gamma(\tau)$ based on *nonlinear* quantile regression. Alternatively, we may consider a two-step procedure that estimates α in the first step and then estimates $\gamma(\tau)$ based on the estimated residuals. The two-step procedure is usually less efficient because the preliminary estimation of α may affect the second-step estimation of $\gamma(\tau)$, but it is computationally much simpler and is widely used in empirical applications.

41.5.2 GARCH Quantile Regression Models

ARCH models are easier to estimate, but cannot parsimoniously capture the persistent influence of long past shocks comparing to the GARCH models. However, quantile regression GARCH models are highly nonlinear and thus complicated to estimate. In particular, the quantile estimation problem in GARCH models corresponds to a restricted nonlinear quantile regression, and conventional nonlinear quantile regression techniques are not directly applicable.

Xiao and Koenker (2009) studied quantile regression estimation of the following linear GARCH(p, q) model:

$$u_t = \sigma_t \cdot \varepsilon_t, \tag{41.18}$$

$$\sigma_t = \beta_0 + \beta_1\sigma_{t-1} + \cdots + \beta_p\sigma_{t-p} + \gamma_1|u_{t-1}| + \cdots + \gamma_q|u_{t-q}|. \tag{41.19}$$

Let $\mathcal{F}_{t-1}$ represents information up to time $t-1$; the τ-th conditional quantile of u_t is given by

$$Q_{u_t}(\tau|\mathcal{F}_{t-1}) = \theta(\tau)^{\top} Z_t, \tag{41.20}$$

where $Z_t = (1, \sigma_{t-1}, \ldots, \sigma_{t-p}, |u_{t-1}|, \ldots, |u_{t-q}|)^{\top}$ and $\theta(\tau)^{\top} = (\beta_0, \beta_1, \ldots, \beta_p, \gamma_1, \ldots, \gamma_q)F^{-1}(\tau)$.

Since Z_t contains $\sigma_{t-k}(k = 1, \cdots, q)$ which in turn depends on unknown parameters $\theta = (\beta_0, \beta_1, \ldots, \beta_p, \gamma_1, \ldots, \gamma_q)$, we may write Z_t as $Z_t(\theta)$ to emphasize the nonlinearity and its dependence on θ. If we use the following nonlinear quantile regression

$$\min_{\theta} \sum_t \rho_\tau\left(u_t - \theta^{\top} Z_t(\theta)\right), \tag{41.21}$$

for a fixed τ in isolation, consistent estimate of θ cannot be obtained since it ignores the global dependence of the σ_{t-k}'s on the entire function $\theta(\cdot)$. If the dependence structure of u_t is characterized by (1) and (1), we can consider the following restricted quantile regression instead of Eq. 41.21:

$$\left(\hat{\pi}, \hat{\theta}\right) = \begin{cases} \arg\min_{\pi,\theta} \sum_i \sum_t \rho_{\tau_i}\left(u_t - \pi_i^{\top} Z_t(\theta)\right) \\ \text{s.t. } \pi_i = \theta(\tau_i) = \theta F^{-1}(\tau_i). \end{cases}$$

Estimation of this global restricted nonlinear quantile regression is complicated. Xiao and Koenker (2009) propose a simpler two-stage estimator that both incorporates the global restrictions and also focuses on the local approximation around the specified quantile. The proposed estimation consists of the following two steps: (i) The first step considers a global estimation to incorporate the global dependence of the latent σ_{t-k}'s on θ. (ii) Then, using results from the first step, we focus on the specified quantile to find the best local estimate for the conditional quantile. Let

$$A(L) = 1 - \beta_1 L - \cdots - \beta_p L^p, \quad B(L) = \gamma_1 + \cdots + \gamma_q L^{q-1};$$

under regularity assumptions ensuring that $A(L)$ is invertible, we obtain an ARCH(∞) representation for σ_t:

$$\sigma_t = a_0 + \sum_{j=1}^{\infty} a_j \left| u_{t-j} \right|. \tag{41.22}$$

For identification, we normalize $a_0 = 1$. Substituting the above ARCH(∞) representation into (1) and (1), we have

$$u_t = \left(a_0 + \sum_{j=1}^{\infty} a_j \left| u_{t-j} \right| \right) \varepsilon_t, \tag{41.23}$$

and

$$Q_{u_t}(\tau | \mathcal{F}_{t-1}) = \alpha_0(\tau) + \sum_{j=1}^{\infty} \alpha_j(\tau) \left| u_{t-j} \right|,$$

where $\alpha_j(\tau) = a_j Q_{\varepsilon_t}(\tau), j = 0, 1, 2, \ldots$.

Let $m = m(n)$ be a truncation parameter; we may consider the following truncated quantile autoregression:

$$Q_{u_t}(\tau | \mathcal{F}_{t-1}) \approx a_0(\tau) + a_1(\tau)|u_{t-1}| + \cdots + a_m(\tau)|u_{t-m}|.$$

By choosing m suitably small relative to the sample size n, but large enough to avoid serious bias, we obtain a sieve approximation for the GARCH model.

One could estimate the conditional quantiles simply using a sieve approximation:

$$\check{Q}_{u_t}(\tau \,|\, \mathcal{F}_{t-1}) = \hat{a}_0(\tau) + \hat{\alpha}_1(\tau) \,|\, u_{t-1} \,| + \cdots + \hat{a}_m(\tau) \,|\, u_{t-m} \,|,$$

where $\hat{a}_j(\tau)$ are the quantile autoregression estimates. Under regularity assumptions

$$\check{Q}_{u_t}(\tau \,|\, \mathcal{F}_{t-1}) = Q_{u_t}(\tau \,|\, \mathcal{F}_{t-1}) + O_p(m/\sqrt{n}).$$

However, Monte Carlo evidence indicates that the simple sieve approximation does not directly provide a good estimator for the GARCH model, but it serves as an adequate preliminary estimator. Since the first step estimation focuses on the global model, it is desirable to use information over multiple quantiles in estimation.

Combining information over multiple quantiles helps us to obtain globally coherent estimate of the scale parameters.

Suppose that we estimate the m-th order quantile autoregression

$$\widetilde{\alpha}(\tau) = \arg\min_{\alpha} \sum_{t=m+1}^{n} \rho_\tau\left(u_t - \alpha_0 - \sum_{j=1}^{m} \alpha_j |u_{t-j}|\right) \tag{41.24}$$

at quantiles $(\tau_1, \ldots, \tau_K)$ and obtain estimates $\widetilde{\alpha}(\tau_k)$, $k = 1, \ldots, K$. Let $\widetilde{\alpha}_0 = 1$ in accordance with the identification assumption. Denote

$$\mathbf{a} = [a_1, \ldots, a_m, q_1, \ldots, q_K]^\top, \quad \boldsymbol{\overline{\pi}} = \left[\widetilde{\alpha}(\tau_1)^\top, \ldots, \widetilde{\alpha}(\tau_K)^\top\right]^\top,$$

where $q_k = Q_{\varepsilon_t}(\tau_k)$, and

$$\phi(\mathbf{a}) = g \otimes \alpha = [q_1, a_1 q_1, \ldots, a_m q_1, \ldots, q_K, a_1 q_K, \ldots, a_m q_K]^\top,$$

where $g = [q_1, \ldots, q_K]^\top$ and $\alpha = [1, a_1, a_2, \ldots, a_m]^\top$; we consider the following estimator for the vector a that combines information over the K quantile estimates based on the restrictions $\alpha_j(\tau) = a_j Q_{\varepsilon_t}(\tau)$:

$$\widetilde{\mathbf{a}} = \arg\min_{\mathbf{a}} (\boldsymbol{\overline{\pi}} - \phi(\mathbf{a}))^\top A_n (\boldsymbol{\overline{\pi}} - \phi(\mathbf{a})), \tag{41.25}$$

where A_n is a $(K(m + 1)) \times (K(m + 1))$ positive definite matrix. Denoting $\widetilde{\mathbf{a}} = (\widetilde{a}_0, \ldots, \widetilde{a}_m)$, σ_t can be estimated by

$$\widetilde{\sigma}_t = \widetilde{a}_0 + \sum_{j=1}^{m} \widetilde{a}_j |u_{t-j}|.$$

In the second step, we perform a quantile regression of u_t on $\widetilde{Z}_t = \left(1, \widetilde{\sigma}_{t-1}, \ldots \widetilde{\sigma}_{t-p}, |u_{t-1}|, \ldots, |u_{t-q}|\right)^\top$ by

$$\min_{\theta} \sum_t \rho_\tau\left(u_t - \theta^\top \widetilde{Z}_t\right); \tag{41.26}$$

the two-step estimator of $\theta(\tau)^\top = (\beta_0(\tau), \beta_1(\tau), \ldots, \beta_p(\tau), \gamma_1(\tau), \ldots, \gamma_q(\tau))$ is then given by the solution of Eq. 41.26, $\widehat{\theta}(\tau)$, and the τ-th conditional quantile of u_t can be estimated by

$$\hat{Q}_{u_t}(\tau|\mathcal{F}_{t-1}) = \hat{\theta}(\tau)^\top \widetilde{Z}_t.$$

Iteration can be applied to the above procedure for further improvement.

Let $\widetilde{\alpha}(\tau)$ be the solution of Eq. 41.24; then under appropriate assumptions, we have

$$\|\widetilde{\alpha}(\tau)-\alpha(\tau)\|^2 = O_p(m/n), \tag{41.27}$$

and for any $\lambda \in \mathcal{R}^{m+1}$,

$$\frac{\sqrt{n}\lambda^\top(\widetilde{\alpha}(\tau)-\alpha(\tau))}{\sigma_\lambda} \Rightarrow N(0,1),$$

where $\sigma_\lambda^2 = f_\varepsilon(F_\varepsilon^{-1}(\tau))^{-2}\lambda^\top D_n^{-1}\sum_n(\tau)D_n^{-1}\lambda$, and

$$D_n = \left[\frac{1}{n}\sum_{t=m+1}^{n}\frac{x_t x_t^\top}{\sigma_t}\right], \Sigma_n(\tau) = \frac{1}{n}\sum_{t=m+1}^{n} x_t x_t^T Y_\tau^2(u_{t\tau}),$$

where $x_t = (1,|u_{t-1}|, \ldots, |u_{t-m}|)^\top$.

Define

$$G = \left.\frac{\partial\phi(\mathbf{a})}{\partial\mathbf{a}^\top}\right|_{\mathbf{a}=\mathbf{a}_0} = \dot{\phi}(\mathbf{a}_0) = [g\otimes J_m \vdots I_K\otimes\alpha_0], g_0 = \begin{bmatrix} Q_{\varepsilon_t}(\tau_1) \\ \cdots \\ Q_{\varepsilon_t}(\tau_K)\end{bmatrix},$$

where g_0 and α_0 are the true values of vectors $g = [q_1, \ldots, q_K]^\top$ and $\alpha = [1, a_1, a_2, \ldots, a_m]^\top$, and

$$J_m = \begin{bmatrix} 0 & \cdots & 0 \\ 1 & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & 1 \end{bmatrix}$$

is an $(m+1)\times m$ matrix and I_K is a K-dimensional identity matrix; under regularity assumptions, the minimum distance estimator $\widetilde{\mathbf{a}}$ solving (Eq. 41.25) has the following asymptotic representation:

$$\sqrt{n}(\hat{\mathbf{a}}-\mathbf{a}_0) = \left[G^\top A_n G\right]^{-1} G^\top A_n\sqrt{n}(\overline{\boldsymbol{\pi}}-\boldsymbol{\pi}) + o_p(1)$$

where

$$\sqrt{n}(\overline{\boldsymbol{\pi}}-\boldsymbol{\pi}) = -\frac{1}{\sqrt{n}}\sum_{t=m+1}^{n}\begin{bmatrix}\left(D_n^{-1}x_t\dfrac{y_{\tau_1}(u_{t\tau_1})}{f_\varepsilon\left(F_\varepsilon^{-1}(\tau_1)\right)}\right) \\ \cdots \\ \left(D_n^{-1}x_t\dfrac{y_{\tau_m}(u_{t\tau_m})}{f_\varepsilon\left(F_\varepsilon^{-1}(\tau_m)\right)}\right)\end{bmatrix} + o_p(1),$$

and the two-step estimator $\hat{\theta}(\tau)$ based on Eq. 41.26 has asymptotic representation:

$$\sqrt{n}\left(\hat{\theta}(\tau)-\theta(\tau)\right)=-\frac{1}{f_{\varepsilon}\left(F_{\varepsilon}^{-1}(\tau)\right)}\Omega^{-1}\left\{\frac{1}{\sqrt{n}}\sum_{t}Z_t y_{\tau}(u_{t\tau})\right\}+\Omega^{-1}\Gamma\sqrt{n}(\tilde{\alpha}-\alpha)+o_p(1),$$

where $a=[a_1, a_2, \ldots, a_m]^{\top}$, $\Omega=E[Z_tZ_t^{\top}/\sigma_t]$, and

$$\Gamma=\sum_{k=1}^{p}\theta_k C_k, C_k=\mathrm{E}\left[(|u_{t-k-1}|,\ldots,|u_{t-k-m}|)\frac{Z_t}{\sigma_t}\right].$$

41.6 An Empirical Application

41.6.1 Data and the Empirical Model

In this section, we apply the quantile regression method to five major world equity market indexes. The data used in our application are the weekly return series, from September 1976 to June 2008, of five major world equity market indexes: the US S&P 500 Composite Index, the Japanese Nikkei 225 Index, the UK FTSE 100 Index, the Hong Kong Hang Seng Index, and the Singapore Strait Times Index. The FTSE 100 Index data are from January 1984 to June 2008. Table 41.1 reports some summary statistics of the data.

The mean weekly returns of the five indexes are all over 0.1 % per week, with the Hang Seng Index producing an average return of 0.23 % per week, an astonishing

Table 41.1 Summary statistics of the data

	S&P 500	Nikkei 225	FTSE 100	Hang Seng	Singapore ST
Mean	0.0015	0.0010	0.0017	0.0023	0.0012
Std. Dev.	0.0199	0.0253	0.0237	0.0376	0.0291
Max	0.1002	0.1205	0.1307	0.1592	0.1987
Min	−0.1566	−0.1289	−0.2489	−0.5401	−0.4551
Skewness	−0.4687	−0.2982	−1.7105	−3.0124	−1.5077
Excess kurtosis	3.3494	2.9958	12.867	9.8971	19.3154
AC(1)	−0.0703	−0.0306	0.0197	0.0891	0.0592
AC(2)	0.0508	0.0665	0.0916	0.0803	0.0081
AC(3)	0.0188	0.0328	−0.0490	−0.0171	0.0336
AC(4)	−0.0039	−0.0418	−0.0202	−0.0122	0.0099
AC(5)	−0.0189	−0.0053	−0.0069	−0.0386	0.0519
AC(10)	−0.0446	−0.0712	0.0138	−0.0345	−0.0227

This table shows the summary statistics for the weekly returns of five major equity indexes of the world. AC(k) denotes autocorrelation of order k. The source of the data is the online data service Datastream increase in the index level over the sample period. In comparison, the average return of Nikkei 225 index is only 0.1 %. The Hang Seng's phenomenal rise does not come without risk. The weekly sample standard deviation of the index is 3.76 %, the highest of the five indexes. In addition, over the sample period the Hang Seng suffered four larger than 15 % drop in weekly index level, with maximum loss reaching 35 %, and there were 23 weekly returns below −10 %! As has been documented extensively in the literature, all five indexes display negative skewness and excess kurtosis. The excess kurtosis of Singapore Strait Times Index reached 19.31, to a large extent driven by the huge 1 week loss of 47.47 % during the 1987 market crash. The autocorrelation coefficients for all five indexes are fairly small. The Hang Seng Index seems to display the strongest autocorrelation with the AR(1) coefficient equal to 0.0891.

We consider an AR-linear ARCH model in the empirical analysis. Thus, the return process is modeled as

$$r_t = \alpha_0 + \alpha_1 r_{t-1} + \cdots + \alpha_s r_{t-s} + u_t, \tag{41.28}$$

where

$$u_t = \sigma_t \varepsilon_t, \sigma_t = \gamma_0 + \gamma_1 |u_{t-1}| + \cdots + \gamma_q |u_{t-q}|,$$

and the τ Conditional VaR of u_t is given by

$$Q_{u_t}(\tau|\mathcal{F}_{t-1}) = \gamma(\tau)' Z_t$$

$$\gamma(\tau)' = (\gamma_0(\tau), \gamma_1(\tau), \ldots, \gamma_q(\tau)), \text{ and } Z_t = (1, |u_{t-1}|, \ldots, |u_{t-q}|)'.$$

For each time series, we first conduct model specification analysis and choose the appropriate lags for the mean equation and the quantile ARCH component. Based on the selected model, we use Eq. 41.28 to obtain a time series of residuals. The residuals are then used in the ARCH VaR estimation using a quantile regression.

41.6.2 Model Specification Analysis

We conduct sequential tests for the significance of the coefficients on lags. The inference procedures we use here are asymptotic inferences. For estimation of the covariance matrix, we use the robust HAC (Heteroskedastic and Autocorrelation Consistent) covariance matrix estimator of Andrews (1991) with the data-dependent automatic bandwidth parameter estimator recommended in that paper. First of all, we choose the lag length in the autoregression,

$$r_t = \alpha_0 + \alpha_1 r_{t-1} + \cdots + \alpha_s r_{t-s} + u_t,$$

using a sequential test of significance on lag coefficients. The maximum lag length that we start with is $s = 9$, and the procedure is repeated until a rejection occurs. Table 41.2 reports the sequential testing results for the S&P 500 index. The t-statistics of all the coefficients are listed for nine rounds of the test. We see that the t-statistic of the coefficient with the maximum number of lags does not become significant until $s = 1$, the ninth round. The preferred model is an AR(1) model. The selected mean equations for all five indexes are reported in Table 41.4.

Our next task is to select the lag length in the ARCH effect

$$u_t = \left(\gamma_0 + \gamma_1 |u_{t-1}| + \cdots + \gamma_q |u_{t-q}|\right)\varepsilon_t.$$

Again, a sequential test is conducted. To calculate the t-statistic, we need to estimate $\omega^2 = \tau(1 - \tau)/f(F^{-1}(\tau))^2$. There are many studies on estimating $f(F^{-1}(t))$, including Siddiqui (1960), Bofinger (1975), Sheather and Maritz (1983), and Welsh (1987). Notice that

$$\frac{dF^{-1}(t)}{dt} = \frac{1}{f\left(F^{-1}(t)\right)}; \tag{41.29}$$

following Siddiqui (1960), we may estimate (Eq. 41.29) by a simple difference quotient of the empirical quantile function. As a result,

$$f\left(\widehat{F^{-1}(t)}\right) = \frac{2h_n}{\hat{F}^{-1}(t + h_n) - \hat{F}^{-1}(t - h_n)} \tag{41.30}$$

where $\hat{F}^{-1}(t)$ is an estimate of $F^{-1}(t)$ and h_n is a bandwidth which goes to zero as $n \to \infty$. A bandwidth choice has been suggested by Hall and Sheather (1988) based on Edgeworth expansion for studentized quantiles. This bandwidth is of order $n^{-1/3}$ and has the following representation:

$$h_{HS} = z_\alpha^{2/3}\left[1.5s(t)/s''(t)\right]^{1/3} n^{-1/3},$$

where z_α satisfies $\Phi(z_a) = 1 - \alpha/2$ for the construction of $1-\alpha$ confidence intervals. In the absence of additional information, $s(t)$ is just the normal density. Starting with $q_{\max} = 10$, a sequential test was conducted and results for the 5 % VaR model of the S&P 500 Index are reported in Table 41.3. We see that in the fourth round, the t-statistic on lag 7 becomes significant. The sequential test stops here, and it suggests that ARCH(7) is appropriate.

Based on the model selection tests, we decide to use the AR(1)-ARCH(7) regression quantile model to estimate 5 % VaR for the S&P 500 index. We also conduct similar tests on the 5 % VaR models for other four indexes. To conserve space we do not report the entire testing process in the paper. Table 41.4 provides a summary of the selected models based on the tests. The mean equations

Table 41.2 VaR model mean specification test for the S&P 500 Index

Round	1st	2nd	3rd	4th	5th	6th	7th	8th	9th
α_0	3.3460	3.3003	3.2846	3.3248	3.2219	3.7304	3.1723	3.0650	3.8125

γ_{10}	1.1326			

This table reports the test results for the 5 % VaR model specification for the S&P 500 Index. The number of lags in the volatility component of the ARCH model is selected according to the test. The table reports the *t*-statistic for the coefficient with the maximum lag in the ARCH equation

Table 41.4 ARCH VaR models selected by the sequential test

Index	Mean Lag	5 % ARCH Lag
S&P 500	1	6
Nikkei 225	1	7
FTSE 100	1	6
Hang Seng	3	6
Singapore ST	2	7

This table summarizes the preferred ARCH VaR models for the five global market indexes. The number of lags in the mean equation and the volatility component of the ARCH model is selected according to the test

generally have one or two lags, except the Hang Seng Index, which has a lag of 3 and displays more persistent autoregressive effect.

For the ARCH equations, at least six lags are needed for the indexes.

41.6.3 Estimated VaRs

The estimated parameters for the mean equations for all five indexes are reported in Table 41.5. The constant term for the five indexes is between 0.11 % for the Nikkei and 0.24 % for the Hang Seng. As suggested by Table 41.1, the Hang Seng seems to display the strongest autocorrelation, and this is reflected in the four lags chosen by the sequential test. Table 41.6 reports the estimated quantile regression ARCH parameters for the 5 % VaR model:

USA – S&P 500 Index. The estimated 5 % VaRs generally range between 2.5 % and 5 %, but during very volatile periods they could jump over 10 %, as what happened in October 1987. During high-volatility periods, there is high variation in estimated VaRs.

Table 41.5 Estimated mean equation parameters

Round	S&P 500	Nikkei 225	FTSE 100	Hang Seng	Singapore ST

γ_7		0.2323			0.1123
		(0.0451)			(0.0517)

This table reports the estimated parameters of the ARCH equation for the 5 % VaR model for the five global indexes. The standard errors are in parentheses under the estimated parameters

Japan – Nikkei 225 Index. The estimated VaR series is quite stable and remains at the 4 % and the 7 % level from 1976 till 1982. Then the Nikkei 225 Index took off and appreciated about 450 % over the next 8 years, reaching its highest level at the end of 1989. This quick rise in stock value is accompanied by high risk, manifested here by the more volatile VaR series. In particular, the VaRs fluctuated dramatically, ranging from a low of 3 % to a high of 15 %. This volatility in VaR may reflect both optimistic market outlook at times and worry about high valuation and the possibility of a market crash. That crash did come in 1990, and

10 years later, the Nikkei 225 Index still hovers around at a level which is about half off the record high in 1989. The 1990s is far from a rewarding decade for investors in the Japanese equity market. Average weekly 5 % VaR is about 5 %, and the variation is also very high.

UK – FTSE 100 Index. The 5 % VaR is very stable and averages about 3 %. They stay very much within the 2–4 % band, except on a few occasions, such as the 1987 global market crash.

Hong Kong – Hang Seng Index. The Hang Seng Index produces an average return of 0.23 % per week. The Hang Seng's phenomenal rise does not come without risk. We mentioned above that the weekly sample standard deviation of the index is 3.76 %, the highest of the five indexes. In addition, the Hong Kong stock market has had more than its fair share of the market crashes.

Singapore – Strait Times Index. Interestingly, the estimated VaRs display a pattern very similar to that of the UK FTSE 100 Index, although the former is generally larger than the latter. The higher risk in the Singapore market did not result in higher return over the sample period. Among the five indexes, the Singapore market suffered the largest loss during the 1987 crash, a 47.5 % drop in a week. The market has since recovered much of the loss. Among the five indexes, the Singapore market only outperformed the Nikkei 225 Index over this period.

41.6.4 Performance of the ARCH Quantile Regression Model

In this section we conduct an empirical analysis to compare VaRs estimated by RiskMetrics and regression quantiles and those by volatility models with the conditional normality assumption. There are extensive empirical evidences supporting the use of the GARCH models in conditional volatility estimation. Bollerslev et al. (1992) provide a nice overview of the issue. Therefore, we compare VaR estimated based on RiskMetrics and GARCH(1,1) model and quantile regression based on ARCH.

To measure the relative performance more accurately, we compute the percentage of realized returns that are below the negative estimated VaRs. The results are reported in Table 41.7. The top panel of the table presents the percentages for the VaRs estimated by the ARCH quantile regression model, the middle panel for the VaRs estimated by the GARCH model with the conditional normal return distribution assumption, and the bottom panel for the VaRs estimated by the RiskMetrics method. We estimate VaRs using these methods at 1 %, 2 %, 5 %, 10 %. Now we have a total of four percentage levels. The regression quantile method produces the closest percentage in general. Both the RiskMetrics method and the GARCH method seem to underestimate VaRs for the smaller percentages and overestimate VaRs for the larger percentages.

The five indexes we analyzed are quite different in their risk characteristics as discussed above. The quantile regression approach seems to be relatively robust and can consistently produce reasonably good estimates of the VaRs at different

Table 41.7 VaR model performance comparison

% VaR	1 %	2 %	5 %	10 %
Quantile regression				
S&P 500	1.319	1.925	5.3108	9.656
Nikkei 225	1.350	2.011	5.7210	10.56
FTSE 100	0.714	1.867	5.6019	9.016
Hang Seng	0.799	2.113	4.9011	9.289
GARCH				
S&P 500	1.3996	1.7641	4.0114	7.6151
Nikkei 225	1.4974	1.7927	4.3676	8.4098
FTSE 100	1.1980	1.6133	3.3891	6.7717
Hang Seng	1.8962	2.8658	3.6653	7.6439
RiskMetrics				
S&P 500	0.3790	0.5199	1.1180	3.2563
Nikkei 225	0.5877	0.9814	1.358	4.1367
FTSE 100	0.2979	0.5796	0.9984	3.5625
Hang Seng	0.7798	0.9822	1.4212	4.1936

This table reports the coverage ratios, i.e., the percentage of realized returns that is below the estimated VaRs. The top panel reports the performance of the VaRs estimated by the quantile regression model. The middle panel reports the results for VaRs estimated by the GARCH model based on the conditionally normal return distribution assumption. The bottom panel reports the results for VaRs estimated by the RiskMetrics method

percentage (probability) levels. The GARCH model with the normality assumption, being a good volatility model, is not able to produce good VaR estimates. The quantile regression model does not assume normality and is well suited to hand negative skewness and heavy tails.

41.7 Conclusion

Quantile regression provides a convenient and powerful method of estimating VaR. The quantile regression approach not only provides a method of estimating the conditional quantiles (VaRs) of existing time-series models; it also substantially expands the modeling options for time-series analysis. Estimating Value at Risk using the quantile regression does not assume a particular conditional distribution for the returns. Numerical evidence indicates that the quantile-based methods have better performance than the traditional J. P. Morgan's RiskMetrics method and other methods based on normality. The quantile regression based method provides an important tool in risk management.

There are several existing programs for quantile regression applications. For example, both parametric and nonparametric quantile regression estimations can be implemented by the function **rq**() and **rqss**() in the package **quantreg** in the computing language **R**, and **SAS** now has a suite of procedures modeled closely on the functionality of the R package quantreg.

DOI 10.1007/978-1-4614-7750-1_42,

of control rights from cash flow rights and earnings quality varies systematically with board structure. I find that the negative association between separation of control rights from cash flow rights and earnings quality is less pronounced in firms with high equity ownership by outside directors. I also document that in firms with high separation of control rights from cash flow rights, those firms with higher proportion of outside directors on the board have higher earnings quality. Overall, my results suggest that outside directors' equity ownership and board independence are associated with better financial reporting outcome, especially in firms with high expected agency costs arising from misalignment of control rights and cash flow rights.

The econometric method employed is regressions of panel data. In a panel data setting, I address both cross-sectional and time-series dependence. Gow et al. (2010, *The Accounting Review 85*(2), 483–512) find that in the presence of both cross-sectional and time-series dependence, the two-way clustering method which allows for both cross-sectional and time-series dependence produces well-specified test statistics. Following Gow et al. (2010, *The Accounting Review 85*(2), 483–512), I employ the two-way clustering method where the standard errors are clustered by both firm and year in my regressions of panel data. Johnston and DiNardo (1997, *Econometrics method*. New York: Mc-Graw Hill) and Greene (2000, *Econometrics analysis*. Upper Saddle River: Prentice-Hall) are two econometric textbooks that contain a detailed discussion of the econometrics issues relating to panel data.

42.1 Introduction

In Asia, corporate ownership concentration is high, and many listed firms are mainly controlled by a single large shareholder (La Porta et al. 1999; Claessens et al. 2000). Asian firms also show a high divergence between control rights and cash flow rights, which allows the largest shareholder to control a firm's operations with a relatively small direct stake in its cash flow rights. Control is often increased beyond ownership stakes through pyramid structures, cross-holdings among firms, and dual class shares (Claessens et al. 2000). It is argued that concentrated ownership facilitates transactions in weak property rights environment by providing the controlling shareholders the power and incentive to negotiate and enforce contracts with various stakeholders (Shleifer and Vishny 1997). As a result of concentrated ownership, the main agency problem in listed firms in Asia is the conflict of interest between the controlling shareholder and minority shareholder. Specifically, controlling shareholder has incentives to expropriate the wealth of minority shareholders by engaging in rent-seeking activities and to mask their private benefits of control by supplying low-quality financial accounting information. Empirical evidence also shows that the quality and credibility of financial accounting information are lower in firms with high separation of control rights and cash flow rights (Fan and Wong 2002; Haw et al. 2004).

An important question is how effective are corporate governance mechanisms in mitigating the agency problems in Asia firms, especially in improving corporate transparency in firms with concentrated ownership. Controlling shareholders in Asia typically face limited disciplinary pressures from the market for corporate control because hostile takeovers are infrequent (La Porta et al. 1999; Fan and Wong 2002). Furthermore, controlling shareholders face little monitoring pressure from analysts because analysts are less likely to follow firms with potential incentives to withhold or manipulate information, such as when the family/management group is the largest control rights blockholder (Lang et al. 2004). In these environments, external corporate governance mechanisms, in particular the market for corporate control and analysts' scrutiny, exert limited disciplinary pressure on controlling shareholders. Consequently, internal corporate governance mechanisms such as the board of directors may be important to mitigate the agency costs associated with the ownership structure of Asian firms. Thus, the primary research questions in this paper are: (1) Do board of directors play a corporate governance role over the financial reporting process in listed firms in Asia? (2) How does the board of director affect financial reporting quality in firms with high expected agency costs arising from the separation of control rights and cash flow rights?

Specifically, this paper examines the relation among outside directors' equity ownership, board independence, and separation of control rights from cash flow rights of controlling shareholder in affecting earnings quality. My empirical strategy is as follows: First, I examine the main effect between earnings quality and (i) outside directors' equity ownership, (ii) the proportion of outside directors on the board, and (iii) the separation of control rights from cash flow rights of the largest ultimate shareholder. This sheds light on my first research question on whether the board of directors plays a corporate governance role over the financial reporting process in listed firms in Asia. Second, I examine the (i) interaction between outside directors' equity ownership and the separation of control rights from cash flow rights and (ii) interaction between the proportion of outside directors on the board and the separation of control rights from cash flow rights, in shaping earnings quality. This addresses the second research question on the effect of board structure (in particular, board independence and equity ownership of outside directors) on financial reporting quality in firms with high expected agency costs arising from the separation of control rights and cash flow rights.

In this paper, I focus on two important attributes of board monitoring – outside directors' equity ownership and board independence – and their association with financial reporting quality. These attributes are important for two reasons.

First, prior research generally finds that in developed economies such as the United States and the United Kingdom, there is a positive association between board independence and earnings quality (Dechow et al. 1996; Klein 2002; Peasnell et al. 2005). However, there is limited evidence on the effect of board independence on the financial accounting process in Asia. My paper attempts to fill this gap. Second, recent research on the monitoring incentives of the board suggests that equity ownership of outside directors plays an important role in mitigating managerial entrenchment (Perry 2000; Ryan and Wiggins 2004). An implication of this stream of research is that even in firms with high board independence, entrenched managers can weaken the monitoring incentives of outside directors by reducing their equity-based compensation. In other words, board independence that is not properly augmented with incentive compensation may hamper the monitoring effectiveness of independent directors over management.

My sample consists of 2,875 firm-year observations during the period 2004–2008 in five Asian countries comprising Indonesia, Malaysia, the Philippines, Singapore, and Thailand. These countries provide a good setting to test the governance potential of the board of directors because shareholders in these countries typically suffer from misaligned managerial incentives, ineffective legal protection, and underdeveloped markets for corporate control (La Porta et al. 1999; Claessens et al. 2000; Fan and Wong 2002).

I measure earnings quality with three financial reporting metrics: (i) discretionary accruals, (ii) mapping of accruals to cash flow, and (iii) informativeness of reported earnings. My results are robust across alternative earnings quality metrics. I find that earnings quality is higher when outside directors have higher equity ownership. This result suggests that internal monitoring of the quality and credibility of accounting information is improved through aligning shareholders' and directors' incentives. Consistent with the monitoring role of outside directors (Fama and Jensen 1983), I also find that earnings quality is positively associated with the proportion of outside directors on the board. This result supports the notion that outside directors have incentives to be effective monitors in order to maintain the value of their reputational capital. Consistent with prior studies (Fan and Wong 2002; Haw et al. 2004), I also document that earnings quality is negatively associated with the separation of control rights from cash flow rights of the largest ultimate shareholder.

More importantly, I document that the negative association between separation of control rights from cash flow rights and earnings quality is less pronounced in firms with high equity ownership by outside directors. This result suggests equity ownership improves the incentives and monitoring intensity of outside directors in firms with high expected agency costs arising from the divergence of control rights from cash flow rights. Furthermore, my result indicates the negative association between separation of control rights from cash flow rights and earnings quality is mitigated by the higher proportion of outside directors on the board. This result provides evidence supporting the corporate governance role of outside directors in constraining managerial discretion over financial accounting process in firms with high levels of misalignment between control rights and cash flow rights. Collectively, my results suggest that strong internal governance structures can alleviate agency problems between the controlling shareholder and minority shareholders. More generally, my results highlight the interplay between board structure and corporate ownership structure in shaping earnings quality.

I perform several robustness tests. My results are robust across different economies. In addition, year-by-year regressions yield qualitatively similar results, suggesting my inferences are not time-period specific. I also include additional country-level institutional variables such as legal origin, country investor protection, and enforcement of shareholder rights. My results are qualitatively similar. Specifically, after controlling for country-level legal institutions, firm-specific internal governance mechanisms, namely – outside directors' equity ownership and board independence – continue to be important in mitigating the negative effects of the divergence between control rights and cash flow rights on earnings quality.

My study has several contributions. First, prior studies find that the divergence of control rights from cash flow rights reduces the informativeness of reported earnings (Fan and Wong 2002) and induces earnings management (Haw et al. 2004). I extend these studies by demonstrating two specific channels at the firm level – equity ownership by outside directors and proportion of outside directors on the board – that mitigate the negative association between earnings quality and divergence of control rights from cash flow rights. This result suggests that the board of directors play an important corporate governance role to alleviate agency problems in firms with entrenched insiders. My findings also complement Fan and Wong's (2005) result that given concentrated ownership, a controlling owner may introduce some monitoring or bonding mechanisms that limit his ability to expropriate minority shareholders and hence mitigate agency conflicts. In the Fan and Wong's study, high-quality external auditors alleviate agency problems in firms with concentrated ownership, whereas in my study, strong board of directors augmented with proper monitoring incentives mitigate agency problems in firms with concentrated ownership.

Second, my results suggest that there is an incremental role for firm-specific internal governance mechanisms, beyond country-level institutions, in improving the quality of financial information. Haw et al. (2004) find that earnings management that is induced by the divergence between control rights and cash flow rights is less pronounced in countries where (i) legal institutions protect minority shareholder rights (such as legal tradition, minority shareholder rights, efficiency of judicial system, or disclosure system) and (ii) in countries with effective extralegal institutions (such as the effectiveness of competition law, diffusion of the press, and tax compliance). My study shows that after controlling for both country-level legal and extralegal institutions, firm-specific internal governance mechanisms, namely, outside directors' incentive compensation and board independence, continue to be important in constraining management opportunism over the financial reporting process in firms with high expected agency costs arising from the divergence between control rights and cash flow rights. To the extent that changes in country-level legal institutions are relatively more costly and more difficult than changes in firm-level governance mechanisms, my result suggests that improvement in firm-specific governance mechanisms can be effective to reduce private benefits of control. My results complement finding in prior studies (Johnson et al. 2000; La Porta et al. 1998; Lang et al. 2004) that firms in countries with weak legal protection substitute with strong firm-level internal governance mechanisms to attract investors. My results also extend the finding in Leuz et al. (2003) that firms located in countries with weaker investor protection have higher earnings management. An important question is what factors may constrain managerial opportunism when country-level investor protection is weak? Because my sample consists of countries with generally weak investor protection, I shed light on this question by documenting that firm-level governance structures matter in improving earnings quality in countries with weak investor protection.

The rest of the paper proceeds as follows. Section 42.2 develops the hypotheses and places my paper in the context of related research. Section 42.3 describes the sample and method. Section 42.4 presents my results. I conclude the paper in Sect. 42.5.

42.2 Prior Research and Hypotheses Development

42.2.1 Equity Ownership of Outside Directors

Recent research examines the compensation structure of outside directors, who play an important monitoring role over management's actions. The central theme in this body of research is that incentive compensation leading to share ownership improves the outside directors' incentives to monitor. Mehran (1995) finds firm performance is positively associated with the proportion of directors' equity-based compensation. Perry (2000) finds that the likelihood of CEO turnover following poor performance increases when directors receive higher equity-based compensation. Shivdasani (1993) finds that probability of a hostile takeover is negatively associated with the percentage of shares owned by outside directors in target firms. He interprets this finding as suggesting that board monitoring may substitute for monitoring from the market of corporate control. Hermalin and Weisbach (1988) and Gillette et al. (2003) develop models where incentive compensation for directors increases their monitoring efforts and effectiveness. Ryan and Wiggins (2004) find that directors in firms with entrenched CEOs receive a significantly smaller proportion of compensation in the form of equity-based awards. Their result suggests that entrenched CEOs use their position to influence directors' compensation, which results in contracts that provide directors with weaker incentives to monitor management.

Internal monitoring is improved through aligning shareholders' and directors' incentives. If higher equity-based compensation contracts provide outside directors with stronger incentives to act in the interests of shareholders, I predict that managerial opportunism over the financial reporting process is reduced when outside directors have higher equity-based compensation. My first hypothesis is:

H1 Earnings quality is positively associated with the outside directors' equity ownership.

42.2.2 Board Independence

There is considerable literature on the role of outside directors in reducing agency problems between managers and shareholders. Fama and Jensen (1983) argue that outside directors have strong incentives to be effective monitors in order to maintain their reputational capital. Prior studies support the notion that board effectiveness in protecting shareholders' wealth is positively associated with the proportion of outside directors on the board (Weisbach 1988; Rosenstein and Wyatt 1990). In the United States, Klein (2002) finds that firms with high proportion of outside directors on the board have lower discretionary accruals. Using a sample of listed firms in the United Kingdom, Peasnell et al. (2005) document that the greater the board independence, the lower the propensity of managers making income-increasing discretionary accruals to avoid reporting losses and earnings reductions. Using US firms subjected to SEC enforcement action for alleged earnings manipulation, Dechow et al. (1996) and Beasley (1996) find that the probability of financial reporting fraud is negatively associated with the proportion of outside directors on the board.

In contrast, in emerging markets, conventional wisdom suggests that the agency conflicts between controlling owners and the minority shareholders may be difficult to mitigate through conventional corporate control mechanisms such as boards of directors (La Porta et al. 1998; Claessens et al. 2000; Fan and Wong 2005; Lee 2007; Lee et al. 2009). However, since the Asian economic crisis in 1997, many countries in Asia took steps to improve their corporate governance environment such as implementing country-specific code of corporate governance. For example, the Stock Exchange of Thailand Code of Best Practice for Directors of Listed Companies was implemented in 1998, the Code of Proper Practices for Directors for the Philippines was implemented in 2000, the Malaysian Code of Corporate Governance was implemented in 2000, and the Singapore Code of Corporate Governance was implemented in 2001. Among the key provisions of the code of corporate governance in these countries is the recommendation to have sufficient independent directors on the board to improve monitoring of management. For example, the 2001 Code of Corporate Governance for Singapore stated that there should be a strong and independent element on the board, which is able to exercise objective judgment on corporate affairs independently from management.

Although compliance with the code of corporate governance is not legally mandatory, listed companies are required to explain deviations from the recommendations of the code of corporate governance.[1]

I posit that in the waves of corporate governance reform in emerging markets in the early 2000s and the guidelines of country-specific code of corporate governance in emphasizing the importance of board independence, there is heightened awareness among outside directors on their increased monitoring responsibilities. To the extent that outside directors in listed firms in Asia perform a corporate governance role, I predict that:

H2 Earnings quality is positively associated with the proportion of outside directors on the board.

42.2.3 Equity-Based Compensation of Outside Directors and Control Divergence

The preceding discussion suggests that higher equity-based incentive compensation for outside directors improves their monitoring efforts. Greater monitoring from outside directors reduces managerial discretion over the financial reporting process (Lee et al. 2008). The benefits of more effective monitoring arising from higher equity ownership are likely to be concentrated in firms with high agency problems arising from the separation of control rights from cash flow rights. Thus, I predict that:

H3 The negative association between separation of control rights from cash flow rights and earnings quality is less pronounced in firms with high equity ownership by outside directors.

42.2.4 Board Independence and Control Divergence

Outside directors play an important corporate governance role in resolving agency problems between managers and shareholders. Following prior studies (Beasley 1996; Dechow et al. 1996; Klein 2002; Lee et al. 2007), higher proportion of outside directors on the board is associated with higher constraints on management discretion over the financial reporting process. I extend this notion to posit that the greater monitoring efforts from a high proportion of outside directors on the

[1]To illustrate, the Singapore Exchange Listing Rules require "listed companies to describe in the annual reports their corporate governance practices with specific reference to the principles of the Code, as well as disclose and explain any deviation from any guideline of the Code. Companies are also encouraged to make a positive confirmation at the start of the corporate governance section of the annual report that they have adhered to the principles and guidelines of the Code, or specify each area of non-compliance. Many of these guidelines are recommendations for companies to disclose their corporate governance arrangements."

board are likely to mitigate the negative effects of the separation of control rights from cash flow rights on earnings quality. Thus, I predict that:

H4 The negative association between separation of control rights from cash flow rights and earnings quality is mitigated by the proportion of outside directors.

42.3 Data

I begin with the Worldscope database to identify listed firms in five Asian countries comprising Indonesia, Malaysia, the Philippines, Singapore, and Thailand during the period 2004–2008. I exclude financial institutions because of their unique financial structure and regulatory requirements. I eliminate observations with extreme values of control variables such as return-on-assets and leverage. I obtain stock price data from the Datastream database. I obtain annual reports for the period 2004–2008 from the Global Report database and company websites. The sample consists of 617 firms for 2,875 firm-year observations during the period 2004–2008 in five Asian countries comprising Indonesia, Malaysia, the Philippines, Singapore, and Thailand.

I collect data on the board characteristics such as board size, the number of independent directors, and equity ownership of directors from the annual report. I also examine the annual report to trace the ultimate owners of the firms. The procedure of identifying ultimate owners is similar to the one used in La Porta et al. (1999).[2] In this study, I measure earnings quality with three financial reporting metrics: (i) discretionary accruals, (ii) mapping of accruals to cash flow, and (iii) informativeness of reported earnings.

Appendix 1 contains detailed description on the econometric method.

42.4 Results

42.4.1 Descriptive Statistics

Table 42.1 presents the descriptive statistics. Mean absolute discretionary accrual as a proportion of lagged assets is 0.062. Mean equity ownership of outside directors (computed as common stock and stock options held by outside directors divided by

[2]In summary, an ultimate owner is defined as the shareholder who has the determining voting rights of the company and who is not controlled by anyone else. If a company does not have an ultimate owner, it is classified as widely held. To economize on the data collection task, the ultimate owner's voting right level is set at 50 % and not traced any further once that level exceeds 50 %. Although a company can have more than one ultimate owner, we focus on the largest ultimate owner. We also identify the cash flow rights of the ultimate owners. To facilitate the measurement of the separation of cash flow and voting rights, the maximum cash flow rights level associated with any ultimate owner is also set at 50 %. However, there is no minimum cutoff level for cash flow rights.

Table 42.1 Descriptive statistics. The sample consists of 617 firms for 2,875 firm-year observations during the period 2004–2008 in five Asian countries comprising Indonesia, Malaysia, the Philippines, Singapore, and Thailand

DISCAC = absolute value of discretionary accruals estimated based on the modified Jones model
AQ = accrual quality measured by Dechow and Dichev's (2002) measure of mapping of accruals to past, present, and future cash from operations
DIROWN = common stock and stock options held by outside directors divided by number of ordinary shares outstanding in the firm
OUTDIR = proportion of outside directors on the board
VOTECASH = voting rights divided by cash flow rights of the largest controlling shareholder
CEODUAL = a dummy variable that equals 1 if the CEO is chairman of board and 0 otherwise
BOARDSIZE = number of directors on the board
LNASSET = natural logarithm of total assets
MB = market value of equity divided by book value of equity
LEV = long-term debt divided by total assets
ROA = net profit after tax divided by total assets

number of ordinary shares outstanding in the firm) is 2.04 %. The mean board size and proportion of outside directors on the board are 7 and 0.489, respectively. CEO chairs the board in 40 % of the firms. Consistent with Fan and Wong's (2002) study of East Asian economies, the firms in my sample also have high divergence of control rights from cash flow rights (mean VOTE = 1.198).

42.4.2 Discretionary Accruals

Table 42.2 presents the estimates of regressions of unsigned discretionary accruals on equity-based compensation, proportion of outside directors on the board, and the separation of control right from cash flow right. Following Gow et al. (2010), I employ the two-way clustering method where the standard errors are clustered by both firm and year in my regressions. In column (1), I document a negative association between the absolute value of discretionary accruals and the equity ownership of outside directors. Results also indicate that firms with higher proportion of outside directors on the board have lower discretionary accruals. I find that

Table 42.2 Regressions of unsigned discretionary accruals. The sample consists of 617 firms for 2,875 firm-year observations during the period 2004–2008 in five Asian countries comprising Indonesia, Malaysia, the Philippines, Singapore, and Thailand. The dependent variable is absolute discretionary accruals computed based on the modified Jones model. All variables are defined in Table 42.1. The t-statistics (in parentheses) are adjusted based on standard errors clustered by firm and year (Petersen 2009). The symbols *, **, and *** denote statistical significance at the 10 %, 5 %, and 1 % levels (two-tailed), respectively

earnings management (as proxied by absolute discretionary accruals) increases as the separation between control rights and cash flow rights of controlling shareholders increases. This result is consistent with the finding in Haw et al. (2004). In column (2), I test whether the positive association between discretionary accruals and the separation between control rights and cash flow rights of controlling shareholder is mitigated by the equity ownership of outside directors. The coefficient on the interaction term between the separation of control rights from cash flow rights and the equity ownership of outside directors (VOTE* DIROWN) is negative and significant at the 1 % level, supporting the hypothesis that in firms with high separation of control rights from cash flow rights, earnings management is reduced when outside directors have higher equity ownership. This finding suggests that greater equity-based compensation increases the monitoring effectiveness of outside directors over the financial reporting process in firms with agency conflicts arising from their control rights from cash flow rights. In addition, the coefficient on the interaction term between the separation of control rights from cash flow rights and the proportion of outside directors (VOTE*OUTDIR) is negative and significant at the 5 % level, supporting the hypothesis that in firms with high separation of control rights from cash flow rights, earnings management is reduced in firms with high proportion of outside directors on the board. This result is consistent with the monitoring role of independent directors to improve the credibility of accounting information in firms with agency problems arising from their concentrated corporate ownership structure.

Table 42.3 Regressions of signed discretionary accruals. The sample consists of 617 firms for 2,875 firm-year observations during the period 2004–2008 in five Asian countries comprising Indonesia, Malaysia, the Philippines, Singapore, and Thailand. In column (1), the sample consists of firms with income-increasing discretionary accruals, and the dependent variable is positive discretionary accruals. In column (2), the sample consists of firms with income-decreasing discretionary accruals, and the dependent variable is negative discretionary accruals. All variables are defined in Table 42.1. All regressions contain dummy control variables for country, year, and industry. The t-statistics (in parentheses) are adjusted based on standard errors clustered by firm and year (Petersen 2009). The symbols *, **, and *** denote statistical significance at the 10 %, 5 %, and 1 % levels (two-tailed), respectively

	(1) Positive DISCAC	(2) Negative DISCAC

I partition the sample into two groups based on the sign of the firms' discretionary accruals. Table 42.3 column (1) presents the results using the subsample of firms with income-increasing discretionary accruals. Results indicate firms with higher equity ownership by outside directors, higher board independence, and lower divergence of control rights from cash flow rights, have lower income-increasing discretionary accruals. More importantly, I find that outside directors' equity ownership and proportion of outside directors mitigate the propensity of firms with high separation of control rights from cash flow rights to make higher income-increasing discretionary accruals. Table 42.3 column (2) presents the results using the subsample of firms with income-decreasing discretionary accruals. I find firms with higher equity ownership, higher board independence, and lower divergence of control rights from cash flow rights, have lower income-decreasing discretionary accruals. Furthermore, I find that equity ownership by outside directors and proportion of outside directors mitigate the propensity of firms with high separation of control rights from cash flow rights to make higher income-decreasing discretionary accruals.

In summary, when outside directors have equity ownership and when board independence is high, firms have *both* lower income-increasing and income-decreasing discretionary accruals, apparently mitigating earnings management

Table 42.4 Regressions of accrual quality. The sample consists of 617 firms for 2,875 firm-year observations during the period 2004–2008 in five Asian countries comprising Indonesia, Malaysia, the Philippines, Singapore, and Thailand. The dependent variable is AQ measured by Dechow and Dichev's (2002) measure of mapping of accruals to past, present, and future cash from operations with higher values of AQ denoting better accrual quality. All variables are defined in Table 42.1. All regressions contain dummy control variables for country, year, and industry. The t-statistics (in parentheses) are adjusted based on standard errors clustered by firm and year (Petersen 2009). The symbols *, **, and *** denote statistical significance at the 10 %, 5 %, and 1 % levels (two-tailed), respectively

Adjusted R2		9.2 %	10.5 %

both on the upside and downside. For firms with greater separation of control rights from cash flow rights of controlling shareholders, those with high equity ownership by outside directors and those with high proportion of outside directors have lower income-increasing and lower income-decreasing discretionary accruals.

42.4.3 Accrual Quality

Table 42.4 presents regressions of accrual quality on corporate ownership structure and board characteristics. Following Gow et al. (2010), I employ the two-way clustering method where the standard errors are clustered by both firm and year in my regressions. In column (1), the coefficient EBC is positive and significant, suggesting that that firms whose directors receive higher equity ownership have higher accrual quality. Firms with high proportion of outside directors have higher accrual quality. The coefficient on VOTE is negative and significant, indicating the firms with high misalignment between control rights and cash flow rights have lower accrual quality. In column (2), the interaction term VOTE*DIROWN is positive and significant at the 1 % level. This finding suggests that firms with

Table 42.5 Regressions of returns on earnings. The sample consists of 617 firms for 2,875 firm-year observations during the period 2004–2008 in five Asian countries comprising Indonesia, Malaysia, the Philippines, Singapore, and Thailand. The dependent variable (RET) is 12-month cumulative raw return ending 3 months after the fiscal year-end. All regressions contain dummy control variables for country, year, and industry. The t-statistics (in parentheses) are adjusted based on standard errors clustered by firm and year (Petersen 2009). The symbols *, **, and *** denote statistical significance at the 10 %, 5 %, and 1 % levels (two-tailed), respectively

	Predicted sign	1	2

N		3,172	3,172
Adjusted R2		11.8 %	13.3 %

higher equity ownership by outside directors have a less pronounced negative association between accrual quality and the separation of control rights from cash flow rights of controlling shareholders. I then test whether board independence attenuates the negative association between accrual quality and the separation of control rights from cash flow rights of controlling shareholders. The interaction term VOTE*OUTDIR is positive and significant at the 5 % level. Hence, for firms with high separation of control rights from cash flow rights of controlling shareholder, those with higher proportion of outside directors have higher accrual quality. Collectively, my results suggest that stronger directors' equity ownership and higher board independence are associated with better financial reporting outcome, especially in firms with high expected agency costs arising from misalignment of control rights and cash flow rights.

42.4.4 Earnings Informativeness

Table 42.5 presents the regression results on earnings informativeness. The coefficient EARN* DIROWN is positive and significant, indicating the greater the equity ownership by outside directors, the higher informativeness of reported earnings. The coefficient EARN*OUTDIR is positive and significant, implying that firms with higher proportion of outside directors have higher informativeness of reported earnings. Consistent with prior studies (Fan and Wong 2002), the coefficient EARN*VOTE is negative and significant, indicating that the separation of control rights from cash flow rights of controlling shareholder reduces the informativeness of reported earnings.

In column (2), I examine the interaction between effectiveness of board monitoring and the divergence of control rights from cash flow rights in affecting earnings informativeness. The interaction term EARN*VOTE* DIROWN is positive and significant at the 1 % level. In firms with high misalignment between control rights from cash flow rights, the informativeness of earnings is higher when outside directors have higher equity ownership. The interaction term EARN*VOTE*OUTDIR is positive and significant at the 5 % level. The negative association between earnings informativeness and the separation between control rights from cash flow rights controlling shareholder is less pronounced in firms with higher proportion of outside directors. In other words, in firms with high misalignment between control rights from cash flow rights, the informativeness of earnings is higher in firms with higher proportion of outside directors.

42.4.5 Robustness Tests

As a sensitivity analysis, I repeat all my tests at the economy level. The economy-by-economy results indicate that earnings quality is positively associated with equity ownership by outside directors and board independence and negatively associated with the separation of cash flow rights from control rights. More importantly, the mitigating effects of equity ownership and board independence on the association between separation of cash flow rights from control rights and earnings quality are not concentrated in any given economy. Year-by-year regressions yield qualitatively similar results, suggesting my inferences are not time-period specific.

As a robustness test, I follow Haw et al. (2004) to include legal institutions that protect minority shareholder rights (proxied by legal tradition, minority shareholder rights, efficiency of judicial system, or disclosure system) and extralegal institutions (proxied by the effectiveness of competition law, diffusion of the press, and tax compliance) in my tests. I continue to document firm-specific internal governance mechanisms, namely, outside directors' equity ownership and board independence, still matter in constraining management opportunism over the financial reporting process, especially in firms with high expected agency costs arising from the divergence between control rights and cash flow rights. Thus, my results suggest that there is an incremental role for firm-specific internal governance mechanisms, beyond country-level institutions, in improving the quality of financial information by mitigating insiders' entrenchment.

42.5 Conclusion

Publicly reported accounting information, which measures a firm's financial position and performance, can be used as important input information in various corporate governance mechanisms such as managerial incentive plans. Whether and how reported accounting information is used in the governance of a firm depends on the quality and credibility of such information. I provide evidence that board of directors plays an important corporate governance role in improving the quality and credibility of accounting information in firms with high agency conflicts arising from their concentrated ownership structure.

I examine the relation among outside directors' equity ownership, board independence, separation of control rights from cash flow rights of controlling shareholder, and earnings quality. I measure earnings quality with three financial reporting metrics: (i) discretionary accruals, (ii) mapping of accruals to cash flow, and (iii) informativeness of reported earnings. I find that earnings quality is positively associated with outside directors' equity ownership and the proportion of outside directors on the board. I document that firms with higher agency problems arising from the separation of control rights from cash flow rights of controlling shareholders have lower earnings quality. The negative association between separation of control rights from cash flow rights and earnings quality is less pronounced in firms with higher equity ownership by outside directors. This finding suggests that equity ownership that aligns outside directors' and shareholders' interest is associated with more effective monitoring of managerial discretion on reported earnings. In addition, the low earnings quality induced by the separation of control rights from cash flow rights is mitigated by the proportion of outside directors on the board. Overall, my results suggest that directors' equity ownership and board independence are associated with better financial reporting outcomes, especially in firms with high expected agency costs arising from misalignment of control rights and cash flow rights.

Appendix 1: Discretionary Accruals

My first proxy for earnings quality is discretionary accruals. A substantial stream of prior studies uses absolute discretionary accruals as a proxy for earnings management (Ashbaugh et al. 2003; Warfield et al. 1995; Klein 2002; Kothari et al. 2005). Absolute discretionary accruals reflect corporate insiders' propensity to inflate reported income to conceal private benefits of control and to understate income in good performance years to create reserves for poor performance in the future. Accruals are estimated by taking the difference between net income and cash flow from operations. I employ the modified cross-sectional Jones (1991) model to decompose total accruals into non-discretionary accruals and discretionary accruals. Specifically, I estimate the following model for each country in each year at the one-digit SIC industry:

$$\mathrm{ACC} = \gamma_1(1/\mathrm{LAG1ASSET}) + \gamma_2(\mathrm{CHGSALE} - \mathrm{CHGREC}) + \gamma_3(\mathrm{PPE}) \quad (42.1)$$

where:
ACC = total accruals, which are calculated as net income minus operating cash flows scaled by beginning-of-year total assets.
LAG1ASSET = total assets at beginning of the fiscal year.
CHGSALE = sales change, which is net sales in year t less net sales in year $t-1$, scaled by beginning-of-year-t total assets.
CHGREC = change in accounts receivables scaled by beginning-of-year-t total assets.
PPE = gross property, plant, and equipment in year t scaled by beginning-of-year-t total assets.

I use the residuals from the annual cross-sectional country-industry regression model in (A1) as the modified Jones model discretionary accruals.

I use the following regression model to test the association between discretionary accruals and board structure:

$$\begin{aligned}\mathrm{DISCAC} = {} & \beta_0 + \beta_1\mathrm{EBC} + \beta_2\mathrm{OUTDIR} + \beta_3\mathrm{VOTE} + \beta_4\mathrm{VOTE} * \mathrm{EBC} \\ & + \beta_5\mathrm{VOTE} * \mathrm{OUTDIR} + \beta_6\mathrm{BOARDSIZE} + \beta_7\mathrm{CEODUAL} \\ & + \beta_8\mathrm{LNASSET} + \beta_9\mathrm{MB} + \beta_{10}\mathrm{LEV} + \beta_{11}\mathrm{ROA} \\ & + \text{Year controls} + \text{Country Controls} \end{aligned} \quad (42.2)$$

where:
DISCAC = absolute value of discretionary accruals estimated based on the modified Jones model (see Eq. 42.1).
DIROWN = common stock and stock options held by outside directors divided by number of ordinary shares outstanding in the firm.
OUTDIR = proportion of outside directors on the board.
VOTE = control rights divided by cash flow rights of the largest controlling shareholder.
BOARDSIZE = number of directors on the board.
CEODUAL = a dummy variable that equals 1 if the CEO is chairman of board and 0 otherwise.
LNASSET = natural logarithm of total assets.
MB = market value of equity divided by book value of equity.
LEV = long-term debt divided by total assets.
ROA = net profit after tax divided by total assets.
Country Controls = a set of country dummy variables.
Year Controls = a set of year dummy variables.

If high equity ownership for outside directors improves the board monitoring of managerial discretion over the financial accounting process, I predict the coefficient β_1 to be negative. Similarly, a negative coefficient for β_2 suggests that board independence curtails managerial opportunism on financial reporting. A positive coefficient β_3 indicates greater separation of control rights from cash flow rights of the largest controlling shareholder induces greater earnings management. I predict the positive association between absolute discretionary accruals and the separation of control rights from cash flow rights to be less pronounced in firms with high equity ownership by outside directors. Thus, I expect coefficient β_4 to be negative. Furthermore, I predict the positive association between absolute discretionary accruals and the separation of control rights from cash flow rights to be less pronounced in firms high proportion of outside directors on the board. Thus, I expect coefficient β_5 to be negative.

Other board characteristics include the total number of directors (BOARDSIZE) and CEO-chairman duality (CEODUAL). The evidence is mixed on whether board size and CEO duality impairs board effectiveness. Thus, ex ante, there is no prediction on the sign on both variables. The model controls for the effects of firm size, growth opportunities, and leverage on discretionary accruals. Large firms have greater external monitoring, have more stable operations and stronger control structures, and hence report smaller abnormal accruals (Dechow and Dichev 2002). Firm size (LNASSET) is measured based on book value of total assets. Because discretionary accruals are higher for firms with higher growth opportunities, I employ the market-to-book equity (MB) ratio to control for the effect of growth opportunities on discretionary accruals (Kothari et al. 2005). I also include financial leverage (LEV), defined as long-term debt divided by total assets, to control for the managerial discretion over the financial accounting process to mitigate constraints of accounting-based debt covenants (Smith and Watts 1992). To control for the effect of firm performance on discretionary accruals, I include firm profitability (ROA), defined as net income divided by total assets. Finally, I include country dummy variables to capture country-specific factors that may affect the development of capital markets and financial accounting quality. I include dummy variables for years and industries to control for time effect and industry effects, respectively.

Appendix 2: Accruals Quality

My second proxy for earnings quality is accruals quality. Dechow and Dichev (2002) propose a measure of earnings quality that captures the mapping of current accruals into last-period, current-period, and next-period cash flows. Francis et al. (2005) find that this measure (which they term accrual quality) is associated with measures of cost of equity capital. My measure of accrual quality is based on Dechow and Dichev's (2002) model relating current accruals to last-period, current-period, and next-period cash flows:

$$\frac{TCA_{j,t}}{Assets} = \gamma_{0,j} + \gamma_{1j}\frac{CFO_{j,t-1}}{Assets} + \gamma_{2j}\frac{CFO_{j,t}}{Assets} + \gamma_{2j}\frac{CFO_{j,t+1}}{Assets} + e_{j,t} \tag{42.3}$$

where:

$TCA_{j,t}$ = firm j's total current accruals in year t = $\Delta CA_{j,t} - \Delta CL_{j,t} - \Delta CASH_{j,t} + \Delta STD_{j,t}$

Assets = firm j's average total assets in year t − 1 and year t

$CFO_{j,t}$ = cash flow from operations in year t is calculated as net income less total accruals (TA) where:

$TA_{j,t} = \Delta CA_{j,t} - \Delta CL_{j,t} - \Delta CASH_{j,t} + \Delta STD_{j,t} - DEPN_{j,t}$ where

$\Delta CA_{j,t}$ = firm j's change in current assets between year t − 1 and year t

$\Delta CL_{j,t}$ = firm j's change in current liabilities between year t − 1 and year t

$\Delta CASH_{j,t}$ = firm j's change in cash between year t − 1 and year t

$\Delta STD_{j,t}$ = firm j's change in debt in current liabilities between year t − 1 and year t

$DEPN_{j,t}$ = firm j's change in depreciation and amortization expense in year t

I estimate Eq. 42.3 for each one-digit SIC industry for each country-year combination. These estimations yield firm- and year-specific residuals, e_{jt}, which form the basis for the accrual quality metric. AQ is the standard deviation of firm j's estimated residuals multiplied by −1. Hence, large values of AQ correspond to high accrual quality.

I employ the following model to test the association between accrual quality and board characteristics:

$$\begin{aligned} AQ = {} & \beta_0 + \beta_1 EBC + \beta_2 OUTDIR + \beta_3 VOTE + \beta_4 VOTE * DIROWN \\ & + \beta_5 VOTE * OUTDIR + \beta_6 CEODUAL + \beta_7 BOARDSIZE \\ & + \beta_8 LNASSET + \beta_9 OPERCYCLE + \beta_{10} NETPPE + \beta_{11} STDSALE \\ & + \beta_{12} STDCFO + \beta_{13} NEGEARN + \text{Country controls} \\ & + \text{Industry Controls} + \text{Year Controls}. \end{aligned} \tag{42.4}$$

where:

AQ = the standard deviation of firm j's residuals from a regression of current accruals on lagged, current, and future cash flows from operations. I multiply the variable by −1 so that higher AQ measure denotes higher accrual quality.

OPERCYCLE = log of the sum of the firm's days accounts receivable and days inventory.

NETPPE = ratio of the net book value of PP&E to total assets.

STDCFO = standard deviation of the firm's rolling 5-year cash flows from operations.

STDSALE = standard deviation of the firm's rolling 5-year sales revenue.

NEGEARN = the firm's proportion of losses over the prior 5 years.

All other variables are previously defined.

If high equity ownership for outside directors improves the board monitoring of managerial discretion over the financial accounting process, I predict coefficient β_1 to be positive. Similarly, a positive coefficient for β_2 suggests that higher board independence is associated with higher accrual quality. If greater agency costs arise from the higher separation of control rights from cash flow rights of the largest controlling shareholder, coefficient β_3 should be negative. I predict that the negative association between accrual quality and the separation of control rights from cash flow rights is mitigated in firms with high equity ownership by outside directors. Thus, I expect coefficient β_4 to be positive. Furthermore, the negative effect of the separation of control rights from cash flow on rights accrual quality should be attenuated in firms with high proportion of outside directors on the board. Thus, I expect coefficient β_5 to be positive.

In Eq. 42.4, the control variables include innate determinants of accrual quality. Briefly, Dechow and Dichev (2002) find that accrual quality is positively associated with firm size and negatively associated with cash flow variability, sales variability, operating cycle, and incidence of losses. Firm size is measured by the natural logarithm of total assets (LNASSET). Operating cycle (OPERCYCLE) is the log of the sum of the firm's days accounts receivable and days inventory. Capital intensity, NETPPE, is proxied by the ratio of the net book value of PP&E to total assets. Cash flow variability (STDCFO) is the standard deviation of the firm's rolling 5-year cash flows from operations. Sales variability (STDSALE) is the standard deviation of the firm's rolling 5-year sales revenue. Incidence of negative earnings realizations, NEGEARN, is measured as the firm's proportion of losses over the prior 5 years.

Appendix 3: Earnings Informativeness

My third proxy of earnings quality is earnings informativeness, measured by the earnings response coefficients (Warfield et al. 1995; Fan and Wong 2002; Francis et al. 2005). The following model is adopted to investigate the relation between earnings informativeness and equity-based compensation, board independence, and separation of control rights from cash flow rights:

$$\begin{aligned}\mathrm{RET} = {} & \beta_0 + \beta_1\mathrm{EARN} + \beta_2\mathrm{EARN} * \mathrm{DIROWN} + \beta_3\mathrm{EARN} * \mathrm{OUTDIR} \\ & + \beta_4\mathrm{EARN} * \mathrm{VOTE} + \beta_5\mathrm{EARN} * \mathrm{VOTE} * \mathrm{EBC} \\ & + \beta_6\mathrm{EARN} * \mathrm{VOTE} * \mathrm{OUTDIR} + \beta_7\mathrm{EARN} * \mathrm{BOARDSIZE} \\ & + \beta_8 * \mathrm{EARN} * \mathrm{CEODUAL} + \beta_9\mathrm{EARN} * \mathrm{LNASSET} \\ & + \beta_{10}\mathrm{EARN} * \mathrm{MB} + \beta_{11}\mathrm{EARN} * \mathrm{LEV} + \beta_{12}\mathrm{EARN} * \mathrm{ROA} \\ & + \text{Year controls} + \text{Country Controls} + \text{Industry Controls} + e\end{aligned} \tag{42.5}$$

where:

RET = 12-month cumulative raw return ending 3 months after the fiscal year-end.

EARN = net income for year t, scaled by the market value of equity at the end of $t - 1$.

All other variables are as previously defined.

The estimated coefficient on β_1 reflects the earnings response coefficient. A positive estimate on β_2 will be consistent with the notion that equity ownership for outside directors is associated with more informative earnings. A positive estimate on β_3 indicates that the greater proportion of outside directors on the board, the greater the informativeness of earnings. From Fan and Wong (2002), I expect coefficient β_4 to be negative, indicating that the reported earnings are less informative when the ultimate shareholder's control rights exceed his cash flow rights. If high equity ownership for outside directors improves their monitoring of management, the negative effects of the divergence of control rights from cash flow rights should be mitigated in firms with high equity-based compensation. I expect coefficient β_5 to be positive. If monitoring intensity is positively associated with the proportion of outside directors on the board, the reduced informativeness of reported earnings in firm with high divergence of control rights from cash flow rights should be mitigated in firms with higher board independence. I expect coefficient β_6 to be positive.

Appendix 4: Adjusting for Standard Errors in Panel Data

Gow et al. (2010) examine several approaches to address issues of cross-sectional and time-series dependence in accounting research. They identified a number of common approaches: Fama-MacBeth, Newey-West, the Z2 statistic, and standard errors clustered by firm, industry, or time. Gow et al. (2010) review each of these approaches and discuss the circumstances in which they produce valid inferences.

This section is drawn heavily from Gow et al. (2010). Correcting for cross-sectional and time-series dependence in accounting research. The Accounting Review 85(2), 483–512. Reader should refer to the paper for details.

(i) **OLS and White Standard Errors**

OLS standard errors assume that errors are both homoskedastic and uncorrelated across observations. While White (1980) standard errors are consistent in the presence of heteroskedasticity, both OLS and White produce misspecified test statistics when either forms of dependence is present.

(ii) **Newey-West**

Newey and West (1987) generalize the White (1980) approach to yield a covariance matrix estimator that is robust to both heteroskedasticity and serial correlation. Gow et al. (2010) find that the Newey-West procedure produces slightly biased estimates of standard errors when time-series dependence alone is present. However, Gow et al. (2010) find that, in the presence of both cross-sectional and time-series dependence, Newey and West method produces misspecified test statistics with even moderate levels of cross-sectional dependence.

(iii) **Fama-MacBeth**

The Fama-MacBeth approach (Fama and MacBeth 1973) is designed to address concerns about cross-sectional correlation. The Fama-MacBeth approach (FM-t) involves estimating T cross-sectional regressions (one for each period) and basing inferences on a t-statistic calculated as

$$t = \frac{\overline{\beta}}{se(\beta)}, \text{where } \overline{\beta} = \frac{1}{T}\sum_{t=1}^{T}\hat{\beta}_t \tag{42.6}$$

and $se(\beta)$ is the standard error of the coefficients based on their empirical distribution. When there is no cross-regression (time-series) dependence, this approach yields consistent estimates of the standard error of the coefficients as T goes to infinity.

Two common variants of the Fama-MacBeth approach appear in the accounting literature. The first variant, FM-i, involves estimating firm- or portfolio-specific time-series regressions with inferences based on the cross-sectional distribution of coefficients. This modification of the Fama-MacBeth approach is appropriate if there is time-series dependence but not cross-sectional dependence. However, FM-i is frequently used when cross-sectional dependence is likely, such as when returns are the dependent variable.

The second common variant of the FM-t approach, FM-NW, is intended to correct for serial correlation in addition to cross-sectional correlation. FM-NW modifies FM-t by applying a Newey-West adjustment in an attempt to correct for serial correlation.

Gow et al. (2010) suggest two reasons to believe that FM-NW may not correct for serial correlation. First, FM-NW involves applying Newey-West to a limited number of observations, a setting in which Newey-West is known to perform poorly. Second, FM-NW applies Newey-West to a time-series of coefficients, whereas the dependence is in the underlying data.

(iv) **Z2 Statistic**

The Z2-t (Z2-i) statistic is calculated using t-statistics from separate cross-sectional (time-series) regressions for each time period (cross-sectional unit) and is given by the expression:

$$Z2 = \frac{\overline{t}}{se(t)}, \text{where } \overline{t} = \frac{1}{T}\sum_{t=1}^{T}\hat{t}_t, \tag{42.7}$$

$se(t)$ is the standard error of the t-statistics based on their empirical distribution, and T is the number of time periods (cross-sectional units) in the sample.

Gow et al. (2010) suggest Z2 may suffer from cross-regression dependence in the same way as the Fama-MacBeth approach does.

(v) **One-Way Cluster-Robust Standard Errors**

A number of studies in our survey use cluster-robust standard errors, with clustering either along a cross-sectional dimension (e.g., analyst, firm, industry, or country) or along a time-series dimension (e.g., year); we refer to the former as CL-i and the latter as CL-t. Cluster-robust standard errors (also referred to as Huber-White or Rogers standard errors) were proposed by White (1980) as a generalization of the heteroskedasticity-robust standard errors of White (1980). With observations grouped into G clusters of Ng observations, for g in $\{1,\ldots,G\}$, the covariance matrix is estimated using the following expression:

$$\hat{V}(\hat{B}) = \left(X'X\right)^{-1}\hat{B}\left(X'X\right)^{-1}, \hat{B} = \sum_{g=1}^{G} X_g' u_g u_g' X_g, \tag{42.8}$$

where Xg is the $Ng \times K$ matrix of regressors, and ug is the Ng-vector of residuals for cluster g.

While one-way cluster-robust standard errors allow for correlation of unknown form within cluster, it is assumed that errors are uncorrelated across clusters. For example, clustering by time (firm) allows observations to be cross-sectionally (serially) correlated but assumes independence over time (across firms). While some studies consider both CL-i and CL-t separately, separate consideration of CL-t and CL-i does not correct for both cross-sectional and time-series dependence. Gow et al. (2010) find that t-statistics for CL-t are inflated in the presence of time-series dependence and t-statistics for CL-i are inflated in the presence of cross-sectional dependence. Thus, when both forms of dependence are present, both CL-t and CL-i produce overstated t-statistics.

(vi) **Two-Way Cluster-Robust Standard Errors**

An extension of cluster-robust standard errors is to allow for clustering along more than one dimension. In contrast to one-way clustering, two-way clustering (CL-2) allows for *both* time-series *and* cross-sectional dependence. For example, two-way clustering by firm and year allows for within-firm (time-series) dependence *and* within-year (cross-sectional) dependence (e.g., the observation for firm j in year t can be correlated with that for firm j in year $t + 1$ and that for firm k in year t). To estimate two-way cluster-robust standard errors, the expression in (A4) is evaluated using clusters along each dimension (e.g., clustered by industry and clustered by year) to yield $V1$ and $V2$. Then the same expression is calculated using the "intersection" clusters (in the example, observations within an industry-year) to yield VI. The two-way cluster-robust estimator V is calculated as $V = V1 + V2 - VI$. Standard econometric software packages (e.g., Stata and SAS) contain routines for calculating one-way cluster-robust standard errors, making it relatively straightforward to implement two-way cluster-robust standard errors. Gow et al. (2010) find that in the presence of both cross-sectional and time-series dependence, the two-way clustering method (by year and by firm) which allows for both cross-sectional and time-series dependence produces well-specified test statistics. Johnston and DiNardo (1997) and Greene (2000) are two econometric textbooks that contain a detailed discussion of the econometrics issues relating to panel data.

Acknowledgment I appreciate the research funding provided by Institute of Certified Public Accountants of Singapore. I would like to dedicate this paper to my late father, Yew-Ming Lee.

Abstract

This chapter examines the rationality and diversity of industry-level forecasts of the yen-dollar exchange rate collected by the Japan Center for International Finance. In several ways we update and extend the seminal work by Ito (1990, *American Economic Review 80*, 434–449). We compare three specifications for testing rationality: the "conventional" bivariate regression, the univariate regression of a forecast error on a constant and other information set variables, and an error correction model (ECM). We find that the bivariate specification, while producing consistent estimates, suffers from two defects: first, the conventional restrictions are sufficient but not necessary for unbiasedness; second, the test has low power. However, before we can apply the univariate specification, we must conduct pretests for the stationarity of the forecast error. We find a unit root in the 6-month horizon forecast error for all groups, thereby rejecting unbiasedness and weak efficiency at the pretest stage. For the other two horizons, we find much evidence in favor of unbiasedness but not weak efficiency. Our ECM rejects unbiasedness for all forecasters at all horizons. We conjecture that these results, too, occur because the restrictions test sufficiency, not necessity.

We extend the analysis of industry-level forecasts to a SUR-type structure using an innovative GMM technique (Bonham and Cohen 2001, *Journal of Business & Economic Statistics, 19*, 278–291) that allows for forecaster cross-correlation due to the existence of common shocks and/or herd effects. Our GMM tests of micro-homogeneity uniformly reject the hypothesis that forecasters exhibit similar rationality characteristics.

43.1 Introduction

This chapter examines the rationality of industry-level survey forecasts of the yen-dollar exchange rate collected by the Japan Center for International Finance (JCIF). Tests of rationality take on additional significance when performed on asset market prices, since rational expectations is a necessary condition for market efficiency. In the foreign exchange market, tests of forward rate unbiasedness simultaneously test a zero risk premium in the exchange rate; hence this joint hypothesis is also called the risk-neutral efficient market hypothesis (RNEMH). The practical significance of such a hypothesis is that if the forward rate is indeed an unbiased predictor of the future spot rate, then exchange risk can be costlessly hedged in the forward market. However, the RNEMH has been rejected nearly universally. Since the risk premium is unobservable, insight into the reason for the rejection of the RNEMH can be gained by separately testing for rationality using survey data on expectations. Because forecasters cannot be assumed to have identical information sets, we must use individual survey forecasts to avoid the aggregation bias inherent in the use of mean or median forecasts.

We use data from the same source as Ito (1990), the seminal study recognizing the importance of using individual data to test rationality hypotheses about the exchange rate. To achieve stationarity of the realizations and forecasts (which each have a unit root), Ito (1990) followed the conventional specification at the time of subtracting the current realization from each. These variables are then referred to as being in "change" form. To test unbiasedness he regressed the future rate of depreciation on the forecasted return and tested the joint restrictions that the intercept equalled zero and the slope coefficient equalled one. At the industry level he found approximately twice as many rejections (at the 1 % level) at the longest horizon (6 months) than at the two shorter horizons (1 and 3 months).

We extend Ito's analysis in two principal respects: the specification of unbiasedness tests and inference in tests for micro-homogeneity of forecasters. One problem with the change specification of unbiasedness tests is that, since there is much more variation in the change in the realization than in the forecast, there is a tendency to under-reject the part of the joint hypothesis that the coefficient on the forecast equals one. This is precisely what we would expect in tests of variables which are near random walks.

Second, and more fundamentally, Ito's (1990) bivariate (joint) regression test of unbiasedness is actually a test of sufficiency, not necessity as well as sufficiency. Following Holden and Peel (1990), the necessary and sufficient condition for unbiasedness is a mean zero forecast error. This is tested in a univariate regression by imposing a coefficient of unity on the forecast and testing the restriction that the intercept equals zero. This critique applies whether or not the forecast and realization are integrated in levels. However, when the realization and forecast are integrated in levels, we must conduct a pretest to determine whether the forecast error is stationary. If the forecast and realization are both integrated and cointegrated, then a necessary and sufficient condition for unbiasedness is that intercept and slope in the cointegrating regression (using levels of the realization and forecast) are zero and one, respectively. We test this hypothesis using Liu and Maddala's (1992) method of imposing the (0, 1) vector, then testing the "restricted" cointegrating residual for stationarity.[1,2]

Third, we use the result from Engle and Granger (1987) that cointegrated variables have an error correction representation. First, we employ the specification and unbiasedness restrictions originally proposed by Hakkio and Rush (1989). However, the unbiasedness tests using the ECM specification produce more rejections over industry groups and horizons than the univariate or bivariate specifications.

[1]If in addition the residuals from the cointegrating regression are white noise, this supports a type of weak efficiency.

[2]Pretesting the forecast error for stationarity is a common practice in testing the RNMEH, but the only study we know of that applies this practice to survey forecasts of exchange rates is Osterberg (2000), and he does not test for a zero intercept in the cointegrating regression.

We conjecture that one possible explanation for this apparent anomaly is that, similar to the joint restrictions in the bivariate test, the ECM restrictions test sufficient conditions for unbiasedness, while the univariate restriction only tests a necessary and sufficient condition. Thus, the ECM has a tendency to over-reject. We then respecify the ECM, so that only the necessary and sufficient conditions are tested. We compare our results to those obtained using the sufficient conditions represented by the joint restrictions as well as the necessary and sufficient condition represented by the univariate restriction.

The second direction in which we extend Ito's (1990) analysis has to do with testing for differences among forecasters' ability to produce rational predictions.[3] We recognize, as does Ito, that differences among forecasters over time indicate that at least some individuals form biased forecasts. (The converse does not necessarily hold, since a failure to reject micro-homogeneity could conceivably be due to the same degree of irrationality of each individual in the panel.) Ito's heterogeneity test is a single-equation test of deviations of individual forecasts from the mean forecast, where the latter may or may not be unbiased. In contrast, we test for differences in individual forecast performance using a micro-homogeneity test, i.e., testing for equal coefficients across the system of individual univariate rationality equations.

In our tests for micro-homogeneity, we expect cross-forecaster error correlation due to the possibility of common macro shocks and/or herd effects in expectations. To this end, we incorporate two innovations not previously used by investigators studying survey data on exchange rate expectations. First, in our micro-homogeneity tests, we use a GMM system with a variance-covariance matrix that allows for cross-sectional as well as moving average and heteroscedastic errors. Here we follow the widely used practice of modeling the individual regression residuals as an MA process of order h-1, where h is the number of periods in the forecast horizon. However, no other researchers have actually tested whether an MA process of this length is required to model the cross-sectional behavior of rational forecast errors. Thus, second, to investigate the nature of the actual MA processes, we use Pesaran's (2004) CD test to examine the statistical significance of the cross-sectional dependence of forecast errors, both contemporaneous and lagged.

The organization of the rest of the chapter is as follows: in Sect. 43.2 we review some fundamental issues in testing rationality in the foreign exchange market. In Sects. 43.3 and 43.4, we conduct various rationality tests on the JCIF data. Section 43.5 contains our micro-homogeneity tests. Section 43.6 summarizes and discusses areas for future research.

[3]Market microstructure theories assume that there is a minimum amount of forecaster (as well as cross-sectional forecast) diversity. Also, theories of exchange rate determination that depend upon the interaction between chartists (or noise traders) and fundamentalists by definition require a certain structure of forecaster heterogeneity.

43.2 Background: Testing Rationality in the Foreign Exchange Market

The Rational Expectations Hypothesis (REH) assumes that economic agents know the true data-generating process (DGP) for the forecast variable. This implies that the market's subjective probability distribution of the variable is identical to the objective probability distribution, conditional on a given information set, Φ_t. Equating first moments of the market, $E_m(s_{t+h}|\Phi_t)$, and objective, $E(s_{t+h}|\Phi_t)$, distributions,

$$E_m(s_{t+h}|\Phi_t) = E(s_{t+h}|\Phi_t), \tag{43.1}$$

where the right-hand side can be shortened to $E_t(s_{t+h})$.

It follows that the REH implies that forecast errors have both unconditional and conditional means equal to zero. A forecast is unbiased if its forecast error has an unconditional mean of zero. A forecast is efficient if its error has a conditional mean of zero. The condition that forecast errors be serially uncorrelated is a subset of the efficiency condition where the conditioning information set consists of past values of the realization and current as well as past values of the forecast.[4]

In this chapter we focus on testing whether forecasters can form rational expectations of future depreciation. If not, then at least part of the explanation for the failure of the RNEMH is due to the failure of the REH. There are two related interest parity conditions. Covered interest parity, an arbitrage condition, holds if $f_{t,h} - s_t = i_t - i_t^*$, i.e., the forward premium is equal to the interest differential between domestic and foreign risk-free assets. Uncovered interest parity holds if $s_{t+h} - s_t^e = i_t - i_t^*$. Because uncovered interest parity assumes both unbiased expectations and risk neutrality, some authors view it as equivalent to the RNEMH (see Phillips and Maynard 2001).

The ability to decompose deviations from UIP into time-varying risk premium and systematic forecast error components also has implications for policymakers. Consider first the possibility of a violation of the risk neutrality hypothesis. According to the portfolio balance model, if a statistically significant time-varying risk premium component is found, this means that $i_t - i_t^*$ is time-varying, which in turn implies that foreign and domestic bonds are not perfect substitutes; changes in relative quantities (which are reflected in changes in current account balances) will affect the interest rate differential. In this way, sterilized official intervention can have significant effects on exchange rates. Second, consider the possibility of a violation of the REH. If a statistically significant expectational error of the destabilizing (e.g., "bandwagon") type is found, and policymakers are more rational than speculators, a policy of "leaning against the wind" could have a stabilizing

[4]It is important to note that the result from one type of rationality test does not have implications for the results from any other types of rationality tests. In this chapter we test for unbiasedness and weak efficiency, leaving the more stringent tests of efficiency with respect to publicly available information for future analysis.

effect on exchange rate movements. (See Cavaglia et al. 1994.) More generally, monetary models of the exchange rate (in which the UIP condition is embedded), which assume model-consistent (i.e., rational) expectations with risk neutrality, generally have not performed well empirically, especially in out-of-sample forecasting. (See, e.g., Bryant 1995.) One would like to be able to attribute the model failure to some combination of a failure of the structural assumptions (including risk neutrality) and a failure of the expectational assumption.

43.2.1 Why Test Rational Expectations with Disaggregated Survey Forecast Data?

Beginning with Frankel and Froot (1987) and Froot and Frankel (1989), much of the literature examining exchange rate rationality in general, and the decomposition of deviations from the RNEMH in particular, has employed the representative agent assumption to justify using the mean or median survey forecast as a proxy for the market's expectation. In both studies, Frankel and Froot found significant evidence of irrationality. Subsequent research has found mixed results. Liu and Maddala (1992, p. 366) articulate the mainstream justification for using aggregated forecasts in tests of the REH. "Although . . .data on individuals are important to throw light on how expectations are formed at the individual level, to analyze issues relating to market efficiency, one has to resort to aggregates." In fact, Muth's (1961, p. 316) original definition of rational expectations seemed to allow for the possibility that rationality could be applied to an aggregate (e.g., mean or median) forecast. '. . . [E]xpectations of firms (or, more generally, the subjective probability distribution of outcomes) tend to be distributed, *for the same information set*, about the predictions of the theory (or the "objective" probability distribution of outcomes).' (Emphasis added.)

However, if individual forecasters have different information sets, Muth's definition does not apply. To take the simplest example, the (current) mean forecast is not in any forecaster's information set, since all individuals' forecasts must be made before a mean can be calculated. Thus, current mean forecasts contain private information (see MacDonald 1992) and therefore cannot be tested for rationality.[5]

Using the mean forecast may also result in inconsistent parameter estimates. Figlewski and Wachtel (1983) were the first to show that, in the traditional bivariate

[5]A large theoretical literature relaxes Muth's assumption that all information relevant for forming a rational forecast is publicly available. Instead, this literature examines how heterogeneous individual expectations are mapped into an aggregate market expectation, and whether the latter leads to market efficiency. (See, e.g., Figlewski 1978, 1982, 1984; Kirman 1992; Haltiwanger and Waldman 1989.) Our paper focuses on individual rationality but allows for the possibility of synergism by incorporating not only heteroscedasticity and autocorrelation consistent standard errors in individual rationality tests but also cross-forecaster correlation in tests of micro-homogeneity. The extreme informational requirement of the REH led Pesaran and Weale (2006) to propose a weaker form of the REH that is based on the (weighted) average expectation using only publicly available (i.e., common) information.

unbiasedness equation, the presence of private information variables in the mean forecast error sets up a correlation with the mean forecast. This inconsistency occurs even if all individual forecasts are rational. In addition, Keane and Runkle (1990) pointed out that, when some forecasters are irrational, using the mean forecast may lead to false acceptance of the unbiasedness hypothesis, in the unlikely event that offsetting individual biases allow parameters to be consistently estimated. See also Bonham and Cohen (2001), who argue that, in the case of cointegrated targets and predictions, inconsistency of estimates in rationality tests using the mean forecast can be avoided if corresponding coefficients in the individual rationality tests pass a test for micro-homogeneity.[6] Nevertheless, until the 1990s, few researchers tested for the rationality of individual forecasts, even when those data were available.

43.2.2 Rational Reasons for the Failure of the Rational Expectations Hypothesis Using Disaggregated Data

Other than a failure to process available information efficiently, there are numerous explanations for a rejection of the REH. One set of reasons relates to measurement error in the individual forecast. Researchers have long recognized that forecasts of economic variables collected from public opinion surveys should be less informed than those sampled from industry participants. However, industry participants, while relatively knowledgeable, may not be properly motivated to devote the time and resources necessary to elicit their best responses. The opposite is also possible.[7] Having devoted substantial resources to produce a forecast of the price of a widely traded asset, such as foreign exchange, forecasters may be reluctant to reveal their true forecast before they have had a chance to trade for their own account.[8]

Second, some forecasters may not have the symmetric quadratic loss function embodied in typical measures of forecast accuracy, e.g., minimum mean squared error. (See Zellner 1986; Stockman 1987; Batchelor and Peel 1998.) In this case, the optimal forecast may not be the MSE. In one scenario, related to

[6]The extent to which private information influences forecasts is more controversial in the foreign exchange market than in the equity or bond markets. While Chionis and MacDonald (1997) maintain that there is little or no private information in the foreign exchange market, Lyons (2002) argues that order flow explains much of the variation in prices. To the extent that one agrees with the market microstructure emphasis on the importance of the private information embodied in dealer order flow, the Figlewski-Wachtel critique remains valid in the returns regression.

[7]Elliott and Ito (1999) show that, although a random walk forecast frequently outperforms the JCIF survey forecasts using an MSE criterion, survey forecasts generally outperform the random walk, based on an excess profits criterion. This supports the contention that JCIF forecasters are properly motivated to produce their best forecasts.

[8]To mitigate the confidentiality problem in this case, the survey typically withholds individual forecasts until the realization is known or (as with the JCIF) masks the individual forecast by only reporting some aggregate forecast (at the industry and total level) to the public.

the incentive aspect of the measurement error problem, forecasters may have strategic incentives involving product differentiation.[9]

In addition to strategic behavior, another scenario in which forecasters may deviate from the symmetric quadratic loss function is simply to maximize trading profits. This requires predicting the direction of change, regardless of MSE.[10]

Third, despite their best efforts, forecasters may find it difficult to distinguish between a temporary and permanent shift in the DGP. This difficulty underlies at least three theories of rational forecast errors: the peso problem, learning about past regime changes, and bubbles.

Below we conduct tests for structural change in estimated unbiasedness coefficients. When unbiasedness cannot be rejected, the structural change test may show certain subperiods in which unbiasedness did not hold. In the obverse case, when unbiasedness can be rejected, the structural change test may show certain subperiods in which unbiasedness cannot be rejected. Either situation would lend some support to the theories attributing bias to the difficulty of distinguishing temporary from permanent shifts.

43.3 Description of Data

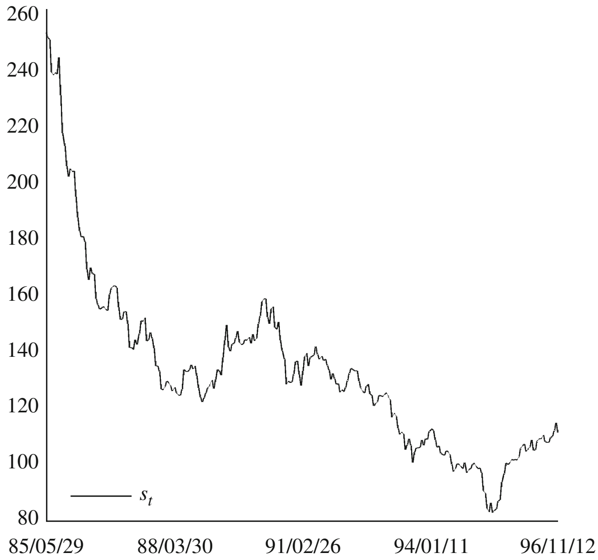
Every 2 weeks, the JCIF in Tokyo conducts telephone surveys of yen/dollar exchange rate expectations from 44 firms. The forecasts are for the future spot rate at horizons of 1 month, 3 months, and 6 months. Our data cover the period May 1985 to March 1996. This data set has very few missing observations, making it close to a true panel. For reporting purposes, the JCIF currently groups individual firms into four industry categories: (1) banks and brokers, (2) insurance and trading companies, (3) exporters, and (4) life insurance companies and importers. On the day after the survey, the JCIF announces overall and industry average forecasts. (For further details concerning the JCIF database, see the descriptions in Ito (1990, 1994), Bryant (1995), and Elliott and Ito (1999).)

Figure 43.1 shows that, over the sample period (one of flexible exchange rates and no capital controls), the yen appreciated dramatically relative to the dollar, from a spot rate of approximately 270 yen/dollar in May 1985 to approximately 90 yen/dollar in March 1996. The path of appreciation was not steady, however. In the first 2 years of the survey alone, the yen appreciated to about 140 per dollar.

[9]Laster et al. (1999) called this practice "rational bias." Prominent references in this growing literature include Lamont (2002), Ehrbeck and Waldmann (1996), and Batchelor and Dua (1990a, b, 1992). Because we have access only to forecasts at the industry average level, we cannot test the strategic incentive hypotheses.

[10]See Elliott and Ito (1999), Boothe and Glassman (1987), LeBaron (2000), Leitch and Tanner (1991), Lai (1990), Goldberg and Frydman (1996), and Pilbeam (1995). This type of loss function may appear to be relevant only for relatively liquid assets such as foreign exchange, but not for macroeconomic flows. However, the directional goal is also used in models to predict business cycle turning points. Also, trends in financial engineering may lead to the creation of derivative contracts in macroeconomic variables, e.g., CPI futures.

Fig. 43.1 Yen-dollar exchange rate versus time



The initial rapid appreciation of the yen is generally attributed to the Plaza meeting in September 1985, in which the Group of Five countries decided to let the dollar depreciate, relative to the other currencies. At the Louvre meeting in February 1987, the Group of Seven agreed to stabilize exchange rates by establishing soft target zones. These meetings may well be interpreted as unanticipated regime changes, since, as we will see below, forecasters generally underestimated the rapid appreciation following the Plaza meeting, then overestimated the value of the yen following the Louvre meeting. Thus, forecasts during these periods may have been subject to peso and learning problems. The period of stabilization lasted until about 1990, when yen appreciation resumed and continued through the end of the sample period.

43.4 Empirical Tests of Rationality

Early studies of the unbiasedness aspect of rationality regressed the level of the realization on the level of the forecast, testing the joint hypothesis that the intercept equalled zero and the slope equalled one.[11] However, since many macroeconomic variables have unit roots, and realizations and forecasts typically share a common stochastic trend, a rational forecast will be integrated and cointegrated with the target series. (See Granger 1991, pp. 69–70.) According to the modern theory of regressions

[11]The efficiency aspect of rationality is sometimes tested by including additional variables in the forecaster's information set, with corresponding hypotheses of zero coefficients on these variables. See, e.g., Keane and Runkle (1990) for a more recent study using the level specification and Bonham and Cohen (1995) for a critique of Keane and Runkle's integration accounting.

with integrated processes (see, *inter alia* Banerjee et al. 1993), conventional OLS estimation and inference produce a slope coefficient that is biased toward one and, therefore, a test statistic that is biased toward accepting the null of unbiasedness. The second generation studies of unbiasedness addressed this inference problem by subtracting the current realization from the forecast as well as the future realization, transforming the levels regression into a "changes" regression. In this specification of stationary variables, unbiasedness was still tested using the same (0, 1) joint hypothesis as in the levels regression. (Ito (1990) is an example of this methodology.) However, an implication of Engle and Granger (1987) is that the levels regression is now interpreted as a cointegrating regression, with conventional t-statistics following nonstandard distributions which depend on nuisance parameters. After establishing that the realization and forecast are integrated and cointegrated, we perform two types of rationality tests. The first is a "restricted cointegration" test due to Liu and Maddala (1992). This is a cointegration test imposing the (0, 1) restriction on the levels regression.

It is significant that, if realization and forecast are cointegrated, Liu and Maddala's (1992) technique is equivalent to regressing a stationary forecast error on a constant and then testing whether the coefficient equals zero (to test unbiasedness) and/or whether the residuals are white noise (to test a type of weak efficiency). Pretests for unit roots in the realization, forecast, and forecast error are required for at least three reasons. First, univariate tests of unbiasedness are invalid if the forecast error is not stationary. Second, following Holden and Peel (1990), we show below (in Sect. 43.4.1.1) that nonrejection of the joint test in the bivariate regression is sufficient but not necessary for unbiasedness, since the joint test is also an implicit test of weak efficiency with respect to the lagged forecast error. A zero intercept in the (correctly specified) univariate test is a necessary as well as sufficient condition for unbiasedness. Third, the Engle and Granger (1987) representation theorem proves that a cointegrating regression such as the levels joint regression (Eq. 43.2 below) has an error correction form that includes both differenced variables and an error correction term in levels. Under the joint null, the error correction term is the forecast error. While the change form of the bivariate regression, is not, strictly speaking, misspecified (since the regressor subtracts s_t, not s^e_{t-1}, from s^e_t), the ECM specification may produce a better fit to the data and, therefore, a more powerful test of the unbiasedness restrictions. We conduct such tests using a form of the ECM due to Hakkio and Rush (1989).

43.4.1 Joint Tests of Unbiasedness and Weak Efficiency

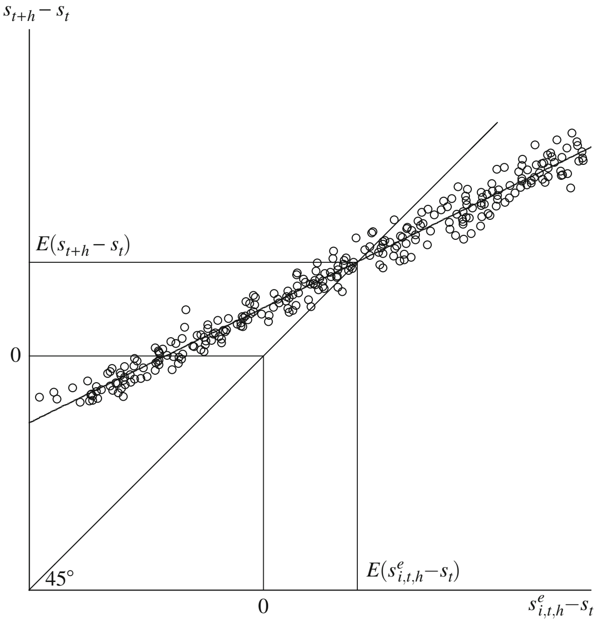
43.4.1.1 The Lack of Necessity Critique

Many, perhaps most, empirical tests of the "unbiasedness" of survey forecasts are conducted using the bivariate regression equation

$$s_{t+h} - s_t = \alpha_{i,h} + \beta_{i,h}\left(s^e_{i,t,h} - s_t\right) + \varepsilon_{i,t,h}. \tag{43.2}$$

It is typical for researchers to interpret their nonrejection of the joint null $(\alpha_{i,h}, \beta_{i,h}) = (0, 1)$ as a necessary condition for unbiasedness. However,

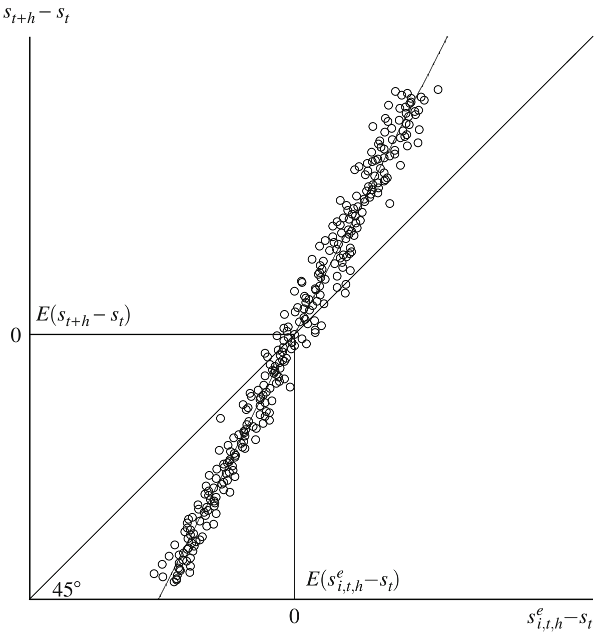
Fig. 43.2 Unbiasedness with $\alpha \neq 0$, $\beta \neq 1$



Holden and Peel (1990) show that this result is a sufficient, though not a necessary, condition for unbiasedness. The intuition for the lack of necessity comes from interpreting the right-hand side of the bivariate unbiasedness regression as a linear combination of two potentially unbiased forecasts: a constant equal to the unconditional mean forecast plus a variable forecast, i.e., $s_{t+h} - s_t = (1 - \beta_{i,h}) \times E(s^e_{i,t,h} - s_t) + \beta_{i,h}(s^e_{i,t,h} - s_t) + \varepsilon_{i,t,h}$. Then the intercept is $\alpha_{i,h} = (1 - \beta_{i,h}) \times E(s^e_{i,t,h} - s_t)$. The necessary and sufficient condition for unbiasedness is that the unconditional mean of the subjective expectation $E[s^e_{i,t,h} - s_t]$ equal the unconditional mean for the objective expectation $E[s_{t+h} - s_t]$. However, this equality can be satisfied without $\alpha_{i,h}$ being equal to zero, i.e., $\beta_{i,h} = 1$.

Figure 43.2 shows that an infinite number of $\alpha_{i,h}$, $\beta_{i,h}$ estimates are consistent with unbiasedness. The only constraint is that the regression line intersects the 45° ray from the origin where the sample mean of the forecast and target are equal. Note that, in the case of differenced variables, this can occur at the origin, so that $\alpha_{i,h} = 0$, but $\beta_{i,h}$ is unrestricted (see Fig. 43.3). It is easy to see why unbiasedness holds: in Figs. 43.2 and 43.3 the sum of all horizontal deviations from the 45° line to the regression line, i.e., forecast errors, equal zero. However, when $\alpha_{i,h} \neq 0$, and $\alpha_{i,h} \neq (1 - \beta_{i,h}) \times E(s^e_{i,t,h} - s_t)$, there is bias regardless of the value of $\beta_{i,h}$. See Fig. 43.4, where the bias, $E(s_{t+h} - s^e_{i,t,h})$, implies systematic underforecasts.

Fig. 43.3 Unbiasedness with $\alpha = 0$, $\beta \neq 1$



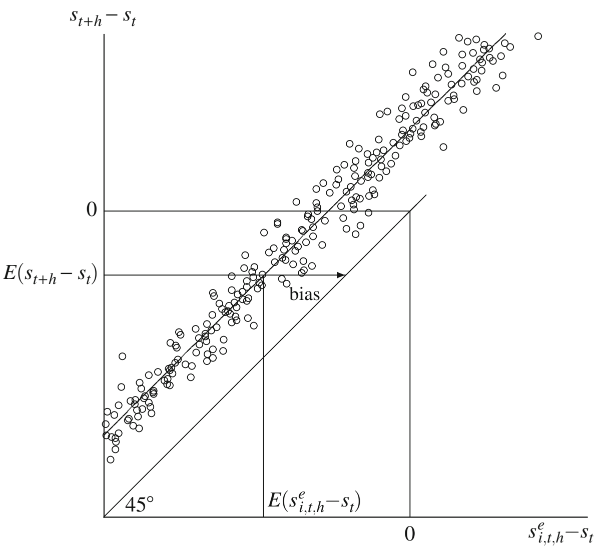


Fig. 43.4 Bias with $\alpha \neq 0$, $\beta = 1$

To investigate the rationality implications of different values for $\alpha_{i,h}$ and $\beta_{i,h}$, we follow Clements and Hendry (1998) and rewrite the forecast error in the bivariate regression framework of Eq. 43.2 as

$$\eta_{i,t,h} = s_{t+h} - s^{e}_{i,t,h} = \alpha_{i,h} + \left(\beta_{i,h} - 1\right)\left(s^{e}_{i,t,h} - s_t\right) + \varepsilon_{i,t,h} \tag{43.3}$$

A special case of weak efficiency occurs when the forecast and forecast error are uncorrelated, i.e.,

$$E\left[\eta_{i,t,h}\left(s^{e}_{i,t,h} - s_t\right)\right] = 0 = \alpha_{i,h}E\left(s^{e}_{i,t,h} - s_t\right) + \left(\beta_{i,h} - 1\right)E\left(s^{e}_{i,t,h} - s_t\right)^2 + E\left[\varepsilon_{i,t,h}\left(s^{e}_{i,t,h} - s_t\right)\right] \tag{43.4}$$

Thus, satisfaction of the joint hypothesis $(\alpha_{i,h}, \beta_{i,h}) = (0,1)$ is also sufficient for weak efficiency with respect to the current forecast. However, it should be noted that Eq. 43.4 may still hold even if the joint hypothesis is rejected. Thus, satisfaction of the joint hypothesis represents sufficient conditions for both unbiasedness and this type of weak efficiency, but necessary conditions for neither.

If $\beta_{i,h} = 1$, then, whether or not $\alpha_{i,h} = 0$, the variance of the forecast error equals the variance of the bivariate regression residual, since then $\text{var}(\eta_{i,t,h}) = (\beta_{i,h} - 1)^2\text{var}(s^e_{i,t,h} - s_t) + \text{var}(\varepsilon_{i,t,h}) + 2(\beta_{i,h} - 1)\text{cov}[(s^e_{i,t,h} - s_t),\varepsilon_{i,t,h}] = \text{var}(\varepsilon_{i,t,h})$. Figure 43.4 illustrates this point. Mincer and Zarnowitz (1969) required only that $\beta_{i,h} = 1$ in their definition of forecast efficiency. If in addition to $\beta_{i,h} = 1$, $\alpha_{i,h} = 0$, then the mean square forecast error also equals the variance of the forecast. Mincer and Zarnowitz emphasized that as long as the loss function is symmetric, as is the case with a minimum mean square error criterion, satisfaction of the joint hypothesis implies optimality of forecasts.

43.4.1.2 Empirical Results of Joint Tests

Since Hansen and Hodrick (1980), researchers have recognized that, when data are sampled more frequently than the forecast horizon (h), forecast errors may follow an h-1 period moving average process. The typical procedure has been to use a variance-covariance matrix which allows for generalized serial correlation. Throughout this chapter, we use the Newey-West (1987) procedure, with the number of lagged residuals set to h-1. To ensure a positive semi-definite VCV matrix, we use a Bartlett window (see Hamilton 1994, pp. 281–84).

In Tables 43.1, 43.2, and 43.3 we report results for the joint unbiasedness tests. We reject the joint hypothesis $(\alpha_{i,h}, \beta_{i,h}) = (0, 1)$ at the 5 % significance level for all groups except banks and brokers at the 1-month horizon (indicating the possible role of inefficiency with respect to the current forecast), but only for the exporters at the 3- and 6-month horizons.

Now consider the results of the separate tests of the joint hypothesis. The significance of the $\alpha_{i,h}$'s in the joint regressions (Eq. 43.2) generally deteriorates

Table 43.1 Joint unbiasedness tests (1-month forecasts)

Individual regressions

with horizon. There are only two rejections at the 5 % level for each of the two shorter horizons. However, the $\alpha_{i,h}$'s are all rejected at the 6.7 % significance level for the 6-month horizon. The test results for the $\beta_{i,h}$'s follow the opposite pattern with respect to horizon. The null that $\beta_{i,h} = 1$ is rejected for all groups at the 1-month horizon, but only for the exporters at the 3-month horizon. There are no rejections at the 6-month horizon. Thus, it appears that the pattern of rejection of the joint hypothesis is predominantly influenced by tests of whether the slope coefficient equals one. In particular, tests of the joint hypothesis at the 1-month horizon are rejected due to failure of this type of weak efficiency, not simple unbiasedness.

For this reason, Mincer and Zarnowitz (1969) and Holden and Peel (1990) suggest that, if one begins by testing the joint hypothesis, rejections in this first stage should be followed by tests of the simple unbiasedness hypothesis in a second stage. Only if unbiasedness is rejected in this second stage should one conclude that forecasts are biased. For reasons described below (in Sect. 43.4.2), our treatment eliminates the first stage, so that unbiasedness and weak efficiency are separately assessed using the forecast error as the dependent variable.

Finding greater efficiency at the longer horizon is unusual, because forecasting difficulty is usually thought to increase with horizon. However, the longer horizon result may not be as conclusive as the $\beta_{i,h}$ statistics suggest. For all tests at all horizons, in only one case can the null hypothesis that $\beta_{i,h}$ equals *zero* not be rejected. Thus, for the longer two horizons (with just the one exception for exporters at the

3-month horizon), hypothesis testing cannot distinguish between the null hypotheses that $\beta_{i,h}$ equals one or zero. Therefore, we cannot conclude that weak efficiency with respect to the current forecast holds while unbiasedness may not. The failure to precisely estimate the slope coefficient also produces R^2s that are below 0.05 in all regressions.[12] The conclusion is that testing only the joint hypothesis has the potential to obscure the difference in performance between the unbiasedness and weak efficiency tests. This conclusion is reinforced by an examination of Figs. 43.5, 43.6, and 43.7, the scatterplots, and regression lines for the bivariate regressions.[13] All three scatterplots have a strong vertical orientation. With this type of data, it is easy to find the vertical midpoint and test whether it is different from zero. Thus, (one-parameter) tests of simple unbiasedness are feasible. However, it is difficult to fit a precisely

[12]As we report in Sect. 43.5, this lack of power is at least consistent with the failure to reject micro-homogeneity at all three horizons.

[13]Note that, for illustrative purposes only, we compute the expectational variable as the four-group average percentage change in the forecast. However, recall that, despite the failure to reject micro-homogeneity at any horizon, the Figlewski-Wachtel critique implies that these parameter estimates are inconsistent in the presence of private information. (See the last paragraph in this subsection.)

estimated regression line to this scatter, because the small variation in the forecast variable inflates the standard error of the slope coefficient. This explains why the $\beta_{i,h}$'s are so imprecisely estimated that the null hypotheses that $\beta_{i,h} = 1$ and 0 are simultaneously not rejected. This also explains why the R^2s are so low. Thus, examination of the scatterplots also reveal why bivariate regressions are potentially misleading about weak efficiency as well as simple unbiasedness. Therefore, in contrast to both Mincer and Zarnowitz (1969) and Holden and Peel (1990), we prefer to separate tests for unbiasedness from tests for (all types of) weak efficiency at the initial stage. This obviates the need for a joint test. In the next section, we conduct such tests, making use of cointegration between forecast and realization where it exists.[14]

More fundamentally, the relatively vertical scatter of the regression observations around the origin is consistent with an approximately unbiased forecast of a random

[14]However, in the general case of biased and/or inefficient forecasts, Mincer and Zarnowitz (1969, p. 11) also viewed the bivariate regression 'as a method of correcting the forecasts . . . to improve [their] accuracy . . . Theil (1966, p. 33) called it the "optimal linear correction."' That is, the correction would involve (1) subtracting $\alpha_{i,h}$ and then (2) multiplying by $1/\beta_{i,h}$. Graphically, this is a translation of the regression line followed by a rotation, until the regression line coincides with the 45° line.

walk-in exchange rate levels.[15] In Figs. 43.8, 43.9, and 43.10, we observe a corresponding time series pattern of variation between the forecasts and realizations in return form. As Bryant lamented in reporting corresponding regressions using a shorter sample from the JCIF, "the regression. . .is. . .not one to send home proudly to grandmother" (Bryant 1995, p. 51). He drew the conclusion that "analysts should have little confidence in a model specification [e.g., uncovered interest parity] setting [the average forecast] exactly equal to the next-period value of the model. . .[M]odel-consistent expectations. . .presume a type of forward-looking behavior [e.g., weak efficiency] that is not consistent with survey data on expectations" (Bryant 1995, p. 40).

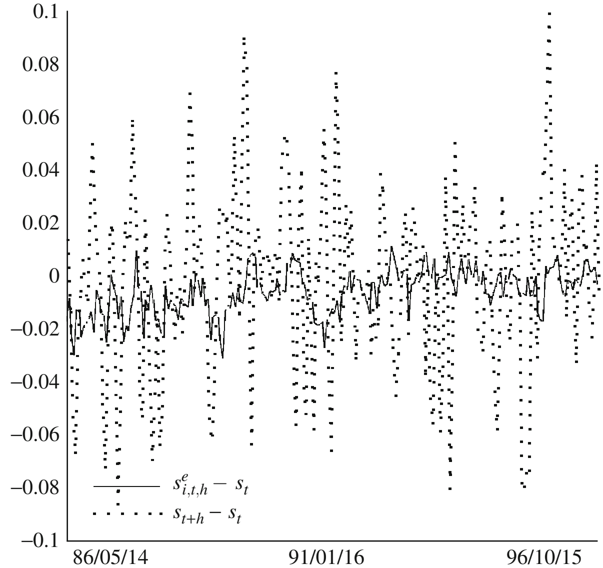
43.4.2 Pretests for Rationality: The Stationarity of the Forecast Error

To test the null hypothesis of a unit root, we estimate the augmented Dickey-Fuller (1979) (ADF) regression

$$\Delta y_{t+1} = \alpha + \beta y_t + \gamma t + \sum_{k=1}^{p} \theta_k \Delta y_{t+1-k} + \varepsilon_{t+1} \tag{43.5}$$

[15]Other researchers (e.g., Bryant 1995) have found similar vertical scatters for regressions where the independent variable, e.g., the forward premium/discount $f_{t,h} - s_t$, the "exchange risk premium" $f_{t,h} - s_{t+h}$, or the difference between domestic and foreign interest rates $(i - i^*)$, exhibits little variation.

Fig. 43.8 Actual and expected depreciation, 1-month-ahead forecast



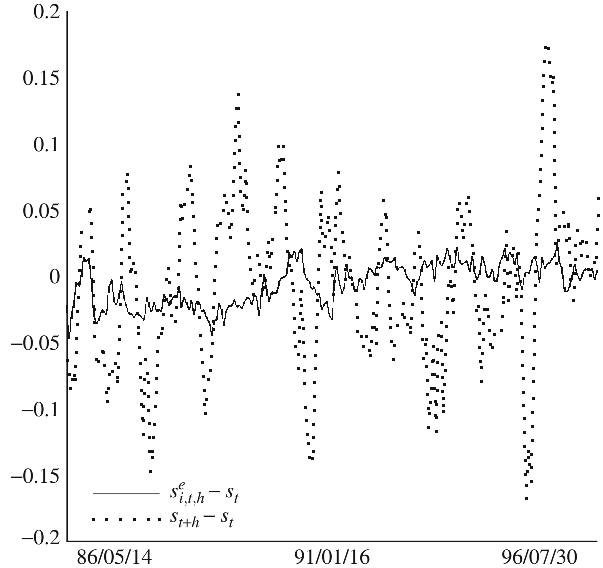


Fig. 43.9 Actual and expected depreciation, 3-month-ahead forecast

where y is the level and first difference of the spot exchange rate, the level and first difference of each group forecast, the residual from the (unrestricted) cointegrating regression, and the forecast error (i.e., the residual from the "restricted" cointegrating equation). The number of lagged differences to include in Eq. 43.5

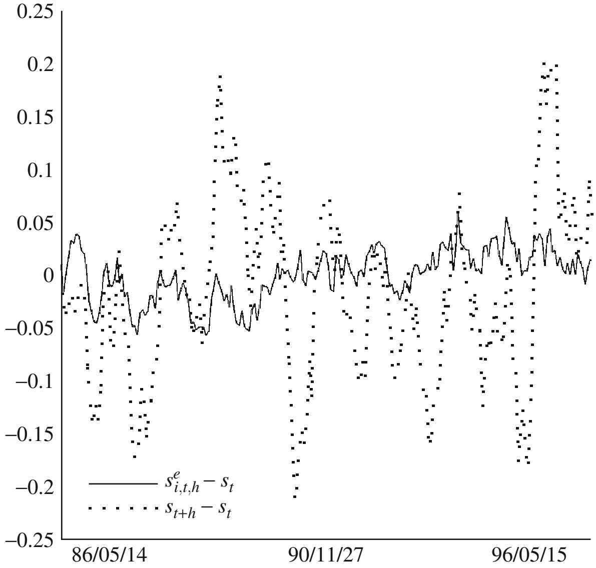

Fig. 43.10 Actual and expected depreciation, 6-month-ahead forecast

is chosen by adding lags until a Lagrange multiplier test fails to reject the null hypothesis of no serial correlation (up to lag 12). We test the null hypothesis of a unit root (i.e., $\beta = 0$) with the ADF t and z tests. We also test the joint null hypothesis of a unit root and no linear trend (i.e., $\beta = 0$ and $\gamma = 0$).

As can be seen in Tables 43.4, 43.5, and 43.6, we fail to reject the null of a unit root in the log of the spot rate in two of the three unit root tests (the exception being the joint null), but we reject the unit root in the h th difference for all three horizons. We conclude that the log of the spot rate is integrated of order one. Similarly, we conclude that the log of the forecast of each spot rate is integrated of order one. Thus, we can conduct cointegration tests on the spot rate and each corresponding forecast. The null of a unit root in the (unrestricted) residual in the "cointegrating regression" is rejected at the 10 % level or less for all groups and horizons except group three (exporters) at the 6-month horizon. Thus, we can immediately reject unbiasedness for the latter group and horizon. Next, since a stationary forecast error is a necessary condition for unbiasedness, we test for unbiasedness (as well as) and weak efficiency in levels using Liu and Maddala's (1992) method of "restricted cointegration." This specification imposes the joint restriction $\alpha_{i,h} = 0$, $\beta_{i,h} = 1$ on the bivariate regression

$$s_{t+h} = \alpha_{i,h} + \beta_{i,h} s^e_{i,t,h} + \varepsilon_{i,t,h} \tag{43.6}$$

and tests whether the residual (the forecast error) is nonstationary. In a bivariate regression, any cointegrating vector is unique. Therefore, if we find that the forecast

errors are stationary, then the joint restriction is not rejected, and (0, 1) must be the unique cointegrating vector.[16] The advantage of the one-step restricted cointegration is that if the joint hypothesis is true, then tests which impose this cointegrating vector have greater power than those which estimate a cointegrating vector. See, e.g., Maynard and Phillips (2001).

Note that the Holden and Peel (1990) critique does not apply in the I(1) case, because the intercept cannot be an unbiased forecast of a nonstationary variable. Thus, the cointegrating regression line of the level realization on the level forecast

[16]It is also possible to estimate the cointegrating parameters and jointly test whether they are zero and one. A variety of methods, such as those due to Saikkonen (1991) or Phillips and Hansen (1990), exist that allow for inference in cointegrated bivariate regressions.

must have both $\alpha = 0$ and $\beta = 1$ for unbiasedness to hold. This differs from Fig. 43.3, the scatterplot in differences, where $\alpha_{i,h} = 0$ but $\beta_{i,h} \neq 1$. Intuitively, the reason for the difference in results is that the scatterplot in levels must lie in the first quadrant, i.e., no negative values of the forecast or realization.

At the 1-month horizon, the null of a unit root in the residual of the restricted cointegrating regression (i.e., the forecast error) is rejected at the 1 % level for all groups. We find nearly identical results at the 3-month horizon; the null of a unit root in the forecast error is rejected at the 5 % level for all groups. Thus, for these regressions we can conduct rationality tests by regressing the forecast error on a constant (hypothesized equal to zero for unbiasedness) and other information set variables (whose coefficients are hypothesized equal to zero for efficiency). (Recall just above that we failed to reject the null of a unit root in the unrestricted residual

for the 6-month forecasts of exporters.) Now, in the case of the restricted residual, the other three groups failed to reject a unit root at the 10 % level in two out of three of the unit root tests.[17] (See Figs. 43.11, 43.12, and 43.13.) Thus, in contrast to the results for the two shorter horizons, at the 6-month horizon, the evidence is clearly in favor of a unit root in the forecast error for all four groups. Therefore, we reject the null of simple unbiasedness because a forecast error with a unit root cannot be mean zero. In fact, given our finding of a unit root in the forecast errors, rationality tests regressing the forecast error on a constant and/or other information set variables would be invalid.

[17] As expected, exporters failed to reject at the 10 % level in all three tests.

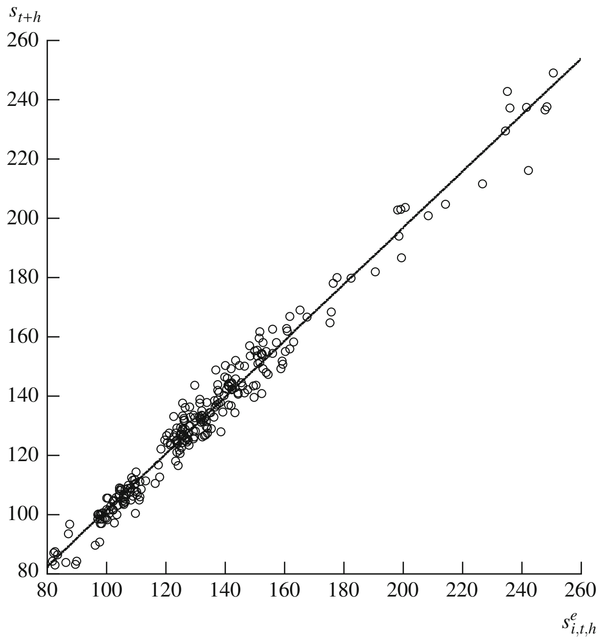

Fig. 43.11 Actual versus expected exchange rate: 1-month-ahead forecast

43.4.3 Univariate Tests for Unbiasedness

The unbiasedness equation is specified as

$$\eta_{i,t,h} = s_{t+h} - s^e_{i,t,h} = \alpha_{i,h} + \varepsilon_{i,t,h}, \tag{43.7}$$

where $\eta_{i,t,h}$ is the forecast error of individual i, for an h-period-ahead forecast made at time t. The results are reported in Tables 43.7 and 43.8. For the 1-month horizon, unbiasedness cannot be rejected at conventional significance levels for any group. For the 3-month horizon, unbiasedness is rejected only for exporters (at a p-value of 0.03). As we saw in the previous subsection, rationality is rejected for all groups at the 6-month horizon, due to nonstationary forecast errors.[18]

In these unbiasedness tests, as well as all others, it is possible that coefficient estimates for the entire sample are not stable over subsamples. The lower panels of Tables 43.7 and 43.8 contain results of the test for equality of intercepts in four equal subperiods, each consisting of approximately 75 biweekly forecasts:

$$\eta_{i,t,h} = s_{t+h} - s^e_{i,t,h} = \alpha_{i,h,1} + \alpha_{i,h,2} + \alpha_{i,h,3} + \alpha_{i,h,4} + \varepsilon_{i,t,h}. \tag{43.8}$$

[18]The direction of the bias for exporters is negative; that is, they systematically underestimate the value of the yen, relative to the dollar. Ito (1990) found the same tendency using only the first two years of survey data (1985–1987). He characterized this depreciation bias as a type of "wishful thinking" on the part of exporters.

For both 1- and 3-month horizons, all four forecaster groups undervalued the yen in the first and third subperiods. This is understandable, as both these subperiods were characterized by overall yen appreciation. (See Fig. 43.1.) Evidently, forecasters underestimated the degree of appreciation. Exporters were the only group to undervalue the yen in the last subperiod as well, although that was not one of overall yen appreciation. This is another perspective on the "wishful thinking" of exporters.[19]

The main difference between the two horizons is in the significance of the test for structural breaks. For the 1-month horizon, the estimates of the individual break dummies generally do not reach statistical significance, and the test for their

[19]Ito (1994) conducted a similar analysis for the aggregate of all forecasters, but without an explicit test for structural breaks.

equality rejects only for the exporters. Thus, the exporters' bias was not constant throughout the sample. In contrast, for the 3-month horizon, the test for no structural breaks is rejected at the 5 % level for all groups, even though unbiasedness itself is rejected for the full sample only for exporters. Even setting aside the bias and variability of exporters' forecasts, our structural break tests allow us to conclude that there is considerably more variation around roughly zero mean forecast errors at the longer horizon. This probably reflects the additional uncertainty inherent in longer-term forecasts.[20]

[20]This is consistent with the finding of nonstationary forecast errors for all groups at the 6-month horizon.

43.4.4 Unbiasedness Tests Using Error Correction Models

As mentioned at the beginning of the previous subsection, the Error Correction Model provides an alternate specification for representing the relationship between cointegrated variables:

$$\begin{aligned} s_{t+h} - s_t = {} & \alpha_{i,h}\left(s_t - \gamma_{i,h} s^e_{i,t-h,h}\right) + \beta_{i,h}\left(s^e_{i,t,h} - s^e_{i,t-h,h}\right) \\ & + \delta_i(\text{lags of } s_{t+h} - s_t) + \eta_i\left(\text{lags of } s^e_{i,t,h} - s^e_{i,t-h,h}\right) + \varepsilon_{i,t,h} \end{aligned} \tag{43.9}$$

According to this specification of the ECM, the change in the spot rate is a function of the change in the forecast, interpreted as a short-run effect, and the current forecast error, interpreted as a long-run adjustment to past disequilibria. $\alpha_{i,h}$, the coefficient of the error correction term, represents the fraction of the forecast error observed at t-h that is corrected by time t. A negative coefficient indicates a stabilizing adjustment of expectations. This formulation of the ECM has the advantage that the misspecification (due to omitted variable bias) of the regression of the differenced future spot rate on the differenced current forecast can be gauged by the statistical significance of the error correction term.[21]

The regressors include the smallest number of lagged dependent variables required such that we do not reject the hypothesis that the residuals are white noise. We impose $\gamma_{i,h} = 1$ when "restricted" cointegration of s_{t+h} and $s^e_{i,t,h}$ is not rejected. Recall that 1- and 3-month forecast errors were found to be stationary, so it was for these two horizons that estimation of the simple unbiasedness equation was possible. Although it would be valid to estimate the ECM at the 6-month horizon using the (unrestricted) stationary cointegrating residual (i.e., for all groups but exporters), we elect not to, because the nonstationarity of the forecast error itself implies a failure of the unbiasedness restrictions.[22]

Then, as first asserted by Hakkio and Rush (1989), the unbiasedness restriction is represented by the joint hypothesis that $-\alpha_{i,h} = \beta_{i,h} = 1$ and all δ and η coefficients equal zero.[23] (The hypothesized coefficient on the error correction term of -1

[21]Zacharatos and Sutcliffe (2002) note that the inclusion of the contemporaneous spot forecast (in their paper, the forward rate) as a regressor assumes that the latter is weakly exogenous; that is, deviations from unbiasedness are corrected only by movements in the realized spot rate. These authors prefer a bivariate ECM specification, in which the change in the future spot rate and the change in the contemporaneous forecast are functions of an error correction term and lags of the dependent variables. However, Zivot (2000) points out that if the spot rate and forecast are contemporaneously correlated, then our single-equation specification does not make any assumptions about the weak exogeneity of the forecast.

[22]Our empirical specification of the ECM also includes an intercept. This will help us to determine whether there are structural breaks in the ECM.

[23]Since we include an intercept, we also test the restriction that the intercept equals zero – both individually and as part of the joint unbiasedness hypothesis.

reflects the unbiasedness requirement that the entire forecast error is corrected within the forecast horizon h.) We also test unbiasedness without including lagged dependent variables but incorporating robust standard errors which allow for generalized serial correlation and heteroscedasticity. This allows comparison with the univariate and bivariate unbiasedness equations.

First, we compare the ECM results to the joint unbiasedness restrictions in the change regressions, using robust standard errors in both cases. Although the estimated coefficient of the error correction term is generally negative, indicating a stable error correction mechanism,[24] the coefficient does not reach a 5 % significance level in any of the regressions. Thus, there is little evidence that the error correction term plays a significant role in the long-run dynamics of exchange rate changes. The ECM test results are nearly identical to the joint unbiasedness test results in Table 43.9. In both specifications, unbiasedness is rejected for three of four groups at the 1-month horizon and not rejected for three of four groups at the 3-month horizon. However, even though the EC term is not (individually) significant in the ECMs, it does provide explanatory power, relative to the joint unbiasedness specification. The R^2s in the ECM, while never more than 0.044, still are greater than in the joint unbiasedness specification, typically by factors of three to five (Tables 43.10, 43.11, and 43.12).

Second, we compare the ECM results to the univariate simple unbiasedness regressions, again using robust standard errors in both cases. The ECM unbiasedness restrictions are rejected at a 5 % level more often than in the simple unbiasedness tests. Whereas the only rejection of simple unbiasedness at the shorter two horizons is for exporters at the 3-month horizon, the ECM restrictions are rejected for three out of four groups at the 1-month horizon as well as for exporters at the 3-month horizon.

While it is uncontroversial that, for testing unbiasedness, the ECM is preferred to the conventional bivariate specification in returns, it is not at all clear that the ECM is preferred to the simple univariate test of unbiasedness. Can the more decisive rejections of unbiasedness using the ECM versus the simple univariate specification be reconciled?[25]

One way to proceed is to determine whether the unbiasedness restrictions imposed on the ECM are necessary as well as sufficient, as is the case for the simple unbiasedness test, or just sufficient, as is the case for the bivariate unbiasedness test. Thus, it is possible that the stronger rejections of unbiasedness in the ECM specification are due to the implicit test of weak efficiency with respect to the current forecast. That is, the Holden and Peel (1990) critique applies to the Hakkio and Rush (1989) test in Eq. 43.9, as well as the joint unbiasedness test in the returns regression. Setting $\beta_{i,h}$, the coefficient of the contemporaneous differenced forecast, equal to one produces an ECM in which the dependent variable is the forecast error:

[24]The only exception is for exporters at the 1-month horizon.

[25]The standard errors in the univariate regression are about the same as those for the ECM. (By definition, of course, the R^2s for the univariate regression equal zero.)

$$s_t - s^e_{i,t,h} = \left(1 + \alpha_{i,h}\right)\left(s_t - s^e_{i,t-h,h}\right) \tag{43.10}$$

Thus, in the ECM the necessary and sufficient condition for unbiasedness is that $\alpha_{i,h}$ equals -1.[26] Table 43.9 contains tests of this conjecture. Here the joint hypothesis that the intercept equals zero and $\alpha_{i,h}$ equals minus one produces exactly the same results as in the simple unbiasedness tests.[27] It is interesting that, even when we can decouple the test for weak efficiency with respect to the current forecast from the unbiasedness test, the test of unbiasedness using this ECM specification still requires weak efficiency with respect to the current forecast error.[28]

43.4.5 Explicit Tests of Weak Efficiency

The literature on rational expectations exhibits even less consensus as to the definition of efficiency than it does for unbiasedness. In general, an efficient forecast incorporates all available information – private as well as public. It follows that there should be no relationship between forecast error and any information variables known to the forecaster at the time of the forecast. Weak efficiency commonly denotes the orthogonality of the forecast error with respect to functions of the target and prediction. For example, there is no contemporaneous relationship between forecast and forecast error which could be exploited to reduce the error. Strong efficiency denotes orthogonality with respect to the remaining variables in the information set. Below we perform two types of weak efficiency tests. In the first type, we regress each group's forecast error on three sets of weak efficiency variables[29]:

[26]Since we estimate the restricted ECM with an intercept, unbiasedness also requires the intercept to be equal to zero.

[27]Since the intercept in Eq. 43.10 is not significant in any regression, the simple hypothesis that $\alpha_{i,h}$ equals one also fares the same as the simple unbiasedness tests.

[28]For purposes of comparison with both the bivariate joint and simple unbiasedness restrictions, we have used the ECM results using the robust standard errors. In all cases testing the ECM restrictions using F-statistics based on whitened residuals produces rejections of all restrictions, simple and joint, except a zero intercept. Hakkio and Rush (1989) found similarly strong rejections of Eq. 43.9, where the forecast was the forward rate.

[29]Notice that the first two sets of weak efficiency variables include the *mean* forecast, rather than the individual group forecast. Our intention is to allow a given group to incorporate information from other groups' forecasts via the *prior* mean forecast. This requires an extra lag in the information set variables, relative to a contemporaneously available variable such as the realized exchange rate depreciation.

1. Single and cumulative lags of the mean forecast error (lagged one period):

$$s_{t+h} - s^e_{i,t,h} = \alpha_{i,h} + \sum_{k=h+1}^{h+7} \beta_{i,t+h-k}\left(s_{t+h-k} - s^e_{m,t+h-k,h}\right) + \varepsilon_{i,t,h} \tag{43.11}$$

2. Single and cumulative lags of mean expected depreciation (lagged one period):

$$s_{t+h} - s^e_{i,t,h} = \alpha_{i,h} + \sum_{k=h+1}^{h+7} \beta_{i,t+h-k}\left(s^e_{m,t+h-k,h} - s_{t-k}\right) + \varepsilon_{i,t,h} \tag{43.12}$$

3. Single and cumulative lags of actual depreciation:

$$s_{t+h} - s^e_{i,t,h} = \alpha_{i,h} + \sum_{k=h}^{h+6} \beta_{i,t+h-k}\left(s_{t+h-k} - s_{t-k}\right) + \varepsilon_{i,t,h} \tag{43.13}$$

For each group and forecast horizon, we regress the forecast error on the most recent seven lags of the information set variable, both singly and cumulatively. We use a Wald test of the null hypothesis $\alpha_{i,h} = \beta_{i,t+h-k} = 0$ and report chi-square test statistics, with degrees of freedom equal to the number of regressors excluding the intercept. If we were to perform only simple regressions (i.e., on each lag individually), estimates of coefficients and tests of significance could be biased toward rejection due to the omission of relevant variables. If we were to perform only multivariate regressions, tests for joint significance could be biased toward nonrejection due to the inclusion of irrelevant variables. It is also possible that joint tests are significant but individual tests are not. This will be the case when the linear combination of (relatively uncorrelated) regressors spans the space of the dependent variable, but individual regressors do not.

In the only reported efficiency tests on JCIF data, Ito (1990) separately regressed the forecast error (average, group, and individual firm) on a single lagged forecast error, lagged forward premium, and lagged actual change. He found that, for the 51 biweekly forecasts between May 1985 and June 1987, rejections increased from a relative few at the 1- or 3-month horizons to virtual unanimity at the 6-month horizon. When he added a second lagged term for actual depreciation, rejections increased “dramatically” for all horizons.

The second type of weak efficiency tests uses the Breusch (1978)-Godfrey (1978) LM test for the null of no serial correlation of order k = h or greater, up to order k = h + 6, in the residuals of the forecast error regression, Eq. 43.11. Specifically, we estimate

$$\hat{\varepsilon}_{i,t,h} = \alpha_{i,h} + \sum_{k=1}^{h-1} \beta_{i,k}\left(s_{t+h-k} - s^e_{i,t-k,h}\right) + \sum_{l=h}^{h+6} \phi_{i,l}\hat{\varepsilon}_{i,t-l,h} + \eta_{i,t,h} \tag{43.14}$$

and test the null hypothesis $H_0 : \beta_{i,h} = \ldots = \beta_{i,h+6} = 0$ for $h = 2,6$.[30,31] Results for all efficiency tests for the 1- and 3-month horizons are presented in Tables 43.13, 43.14, 43.15, 43.16, 43.17, 43.18, 43.19, and 43.20. (Recall that the nonstationarity of the forecast errors at the 6-month horizon is an implicit rejection of weak efficiency.) For each group, horizon, and variable, there are seven individual tests, i.e., on a single lag, and six joint tests, i.e., on multiple lags. These 13 tests are multiplied by four groups times two horizons times three weak efficiency variables for a total of 312 efficiency tests.

Using approximately nine more years of data than Ito (1990), we find many rejections. In some cases, nearly all single lag tests are rejected, yet few, if any, joint tests are rejected. (See, e.g., expected depreciation at the 3-month horizon.) In other cases, nearly all joint tests are rejected, but few individual tests. (See, e.g., actual depreciation at the 3-month horizon.) Remarkably, all but one LM test for serial correlation at a specified lag produces a rejection at less than a 10 % level, with most at less than a 5 % level. Thus, it appears that the generality of the alternative hypothesis in the LM test permits it to reject at a much greater rate than the conventional weak efficiency tests, in which the variance-covariance matrix incorporates the Newey-West-Bartlett correction for heteroscedasticity and serial correlation. Finally, unlike Ito (1990), we find no strong pattern between horizon length and number of rejections.

43.5 Micro-homogeneity Tests

In addition to testing the rationality hypotheses at the individual level, we are interested in the degree of heterogeneity of coefficients across forecasters. Demonstrating that individual forecasters differ systematically in their forecasts (and forecast-generating processes) has implications for the market microstructure research program. As Frankel and Froot (1990, p. 182) noted, "the tremendous volume of foreign exchange trading is another piece of evidence that reinforces the idea of heterogeneous expectations, since it takes differences among market participants to explain why they trade."

Micro-homogeneity should have implications for rationality as well. Intuitively, if all forecasters pass rationality tests, then their corresponding regression coefficients should be equal. However, the converse is not necessarily true: if all forecasters have equal regression coefficients, they will not satisfy rationality conditions if they are all biased or inefficient to the same degree with respect to

[30]This is a general test, not only because it allows for an alternative hypothesis of higher-order serial correlation of specified order but also because it allows for serial correlation to be generated by AR, MA, or ARMA processes.

[31]We use the F-statistic because the χ^2 test statistics tend to over-reject, while the F-tests have more appropriate significance levels (see Kiviet 1987).

Degrees of freedom (n) represent number of regressors, excluding intercept (n = 1 for single lag, n = max. lag −2 for cumulative lags)

the same variables. For the univariate unbiasedness regressions, the null of micro-homogeneity is given by H_0: $\alpha_{ih} = \alpha_{jh}$, for all $i, j \neq i$. Before testing for homogeneous intercepts in Eq. 43.7, we must specify the form for our GMM system variance-covariance matrix. Keane and Runkle (1990) first accounted for cross-sectional correlation (in price level forecasts) using a GMM estimator on pooled data. Bonham and Cohen (2001) tested the pooling specification by replacing Zellner's (1962) SUR variance-covariance matrix with a GMM counterpart that incorporates the Newey-West single-equation corrections (used in our individual equation tests above) plus allowances for corresponding cross-covariances, both contemporaneous and lagged. Bonham and Cohen (2001)

forecasters is 58 % of the average forecast variance. In contrast, we use Pesaran's (2004) CD (cross-sectional dependence) test to check for lagged as well as contemporaneous correlations of forecast errors among pairs of forecasters:

$$CD = \sqrt{\frac{2T}{N(N-1)}} \sum_{i=1}^{N-1} \sum_{j=i+1}^{N} \hat{\rho}_{ij}, \tag{43.15}$$

where T is the number of time periods, N = 4 is the number of individual forecasters, and $\hat{\rho}_{ij}$ is the sample correlation coefficient between forecasters i and j, $i \neq j$.

Under the null hypothesis of no cross-correlation, $CD \sim^{a} N(0, 1)$.[33] See Table 43.21 for CD test results. We tested for cross-correlation in forecast errors from lag zero up to lags four and eight for the 1 and 3-month forecast horizons, respectively. (The nonstationarity of the 6-month forecast error precludes using the CD test at that horizon.) At the 1-month horizon, cross-correlations from lags zero to four are each significant at the 5 % level. Since rational forecasts allow for (individual) serial correlation of forecast errors at lags of h-1 or less, and h = 2 for the 1-month horizon, the cross-correlations at lags two through four indicate violations of weak efficiency. Similarly, at the 3-month horizon, where h-1 = 5, there is significant cross-correlation at lag six.[34] However, it should be noted that, for many lags shorter than h, one cannot reject the null hypothesis that there are no cross-correlated forecast errors.

[33]Unlike Breusch and Pagan's (1980) LM test for cross-sectional dependence, Pesaran's (2004) CD test is robust to multiple breaks in slope coefficients and error variances, as long as the unconditional means of the variables are stationary and the residuals are symmetrically distributed.

[34]There are three instances of statistically significant negative test statistics for lags greater than h-1, none for lags less than or equal to h-1. Thus, some industries produce relatively high forecast errors several periods after others produce relative low forecast errors, and this information is not fully incorporated in some current forecasts.

Nevertheless, in our micro-homogeneity tests, we follow Bonham and Cohen (2001), allowing for an MA(h-1) residual process, both individually and among pairs of forecast errors. (See the Appendix 1 for details.) By more accurately describing the panel's residual variance-covariance structure, we expect this systems approach to improve the consistency of our estimates. Consider first the four bivariate regressions in Tables 43.1, 43.2, and 43.3. Recall that we rejected the joint hypothesis ($\alpha_{i,h}$, $\beta_{i,h}$) = (0, 1) at the 5 % significance level for all groups at the 1-month horizon (indicating the possible role of inefficiency with respect to the

current forecast), but only for the exporters at the 3- and 6-month horizons. However, there are no rejections of micro-homogeneity for any horizon.[35]

The micro-homogeneity test results are very different for both the 1- and 3-month systems of univariate unbiasedness regressions in Tables 43.7 and 43.8. (Recall that

[35]The nonrejection of micro-homogeneity in bivariate regressions does not, however, mean that one can avoid aggregation bias by using the mean forecast. Even if the bivariate regressions were correctly interpreted as joint tests of unbiasedness and weak efficiency with respect to the current forecast, and even if the regressions had sufficient power to reject a false null, the micro-homogeneity tests would be subject to additional econometric problems. According to the Figlewski-Wachtel (1983) critique, successfully passing a pretest for micro-homogeneity does not ensure that estimated coefficients from such consensus regressions will be consistent. See Sect. 43.2.1.

unbiasedness was rejected for all groups at the 6-month horizon due to the nonstationarity of the forecast error.) Despite having only one failure of unbiasedness at the 5 % level for the two shorter horizons, micro-homogeneity is rejected at a level of virtually zero for both horizons. The rejection of micro-homogeneity at the 1-month horizon occurs despite the failure to reject unbiasedness for any of the industry groups. We hypothesize that the consistent rejection of micro-homogeneity regardless of the results of individual unbiasedness tests is the result of sufficient variation in individual bias estimates as well as precision in these estimates. According to these tests, aggregation of individual forecasts into a mean forecast is invalid at all horizons.

In addition to testing the weak efficiency hypothesis at the individual level, we are interested in the degree of heterogeneity of coefficients across forecasters. Here the null of micro-homogeneity is given by H_0: $\phi_{il} = \phi_{jl}$, for $l = h, \ldots h + 6$, for all i, $j \neq i$. As explained in the section on efficiency tests, there are 312 tests (not 468, due to a nonstationary forecast error for all four groups at the 6-month horizon)/four groups = 83 micro-homogeneity tests. The null hypothesis of equal coefficients is $H_0 : \alpha_{i,h} = \alpha_{j,h}, \beta_{i,t+h-k} = \beta_{j,t+h-k}$ for all $i, j \neq i$. As with the micro-homogeneity tests for unbiasedness, our GMM variance-covariance matrix accounts for serial correlation of order h-1 or less, generalized heteroscedasticity, and cross-sectional correlation or order h-1 or less. We report $\chi^2(n)$ statistics, where n is the number of coefficient restrictions, with corresponding p-values. Rather than perform all 83 micro-homogeneity tests, we choose a sample consisting of the shortest and longest lag for which there are corresponding individual and joint tests (i.e., for the k = h + 1st and k = h + 6th lag). Thus, there are four tests (two individual and two corresponding joint tests) times two horizons times three variables for a total of 24 tests. Every one of the micro-homogeneity tests are rejected at the 0 % level. As pointed out by Bryant (1995), a finding of micro-heterogeneity in unbiasedness and weak efficiency tests also casts doubt on the assumption of a rational representative agent commonly used in macroeconomic and asset-pricing models (Table 43.22).

43.5.1 Ito's Heterogeneity Tests

In Table 43.23, we replicate Ito's (1990) and Elliott and Ito's (1999) test for forecaster "heterogeneity." This specification regresses the deviation of the individual forecast from the cross-sectional average forecast on a constant. Algebraically, Ito's regression can be derived from the individual forecast error regression by subtracting the mean forecast error regression. Thus, because it simply replaces the forecast error with the individual deviation from the mean forecast, it does not suffer from aggregation bias (c.f. Figlewski and Wachtel (1983)) or pooling bias (c.f. Zarnowitz 1985) (Table 43.24).[36, 37]

$$s^e_{i,t,h} - s^e_{m,t,h} = \left(\alpha_{i,h} - \alpha_m\right) + \left(\varepsilon_{i,t,h} - \varepsilon_{m,t}\right) \quad (43.16)$$

As above, we use the Newey-West-Bartlett variance-covariance matrix.

One may view Ito's "heterogeneity" tests as complementary to our micro-homogeneity tests. On the one hand, one is not certain whether a single (or pair of?) individual rejection(s) of, say, the null hypothesis of a zero mean deviation in Ito's test would result in a rejection of micro-homogeneity overall. On the other hand, a rejection of micro-homogeneity does not tell us which groups are the most significant violators of the null hypothesis. It turns out that Ito's mean deviation test produces rejections at a level of 6 % or less for all groups at all horizons except for

[36]Recall that our group results are not entirely comparable to Ito's (1990), since our data set, unlike his, combines insurance companies and trading companies into one group and life insurance companies and import-oriented companies into another group.

[37]Chionis and MacDonald (1997) performed an Ito-type test on individual expectations data from Consensus Forecasts of London.

banks and brokers at the 1-month horizon and life insurance and import companies at the 6-month horizon.[38] Since Ito's regressions have a similar form (though not a similar economic interpretation) to the tests for univariate unbiasedness in Tables 43.7 and 43.8, it is not surprising that micro-homogeneity tests on the four-equation system of Ito equations produce rejections at a level of virtually zero for all three horizons.

43.6 Conclusions

In this chapter, we undertake a reexamination of the rationality and diversity of JCIF forecasts of the yen-dollar exchange rate. In several ways we update and extend the seminal paper by Ito (1990). In particular, we have attempted to explore the nature of rationality tests on integrated variables. We show that tests based on the "conventional" bivariate regression in change form, while correctly specified in terms of integration accounting, have two major shortcomings. First, following Holden and Peel (1990), they are misspecified as unbiasedness tests, because rejection of the (0, 1) restriction on the slope and intercept is a sufficient, not a necessary, condition for unbiasedness. Only a zero restriction on the intercept in a regression of the forecast error on a constant is both necessary and sufficient for unbiasedness. Second, tests using the bivariate specification suffer from a lack of power. Yet, this is exactly what we would expect in an asset market whose price is a near random walk: the forecasted change is nearly unrelated to (and varies much less than) the actual change.

In contrast, we conduct pretests for rationality based on determining whether the realization and forecast are each integrated and cointegrated. In this case, following Liu and Maddala (1992), a "restricted" cointegration test, which imposes a (0, 1) restriction on the cointegrating vector, is necessary for testing unbiasedness. (We show that the Holden and Peel (1990) critique does not apply if the regressor and regressand are cointegrated.) If a unit root in the restricted residual is rejected, then the univariate test which regresses the forecast error on a constant is equivalent to the restricted cointegration test. Testing this regression for white noise residuals is one type of weak efficiency test. Testing other stationary regressors in the information set for zero coefficients produces additional efficiency tests.

In the univariate specification, we find that, for each group, the ability to produce unbiased forecasts deteriorates with horizon length: no group rejects unbiasedness at the 1-month horizon, but all groups reject at the 6-month horizon, because the forecast errors are nonstationary. Exporters consistently perform worse than the other industry groups, with a tendency toward depreciation bias.

[38]Elliott and Ito (1999), who have access to forecasts for the 42 individual firms in the survey, find that, for virtually the same sample period as ours, the null hypothesis of a zero deviation from the mean forecast is rejected at the 5 % level by 17 firms at the 1-month horizon, 13 firms for the 3-month horizon, and 12 firms for the 6-month horizon. These authors do not report results by industry group.

Using only 2 years of data, Ito (1990) found the same result for exporters, which he described as a type of "wishful thinking."

The unbiasedness results are almost entirely reversed when we test the hypothesis using the conventional bivariate specification. That is, the joint hypothesis of zero intercept and unit slope is rejected for all groups at the 1-month horizon, but only for exporters and the 3- and 6-month horizons. Thus, in stark contrast to the univariate unbiasedness tests, as well as Ito's (1990) bivariate tests, forecast performance does not deteriorate with increases in the horizon.

Also, since Engle and Granger (1987) have showed that cointegrated variables have an error correction representation, we impose joint "unbiasedness" restrictions first used by Hakkio and Rush (1989) on the ECM. However, we show that these restrictions also represent sufficient, not necessary, conditions, so these tests could tend to over-reject. We then develop and test restrictions which are both necessary and sufficient conditions for unbiasedness. The test results confirm that the greater rate of rejections of the joint "unbiasedness" restrictions in the ECM is caused by the failure of the implicit restriction of weak efficiency with respect to the lagged forecast. When we impose the restriction that the coefficient of the forecast equals one, the ECM unbiasedness test results mimic those of the simple univariate unbiasedness tests. For this data set, at least, it does not appear that an ECM provides any value added over the simple unbiasedness test. Furthermore, since the error correction term is not statistically significant in any regressions, it is unclear whether the ECM provides any additional insight into the long-run adjustment mechanism of exchange rate changes.

The failure of more general forms of weak efficiency is borne out by two types of explicit tests for weak efficiency. In the first type, we regress the forecast error on single and cumulative lags of mean forecast error, mean forecasted depreciation, and actual depreciation. We find many rejections of weak efficiency. In the second type, we use the Godfrey (1978) LM test for serial correlation of order h through h + 6 in the residuals of the forecast error regression. Remarkably, all but one LM test at a specified lag length produces a rejection at less than a 10 % level, with most at less than a 5 % level. (As in the case of the univariate unbiasedness test, all weak efficiency tests at the 6-month horizon fail due to the nonstationarity of the forecast error.)

Whereas Ito (1990) and Elliott and Ito (1999) measured diversity as a statistically significant deviation of an individual's forecast from the cross-sectional average forecast, we perform a separate test of micro-homogeneity for each type of rationality test – unbiasedness as well as weak efficiency – that we first conducted at the industry level. In order to conduct the systems estimation and testing required for the micro-homogeneity test, our GMM estimation and inference make use of an innovative variance-covariance matrix that extends the Keane and Runkle (1990) counterpart from a pooled to an SUR-type structure. Our variance-covariance matrix takes into account not only serial correlation and heteroscedasticity at the individual level (via a Newey-West-Bartlett correction) but also forecaster cross-correlation up to h-1 lags. We document the statistical significance of the cross-sectional correlation using Pesaran's (2004) CD test.

In the univariate unbiasedness tests, we find that, irrespective of the ability to produce unbiased forecasts at a given horizon, micro-homogeneity is rejected at virtually a 0 % level for all horizons. We find this result to be somewhat counter-intuitive, in light of our prior belief that micro-homogeneity would be more likely to obtain if there were no rejections of unbiasedness. Evidently, there is sufficient variation in the estimated bias coefficient across groups and/or high precision of these estimates to make the micro-homogeneity test quite sensitive. Micro-homogeneity is also strongly rejected in the weak efficiency tests.

In contrast to the results with the univariate unbiasedness specification, micro-homogeneity is not rejected at any horizon in the bivariate regressions. We conjecture that the imprecise estimation of the slope coefficient makes it difficult to reject joint hypotheses involving this coefficient.

In conclusion, we recommend that all rationality tests be undertaken using simple univariate specifications at the outset (rather than only if the joint bivariate test is rejected, as suggested by Mincer and Zarnowitz (1969) and Holden and Peel (1990) and employed by Gavin (2003)). Before conducting such tests, one should test the restricted cointegrated regression residuals, i.e., the forecast error, for stationarity. Clearly, integration accounting and regression specification matter for rationality testing.

While our rationality tests do not attempt to explain cross-sectional dispersion, the widespread rejection of micro-homogeneity in different specifications of unbiasedness and weak efficiency tests[39] provides more motivation for the classification of forecasters into types (e.g., fundamentalist and chartist/noise traders) than for simply assuming a representative agent (with rational expectations).

There are characteristics of forecasts other than rationality which are of intrinsic interest. Given our various rejections of rational expectations, it is natural to explore what expectational mechanism the forecasters use. Ito (1994) tested the mean JCIF forecasts for extrapolative and regressive expectations, as well as a mixture of the two.[40] Cohen and Bonham (2006) extend this analysis using individual forecast-generating processes and additional learning model specifications. And, much of the literature on survey forecasts has analyzed the accuracy of predictions, typically ranking forecasters by MSE. One relatively unexplored issue is the statistical significance of the ranking, regardless of loss function. However, other loss functions, especially nonsymmetric ones, are also reasonable. For example, Elliott and Ito (1999) have ranked individual JCIF forecasters using a profitability criterion. As mentioned in Sect. 43.2.2, the loss function may incorporate strategic considerations that result in “rational bias.” Such an exploration would require more disaggregated data than the JCIF industry forecasts to which we have access.

[39]We put less weight on the results of the weaker tests for micro-homogeneity in the bivariate regressions.

[40]He also included regressors for adaptive expectations and the forward premium.

Appendix 1: Testing Micro-homogeneity with Survey Forecasts

The null hypothesis of micro-homogeneity is that the slope and intercept coefficients in the equation of interest are equal across individuals. This chapter considers the case of individual unbiasedness regressions such as Eq. 43.2 in the text, repeated here for convenience,

$$s_{t+h} - s_t = \alpha_{i,h} + \beta_{i,h}\left(s^e_{i,t,h} - s_t\right) + \varepsilon_{i,t,h} \tag{43.17}$$

and tests $H_0 : \alpha_1 = \alpha_2 = \ldots = \alpha_N$ and $\beta_1 = \beta_2 = \ldots = \beta_N$.

Stack all N individual regressions into the Seemingly Unrelated Regression system

$$S = \mathbf{F}\theta + \varepsilon \tag{43.18}$$

where S is the $NT \times 1$ stacked vector of realizations, s_{t+h}, and $\mathbf{F}$ is an $NT \times 2N$ block diagonal data matrix:

$$\mathbf{F} = \begin{bmatrix} \mathbf{F}_1 & & \\ & \ddots & \\ & & \mathbf{F}_N \end{bmatrix}. \tag{43.19}$$

Each $\mathbf{F}_i = [\iota\ s^e_{i,t,h}]$ is a $T \times 2$ matrix of ones and individual i's forecasts, $\theta = [\alpha_1\ \beta_1 \ldots \alpha_N\ \beta_N]'$, and ε is an $NT \times 1$ vector of stacked residuals. The vector of restrictions, $R\theta = r$, corresponding to the null hypothesis of micro-homogeneity is normally distributed, with $R\theta - r \sim N[0, R(\mathbf{F}'\mathbf{F})^{-1}\mathbf{F}'\Omega\mathbf{F}(\mathbf{F}'\mathbf{F})^{-1}R']$, where R is the $2(N-1) \times 2N$ matrix

$$R = \begin{bmatrix} 1 & 0 & -1 & 0 & \ldots & 0 \\ 0 & 1 & 0 & -1 & 0 & \vdots \\ \vdots & 0 & \ddots & \ddots & \ddots & 0 \\ 0 & \ldots & 0 & 1 & 0 & -1 \end{bmatrix}, \tag{43.20}$$

and r is a $2(N-1) \times 1$ vector of zeros. The corresponding Wald test statistic, $\left(R\hat{\theta} - r\right)' \left[R(\mathbf{F}'\mathbf{F})^{-1}\mathbf{F}'\hat{\Omega}\mathbf{F}\left(\mathbf{F}'\mathbf{F}\right)^{-1}R'\right]\left(R\hat{\theta} - r\right)$, is asymptotically distributed as a chi-square random variable with degrees of freedom equal to the number of restrictions, $2(N-1)$.

For most surveys, there are a large number of missing observations. Keane and Runkle (1990), Davies and Lahiri (1995), Bonham and Cohen (1995, 2001), and to the best of our knowledge all other papers which make use of pooled regressions in tests of the REH have dealt with the missing observations using the same approach. The pooled or individual regression is estimated by eliminating the missing data points in both the forecasts and the realization. The regression residuals are then padded with zeros in place of missing observations to allow for the calculation of own and cross-covariances. As a result, many individual variances and cross-covariances are calculated with relatively few pairs of residuals. These individual cross-covariances are then averaged. In Keane and Runkle (1990) and Bonham and Cohen (1995, 2001) the assumption of $2(k + 1)$ second moments, which are common to all forecasters, is made for analytical tractability and for increased reliability. In contrast to the forecasts from the Survey of Professional Forecasters used in Keane and Runkle (1990) and Bonham and Cohen (1995, 2001), the JCIF data set contains virtually no missing observations. As a result, it is possible to estimate each individual's variance-covariance matrix (and cross-covariance matrix) rather than average over all individual variances and cross-covariance pairs as in the aforementioned papers.

We assume that for each forecast group i,

$$\begin{aligned}
&E\left[\varepsilon_{i,t,h}\varepsilon_{i,t,h}\right] = \sigma_{i,0}^2 \text{ for all } i, t,\\
&E\left[\varepsilon_{i,t,h}\varepsilon_{i,t+k}\right] = \sigma_{i,k}^2 \text{ for all } i, t, k \text{ such that } 0 < k \le h, \\
&E\left[\varepsilon_{i,t,h}\varepsilon_{i,t+k}\right] = 0 \text{ for all } i, t, k \text{ such that } k > h,
\end{aligned} \tag{43.21}$$

Similarly, for each pair of forecasters i and j, we assume

$$\begin{aligned}
E\left[\varepsilon_{i,t,h}\varepsilon_{j,t}\right] &= \delta_{i,j}(0) \quad \forall i,j,t,\\
E\left[\varepsilon_{i,t,h}\varepsilon_{j,t+k}\right] &= \delta_{i,j}(k) \ \forall i,j,t,k \text{ such that } k \ne 0, \text{and} -h \le k \le h.\\
E\left[\varepsilon_{i,t,h}\varepsilon_{j,t+k}\right] &= 0 \qquad \forall i,j,t,k \text{ such that } k > |h|.
\end{aligned} \tag{43.22}$$

Thus, each pair of forecasters has a different $T \times T$ cross-covariance matrix:

$$\mathbf{P}_{i,j} = \begin{bmatrix}
\delta_{i,j}(0) & \delta_{i,j}(-1) & \dots & \delta_{i,j}(-h) & 0\\
\delta_{i,j}(1) & \delta_{i,j}(0) & \delta_{i,j}(-1) & \dots & 0\\
\vdots & \ddots & \ddots & \ddots & \vdots\\
 & \dots & \delta_{i,j}(1) & \delta_{i,j}(0) & \delta_{i,j}(-1)\\
0 & \delta_{i,j}(h) & \dots & \delta_{i,j}(1) & \delta_{i,j}(0)
\end{bmatrix}, \tag{43.23}$$

Finally, note that $P_{i,j} \ne P_{j,i}$, rather $P'_{i,j} = P_{j,i}$. The complete variance-covariance matrix, denoted Ω, has dimension $NT \times NT$, with matrices $\mathbf{Q}_i$ on the main diagonal and $\mathbf{P}_{i,j}$ off the diagonal.

The individual Q_i, variance-covariances matrices are calculated using the Newey and West (1987) heteroscedasticity-consistent, MA(j)-corrected form. The $P_{i,j}$ matrices are estimated in an analogous manner.

Stochastic Volatility Structures and Intraday Asset Price Dynamics

44

Gerard L. Gannon

Contents

Abstract

The behavior of financial asset price data when observed intraday is quite different from these same processes observed from day to day and longer sampling intervals. Volatility estimates obtained from intraday observed data can be badly distorted if anomalies and intraday trading patterns are not accounted for in the estimation process.

In this paper I consider conditional volatility estimators as special cases of a general stochastic volatility structure. The theoretical asymptotic distribution of the measurement error process for these estimators is considered for particular

features observed in intraday financial asset price processes. Specifically, I consider the effects of (i) induced serial correlation in returns processes, (ii) excess kurtosis in the underlying unconditional distribution of returns, (iii) market anomalies such as market opening and closing effects, and (iv) failure to account for intraday trading patterns.

These issues are considered with applications in option pricing/trading strategies and the constant/dynamic hedging frameworks in mind. Empirical examples are provided from transactions data sampled into 5-, 15-, 30-, and 60-min intervals for heavily capitalized stock market, market index, and index futures price processes.

Keywords

ARCH • Asymptotic distribution • Autoregressive parameters • Conditional variance estimates • Constant/dynamic hedging • Excess kurtosis • Index futures • Intraday returns • Market anomalies • Maximum likelihood estimates • Mis-specification • Mis-specified returns • Persistence • Serial correlation • Stochastic volatility • Stock/futures • Unweighted GARCH • Volatility co-persistence

44.1 Introduction

One issue considered in Nelson (1990a) is whether it is possible to formulate an ARCH data generation process that is similar to the true process, in the sense that the distribution of the sample paths generated by the ARCH structure and the underlying diffusion process becomes “close” for increasingly finer discretizations of the observation interval. Maximum likelihood estimates are difficult to obtain from stochastic differential equations of time-varying volatility common in the finance literature. If the results in Nelson hold for “real-time” data when ARCH structures approximate a diffusion process, then these ARCH structures may be usefully employed in option pricing equations. In this paper I consider the ARCH structure as a special case of a general stochastic volatility structure. One advantage of an ARCH structure over a general stochastic volatility structure lies in computational simplicity. In the ARCH structure, it is not necessary for the underlying processes to be stationary or ergodic. The crucial assumption in an option pricing context is that these assumed processes approach a diffusion limit. These assumed diffusion limits have been derived for processes assumed to be observed from day-to-day records. Given that market anomalies such as market opening and market closing effects exist, any volatility structure based on observations sampled on a daily basis will provide different volatility estimates. Evidence of these intraday anomalies and effects on measures of constant volatility is reported in Edwards (1988) and Duffie et al. (1990). Brown (1990) argues that the use of intraday data in estimating volatility within an option pricing framework leads to volatility estimates that are too low. This can be overcome by rescaling, assuming the anomalies are accounted for.

Better estimates of volatility may then be obtained by employing intraday observations and allowance made for anomalies and trading activity within conditional volatility equations. However, mis-specifications in either or both first- and second-moment equations may mitigate against satisfying the conditions for an approximate diffusion limit. Then it is important to investigate cases where the diffusion limit is not attainable and identify the factors which help explain the behavior of the process. If these factors can be accounted for in the estimation process then these formulations can be successfully employed in options pricing and trading strategies.

The specific concern in this paper is the effect on the asymptotic distribution of the measurement error process and on parameter estimates, obtained from the Generalized ARCH (GARCH(1,1)) equations for the conditional variance, as the observation interval approaches transactions records ($d \rightarrow 0$). Three issues are considered for cases where the diffusion limit may not be achieved at these observation intervals. The first issue is the effect of mis-specifying the dynamics of the first-moment-generating equation on resultant GARCH(1,1) parameter estimates. The second issue is the effect on measures of persistence obtained from the GARCH structure when increasing kurtosis is induced in the underlying unconditional distribution as $d \rightarrow 0$. This leads to a third issue which is concerned with evaluating effects of inclusion of weighting (mixing) variables on parameter estimates obtained from these GARCH(1,1) equations. If these mixing variables are important then standard, GARCH equation estimates will be seriously distorted. These mixing variables may proxy the level of activity within particular markets or account for common volatility of assets trading in the same market.

Sampling the process too finely does result in induced positive or negative serial correlation in return processes. The main distortion to the basis change is generated from cash index return equations. However, the dominant factor distorting unweighted GARCH estimates is induced excess kurtosis in unconditional distributions of returns. Many small price changes are dominated by occasional large price changes. This effect leads to large jumps in the underlying distribution causing continuity assumptions for higher derivatives of the conditional variance function to break down.

These observations do not directly address issues related to intraday market trading activity and possible contemporaneous volatility effects transmitted to and from underlying financial asset price processes. This effect was considered within the context of a structural Simultaneous Volatility (SVL) model in Gannon (1994). Further results for the SVL model are documented, along with results of parameter estimates, in Gannon (2010). In this paper the intraday datasets on cash index and futures price processes from Gannon (2010) are again employed to check the effects on parameter estimates obtained from GARCH and weighted GARCH models. A set of intraday sampled stock prices are also employed in this paper. The relative importance of mis-specification of the second-moment equation dynamics over mis-specification of first-moment equation dynamics is the most important issue. If intraday trading effects are important, this has implications for smoothness and continuity assumptions necessary in deriving diffusion limit results for the unweighted GARCH structure.

If these effects are severe then an implied lower sampling boundary needs to be imposed in order to obtain sensible results. This is because the measure of persistence obtained from GARCH structures may approach the Integrated GARCH (IGARCH) boundary and become explosive or conditional heteroskedasticity may disappear. This instability can be observed when important intraday anomalies such as market opening and closing effects are not accounted for within the conditional variance specifications. Distortions to parameter estimates are most obvious when conditional second-moment equations are mis-specified by failure to adequately account for observed intraday trading patterns. These distortions can be observed across a wide class of financial assets and markets.

If these financial asset price processes have active exchange traded options contracts written on these "underlying assets," it is important to study the intraday behavior of these underlying financial asset price processes. If systematic features of the data series can be identified then it is possible to account for these features in the estimation process. Then intraday estimates of volatility obtained from conditional variance equations, which incorporate structural effects in first and/or conditional second-moment equations, can be usefully employed in option pricing equations. Identifying intraday anomalies and linking trading activity to contemporaneous volatility effects mean the improved estimator can be employed within a trading strategy. This can involve analysis of the optimal time to buy options within the day to minimize premium cost. Alternatively, optimal buy or sell straddle strategies based on comparison of estimated volatility estimates relative to market implied volatility can be investigated. In this paper I focus on theoretical results which can explain the empirically observed behavior of these estimators when applied to intraday financial asset price processes. I start by summarizing relevant results which are currently available for conditional variance structures as the observation interval reduces to daily records (h→0). These results are modified and extended in order to accommodate intraday observation intervals. The alternative first-moment-generating equations are described and the basis change defined and discussed within the context of the co-persistence structure. I then focus on the general GARCH structure and state some further results for specific cases of the GARCH and weighted GARCH (GARCH-W) structure.

44.2 Stochastic Volatility and GARCH

Nelson and Foster (1994) derive and discuss properties for the ARCH process as the observation interval reduces to daily records (h→0) when the underlying process is driven by an assumed continuous diffusion process. Nelson and Foster (1991) generalized a Markov process with two state variables, ${}_hX_t$ and ${}_h\sigma_t^2$, only one of which ${}_hX_t$ is ever directly observable. The conditional variance ${}_h\sigma_t^2$ is defined conditional on the increments in ${}_hX_t$ per unit time and conditional on an information set ${}_h\varsigma_t$. Modifying the notation from h to d (to account for intraday discretely observed data), and employing the notation $d \to 0$ to indicate reduction in the observation interval from above, when their assumptions 2, 3, and 1′ hold, when d is small, ${}_dX_t$, $\varphi({}_d\sigma_t^2))$ is referred to as a near diffusion if for any T, $0 \le T \le \infty$, $({}_dX_t,\ \varphi\ ({}_d\sigma_t^2))_{0 \le t \le T} \Rightarrow (X_t,\ \varphi(\sigma_t^2))_{0 \le t \le T}$.

If we assume these data-generating processes are near diffusions, then the general discrete time stochastic volatility structure, defined in Nelson and Foster (1991), may be described using the following modified notation:

$$\begin{bmatrix} {}_dX_{(k+1)d} \\ \varphi\left({}_d\sigma^2_{(k+1)d}\right) \end{bmatrix} = \begin{bmatrix} {}_dX_{kd} \\ \varphi\left({}_d\sigma^2_{kd}\right) \end{bmatrix} + d\ .\begin{bmatrix} \mu({}_dX_{kd}, \sigma_{kd}) \\ \lambda({}_dX_{kd}, {}_d\sigma_{kd}) \end{bmatrix} + d^{1/2}\begin{bmatrix} {}_d\sigma^2_{kd} & \Lambda_{\varphi,x}({}_dX_{kd}, {}_d\sigma_{kd}) \\ \Lambda_{\varphi,x}({}_dX_{kd}, {}_d\sigma_{kd}) & \Lambda^2({}_dX_{kd}, {}_d\sigma_{kd}) \end{bmatrix}^{\frac{1}{2}} \begin{bmatrix} {}_dZ_{1,kd} \\ {}_dZ_{2,kd} \end{bmatrix} \tag{44.1}$$

where $({}_dZ_{1,kd},{}_d\ Z_{2,kd})_{k=0,\infty}$ is i.i.d. with mean zero and identity covariance matrix. In Eq. 44.1 d is the size of the observation interval, X may describe the asset price return, and σ^2 the volatility of the process. It is not necessary to assume the data-generating processes are stationary or ergodic, but the crucial assumption is that the data-generating processes are near diffusions.

In the ARCH specification, ${}_dZ_{2,kd}$ is a function of ${}_dZ_{1,kd}$ so that ${}_d\sigma^2_{kd}({}_dh_{kd})$ can be inferred from past values of the one observable process ${}_dX_{kd}$. This is not true for a general stochastic volatility structure where there are two driving noise terms.

For the first-order Markov ARCH structure, a strictly increasing function of estimates ${}_d\hat{\sigma}_t^2\left({}_d\hat{h}_t\right)$ of the conditional variance process ${}_d\sigma_t^2({}_dh_t)$ is defined as $\phi(\sigma^2)$, and estimates of the conditional mean per unit of time of the increments in X and $\phi(\sigma^2)$ are defined as $\hat{\mu}\left(x,\ \hat{\sigma}\right)$ and $\hat{\kappa}\left(x,\ \hat{\sigma}\right)$. Estimates of ${}_d\sigma^2_{kd}$ are updated by the recursion:

$$\phi\left({}_d\hat{\sigma}^2_{(k+1)d}\right) = \sigma\left({}_d\hat{\sigma}^2_{kd}\right) + d\,\hat{\kappa}\left({}_dX_{kd}, {}_d\hat{\sigma}_{kd}\right) + d^{1/2}a\left({}_dX_{kd}, {}_d\hat{\sigma}_{kd}\right)g\left({}_dZ_{1,kd}, {}_d\hat{X}_{kd}, {}_d\hat{\sigma}^2_{kd}\right) \tag{44.2}$$

where $\hat{\kappa}\,(.), a(.), \hat{\mu}\,(.)$, and g(.) are continuous on bounded $(\varphi(\sigma^2),\ x)$ sets and $g(z_1,\ x.\sigma^2)$ assumed continuous everywhere with the first three derivatives of g with respect to z_1 well defined and bounded. The function $g({}_dZ_{1,kd},.)$ is normalized to have mean zero and unit conditional variance. Nonzero drifts in $\phi\left({}_d\sigma^2_{kd}\right)$ are allowed for in the $\hat{\kappa}\,(.)$ term and non-unit conditional variances accounted for in the a(.) term. The second term on the right measures the change in $\phi\left({}_d\sigma^2_{kd}\right)$ forecast by the ARCH structure while the last term measures the surprise change.

The GARCH(1,1) structure is obtained by setting $\phi(\sigma^2) = \sigma^2$, $\hat{\kappa}(x,\sigma) = (\omega - \theta\sigma^2)$, $g(z_1) = (z_1^2 - 1)/\mathrm{SD}(z_1^2)$, and $a(x,\sigma) = \alpha \,.\, \sigma^2 \,.\, \mathrm{SD}(z_1^2)$. The parameters ω, θ, and α index a family of GARCH(1,1) structures. In a similar manner the EGARCH volatility structure can be defined. That is, by selecting $\phi(.)$, $\hat{\kappa}(.)$, g(.), and a(.), various "filters" can be defined within this framework.

Other conditions in Nelson and Foster (1991) define the rate at which the normalized measurement error process ${}_dQ_t$ mean reverts relative to $({}_dX_t, {}_d\sigma_t^2)$. It becomes white noise as d→0 on a standard time scale but operates on a faster time scale mean-reverting more rapidly. Asymptotically optimal choice of a(.) and ϕ(.) given g(.) can be considered with respect to minimizing the asymptotic variance of the measurement error. This is considered on a faster time scale (T + τ) than T. The asymptotically optimal choice of g(.) depends upon the assumed relationship between Z_1 and Z_2. In the ARCH structure, Z_2 is a function of Z_1 so that the level driving ${}_d\sigma_t^2$ can be recovered from shocks driving ${}_dX_t^2$. Without further structure in the equation specified for σ_t^2, we are unable to recover information about changes in σ_t^2. Their discussion is strictly in terms of constructing a sequence of optimal ARCH filters which minimize the asymptotic variance of the asymptotic distribution of the measurement errors. This approach is not the same as choosing an ARCH structure that minimizes the measurement error variance for each d.

The asymptotic distribution of the measurement error process, for large τ and small d,

$$\left[{}_d\hat{\sigma}^2_{T+\tau d^{1/2}} - {}_d\sigma^2_{T+\tau d^{1/2}} \,\middle|\, \left({}_dQ_T, {}_d\sigma_T^2, {}_dX_T\right)\right] = \left(q, \sigma^2, x\right)$$

with derivatives evaluated as $\phi'\left({}_d\sigma_T^2\right)$, $\varphi'\left({}_d\sigma_T^2\right)$, etc. and the notation simplified as ϕ' and φ' is approximately normal with mean

$$d^{1/2}\frac{(2\sigma^2\varphi')\left[\hat{\kappa}_d/\varphi' - a^2\varphi''/2(\varphi')^3 - \lambda_d/\phi' + \Lambda^2\phi'^3\right] + 2a\sigma.\left[\mu_d - \hat{\mu}_d\right].E[g_z]}{a\,.\,E[Z_1\,.\,g_z]} \tag{44.3}$$

and variance

$$d^{1/2}\frac{(2\sigma^2\phi')\,.\,(a^2/\phi') + \lambda^2/[\varphi']^2 - 2a\Lambda.\mathrm{Cov}(Z_2, g)/[\sigma'][\varphi']}{a.E[Z_1.g_z]}. \tag{44.4}$$

General results in Nelson and Foster (1991, 1994) for the GARCH(1,1) structure are that GARCH(1,1) can be more accurately measured firstly the less variable and the smaller is ${}_d\sigma_t^2$, second the thinner the tails of Z_1, and third the more the true data-generating mechanism resembles an ARCH structure as opposed to a stochastic volatility structure. If the true data-generating process is GARCH(1,1), then Corr $(Z_1^2, Z_2) = 1$.

As d→0, the first result will generally hold, and the second can be checked from the unconditional distribution of the returns process. The latter result is the most difficult to evaluate. Now reconsider some assumptions necessary to obtain these results and reasons these assumptions may not hold when d→0.

(i) Mis-specification of the difference between the estimated and true drift in mean, $\left[{}_d\hat{\mu}_t - {}_d\mu_t\right]$, is assumed fixed as d→0 so that effects of mis-specifying this drift has an effect that vanishes at rate $d^{1/2}$ and is negligible asymptotically. These terms do not appear in the expression for the variance of the asymptotic distribution of the measurement error. As d→0, the effect of bid/ask bounce and order splitting in futures price processes and non-trading-induced effects on market indices becomes more severe. Mis-specification of the drift in the mean is not constant. Whether this effect transfers to estimates of conditional variances is an empirical issue.

(ii) The conditional variance of the increments in ${}_d\sigma_t^2$ involves the fourth moment of ${}_dZ_{1,kd}$ so that the influence of this fourth moment remains as the diffusion limit is approached. Excess kurtosis is a feature of intraday financial price changes.

(iii) Values of $\hat{\kappa}_d$ and λ_d are considered fixed as d→0 so that effects of mis-specifying the drift in σ^2 has an effect that also vanishes at rate $d^{1/2}$. As well, although these drift terms enter the expression for the asymptotic bias of the measurement error, these also do not appear in the expression for the asymptotic variance. The term g_z represents part of the "surprise" change in the recursion defined in Eq. 44.2 and is directly linked to departures from normality observed in point (ii). These departures from normality can be generated by extremes in Z_1 induced by large jumps in the underlying distribution. In this case first and second derivatives of ϕ may be discontinuous throughout the sample space as well. Then the expression for the bias in this asymptotic distribution of the measurement errors may be explosive.

(iv) The ARCH specification of the drift in mean and variance only enters the $0_p(d^{1/2})$ terms of the measurement error. Asymptotically, the differences in the conditional variance specifications are more important, appearing in the $0_p(d^{1/4})$ terms. If the conditional variance specification is not correct then the measurement error variance is affected. This is because matching the ARCH and true variance of the variance cannot proceed.

I will consider these issues further by generalizing a theoretical framework in which to address each in the above order. Firstly I consider the relationship between serial correlation in returns on the market index, the index futures, and basis change as d→0. Second, these effects are considered in the context of the co-persistence structure for the basis change. Finally, I consider effects on conditional variance parameter estimates when mixing and weighting variables are included in the equations for the conditional variance.

44.3 Serial Correlation in Returns

Consider a first-order autoregressive process for the spot asset price return (an AR(D) representation):

$$\mathrm{s_t} = \rho_1 \mathrm{s_{t-1}} + \mathrm{e_t} \tag{44.5}$$

where $\mathrm{s_t}$ is the return on the asset (the difference in the natural logarithm of the spot asset price levels or the difference in the spot asset price levels) between time t and t−1, ρ_1 is the first-order serial correlation coefficient between s at time t and t−1 and $\mathrm{e_t}$ is an assumed homoskedastic disturbance term, σ_e^2 and $-1 < \rho_1 < 1$. This equation provides an approximation to the time-series behavior of the spot asset price return.

An alternative specification to Eq. 44.5 is a simple autoregressive equation for the level of the spot asset price S (or natural logarithm of the levels) at time t and t−1, (an AR(L) representation)

$$S_t = \rho_1 S_{t-1} +_t a_t \tag{44.6}$$

where $\mathrm{a_t}$ is an assumed homoskedastic disturbance term, σ_a^2, and the value of ϕ_1 may be greater or less than one.

The assumed bid/ask bounce in futures price changes is approximated by a MA (1) process in Miller et al. (1994). For the index futures price, this specification is

$$f_t = a_t + \theta_1 a_{t-1}, \tag{44.7}$$

where $\mathrm{f_t}$ is the index futures price change and $\mathrm{a_t}$ is an assumed mean zero, serially uncorrelated shock variable with a homoskedastic variance, σ_a^2, and $-1 < \theta_1 < 0$.

The basis change is defined as

$$b_t = f_t - i_t, \tag{44.8}$$

where *f* and *i* are the index futures return and index portfolio return, respectively.

Whether shocks generated from Eqs. 44.5 or 44.6 generate differences in parameter estimates and measures of persistence obtained from conditional second-moment equations is an issue. Measures of persistence for the basis change may be badly distorted from employing index futures and index portfolio changes. Measures of persistence for index futures and index portfolios may be badly distorted by employing observed price changes.

The simplest GARCH structure derived from Eq. 44.1 for the conditional variance is the GARCH(1,1):

$$h_t = \omega + \alpha_1 \varepsilon_{t-1}^2 + \beta_1 h_{t-1} \tag{44.9}$$

where $\mathrm{h_t}(\sigma_t^2)$ is the conditional variance at time t and ε_{t-1}^2 are squared unconditional shocks generated from any assumed first-moment equation and $0 \leq \alpha_1, \beta_1 \leq 1$ and

$\alpha_1 + \beta_1 \leq 1$. This parameterization is a parsimonious representation of an ARCH (p') process where a geometrically declining weighting pattern on lags of ε^2 is imposed. This is easily seen by successive substitution for $h_{t-j}(j = 1, \ldots, J)$ as $J \rightarrow \infty$,

$$h_t = \omega\left(1 + \beta_1 + \cdots + \beta_1^J\right) + \alpha_1\left(\varepsilon_{t-1}^2 + \beta_1\varepsilon_{t-2}^2 + \cdots + \beta_1^J\varepsilon_{t-J-1}^2\right) + \text{Remainder}. \tag{44.10}$$

Now consider Eq. 44.6, with ϕ_1 fixed at 1, as representing one mis-specified spot asset price process, Eq. 44.5 representing the mis-specified differenced autoregressive process, and Eq. 44.7 representing the mis-specified differenced moving average process. Taking expected values, then the unconditional variance when Eq. 44.6 is the mis-specified representation and ϕ_1 set equal to one is

$$E\left(s_t^2\right) = E\left(a_t^2\right). \tag{44.11}$$

When Eq. 44.7 is the moving average (MA) representation, the unconditional variance relative to shocks generated via Eq. 44.11 is

$$E\left(s_t^2\right)_{MA} = E\left[\left(1 + \theta^2\right)a_t^2\right], \tag{44.12}$$

and when Eq. 44.5 is the autoregressive (AR) representation, the unconditional variance relative to shocks generated via Eq. 44.11 is

$$E\left(s_t^2\right)_{AR} = E\left[\left(\frac{1 - \rho_1}{1 + \rho_1}\right)\left(a_t^2\right)\right]. \tag{44.13}$$

The conditional variance from a GARCH(1,1) structure for Eq. 44.11 can be rewritten as

$$\begin{aligned} h_t(s) = {} & \omega\left(1 + \beta_1 + \cdots + \beta_1^J\right) + \alpha_1\left(a_{t-1}^2 + \beta_1 a_{t-2}^2 + \cdots + \beta_1^J a_{t-J-1}^2\right) \\ & + \text{Remainder}. \end{aligned} \tag{44.14}$$

If Eq. 44.7 is the representation, then, relative to the conditional variance equation from Eq. 44.11,

$$\begin{aligned} h_t(s)_{MA} = {} & \omega\left(1 + \beta_1 + \cdots + \beta_1^J\right) + \alpha_1\left(1 + \theta^2\right)a_{t-1}^2 + \beta\left(1 + \theta^2\right)a_{t-2}^2 \\ & + \cdots\beta_1^J\left(1 + \theta^2\right)a_{t-J-1}^2\Big) + \text{Remainder}, \end{aligned} \tag{44.15}$$

and if Eq. 44.5 is the representation, then, relative to the conditional variance equation from Eq. 44.11,

$$\begin{aligned} \mathrm{h_t(s)_{AR}} &= \omega\left(1+\beta_1+\cdots+\beta_1^J\right) \\ &\quad + \alpha_1\left(\left(\frac{1-\rho_1}{1+\rho_1}\right)a_{t-1}^2 + \beta_1\left(\frac{1-\rho_1}{1+\rho_1}\right)a_{t-2}^2 + \cdots \beta_1^J\left(\frac{1-\rho_1}{1+\rho_1}\right)a_{t-J-1}^2\right) + \text{Remainder}. \end{aligned} \tag{44.16}$$

If ω, α_1, and β_1 were equivalent in Eqs. 44.14, 44.15, and 44.16, when the conditional variance is driven by Eq. 44.7 with θ_1 negative, then $h_t(s)_{MA} > h_t(s)$, and when the conditional variance is driven by Eq. 44.5 with ρ_1 negative, then $h_t(s)_{AR} > h_t(s)$ and with ρ_1 positive then $h_t(s)_{AR} < h_t(s)$. However, given the scaling factor in Eq. 44.15 relative to Eq. 44.16, the potential for distortions to GARCH parameter estimates is greater when the underlying process is driven by Eq. 44.5 relative to Eq. 44.7.

44.4 Persistence, Co-Persistence, and Non-Normality

Now define ε_t as shocks from any of the assumed first-moment equations from Sect. 3 with the following simplified representation of a GARCH(1,1) structure obtained from Eq. 44.1 where $h_t(\sigma_t^2)$ represents the conditional variance and $z_t({}_dZ_{1\ ,kd})$ the stochastic part:

$$\varepsilon_t = \sqrt{h_t}\, z_t \quad z_t \sim \mathrm{NID}(0,1). \tag{44.17}$$

In the univariate GARCH(1,1) structure, h_t converges and is strictly stationary if $E[\ln(\beta_1 + \alpha_1 z_{t-i}^2)] < 0$. Then $\sum_{i=1,kd} \ln(\beta_1 + \alpha_1 z_{t-i}^2)$ is a random walk with negative drift which diverges to $-\infty$ as the observation interval reduces.

Now consider the co-persistence structure in the context of the constant hedging model. Defining the true processes for the differences in the natural logarithm of the spot index price and the natural logarithm of the futures price as

$$\begin{aligned} i_t &= \gamma_1 \xi_t + \eta_{it} \\ f_t &= \gamma_2 \xi_t + \eta_{ft}, \end{aligned} \tag{44.18}$$

the common "news" factor ξ_t is IGARCH, in the co-persistence structure, while the idiosyncratic parts are assumed jointly independent and independent of ξ_t and not IGARCH. The individual processes have infinite unconditional variance. If a linear combination is not IGARCH, then the unconditional variance of the linear combination is finite and a constant hedge ratio (defined below) leads to substantial reduction in portfolio risk.

A time-varying hedge ratio can lead to greater reduction in portfolio risk under conditions discussed in Ghose and Kroner (1994) when the processes are co-persistent in variance. From a practical perspective, account needs to be taken of the rebalancing costs of portfolio adjustment.

A nonoptimal restricted linear combination is the basis change defined as the difference between the change in the log of the index futures price and change in the log of the spot index level. This implied portfolio is short 1 unit of the spot for every unit long in the futures. For the futures and spot price processes reported in McCurdy and Morgan (1987), the basis change is co-persistent in variance.

If there are "news factors" $\xi_{f\,t} \neq \xi_{i\,t}$, then the constant hedge ratio may not exist. Define these processes as

$$\begin{aligned} i_t &= \gamma_1 \xi_{i\,t} + \eta_{i\,t} \\ f_t &= \gamma_2 \xi_{f\,t} + \eta_{f\,t} \end{aligned} \tag{44.19}$$

then the estimated constant hedge ratio which is short g units of the spot for every 1 unit long in the futures is

$$\hat{\gamma} = \left[\frac{\hat{\mathrm{cov}}\ (\mathrm{f}, \mathrm{i})}{\hat{\mathrm{var}}\ (\mathrm{i})}\right]_{|\mathrm{t}} = \left[\hat{\gamma}_2\left[\frac{\mathrm{p}\sqrt{\hat{\mathrm{var}}\ [\xi_\mathrm{f}]\ \hat{\mathrm{var}}\ [\xi_\mathrm{i}]}}{\hat{\mathrm{var}}\ [\xi_\mathrm{i}]}\right] + \mathrm{var}\left(\hat{\eta}_i\right)\right]_{|\mathrm{t}} \tag{44.20}$$

where $\hat{\rho}$ is the correlation between ξ_{ft} and ξ_{it}.

When both ξ_f and ξ_i follow IGARCH processes and no common factor structure exists, then the estimated constant hedge diverges. Ghose and Kroner (1994) investigate this case.

When ξ_{ft} follows an IGARCH process but ξ_{it} is weak GARCH, then the estimated constant hedge ratio cannot be evaluated. There are two problems:

(a) The estimated sample variance of ξ_f in Eq. 44.20 is infinite as $T \to \infty$.

(b) $p = \left[\left[c\ o\hat{v}\left[\xi_f\right]\right] / \sqrt{v}\ \hat{a}\ r\left[\xi_f\right]\ v\hat{a}r\ \left[\xi_i\right]\right]_{|t}$ so that there is no linear combination of ξ_f and ξ_i which can provide a stationary unconditional variance.

This last observation has a direct parallel from the literature for cointegration in the means of two series.

If ξ_f is an approximate I(1) process and ξ_i is I(0), then there is no definable linear combination of ξ_f and ξ_i.

When observing spot index and futures prices over successively finer intervals, the co-persistence structure may not hold for at least two further reasons. This argument relates directly to the horizon t+kd for the hedging strategy. This argument also relates directly to distortions possibly induced onto a dynamic hedging strategy, as d→0.

Perverse behavior can be observed in spot index level changes as oversampling becomes severe. The smoothing effect due to a large proportion of the portfolio entering the non- and thin-trading group generates a smoothly evolving process with short-lived shocks generated by irregular news effects.

General results assume that the z_t's are drawn from a continuous distribution. When sampling futures price data at high frequency, then the discrete nature of the price recording mechanism guarantees that there are discontinuities in return-generating processes. The distribution of the z_t's can become extremely peaked due to multiple small price changes and can have very long thin tails due to abrupt shifts in the distribution. As $d \to 0$, $-\infty < E[1n(\beta_1 + \alpha_1 z_{t-i}^2)] < +\infty$ for a large range of values for $0 \leq \alpha_1$, $\beta_1 \leq 1$ and $\alpha_1 + \beta_1 < 1$, and this depends on the distribution induced by oversampling and resultant reduction in $(\alpha_1 + \beta_1)$. In the limit $E[(z_t)^4]/[E(z_t^2)]^2 \to \infty$. Then even-numbered higher moments of z_t are unbounded as $d \to 0$. This oversampling can lead to two extreme perverse effects generated by bid/ask bounce or zero price changes. The effect depends upon liquidity in the respective markets.

44.4.1 Case 1

$$\alpha_1 \to 1, \alpha_1 + \beta_1 > 1 \text{ and } E\left[\ln\left(\beta_1 + \alpha_1 z_{t-i}^2\right)\right] > 0.$$

The intuitive explanation for this result relies on oversampling (not overdifferencing) in highly liquid markets. The oversampling approaches analysis of transactions. At this level bid/ask bounce and order splitting require an appropriate model. Any arbitrary autoregressive model, for unconditional first moments, generates unconditional shocks relating predominantly to behavior of the most recent shock. These effects carry through to conditional squared innovations.

44.4.2 Case 2

Oversampling can produce many zero price changes in thin markets. In this latter case as $d \to 0$ then $\alpha_1 + \beta_1 \to 0$.

This explanation can apply to relatively illiquid futures (and spot asset) price changes. That is, conditional heteroskedasticity disappears as oversampling becomes severe.

The effect on the basis change when there is a relatively illiquid futures market and oversampling may be badly distorted. As well, failure to account for anomalies in conditional variance equations can severely distort estimates.

44.5 Weighted GARCH

Recall from Eq. 44.1 that $\hat{\kappa}$ is a function defining the estimated drift in $\left\{\phi\left({}_d\sigma_t^2\right)\right\}$ so that λ is a function defining true drift in $\{\varphi({}_d\sigma_t^2)\}$. In the ARCH structure, the drift in $h_t(\sigma_t^2)$ in the diffusion limit is represented by $\hat{\kappa}/\phi' - a^2\phi''/2(\phi')^3$, whereas for the stochastic differential equation defined from assumptions 2, 3, and 1′ in Nelson and

Foster (1991, 1994), this diffusion limit is $\lambda/\varphi' + \Lambda^2\varphi''/2\,(\varphi')^3$. The effect on the expression for the bias in the asymptotic distribution of the measurement error process can be explosive if derivatives in the terms $a^2\phi''/2(\phi')^3 - \Lambda^2\varphi''/2(\varphi')^3$ cannot be evaluated because of discontinuities in the process. This can happen when important intraday effects are neglected in the conditional variance equation specification. As well, the bias can diverge as $d \to 0$ if the ${}_dZ_{1,kd}$ terms are badly distorted.

Occasional large jumps in the underlying distribution contribute large $O_p(1)$ movements while the near diffusion components contribute small $O_p(d^{1/2})$ increments. When sampling intraday financial data, there are often many small price changes which tend to be dominated by occasional large shifts in the underlying distribution.

Failure to account for intraday effects (large shocks to the underlying distribution) can lead to a mixture of $O_p(1)$ and $O_p(d^{1/2})$ effects in the process. One approach is to specify this mixed process as a jump diffusion. An alternative is to account for these effects by incorporating activity measures in the specification of conditional variance equations.

It follows that failure to account for these $O_p(1)$ effects can lead to an explosive measurement error $\left[{}_d\hat{h}_t - {}_dh_t\right]$. However, in empirical applications this measurement error is unobservable since ${}_dh_t$ is unobservable. Failure to account for these jumps in the underlying distribution imply that the unweighted GARCH(1,1) structure cannot satisfy the necessary assumptions required to approximate a diffusion limit.

44.6 Empirical Examples

The first issue is the effect of possible mis-specification of the first-moment equation dynamics and resultant effect on estimates of persistence of individual processes as $d \to 0$. If the effect is not important (mean irrelevance) then the focus of attention is on the estimates from the co-persistence structure and implications for a constant hedge ratio.

The second issue is the effect of inclusion of variables to proxy intraday activity on measures of persistence. However, it is still important to consider possible effects from mis-specifying the first-moment equation on parameter estimates obtained from conditional variance equations as $d \to 0$. If there is strong conditioning from measures of activity onto the market price processes, the conditioning should be independent of specification of the dynamics of the first-moment equation (mean irrelevance).

44.6.1 Index Futures, Market Index, and Stock Price Data

The data has been analyzed for the common trading hours for 1992 from the ASX and SFE, i.e., from 10.00 a.m. to 12.30 p.m. and from 2.00 p.m. to 4.00 p.m.

This dataset was first employed in examples reported in Gannon (1994) and a similar analysis undertaken in Gannon (2010) for the SVL models as is undertaken in this paper for the GARCH and GARCH-W models. Further details of the sampling and institutional rules operating in these markets are briefly reported in the Appendix of this paper. Transactions for the Share Price Index futures (SPI) were sampled from the nearest contract 3 months to expiration. The last traded price on the SPI levels and stock price levels were then recorded for each observation interval. The All Ordinaries Index (AOI) is the recorded level at the end of each observation interval. During these common trading hours, the daily average number of SPI futures contracts traded 3 months to expiration was 816. As well, block trades were extremely rare in this series. Transactions on the heavily capitalized stock prices were extremely dense within the trading day.

These seven stocks were chosen from the four largest market capitalized groupings according to the ASX classification code in November 1991, i.e., general industrial, banking, manufacturing, and mining. The largest capitalized stocks were chosen from the first three categories as well as the four largest capitalized mining stocks. This selection provides for a diversified portfolio of very actively traded stocks which comprised 32.06 % of total company weights from the 300 stocks comprising the AOI.

All datasets were carefully edited in order to exclude periods where the transaction capturing broke down. The incidence of this was rare. As well, lags were generated and therefore the effects of overnight records removed. A natural logarithmic transformation of the SPI and AOI prices is undertaken prior to analysis.

Opening market activity for the SPI is heaviest during the first 40 min of trading. Trade in the SPI commences at 9.50 a.m. but from 10.30 a.m. onwards volume of trade tapers off until the lunchtime close. During the afternoon session, there is a gradual increase in volume of trade towards daily market close at 4.10 p.m. Excluding the market opening provides the familiar U-shaped pattern of intraday trading volume observed on other futures markets. SPI price volatility is highest during the market opening period with two apparent reverse J-shaped patterns for the two daily trading sessions (small J effect in afternoon session). The first and last 10 min of trade in the SPI are excluded from this dataset.

Special features govern the sequence at which stocks open for trade on the ASX. Individual stocks are allocated a random opening time to within plus or minus 30 s of a fixed opening time. Four fixed opening times, separated by 3-min intervals starting at 10.00 a.m., operated throughout 1992. Four alphabetically ordered groups then separately opened within the first 10 min of trading time. The last minute of trading on the ASX is also subject to a random closing time between 3.59 p.m. and 4.00 p.m. The effect of these institutional procedures on observed data series can be potentially severe.

Both of these activity effects in market opening prices of trading on the SFE, and ASX should be accounted for in the estimation process.

Table 44.1 Autoregressive parameter estimates for SPI, AOI, and basis change

Interval	f_t	i_t	b_t
Full day

05 min	0.0532	0.3284	−0.0968
	(5.84)	(38.2)	(−10.7)

Asymptotic t-statistics in brackets
$f_t = F_t - F_t$ is the difference in the observed log level of the SPI
$i_t = I_t - I$ is the difference in the observed log level of the AOI
Equation 44.5, i.e., an autoregressive specification for the differences, an [AR(D)], is estimated for both data series with one lag only for the autoregressive parameter
Dummy variables are included, for the first data series, in order to account for market opening effects for the SPI, institutional features governing market opening on the ASX and therefore effects transmitted to the basis change. Two separate dummy variables are included for the first pair of 5-min intervals
This form for the basis change is $b_t = f_t - i_t$
In the lower panel, results are reported from synchronized trading from 10.30 a.m. That is, the first 40 min and first 30 min of normal trade in the SPI and AOI, respectively, is excluded

44.6.2 Estimates of the Autoregressive Parameters

In Table 44.1 the first-order autoregressive parameter estimate is reported for the observed differenced series for the SPI (f), AOI (i), and basis change (b). In the top panel, these parameter estimates are from observations for the full (synchronized) trading day. These equations include dummy variables to account for institutional market opening effects. In the following tables of results, SING refers to singularities in the estimation process.

For the SPI futures price process, low first-order negative serial correlation is initially detected in the log of the price change. As the sampling interval is reduced, low first-order positive serial correlation can be detected in the series. This feature of the data accords with order splitting and non-trading-induced effects.

Low positive first-order serial correlation can be detected in differences of the log of the market index and serial correlation increases. Positive serial correlation is high at 15-min intervals for the opening excluded set. When sampling the market index at 5-min intervals, substantial positive first-order serial correlation is detected in the log of the price change process. Miller et al. (1994) demonstrate that thin trading and non-trading in individual stocks induce a positive serial correlation in the observed spot index price change process. However, the smoothing effect from non-trading in individual stocks, averaging bid/ask bounce effects in heavily traded stocks, and under-differencing the aggregate process also contribute.

Of interest is the reduction in serial correlation of the basis spread as d → 0. As the log futures price change moves into the order splitting/non-price change region, positive serial correlation is induced in the log of the futures price change. This, in part, helps offset the increasing positive serial correlation induced in the log of the spot index.

44.6.3 Conditional Variance Estimates

Allowing for and excluding market open/closing effects in first-moment equations make little difference to GARCH parameter estimates. This observation holds for alternative specifications of the dynamics for the first-moment equation at 30- and 15-min intervals. However, mis-specifying the first-moment equation dynamics is important in the conditional second-moment equations for the AOI at 5-min intervals.

The GARCH(1,1) estimates for the SPI, AOI, and basis are generated from Eq. 44.6, i.e., an autoregressive specification of the levels AR(L) and Eq. 44.5 the AR(D), respectively (Table 44.2).

Opening dummy variables are incorporated in both first-moment and conditional second-moment equations for the full-day data series. Two dummy variables, corresponding to the first- two 5-min intervals, are included in both first and conditional second-moment equations for the full-day data series. Results in the lower panel are obtained from excluding all trade in the SPI and AOI prior to 10.30 a.m.

At 5-min sampling intervals, a transient effect is introduced into the unconditional distributions which carries through to the conditional variance estimates. Values for α_1 and β_1 differ both within the same data series for alternative first-moment equations and across data series for the same form of first-moment equation. For one extreme case (with exclusion of market opening), the GARCH parameter estimates for the AOI and therefore the basis change do depend on the mis-specification of the first-moment equation.

From the first set of results (full day), it would appear as if the SPI is persistent in variance, the AOI is not and neither is the basis change persistent in variance.

A second extreme case occurs at 30- and 15-min intervals (with exclusion of market opening). In this case GARCH parameter estimates are almost identical for alternative specifications of the dynamics of the first-moment equation. However, for the AOI the sum of the GARCH parameter estimates is near the IGARCH boundary, and the same feature is observed in the basis change.

It would appear that, given anomalies are adequately accounted for, mis-specification of the (weak) dynamic structure of price changes in these processes is only relevant for estimating these GARCH equations for the AOI at 5-min intervals. The important issue is the correct specification of the market opening effects.

These preliminary results have been obtained from observations sampled for all four futures contracts and a continuous series constructed for 1992. The AOI is not affected by contract expiration. In Table 44.3, GARCH(1,1) estimates for the separate SPI futures contracts, 3 months to expiration, and synchronously sampled observations on the AOI are recorded. The full data series corresponding to synchronized trading on the SFE and ASX is employed.

The same form of dummy variable set was imposed in both first and second-moment equations. As well, a post-lunchtime dummy is included to account for the

GARCH(1,1) parameter estimates for the 3 months corresponding to expiration of the March, June, September, and December contracts for 1992. Full-day data series are employed with opening and post-lunchtime dummy variables in both first and conditional second-moment equations. An AR(L) specification of the (log) mean equation is employed for these results

break in daily market trade at the SFE during 1992. The log of levels is specified for the first-moment equations.

There is some instability within this set of parameter estimates. However, a similar pattern emerges within the set of futures and the set of market index estimates as was observed for the full-day series for 1992. The futures conditional variance parameter estimates are close to the IGARCH boundary while the index conditional variance estimates are not. This again implies that these processes cannot be co-persistent in variance for these samples and observation intervals.

In order to obtain further insight into the, seemingly, perverse results for the market index, a similar analysis was undertaken on seven of the largest market capitalized stocks which comprised the AOI during 1992.

Relevant market opening and closing dummy variables were included in both first and conditional second-moment equations accordingly. These effects were not systematic in the first-moment equations and are not reported. The stock price processes have not been transformed to natural logarithmic form for these estimations. This is because the weighted levels of the stock prices are employed in construction of the market index.

As the observation interval is reduced for these stock prices:

(i) The autoregressive parameter estimates for the price levels equation converges to a unit root.
(ii) The first-order serial correlation coefficient for the price difference equation moves progressively into the negative region.

If these were the only stocks comprising the construction of the index, then we might expect to see increasing negative serial correlation in the index. But this observation would only apply if these processes were sampled from a continuous process which was generated by a particular form of ARMA specification. Only in the case of data observed from a continuous process could the results on temporal aggregation of ARMA processes be applied.

These results should not be surprising as the combination of infrequent price change and "price bounce" from bid/ask effects starts to dominate the time series. As well, these bid/ask boundaries can shift up and down. When these processes are aggregated, the effects of price bounce can cancel out. As well, the smoothing effect of thinly and zero traded stocks within the observation intervals dampens and offsets individual negative serial correlation observed in these heavily traded stocks (Table 44.4).

Some of these autoregressive parameter estimates are quite high for the AR(D) specifications. However, it is apparent that there is almost no difference in GARCH(1,1) estimates from either the AR(L) or AR(D) specifications at each observation interval for any stock price. In some instances estimation breaks down at 5 min intervals.

If the conditional variances of these stock price movements contain common news and announcement effects, then it should not be surprising that the weighted aggregated process is not persistent in variance. This can happen when news affects all stocks in the same market. As well, smoothing effects from thin-traded stocks help dampen volatility shocks observed in heavily traded stocks. These news and announcement effects may be irrelevant when observing these same processes at daily market open to open or close to close. These news and announcement effects may be due to private information filtering onto the market prior to and following market open. It is during this period that overnight information effects can be observed in both price volatility and volume. As well, day traders and noise traders are setting positions. However, the ad hoc application of dummy variables is not sufficient to capture the interaction between volatility and volume. In the absence of specific measures of these news "variables," the effects cannot be directly incorporated into a structural model. However, these effects are often captured in the price volatility and reflected in increased trading activity.

44.6.4 Weighted GARCH Estimates

Weighted GARCH estimates for the futures (log) price process with the accumulated number of futures contracts traded within the interval t to t−1 are reported in Table 44.5. This choice ensures that volume measures are recorded within the interval that actual prices define.

The weighting variable employed in the index (log) price process is the squared shock from the futures price mean equation within the interval t to t−1. There is no natural "volume" of trade variable available for the market index. The form of mean

Asymptotic t-statistics in brackets
Column 1 contains the observation interval
Column 2 contains the autoregressive parameter from an AR(L) specification of the price levels equation
Column 3 contains the first-order autoregressive parameter estimate from an AR(D) specification of the price change
Columns 4 and 5 contain the GARCH(1,1) parameter estimates from an AR(L) specification of the price levels equation
Columns 6 and 7 contain the corresponding estimates from an AR(D) specification of the price changes

equation is the same as the generated corresponding results for Table 44.3, i.e., an AR(L). However, the results are almost identical when alternative forms for the mean equation are employed, i.e., AR(L) and AR(D).

The specifications generating the reported stock price estimates are augmented to include a measure of trade activity within the observation interval. These measures are the accumulated number of stocks traded in each individual stock within the interval t to t−1. The estimates are reported in Table 44.6. The conditional variance parameter estimates are almost identical from the AR(L) and AR(D) specifications of the mean equation. The logarithmic transformation has not been taken for these stock prices.

Direct comparison of these GARCH parameter estimates (α_1 and β_1) with those from the unweighted GARCH(1,1) estimates demonstrates the importance of this measure of activity. The change in GARCH parameter estimates is striking.

The measures of persistence from these weighted estimates are never near the IGARCH boundary. These effects are summarized in Table 44.7.

These results are generated from an AR(L) specification of the first-moment equation. By adequately accounting for contemporaneous intraday market activity, the time persistence of volatility shocks becomes less relevant. It follows that deviations of the estimated conditional variance from the true (unobservable) conditional variance are reduced (Table 44.8).

44.6.5 Discussion

In this section some empirical evidence is documented on the behavior of unconditional first and conditional second-moment effects for the market index, futures contracts written on the market index, and for heavily traded stock prices. These results are for Australian financial assets sampled on an intraday basis as the observation interval approaches transactions time $d \to 0$.

The specific empirical findings were:

1. The autoregressive parameter estimate from a difference equation for the log of the index futures is initially negative but moves into the positive region. This can be attributed to bid/ask bounce being dominated by order splitting and non-trading effects.
2. The autoregressive parameter estimate from a difference equation for the log of the market index displays increasing positive serial correlation. This can be attributed to non-trading smoothing effects in low capitalized stocks, averaging of bid/ask bounce effects, and under-differencing the aggregated index.

3. The basis change between the log futures price change and the log index level change displayed two surprising effects:
   (i) The autoregressive parameter for the basis change is initially negative, but the strength of this effect weakens. This can be attributed to the log of the

futures price change behavior where the autoregressive parameter moved into the positive region and price change became less frequent.

(ii) The unweighted log of the futures price change was close to the IGARCH boundary. For the full-day data series, the log of the market index change was not close to the IGARCH boundary and neither was the basis change. When market opening trade was excluded, the log of the futures price change, the log of the market index price change, and the basis change were close to the IGARCH boundary although this effect dissipated as $d \rightarrow 0$. However, volume of trade on both the SFE and ASX is heaviest within this excluded interval. It follows that any conclusions concerning the co-persistence structure would be misleading from this intraday data.

4. The autoregressive parameter from a levels equation for the stock prices converges to a unit root. This can be attributed to small and zero price change effects.
5. The autoregressive parameter from a difference equation for the stock prices displays increasing tendency towards and into the negative serial correlation region. This can be attributed to price bounce effects where the boundaries are tight and relatively stable.
6. GARCH(1,1) or weighted GARCH conditional variance parameter estimates do not depend on the specification of the dynamics of first-moment equation for 30- and 15-min intervals of these futures, market index, and stock price processes.

30 min	0.687	0.079	0.445	0.145	0.990	0.137		
15 min	0.819	0.000	0.763	0.108	0.843	0.056		

An AR(L) specification has been employed to generate these results
The measure of persistence is the calculated as a+b from the conditional variance equations
G represents persistence obtained from a GARCH(1,1) specification
G-W represents persistence obtained from a weighted GARCH specification
SING indicates that one or more of these GARCH parameters could not be evaluated due to singularities

The GARCH(1,1) parameter estimates for the AOI at 5-min intervals were different when alternative forms of first-moment equations were specified. There was no perceivable difference in the other processes at this sampling frequency. It would then appear that increasing positive serial correlation (smoothing) in the observed returns process has a greater distorting effect on GARCH(1,1) parameter estimates than increasing negative serial correlation (oscillation) in observed returns processes. The most important effect is mis-specification of the conditional variance equations from failure to adequately account for the interaction between market activity and conditional variance (volatility).

Some implications of these results are:

7. When aggregating stock prices, which may be close to the IGARCH boundary, persistence in variance can be low for the market index because (i) there is common persistence present in heavily traded stock prices which when aggregated do not display persistence in variance because heavily traded stock prices react to market specific news instantaneously, (ii) the smoothing effect of less heavily traded stocks dampens the volatility clustering which is often observed in other financial assets such as exchange rates, and (iii) high volatility and volume of trade effects within these markets following opening is better measured by employing relevant measures of activity than an ad hoc approach.
8. There is a strong and quantifiable relationship between activity in these markets and volatility.

44.7 Conclusion

The behavior of financial asset price data observed intraday is quite different from these data observed at longer sampling intervals such as day to day. Market anomalies which distort intraday observed data mean that volatility estimates obtained from data observed from day-to-day trades will provide different volatility estimates. This latter feature then depends upon when the data is sampled within the trading day. If these anomalies and intraday trading patterns are accounted for in the estimation process, then better estimates of volatility are obtainable by employing intraday observed data. However, this is dependent on a sampling interval that is not so fine that these estimators break down.

The specific results indicate that serial correlation in returns processes can distort parameter estimates obtainable from GARCH estimators. However, induced excess kurtosis may be a more important factor in distortions to estimates. The most important factor is mis-specification of the conditional variance (GARCH) equation from omission of relevant variables which explain the anomalies and trading patterns observed in intraday data. Measures of activity do help explain systematic shifts in the underlying returns distribution and in this way help explain "jumps" in the volatility process. This effect can be observed in the likelihood function and in asymptotic standard errors of weighting (mixing) variables. One feature is that the measure of volatility persistence observed in unweighted univariate volatility estimators is reduced substantially with inclusion of weighting variables.

Appendix

At the time the ASX data were collected, the exchange had just previously moved from floor to screen trading with the six main capital city exchanges linked via satellite and trade data streamed to trading houses and brokers instantaneously via a signal G feed. The SFE maintained Pit trading for all futures and options on futures contracts at the time.

Legal restrictions on third party use and development of interfaces meant the ASX had a moratorium on such usage and development. The author was required to obtain special permission from the ASX to capture trade data from a live feed from broking house Burdett, Buckeridge, and Young (BBY). There was a further delay in reporting results of research following the legal agreement obtained from the ASX.

Trade data for stock prices and volume of trade were then sampled into 5-min files and subsequently into longer sampling interval files. The market index was refreshed at 1-min intervals and the above sampling scheme repeated. Futures price trades were supplied in two formats via feed: Pit (voice recorded) data and Chit data. Although the Pit data provides an instantaneous record of trade data during the trading day, some trades are lost during frantic periods of activity. The Chit records are of every trade (price, volume, buyer, seller, time stamped to the nearest second, etc.). The recorded Chits are placed in a wire basket on a carriageway and transferred up the catwalk where recorders on computers enter details via a set of simplified keystrokes. The average delay from trade to recording is around 30 s for the Chit trades. These are then fed online to trading houses and brokers. At the end of the trading day, these recorded trades are supplemented with a smaller set of records that were submitted to the catwalk late, e.g., morning trades that may have gone to lunch in a brokers pocket and submitted during the afternoon session and also some late submitted trades.

We created the intraday sampled files from both the Pit and Chit records. However, we employed the Chit trades for analysis in this paper so as to have the correct volume of trade details for each trading interval. All trades were reallocated using the time stamps to the relevant time of trade, including trades not submitted on time but supplied as an appendix to the trading day data. In this study the average number of late Chits were not a high proportion of daily trades. These futures price records were then sampled into relevant 5-min records and longer sampling frames generated in the same manner as was employed for the stock prices.

For all series the first price and last price closest to the opening and closing nodes for each sampling interval were recorded with volume of trade the accumulated volume of trade within the interval defined by first and last trade.

Optimal Asset Allocation Under VaR Criterion: Taiwan Stock Market

45

Ken Hung and Suresh Srivastava

Contents

Abstract

Value at risk (VaR) measures the worst expected loss over a given time horizon under normal market conditions at a specific level of confidence. These days, VaR is the benchmark for measuring, monitoring, and controlling downside financial risk. VaR is determined by the left tail of the cumulative probability distribution of expected returns. Expected probability distribution can be generated assuming normal distribution, historical simulation, or Monte Carlo simulation. Further, a VaR-efficient frontier is constructed, and an asset allocation model subject to a target VaR constraint is examined.

This paper examines the riskiness of the Taiwan stock market by determining the VaR from the expected return distribution generated by historical simulation. Our result indicates the cumulative probability distribution has a fatter left tail, compared with the left tail of a normal distribution. This implies a riskier market.

45.1 Introduction

Risk is defined as the standard deviation of unexpected outcomes, also known as volatility. Financial market risks are of four types: interest rate risk, exchange rate risk, equity risk, and commodity risk. For a fixed-income portfolio, the linear exposure to the interest rate movement is measured by duration. Second-order exposure is measured by convexity. In the equity market, linear exposure to market movement is measured by the systematic risk or beta coefficient. In the derivative markets, the first-order sensitivity to the value of underlying asset is measured by *delta*, and second-order exposure is measured by *gamma*. Innovations in the financial markets have introduced complicated portfolio choices. Hence, it is becoming more difficult for managers to get useful and practical tools of market risk measurement. The simple linear considerations such as Basis Point Value, or first- or second-order volatility, are inappropriate. They can't accurately reflect risk at the time of dramatic price fluctuation.

VaR (value at risk) has become a popular benchmark for the downside risk measurement.[1] VaR converts the risks of different financial products into one common standard: potential loss, so it can estimate market risk for various kinds of investment portfolio. VaR is used to estimate the market risk of financial assets. Special concern of the market risk is the downside risk of portfolio values resulting from the fluctuation of interests, exchange rates, stock prices, or commodity prices. VaR is consistent in estimating the financial risk estimation. It indicates risk of dollar loss of portfolio value. Now the risks exposure of different investment portfolios (such as equity and fixed income) or different financial products (such as interest rate swaps and common stock) have a common basis for direct comparison. For decision makers, VaR is not only a statistical summary; it can also be used as a management and risk control tool to decide capital adequacy, asset allocation, synergy-based salary policy, and so on.

[1]Extensive discussion of value at risk can be found in Basak and Shapiro (2001), Beder (1995), Dowd (1998), Fong and Vasicek (1997), Hendricks (1996), Hoppe (1999), Jorion (1997, 1997), Schachter (1998), Smithson and Minton (1996a, b), and Talmor (1996).

VaR is a concept widely accepted by dealers, investors, and legislative authorities. J.P. Morgan has advocated VaR and incorporated it in RiskMetrics (Morgan 1996). RiskMetrics contain most of the data and formulas used to estimate daily VaR, including daily updated fluctuation estimations for hundreds of bonds, securities, currencies, commodities, and financial derivatives. Regulatory authorities and central bankers from various countries at Basel Committee meetings agreed to use VaR as the risk-monitoring tool for the management of capital adequacy. VaR has also been widely accepted and employed by securities corporations, investment banks, commercial banks, retirement funds, and nonfinancial institutions. Risk managers have employed VaR in ex-post evaluation, that is, to estimate and justify the current market risk exposure.[2] Confidence-based risk measure was first proposed by Roy (1952).

The inclusion of VaR into the asset allocation model means the inclusion of downside risk into model constraints. Within the feasible scope of investment portfolio that meets shortfall constraints, the optimal investment portfolio is decided by maximum expected return. The definition of shortfall constraint is that the probability of investment portfolio value dropping to a certain level is set as the specific disaster probability. The asset allocation framework that takes VaR as one of its constraints has increased the importance of VaR and has employed VaR as an ex-ante control tool of market risk.

45.2 Value at Risk

One difficulty in estimating VaR is the choice of various VaR methods and corresponding hypotheses. There are three major methods to estimate VaR: variance-covariance analysis, historical simulation, and Monte Carlo simulation. Variance-covariance analysis assumes that market returns for financial products are normally distributed, and VaR can be determined from market return's variance and covariance. The normal distribution hypothesis of variance-covariance analysis makes it easy to estimate VaR at different reliability and different holding period (see Appendix 1). Its major disadvantage is that the return in the financial market is usually not in normal distribution and has fat tails. This means the probability of extreme loss is more frequent than estimated by variance-covariance analysis.

Historical simulation assumes the future market return of the investment portfolio is identical to the past returns; hence, the attributes of current market can be used to simulate the future market return (Hendricks 1996; Hull and White 1998). Historical simulation approach does not suffer from the tail-bias problem, for it does not assume normal distribution. It relies on actual market return distribution, and the estimation reflects what happened during the past sample period. It has another advantage over variance-covariance analysis: it can be used for nonlinear products, such as commodity derivatives. However, the problem with historical

[2]Institutional use of VaR can be found in Basel (1995, 1998a, b, c, 1999), Danielsson et al. (1998), and Danielsson Hartmann and de Vries (1998).

simulation is its sensitivity to sample data. Many scholars pointed out that if October 1987 is included into the observation period, then it would make great difference to the estimation of VaR. Another problem with historical simulation is that the left tail of actual return distribution is at zero stock prices. In other words, it would not be accurate to assume a zero probability of loss that is greater than the past loss. Lastly, the estimation of historical simulation is more complicated than that of variance-covariance analysis. The VaR needs to be reestimated every time the level of reliability or holding period changes.

Monte Carlo simulation can be used to generate future return distribution for a wide range of financial products. It is done in two steps. First, a stochastic process is specified for each financial variable along with appropriate parameters. Second, simulated prices are determined for each variable, and portfolio loss is calculated. This process is repeated 1,000 times to produce a probability distribution of losses. Monte Carlo simulation is the most powerful tool for generating the entire probability distribution function and can be used to calculate VaR for a wide range of financial products. However, it is time consuming and expensive to implement.

Modern investment portfolio theories try to achieve optimal asset allocation via maximizing the risk premium per unit risk, also known as the Sharpe ratio (Elton and Gruber 1995). Within the framework of mean-variance, market risk is defined as the expected probable variance of investment portfolio. To estimate risk with standard deviation implies investors pay the same attention to the probabilities of negative and positive returns. Yet investors have different aversion to investment's downside risk than to capital appreciation. Some investors may use semi-variance to estimate the downside risk of investment. However, semi-variance has not become popular.

Campbell et al. (2001) have developed an asset allocation model that takes VaR as one of its constraints. This model takes the maximum expected loss preset by risk managers (VaR) as a constraint to maximize expected return. In other words, the optimal investment portfolio deduced from this model meets the constraint of VaR. This model is similar to the mean-variance model that generates the Sharpe index. If the expected return is a normal distribution, then this model is identical with mean-variance model. Details of this model are presented in the Appendix.

Other researchers have examined four models to introduce VaR for ex-ante asset allocation of optimal investment portfolio: mean-variance (MV) model, mini-max (MM) model, scenario-based stochastic programming (SP) model, and a model that combines stochastic programming and aggregation/convergence (SP-A). The investment portfolio constructed using the SP-A model has a higher return in all empirical and simulation tests. Robustness test indicates that VaR strategy results in higher risk tolerance than risk assessment that takes severe loss into consideration. Basak and Shapiro (2001) pointed out that the drawback of risk management lies in its focus on loss probability instead of loss severity. Although loss probability is a constant, when severe loss occurs, it has greater negative consequence than non-VaR risk management.

Lucas and Klaassen (1998) pointed out the importance of correctly assessing the fat-tailed nature of return distribution. If the real return is not in normal distribution, the asset allocation under the hypothesis of normal distribution will result in non-efficiency or non-feasibility. An excellent discussion of VaR and risk measurements is presented by Jorion (2001).

45.3 Empirical Results

In July 1997, financial crisis broke out in Southeast Asian nations and then proliferated to other Asian regions and led to a series of economic problems. Taiwan had also been attacked by financial crisis in late 1998. Domestic financial markets fluctuated. Corporations and individuals greatly suffered. The proliferation of financial crisis within or among countries makes it impossible for corporations and individuals to ignore market risk. Risk measurement is the first thing to do before investment.

The Taiwan market general weighted stock index, individual weighted stock price indexes, and interbank short loan interest rate used in this research paper are obtained from the data base of AREMOS. We divide the historical period into two groups, from 1980 to 1999 and from 1991 to 1999, so as to analyze the impact of violent stock market fluctuation on VaR estimation, such as the New York stock market collapse in October 1987 and Taiwan stock market dramatic uprising from 1988 to 1990. The first period is rather long and can indicate the nature of dramatic stock fluctuation. The second period is rather short and can reflect the change of stock market tendency.

This paper employs historical simulation to reproduce the daily fluctuations of returns for electrical machinery, cement, food, pulp and paper, plastics and petroleum, and textile and fiber stocks trading in the Taiwan stock market during the periods of 1980–1999 and 1991–1999. We estimate their VaRs under reliability levels of 95 %, 97.5 %, and 99 %. The expected return of investment portfolio in 1999 is the sum of annual mean returns of various stocks multiplied with their respective weights. We use this expected return to estimate year 1999 optimal stock holding proportion and analyze the impact of different historical simulation periods on optimal asset allocation.

Table 45.1 presents the summary of TSE general weighted stock index (daily data) and estimated VaR for periods 1980–1999 and 1991–1999. Table 45.2 presents cumulative probability distributions of TSE daily index return for the 1980–1999 period and daily returns under the assumption of normality. It shows that at confidence level lower than 95.8 % (e.g., 90 %), the left-tail probability for

Table 45.1 Summary of Taiwan Stock Exchange (TSE) daily index

Period	Mean return	Standard deviation	Kurtosis	VaR*
1980–1999	0.06 %	1.67 %	2.735	0.0263
1991–1999	0.04 %	1.60 %	2.464	0.0249

Annualized return for the two periods is 23.64 % and 11.87 %, respectively. VaR* is the maximum expected return loss for 1-day holding period at a reliability level of 95 %

Period: 1980–1999

historical distribution is higher than the normal return probability (4.2 %). Hence, under the normal distribution assumption, the VaR is overestimated, and this leads to an overcautious investment decision. At confidence level higher than 95.8 % (e.g., 97.5 %), the left-tail probability for historical distribution is lower than the normal return probability (4.2 %). Hence, under the normal distribution assumption, the VaR is underestimated, and this leads to an overactive investment decision.

Figure 45.1 is the graphical presentation of the data in Table 45.2. The solid blue line represents cumulative probability distributions of TSE daily index return, and the dashed red line represents the normal distribution. The bottom panel is the enlarged view of the left tail. This graph also indicates that VaR estimated using extreme values of historical distribution will lead to an overactive investment decision.

Table 45.3 reports annualized returns and standard deviations for TSE daily index and six selected industries: cement, electrical machinery, food, pulp and paper, plastics and petroleum, and textile and fiber. For the 1980–1999 period, the food industry had the greatest risk with a standard deviation of 53.47 % and 15.13 % annual return, whereas the overall market had a standard deviation of 50.80 % with 23.22 % annual return. Textile and fiber was the least risky industry with a standard deviation of 41.21 % and 12.78 % annual return. For the 1991–1999 period, the electrical machinery industry had the greatest risk with a standard

to VaR-efficient portfolios of electrical machinery and plastics and petroleum stocks, and the lower panel in Fig. 45.2 refers to VaR-efficient portfolios of cement and food stocks. VaR is set at the 95 % confidence level. Table 45.4 presents portfolio weights for different combinations of industry stocks at different levels of confidence. Asset allocations for most of the industry combinations represent corner solutions, i.e., 100 % investment in one industry. For example, when electrical machinery stocks are combined with stocks from any other industry, the optimal portfolio is 100 % investment in electrical machinery stocks, for both the time periods and the three confidence levels. Asset allocation for cement stocks is dominated by the other five industry stocks. Allocations of food stocks dominate all other stock weights except electrical machinery. The general nature of asset allocation is the same for both time periods and the confidence levels.

Suppose an investor selects the VaR constraint for maximizing S(p) at a specified level of confidence (say 95 %) and the actual VaR(c, p*) is at a higher level (97.5 %); then VaR(portfolio) will be greater that target VaR*. In this case investors will have to invest a portion of the fund in T-bills ($B > 0$, defined in Appendix). This will make investment VaR(c, p*) equal to the VaR* in the preset

constraint. In opposite case, the VaR* constraint is specified at a higher level than the portfolio VaR(c, p*); then investors will borrow money to invest in risky assets ($B < 0$). Tables 45.5 and 45.6 list examples of investment in two-industry stocks and T-bills for periods 1980–1999 and 1991–1999, respectively. In each case, the target VaR* in the preset constraint is at a 95 % level of confidence, and 1,000 yuan is invested in the portfolio. In the first panel of Table 45.5, 1,000 yuan is invested in

Two-industry portfolio with initial investment of 1,000 yuan
Allocations for other industry combinations are available to interested readers

electrical machinery stocks and 0 in cement stocks. These allocations are from Table 45.4. Portfolio VaR(c, p*) is 31.12, 42.57, and 53.92 yuan at 95 %, 97.5 %, and 99 % respectively. This leads to the lending of 0, 121, and 216 yuan to meet the target VaR of 31.12. Thus, a 97.5 % portfolio consists of 87.9 % in electrical machinery stocks, 0 in cement stocks, and 21.1 % in T-bills.

45.4 Conclusion

TSE daily index was found to be riskier than the market risk under the assumption of normal distribution for market returns. This resulted in the left tail of cumulative return distribution being fatter and a higher value at risk, indicating an overactive investment activity. For asset allocation model under a constrained VaR framework, most of the optimal portfolios have predominant investment in stocks from one industry. Hence, it will be inappropriate to comment on the optimal allocation of future investment portfolio based on the past stock performance of this unique period studied.

Appendix 1: Value at Risk

Let W_0 be the initial investment and R be the rate of return of a portfolio. The value of the portfolio at the end of the target horizon will be $W = W_0(1 + R)$. Let μ and σ be the expected return and standard deviation of R. The lowest portfolio value at the confidence level c is defined as $W^* = W_0\ (1 + R^*)$. The *relative VaR* is the dollar loss relative to the mean:

$$VaR(\text{mean}) = E(W) - W^* = -W_0(R^* - \mu) \tag{45.1}$$

The *absolute VaR* is the dollar loss relative to zero:

$$VaR(\text{zero}) = W_0 - W^* = -W_0R^* \tag{45.2}$$

W^* and R^* are minimum value and cutoff return, respectively. In this paper we are discussing *absolute VaR*. The general form of *VaR* can be derived from the probability distribution of the future portfolio value f(w). For a given confidence level c, the worst possible portfolio value W^* is such that probability of exceeding W^* is c:

$$c = \int_{\mathrm{W}*}^{\infty} f(w)dw \tag{45.3}$$

The probability of a value lower than W^*, $\mathrm{p} = \mathrm{P}(\mathrm{w} \leq \mathrm{W}^*)$ is 1–c:

$$\mathrm{p} = \mathrm{P}(\mathrm{w} \leq \mathrm{W}^*) = 1 - \mathrm{c} = \int_{-\infty}^{\mathrm{W}*} f(w)dw \tag{45.4}$$

Typical confidence level c is 95 %. This computation of VaR does not require estimation of variance-covariance matrix.

When portfolio returns are normally distributed, then distribution f(w) can be translated into a standard normal distribution Φ(ε), where ε has mean zero and standard deviation of one. VaR can be determined from the tables of the cumulative standard normal distribution:

$$\mathrm{VaR} = \mathrm{N}(1-\mathrm{c}) = \int_{-\infty}^{1-c} \varphi(\varepsilon)d\varepsilon \tag{45.5}$$

and the cutoff return $R^* = -z\sigma + \mu$. This Appendix is based on Jorion (2001). Details of normal distribution can be found in Johnson and Wichern (2007).

Appendix 2: Optimal Portfolio Under a VaR Constraint

We present an asset allocation model under a value-at-risk constraint. This model sets maximum expected loss not to exceed the VaR for a selected investment horizon, T at a given confidence level. Then asset proportions are allocated across the portfolio such that the wealth at the end of investment horizon is maximized. Suppose W_0 is the investor's initial wealth and B is the amount that the investor can borrow ($B > 0$) or lend ($B < 0$) at the risk-free interest rate r_f. Let n be the number of risky assets, γ_i be the fraction invested in risky asset i, and P(i, t) be the price of asset I at time t. Then the initial value of the portfolio

$$W_0 + B = \sum_{i=1}^{n} \gamma_i P(i, 0) \tag{45.6}$$

represents the budget constraint.

Let VaR* be the target VaR consistent with investor's risk aversion and W_T be the wealth at the end of the holding period, T. The downside risk constraint can be written as

$$\Pr\{(W_0 - W_T) \geq \mathrm{VaR}^*\} \leq (1-\mathrm{c}) \tag{45.7}$$

where Pr {.} denotes the expected probability conditioned on information available at time, $t = 0$, and c is the confidence level. Equation 45.2 can be written as

$$\Pr\{W_T \geq (W_0 - \mathrm{VaR}^*)\} \leq (1-\mathrm{c}) \tag{45.8}$$

Let r_p be the total portfolio return at the end of the holding period and T then the expected wealth at the end of holding period; T can be written as

$$\mathrm{E}(W_T) = (W_0 + B)\left(1 + r_p\right) - B(1 + r_f) \tag{45.9}$$

Investor's constrained wealth maximizing objective can be written as

$$\begin{aligned} &\text{Max.}\ \ E(W_T) \\ &\text{s.t.}\quad \Pr\{W_T \leq (W_0 - VaR^*)\} \leq (1-c) \end{aligned} \tag{45.10}$$

Performance measure $S(p)$ and borrowed amount can be deduced from Eq. 45.5. Let p^* be the maximizing portfolio and $q(\mathrm{c}, p)$ defines the quantile that corresponds to probability (1 − c) which can be obtained from portfolio return's cumulative density function. Maximizing portfolio p^* is defined as

$$p^* : \max_p \quad S(p) = \frac{r_p - r_f}{W_0 r_f - W_0 q(c, p)} \tag{45.11}$$

Initial wealth in the denominator of Eq. 45.6 is a scale constant and does not affect the asset allocation. Let VaR(c, p) denote portfolio p's VaR, and then the denominator of Eq. 45.6 can be written as

$$\Phi(c, p) = \mathrm{W_0 r_f} - \mathrm{VaR}(c, p) \tag{45.12}$$

If we consider $\mathrm{r_f}$ as the benchmark return, then $\Phi(c, p)$ represents potential for portfolio losses at the confidence level c. Performance measure S(p) represents Sharpe-like reward-risk ratio, and optimization problem becomes

Optimal portfolio:

$$p^* : \max_p \quad S(p) = \frac{r_p - r_f}{\Phi(c, p)}$$

Optimal portfolio allocation is independent of the initial wealth. It is also independent of the target VaR*. Risk measure Φ(c, p*) depends on VaR(c, p*) and not on VaR*. Investors first allocates the wealth among risky assets and then decides borrowing or lending depending on the value of {VaR* − VaR(c, p*)}. Borrowed amount B can be written as

$$B = \frac{W_0(VaR^* - VaR(c, p^*))}{\Phi'(c, p')}$$

If {VaR* − VaR(c, p*)} is positive, then there is an opportunity to increase the portfolio return by borrowing at the risk-free rate and invest it in risky asset. If {VaR* − VaR(c, p*)} is negative, then the portfolio risk needs to be reduced by investing a portion of the initial wealth in the risk-free asset. In either case the relative proration of funds invested in risky assets remains the same. Since VaR(c, p*) depends on the choice of holding period, confidence level, VaR estimation technique, and the assumption regarding the expected return distribution, the borrowing ($B > 0$) or lending ($B < 0$) will also change. This Appendix is based on Campbell et al. (2001).

Alternative Methods for Estimating Firm's Growth Rate

Contents

Abstract

The most common valuation model is the dividend growth model. The growth rate is found by taking the product of the retention rate and the return on equity. What is less well understood are the basic assumptions of this model. In this paper, we demonstrate that the model makes strong assumptions regarding the financing mix of the firm. In addition, we discuss several methods suggested in the literature on estimating growth rates and analyze whether these approaches are consistent with the use of using a constant discount rate to evaluate the firm's assets and equity.

This chapter is a slightly revised version of Chapter 64 of *Encyclopedia of Finance*, 2nd Edition and Brick et al. (2014).

The literature has also suggested estimating growth rate by using the average percentage change method, compound-sum method, and/or regression methods. We demonstrate that the average percentage change is very sensitive to extreme observations. Moreover, on average, the regression method yields similar but somewhat smaller estimates of the growth rate compared to the compound-sum method. We also discussed the inferred method suggested by Gordon and Gordon (1997) to estimate the growth rate. Advantages, disadvantages, and the interrelationship among these estimation methods are also discussed in detail.

46.1 Introduction

One of the more highly used valuation models is that developed by Gordon and Shapiro (1956) and Gordon (1962) known as the dividend growth model. In security analysis and portfolio management, growth rate estimates of earnings, dividends, and price per share are important factors in determining the value of an investment or a firm. These publications demonstrate that the growth rate is found by taking the product of the retention rate and the return on equity. What is less well understood are the basic assumptions of this model. In this paper, we demonstrate that the model makes strong assumptions regarding the financing mix of the firm.

In addition, we will also discuss several methods suggested in the literature on estimating growth rates. We will analyze whether these approaches are consistent with the use of using a constant discount rate to evaluate the firm's assets and equity. In particular, we will demonstrate that the underlying assumptions of the internal growth rate model (whereby no external funds are used to finance growth) is incompatible with the constant discount rate model of valuation.

The literature has also suggested estimating growth rate by taking the average of percentage change of dividends over a sample period, taking the geometric average of the change in dividends or using regression analysis to estimate the growth rate (e.g., Lee et al. 2009; Lee et al. 2012; Lee et al. 2000; and Ross et al. 2010). Gordon and Gordon (1997) suggest first using the Capital Asset Pricing Model (*CAPM*) to determine the cost of equity of the firm and then using the dividend growth model to infer the growth rate. Advantages, disadvantages, and the interrelationship among these estimation methods are also discussed in detail.

This paper is organized as follows. In Sect. 46.2 we present the Gordon and Shapiro model (1956). We discuss the inherent assumptions of the model and its implied method to estimate the growth rate. Section 46.3 analyzes the internal growth rate and sustainable growth rate models. Section 46.4 describes leading statistical methods for estimating firm's growth rates. We will also present the inferred method suggested by Gordon and Gordon (1997) to estimate the growth rate. Concluding remarks appear in Sect. 46.5.

46.2 The Discounted Cash Flow Model and the Gordon Growth Model

The traditional academic approach to evaluate a firm's equity is based upon the constant discount rate method. One approach uses the after-tax weighted average cost of capital as a discount rate. This model is expressed as:

$$Value\ of\ Equity = \sum_{t=1}^{\infty} \frac{CF_{ut}}{(1 + ATWACOC)^t} - Debt_t, \tag{46.1}$$

where CF_{ut} is the expected unlevered cash flow of the firm at time t and $Debt_t$ is the market value of debt outstanding. $ATWACOC$ equals $L(1 - \tau)R_d + (1 - L)r$ where L is the market value proportion of debt, τ is the corporate tax rate, R_d is the cost of debt and r is the cost of equity. The first term on the right hand side of Eq. 46.1 is the value of the assets. Subtracting out the value of debt yields the value of equity. The price per share is therefore the value of equity divided by the number of shares outstanding. Alternatively, the value of equity can be directly found by discounting the dividends per share by the cost of equity, or more formally:

$$Value\ of\ Common\ Stock\ (P_0) = \sum_{t=1}^{\infty} \frac{d_t}{(1 + r)^t}, \tag{46.2}$$

where d_t is the dividend per share at time t. Boudreaux and Long (1979), and Chambers et al. (1982) demonstrate the equivalence of these two approaches assuming that the level of that the level of debt is a constant percentage of the value of the firm.[1] Accordingly:

$$\frac{\sum_{t=1}^{\infty} \frac{X_t}{(1 + ATWACOC)^t} - Debt_t}{\text{\#of Shares Outstaning}} = \sum_{t=1}^{\infty} \frac{d_t}{(1 + r)^t} \tag{46.3}$$

If we assume that dividends per share grow at a constant rate g, then Eq. 46.2 is reduced to the basic dividend growth model[2]:

$$P_0 = \frac{d_1}{(r - g)}. \tag{46.4}$$

[1]See Brick and Weaver (1984, 1997) concerning the magnitude of error in the valuation using a constant discount rate when the firm does not maintain a constant market based leverage ratio.

[2]Gordon and Shapiro's (1956) model assume that dividends were paid continuously and hence $P_0 = d_1/(r - g)$.

Gordon and Shapiro (1956) demonstrates that if b is the fraction of earnings retained within the firm, and r is the rate of return the firm will earn on all new investments, then $g = br$. Let I_t denote the level of new investment at time t. Because growth in earnings arises from the return on new investments, earnings can be written as:

$$E_t = E_{t-1} + rI_{t-1}, \tag{46.5}$$

where E_t is the earnings in period t.[3] If the firm's retention rate is constant and used in new investment, then the earnings at time t is

$$E_t = E_{t-1} + rbE_{t-1} = E_{t-1}(1 + rb). \tag{46.6}$$

Growth rate in earnings is the percentage change in earnings and can be expressed as

$$g_E = \frac{E_t - E_{t-1}}{E_{t-1}} = \frac{E_{t-1}(1 + rb) - E_{t-1}}{E_{t-1}} = rb. \tag{46.7}$$

If a constant proportion of earnings is assumed to be paid out each year, the growth in earnings equals the growth in dividends, implying $g = br$. It is worthwhile to examine the implication of this model for the growth in stock prices over time. The growth in stock price is

$$g_P = \frac{P_{t+1} - P_t}{P_t}. \tag{46.8}$$

Recognizing that P_t and P_{t+1} can be defined by Eq. 46.4, while noting that d_{t+2} is equal to $d_{t+1}(1 + br)$ then:

$$g_P = \frac{\dfrac{d_{t+2}}{k - rb} - \dfrac{d_{t+1}}{k - rb}}{\dfrac{d_{t+1}}{k - rb}} = \frac{d_{t+2} - d_{t+1}}{d_{t+1}} = \frac{d_{t+1}(1 + br) - d_{t+1}}{d_{t+1}} = br. \tag{46.9}$$

Thus, under the assumption of a constant retention rate, for a one-period model, dividends, earnings, and prices are all expected to grow at the same rate.

The relationship between the growth rate, g, the retention rate, b, and the return on equity, r, can be expanded to a multi-period setting as the following numerical example illustrates. In this example, we assume that the book value of the firm's assets equal the market value of the firm. We will assume that the growth rate of the firm sales and assets is 4 % and the tax rate is equal to 40 %. The book value of the

[3]Earnings in this model are defined using the cash-basis of accounting and not on an accrual basis.

assets at time 0 is \$50 and we assume a depreciation rate of 10 % per annum. The amount of debt outstanding is \$12.50 and amount of equity outstanding is \$37.50. We assume that the cost of debt, R_d, is 12 % and the cost of equity, r, is 25 %, implying an *ATWACOC* of 20.55 %. The expected dividend at $t = 1$, d_1, must satisfy Eq. 46.4. That is, $37.50 = d_1/(0.25 - 0.04)$.

The unlevered cash flow is defined as Sales less Costs (excluding the depreciation expense) less Investment less the tax paid. Tax paid is defined as the tax rate (which we assume to be 40 %) times Sales minus Costs minus the Depreciation Expense. Recognizing that the value of the firm is given by $CF_{u1}/(ATWACOC - g)$, if firm value is \$50, $g = 4$ % and *ATWACOC* is 20.55 %, then the expected unlevered cash flow is at time 1 is \$8.28. We assume that the asset turnover ratio is 1.7. Hence, if assets at time 0 is \$50, the expected sales at time 1 is \$85. To obtain the level of investment, note that the depreciation expense at time 1 is \$5. If the book value of assets equals \$52, then the firm must invest \$7. To obtain an expected unlevered cash flow at $t = 1$ of \$8.28, the Gross Profit Margin is assumed to be approximately 26.03 %, resulting in expected costs at time 1 of \$62.88. The interest expense at time 1, is the cost of debt times the amount of debt outstanding at time zero, or \$1.50. The Earnings Before Taxes (*EBT*) is defined as Sales – Costs – Interest Expense – Depreciation Expense, which equals \$15.63 at time 1. 40 % of *EBT* is the taxes paid or \$6.25 resulting in a net income (*NI*) of \$9.38. *ROE*, which equals Net Income/Book Value of Equity at the beginning of the period is 25 %. Since the aggregate level of dividends at time 1 is \$7.88, then the dividend payout ratio $(1 - b)$ is 84 %. Note that b is therefore equal to 16 % and $b \times ROE = 4\%$.[4]

Further note that the firm will increase its book value of equity via retention of *NI* by \$1.50 (*RE* in the table). In order to maintain a leverage ratio of 25 %, the firm must increase the level of debt from time 0 to time 1 by \$0.50. The entries for time periods 2–5 follow the logical extension of the above discussion, and as shown in the table, the retention rate b is 16 % and $ROE = 25$ % for each period. Again the product of b and *ROE* results in the expected growth rate of 4 %. Further note, that $g = 4$ % imply that sales, costs, book value of asset, depreciation, unlevered cash flow, cash flow to stockholders, value of debt and value of equity to increase by 4 % per annum.

Investors may use a one-period model in selecting stocks, but future profitability of investment opportunities plays an important role in determining the value of the firm and its *EPS* and dividend per share. The rate of return on new investments can be expressed as a fraction, c (perhaps larger than 1), of the rate of return security holders require (r):

$$k = cr. \tag{46.10}$$

[4]Generally, practioners define ROE as the ratio of the Net Income to the end of year Stockholders Equity. Here we are defining ROE as the ratio of the Net Income to the beginning of the year Stockholders Equity. Brick et al. (2012) demonstrate that the practitioner's definition is one of the sources for the Bowman Paradox reported in the Organization Management literature.

Table 46.1 The book value of the firm's assets equal the market value of the firm (growth rate is 4 %)

	0	1	2	3	4	5

Tax		\$6.25	\$6.50	\$6.76	\$7.03	\$7.31
NI		\$9.38	\$9.75	\$10.14	\$10.55	\$10.97
DIV		\$7.88	\$8.19	\$8.52	\$8.86	\$9.21
New debt		\$.50	\$0.52	\$0.54	\$0.56	\$0.59
CF_u		\$8.28	\$8.61	\$8.95	\$9.31	\$9.68
Firm value	\$50.00	\$52.00	\$54.08	\$56.24	\$58.49	\$60.83
Investment		\$7.00	\$7.28	\$7.57	\$7.87	\$8.19
Vequity	\$37.50	\$39.00	\$40.56	\$42.18	\$43.87	\$45.62
RE		\$1.50	\$1.56	\$1.62	\$1.69	\$1.75
ROE		0.25	0.25	0.25	0.25	0.25
1-b		0.84	0.84	0.84	0.84	0.84
g		0.04	0.04	0.04	0.04	0.04

Substituting this into the well-known relationship that $r = \frac{d_1}{P_0} + g$ and rearranging, we have

$$k = \frac{(1-b)E_1}{(1-cb)P_0}. \tag{46.11}$$

If a firm has no extraordinary investment opportunities ($r = k$), then $c = 1$ and the rate of return that security holders require is simply the inverse of the stock's price to earnings ratio. In our example of Table 46.1, *NI* at time 1 is \$9.38 and the value of equity at time 0 is \$37.50. The ratio of these two numbers (which is equivalent to *EPS*/*P*) is *ROE* or 25 %.

On the other hand, if the firm has investment opportunities that are expected to offer a return above that required by the firm's stockholders ($c > 1$), the earnings to price ratio at which the firm sells will be below the rate of return required by investors. To illustrate consider the following example whereby market value of the

Table 46.2 The market value of the firm and equity is greater than its book value

firm and equity is greater than its book value. This example is depicted in Table 46.2. The basic assumptions of the model is as follows: We will assume that the growth rate of the firm sales and book value of the assets is 4 %. The book value of the assets at time 0 is again $50 and we assume a depreciation rate of 10 % per annum. However, note that the market value of the firm is $60. The entries for Debt and Equity represent market values. The amount of debt outstanding is $12.50 and amount of equity outstanding is now $47.50. We assume that the cost of debt, R_d, is 12 % and the cost of equity, r, is 25 %, implying an *ATWACOC* of 21.29 %. For the valuation of the firm to be internally consistent, the unlevered cash flow at time 1 is $10.38. Similarly, the value of equity to be internally consistent, the expected dividends at $t = 1$ is $9.98. Note that net income is $11.88 implying a dividend payout ratio of 84 % and a retention rate of 16 %. The *book value based ROE*, k, is found by taking the net income divided by the book value of equity. In our example, implied book value of equity is $37.50. Hence, $k = 31.68$ %, implying that the book value ROE is greater than the cost of equity which is the required rate of return. But g is given by the *market value based ROE* which is defined as Net Income over market value of equity. That is $r = 25$ %. Note again, br is 4 %.

An investor could predict next year's dividends, the firm's long-term growth rate, and the rate of return stockholders require (perhaps using the *CAPM* to estimate r) for holding the stock. Equation 46.4 could then be solved for the theoretical price of the stock that could be compared with its present price. Stocks that have theoretical prices above actual price are candidates for purchase; those with theoretical prices below their actual price are candidates for sale or for short sale.

46.3 Internal Growth Rate and Sustainable Growth Rate Models

The internal growth rate model assumes that the firm can only finance its growth by its internal funds. Consequently, the cash to finance growth must come from only retained earnings. Therefore, retained earnings can be expressed as

$$\begin{aligned}\text{Retained Earnings} &= \text{Earnings} - \text{Dividends}\\ &= \text{Profit Margin} \times \text{Total Sales-Dividends}\\ &= p(S+\Delta S) - p(S+\Delta S)(1-b)\\ &= pb(S+\Delta S),\end{aligned} \tag{46.12}$$

where

$p =$ the profit margin on all sales;

$S =$ annual sales; and

$\Delta S =$ the increase in sales during the year.

Because retained earnings is the only source of new funds, the use of cash represented by the increase in assets must equal the retained earnings:

$$\text{Uses of Cash} = \text{Sources of Cash}$$

$$\text{Increases in Assets} = \text{Retained earnings}$$

$$\begin{aligned}\Delta ST &= p(S+\Delta S)b\\ &= pbS + pb\Delta S,\end{aligned}$$

$$\Delta S[T - pb] = pSb,$$

$$\frac{\Delta S}{S} = \frac{pb}{T - pb}, \tag{46.13}$$

where $T =$ the ratio of total assets to sales. If we divide both numerator and denominator of Eq. 46.13 by T and make rearrange the terms, then we can show that the internal growth rate is:

$$g = \frac{\Delta S}{S} = \frac{pb/T}{1 - pb/T} = \frac{b \times ROA}{1 - b \times ROA}, \tag{46.14}$$

where *ROA* is the return on assets. The internal growth rate is the maximum growth rate that can be achieved without debt or equity kind of external financing. But note this assumption of not issuing new debt or common stock to finance growth is inconsistent with the basic assumption of the constant discount rate models that the firm maintains a constant market based leverage ratio. Hence, this model cannot be used to estimate the growth rate and be employed by the Gordon Growth Model.

Higgins (1977, 1981, 2008) has developed a sustainable growth rate under assumption that firms can generate new funds by using retained earnings or issuing debt, but not issuing new shares of common stock. Growth and its management present special problems in financial planning. From a financial perspective, growth is not always a blessing. Rapid growth can put considerable strain on a company's resources, and unless management is aware of this effect and takes active steps to control it, rapid growth can lead to bankruptcy. Assuming a company is not raising new equity, the cash to finance growth must come from retained earnings and new borrowings. Further, because the company wants to maintain a target debt-to-equity ratio equal to *L*, each dollar added to the owners' equity enables it to increase its indebtedness by $*L*. Since the owners' equity will rise by an amount equal to retained earnings, the new borrowing can be written as:

$$\begin{aligned}\text{New Borrowings} &= \text{Retained Earnings} \times \text{Target Debt-to-Equity Ratio} \\ &= pb(S + \Delta S)L.\end{aligned}$$

The use of cash represented by the increase in assets must equal the two sources of cash (retained earnings and new borrowings)[5]:

$$\text{Uses of Cash} = \text{Sources of Cash}$$

$$\text{Increases in Assets} = \text{Retained Earnings} + \text{New Borrowing}$$

$$\begin{aligned}\Delta ST &= pb(S + \Delta S) + pb(S + \Delta S)L \\ &= pb(1 + L)S + pb(1 + L)\Delta S\end{aligned}$$

$$\Delta S[T - pb(1 + L)] = pb(1 + L)S$$

$$g = \frac{\Delta S}{S} = \frac{pb(1 + L)}{T - pb(1 + L)}. \tag{46.15}$$

[5]Increased in Assets is the net increase in assets. The total investment should also include the depreciation expense as can be seen in our examples delineated in Tables 46.1 and 46.2. But depreciation expense is also a source of funding. Hence, it is netted out in the relationship between increases in assets and retained earnings and new borrowings.

In Eq. 46.15 the $\Delta S/S$ or g is the firm's sustainable growth rate assuming no infusion of new equity. Therefore, a company's growth rate in sales must equal the indicated combination of four ratios, p, b, L, and T. In addition, if the company's growth rate differs from g, one or more of the ratios must change. For example, suppose a company grows at a rate in excess of g, then it must either use its assets more efficiently, or it must alter its financial policies. Efficiency is represented by the profit margin and asset-to-sales ratio. It therefore would need to increase its profit margin (p) or decrease its asset-to-sales ratio (T) in order to increase efficiency. Financial policies are represented by payout or leverage ratios. In this case, a decrease in its payout ratio (1-b) or an increase in its leverage (L) would be necessary to alter its financial policies to accommodate a different growth rate. It should be noted that increasing efficiency is not always possible and altering financial policies are not always wise.

If we divide both numerator and denominator of Eq. 46.15 by T and rearrange the terms, then we can show that the sustainable growth rate can be shown as

$$g = \frac{\Delta S}{S} = \frac{pb(1+L)/T}{1 - pb(1+L)/T} = \frac{b \times ROE}{1 - b \times ROE}. \tag{46.16}$$

Please note that, in the framework of internal growth rate and sustainable growth rate presented above, the source of cash are taken from the end of period values of assets and assumed that the required financing occurs at the end of the period. However, Ross et al. (2010) show that if the source of cash is from the beginning of the period, the relationship between the use and the source of cash can be expressed for the internal growth rate model as $\Delta ST = pSb$ and for the sustainable growth rate model, $\Delta ST = pbS + pbSL$. Such relationship will result an internal growth rate of $b \times ROA$ and a sustainable growth rate of $b \times ROE$. For example, Table 46.3 assumes identical assumptions to that of Table 46.1, but now we will assume a growth rate of 4.1667 % and use total asset, total equity, and total debt from the beginning of the period balance sheet to calculate the net income. Recall that ROE is the net income divided by stockholders' equity at the beginning of the period. Note that the product of ROE and b will yield 4.1667 %.

Note that the intent of the Higgins' sustainable growth rate allows only internal source and external debt financing. Chen et al. (2013) incorporate Higgins (1977) and Lee et al. (2011) frameworks, allowing company use both external debt and equity, and derive a generalized sustainable growth rate as

$$g(t) = \frac{b \times ROE}{1 - b \times ROE} + \frac{\lambda \cdot \Delta n \cdot P/E}{1 - b \times ROE}, \tag{46.17}$$

where

$\lambda =$ degree of market imperfection;
$\Delta n =$ number of shares of new equity issued;
$P =$ price per share of new equity; and
$E =$ total equity.

Table 46.3 The book value of the firm's assets equal the market value of the firm (sustainable growth rate is 4.1667 %)

g		0.041667	0.041667	0.041667	0.041667	0.041667

Comparing Eq. 46.17, the generalized sustainable growth rate has an additional positive term, $\frac{\lambda \cdot \Delta n \cdot p/E}{1-(1-D)ROE}$, when the new equity issue is taken into account. Therefore, Chen et al. (2013) show that Higgins' (1977) sustainable growth rate is underestimated because of the omission of the source of the growth related to new equity issue.

46.4 Statistical Methods

Instead of relying on financial ratios to estimate firm's growth rates, one may use statistical methods to determine firm's growth rates. A simple growth rate can be estimated by calculating the percentage change in earnings over a time period, and taking the arithmetic average. For instance, the growth rate in earnings over one period can be expressed as:

$$g_t = \frac{E_t - E_{t-1}}{E_{t-1}}. \tag{46.18}$$

The arithmetic average is given by

$$\overline{g} = \frac{1}{n}\sum_{t=1}^{n} g_t. \tag{46.19}$$

A more accurate estimate can be obtained by solving for the compounded growth rate:

$$X_t = X_0(1+g)^t, \tag{46.20}$$

or

$$g = \left(\frac{X_t}{X_0}\right)^{1/t} - 1, \tag{46.21}$$

where

X_0 = measure in the current period (measure can be sales, earnings, or dividends); and

X_t = measure in period t.

This method is called the *discrete compound sum* method of growth-rate estimation. For this approach to be consistent with the dividend growth model, the duration of each period (e.g., quarterly or yearly) must be consistent with the compounding period used in the dividend growth model.

Another method of estimating the growth rate uses the continuous compounding process. The concept of continuous compounding process can be expressed mathematically as

$$X_t = X_0 e^{gt}. \tag{46.22}$$

Equation 46.21 describes a discrete compounding process and Eq. 46.22 describes a continuous compounding process. The relationship between Eqs. 46.21 and 46.22 can be illustrated by using an intermediate expression such as:

$$X_t = X_0\left(1 + \frac{g}{m}\right)^{mt}, \tag{46.23}$$

where m is the frequency of compounding in each year. If $m = 4$, Eq. 46.23 implies a quarterly compounding process; if $m = 365$, it describes a daily process; and if m approaches infinity, it describes a continuous compounding process. Thus Eq. 46.22 can be derived from Eq. 46.23 based upon the definition

$$\lim_{m \to \infty} \left(1 + \frac{1}{m}\right)^m = e. \tag{46.24}$$

Then the continuous analog for Eq. 46.20 can be rewritten as

$$\lim_{m \to \infty} X_t = \lim_{m \to \infty} X_0 \left(1 + \frac{g}{m}\right)^{mt} = X_0 \lim_{m \to \infty} \left(1 + \frac{1}{m/g}\right)^{\left(\frac{m}{g}\right)gt} = X_0 e^{gt}. \tag{46.25}$$

Therefore, the growth rate estimated by continuous compound-sum method can be expressed by

$$g = \frac{1}{t} \ln \frac{X_t}{X_0}. \tag{46.26}$$

If you estimate the growth rate via Eq. 46.26, you are implicitly assuming the dividends are growing continuously and therefore the dividend growth model. In this case, according to Gordon and Shapiro's (1956) model, $P_0 = d_0/(r - g)$.

To use all the information available to the security analysts, two regression equations can be employed. These equations can be derived from Eqs. 46.20 and 46.22 by taking the logarithm (*ln*) on both sides of equation:

$$\ln X_t = \ln X_0 + t \ln(1 + g). \tag{46.27}$$

If Eq. 46.27 can be used to estimate the growth rate, then the antilog of the regression slope estimate would equal the growth rate. For the continuous compounding process,

$$\ln X_t = \ln X_0 + gt. \tag{46.28}$$

Both Eqs. 46.27 and 46.28 indicate that X_n is linearly related to t; and the growth rate can be estimated by the ordinary least square (OLS) regression. For example, growth rates for *EPS* and *DPS* can be obtained from an OLS regression by using

$$\ln\left(\frac{\text{EPS}_t}{\text{EPS}_0}\right) = a_0 + a_1 T + \varepsilon_{1t}, \tag{46.29}$$

and

$$\ln\left(\frac{\text{DPS}_t}{\text{DPS}_0}\right) = b_0 + b_1 T + \varepsilon_{2t}, \tag{46.30}$$

where EPS_t and DPS_t are earnings per share and dividends per share, respectively, in period t, and T is the time indicators (i.e., $T = 1, 2, \ldots, \text{n}$). We denote $\hat{a}_1$ and $\hat{b}_1$ as

Table 46.4 Dividend behavior of firms Pepsico and Wal-Mart in dividends per share (*DPS*)

Year	T	PEP	WMT	Year	T	PEP	WMT
1981	1	3.61	1.73	1996	16	0.72	1.33
1982	2	2.4	2.5	1997	17	0.98	1.56
1983	3	3.01	1.82	1998	18	1.35	1.98
1984	4	2.19	1.4	1999	19	1.4	1.25
1985	5	4.51	1.91	2000	20	1.51	1.41
1986	6	1.75	1.16	2001	21	1.51	1.49
1987	7	2.30	1.59	2002	22	1.89	1.81
1988	8	2.90	1.11	2003	23	2.07	2.03
1989	9	3.40	1.48	2004	24	2.45	2.41
1990	10	1.37	1.9	2005	25	2.43	2.68
1991	11	1.35	1.14	2006	26	3.42	2.92
1992	12	1.61	1.4	2007	27	3.48	3.17
1993	13	1.96	1.74	2008	28	3.26	3.36
1994	14	2.22	1.02	2009	29	3.81	3.73
1995	15	2.00	1.17	2010	30	3.97	4.2

the estimated coefficients for Eqs. 46.29 and 46.30. The estimated growth rates for *EPS* and *DPS*, therefore, are $\exp(\hat{a}_1) - 1$ and $\exp(\hat{b}_1) - 1$ in terms of discrete compounding process and $\hat{a}_1$ and $\hat{b}_1$ in terms of continuous compounding process.[6]

Table 46.4 provides dividends per share of Pepsico and Wal-Mart during the period from 1981 to 2010. Using the data in Table 46.4 for companies Pepsico and Wal-Mart, we can estimate the growth rates for their respective dividend streams. Table 46.5 presents the estimated the growth rates for Pepsico and Wal-Mart by arithmetic average method, geometric average method, compound-sum method, and the regression method in terms of discrete and continuous compounding processes. Graphs of the regression equations for Pepsico and Wal-Mart are shown in Fig. 46.1.

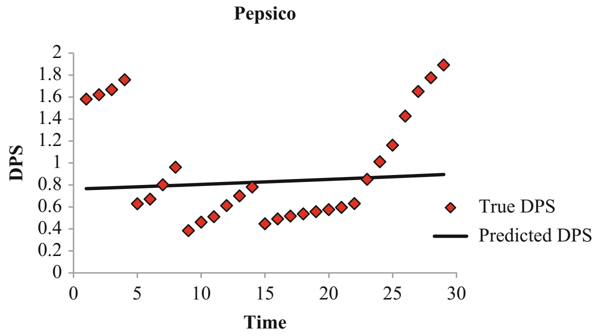
The slope of the regression for Pepsico shows an estimated coefficient for the intercept is 0.56. The estimated intercept for Wal-Mart is 7.04. The estimated growth rates for Pepsico and Wal-Mart, therefore, are 0.56 % and 7.29 % in terms of discrete compounding process. Figure 46.1 also shows the true DPS and predicted DPS for Pepsico and Wal-Mart. We find that the regression method, to some extent, can estimate the growth rate for Wal-Mart more precisely than for Pepsico. Comparing to the geometric average method, the regression method yields a similar value of the estimated growth rate for Wal-Mart, while not for Pepsico.

There are some complications to be aware of when employing the arithmetic average, the geometric average, and regression model in estimating the growth rate. The arithmetic average is quite sensitive to extreme values. The arithmetic average, therefore, has an upward bias that increases directly with the variability of the data.

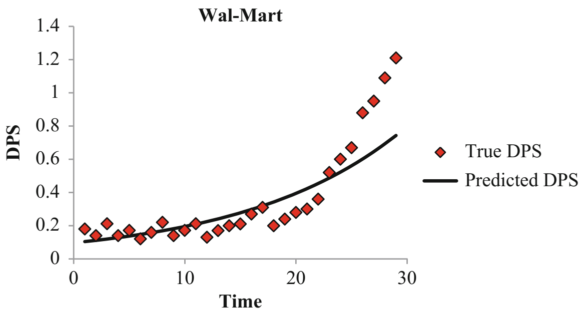
[6]If the earnings (or dividend) process follows Eq. 46.27, we can get same results from the non-restricted model as Eqs. 46.29 and 46.30.

Table 46.5 Estimated dividend growth rates for Pepsico and Wal-Mart

	Pepsico (%)	Wal-Mart (%)
Arithmetic average	4.64	8.99
Geometric average	0.99	5.45
Compound-sum method	0.99	5.30
Regression method (continuous)	0.56	7.04
Regression method (discrete)	0.56	7.29



$$\ln\left(\frac{DPS_t}{DPS_0}\right) = \underset{(0.0056)}{-0.6236} + \underset{(0.0113)}{0.1947}\, T + \varepsilon_t$$



$$\ln\left(\frac{DPS_t}{DPS_0}\right) = \underset{(0.1286)}{-0.9900} + \underset{(0.0075)}{0.0704}\, T + \varepsilon_t$$

Fig. 46.1 Regression models for Pepsico and Wal-Mart

Consider the following situation. Dividends in years 1, 2 and 3 are \$2, \$4 and \$2. The arithmetic average of growth rate is 25 % but the true growth rate is 0 %. The difference in the two average techniques will be greater when the variability of the data is larger. Therefore, it is not surprising that we find differences in the estimated growth rates using arithmetic average and geometric average methods for Pepsico and Wal-Mart in Table 46.5.

Table 46.6 Estimated dividend growth rates for 50 randomly selected companies

	50 Firms (%)	Firms with positive growth (35 firms) (%)	Firms with negative growth (15 firms) (%)
Arithmetic average	4.95	7.27	−0.47
Geometric average	0.93	3.00	−3.88
Compound-sum method	0.83	2.91	−4.02
Regression method (continuous)	0.66	2.32	−3.22
Regression method (discrete)	0.71	2.37	−3.15

The regression method uses more available information than the geometric average, discrete compounding and continuous compounding methods in that it takes into account the observed growth rates between the first and last period of the sample. A null hypothesis test can be used to determine whether the growth rate obtained from the regression method is statistically significantly different from zero or not. However, logarithms cannot be taken with zero or negative numbers. Under this circumstance the arithmetic average will be a better alternative.

We further randomly select 50 companies from S&P 500 index firms, which paid dividends during 1981–2010, to estimate their dividend growth rates by arithmetic average method, geometric average method, compound-sum method, and the regression method in terms of discrete and continuous compounding processes. Table 46.6 shows averages of estimated dividend growth rates for 50 random companies by different methods. As we discussed before, the arithmetic average is sensitive to extreme values and has an upward bias. We, therefore, find a larger average of the estimated dividend growth rate using the arithmetic average method. We also find that on average, the geometric, and compound sum methods yield relatively smaller growth rate estimates as compared to the estimates obtained using the regression methods to estimate growth rate. However, it appears that estimates obtained using the geometric, compound sum and regression methods are very similar.

Finally, Gordon and Gordon (1997) suggest that one can infer the growth rate using the dividend growth model. In particular, the practitioner can use regression analysis to calculate the beta of the stock and use the *CAPM* to estimate the cost of equity. Since

$$P_0 = \frac{d_0(1+g)}{(r-g)} \tag{46.31}$$

and the price of the stock is given by the market, the cost of equity is obtained using the *CAPM*, and d_0 and the current dividend is known, one can infer the growth rate using Eq. 46.31. If the inferred growth rate is less than the practitioner's estimate, then the recommendation will be to buy the stock. On the other hand, if the inferred growth is greater than the practitioner's estimate, the recommendation will be to sell the stock. However, it should be noted that the explanatory power of the *CAPM* to explain the relationship between stock returns and risk has been extensively questioned in the literature. See for example, Fama and French (1992).

46.5 Conclusion

The most common valuation model is the dividend growth model. The growth rate is found by taking the product of the retention rate and the return on equity. What is less well understood are the basic assumptions of this model. In this paper, we demonstrate that the model makes strong assumptions regarding the financing mix of the firm. In addition, we discuss several methods suggested in the literature on estimating growth rates and analyze whether these approaches are consistent with the use of using a constant discount rate to evaluate the firm's assets and equity. In particular, we demonstrate that the underlying assumptions of the internal growth rate model (whereby no external funds are used to finance growth) are incompatible with the constant discount rate model of valuation. The literature has also suggested estimating growth rate by using the average percentage change method, compound-sum method, and/or regression methods. We demonstrate that the average percentage change is very sensitive to extreme observations. Moreover, on average, the regression method yields similar but somewhat smaller estimates of the growth rate compared to the compound-sum method. We also discussed the inferred method suggested by Gordon and Gordon (1997) to estimate the growth rate. Advantages, disadvantages, and the interrelationship among these estimation methods are also discussed in detail. Choosing an appropriate method to estimate firm's growth rate can yield a more precise estimation and be helpful for the security analysis and valuation. However, all of these methods use historical information to obtain growth estimates. To the extent that the future may differ from the past, will ultimately determine the efficacy of any of these methods.

Econometric Measures of Liquidity

47

Jieun Lee

Contents

Abstract

A security is *liquid* to the extent that an investor can trade significant quantities of the security quickly, at or near the current market price, and bearing low transaction costs. As such, liquidity is a multidimensional concept. In this chapter, I review several widely used econometrics or statistics-based measures that researchers have developed to capture one or more dimensions of a security's liquidity (i.e., limited dependent variable model (Lesmond, D. A. et al. *Review of Financial Studies, 12*(5), 1113–1141, 1999) and autocovariance of price changes (Roll, R., *Journal of Finance, 39*, 1127–1139, 1984). These alternative proxies have been designed to be estimated using either low-frequency or high-frequency

data, so I discuss four liquidity proxies that are estimated using low-frequency data and two proxies that require high-frequency data. Low-frequency measures permit the study of liquidity over relatively long time horizons; however, they do not reflect actual trading processes. To overcome this limitation, high-frequency liquidity proxies are often used as benchmarks to determine the best low-frequency proxy. In this chapter, I find that estimates from the effective tick measure perform best among the four low-frequency measures tested.

Keywords

Liquidity • Transaction costs • Bid-ask spread • Price impact • Percent effective spread • Market model • Limited dependent variable model • Tobin's model • Log likelihood function • Autocovariance • Correlation analysis

47.1 Introduction

A security is *liquid* to the extent that an investor can trade significant quantities of the security quickly, at or near the current market price, and bearing low transaction costs. A security's liquidity is an important characteristic variable, relevant in asset pricing studies, studies of market efficiency, and even corporate finance. In the asset pricing literature, researchers have considered whether liquidity is a priced risk factor (e.g., Amihud and Mendelson 1986; Brennan and Subrahmanyam 1996; Amihud 2002; Pastor and Stambaugh 2003). In corporate finance, researchers have found that liquidity is related to capital structure, mergers and acquisitions, and corporate governance (e.g., Lipson 2003; Lipson and Mortal 2007, 2009; Bharath 2009; Chung et al. 2010).

In these and many other studies, researchers have chosen from a variety of liquidity measures that have been developed. In turn, the variety of available liquidity measures reflects the multidimensional aspect of liquidity. Note that the definition of liquidity given above features four dimensions of liquidity: trading quantity, trading speed, price impact, and trading cost. Some extant measures focus on a single dimension of liquidity, while others encompass several dimensions. For instance, the bid-ask spread measure in Amihud and Mendelson (1986), the estimator of the effective spread in Roll (1984), and the effective tick estimator in Goyenko et al. (2009) relate to the trading cost dimension. The turnover measure of Datar et al. (1998) captures the trading quantity dimension. The measures in Amihud (2002) and Pastor and Stambaugh (2003) are relevant to price impact. The number of zero trading volume days in Liu (2006) emphasizes trading speed. Finally, and different from the others, the measure in Lesmond et al. (1999) encompasses several dimensions of liquidity.

Among the available measures, this chapter focuses on six liquidity proxies, including four that are commonly estimated using low-frequency data (i.e., daily closing prices) and two that are commonly estimated using high-frequency data (i.e., intraday trades and quotes). The low-frequency measures are in Roll (1984), Goyenko et al. (2009), Lesmond et al. (1999), and Amihud (2002).

The high-frequency measures are the percent quoted spread and the percent effective spread. The low-frequency proxies are advantageous because they are more amenable to the study of liquidity over relatively long time horizons and across countries. However, they are limited because they do not directly reflect actual trading processes, while the high-frequency measures do. Thus, high-frequency liquidity proxies are often used as benchmarks to determine the best low-frequency proxy. This is not a universal criterion, however, because each measure captures a different dimension of liquidity and may lead to different results in specific cross-sectional or time-series applications.

The remainder of this chapter is organized as follows. In Sects. 47.2 and 47.3, I introduce and briefly discuss each of the low-frequency and high-frequency liquidity measures, respectively. Section 47.4 provides an empirical analysis of these liquidity measures, including the aforementioned test of the best low-frequency measure. Section 47.5 concludes.

47.2 Low-Frequency Liquidity Proxies

Below I describe four widely used measures of liquidity: the Roll (1984) measure; effective tick; the Amihud (2002) measure; and the Lesmond et al. (1999) measure.

47.2.1 The Roll Measure

Roll (1984) develops a measure of the *effective* bid-ask spread. He assumes that the true value of a stock follows a random walk and that P_t, the observed closing price on day t, is equal to the stock's true value plus or minus half of the effective spread. He also assumes that a security trades at either the bid price or the ask price, with equal frequency. This relationship can be expressed as follows:

$$P_t = P_t^* + Q_t \frac{S}{2}$$

$$Q_t \sim \mathrm{IID}\begin{bmatrix} +1 \text{ with probability } 1/2 \ \text{(buyer initiated)} \\ -1 \text{ with probability } 1/2 \ \text{(seller initiated)} \end{bmatrix}$$

where Q_t is an order-type indicator variable, indicating whether the transaction at time t is at the ask (buyer-initiated) or at the bid (seller-initiated) price. His assumption that P_t^* is the fundamental value of the security implies that $E[Q_t] = 0$; hence, $\Pr(Q_t = 1) = \Pr(Q_t = -1) = 1/2$. Also, there are no changes in the fundamental value of the security (i.e., over a short horizon).

It follows that the process for price changes ΔP_t is

$$\Delta P_t = \Delta P_t^* + \left(Q_t - Q_{(t-1)}\right)\frac{S}{2} = \left(Q_t - Q_{(t-1)}\right)\frac{S}{2}.$$

Under the assumption that Q_t is IID, the variance and covariance of ΔP_t can be easily calculated:

$$\mathrm{var}[\Delta P_t] = \frac{s^2}{2}.$$

$$\mathrm{cov}[\Delta P_t, \Delta P_{t-1}] = -\frac{s^2}{4}.$$

$$\begin{aligned}
\mathrm{cov}[\Delta P_t, \Delta P_{t-1}] &= \mathrm{cov}\left[\frac{s}{2}(Q_t - Q_{t-1}), \frac{s}{2}(Q_{t-1} - Q_{t-2})\right] \\
&= \frac{s^2}{4}[\mathrm{cov}(Q_t - Q_{t-1}), \mathrm{cov}(Q_{t-1} - Q_{t-2})] \\
&= \frac{s^2}{4}[\mathrm{cov}(Q_t, Q_{t-1}) - \mathrm{cov}(Q_{t-1}, Q_{t-1}) \\
&\quad + \mathrm{cov}(Q_{t-1}, Q_{t-2}) - \mathrm{cov}(Q_t, Q_{t-2})] \\
&= \frac{s^2}{4}[-\mathrm{var}(Q_{t-1})] = -\frac{s^2}{4}\left[\frac{1}{2}(1-0)^2 + \frac{1}{2}(-1-0)^2\right] = -\frac{s^2}{4}
\end{aligned}$$

$$\mathrm{cov}[\Delta P_t, \Delta P_{k-1}] = 0, k > 1.$$

Solving for S yields Roll's effective spread estimator:

$$S = 2\sqrt{-\mathrm{Cov}\left(\Delta P_{t,}, \Delta P_{t-1}\right)}.$$

Roll's measure is simple and intuitive: If P* is fixed so that prices take only two values, bid or ask, and if the current price is the bid, then the change between current price and previous price must be either 0 or –s and the price change between current price and next price must be either 0 or s. Analogous possible price changes apply when the current price is the ask.

The Roll measure S is generally estimated using daily data on price changes. Roll (1984) and others have found that for some individual stocks, the autocovariance that defines S is positive, rather than negative, so that S is undefined. In this case, researchers generally choose one of three solutions: (1) treat the observation as missing, (2) set the Roll spread estimate to zero, or (3) multiply the covariance by negative one, calculate S, and multiply this estimate by negative one to produce a negative spread estimate. In my empirical analysis to follow, I find that results are insensitive to the alternative solutions, so I only report results of setting S to zero when the observed autocovariance is positive.

47.2.2 Effective Tick

Goyenko et al. (2009) and Holden (2009) develop an *effective tick* measure that is based on price clustering and changes in tick size. Below I describe the effective tick measure in Goyenko et al. (2009), which is elegant in its simplicity.

Consider four possible bid-ask spreads for a stock: \$1/8, \$1/4, \$1/2, and \$1. If the spread is \$1/4, the authors assume that bid and ask prices are associated with only even quarters. Thus, if an odd-eighth transaction price shows up, it is instead inferred that the spread is \$1/8. The number of quotes that occur at \$1/8 spread is given by N_1. The number of quotes at odd-quarter fractions (\$1/8 and \$1/4) is N_2. The number of quotes at odd-half (\$1/8, \$1/4, and \$1/2) is N_3. Finally, the number of whole dollar quotes is given by N_4. The following is the proportion of each price fraction observed during the day:

$$F_i = \frac{Ni}{\sum_{i=1}^{I} Ni} \quad \text{for } i = 1, \ldots, I.$$

Next, suppose that the unconstrained probability of the effective *i*th estimated spread is

$$\begin{array}{c} 2F_i \;\; i = 1 \\ U = 2F_i - F_{i-1} \;\; i = 2, \ldots, i \\ F_i - F_{i-1} \;\; i = I. \end{array}$$

The effective tick is a simply probability-weighted average of effective spread size divided by average price in a given time interval:

$$\text{Effective Tick}_{it} = \frac{\sum_{i=1}^{I} a * S_i}{P},$$

where the probability a is constrained to be nonnegative and to be no more than 1 minus the probability of a finer spread, S is the spread, and P is the average price in the time interval.

To obtain estimates of effective tick in this chapter, I must deal with changes in minimum tick size that were instituted over time in the US equity markets. For NYSE, AMEX, and NASDAQ stocks from 1/93 to 5/97, I used a fractional grid accounting for price increments as small as \$1/8. For NYSE and AMEX (NASDAQ) stocks from 6/97 to 1/01 (6/97 to 3/01), I used a minimum tick size increment of \$1/16. Thereafter, I used a decimal grid for all stocks.

47.2.3 Amihud (2002)

The measures in Amihud (2002) and Pastor and Stambaugh (2003) both purport to capture the price impact dimension of liquidity. Goyenko et al. (2009) show that the Amihud (2002) measure performs well in measuring price impact while the Pastor and Stambaugh (2003) measure is dominated by other measures. Pastor and Stambaugh (2003, p. 679) also caution against their measure as a liquidity measure for individual stocks, reporting large sampling errors in individual estimates.

Referring also to Hasbrouck (2009), I do not discuss the Pastor and Stambaugh (2003) measure. The Amihud (2002) measure is a representative proxy for price impact, i.e., the daily price response associated with one dollar of trading volume:

$$\mathrm{Ami}_{\mathrm{it}} = \frac{|\mathrm{Ret}_{\mathrm{it}}|}{\mathrm{Vol}_{\mathrm{it}}},$$

where $\mathrm{Ret}_{\mathrm{it}}$ is the stock i's return on day t and $\mathrm{Vol}_{\mathrm{it}}$ is the stock i's dollar volume on day t. The average is calculated over all positive-volume days, since the ratio is undefined for zero volume days.

47.2.4 Lesmond, Ogden, and Trzcinka (LOT 1999)

The Lesmond et al. (LOT 1999) liquidity measure is based on the idea that an informed trader observing a mispriced stock will execute a trade only if the difference between the current market price and the true price exceeds the trader's transaction costs; otherwise, no trade will occur. Therefore, they argue that a stock with high transaction costs will have less frequent price movements and more zero returns than a stock with low transaction costs. Based on this relationship, they develop a measure of the marginal trader's effective transaction costs for an individual stock. Their measure utilizes the limited dependent variable regression model of Tobin (1958) and Rosett (1959) applied to the "market model."

47.2.4.1 Market Model

The basic market model is a regression of the return, R^*_{it} on security i and period t, on the contemporaneous market return, R_{mt}:

$$R^*_{\mathrm{it}} = a_i + \beta_i R_{\mathrm{mt}} + \varepsilon_{\mathrm{it}} \tag{47.1}$$

The market model implies that a security's return reflects the effect of new information on the value of the stock, which can be divided into two components: contemporaneous market-wide information ($\beta_i R_{\mathrm{mt}}$) and firm-specific information $\varepsilon_{\mathrm{it}}$. In an ideal market without frictions such as transaction costs, new information will be immediately reflected into the security's price, so R^*_{it} is the true return on security i.

47.2.4.2 Relationship Between Observed and True Returns

In the presence of transaction costs, investors will trade only when the marginal profits exceed the marginal transaction costs. In this context, transaction costs would include various dimensions such as bid-ask spread, commissions, and price impact, as well as taxes or short-selling costs, because investors make trading decisions after considering overall transaction costs. Transaction costs inhibit informative trades and therefore drive a wedge between observed returns and true

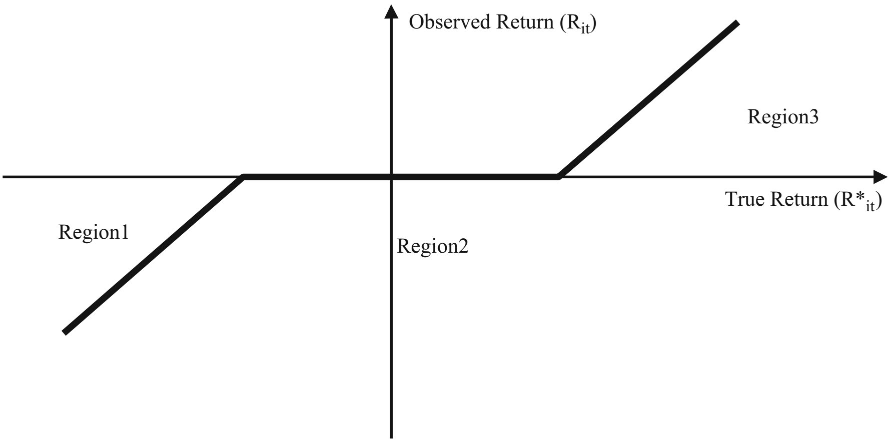

Fig. 47.1 This figure illustrates the relationship between the observed return on a stock in the presence of transaction costs that inhibit trading, R_{it}, and its true return in the absence of transaction costs, R^*_{it}, where the latter reflects the true effects of new market-wide or firm-specific information. The relationship can be divided into three regions: (1) Region 1, where the value of new information is negative and exceeds transaction costs; (2) Region 2, where the transaction costs exceed the value of new information regardless of the direction of the value of information; and (3) Region 3, where the value of new information is positive and exceeds transaction costs

returns. In the presence of transaction costs, Lesmond et al. (1999) propose the following relationship between observed and true returns:

$$R_{it} = R^*_{it} - \mu S_i, \tag{47.2}$$

where μS_i is the spread adjustment for security i, R_{it} is the observed return, and R^*_{it} is true return.

Specifically, the relationship is as follows:

$$\begin{array}{lll} R_{it} = R^*_{it} - \alpha_{1i} & \text{if} & R^*_{it} < \alpha_{1i} \\ R_{it} = 0 & \text{if} & \alpha_{1i} < R^*_{it} < \alpha_{2i} \\ R_{it} = R^*_{it} - \alpha_{2i} & \text{if} & R^*_{it} > \alpha_{2i} \end{array} \tag{47.3}$$

where $\alpha_{1i} < 0$ and $\alpha_{2i} > 0$. α_{1i} is the transaction costs for the marginal investor when information has a negative shock (selling), and α_{2i} is the transaction costs for the marginal investor when information has a positive shock (buying). Consequently, the difference between α_{1i} and α_{2i} is a measure of round-trip transaction costs.

If the true return exceeds transaction costs, the marginal investor will continuously trade, and the market price will respond until, for the next trade, marginal profit is equal to marginal transaction costs. If the transaction costs are greater than true returns, then the marginal investors will not trade, price will not move, and consequently the zero returns will occur. Therefore, in this model the frequency of zero returns is a simple alternative measure of transaction costs. The relationship between observed returns and true returns is illustrated in Fig. 47.1.

47.3 High-Frequency Liquidity Proxies

Next I describe two well-known spread proxies that can be estimated using high-frequency data. These are the percent quoted spread and percent effective spread.

47.3.1 Percent Quoted Spread

The ask (bid) quotation is the price at which shares can be purchased (sold) with immediacy. The difference, known as the percent quoted spread, is the cost of a round-trip transaction and is generally expressed as a proportion of the average of the bid and ask prices:

$$\text{Percent quoted spread}_{\text{it}} = \frac{\text{Ask}_{\text{it}} - \text{Bid}_{\text{it}}}{\text{M}_{\text{it}}}.$$

In the empirical analysis in the next section, I estimate percent quoted spreads using high-frequency data. Following convention, for each stock and trading day, I find the highest bid and lowest ask prices over all venues at every point during the day, denoting these "inside" ask and bid prices as Ask_{it} and Bid_{it}, respectively. M_{it} is then the average of, or midpoint between, Ask_{it} and Bid_{it}. I then calculate the average percent quoted spread for a stock and day as the time-weighted average of all spreads observed for that stock during the day. Finally, *percent quoted spread* for each stock is calculated by averaging the daily estimates across all trading days within a given month.

47.3.2 Percent Effective Spread

Some trades occur *within* the range of inside bid and ask quotes, as when simultaneous buy and sell market orders are simply crossed. Thus, the inside bid-ask spread may overestimate the realized amount of this component of transaction costs. Hasbrouck's (2009) measure of *percent effective spread* attempts to adjust for this bias. For a given stock, percent effective spread is computed for all trades relative to the prevailing quote midpoint:

$$\text{Percent effective spread}_{\text{it}} = 2\text{D}_{\text{it}}\left(\frac{\text{P}_{\text{it}} - \text{M}_{\text{it}}}{\text{M}_{\text{it}}}\right),$$

where, for stock i, D_{it} is the buy-sell indicator variable which takes a value of 1 (–1) for buyer-initiated (seller-initiated) trades, P_{it} is the transaction price, and M_{it} is the midpoint of the most recently posted bid and ask quotes. The average percent effective spread for each day is a trade-weighted average across all trades during the day. The monthly percent effective spread for each security is calculated by averaging across all trading days within a given month.

47.4 Empirical Analysis

47.4.1 Data

I estimate liquidity measures for NYSE, AMEX, and NASDAQ common stocks over the years 1993–2008. I estimate the low-frequency measures using daily data from the Center for Research in Security Prices (CRSP) database. I estimate the high-frequency measures using the New York Stock Exchange Trades and Automated Quotes (TAQ) database. TAQ data is available only since 1993, which is therefore the binding constraint in terms of staring year. In order to be included in the sample, a stock must have at least 60 days of past return data. I discard certificates, American Depositary Receipts (ADRs), shares of beneficial interest, units, companies incorporated outside United States, American Trust components closed-end funds, preferred stocks, and Real Estate Investment Trusts (REITs).

Regarding estimating the high-frequency measures, I determine the highest bid and lowest ask across all quoting venues at every point during the day (NBBO quotes) and then follow filters referring to Huang and Stoll (1997) and Brownless and Gallo (2006). To reduce errors and outliers, I remove (1) quotes if either the bid or ask price is negative; (2) quotes if either the bid or ask size is negative; (3) quotes if bid-ask spread is greater than \$5 or negative; (4) the quotes if transaction price is negative; (5) quotes before-the-open and after-the-close trades and quotes; (6) quotes if the bid, ask, or trade price differ by more than 20 % from the previous quote or trade price; (7) quotes originating in market other than the primary exchange because regional quotes tend to closely follow the quotes posted by the primary exchange; and (8) %effective spread/%quoted spread>4.0.

47.4.2 Empirical Results

Table 47.1 reports correlations among the various liquidity estimates. In this table, observations are pooled across all stocks and all months. All correlations are reliably positive and substantial in magnitude, ranging from 0.382 to 0.971. The two high-frequency measures, percent effective spread and percent quoted spread, are very highly correlated (0.971). Using percent effective spread as our high-frequency "benchmark," its correlations with the low-frequency measures are 0.742 (Roll), 0.757 (effective tick), 0.621 (Amihud), and 0.586 (LOT). Based on the aforementioned criterion, these results indicate that the effective tick and Roll measures are the "best" low-frequency measures, as they have the highest correlation with percent effective spread.

Table 47.2 presents the time-series means of monthly correlations of percent effective spread with each of the low-frequency measures for the full sample period as well as subperiods 1993–2000 (pre-decimalization) and 2001–2008 (post-decimalization). For three of the four low frequencies measured, the correlation with percent effective spread is higher in the first subperiod than the second subperiod, which may reflect differential effects of decimalization on the various

Table 47.1 Pooled correlations

	ES	QS	Roll	Eff. tick	Ami	LOT
ES	1					
QS	0.971	1				
Roll	0.742	0.744	1			
Eff. tick	0.757	0.760	0.638	1		
Ami	0.621	0.631	0.512	0.472	1	
LOT	0.586	0.562	0.710	0.541	0.382	1

This table presents correlations among the liquidity estimates based on the pooled sample of monthly time-series and cross-sectional observations. Observation can be dropped if there are fewer than 60 days observations for the firm or if liquidity estimates are missing

Table 47.2 Average cross-sectional correlations with percent effective spread, monthly estimates

	Roll	Eff. tick	Ami	LOT
1993–2008	0.662	0.685	0.684	0.561
1993–2000	0.748	0.754	0.662	0.670
2001–2008	0.576	0.615	0.706	0.452

For each month, I estimate the cross-sectional correlation between the liquidity proxies from the low-frequency data and percent effective spread from TAQ. This table presents the average cross-sectional correlations across all months. A stock is excluded only if it trades for less than 60 days prior to an observation or if liquidity estimates are missing

Table 47.3 Summary statistics for stock-by-stock time-series correlations

	N	Roll	Eff. tick	Ami	LOT
Full	13,374	0.319	0.578	0.603	0.308
NYSE	3,137	0.180	0.694	0.690	0.201
AMEX	1,597	0.231	0.517	0.643	0.310
NASDAQ	9,870	0.353	0.534	0.567	0.335

For each stock, I estimate the time-series correlation between the estimated liquidity measure and percent effective spread from TAQ. The table presents the average time-series correlation across all stocks. Observations are dropped if there are fewer than 60 days observations for the firm or if a spread estimate is missing

dimensions of liquidity. For the full period as well as the first subperiod, effective tick has the correlation with percent effective spread, while for the second period the Amihud measure has the highest correlation with percent effective spread.

Table 47.3 shows stock-by-stock time-series correlations between the high-frequency measure percent effective spread and each of the low-frequency measures, using the full-period data but also breaking the observations down by the exchange on which a stock trades. For the full sample as well as every exchange, the Amihud and effective tick estimates have relatively high correlations with percent effective spread, while the correlations are relatively low for the Roll and LOT measures.

Overall, based on the suggested criteria of correlation with a high-frequency measure, the effective tick measure is best among the low-frequency measures tested, as it exhibits higher correlations with percent effective spread based on time-series, cross-sectional, and pooled tests. Again, though, I caution that, since each liquidity measure captures only part of the multidimensional nature of liquidity, it is difficult to judge which measure is best.

47.5 Conclusions

This chapter discusses several popular measures of liquidity that are based on econometric approaches and compares them via correlation analysis. Among the four low-frequency liquidity proxies, I find that the effective tick measure is generally more highly correlated with the high-frequency measure (i.e., percent effective spread). Thus, by this criterion the effective tick measure is the "best" low-frequency measure of liquidity. However, since each liquidity measure captures only part of the multidimensional nature of liquidity, it is difficult to judge which measure is best. Consequently, from among the available measures of liquidity, a researcher should choose the measure that is consistent with their research purpose or perhaps consider employing several of them.

Appendix 1: Solution to LOT (1990) Model

To estimate transaction costs based on their model in Eq. 47.3, Lesmond et al. (1999) introduce the limited dependent variable regression model of Tobin (1958) and Rosett (1959). Tobin's model specifies that data are available for the explanatory variable, x, for all the observation while data are only partly observable for the dependent variable, y, and for the other unobservable region, the information is given whether or not data are above a certain *threshold*.

Considering this aspect of Tobin's model, the limited dependent variable model is an appropriate econometric method for the LOT model because a nonzero observed return occurs only when marginal profit exceeds marginal transaction costs.

Assuming that market model is correct in the presence of transaction costs, Lesmond et al. (1999) estimate transaction costs on the basis of Eqs. 47.1 and 47.3. The equation system is

$$R_{it}^* = \beta_{it} R_{mt} + \varepsilon_{it},$$

where

$$\begin{aligned} R_{it} &= R_{it}^* - \alpha_{1i} && \text{if} \quad R_{it}^* < \alpha_{1i} \\ R_{it} &= 0 && \text{if} \quad \alpha_{1i} < R_{it}^* < \alpha_{2i} \\ R_{it} &= R_{it}^* - \alpha_{2i} && \text{if} \quad R_{it}^* > \alpha_{2i} \end{aligned} \tag{47.4}$$

The solution to this limited dependent regression variable model requires a likelihood function to be maximized with respect to α_{1i}, α_{2i}, β_i, and σ_i.

$$\begin{aligned} L(\alpha_{1i}, \alpha_{2i}, \beta_i, \sigma_i / R_{it}, R_{mt}) = & \prod_1 \text{Ø}\left(\frac{R_{it} + \alpha_{1i} - \beta_i R_{mt}}{\sigma_i}\right) \\ & \prod_2 \left[\Phi\left(\frac{R_{it} + \alpha_{2i} - \beta_i R_{mt}}{\sigma_i}\right) - \Phi\left(\frac{R_{it} + \alpha_{1i} - \beta_i R_{mt}}{\sigma_i}\right)\right] \\ & \prod_3 \text{Ø}\left(\frac{R_{it} + \alpha_{2i} - \beta_i R_{mt}}{\sigma_i}\right), \end{aligned} \tag{47.5}$$

where Ø refers to the standard normal density function and Φ refers to the cumulative normal distribution. The product is over the Region 1, 2, and 3 of observations for which $R^*_{it} < \alpha_{1i}$, $\alpha_{1i} < R^*_{it} < \alpha_{2i}$, and $R^*_{it} > \alpha_{2i}$, respectively. The log likelihood function is

$$\begin{aligned} \log\ L = & \Sigma_1 \log\left[\frac{1}{(2\pi\sigma_i{}^2)\frac{1}{2}}\right] - \frac{1}{2\sigma_i{}^2}\Sigma_1(R_{it} + \alpha_{1i} - \beta_i R_{mt})^2 + \Sigma_2 \log[\Phi_2 - \Phi_1] \\ & + \Sigma_3 \log\left[\frac{1}{(2\pi\sigma_i{}^2)^{\frac{1}{2}}}\right] - \frac{1}{2\sigma_i{}^2}\Sigma_3(R_{it} + \alpha_{2i} - \beta_i R_{mt})^2. \end{aligned} \tag{47.6}$$

Given Eq. 47.6, α_{1i}, α_{2i}, β_i, and σ_i can be estimated. The difference between α_{2i} and α_{1i} is the proxy of a round-trip transaction cost in the LOT model.

Abstract

We present the first empirical evidence for the validity of the ARMA-GARCH model with tempered stable innovations to estimate 1-day-ahead value at risk in futures markets for the S&P 500, DAX, and Nikkei. We also provide empirical support that GARCH models based on normal innovations appear not to be as well suited as infinitely divisible models for predicting financial crashes. The results are compared with the predictions based on data in the cash market. We also provide the first empirical evidence on how adding trading volume to the GARCH model improves its forecasting ability.

In our empirical analysis, we forecast 1 % value at risk in both spot and futures markets using normal and tempered stable GARCH models following a quasi-maximum likelihood estimation strategy. In order to determine the accuracy of forecasting for each specific model, backtesting using Kupiec's proportion of failures test is applied. For each market, the model with a lower number of violations is preferred. Our empirical result indicates the usefulness of classical tempered stable distributions for market risk management and asset pricing.

Keywords

Infinitely divisible models • Tempered stable distribution • GARCH models • Value at risk • Kupiec's proportion of failures test • Quasi-maximum likelihood estimation strategy

48.1 Introduction

Predicting future financial market volatility is crucial for risk management of financial institutions. The empirical evidence suggests that a suitable market risk model must be capable of handling the idiosyncratic features of volatility, that is, daily returns time variant amplitude and volatility clustering. There is a well-developed literature in financial econometrics that demonstrates how autoregressive conditional heteroskedastic (ARCH) and generalized ARCH (GARCH) models – developed by Engle (1982) and Bollerslev (1986), respectively – can be employed to explain the clustering effect of volatility[1]. Moreover, the selected model should consider the stylized fact that asset return distributions are not normally distributed, but instead have been shown to exhibit patterns of leptokurtosis and skewness.

[1]For a description of ARCH and GARCH modeling, see Chap. 8 in Rachev et al. (2007). The chapter of the same reference describes ARCH and GARCH modeling with infinite variance innovations. Engle et al. (2008) provide the basics of ARCH and GARCH modeling with applications to finance.

Taking a different tact than the ARCH/GARCH with normal innovations approach for dealing with the idiosyncratic features of volatility, Kim et al. (2010) formulate an alternative model based on subclasses of the infinitely divisible (ID) distributions. More specifically, for the S&P 500 return, they empirically investigate five subclasses of the ID distribution, comparing their results to that obtained using GARCH models based on innovations that are assumed to follow a normal distribution. They conclude that, due to their failure to focus on the distribution in the tails, GARCH models based on the normal innovations may not be as well suited as ID models for predicting financial crashes.

Because of its popularity, most empirical studies have examined value at risk (VaR) as a risk measure. These studies have focused on stock indices. For example, Kim et al. (2011), and Asai and McAleer (2009) examine the S&P 500, DAX 30, and Nikkei 225 stock indices, respectively. A few researchers have studied this risk measure for stock index futures contracts: Huang and Lin (2004) (Taiwan stock index futures) and Tang and Shieh (2006) (S&P 500, Nasdaq 100, and Dow Jones stock index futures). As far as we know, there are no empirical studies comparing VaR spot and futures indices. For this reason, we compare the predictive performance of 1-day-ahead VaR forecasts in these two markets.

We then introduce trading volume into the model, particularly, within the GARCH framework. There are several studies that relate trading volume and market volatility for equities and equity futures markets. Studies by Epps and Epps (1976), Smirlock and Starks (1985), and Schwert (1989) document a positive relation between volume and market volatility. Evidence that supports the same relation for futures is provided by Clark (1973), Tauchen and Pitts (1983), Garcia et al. (1986), Ragunathan and Peker (1997), and Gwilym et al. (1999). Collectively, these studies clearly support the theoretical prediction of a positive and contemporaneous relationship between trading volume and volatility. This result is a common empirical finding for most financial assets, as Karpoff (1987) showed when he summarized the results of several studies on the positive relation between price changes and trading volume for commodity futures, currency futures, common stocks, and stock indices.

Foster (1995) concluded that not only is trading volume important in determining the rate of information (i.e., any news that affects the market), but also lagged volume plays a role. Although contemporary trading volume is positively related to volatility, lagged trading volume presents a negative relationship. Empirically, investigating daily data for several indices such as the S&P 500 futures contract, Wang and Yau (2000) observe that there is indeed a negative link between lagged trading volume and intraday price volatility. This means that an increase in trading volume today (as a measure of liquidity) will imply a reduction in price volatility tomorrow. In their study of five currency futures contracts, Fung and Patterson (1999) do in fact find a negative relationship between return volatility and past trading volume. In their view, the reversal behavior of volatility with trading volume is generally consistent with the overreaction hypothesis (see Conrad et al. 1994) and supports the sequential information hypothesis (see Copeland 1976), which explains the relationship between return volatility and trading volume.

Despite the considerable amount of research in this area, there are no studies that use trading volume in an effort to improve the capability of models to forecast 1-day-ahead VaR. Typically, in a VaR context, trading volume is only employed as a proxy for "liquidity risk" – the risk associated with trying to close out a position. In this paper, in contrast to prior studies, we analyze the impact of introducing trading volume on the ability to enhance performance in forecasting VaR 1 day ahead. We empirically test whether the introduction of trading volume will reduce the number of violations (i.e., the number of times when the observed loss exceeds the estimated one) in the spot and futures equity markets in the USA, Germany, and Japan.

The remainder of this paper is organized as follows. ARMA-GARCH models with normal and tempered stable innovations are reviewed in Sect. 48.2. In Sect. 48.3, we discuss parameter estimation of the ARMA-GARCH models and forecasting daily return distributions. VaR values and backtesting of the ARMA-GARCH models are also reported in Sect. 48.2, along with a comparison of the results for (1) the spot and futures markets and (2) the normal and tempered stable innovations. Trading volume is introduced into the ARMA-GARCH model with tempered stable innovations in Sect. 48.4. VaR and backtesting of the ARMA-GARCH with different variants of trading volume are presented and compared to the results for models with and without trading volume. We summarize our principal findings in Sect. 48.5.

48.2 ARMA-GARCH Model with Normal and Tempered Stable Innovations

In this section, we provide a review of the ARMA-GARCH models with normal and tempered stable innovations. For a more detailed discussion, see Kim et al. (2011).

Let $(S_t)_{t\geq 0}$ be the asset price process and $(y_t)_{t\geq 0}$ be the return process of $(S_t)_{t\geq 0}$ defined by $y_t = \log \frac{S_t}{S_t - 1}$. The ARMA(1,1)-GARCH(1,1) model is

$$\begin{cases} y_t = ay_{t-1} + b\sigma_{t-1}\varepsilon_{t-1} + \sigma_t\varepsilon_t + c_t \\ \sigma_t^2 = \alpha_0 + \alpha_1\sigma^2{}_{t-1}\varepsilon^2{}_{t-1} + \beta_1\sigma^2{}_{t-1} \end{cases}. \tag{48.1}$$

where $\varepsilon_0 = 0$ and a sequence $(\varepsilon_t)_{tcN} = 0$ of independent and identically distributed (iid) real random variables. The innovation ε_t is assumed to follow the standard normal distribution. This ARMA(1,1)-GARCH(1,1) model is referred to as the "normal-ARMA-GARCH model."

If the ε_ts are assumed to be tempered stable innovations, then we obtain a new ARMA(1,1)-GARCH(1,1) model. In this paper, we will consider the standard classical tempered stable (denoted by stdCTS) distributions. This ARMA(1,1)-GARCH(1,1) model is defined as follows: CTS-ARMA-GARCH model, $\varepsilon_t \sim stdCTS(\alpha, \lambda_+, \lambda_-)$. This distribution does not have a closed-form solution for its probability density function. Instead, it is defined by its characteristic function as follows: Let $\alpha \in (0,2)\setminus\{1\}, C, \lambda_+, \lambda_- > 0$, and $m \in \mathbb{R}$. Then a random variable X is said to follow the classical tempered stable (CTS) distribution if the characteristic function of X is given by

$$\begin{aligned}\phi_x(u) &= \phi_{CTS}\left(u : \alpha,\ C, \lambda_+, \lambda_-, m\right)\\ &= \exp\left(ium - iuCT(1-\alpha)\left(\lambda_+^{\alpha-1} - \lambda_-^{\alpha-1}\right)\right.\\ &\quad \left. + C\Gamma(-\alpha)\left((\lambda_+ - iu)^\alpha - \lambda_+^\alpha + (\lambda_- - iu)^\alpha - \lambda_-^\alpha\right)\right),\end{aligned} \tag{48.2}$$

and we denote $X \sim CTS(\alpha, C, \lambda_+, \lambda_-, m)$.

The cumulants of X are defined by

$$C_n(X) = \frac{1}{i^n}\frac{\partial^n}{\partial u^n}\ \log E\left[e^{iuX}\right]|u = 0,\ \ n = 1, 2, 3, \ldots.$$

For the tempered stable distribution, we have $E[X] = c_1(X) = m$. The cumulants of the tempered stable distribution for $n = 2, 3, \ldots$ are

$$c_n(X) = C\Gamma(n-\alpha)\left(\lambda_+^{\alpha-n} + (-1)^n \lambda_-^{a-n}\right).$$

By substituting the appropriate value for the two parameters m and C into the three tempered stable distributions, we can obtain tempered stable distributions with zero mean and unit variance. That is, $X \sim CTS(\alpha, C, \lambda_+, \lambda_-, 0)$ has zero mean and unit variance by substituting

$$C = \left(\Gamma(2-\alpha)\left(\lambda_+^{\alpha-2} + \lambda_-^{\alpha-2}\right)\right)^{-1}. \tag{48.3}$$

The random variable X is referred to as the standard CTS distribution with parameters $(\alpha, \lambda_+, \lambda_-)$ and denoted by $X \sim stdCTS(\alpha, \lambda_+, \lambda_-)$.

48.3 VaR for the ARMA-GARCH Model

In this section, we discuss VaR for the ARMA-GARCH model with normal and tempered stable innovations.

48.3.1 VaR and Backtesting

The definition of VaR for a significance level η is

$$\text{VaR}_\eta(X) = -\inf\{x \in \mathbb{R} | P(X \le x) > \eta\}.$$

If we take the ARMA-GARCH model described in Sect. 48.2, we can define VaR for the information until time t with significance level η as[2]

$$\mathrm{VaR}_{t,\eta}(y_{t+1}) = -\inf\{x \in \mathbb{R} | P_t(y_{t+1} \le x) > \eta\},$$

where $P_t(A)$ is the conditional probability of a given event A for the information until time t.

Two models are considered: normal-ARMA(1,1)-GARCH(1,1) and stdCTS-ARMA(1,1)-GARCH(1,1). For both models, the parameters have been estimated for the time series between December 14, 2004 and December 31, 2008. For each daily estimation, we worked with 10 years of historical daily performance for the S&P 500, DAX 30, and Nikkei 225 spot and futures indices. More specifically, we used daily returns calculated based on the closing price of those indices. In the case of futures indices, we constructed a unique continuous time series using the different maturities of each futures index following the methodology proposed by Carchano and Pardo (2009).[3] Then, we computed VaRs for both models.

The maximum likelihood estimation method (MLE) is employed to estimate parameters of the normal-ARMA(1,1)-GARCH(1,1) model. For the CTS distribution, the parameters are estimated as follows[4]:

1. Estimate parameters α_0, α_1, β_1, α, b, c with normal innovations by the MLE. Volatility clustering is captured by the GARCH model.
2. Extract residuals using those parameters. The residual distribution still presents fat tail and skewness.
3. Fit the parameters of the innovation distribution (CTS) to the extracted residuals using MLE. The fat tailed and skewed features of the residual distribution are captured.

In order to determine the accuracy of VaR for the two models, backtesting using *Kupiec's proportion of failures test* (Kupiec 1995) is applied. We first calculate the number of violations. Then, we compare the number of violations with the conventional number of exceedances at a given significance level. In Table 48.1 the number of violations and p-values for Kupiec's backtest for the three stock indices over the 41-year periods are reported. Finally, we sum up the number of violations and their related p-values for 1 % VaRs for the normal and CTS-ARMA-GARCH models.

[2]VaR on the CTS distribution is described in the Appendix.

[3]Thus, the last trading day of the front contract is chosen as the rollover date. Then, the return of the day after the rollover date is calculated as the quotient between the closing price of the following contract and the previous closing price of such contract. By doing so, all the returns are taken from the same maturity.

[4]A quasi-MLE strategy is followed because the ARMA-GARCH CTS model has too many parameters. If all the parameters are estimated at once, then the GARCH parameters go to zero. This strategy is also followed in Kim et al. (2009, 2010, 2011). For a discussion of the quasi- MLE methodology, see Rachev et al. (2007, pp. 292–293) or Verbeek (2004, pp. 182–184).

Table 48.1 Normal-ARMA-GARCH versus CTS-ARMA-GARCH

	1 year (255 days)			
	Dec. 14, 2004	Dec. 16, 2005	Dec. 21, 2006	Dec. 28, 2007
	~ Dec. 15, 2005	~ Dec. 20, 2006	~ Dec. 27, 2007	~ Dec. 31, 2008

	DAX 30 spot			
Normal-ARMA-GARCH	4(0.3995)	4(0.3995)	3(0.7829)	6(0.0646)
CTS-ARMA-GARCH	4(0.3995)	4(0.3995)	3(0.7829)	4(0.3995)
	DAX 30 futures			
Normal-ARMA-GARCH	3(0.7829)	5(0.1729)	6(0.0646)	6(0.0646)
CTS-ARMA-GARCH	3(0.7829)	4(0.3995)	6(0.0646)	3(0.7829)
	Nikkei 225 spot			
Normal-ARMA-GARCH	2(0.7190)	4(0.3995)	5(0.1729)	5(0.1729)
CTS-ARMA-GARCH	1(0.2660)	3(0.7829)	4(0.3995)	5(0.1729)
	Nikkei 225 futures			
Normal-ARMA-GARCH	2(0.7190)	2(0.7190)	7(0.0211)	5(0.1729)
CTS-ARMA-GARCH	5(0.1729)	5(0.1729)	6(0.0646)	6(0.0646)

The number of violations (*N*) and *p*-values of Kupiec's proportion of failures test for the S&P 500, DAX 30, and Nikkei 225 spot and futures indices data has been shown. Normal-ARMA-GARCH and CTS-ARMA-GARCH compared

Based on Table 48.1, we conclude the following for the three stock indices. First, a comparison of the normal and tempered stable models indicates that there are no cases using the tempered stable model at the 5 % significance level, whereas the normal model is rejected five times. This evidence is consistent with the findings of Kim et al. (2011). Second, a comparison of the spot and futures indices indicates that spot data provide less than or the same number of violations than futures data. One potential explanation is that futures markets are more volatile, particularly, when the market falls.[5] This overreaction to bad news could cause the larger number of violations.

[5]We compared the spot and futures series when the markets discount bad news (negative returns). We find that for the three stock indices, futures volatility is significantly greater than spot volatility at a 5 % significance level. Moreover, for all three stock indices, the minimum return and the 1 % percentile return are also lower for futures data than spot data.

48.4 Introduction of Trading Volume

In the previous section, we showed the usefulness of the tempered stable model for stock index futures. Motivated by the vast literature linking trading volume and volatility, for the first time we investigate whether the introduction of trading volume in the CTS model could improve its ability to forecast 1-day-ahead VaR.

Let $(St)_{t\geq 0}$ be the asset price process and $(y_t)_{t\geq 0}$ be the return process of $(S_t)_{t\geq 0}$ defined by $y_t = \log \frac{S_t}{S_t - 1}$. We propose the following ARMA(1,1)-GARCH(1,1) with trading volume model:

$$\begin{cases} y_t = ay_{t-1} + b\sigma_{t-1}\varepsilon_{t-1} + \sigma_t\varepsilon_t + c \\ \sigma_t^2 = \alpha_0 + \alpha_1{\sigma^2}_{t-1}{\varepsilon^2}_{t-1} + \beta_1{\sigma^2}_{t-1} + \gamma_1 Vol_{t-1}, \end{cases} \tag{48.4}$$

where $\varepsilon_0 = 0$ and a sequence $(\varepsilon_t)_{tcN} = 0$ of *iid* real random variables. The innovation ε_t is assumed to be the tempered stable innovation. We will consider the standard classical tempered stable distributions. This new ARMA(1,1)-GARCH(1,1)-V model is defined as follows:

$$\text{CTS-ARMA-GARCH-V model} : \varepsilon_t \sim stdCTS(\alpha, \lambda_+, \lambda_-).$$

The inclusion of lagged volume as an independent variable along with lagged volatility into the model may cause a problem of multicollinearity. In order to determine the seriousness of the problem, we calculated the model without volume, extracted the GARCH series, and determined the degree of collinearity between both variables. The most recommended measure in the literature is to calculate the condition index following Belsley et al. (1980) and observe if the index exceeds 20, in which case collinearity is considered to be grave. In our case, the calculated value was 4.9268, 3.2589, and 4.5569 for the S&P, DAX, and Nikkei, respectively. Therefore, we concluded that collinearity is a minor problem.

Moreover, the ARMA-GARCH model is only affected in the GARCH framework, particularly the equation coefficients (i.e., the volume variable can appear insignificant when it is indeed significant), but not the numerical estimation of the variance; neither is the forecast power of the global model. As our objective is to forecast the VaR, we believe that the multicollinearity problem can be ignored because the results will not be affected.

48.4.1 Different Variants of Trading Volume

For the S&P 500 cash and futures markets, we test the following versions of trading volume in order to determine which one would be the most appropriate:

- Lagged trading volume in levels: V(t − 1)
- Logarithm of lagged trading volume: log [V(t − 1)]
- Relative change of lagged trading volume: log [V(t − 1)/V(t − 2)]

Table 48.2 CTS-ARMA-GARCH with lagged volume

	1 year (255 days)			
	Dec. 14, 2004	Dec. 16, 2005	Dec. 21, 2006	Dec. 28, 2007
	∼ Dec. 15, 2005	∼ Dec. 20, 2006	∼ Dec. 27, 2007	∼ Dec. 31, 2008
	N(p-value)	N(p-value)	N(p-value)	N(p-value)
Model	S&P 500 spot			
CTS-ARMA-GARCH-V(t − 1)	16(0.0000)	10(0.0004)	23(0.0000)	26(0.0000)
CTS-ARMA-GARCH-log [V(t − 1)]	1(0.2660)	4(0.3995)	10(0.0004)	6(0.0646)
CTS-ARMA-GARCH-ln [V(t − 1)/V(t − 2)]	0	2(0.7190)	6(0.0646)	5(0.1729)
	S&P 500 futures			
CTS-ARMA-GARCH-V(t − 1)	1(0.2660)	11(0.0001)	4(0.3995)	6(0.0646)
CTS-ARMA-GARCH-log [V(t − 1)]	1(0.2660)	3(0.7829)	4(0.3995)	5(0.1729)
CTS-ARMA-GARCH-ln [V(t − 1)/V(t − 2)]	1(0.2660)	3(0.7829)	3(0.7829)	5(0.1729)
CTS-ARMA-GARCH-V$($t$ − 1)	0	1(0.2660)	15(0.0000)	3(0.7829)
CTS-ARMA-GARCH-log [V$($t$ − 1)]	3(0.7829)	3(0.7829)	4(0.3995)	5(0.1729)
CTS-ARMA-GARCH-ln [V$($t$ − 1)/V$($t$ − 2)]	2(0.7190)	0	8(0.0061)	8(0.0061)

The number of violations (N) and p-values of Kupiec's proportion of failures test for the S&P 500 spot and futures indices with the different variants of volume using the stdCTS-ARMA(1,1)-GARCH(1,1) model has been shown. V(t − 1), log [V(t − 1)], and ln [V(t − 1)/V(t − 2)] stand for levels, logarithm, and relative change of the lagged trading volume, respectively. V$($t$ − 1), log [V$($t$ − 1)], and ln [V$($t$ − 1)/V$($t$ − 2)] stand for levels, logarithm, and relative change of the lagged trading volume in dollars, respectively

The spot series trading volume is in dollars; for the futures series, the trading value is in number of contracts. We can calculate the volume of the futures market in dollars too. The tick value of the S&P 500 futures contract is 0.1 index points or $25. Multiplying the number of contracts by the price and finally by $250 (the contract's multiple), we obtain the trading volume series for the futures contract in dollars. Thus, for the futures contract we get three new versions of trading volume to test:

- Lagged trading volume in dollars: V$($t$ − 1)
- Logarithm of trading volume in dollars: log [V$($t$ − 1)]
- Relative change of lagged trading volume in dollars: log [V$($t$ − 1)/V$($t$ − 2)]

By doing that, we can determine which series (in dollars or in contracts) seems to be more useful for the futures index.

In Table 48.2 we report the number of violations and p-values of Kupiec's backtest for the different versions of the CTS-ARMA-GARCH-V model for the S&P 500 spot and futures indices. We count the number of violations and the corresponding *p*-values for 1 %-VaRs of both markets. From Table 48.2, we conclude the following:

- The model with the lagged trading volume in level is rejected at the 1 % significance level in all 4 years for the S&P 500 spot, and for the second period (2005–2006) for the S&P 500 futures.
- The logarithm of trading volume in the model is rejected at the 5 % significance level for the spot market for the third period (2006–2007), but it is not rejected in any period for the futures market.
- The relative change of the lagged volume is not rejected at the 5 % significance level in any period in either market. Of the three versions of trading volume tests, this version seems to be the most useful for both spot and futures markets.
- The results for trading volume in contracts and the trading volume in dollars in the futures market indicate that the former is rejected at the 1 % significance level only for the lagged trading volume in level in the second period (2005–2006). Trading volume in dollars is rejected three times, for the lagged trading volume in levels for the third period (2006–2007) and for the lagged relative trading volume change in the last two periods (2006–2007 and 2007–2008). These findings suggest that the trading volume in contracts is the preferred measure.

48.4.2 Lagged Relative Change of Trading Volume

As we have just seen, the variant of trading volume that seems more useful for forecasting 1-day-ahead VaR using CTS-ARMA-GARCH is the relative change of trading volume. Next, we compare the original CTS-ARMA-GARCH model with the new CTS-ARMA-GARCH-V model where V is the lagged relative change of trading volume. Table 48.3 shows the number of violations and *p*-values of Kupiec's backtest for the two models for the three stock indices and both markets. We sum up the number of violations and the corresponding *p*-values for 1 % VaRs for each case.

Our conclusions from Table 48.3 are as follows. For the spot markets, the introduction of trading volume does not mean a reduction in the number of violations in any period for any index. However, for the futures markets, the numbers of violations are the same or lower for the model with trading volume than with the original model. Thus, by introducing trading volume, we get a slightly more conservative model, increasing the VaR forecasted for futures equity markets.

48.4.3 Lagged Trading Volume or Forecasting Contemporaneous Trading Volume

Although there is some evidence which supports the relationship between lagged trading volume and volatility, the literature is not as extensive as the studies that establish a strong link between volatility and contemporaneous trading

The number of violations (N) and p-values of Kupiec's proportion of failures test for the S&P 500, DAX 30, and Nikkei 225 spot and futures indices has been reported. CTS-ARMA-GARCH and CTS-ARMA-GARCH with lagged relative change of trading volume compared

volume. As there are countless ways to try to forecast trading volume, we begin by introducing contemporaneous trading volume relative change in the model as a benchmark to assess whether it is worthwhile to forecast trading volume.

In Table 48.4 we show the number of violations and p-values of Kupiec's backtest for the CTS-ARMA-GARCH with contemporaneous and lagged relative change of trading volume for the three stock indices for both markets. We count the number of violations and the corresponding p-values for 1 % VaRs for the six indices.

Our conclusions based on the results reported in Table 48.4 are as follows. First, with the exception of the S&P 500 futures, the introduction of the contemporaneous relative change of trading volume in the model is rejected at the 1 % significance level for the last period analyzed (2007–2008). In the case of the S&P

The number of violations (N) and p-values of Kupiec's proportion of failures test for the S&P 500, DAX 30, and Nikkei 225 spot and futures indices has been shown. CTS-ARMA-GARCH with the relative change of trading volume and CTS-ARMA-GARCH with lagged relative change of trading volume compared

500 futures, it is rejected at the significance level of 5 % for the third period (2006–2007). Second, the model with lagged relative change of trading volume is not rejected for any stock index or market. It seems to be more robust than contemporaneous trading volume (although, in general, there are fewer violations when using it).

Our results suggest that it is not worth making an effort to predict contemporaneous trading volume because the forecasts will be flawed and two variables would have to be predicted (VaR and contemporaneous trading volume). Equivalently, the lagged trading volume relative change appears to be more robust because it is not rejected in any case, although it provides a poor improvement to the model.

48.5 Conclusions

Based on an empirical analysis of spot and futures trading for the S&P 500, DAX 30, and Nikkei 225 stock indices, in this paper we provide empirical evidence about the usefulness of using classical tempered stable distributions for predicting 1-day-ahead VaR. Unlike prior studies that investigated CTS models in the cash equity markets, we analyzed their suitability for both spot markets and futures markets. We find in both markets the CTS models perform better in forecasting 1-day-ahead VaR than models that assume innovations follow the normal law.

Second, we introduced trading volume into the CTS model. Our empirical evidence suggests that lagged trading volume relative change provides a slightly more conservative model (i.e., reduces the number of violations) to predict 1-day-ahead VaR for stock index futures contracts. We cannot state the same for the cash market because the results are mixed depending on the index. After that, we introduced contemporaneous trading volume to try to improve the forecasting ability of the model, but in the end, it did not seem to be worth the effort. That is, trading volume appeared not to offer enough information to improve forecasts.

Finally, we compared the number of violations of the estimated VaR in the spot and futures equity markets. For the CTS model without volume, in general, we find fewer violations in the spot indices than in the equivalent futures contracts. In contrast, our results suggest that the number of violations in futures markets is less in the case of the CTS model with trading volume in comparison to the CTS model that ignores trading volume. But if we contrast spot and futures equity markets, violations are still greater for futures than in spot markets. A possible reason is that futures markets demonstrate extra volatility or an overreaction when the market falls with respect to their corresponding spot markets.

Appendix: VaR on the CTS Random Variable

Let X be a CTS random variable. Since the CTS random variable is continuous and infinitely divisible, we obtain $\mathrm{VaR}_\eta(X) = -F_X(\eta)$, where the cumulative distribution function F_X of X is provided by the following proposition.

Proposition Let X be an infinitely divisible random variable and $\phi_x(u)$ be the characteristic function of X. If there is a $\rho > 0$ such that $|\phi_x(Z)| < \infty$ for all the complex z with $\Im(z) = \rho$, then

$$F_X(x) = \frac{e^{x\rho}}{\pi} \Re\left(\int_0^{\infty} e^{-ixu} \frac{\phi_X(u+i\rho)}{\rho - ui} du\right), \text{for } x \in \mathbb{R} \tag{48.5}$$

where $\Re(z)$ is the real part of a complex number z.

Proof By the definition of the cumulative density function, we have

$$F_X(x) = P(X \leq x) = \int_{-\infty}^{x} fX(t)dt,$$

where $f_X(x)$ is the density function of X. The probability density function $f_X(t)$ can be obtained from the characteristic function ϕ_X by the complex inverse formula (see Doetsch 1970); that is,

$$fX(t) = \frac{1}{2\pi} \int_{-\infty+i\rho}^{\infty+i\rho} e^{-itz} \phi_X(z)dz,$$

and we have

$$\begin{aligned} F_X(x) &= \int_{-\infty}^{x} \frac{1}{2\pi} \int_{-\infty+ip}^{\infty+ip} e^{-itz} \phi_X(z)dzdt \\ &= \frac{1}{2\pi} \int_{-\infty+ip}^{\infty+ip} \int_{-\infty}^{x} e^{-itz} dt\phi_X(z)dz. \end{aligned}$$

Note that if $\rho > 0$, then

$$\lim_{t\to-\infty} \left|e^{-it(a+i\rho)}\right| = \lim_{t\to\infty} \left|e^{it(a+i\rho)}\right| = \lim_{t\to\infty} e^{-\rho t} = 0, \quad a \in \mathbb{R},$$

and hence

$$\int_{-\infty}^{x} e^{-itz} dt = -\frac{1}{iz}\left[e^{-itz}\right]_{-\infty}^{x} = -\frac{1}{iz} e^{-ixz}$$

where $z \in \mathbb{C}$ with $\Im(z) = \rho$ Thus, we have

$$\begin{aligned} F_X(x) &= -\frac{1}{2\pi} \int_{-\infty+ip}^{\infty+ip} \frac{1}{iz} e^{-ixz} \phi_X(z)dz \\ &= -\frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{1}{i(u+i\rho)} e^{-ix(u+i\rho)} \phi_x(u+i\rho)du \\ &= \frac{e^{x\rho}}{2\pi} \int_{-\infty}^{\infty} e^{-ixu} \frac{\phi_X(u+i\rho)}{\rho - iu} du. \end{aligned}$$

Let

$$g_\rho(u) = \frac{\phi_X(u + i\rho)}{\rho - iu}.$$

Then we can show that $g_\rho(-u) = \overline{g_\rho(u)}$ with $u \in \mathbb{R}$ and hence we have

$$\int_{-\infty}^{\infty} e^{-ixu} g_\rho(u) du = 2\Re\left(\int_0^{\infty} e^{-ixu} g_\rho(u) du\right).$$

Therefore, we obtain Eq. 48.5.

Abstract

Securities trading is one of the few business activities where a few seconds processing delay can cost a company big fortune. The growing competition in the market exacerbates the situation and pushes further towards instantaneous trading even in split second. The key lies on the performance of the underlying information system. Following the computing evolution in financial services, it was a centralized process to begin with and gradually decentralized into a distribution of actual application logic across service networks. Financial services have tradition of doing most of its heavy-duty financial analysis in overnight batch cycles. However, in securities trading it cannot satisfy the need due to its ad hoc nature and requirement of fast response. New computing paradigms, such grid and cloud computing, aiming at scalable and virtually standardized distributed computing resources, are well suited to the challenge posed by the capital market practices. Both consolidate computing resources by introducing a layer of middleware to orchestrate the use of geographically distributed powerful computers and large storages via fast networks. It is nontrivial to harvest the most of the resources from this kind of architecture. Wiener process plays a central role in modern financial modeling. Its scaled random walk feature, in essence, allows millions of financial simulation to be conducted simultaneously. The sheer scale can only be tackled via grid or cloud computing. In this study the core computing competence for financial services is examined. Grid and cloud computing will be briefly described. How the underlying algorithm for financial analysis can take advantage of grid environment is chosen and presented. One of the most popular practiced algorithms Monte Carlo simulation is used in our case study for option pricing and risk management. The various distributed computational platforms are carefully chosen to demonstrate the performance issue for financial services.

49.1 Introduction

49.1.1 Information Technology (IT) for Financial Services

The finance services industry involves a broad range of organizations such as banks, credit card companies, insurance companies, consumer finance companies, stock brokerages, investment funds, and some government-sponsored enterprises. The industry represents a significant share of the global market. Information technology (IT) in the financial service industry is considered as an indispensable tool for productivity as well as competitiveness in the market. The IT spending in financial service industry grows constantly across different industry verticals (banking, insurance, and securities and investments). The impact directly from the use of advanced IT brings on financial services industry on the rise.

The structure of the industry has changed significantly in the last two decades as companies, which are not traditionally viewed as financial service providers, have taken advantage of opportunities created by technology to enter the market. New technology-based services keep emerging. These changes are direct result of the interaction of technology with the industrial environment, such as economic atmosphere, societal pressures, and the legal/regulatory environment in which the financial service industry operates. The effects of IT on the internal operations, the structure, and the types of services offered by the financial service industry have been particularly profound (Phillips et al. 1984; Hauswald and Marquez 2003; Griffiths and Remenyi 2003). IT technology has been and continues to be both a motivator and facilitator of change in the financial service industry, which ultimately leads to competitiveness of the industry. The change is in particular radical after 1991 when the World Wide Web was invented by Tim Berners-Lee and his group for information sharing in the community of high energy physics. It was later introduced to the rest of the world, which subsequently changed the face of how people doing business today.

Informational considerations have long been recognized to determine not only the degree of competition but also the pricing and profitability of financial services and instruments. Recent technological progress has dramatically affected the production and availability of information, thereby changing the nature of competition in such informationally sensitive markets. Hauswald and Marquez (2003) investigate how advances in information technology (IT) affect competition in the financial services industry, particularly credit, insurance, and securities markets. Two aspects of improvement in IT are focused: better processing and easier dissemination of information. In other words, two dimensions of technology progress that affect competition in financial services can be defined as advances in the ability to process and evaluate information and in the ease of obtaining information generated by competitors. While better technology may result in improved information processing, it might also lead to low cost or even free access to information through, for example, informational spillovers. They show that in the context of credit screening, better access to information decreases interest rates and the returns from screening. On the other hand, an improved ability to process information increases interest rates and bank profits. Hence predictions regarding financial claims' pricing hinge on the overall effect ascribed to technological progress. Their results conclude that in general financial market informational asymmetries drive profitability.

The viewpoint of Hauswald and Marquez is adopted in this work. Assuming competitors in the dynamics of financial market possess similar capacity, the informational asymmetries can be created sometimes only between seconds and now are possible to be achieved through the outperformance of underlying IT platforms.

49.1.2 Competitiveness Through IT Performance

Following the computing evolution in financial services, it was a centralized process to begin with and gradually decentralized into a distribution of practical

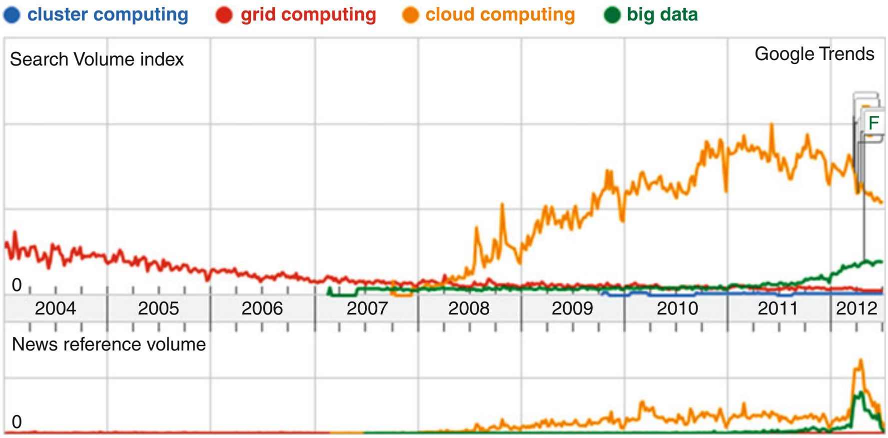

Fig. 49.1 The trend history from Google Trend according to global Search Volume and global News Reference Volume, in which the alphabetic letters represent the specific events that relate to each curve

trading application logic across service networks. Financial services have tradition of doing most of its heavy lifting financial analysis in overnight batch cycles. However, in securities trading it cannot satisfy the need due to its ad hoc nature and requirement of fast response.

New computing paradigms, grid computing and cloud computing were subsequently emerged in the last decade. The grid computing was initially incorporated into the core context of a well-referenced Atkins' report of National Science Board of the United States, namely, "Revolutionizing Science and Engineering Through Cyberinfrastructure" (Atkins et al. 2003), which lays down a visionary path for future IT platform development of the world. One may observe this trend from statistics from Google Trend regarding the global Search Volume and global News Reference Volume of key phrases of "cluster computing," "grid computing," "cloud computing," and "Big Data" (Fig. 49.1), which represents four main stream computing paradigms in high-end quantitative analysis.

Cluster computing is a group of coupled computers that work closely together so that in many respects they can be viewed as though they are a single computer. They are connected with high-speed local area networks and the purpose is usually to gain more compute cycles with better cost performance and higher availability. The grid computing aims at virtualizing scalable geographically distributed computing and observatory resources to maximize compute cycles and data transaction rates with minimum cost. Cloud computing is more of recent development owing to the similar technology used in global information services providers, such as Google and Amazon. The cloud is referred to as a subset of Internet if to be explained in a simplest fashion. Within the cloud the computers also talk with servers instead of communicating with each other similarly to that of peer-to-peer computing (Milojicic et al. 2002). There are no definitive definitions for the above terminology. However, people tend to view clusters as one of foundational components of grids, or grids as a meta-cluster on wide area networks. This is also known as horizontal integration. The cloud virtualizes further the compute, store, and network in a utility sense and provides an interface between users and grids. We refer to Foster et al. (2008) and Yelick et al. (2011) for a comparison. This perspective considers grids as a backbone of cyberinfrastructure to support the clouds. Similarly, in early days of development of grids, there is a so-called "@HOME" style PC grids (Korpela et al. 2001), which are exactly working on at least ten of thousands of PCs, in which owners of PCs donate their CPU times when their machines are in idle. The PC grids can be specifically categorized as clouds.

Figure 49.1 shows that there is a gradual drop in the curve of search volume for grid computing and cluster computing, and many surges, grows but a recent quick drop on cloud computing since its introduction in mid-2007. The new rising technology is Big Data (Bughin et al. 2010), which implies a paradigm shift from compute centric, network centric gradually to data-centric computing. However, the size of the search volume strongly relates to the degree of maturity of each computing paradigm. This is obvious in cluster computing. Clusters are the major market products, either in supercomputers from big vendors, such as IBM, HP, SGI, and NEC, or from aggregation of PCs in university research laboratories. Figure 49.1 also implies constant market need for high-end computing. The performance and security issues are fundamental to general distributed and parallel computing, which also remain as a challenge to cluster, grid, cloud, and Big Data (Lauret et al. 2010; Ghoshal et al. 2011; Ramakrishnan et al. 2011). Performance models in compute-based grid, which is also cloud-like, environment, are adopted in this work. The general definitions of grid and cloud computing will be introduced and briefly compared. To tackle the core performance issue, grids are chosen to demonstrate how fundamental financial calculations can be improved, hence leverage the financial service.

Grid computing, following by cloud computing as shown in Fig. 49.1, has been matured to serve as a production environment for finance services in recent years. Grid computing is well suited to the challenge posed by the capital market practices. In this study the core computing competence for financial services will be examined and how underlying algorithms for financial analysis can take advantage of grid environment scrutinized. One of the most popular practiced algorithms is Monte Carlo simulation (MCS), and it will be specifically used in our case study for calculations of option pricing and for value at risk (VaR) in risk management.

Three grid platforms are carefully chosen to exploit the performance issue for financial services. The first one is traditional grid platform with heterogeneous and distributed resources. Usually digital packets are connected via optical fibers. For long distance, depending on network traffics, it will produce approximately 150-300 microseconds (mm) latency across the Pacific Ocean. This is the physical constrain of light speed when traveling through the fiber channels. Therefore, even in split-second packets can still travel to anywhere in the world. The Pacific Rim Applications and Grid Middleware Assembly (PRAGMA) grid is a typical example, which linked with 14 countries and 36 sites. The system is highly heterogeneous. The computer nodes mounted to PRAGMA grid range from usual PC clusters to high-end supercomputers. The second one is a special Linux, or DRBL, PC cluster. It converts system into a homogenous Linux system and exploits the compute cycles of the cluster. The intention is to provide dynamic and flexible resources to cope better with uncertainty of the traders' cycle demand. Finally, PC grid is chosen to demonstrate finance services that can be effectively conducted through a cloud-based computing. The usefulness of PC grid is based on the fact that 90 % of CPUs time of PCs were in idled status.

49.2 Performance Enhancement

In this section two types of grid systems, compute intensive and data intensive, respectively, are introduced. The classification of the types is based on various grid applications. Traditionally, the grid systems provide a general platform to harvest or to scavenge, if used only in idle status, compute cycles for a collection of resources across boundaries of institutional administration. In real world most applications are in fact data centric. For example, in a trading center, it collects tick-by-tick volume data from all related financial markets and is driven by informational flows, hence typical data centric. However, as noted in Sect. 49.3.2.1, the core competence still lies on the performance enhancement of the IT system. The following two subsections will give more details of compute intensive as well as data-intensive grid systems by a survey of current development of grids specifically for financial services. In some cases, e.g., high-frequency data with real-time analysis, two systems have to work together to get better performance. Our emphasis will be more on compute intensive grid system.

49.2.1 High-End Computing Technology

49.2.1.1 Definitions of High-End Computing

Grid was coined by Ian Foster (Foster and Kessleman 2004) who gave the essence of the definitions as below:

> The sharing that we are concerned with is not primarily file exchange but rather direct access to computers, software, data, and other resources, as is required by a range of collaborative problem solving and resource-brokering strategies emerging in industry, science, and engineering. This sharing is, necessarily, highly controlled, with resource providers and consumers defining clearly and carefully just what is shared, who is allowed to share, and the conditions under which sharing occurs. A set of individuals and/or institutions defined by such sharing rules form what we call a *virtual organization*.

The definition is centered on the concept of virtual organization, but it is not explicit enough to explain what the grid is. Foster then provides additional checklist as below to safeguard the possible logic pitfalls of the definition. Hereby, grid is a system that:

1. Coordinates resources that are not subject to centralized control.

   A grid integrates and coordinates resources and users that live within different control domains – for example, the user's desktop vs. central computing, different administrative units of the same company, or different companies – and addresses the issues of security, policy, payment, membership, and so forth that arise in these settings. Otherwise, we are dealing with a local management system.

2. Using standard, open, general-purpose protocols and interfaces.

   A grid is built from multipurpose protocols and interfaces that address such fundamental issues as authentication, authorization, resource discovery, and resource access. As I discuss further below, it is important that these protocols and interfaces be *standard* and *open*. Otherwise, we are dealing with an application specific system.

3. *To deliver nontrivial qualities of service*.

   A grid allows its constituent resources to be used in a coordinated fashion to deliver various qualities of service, relating, for example, to response time, throughput, availability, and security, and/or co-allocation of multiple resource types to meet complex user demands, so that the utility of the combined system is significantly greater than that of the sum of its parts.

The definition of grid thus far is well accepted and has been stably used up to now. The virtual organization (VO) has strong implication of community driven and collaborative sharing of distributed resources. The advance of development of optical fiber network in recent years plays a critical role of why grids can be a reality. It is also the reason why now the computing paradigm shifts to distributed/grid computing.

Additionally, perhaps the most generally useful definition is that *a grid consists of shared heterogeneous computing and data resources networked across administrative boundaries*. Given such a definition, a grid can be thought of as both an access method and a platform, with grid middleware being the critical software that enables grid operation and ease of use.

The term "cloud computing" has been used to refer to different concepts, models, and services over the last few years. The definition for cloud computing provided by the National Institute of Standards and Technology (NIST) is well received in the IT community, which defines cloud computing as *a model for enabling convenient, on-demand network access to a shared pool of configurable computing resources (*e.g., *networks, servers, storage, applications, and services) that can be rapidly provisioned and released with minimal management effort service provider interaction* (Mell and Grance 2011). The model gains popularity in the industry for its emphasis on pay-as-you-go and elasticity, the ability to quickly expand and collapse the utilized service as demand requires. Thus new approaches to distributed computing and data analysis have also emerged in conjunction with the growth of cloud computing. These include models like MapReduce (Dean and Ghemawat 2004) and scalable key-value stores like Big Table (Chang et al. 2006).

From the high-end computing perspective, cloud computing technology allows users to have the ability to get on-demand access to resources to replace or supplement existing systems, as well as the ability to control the software environment. Yet the core competence still lies on the performance of financial calculation and further of the transactions of financial processes. This work will focus on the core competence in financial calculation based on grid environment. Grid computing technology will be used to explain how the core financial calculations can be significantly accelerated in various distributed and parallel computing environments. The calculation models in this work can be easily migrated to pure cloud environments.

49.2.1.2 Essence of IT Technology

To realize the above goal, it needs to handle technically interoperability of middleware that is capable of communicating between heterogeneous computer systems across institutional boundaries. The movement of grid began in 1996 by Ian Foster and Kessleman (2004). Before their development, another branch of high-performance computing that focuses on connecting geographically distributed supercomputers to achieve one single grand task had been developed by Smarr and Catlett (1992). They coined such a methodology as metacomputing and their query has been how we can have infinite computing power under the physical limit, such as Moore's Law. However, it remains to be less useful because its limit goal on pursuing top performance without noticing practical use in real world. The idea lives on and generates many tools dedicated to high-performance/high-throughput computing, such as Condor (Litzkow et al. 1988), Legion (Grimshaw and Wulf 1997), and UNICORE (Almond and Snelling 1999). Condor, as suggested by the name of the project, is devised to scavenge a large cluster of idle workstations. Legion is closer to the development of worldwide virtual computer. The goal of UNICORE is even much simpler and practical. It was developed when Germany government decided to consolidate their five national supercomputer centers into a virtual one to reduce the management cost and needed a software tool to integrate them, hence the UNICORE. These tools were successful under their development scope. However they fail to meet the first and the second items in Foster's checklist in the previous section.

The emergency of grids follows the similar path as that of Condor and Legion at the first place, in which its development aims at resources sharing in high-performance computing. However, its vision in open standards and the concept of virtual organization allows its development go far beyond merely cluster supercomputers together. It gives a broader view of resources sharing, in which it is not only limited to the sizable computing cycles and storage space to be shared but also extended virtually to calculable machines that are able to hook up to the Internet, such as sensors and sensor loggers, storage servers, and computers. Since 1996, Foster and his team have been developing software tools to achieve the purpose. Their software Globus Toolkit (Foster and Kessleman 2004) is now a de facto middleware for grids. However, the ambitious development is still considered insufficient to meet the ever-growing complexity of grid systems.

As mentioned earlier that grid is based on open specifications and standards, they allow all stakeholders within the virtual organization/grid to communicate with each other with ease and enable ones more to focus on integrated value creation activities. The open specifications and standards are made by the community of Open Grid Forum (OGF), which plays as a standard body and made, discussed, and announced new standards during regular OGF meetings. Grid Specifications and Standards include architecture, scheduling, resource management, system configuration, data, data movement, security, and grid security infrastructure. In 2004, OGF announced Globus Toolkit version, which adopts both the open standard of grid, Open Grid Services Architecture (OGSA), and the more widely adopted World Wide Web standard, web services resource framework (WSRF), which ultimately enable grids to tackle issues of both scalability and complexity of very large grid systems.

49.2.2 Compute Intensive IT Systems

The recent development of computational finance based on grids is hereby scrutinized and remarks given. Our major interest is to see if the split-second performance is well justified under the grid architecture. Also, real-time issue with real market parametric data should be used as input for practical simulation. In addition, issues of intersystem, interdisciplinary and geographically distribution of resources, and the degree of virtualization are crucial to the success of such a grid. The chosen projects are reviewed and discussed as follows:

1. PicsouGrid

   This is a French grid project for financial service. It provides a general framework for computation finance and targets on applications of option trading, option pricing, Monte Carlo simulation, aggregation of statistics, etc. (Stokes-Rees et al. 2007). The key for this development is the implementation of the middleware ProActive. ProActive is an in-house Java library for distributed computing developed by INRIA Sophia Antipolis, France. It provides transparent asynchronous distributed method calls and is implemented on top of Java RMI. It is also used in commercial applications. It also provides fault tolerance mechanism. The architecture is shown in Fig. 49.2, which is very similar to most of grid applications apart from the software stack used. The option pricing was tested in an approximately 894 CPUs. The underlying computer systems are heterogeneous. The system is used for metacomputing. As a result, the system has to specifically design to orchestrate and to synchronize and re-synchronize the whole distributed processes for one calculation. Once the grid system requires synchronization between processes, which implies stronger coupling of algorithm of interest, the performance will be seriously affected. There is no software treatment to solve such problems and should be tackled by physical infrastructure, e.g., optical fiber network with Layer 2 light path.

2. FinGrid

   FinGrid stands for Financial Information Grid. Its study includes components of bootstrapping, sentimental analysis, and multi-scale analysis, which focuses on information integration and analysis, e.g., data mining. It takes advantage of the huge collection of numerical and textual data simultaneously to emphasize the study of societal issues (Amad et al. 2004; Ahmad et al. 2005; Gillam et al. 2005). The architecture of FinGrid is shown in Fig. 49.3. It is a typical 3-tier system, in which the first tier facilitates the client in sending a request to one of the services: Text Processing Service or Time Series Service; the second tier

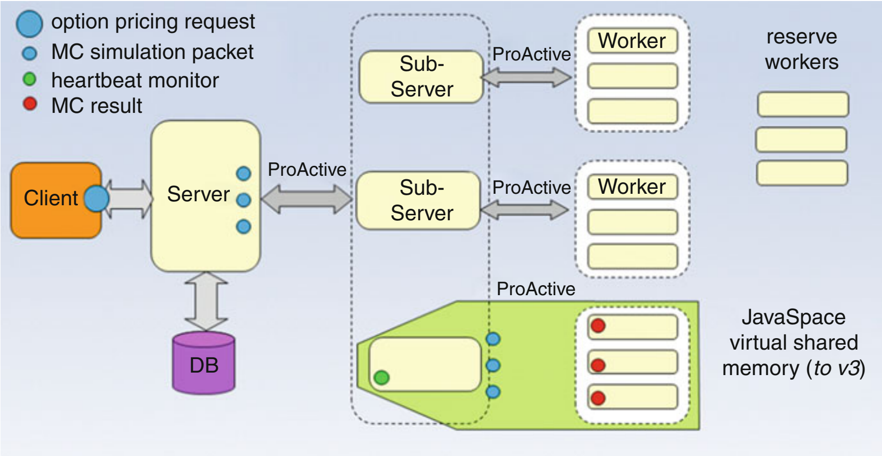

Fig. 49.2 Architecture of PicsouGrid for option pricing based on Monte Carlo simulation (Stokes-Rees et al. 2007)

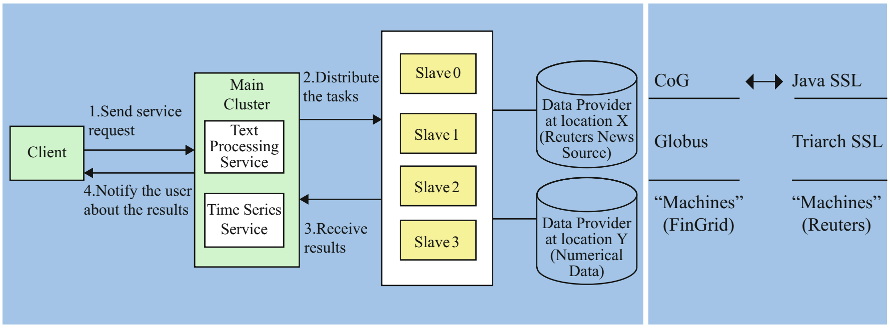

Fig. 49.3 The architecture of Financial Information Grid (FinGrid)

facilitates the execution of parallel tasks in the main cluster and is distributed to a set of slave machines (nodes), and the third tier comprises the connection of the slave machines to the data providers. This work focuses on small scale and dedicated grid system. It pumps in real and live numerical and textual data from say Reuters and performs real-time sophisticated data mining analysis. This is a good prototype for financial grid. However, it will encounter similar problem as that of PicsouGrid if it is to scale up. The model is more successful in automatically combining real data and the analysis.

3. IBM Japan collaborates with life insurance company and adopts PC grids concept to scavenge more compute cycles (Tanaka 2003):

   In this work an integrated risk management system (see Fig. 49.4) is modified, in which the future scenarios of red circle of Fig. 49.4 are send via grid middleware to a cluster of PCs. According to the size of the given PCs, the

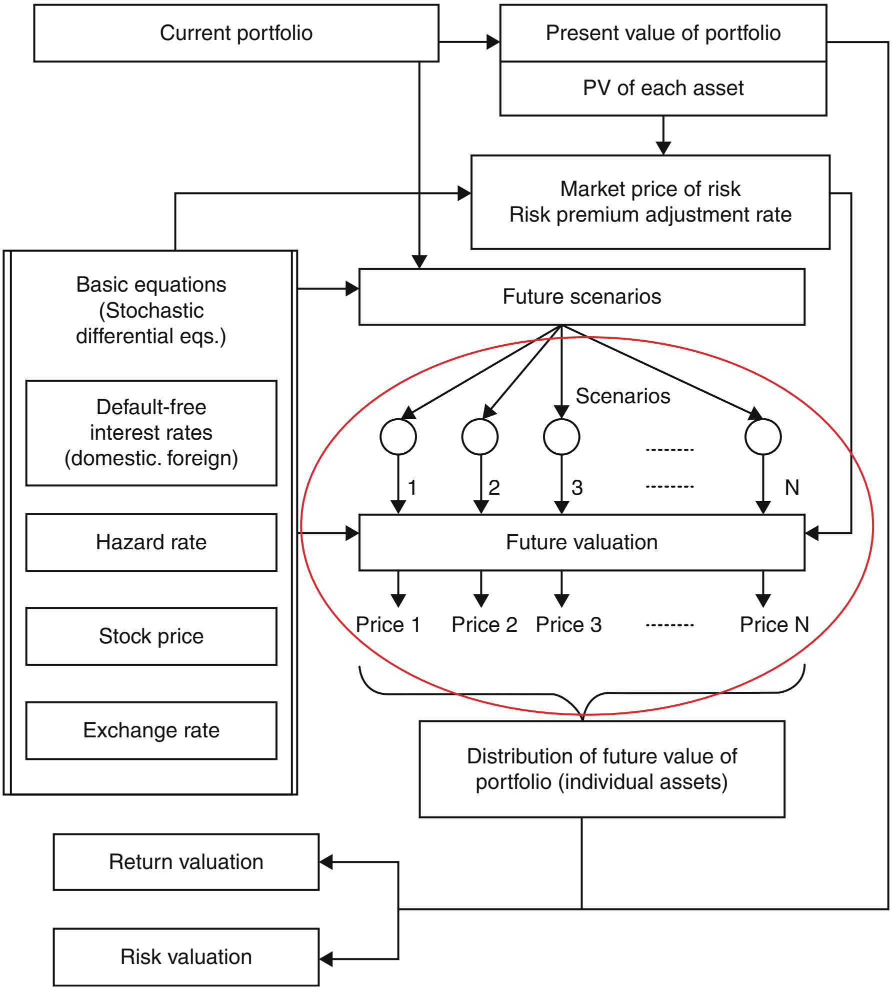

Fig. 49.4 Architecture of Integrated Risk Management System (Tanaka 2003)

number scenarios are then divided in a work balanced manner for each PC. This is the most typical use of compute intensive grid systems and a good practice for production system. However, the key issues that discussed in the above two cases cannot be answered in this study. Similar architecture can also be found in EGrid (Leto et al. 2005).

4. UK e-Science developed a grid service discovery in the financial market sector focusing on integration of different knowledge flows (Bell and Ludwig 2005).

From application's viewpoint, business and technical architecture of financial service applications may be segmented by product, process, or geographic concerns. Segmented inventories make inter silo reuse difficult. The service integration model is adopted and a loosely coupled inventory – containing differing explicit

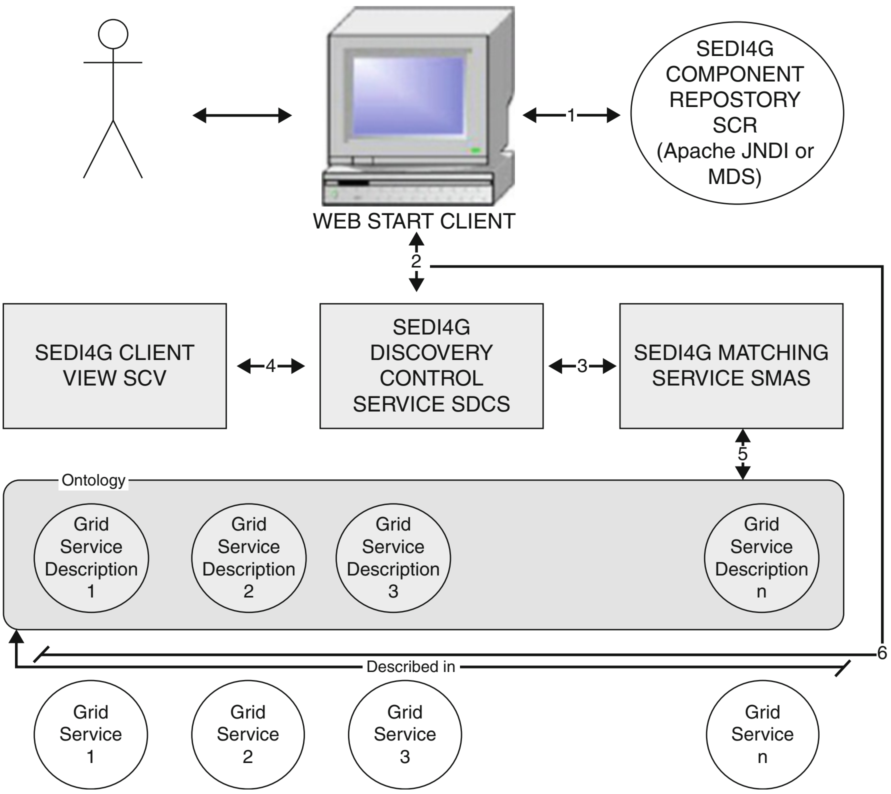

Fig. 49.5 The semantic discovery for Grid Services Architecture (SEDI4G) (Bell and Ludwig 2005)

capability knowledge. Three use cases were specifically chosen in this work to explore the use of semantic searching:

Use case 1 – Searching for trades executed with a particular counterparty

Use case 2 – Valuing a portfolio of interest rate derivative products

Use case 3 – Valuing an option-based product

The use cases were chosen to provide examples of three distinct patterns of use – aggregation, standard selection, and multiple selection. The architecture (see Fig. 49.5) is bound specifically with the user cases. The advantage for grid in this case is that it can be easily tailored into specific user need to integrate different applications, which is a crucial strength of using grid.

49.2.3 Data-Intensive IT Systems

Grid in financial services from the perspective of web services towards financial services industry. The perspective is more on transactional side. Once the bottleneck of compute cycle is solved, the data-centric nature will play the key role again.

The knowledge flows back to the customized business logic should provide the best path for users to access the live data of interest. There is no strong focus of development on this data-intensive grid system. Even in FinGrid, which claims in streaming live data for real-time analysis, the data issue remains part of compute grids. However, the need for dynamic data management is obvious as mentioned in Amad et al. (2004). Hereby, we like to introduce and implement a dynamic data management software Ring Buffer Network Bus (RBNB) DataTurbine to serve such a purpose.

RBNB DataTurbine was used recently to support global environmental observatory network, which involves linking with ten of thousand of sensors and is able to obtain the observed data online. It meets grid/cyberinfrastructure (CI) requirements with regard to data acquisition, instrument management, and state-of-health monitoring including reliable data capture and transport, persistent monitoring of numerous data channels, automated processing, event detection and analysis, integration across heterogeneous resources and systems, real-time tasking and remote operations, and secure access to system resources. To that end, streaming data middleware provides the framework for application development and integration.

Use cases of RBNB DataTurbine include adaptive sampling rates, failure detection and correction, quality assurance, and simple observation (see Tilak et al. 2007). Real-time data access can be used to generate interest and buy-in from various stakeholders. Real-time streaming data is a natural model for many applications in observing systems, in particular event detection and pattern recognition. Many of these applications involve filters over data values, or more generally, functions over sliding temporal windows. The RBNB DataTurbine middleware provides a modular, scalable, robust environment while providing security, configuration management, routing, and data archival services. The RBNB DataTurbine system acts as an intermediary between dissimilar data monitoring and analysis devices and applications. As shown in Fig. 49.6, a modular architecture is used, in which a source or "feeder" program is a Java application that acquires data from an external live data sources and feeds it into the RBNB server. Additional modules display and manipulate data fetched from the RBNB server. This allows flexible configuration where RBNB serves as a coupling between relatively simple and "single purpose" suppliers of data and consumers of data, both of which are presented a logical grouping of physical data sources. RBNB supports the modular addition of new sources and sinks with a clear separation of design, coding, and testing (ref. Fig. 49.6). From the perspective of distributed systems, the RBNB DataTurbine is a "black box" from which applications and devices send data and receive data. RBNB DataTurbine handles all data management operations between data sources and sinks, including reliable transport, routing, scheduling, and security. RBNB accomplishes this through the innovative use of memory and file-based ring buffers combined with flexible network objects. Ring buffers are a programmer-configurable mixture of memory and disk, allowing system tuning to meet application-dependent data management requirements. Network bus elements perform data stream multiplexing and routing. These elements

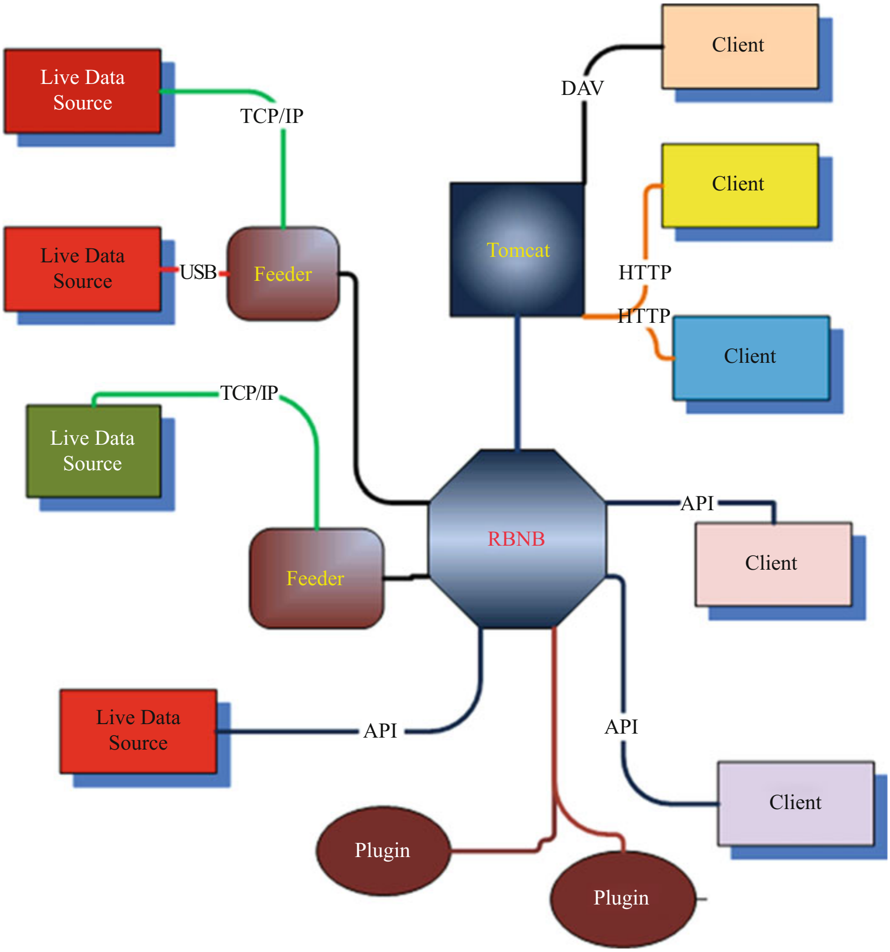

Fig. 49.6 RBNB DataTurbine use scenario for collaborative applications

combine to support seamless real-time data archiving and distribution over existing local and wide area networks. Ring buffers also connect directly to client applications to provide streaming-related services including data stream subscription, capture, rewind, and replay. This presents clients with a simple, uniform interface to real-time and historical (playback) data.

49.3 Distributed and Parallel Financial Simulation

In the previous sections, we address issues of incorporating IT technology for financial competitiveness and derive that the core lies on the performance of IT platform, providing the competitors in the market have similar capacity and are equally informed. Grid technology, as the leading IT development in high-performance computing, is introduced as the cutting-edge IT platform to meet our goal. Many companies have adopted similar technology of grids with success as mentioned in Sect. 49.1. There are also increasing research interests, which result in the work discussed in Sect. 49.2.3. Better performance, however, cannot be achieved by merely using a single architecture as observed in the cases of Sect. 49.2.3. The architecture obviously has to be specifically chosen for the analysis of interest. Simultaneously, the analysis procedures have to be tailored into the chosen architecture for performance fine-tune.

In this section, we will introduce and discuss analysis procedures of financial simulation and how to tailor the analysis procedures into grid architectures by distribution and parallelism. The popular calculations for option pricing and for value at risk (VaR) in trading practice are used to serve the purpose. The calculation is based on Monte Carlo simulation, which is chosen not only because it is a well-received approach due to the absence of straightforward closed-form solutions for many financial models but also a numerical method intrinsically suited to mass distribution and mass parallelism. The success of Monte Carlo simulation lies on the quality of random number generator, which will be discussed in details at the end of the section.

49.3.1 Financial Simulation

There are wide variety of sophisticated financial models developed, to name a few, ranging from analysis in time series, fractals, nonlinear dynamics, and agent-based modeling to applications in optional pricing, portfolio management, and market risk measure, etc. (Schmidt 2005), in which option pricing and VaR calculations of market risk measure can be considered crucial and one of the most practiced activities in market trading.

49.3.1.1 Option Pricing

An option is an agreement between two parties to buy or sell an asset at a certain time in the future for a certain price. There are two types of options:

Call Option: A call option is a contract that gives the right to its holder (i.e., buyer) without creating an obligation, to buy a prespecified underlying asset at a predetermined price. Usually this right is created for a specific time period, e.g., 6 months or more. If the option can be exercised only at its expiration (i.e., the underlying asset can be purchased only at the end of the life of the option), the option is referred to as a European-style Call Option (or European Call). If it can be exercised any date before its maturity, the option is referred to as an American-style Call Option (or American Call).

Put Option: A put option is a contract that gives its holder the right without creating the obligation to sell a prespecified underlying asset at a predetermined price. If the option can be exercised only at its expiration (i.e., the underlying asset can be sold only at the end of the life of the option), the option is referred to as a European-style Put Option (or European Put). If it can be exercised any date before its maturity, the option is referred to as an American-style Put Option (or American Put).

To price options in computational finance, we use the following notation: K is the strike price; T is the time to maturity of the option; S_t is the stock price at time t; r is the risk-free interest rate; μ is the drift rate of the underlying asset (a measure of the average rate of growth of the asset price); σ is the volatility of the stock; and V denotes the option value. Here is an example to illustrate the concept of option pricing. Suppose an investor enters into a call option contract to buy a stock at price K after 3 months. After 3 months, the stock price is S_t. If $S_t > K$ then one can exercise one's option by buying the stock at price K and by immediately selling in the market to make a profit of $S_T - K$. On the other hand, if he $S_T - K$ to be buy the stock. Hence, we see that a call option to buy the stock at time T at price K will get payoff $(S_T - K)^+$, where $(S_T - K)^+ \equiv \max(S_T - K, 0)$ (Schmidt 2005; Hull 2003).

49.3.1.2 Market Risk Measurement Based on VaR

Market risks are the prospect of financial losses or gains, due to unexpected changes in market prices and rates. Evaluating the exposure to such risks is nowadays of primary concern to risk managers in financial institutions. Until the late 1980s market risk was estimated through gap and duration analysis (interest rates), portfolio theory (securities), sensitivity analysis (derivatives), or scenarios analysis. However, all these methods could be either applied only to very specific assets or relied on subjective reasoning.

Since the early 1990s a commonly used market risk estimation methodology has been the value at risk (VaR). A VaR measure is the highest possible loss L incurred from holding the current portfolio over a certain period of time at a given confidence level (Dowd 2002):

$$\mathrm{P}(L > VaR) \leq 1 - c \tag{49.1}$$

where c is the confidence level, typically 95 %, 97.5 %, or 99 %, and P is cumulative distribution function. By convention, $L = -\Delta X(\tau)$, where $\Delta X(\tau)$ is the relative change (return) in portfolio value over the time horizon τ. Hence, large values of L correspond to large losses (or large negative returns).

The VaR figure has two important characteristics: (1) it provides a common consistent measure of risk across different positions and risk factors and (2) it takes into account the correlations or dependencies between different risk factors. Because of its intuitive appeal and simplicity, it is no surprise that in a few years value at risk has become the standard risk measure used around the world. However, VaR has a few deficiencies, among them the non-subadditivity – a sum of VaR's two portfolios can be smaller than the VaR of the combined portfolio. To cope with these shortcomings, Artzner et al. proposed an alternative measure that satisfies the assumptions of a coherent risk measure. The expected shortfall (ES), also called expected tail loss (ETL) or conditional VaR, is the expected value of the losses in excess of VaR:

$$\mathrm{ES} = \mathrm{E}(L|L > VaR) \tag{49.2}$$

It is interesting to note that although new to the finance industry – expected shortfall has been familiar to insurance practitioners for a long time. It is very similar to the mean excess function which is used to characterize claim size distribution; see (Cizek et al. 2011).

The essence of the VaR and ES computations is estimation of low quantiles in the portfolio return distributions. Hence, the performance of market risk measurement methods depends on the quality of distribution assumptions on the underlying risk factors. Many of the concepts in theoretical and empirical finance developed over the past decades, including the classical portfolio theory, the Black-Scholes-Merton option pricing model, and even the RiskMetrics variance-covariance approach to VaR rest upon the assumption that asset returns follow a normal distribution. The assumption is not justified by real market data. Our interest is more on the calculation side. For interested readers we refer further to (Weron 2004).

49.3.2 Monte Carlo Simulations

49.3.2.1 Monte Carlo and Quasi-Monte Carlo Methods

In general, Monte Carlo (MC) and quasi-Monte Carlo (QMC) methods are applied to estimate the integral of function $f(x)$ over $[0, 1]^d$ unit hypercube where d is the dimension of the hypercube:

$$I = \int_{[0,1]^d} f(x)dx \tag{49.3}$$

In MC methods, I is estimated by evaluating $f(x)$ at N independent points randomly chosen from a uniform random distribution over $[0, 1]^d$ and then evaluating average

$$\hat{I} = \frac{1}{N}\sum_{i=1}^{N} f(x_i) \tag{49.4}$$

From the law of large numbers, $\hat{I} \to I$ as $N \to \infty$. The standard deviation is

$$\sqrt{\frac{1}{N-1}\sum_{i=1}^{\mathrm{N}} (f(x_i) - I)^2} \tag{49.5}$$

Therefore, the error of MC methods is proportional to $N^{-1/2}$.

QMC methods compute the above integral based on low-discrepancy (LD) sequences. The elements in a LD sequence are "uniformly" chosen from $[0, 1]^d$ rather than "randomly." The discrepancy is a measure to evaluate the uniformity of points over $[0, 1]^d$. Let $\{q_n\}$ be a sequence in $[0, 1]^d$; the discrepancy D_N^* of q_n is defined as follows, using Niederreiter's notation (Niederreiter 1992):

$$D_N^*(q_n) = \sup_{B \in [0,1)^d} \left| \frac{A(B, q_n)}{N} - v_d(B) \right| \tag{49.6}$$

where B is a subcube of $[0, 1]^d$ containing the origin, $A(B, q_n)$ is the number of points in q_n that fall into B, and $V_d(B)$ is the d-dimensional Lebesgue measure of B. The elements of q_n are said uniformly distributed if its discrepancy $D_N^* \to 0$ as $N \to \infty$. From the theory of uniform distribution sequences (Kuipers and Niederreiter 1974), the estimate of the integral using a uniformly distributed sequence $\{q_n\}$ is $\hat{I} = \frac{1}{N}\sum_{n=1}^{N} f(q_n), as\, N \to \infty$ then $\hat{I} \to I$. The integration error bound is given by the Koksman-Hlawka inequality:

$$\left| I - \frac{1}{N}\sum_{n=1}^{N} f(q_n) \right| \le V(f) D_N^*(q_n) \tag{49.7}$$

where $V(f)$ is the variation of the function in the sense of Hardy and Krause (see Kuipers and Niederreiter 1974), which is assumed to be finite.

The inequality suggests a smaller error can be obtained by using sequences with smaller discrepancy. The discrepancy of many uniformly distributed sequences satisfies $O((\log N)^d/N)$. These sequences are called low-discrepancy (LD) sequences (Chen et al. 2006). Inequality (49.7) shows that the estimates using a LD sequence satisfy the deterministic error bound $O((\log N)^d/N)$.

49.3.2.2 Monte Carlo Simulations for Option Pricing

Under the risk-neutral measure, the price of a fairly valued European call option is the expectation of the payoff $E[e^{-rT}(S_T - K)^+]$. In order to compute the expectation, Black and Scholes (1973) modeled the stochastic process generating the price of a non-dividend-paying stock as geometric Brownian motion:

$$dS_t = \mu S_t dt + \sigma S_t dW_t \tag{49.8}$$

where W is a standard Wiener process, also known as Brownian motion. Under the risk-neutral measure, the drift μ is set to $\mu = r$.

To simulate the path followed by S, suppose the life of the option has been divided into n short intervals of length $\Delta t (\Delta t = T/n)$, the updating of the stock price at $t + \Delta t$ from t is (Hull 2003):

$$S_{t+\Delta t} - S_t = r S_t \Delta t + \sigma S_t Z \sqrt{\Delta t} \tag{49.9}$$

where Z is a standard random variable, i.e., $Z{\sim}(0,1)$. This enables the value of $S_{\Delta t}$ to be calculated from initial value S_t at time Δt, the value at time $2\Delta t$ to be calculated from $S_{\Delta t}$, and so on. Hence, a completed path for S has been constructed.

In practice, in order to avoid discretization errors, it is usual to simulate ln$S$ rather than S. From It ô's lemma, the process followed by of Eq. 49.9 is (Bratley and Fox 1988)

$$d\ln S = \left(r - \frac{\sigma^2}{2}\right)dt + \sigma dz \tag{49.10}$$

so that

$$\ln S_{t+\Delta t} - \ln S_t = \left(r - \frac{\sigma^2}{2}\right)dt + \sigma Z\sqrt{\Delta t} \tag{49.11}$$

or equivalently

$$S_{t+\Delta t} = S_t \exp\left[\left(r - \frac{\sigma^2}{2}\right)dt + \sigma Z\sqrt{\Delta t}\right] \tag{49.12}$$

Substituting independent samples $Z_i, \cdots, Z_n$ from the normal distribution into (Eq. 49.12) yields independent samples ${S_T}^{(i)}$, $i = 1, \cdots, n$, of the stock price at expiry time T. Hence, the option value is given by

$$V = \frac{1}{n}\sum_{i=1}^{n} V_i = \frac{1}{n}\sum_{i=1}^{n} e^{-rT}\max\left[{S_T}^{(i)} - K, 0\right] \tag{49.13}$$

The QMC simulations follow the same steps as the MC simulations, except that the pseudorandom numbers are replaced by LD sequences. The basic LD sequences known in literature are Halton (1960), Sobol (1967), and Faure (1982). Niederreiter (1992) proposed a general principle of generating LD sequences. In finance, several examples have shown that the Sobol sequence is superior to others. For example, Galanti and Jung (1997) observed that the Sobol sequence outperforms the Faure sequence, and the Faure marginally outperforms the Halton sequence. In this research, we use Sobol sequence in our experiments. The generator used for generating the Sobol sequence comes from the modified algorithm 659 of Joe and Kuo (2003).

49.3.2.3 Monte Carlo Bootstrap for VaR

Monte Carlo simulation is applicable with virtually any model of changes in risk factors and any mechanism for determining a portfolio's value in each market scenario. But revaluing a portfolio in each scenario can present a substantial computational burden, and this motivates research into ways of improving the efficiency of Monte Carlo methods for VaR.

The bootstrap (Efon 1981; Efron and Tibshirani 1986) is a simple and straightforward method for calculating approximated biases, standard deviations, confidence intervals, and so forth, in almost any nonparametric estimation problem. Method is a keyword here, since little is known about the bootstrap's theoretical basis, except that (a) it is closely related to the jackknife in statistic inferring; (b) under reasonable condition, it gives asymptotically correct results; and (c) for some simple problems which can be analyzed completely, for example, ordinary linear regression, the bootstrap automatically produces standard solutions.

The bootstrap method is straightforward. Suppose we observe returns $X_i = x_i$, $i = 1, 2, \cdots, n$, where the X_i are independent and identically distributed (iid) according to some unknown probability distribution F. The X_i may be real valued and two-dimensional or take values in a more complicated space. A given parameter $\theta(F)$, perhaps the mean, median, correlation, and so forth, is to be estimated, and we agree to use the estimate $\hat{\theta} = \theta\left(\hat{F}\right)$, where $\hat{F}$ is the empirical distribution function putting mass $1/n$ at each observed value x_i. We wish to assign some measure of accuracy to $\hat{\theta}$.

Let $\sigma(F)$ be some measure of accuracy that we would use if F were known, for example, $\sigma(F) = \mathrm{SD}_F\left(\hat{\theta}\right)$, the standard deviation of $\hat{\theta}$ when $X_1, X_2, \cdots, X_n \sim F^{(idd)}$. The bootstrap estimate of accuracy $\hat{\sigma} = \sigma\left(\hat{F}\right)$ is the nonparametric maximum likelihood estimate of $\sigma(F)$. In order to calculate $\hat{\sigma}$ it is usually necessary to employ numerical methods. (a) A bootstrap sample $X_1^*, X_2^*, \cdots, X_n^*$ is drawn from $\hat{F}$, in which each X_i^* independently takes value x_j with probability $1/n$, $j = 1, 2, \cdots, n$. In other words, $X_1^*, X_2^*, \cdots, X_n^*$ is an independent sample of size n drawn with replacement from the set of observations $\{x_1,x_2, \cdots, x_n\}$. (b) This gives a bootstrap empirical distribution function $\hat{F}^*$, the empirical distribution of the n values $X_1^*, X_2^*, \cdots, X_n^*$, and a corresponding bootstrap value $\hat{\theta}^* = \theta\left(\hat{F}^*\right)$. (c) Steps (a) and (b) are repeated, independently, in a large number of times, say N, giving bootstrap values $\hat{\theta}^{*1}, \hat{\theta}^{*2}, \cdots, \hat{\theta}^{*N}$. (d) The value of $\hat{\sigma}$ is approximated, in the case where $\sigma(F)$ is the standard deviation by the sample standard deviation of the $\hat{\theta}^*$ values, where

$$\frac{\hat{\mu} = \sum_{j=1}^{n} \hat{\theta}^{*j}}{N} \tag{49.14}$$

and

$$\hat{\sigma}^2 = \frac{\sum_{j=1}^{n} \left(\hat{\theta}^{*j} - \hat{\mu}\right)^2}{N - 1} \tag{49.15}$$

49.3.3 Distribution and Parallelism Based on Random Number Generation

Financial variables, such as prices and returns, are random time-dependent variables. Wiener process plays the central role in modeling. As shown in

Eqs. 49.8 and 49.9 for approximating the underlying prices $S_{t+\Delta t}$, or the bootstrap samples of return X_i^*, the solution methods involve basic market parameters, drift μ, volatility σ, and risk-free interest rate r, current underlying price S or return X, strike price K, and Wiener process, which is related to time to maturity Δt and standard random variable Z, i.e., $\Delta W = Z\sqrt{\Delta t}$. Monte Carlo methods simulate this nature of the Brownian motion directly. It follows Wiener process and approximates the standard random variable Z by introducing pseudo *iid* random number into each Wiener process. When the simulation number is large enough, e.g., if n in Eq. 49.13 is large enough, the mean value will approach the exact solution. The large number for n also implies the performance problems are the key problems for Monte Carlo methods. One the other hand, the *iid* property of the random number Z shows possible solution to tackle the performance problem through mass distribution and/or parallelism. The solution method centers on the random number generation.

The techniques of random number generation can be developed in a simple form through the approximation of a d-dimensional integral, e.g., (Eq. 49.3). Mass distribution and parallelism required solutions of for large dimension. However, most modern techniques in random number generation have limitations. In this study, both tradition pseudorandom number generation and high-dimensional low-discrepancy random number generator are considered.

Following Sect. 49.3.2.1 better solution can be achieved by making use of Sobol sequences, which were proposed by Sobol (1967). A computer implementation in Fortran 77 was subsequently given by Bratley and Fox (1988) as Algorithm 659. Other implementations are available as C, Fortran 77, or Fortran 90 routines in the popular Numerical Recipes collection of software. However, as given, all these implementations have a fairly heavy restriction on the maximum value of d allowed. For Algorithm 659, Sobol sequences may be generated to approximate integrals in up to 40 dimensions, while the Numerical Recipes routines allow the generation of Sobol sequences to approximate integrals in up to six dimensions only. The FinDer software of Paskov and Traub (1995) provides an implementation of Sobol sequences up to 370 dimensions, but it is licensed software. As computers become more powerful, there is an expectation that it should be possible to approximate integrals in higher and higher dimensions. Integrals in hundreds of variables arise in applications such as mathematical finance (e.g., see Paskov and Traub (1995)). Also, as new methods become available for these integrals, one might wish to compare these new methods with Sobol sequences. Thus, it would be desirable to extend these existing implementations such as Algorithm 659 so they may be used for higher-dimensional integrals. We remark that Sobol sequences are now considered to be examples of (t, d)-sequences in base 2. The general theory of these low-discrepancy (t, d)-sequences in base b is discussed in detail in Niederreiter (1992). The generation of Sobol sequences is clearly explained in Bratley and Fox (1988). We review the main points so as to show what extra data would be required to allow Algorithm 659 to generate Sobol sequences to approximate integrals in more than 40 dimensions. To generate the j th component of the points in a Sobol sequence, we need to choose a primitive polynomial of some degree *sj* in the field $\mathbb{Z}_2$, that is, a polynomial of the form

$$x^{s_j} + a_{1,j}x^{s_j-1} + \cdots + a_{s_j-1,j}x + 1, \tag{49.16}$$

where the coefficients $a_{1,j}\_\cdots\_a_{s_j}-1,j$ are either 0 or 1.

We use these coefficients to define a sequence $\{\mathrm{m}_{1,\ j},\ \mathrm{m}_{2,\ j,}\ \cdots\}$ of positive integers by the recurrence relation

$$\begin{aligned} m_{k,j} = a_{1,j}m_{k-1,j} \oplus 2^2 a_{2,j}m_{k-2,j} \oplus \cdots \\ \oplus 2^{s_j-1}a_{s_j-1,j}m_{k-s_j+1,j} \oplus 2^{s_j}a_{s_j,j}m_{k-s_j,j} \oplus m_{k-s_j,j} \end{aligned} \tag{49.17}$$

for $k \geq s_j + 1$, where $\oplus$ is the bit-by-bit exclusive-OR operator. The initial values $m_{1,j}, m_{2,j}, \cdots, m_{s_j,j}$ can be chosen freely provided that each $M_{k,j}$, $1 \leq k \leq s_j$ is odd and less than 2^k. The "direction numbers" $\{v_{1,j}, v_{2,j}, \cdots\}$ are defined by

$$v_{1,j} \equiv \frac{m_{k,j}}{2^k} \tag{49.18}$$

Then $x_{i,j}$, the j th component of the ith point in a Sobol sequence, is given by

$$x_{i,j} = b_1 v_{1,j} \oplus b_2 v_{2,j} \oplus \cdots \tag{49.19}$$

Where b_l is the lth bit from the right when i is written in binary, that is, $(\cdots b_2 b_1)_2$ is the binary representation of i. In practice, a more efficient Gray code implementation proposed by Antonov and Saleev (1979) is used; see Bratley and Fox (1988) for details. We then see that the implementation in Bratley and Fox (1988) may be used to generate Sobol sequences to approximate integrals in more than 40 dimensions by providing more data in the form of primitive polynomials and direction numbers (or equivalently, values of $m_{1,j}, m_{2,j}, \cdots, m_{s_j,j}$). When generating such Sobol sequences, we need to ensure that the primitive polynomials used to generate each component are different and that the initial values of the $m_{k,j}$'s are chosen differently for any two primitive polynomials of the same degree. The error bounds for Sobol sequences given in Sobol (1967) indicate we should use primitive polynomials of as low a degree as possible. We discuss how additional primitive polynomials may be obtained in the next section. After these primitive polynomials have been found, we need to decide upon the initial values of the $m_{k,j}$ for $1 \leq k \leq s_j$. As explained above, all we require is that they be odd and that $m_{k,j} < 2^k$. Thus, we could just choose them randomly, subject to these two constraints. However, Sobol and Levitan (1976) introduced an extra uniformity condition known as Property A. Geometrically, if the cube $[0, 1]^d$ is divided up by the planes $x_j = 1/2$ into 2^d equally sized subcubes, then a sequence of points belonging to $[0, 1]^d$ possesses Property A if, after dividing the sequence into consecutive blocks of 2^d points, each one of the points in any block belongs to a different subcube. Property A is not that useful to have for large d because of the computational time required to approximate an integral using 2^d points. Also, Property A is not enough to ensure that there are no bad correlations between pairs of dimensions. Nevertheless, Property A would seem a reasonable criterion to use in deciding upon a choice of the initial $m_{k,j}$. The numerical results for Sobol sequences given in Sect. 49.4 suggest that the direction numbers obtained here are indeed reasonable. Other ways of obtaining the direction numbers are also possible. For example, in Cheng and Druzdzel (2000), the initial direction numbers are obtained by an interesting technique of minimizing a measure of uniformity in two dimensions. This technique may alleviate the problem of bad correlations between pairs of dimensions that was mentioned above. Sobol (1967) showed that a Sobol sequence used to approximate a d-dimensional integral possesses Property A if and only if

$$\det(V_d) = 1(\mathrm{mod}2), \tag{49.20}$$

where V_d is the $d \times d$ binary matrix defined by

$$V_d = \begin{bmatrix} v_{1,1,1} & v_{2,1,1} & \cdots & v_{d,1,1} \\ v_{1,2,1} & v_{2,2,1} & & v_{d,2,1} \\ \vdots & & \ddots & \vdots \\ v_{1,d,1} & v_{2,d,1} & \cdots & v_{d,d,1} \end{bmatrix} \tag{49.21}$$

With $v_{k,j,1}$ denoting the first bit after the binary point of $v_{k,j,}$. The primitive polynomials and direction numbers used in Algorithm 659 are taken from Sobol and Levitan (1976), and a subset of this data may be found in Sobol (1967). Though it is mentioned in Sobol (1967) that Property A is satisfied for $d \leq 16$, that is, $\det(V_d) = 1$ (mod 2) for all $d \leq 16$, our calculations showed that Property A is actually satisfied for $d \leq 16$. As a result, we change the values of the $m_{k,j}$ for $21 \leq j \leq 40$, but keep the primitive polynomials. For $j \geq 41$, we obtain additional primitive polynomials. The number of primitive polynomials of degree s is $\phi(2^s - 1)/s$, where ϕ is Euler's totient function. Including the special case for $j = 1$ when all the $M_{k,j}$ are 1, this allows us to approximate integrals in up to dimension $d = 1{,}111$ if we use all the primitive polynomials of degree 13 or less. We then choose values of the $M_{k,j}$ so that we can generate Sobol sequences satisfying Property A in dimensions d up to 1,111. This is done by generating some values randomly, but these are subsequently modified so that the condition $\det(V_d) = 1$ (mod 2) is satisfied for all d up to 1,111. This process involves evaluating values of the $v_{k,j,1}$'s to obtain the matrix V_d and then evaluating the determinant of V_d. A more detailed discussion of this strategy is given in the next section. It is not difficult to produce values to generate Sobol's points for approximating integrals in even higher dimensions.

The following figures are the two-dimensional plots of high-dimensional Sobol sequences of Joe and Kuo with $d = 1{,}000$. It is compared with pseudorandom number

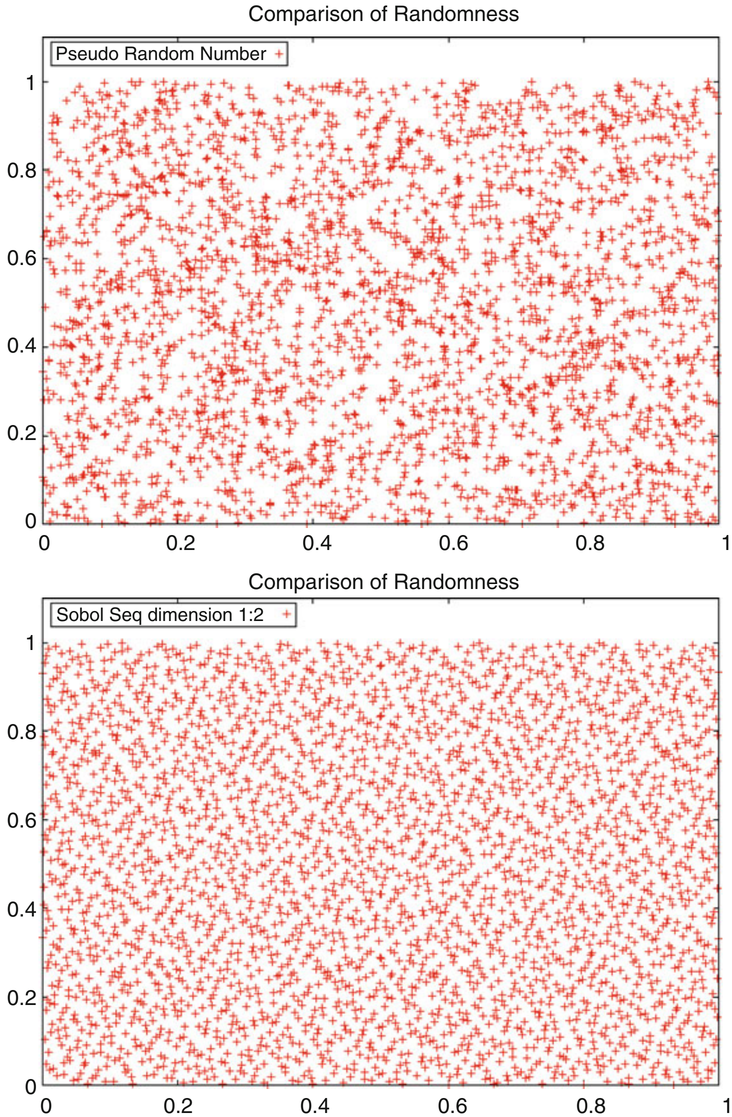

Fig. 49.7 Pseudorandom number plot comparing with quasi-random number of Sobol for dimensions 1 and 2

generation. The number of sampling points is 3,000. In Fig. 49.7 pseudorandom number is plotted in comparison with that of quasi-random number of Sobol. The leading dimensions 1 and 2 of Sobol sequences are used. The improvement is immense. In order to understand more of the nature of Sobol sequences, we chose prime dimensional numbers 499, 503, 991, and 997, respectively, as suggested by Joe

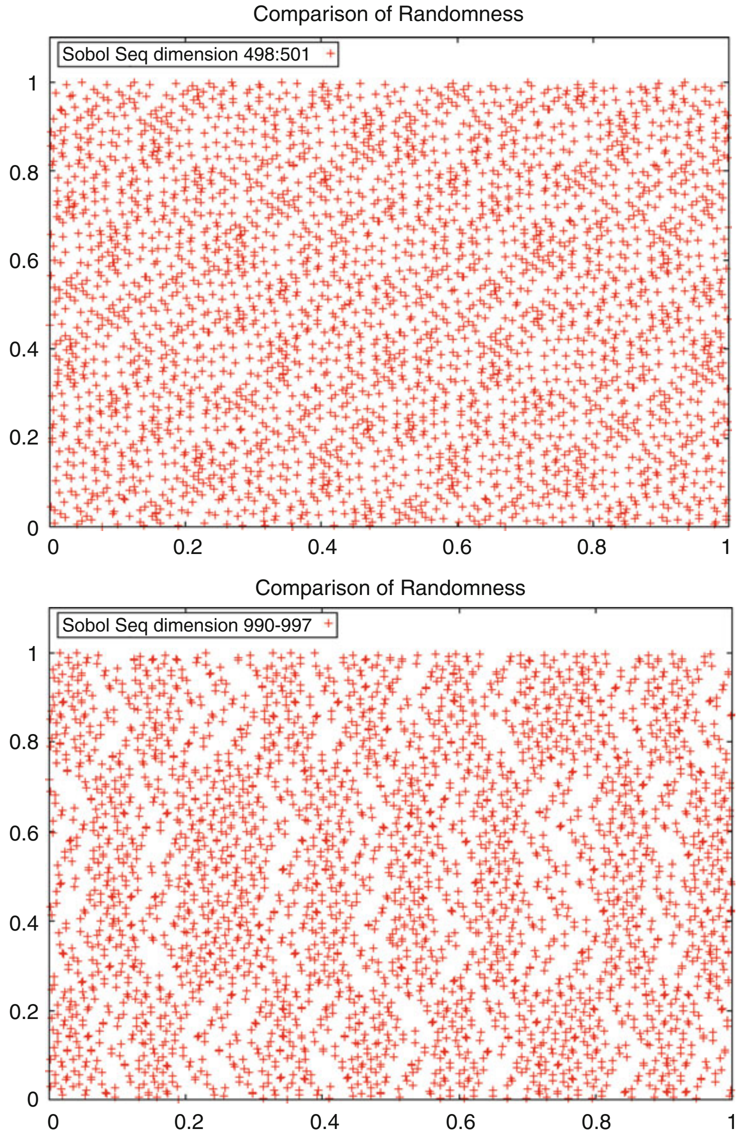

Fig. 49.8 Comparison of adjacent dimensions in quasi-random number Sobol sequence. The dimensions are chosen according to prime numbers. There is a high discrepancy found in higher dimensions of Sobol sequence modified by Joe and Kuo (2003)

and Kuo. The results are plotted in Figs. 49.8 and 49.9. It is found that there are stronger correlations between Sobol sequences of nonadjacent dimensions in the fashion of the dimensional comparison of their randomness. Larger numbers of sampling points, e.g., 10,000, are also tested and the patterns persist. It implied the

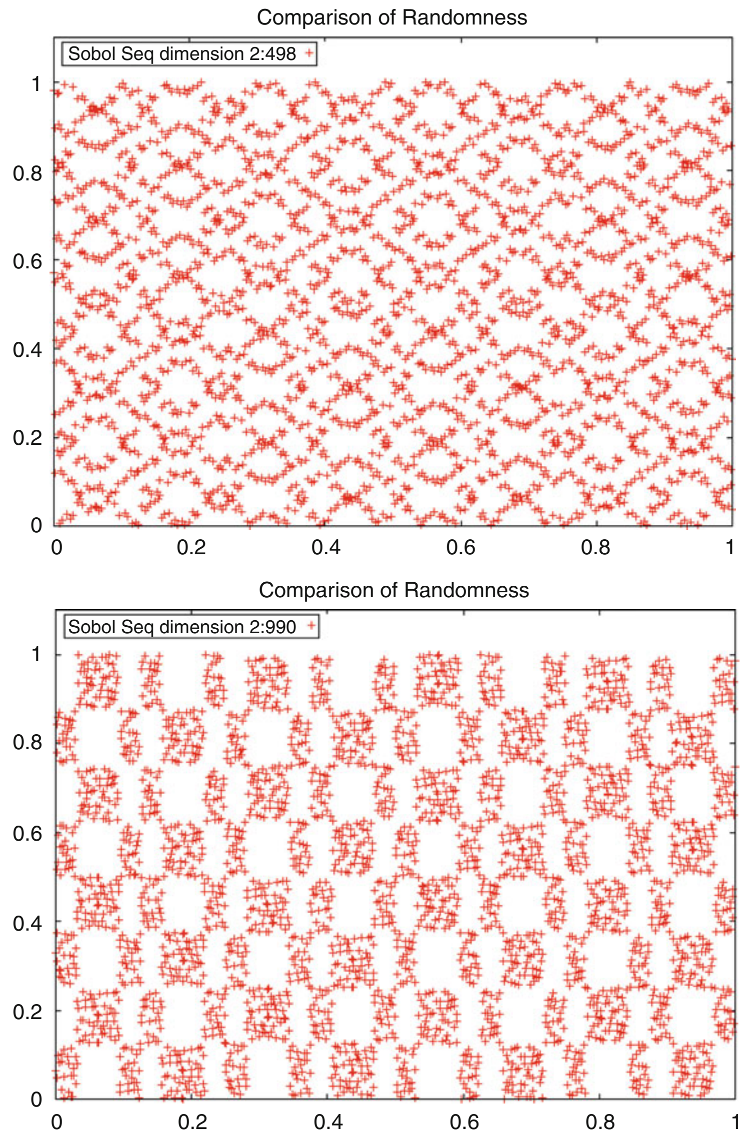

Fig. 49.9 Comparison of nonadjacent dimensions. High discrepancy is found in their correlations and forms clusters of islands in the distribution

violation of *idd* assumption and may incur problems in mass distribution and parallelism, in which each process the random number is generated independently without knowing what other processes are doing. The dependency may deteriorate the quality of randomness. Nevertheless, in our numerical experiments, there are no significant differences found thus far (Figs. 49.10 and 49.11).

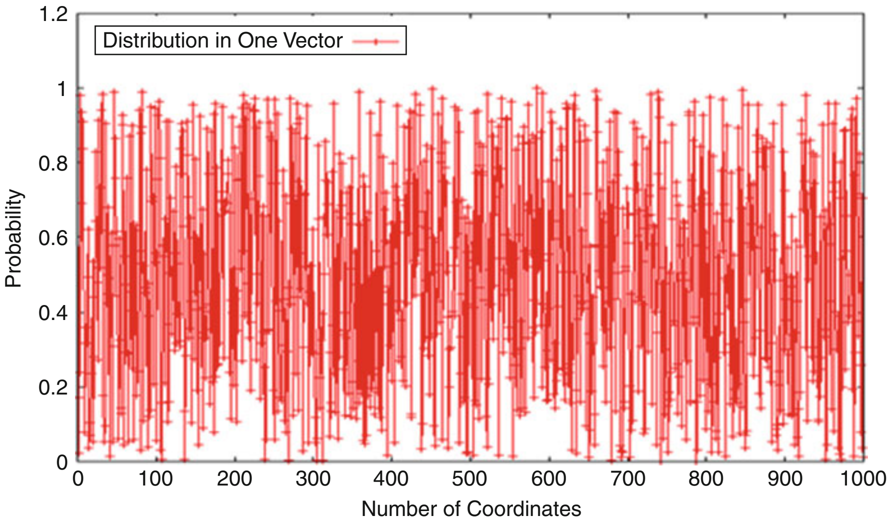

Fig. 49.10 The distribution of probability in directional vector $v_{i,j}$ of Sobol sequences at $i = 3{,}000$ with $j \in \{1, \cdots, 1000\}$. The mean of the distribution is 0.491357, which approaches the mean of the normal distribution 0.5

49.4 Case Study and Discussions

49.4.1 Case Study

49.4.1.1 Asian Options and Rainbow Options

To demonstrate what the grid computing can contribute to the financial service in a significant manner, two kinds of popular options, Asian options and rainbow options, are chosen for Monte Carlo pricing model. Asian options have payoffs that depend on the average price of the underlying asset such as stocks, commodities, or financial indices. However, there is no exact closed-form formula existed for these popular options. Rainbow options, also known as basket options, are referred to as an entire class of options which consist of more than one underlying asset. Rainbow options usually call or put on the best or worst of the underlying assets, or options which pay the best or worst of the assets. They are excellent tools for hedging risk of multiple assets. The rainbow options are therefore used for our bootstrap calculations of VaR.

49.4.1.2 Parallelization, Distribution, and Message Passing Interface (MPI)

MPI is a library specification for message passing, proposed and developed as a standard by a broadly based committee of vendors, developers, and users (Snir et al. 1996). MPI was designed for high performance on both massively parallel

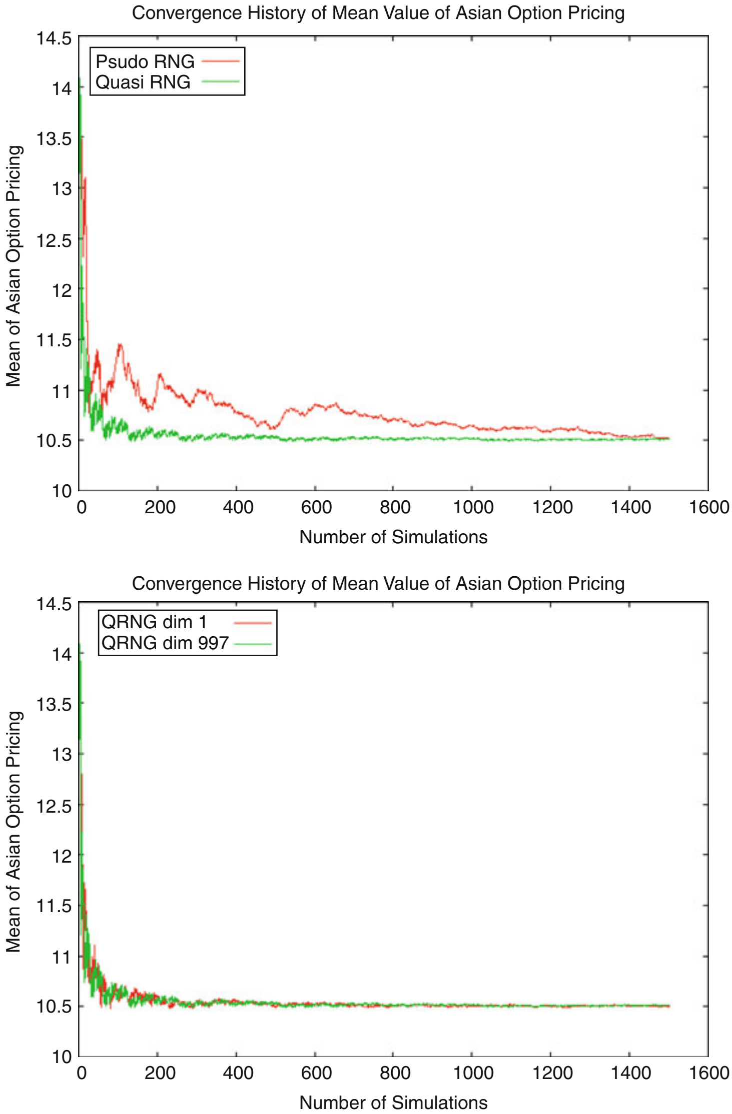

Fig. 49.11 The convergence history of the mean value of Asian option pricing with risk-free interest rate $r = 0.1$, underlying asset spot price $S = 100$, strike price $X = 100$, duration to maturity $T = 1$, and volatility $\sigma = 0.3$: The comparison is based on a single dimension of the extended high-dimensional Sobol sequences. The quasi-random number generator (QRNG) outperforms pseudorandom number generator. The test also is conducted to compare the convergence history between different dimensions in Sobol sequences and found that all perform consistently as shown in the *right* figure, in which the low dimension and high dimension are chosen for the comparison

machines and on distributed clusters. The MPI standard is nowadays widely accepted and used in the community of high-performance computing.

The basic MPI functions are point-to-point pair-wise message passing for send and for receive. Collective communications are also provided for ease of use as well as better performance. These communication methods, when used in supercomputers, do facilitate the parallelization of numerical methods that require both heavy compute cycles and stronger dependency between parallel processes.

Recent development of supercomputer, affected by the popularity of cluster computing in PCs, tends to be designed hierarchically scalable. Further extension of clusters of supercomputers can be regarded as initial concept of grids (see Sect. 49.2). The use of MPI is straightforward in this kind of hardware architecture and interlink of networks. There is always an obvious physical limitation in this architecture, which is also proportional to the limitation of the investment of governmental research funding. People tend to use mass distribution of computers, mostly PCs, which linked loosely in the Internet cloud. The terminology cloud is often used in networking community to show that in the Internet there is no specific network path from one computer to another. MPI working in such an environment is expected to be inefficient and unstable, e.g., high network latency induced packet lost in long-distance real-time communication. In the following sections three specific platforms, including local clusters, geographically distributed large clusters, and PC grids with ten of thousand of PCs connected in the cloud, will be used for the financial calculations to demonstrate benefits in using grids.

49.4.1.3 Empirical Study for Data Grid System

In order to demonstrate the usefulness of grid system, in particular in data-intensive application, the real market data are used, including daily from iShares (Morgan Stanley Capital International) MSCI Taiwan Index (ETF) and Taiwan Stock Exchange Center (TSEC) weighted index, extracted specifically from May 31, 2005, to May 31, 2008, and 30 days tick-by-tick trading data from Taiwan Futures Exchange Center (TAIFEX).

49.4.2 Grid Platforms Tests

The various grid platforms are carefully chosen to demonstrate the performance issue in finance services, which include a small diskless remote boot Linux (DBRL) PC clusters, large-scale and geographically widely distributed test-bed the Pacific Rim Applications and Grid Middleware Assembly (PRAGMA) compute grid, and a densely distributed at-home style PC grid, which resembles the clouding computing.

49.4.2.1 Diskless Remote Boot Linux (DRBL) Cluster

DRBL is an in-house program of National Center for High-Performance Computing (NCHC) and was an original software product developed by Steven Shiau and his group under the auspice of National Knowledge Innovation Grid (KING) of

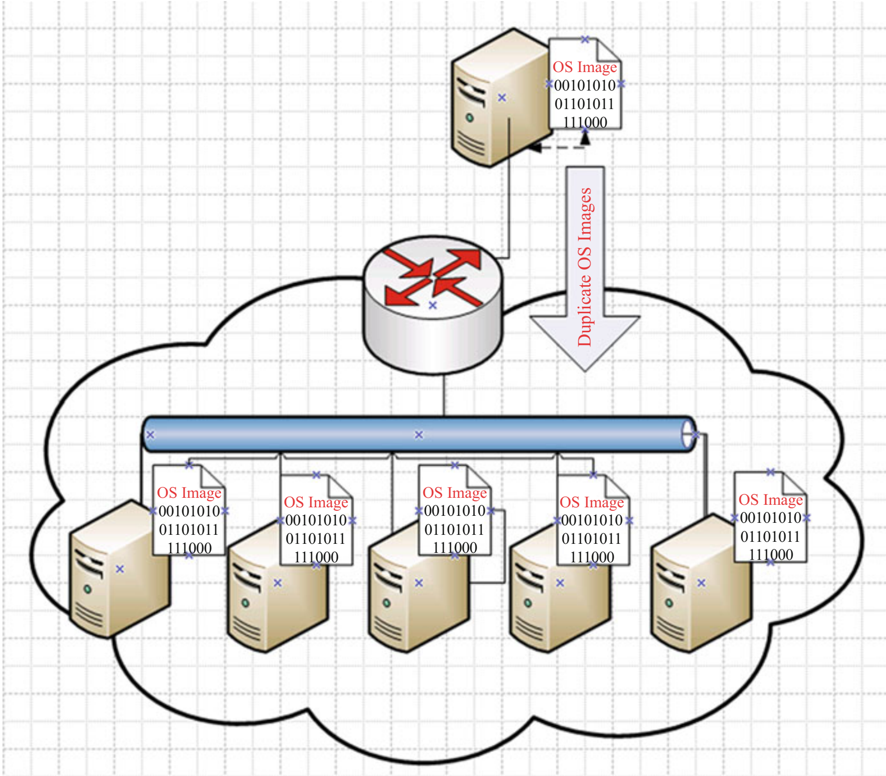

Fig. 49.12 The schematic of DRBL system: DRBL duplicates image files of operational system via network to the clients, in which the clients' original operational systems are untouched. Therefore, the clients are temporarily turned into dedicated compute resources, which also provide additional security to financial data

Taiwan. It was developed initially as a centralized system management tool aiming at small and median size of PC clusters. It is nowadays recognized internationally as one of the most advanced mass backup solutions. Here DRBL is used as an alternative scavenger for compute cycles of spare clusters. When needed, it converts systems of PC clusters into an aggregated and homogenous Linux system, simultaneously with a mass backup of the original systems, and recovered back the original systems once the need was satisfied. The most popular use is to convert a PC classroom into a compute Linux cluster. In such a case, compute cycles of the clusters can be fully exploited. In a grid environment, this is a perfect case to resources scaleup when in contingent need and once the situation relieved resources will be released correspondingly. Such a dynamic feature can be beneficial for the financial services.

The schematic of DRBL system can be shown in Fig. 49.12, where DRBL duplicates image files of an operational system, e.g., Linux kernel, via network to

Table 49.1 Comparison of performance between DRBL-based PC platform with 32 nodes, FORMOSA II of NCHC with a batch job of 32 nodes and IBM Cluster 1350 with a batch job of 32 nodes. The PCs are 20 XEON 2.6 GHz and 4GB RAM

the clients. The clients' original operational systems are not used. The clients are therefore temporarily turned into dedicated compute resources, which also provide additional security to financial data.

The test case here involves Monte Carlo simulations on Asian option pricing, on rainbow option pricing and on a bootstrap VaR calculation, respectively (see Sect. 49.3.2). The market parameters are given as risk-free interest rate $r = 0.1$, underlying asset spot price $S = 100$, strike price $X = 100$, duration to maturity $T = 125$, and volatility $\sigma = 0.3$. For the rainbow options a linear weighted combination of 4 underlying assets is assumed with underlying prices of $S_i = 100, 110, 120,$ and 130 and the corresponding weightings of volatility $\sigma_i = 0.3,$ 0.4, 0.5, and 0.6. The correlation matrix is taken to be

$$\rho_{ij} = \begin{pmatrix} 0.5 & 0.4 & 0.5 \\ 0.4 & 0.3 & 0.4 \\ 0.5 & 0.4 & 0.6 \end{pmatrix}$$

The calculation of the VaR uses the same 4-dimensional rainbow options with additional expectation of return 0.07, 0.08, 0.09, and 0.10, respectively. They are calculated in DRBL cluster as well as benchmarked with two cluster-based supercomputers in NCHC. The results are shown in Tables 49.1 and 49.2.

In Table 49.1, instead of giving a total wall clock time of the calculation with some given numbers of Monte Carlo simulations or paths, a more useful averaged single Monte Carlo simulation based on 1,000,000 simulations is used to demonstrate the performance when different system architectures are used. The results show that the traditional big irons, i.e., supercomputers, still outperform the cluster.

Yet, considering there is no extra cost invested in the computing resources and still obtains compute cycle in a sizable manner, the approach is appealing to be further developed in to a fully operational production system.

49.4.2.2 Pacific Rim Applications and Grid Middleware Assembly (PRAGMA) Grid

The Pacific Rim Applications and Grid Middleware Assembly (PRAGMA), founded in 2002, is an open international organization that focuses on a variety of practical issues of building international scientific collaborations in a number of application areas. PRAGMA grid is established by the resources and data computing working group as a global grid test-bed for benchmarking the interoperability of grid middleware and the usability and productivity of grids. The PRAGMA grid consists of physical resources as well as system administration supports from 29 institutions across 5 continents and 14 countries. It is an instantiation of a useful, interoperable, and consistently available grid system that is neither dictated by the needs of a single science domain nor funded by a single national agency. It does not have uniform yet robust infrastructure management and supports a wide range of scientific applications. The software stack of the system is shown in (Fig. 49.13).

The PRAGMA grid successfully tackles the issues of distance and time zone differences among sites, lack of infrastructure tools for heterogeneous global grid, nonuniform system and network environments, and diverse application requirements. For more technical details both in theory and practice we refer to (Abramson et al. 2006)

Following the similar test case in Sect. 49.4.2.2, but extended the platform with a collection of clusters across institute boundaries, the common job submission is executed via a homogeneous middleware Globus Toolkit. We demonstrate the usefulness of the platform by grouping compute resources across national boundaries and still achieve good performance. The results are shown in Tables 49.3 and 49.4.

49.4.2.3 At-Home Style PC Grid

With the continued penetration of personal computers and the remarkable improvement of CPU processing speed, 80–90 % of most PCs' processing power is untapped, according to a study. This does not mean that many PCs remain turned off, but that the capacity of the CPU, the brain of the PC, is not fully utilized. In case the CPU is more extensively used when a task requiring an enormous number of operations, such as three-dimensional graphical processing, is assigned, it sits idle most of the time during word processing and Internet browsing because CPU processing speeds are much faster than the speeds of input from the keyboard or the communication line.

This fact led to the idea of virtually gathering the power of idle CPUs to use as a computer resource. In other words, this means networking numerous computers to make them work like a single high-performance computer and assigning complex processing tasks to it. The assigned task will be divided into a myriad of small tasks

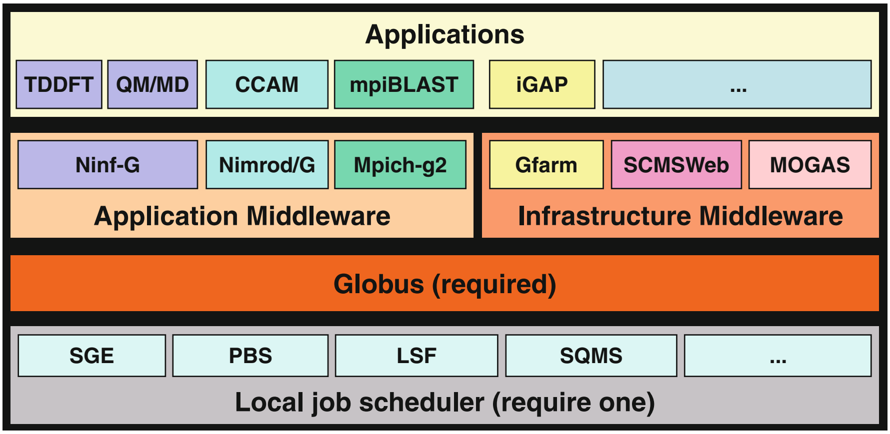

Fig. 49.13 Software stack developed in the PRAGMA grid

Table 49.3 Comparison of performance between Group A, which consists of 13 nodes from NCHC and 15 from UCSD, and Group B, which consists of 122 nodes collectively from UCSD, AIST, NCHC, and Osaka University. and allocated to individual computers on the grid-like network. Even with increasingly faster CPUs, the power of PCs is not comparable to those of supercomputers, but in a networked environment where individual PCs simply process complex task in parallel, PCs can deliver surprisingly high performance. This is the core concept of CP grid computing, and it came into a reality several years ago (Table 49.5).

The commoditization and the increased processing speed of PCs lead the growth of idle CPU power. This will facilitate the construction of PC grid computing system along with improvement of communication environment by broadband connectivity (Chen et al. 2006). In practice, a PC grid platform Korea@Home (or K@H) is used in our study. Its architecture is shown in Fig. 49.14. It is based on MS Windows. Asian option pricing is used to demonstrate the performance of the

Table 49.5 Summary of the case for the PC grid calculations

Asian option pricing	Statistics
Number of Monte Carlo path	1,000,000 × 10.000
The running period (1) (wall clock time)	28 h 51 m *(104,911 s)*
Number of jobs	10,000
CPU time per job	28 ~ 30 s
Total running time (2) (wall clock time)	4 days 14 h 31 m (397,919 s)
Speedup ratio $\frac{(2)}{(1)}$	3.79

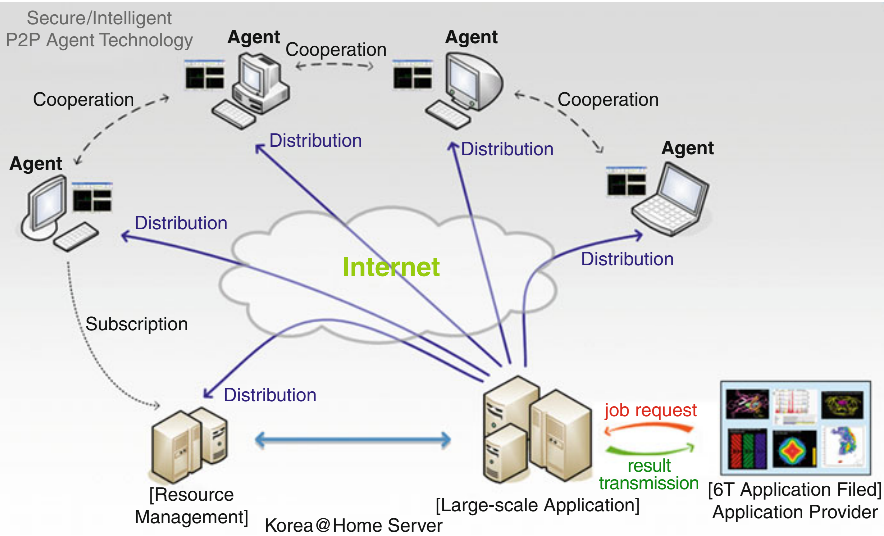

Fig. 49.14 The architecture of Korea@Home, a specific @Home style PC grid used in our case study (Jun-Weon Yoon 2008)

system, in which the number of iterations is taken to be 1,000,000. The duration to maturity is further divided by 10,000 periods, which push the system to run on the mass parallel system of K@H. To tackle this scale, or even larger scale for all kinds of possible scenarios in real trading practice, an off-line distributed and parallel approach is adopted. The total number of Monte Carlo simulation is 1,000,000 × 10,000. It was divided into 10,000 jobs and each job consists of 1,000,000 Monte Carlo simulations. The market parameters are given as above.

The results demonstrated here are not as good as expected (see Table 49.1). It shows that the speedup ratio is only 3.79. In this test, K@H further divides the jobs into ten groups. Each group was send and run in a sequential fashion, which causes the low speedup ratio. However, if one looks into the executed CPU time for each job, our assumption is still valid. We simulated the result in a small cluster with the same scenario and Monte Carlo paths. The result shows 90 % speedup can be easily achieved.

49.4.2.4 RBNB Data Grid

RBNB DataTurbine in market data streaming is implemented here (see Fig. 49.15), in which the real data from iShares MSCI Taiwan Index (ETF) and TSEC weighted index from May 31, 2005, to May 31, 2008, and 30 days tick-by-tick trading data from Taiwan Futures Exchange Center (TAIFEX) are used and open in different file-based online channels from the RBNB DataTurbine. The purpose is to dynamically manage the high-frequency market data and connect the data with analysis applications on the fly. The system implemented up-to-date large-scale dynamic and static data management.

49.5 Conclusions

Securities trading is one of the few business activities where a few seconds processing delay can cost a company big fortune. The growing competitive in the market exacerbates the situation and pushes further towards instantaneous trading even in split second. The key lies on the performance of the underlying information system. Following the computing evolution in financial services, it was a centralized process to begin with and gradually decentralized into a distribution of actual application logic across service networks. Financial services have tradition of doing most of its heavy lifting financial analysis in overnight batch cycles. However, in securities trading it cannot satisfy the need due to its ad hoc nature and requirement of immediate response. A new computing paradigm, grid computing, aiming at virtualizing scale-up distributed computing resources, is well suited to the challenge posed by the capital market practices.

In this study we revisit the theoretical background of how performance will affect the market competition. The core concept lies on information asymmetry. Due to the advance of IT, even in split second, it will be a matter of win or lose in real market practice. After establishing the motivation, we review recent grid development specifically used for finance service. Monte Carlo simulations are chosen not only because of its popularity in real world but also because of its nature so-called “fine grain” or mass parallelism approach. The success of Monte Carlo simulations lies on better random number generators. The well-recognized Sobol sequences as a quasi-random number generator are carefully studied to ensure the quality of Monte Carlo simulations when employed for mass parallelism. Then some popular basic option pricing models, collectively Asian option pricing, rainbow option pricing, and VaR calculation with constant market parameters, are introduced as drivers to introduce more details of grids for better finance service. Finally, we test various grid platforms, based on the methodology of mass parallelism and mass distribution, with the drivers. The real market data are also used, but at this stage they are only used to demonstrate the dynamic data management, in which grids can offer better.

During this study, we encountered system architect Koschnick from Zürcher Kantonalbank of Switzerland (Koschnick 2008). Coincidentally, the system they plan to migrate from big irons is the similar system to that of DRBL with additional

Fig. 49.15 RBNB DataTurbine streaming open for data channels of iShares MSCI Taiwan Index (ETF) and TSEC weighted index from May 31, 2005, to May 31, 2008, and 30 days tick-by-tick trading data from Taiwan Futures Exchange Center (TAIFEX) (Real data plot in collaboration with Strandell et al. 2007)

virtual local area networks (VLAN) for security. The system is used for overnight batch job as well as real-time trading practice. It is confirmed that for the years to come, financial services providers will adopt more grid or grid-based technology to enhance their competitiveness.

Our future work will be following the current work, continuously using the current grid platforms and extending them to the use high-frequency real market data. Along the track of this development, we will also develop sophisticated Monte Carlo-based option pricing and risk management based on tick-by-tick daily market information.

Long-Run Stock Return and the Statistical Inference

50

Yanzhi Wang

Contents

Abstract

This article introduces the long-run stock return methodologies and their statistical inference. The long-run stock return is usually computed by using a holding strategy more than 1 year but up to 5 years. Two categories of long-run return methods are illustrated in this article: the event-time approach and calendar-time approach. The event-time approach includes cumulative abnormal return, buy-and-hold abnormal return, and abnormal returns around earnings announcements. In former two methods, it is recommended to apply the empirical distribution (from the bootstrapping method) to examine the statistical inference, whereas the last one uses classical *t*-test. In addition, the benchmark selections in the long-run return literature are introduced. Moreover, the calendar-time approach contains mean monthly abnormal return, factor models, and Ibbotson's

RATS, which could be tested by time-series volatility. Generally, calendar-time approach is more prevailing due to its robustness, yet event-time method is still popular for its ease of implementation in the real world.

50.1 Introduction

The long-run stock return has been an important facet of the stock performance of firms since the 1990s. Ritter (1991) starts the line of long-run return studies by investigating the initial public offering (IPO) cases. He finds that the post-IPO stock performance is poor in the long run. His paper is then followed by many scholars who study other important corporate events and asset pricing anomalies.[1] Fama (1998) reviews these papers which engage in long-run event studies. Hence, the long-run return method is nowadays a standard way for the stock performance of firms.

I review the methodologies about the long-run stock abnormal return in this article. Since the mid-1990s, some papers started to be aware of the properties of long-term stock performance and suggested various ways to calculate the long-run abnormal return. Therefore, Barber and Lyon (1997), Kothari and Warner (1997), and Lyon et al. (1999) review and compare long-run return methods in the late 1990s. Based on these methodology papers, I update recent developments about the new methods that are not mentioned in these two papers, such as the earnings announcement abnormal return applications (La Porta et al. 1997), conditional market model method (Eberhart et al. 2004; Petkova and Zhang 2005), Ibbotson's RATS (Ibbotson 1975; Agrawal et al. 1992; Peyer and Vermaelen 2009), and zero-investment portfolio method (Daniel and Titman 1997; Eberhart et al. 2004). I also make a clearer categorization on these long-run stock return methodologies given that the long-run return methodologies nowadays are much more mature than in the late 1990s.

Two main categories of the long-run stock performance illustrated in this paper are event-time and calendar-time approaches. The event-time approach includes cumulative abnormal return (CAR), buy-and-hold abnormal return (BHAR), rebalanced buy-and-hold abnormal return (RBHAR), and abnormal returns around

[1]For corporate events, papers have studied seasoned equity offerings, mergers, dividend initiations and omissions, quarterly earnings announcements, share repurchases, proxy flights, stock splits and spinoffs, and other corporate events for their long-run stock performance. For asset pricing anomalies, papers investigate value premium, momentum profit, research and development profit, accrual effect, asset growth, net share issuance, and other anomalies in terms of the long-term impact.

earnings announcements. The calendar-time approach contains mean monthly abnormal return (MMAR), Ibbotson's RATS, and factor models. The factor model has various specifications, in which Fama and French (1993) three-factor model and Carhart (1997) four-factor model are most prevailing two.

In addition, to estimate the *abnormal* return, the benchmark is vital because a misspecification of the matching procedure yields an incorrect statistical inference and leads to the statistical type I or type II error. For event-time approach, either a matching firm or a matching portfolio can control for the firm characteristic effect (Daniel and Titman 1997). Yet, the more relevant problems are how we should select the weighting scheme and what the matching criterion should be. On one hand, the selection of the weighting scheme determines the degree of the abnormal return and involves in different magnitude of transaction costs from the rebalancing problem. On the other hand, different matching methods may result in a superior or an inferior statistical inference, particularly the skewness of the long-run return estimation.

For MMAR of the calendar-time approach, the benchmark selection problem is similar to what we may face in the event-time approach. Yet, the family of factor models has a simpler benchmark problem because the only issue is the factor model specification (e.g., a three-factor or a four-factor model). The same situation applies the Ibbotson's RATS that we only pay attention to the market model setting, namely, adding more independent variables in the market model. Nevertheless, few complicated modifications for the factor models are employed in the long-run return studies, such as conditional market model and the zero-investment portfolio method in factor model. The former deals with the time-varying systematic risk loadings in the market model, whereas the later is to combine the factor model method with the matching methods in the event-time approach. In general, the robustness of calendar-time approach raises its popularity in recent finance studies.

The rest of this paper is organized as follows. Section 50.2 introduces the long-run return estimation in event-time approach. Section 50.3 states the calendar-time method applied in the long-run stock return estimation. Finally, Sect. 50.4 concludes this review paper.

50.2 Long-Run Return Estimation in Event-Time Approach

To estimate the long-run stock return, it is nature to identify an event to track the stock performance of a firm. Figure 50.1a shows a general time line for the long-run return estimation. For any specific event and its event day noted by day 0, we can start a holding strategy by purchasing the stock from event day 0 to 251th day (for 1-year return), to 503th day (for 2-year return), 755th day (for 3-year return), to 1,007th day (for 4-year return), or to 1,259th day (for 5-year return). Papers usually compute the long-run stock return up to 5 years (Ritter 1991). As indicated in Fig. 50.1a, an accounting reporting lag is required between the event date and the previous fiscal year-end with at least 4 months.

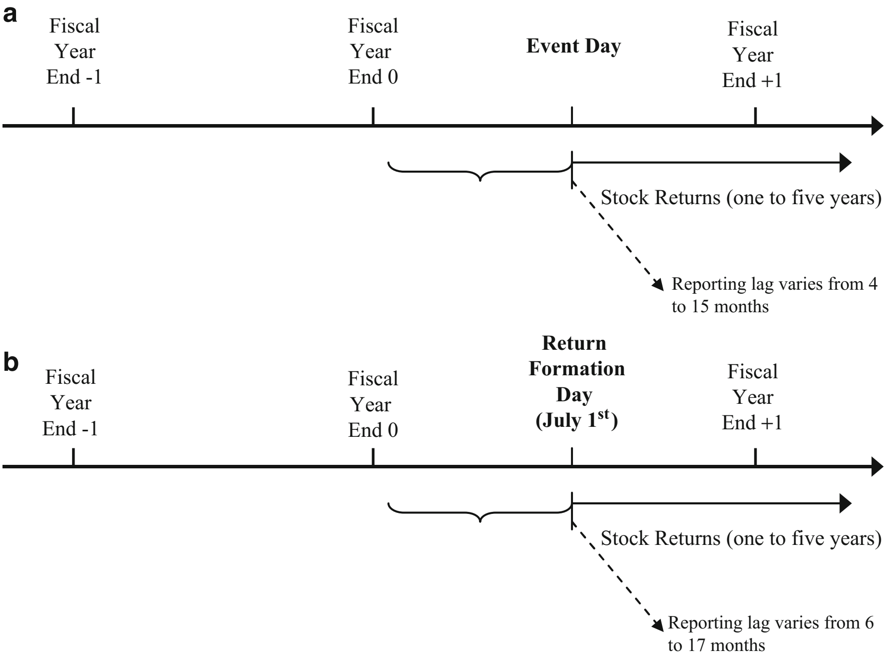

Fig. 50.1 (**a**) time line of general event study. (**b**) time line of asset pricing study

For the asset pricing study, we usually do not have a specific event day for tracking the compounding daily returns. As suggested in Fama and French (1992, 1993), a general investment strategy starts the return formation from 1 July of each year by exerting the accounting information in the previous fiscal year-end with at least 6 months reporting lag. Figure 50.1b shows the time line for asset pricing studies. Because asset pricing papers start from 1st July, the long-run returns are estimated based on compounded monthly returns. Basically, 1-year return includes 12 monthly returns, while 5-year return is computed upon 60 monthly returns.

50.2.1 Return Estimations: CAR, BHAR, and Earnings Announcement Returns

The cumulative abnormal return (CAR) is estimated as follows. For a given benchmark $E(R_{i,t})$, the abnormal return $AR_{i,t} = R_{i,t} - E(R_{i,t})$. The average of estimations for CAR is

$$\overline{CAR} = \sum_{t=1}^{T} \frac{\sum_{i=1}^{N} AR_{i,t}}{N}, \tag{50.1}$$

in which the N_t is for number of observations at time t and T for the holding period (252 for a year if the return is computed based on daily returns; 12 for a year if the return is computed based on monthly returns).

The buy-and-hold abnormal return is defined as

$$\overline{BHAR} = \sum_{i=1}^{N} \frac{\left[\prod_{t=1}^{T} \left(1 + R_{i,t}\right)\right] - 1}{N} - \sum_{i=1}^{N} \frac{\left[\prod_{t=1}^{T} \left(1 + E\left(R_{i,t}\right)\right)\right] - 1}{N}. \tag{50.2}$$

Thus, we can use classical t-test or other methods (will be illustrated in later section) to carry out the statistical inference for CAR and BHAR. One modification on BHAR is the rebalanced buy-and-hold abnormal return (RBHAR), which comes from the combination of rebalanced return (R^{reb}) and BHAR. Given the rebalanced return as

$$R^{\text{reb}} = \prod_{t=1}^{T} \left(1 + \frac{\sum_{i=1}^{N} R_{i,t}}{N} \right) - 1, \tag{50.3}$$

the RBHAR is to calculate buy-and-hold return for a certain period (e.g., a year) and rebalance the portfolio equally for every specific period. Taking the 1-year rebalanced BHAR as the example, we should compute 1-year BHAR for each event year (i.e., first to fifth event year) and obtain the average BHAR for every event year. Finally, we obtain compounding return for this average rebalanced BHAR with yearly rebalancing. Because BHAR has inflated compounding return, which results in many outliers in the long-run return estimation, RBHAR with rebalancing every year is able to reduce the impact from extreme values (Ikenberry et al. 1995; Chan et al. 2010). In general, RBHAR could be described as

$$\begin{aligned} \overline{RBHAR} = &\prod_{\text{year1}}^{\text{year5}} \left\{ 1 + \sum_{i=1}^{N} \frac{\left[\prod_{j=1}^{T} \left(1 + R_{i,j}\right)\right] - 1}{N} \right\} \\ &- \prod_{\text{year1}}^{\text{year5}} \left\{ 1 + \sum_{i=1}^{N} \frac{\left[\prod_{j=1}^{T} \left(1 + E\left(R_{i,j}\right)\right)\right] - 1}{N} \right\} \end{aligned} \tag{50.4}$$

Note that T stands for 252 days as an event year, and year 1 to year 5 represent the first event year to the fifth event year.

Distinct from CAR and BHAR, the quarterly earnings announcement return is the estimate of the long-term stock performance by successive short-term quarterly announcement returns (La Porta et al. 1997; Denis and Sarin 2001; Chan et al. 2004). In other words, we can use the 2-day or 3-day abnormal returns around quarterly announcement dates, and the successive earnings surprises should be aligned with the long-run stock abnormal return. The benchmark selection determines the long-run abnormal return estimation because of its statistical property (will be discussed in next section), so the results may be changed when benchmark settings are altered. This sensitive outcome driven from the benchmark problem leads to an inconclusive long-run abnormal return. Yet, the short-run return is not sensitive to the selection of benchmarks. For example, given 10 % and 20 % of market index returns, the 3-day market index returns are expected to be 0.12 % and 0.24 % only. When an event occurs, the 3-day announcement return could be generally above 1 %, which significantly exceeds any selected benchmark returns. Therefore, if a corporate event is followed by profitability improvements that are not observed by investors, then there should be successive earnings surprises following the event date, and the short-term announcement abnormal returns around the earnings announcement dates should be positive. To capture the long-run abnormal return, papers usually study 12–20 quarters (for 3–5 years) for the quarterly earnings announcement abnormal return. Generally, the quarterly earnings announcement abnormal returns capture about 25–40 % of the long-run stock return of a firm (Bernard and Thomson 1989; Sloan 1996).

50.2.2 Benchmark Problem

Long-run stock return has some issues regarding the calculation and testing when we select the benchmarks for the expected return of the firm. Namely, the conventional methodologies for the long-run stock return might be biased if the chosen matching procedure is inappropriate. First, some long-term return measures have the rebalancing and new-listing biases problems. Second, long-run stock return is positive skewed, thus the traditional t-test is inappropriate for the long-run return. Although I will review the skewness-adjusted t-statistics and empirical p-value in the next section, matching firm method is another way to alleviate the skewness concern in the long-run return studies.

The first benchmark for the expected return is the CRSP equal-weighted index return, which includes whole stocks in CRSP database and computes the simple average of stock returns. However, this approach involves rebalancing problem, which ignores the transaction costs from broker's fee and tax to the government. To maintain the weights on stocks equally, investors must sell profitable stocks and buy stocks with loss. This rebalancing leads to huge transaction costs that are not considered in the CRSP equal-weighted index return, making the abnormal return underestimated. In fact, CAR per se also has this rebalancing problem because of its average in cross section.

The second benchmark is the CRSP value-weighted index return, which also comes from CRSP database. This index return uses firm value (equal to the price timing shares outstanding) as the weighted scheme to compute the weighted average of stock returns. Most importantly, it is a rebalance-free benchmark and accordingly has no transaction cost during the holding period (except the beginning and end). Therefore, recent papers tend to use CRSP value-weighted index return instead of CRSP equal-weighted index return as the benchmark return.

The third benchmark is the reference portfolio return. Before constructing the reference portfolio, we may need matching criterions. As the important pricing factors, size and book-to-market (BM) ratio are the two most important in determining the expected return (Fama and French 1992, 1993, 1996; Lakonishok et al. 1994; Daniel and Titman 1997). In particular, we have to determine the matching pool, which includes stocks that are irrelevant to the sample firm. We form 50 size and book-to-market portfolios (ten size portfolios and five book-to-market portfolios in each size decile) where the size and book-to-market cutoff points are obtained from stock in NYSE exchange. We then are able to compute either equal-weighted or value-weighted portfolio return as the expected return.

The last one is the matching firm method. Because the long-run stock return is positive skewed, we may take the long-run return of the matching firm as the expected return. The skewed return of the sample firm and skewed return of the matching firm offset each other and make the abnormal return symmetric (Barber and Lyon,1997). In addition, matching firm method avoids the new-listing bias and rebalancing problem. In general, the matching criterions of the matching firm are similar to the reference portfolio. Within each reference portfolio, a matching firm could be selected by minimizing the book-to-market difference between the sample firm and the matching firm (Ikenberry et al. 1995). Sometimes, papers use few matching firms but not single matching firm as the benchmark to avoid few outlier impacts (e.g., Lee 1997) or use different matching variable (e.g., Ikenberry and Ramnath 2002; Eberhart et al. 2004). Generally, various matching methods under size and book-to-market effect controls do not largely change the results.

50.2.3 Statistical Inference

The most important statistical problem for the long-run abnormal return is the skewness. The minimum loss of a long-term stock investment is -100 % while the maximum potential gain approaches infinite. Thus, the distribution of the long-run stock return is positive skewed. If we test the long-run stock return by a standard normal distribution, then we tend to reject the null hypothesis (that suggests no abnormal return) for negative returns and accept the null for positive returns. This misspecification leads to a type I error in the distributional left tail but causes a type II error in the distributional right tail.

To solve the skewness problem, Barber and Lyon (1997) suggest the matching firm method because abnormal stock return is the return difference between the sample firm and matching firm, making the skewness from matching firm and sample firm offset by each other. In addition, there are two ways to alleviate the testing problem under the skewness, one is the skewness-adjusted t-statistic and the other is the empirical p-value, suggested by Ikenberry et al. (1995) and Lyon et al. (1999).

Given an abnormal return AR_i, the skewness-adjusted t-statistic illustrated by Lyon et al. (1999) is tested as follows:

$$t_{sa} = \sqrt{N}(S) + \frac{1}{3}\hat{\gamma}S^2 + \frac{1}{6N}\hat{\gamma},$$

where

$$S = \frac{\overline{AR}}{\sigma(AR_i)}, \text{and } \hat{\gamma} = \frac{\sum_{i=1}^{N}\left(AR_i - \overline{AR}\right)^3}{N\sigma(AR_i)^3}. \tag{50.5}$$

Note that the S is the conventional t-statistic and $\hat{\gamma}$ is the coefficient for the skewness adjustment.

The second suggested statistical inference method is the empirical p-value. This approach uses bootstrapping method to construct an empirical distribution with general long-term return features. We use bootstrapping method to select the pseudo-sample firm. Thus, we are able to compare sample firm and pseudo-sample firm as the base of the empirical p-value. In fact, it is possible that we may face moment conditions (higher than third moment condition) in the long-term return estimation, and the skewness-adjusted t-statistic is not enough to capture the return characteristic. Also, the strong cross-sectional correlations among sample observations in BHARs can lead to poorly specified test statistics (Fama 1998; Lyon et al. 1999; Brav 2000). Under the empirical distribution, we can examine the statistical inference without a parametric distribution but are able to capture more unknown statistical features.

As mentioned above, the empirical p-value is generated from the empirical distribution from bootstrapping, and the empirical distribution well controls the skewness and time-dependent properties of the long-run stock returns (Ikenberry, et al. 1995; and Lyon et al. 1999; Chan et al. 2004). In addition, this empirical p-value also solves the statistical inference problem in RBHAR because we may have too few observations in times series for computing standard deviation.[2] To construct the empirical distribution, we need to find pseudo-sample firms that share similar firm characteristics as the sample firm but do not have the interested corporate events. Next, we construct 25 size and book-to-market portfolios (five size portfolios and five book-to-market portfolios in each size quintile) from all

[2]For example, if we compute a 5-year RBHAR, then we have five averages of BHARs in five event years only.

nonevent firms. The nonevent firm selection criterions are similar to the matching firm selection. Then, we randomly sample one pseudo-sample firm out of the corresponding portfolio for each sample firm. For example, if an event firm is with the second size quintile and third book-to-market quintile, then we randomly choose a pseudo firm that is also with the second size quintile and third book-to-market quintile. Hence, we are able to obtain N pseudo firms for N sample firms. Upon these pseudo-sample firms, we calculate the long-run return by CAR, BHAR, or RBHAR method. Finally, we repeat the sampling and long-run return estimation for 1,000 times and obtain 1,000 averages of long-run returns for pseudo-sample firms. The empirical distribution is plotted according to the frequency distribution diagram of those 1,000 average returns of pseudo-sample firms. If the long-run return is larger than the $(1-\alpha)$ percentile of the 1,000 average pseudo-sample firm returns, then we obtain the p-value as α for testing the *positive* average abnormal return. Similarly, if the long-run return is smaller than α percentile of the 1,000 average pseudo-sample firm returns, then we obtain the p-value as α for testing the *negative* average abnormal return.

Figures 50.2a–50.2d are empirical distributions for 1-year to 4-year long-run returns upon size/book-to-market controlled pseudo-sample firms of US repurchase firms during 1980–2008. I collect the repurchase data from SDC database as the example for the empirical distribution construction. For those empirical distributions, it is obvious that 4-year return has more outliers than 1-year return. Moreover, the 4-year return figure has lower kurtosis and is more positive skewed. Obviously, the shape of long-run returns does not obey normal distribution, and the empirical p-value is more relevant to the long-run abnormal return testing.

I also show the specification (statistical size) for different long-run return methods in Table 50.1, which is obtained from Table 5 of Barber and Lyon (1997) and Table 3 of Lyon et al. (1999). They show the percentage of 1,000 random samplings from 200 firms rejecting the null hypothesis that suggests no abnormal return in terms of CAR, BHAR, and RBHAR with different benchmark and testing methods. First, the CAR with matching portfolio as the benchmark has type I error in left tail when measuring the abnormal return in 5 years. Second, the matching firm method yields good specification no matter how we focus on size control, BM control, or a combination control for both size and BM ratio. Third, skewness-adjusted t-statistics has type I error, implying that skewness is not the only statistical feature that we should address. Forth, empirical p-value method performs well even when adopting the reference portfolio as the benchmark, at least for 10 % significance level.

Figure 50.3 shows the testing power of alternative tests by using BHAR as the primary method, and this figure is originally plotted in Fig. 1 of Lyon et al. (1999). The empirical distribution performs better in testing power than classical t-test, no matter what the standard empirical distribution or the bootstrapped skewness-adjusted t-statistic is employed.

In sum, in the event-time approach, the BHAR is suggested. Matching firm is a better matching method than other approaches. In statistical testing, the empirical p-value could be the best way due to its well statistical size control and testing power.

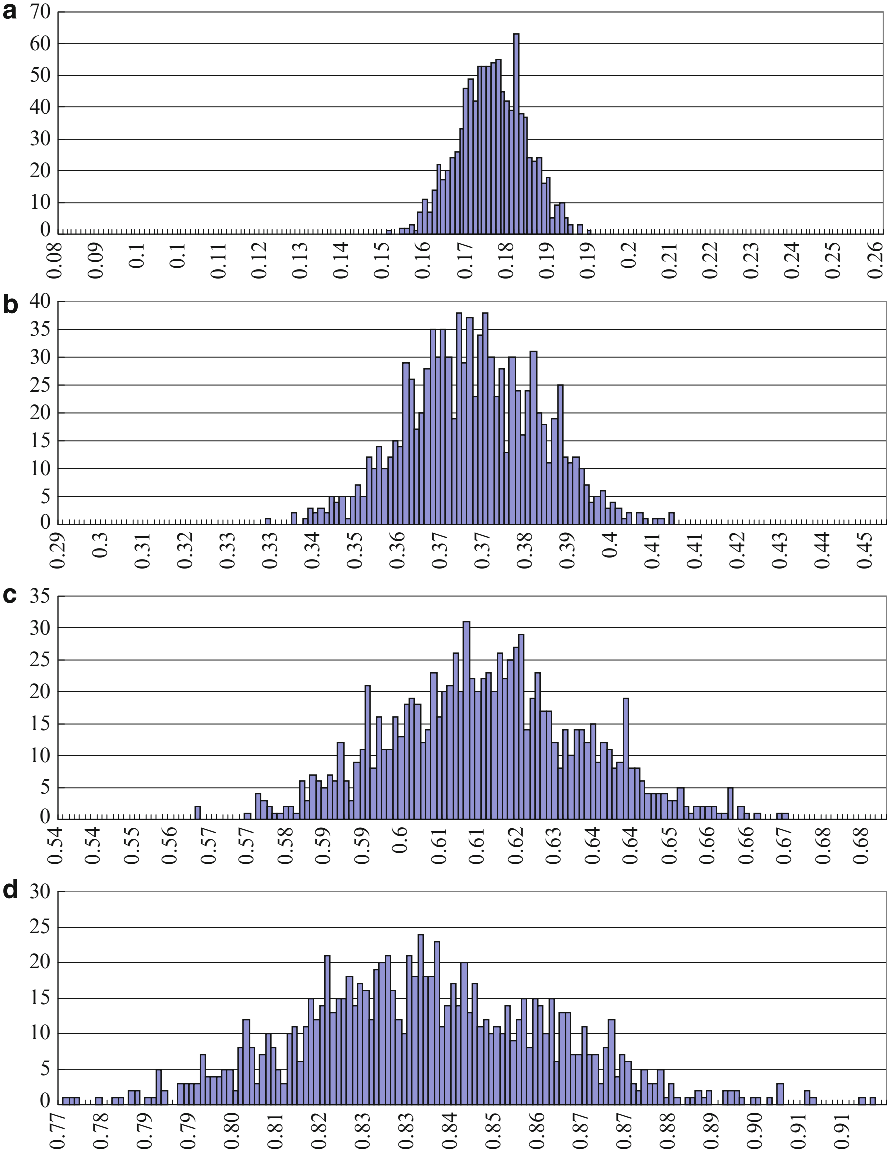

Fig. 50.2 (**a**) One-year return distribution of size/BM controlled pseudo-sample firms. (**b**) Two-year return distribution of size/BM controlled pseudo-sample firms. (**c**) Three-year return distribution of size/BM controlled pseudo-sample firms. (**d**) Four-year return distribution of size/BM controlled pseudo-sample firms

Table 50.1 Specification (size) for alternative statistical tests

A: Specification (size) for CAR with different benchmarks								
Two-tailed theoretical significant level (%)	1		5		10			
Theoretical cumulative density function (%)	0.5	99.5	2.5	97.5	5.0	95.0		
Description of return benchmark							Mean	Skew
Panel C: 60-month CARs								
Size deciles	0	2.4*	0.6	8.0*	1.2	14.7*	3.45	1.11
Book-to-market deciles	0.1	0.7	1.9	4.4*	2.6	7.6*	1.47	1.24
Fifty size/book-to-market portfolio	0.2	1.3*	0.9	5.5*	2.2	10.0*	2.10	1.21
Equally weighted market index	0.0	5.5*	0.2	17.3*	0.5	25.1*	6.27	1.11
Size-matched control firm	0.6	0.3	2.1	2.2	5.2	4.3	−0.59	−0.14
Book-to-market-matched control firm	0.4	0.8	2.9	3.1	5.2	5.4	0.00	−0.01
Size-/book-to-market-matched control firm	0.2	0.4	2.4	2.3	4.3	4.3	−0.63	0.07
Fama-French three-factor model α	0.5	0.3	2.1	2.3	4.9	5.1	−0.94	−1.76

B: Specification (size) for BHAR with different benchmarks							
Statistic	Benchmark	Two-tailed theoretical significance level					
		1 %		5 %		10 %	
		Theoretical cumulative density function (%)					
		0.5	99.5	2.5	97.5	5	95
t-Statistic	Rebalanced size/book-to-market portfolio	11.7*	0.0	23.7*	0.0	33.2*	0.2
t-Statistic	Buy-and-hold size/book-to-market portfolio	2.4*	0.0	6.1*	0.5	10.5*	1.6
Skewness-adjusted t-statistic	Buy-and-hold size/book-to-market portfolio	1.4*	0.4	4.4*	1.7	8.2*	4.8
t-Statistic	Size/book-to-market control firm	0.1	0.1	3.0	1.9	5.4	3.9
Bootstrapped skewness-adjusted t-statistic	Buy-and-hold size/book-to-market portfolio	0.6	1.2*	2.2	3.1	5.0	5.7
Empirical p-value	Buy-and-hold size/book-to-market portfolio	0.2	1.5*	2.7	3.7*	4.9	6.3

This table is from Table 5 of Barber and Lyon (1997, p. 363) and Table 3 of Lyon et al. (1999, p. 179). The numbers presented represent the percentage of 1,000 random samples of 200 firms that reject the null hypothesis of 5-year CAR (Panel A) and buy-and-hold abnormal return (Panel B) at the theoretical significance levels of 1 %, 5 %, or 10 % in favor of the alternative hypothesis of a significantly negative abnormal return (i.e., calculated p-value is less than 0.5 % at the 1 % significance level) or a significantly positive abnormal return (calculated p-value is greater than 99.5 % at the 1 % significance level). The alternative statistics and benchmarks are described in detail in the main text. * indicates the percentage is significantly different from the theoretical significance level at the 5 % (Panel A) and 1 % level (Panel B), one-sided binomial test statistic

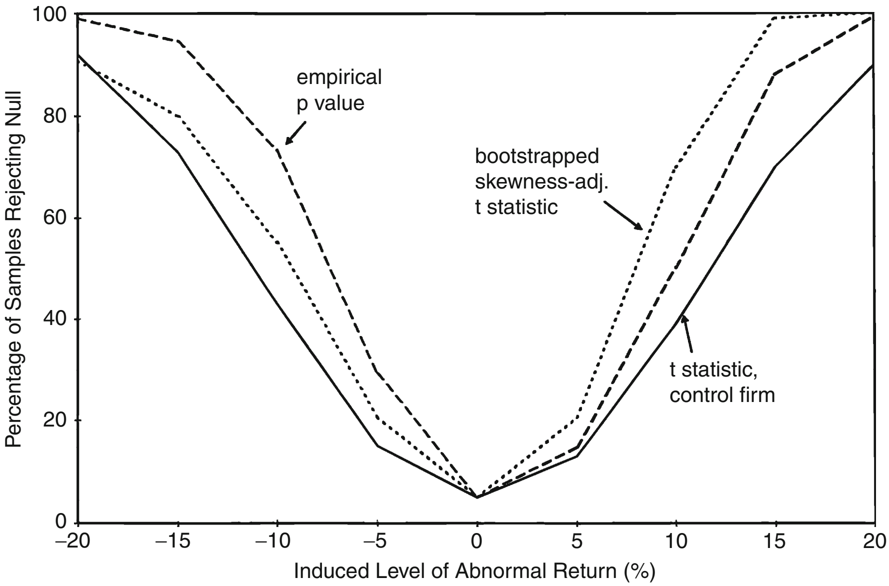

Fig. 50.3 Power of alternative tests in random ample. This figure is from Fig. 1 of Lyon et al. (1999, p. 180). The percentage of 1,000 random samples of 200 firms rejecting the null hypothesis of no annual buy-and-hold abnormal return at various induced levels of abnormal return (horizontal axis) based on control firm method, bootstrapped skewness-adjusted *t*-statistic, and empirical *p*-values

50.3 Long-Run Return Estimation in Calendar-Time Approach

A potential problem in the event-time return estimations is the cross-sectional dependence. For example, buy-and-hold return is computed over a long horizon; it is possible that many sample firms' returns overlap with each other, making strong cross-sectional correlations among long-horizon returns. This cross-sectional dependence is even more profound when we have repeating events by the same firm, such as repurchase, SEO, merger, and stock splits. In addition, buy-and-hold returns also enlarge the long-run abnormal return because of the inflated returns stemming from the compounding effect. Therefore, the long-run return results might disappear if we apply other methodologies to compute the long-run abnormal return (Mitchell and Stafford 2000). Fama (1998) also documents that the long-run stock return should be examined by the value-weighted factor model since the buy-and-hold return usually uses an equal-weighted scheme that is related to the ignored transaction costs. Although Loughran and Ritter (2000) suggest that the value-weighted factor model is the least powerful test for long-run returns, the calendar-time method could be always a robust check for our long-run return estimation.

To estimate the abnormal return in calendar time, we need to form a monthly portfolio for each calendar month. The portfolio return could be generated by an equal-weighted, value-weighted, or a log-value-weighted method (Ikenberry et al. 2000). Upon these monthly returns in calendar time, we are able to carry out the mean monthly abnormal return or factor model analysis.

50.3.1 Return Estimations: Mean Monthly Return and Factor Models

The first method in the calendar-time approach is the mean monthly abnormal return (MMAR). We can start from a 5-year holding strategy on a corporate event. For any given calendar month (e.g., June 2002), we need to include a stock if it had the corporate event in the past 60 months (e.g., looking backward at a period of May 2002–June 1997). We then need to form a monthly portfolio for this specific calendar month, and the portfolio return could be computed upon equal-weighted, value-weighted or log-value-weighted scheme. Next, we repeat the abovementioned step for all calendar months throughout the sample period, and then the mean monthly return is the time-series average of monthly portfolio returns.

Similar to the benchmark problem in event-time approach, we need to select the CRSP market index return, reference portfolio, or the matching firm as the benchmark for the MMAR. For any benchmark $E(R_i)$, the MMAR is

$$MMAR = \frac{\sum_{t=1}^{T} \left(R_t^P - R_t^M\right)}{T},$$

where

$$R_t^P = \frac{\sum_{i=1}^{N_t} w_{i,t} R_{i,t}}{N_t}, \text{ and } R_t^M = \frac{\sum_{i=1}^{N_t} w_{i,t} E\left(R_{i,t}\right)}{N_t}. \tag{50.6}$$

T is for calendar month in this setting; R_t^P is the monthly portfolio return of sample firms; R_t^M is the monthly portfolio return of benchmarks; and N_t is the number of observations in each calendar month. The statistical inference can be either classical t-statistic or the Newey and West (1987) estimation.

As suggested by Fama (1998), Mitchell and Stafford (2000), and Schultz (2003), factor model is a robust method in estimating the long-run stock abnormal return. The standard Fama and French three-factor and Carhart four-factor models could be described as

$$R_t^P - r_{f,t} = \alpha + \beta\left(r_{m,t} - r_{f,t}\right) + sSMB_t + hHML_t + e_t, \tag{50.7}$$

$$R_t^P - r_{f,t} = \alpha + \beta\left(r_{m,t} - r_{f,t}\right) + sSMB_t + hHML_t + mMOMENTUM_t + e_t, \tag{50.8}$$

where R_t^P is the sample firm portfolio return for each calendar month, and could be obtained from the equal-weighted, value-weighted, or log-value-weighted average. This average return in calendar is similar to what we compute in the MMAR. r_f is the risk-free rate, usually the short-term Treasury bill rate; r_m is usually computed as CRSP value-weighted index return; *SMB* is small firm portfolio return minus big-firm portfolio return; *HML* is the high book-to-market portfolio return minus low book-to-market portfolio return; *MOMENTUM* is the winner portfolio return minus loser portfolio return where winner and loser portfolios are identified by past 1-year return. *SMB*, *HML*, and *MOMENTUM* are applied to control size and book-to-market and momentum effects, respectively (Fama and French 1992, 1993; Jegadeesh and Titman 1993; Lakonishok et al. 1994; Carhart 1997). The abnormal return is the regression intercept and can be tested based on the *t*-values or Newey and West (1987) estimator.

Next, I introduce a modification of the factor model analysis: the zero-investment portfolio method. Daniel and Titman (1997) and Eberhart et al. (2004) study the long-run return by using the zero-investment portfolio approach to control for both risk and firm characteristic effects. To form the factor model under a zero-investment portfolio strategy, we have to buy sample stocks and short-sell matching stocks. Taking Carhart (1997) four-factor model as the example, we have

$$\begin{aligned} R_t^P - R_t^M = {} & \left(\alpha^P - \alpha^M\right) + (\beta_P - \beta_M)\left(r_{m,t} - r_{f,t}\right) + (s_P - s_M)SMB_t \\ & + (h_P - h_M)HML_t + (m_P - m_M)MOMENTUM_t + e_t, \end{aligned} \tag{50.9}$$

and we use $(\alpha^P – \alpha^M)$ as the abnormal return controlling for both risks and firm characteristics. It is also the hedging portfolio return controlled for the common risk factors. The matching firm selection criterions can apply the steps in benchmark problem section. For other modifications of the factor model analysis, Eberhart et al. (2004) provide more examples in their Table 3.

50.3.2 Conditional Market Model and Ibbotson's RATS

One major challenge to the standard market model is that the risk loadings are assumed to be unchanged. To estimate the factor loadings, we usually need long time series to obtain the estimated risk loadings, and the fixed risk loading over time is naturally assumed in the OLS analysis. Yet, the magnitude of the risk of a firm could be changed; in particular many corporate events change the risk of the firm (e.g., R&D increases could be followed by risk increases, and share repurchase could be followed by risk decreases). Accordingly it is needed to introduce the conditional market model to address the time-varying market model.

There are at least two ways to address the time-varying risks in the regression model as the conditional market model. To simplify the problem, I use the CAPM as the first example. First, the systematic risk could change along with some firm characteristics and macroeconomic variables. Petkova and Zhang (2005) use the following regression analysis to estimate abnormal return:

$$R_t^P - r_{f,t} = \alpha + (b_0 + b_1 DIV_t + b_2 DEF_t + b_3 TERM_t + b_4 TB_t)\left(r_{m,t} - r_{f,t}\right) + e_t. \tag{50.10}$$

$(b_0 + b_1 DIV_t + b_2 DEF_t + b_3 TERM_t + b_4 TB_t)$ is the β_t that accommodates to the time-varying risk loading. They assume that the risk changes with the dividend yield (DIV), the default spread (DEF), the term spread (TERM), and the short-term Treasury bill rate (TB). Again, the abnormal return is the intercept α.

The second method is the rolling regression, as suggested by Petkova and Zhang (2005) and Eberhart et al. (2004). If we have a sample period from January 1990, then we can use the portfolio returns in the first 60 months (i.e., January 1990–December 1994) to carry out the Carhart (1997) four-factor regression. We substitute the estimated factor loadings from these 60 monthly returns into the equity premiums in 61th month (i.e., January 1995) and then obtain the expected portfolio return for 61th month. Thus, the abnormal return for 61th month is from the portfolio return of the sample firm minus the expected portfolio return. Next, we need to repeat the abovementioned steps for every month by rolling return windows. Finally, we estimate the abnormal return as the average of abnormal returns across time and use the time-series volatility to test the statistical significance.

The final method relating to the time-varying risk is the Ibbotson (1975) RATS though it is not under the family of the factor model analysis. The original setting of Ibbotson RATS is designed for the long-run return estimation, yet recent papers use this method combining the factor model analysis to measure the long-run abnormal return (e.g., Peyer and Vermaelen 2009). Based on Carhart (1997) four-factor model, we regress the security excess return on the Carhart (1997) four factors for each month in the event time. Given a 60-month holding strategy, we have to carry out this regression for 1st month to 60th month following the corporate event date. Then, the abnormal return for month τ is the intercept of this four-factor regression:

$$R_{i,t} - r_{f,t} = \alpha_\tau + \beta_\tau\left(r_{m,t} - r_{f,t}\right) + s_\tau SMB_t + h_\tau HML_t + m_\tau MOMENTUM_t + e_t. \tag{50.11}$$

The regression analysis is similar to what I introduce in Eq. 50.8; however, the regression is examined every event month τ. For every event month or event year, we can obtain the average abnormal return as the average of the intercepts (α_τ), which is obtained from a model allowing time-varying risks.

50.4 Conclusion

The long-run return studies have been investigated for many corporate events and asset pricing studies in the past two decades. I introduce the long-run stock return methodologies and their statistical inference adopted in recent papers. Two categories of long-run return methods are illustrated: the event-time approach and calendar-time approach. Under the event-time category, we have methods including cumulative abnormal return, buy-and-hold abnormal return, and abnormal returns around earnings announcements. Although the event-time approach is able to be implemented as an investment strategy in real world, it also raises more benchmark and statistical inference problems. Under the calendar-time category, we have mean monthly abnormal return, factor models, and Ibbotson's RATS. Generally, calendar-time approach is more popular due to its robustness and variety. For any long-run return study, I may suggest that combining works on those methodologies could be necessary.

Abstract

This study utilizes the parametric approach (GARCH-based models) and the semi-parametric approach of Hull and White (Journal of Risk 1: 5–19, 1998) (HW-based models) to estimate the Value-at-Risk (VaR) through the accuracy evaluation of accuracy for the eight stock indices in Europe and Asia stock markets. The measure of accuracy includes the unconditional coverage test by Kupiec (Journal of Derivatives 3: 73–84, 1995) as well as two loss functions, quadratic loss function, and unexpected loss. As to the parametric approach, the parameters of generalized autoregressive conditional heteroskedasticity (GARCH) model are estimated by the method of maximum likelihood and the quantiles of asymmetric distribution like skewed generalized student's t (SGT) can be solved by composite trapezoid rule. Sequentially, the VaR is evaluated by the framework proposed by Jorion (*Value at Risk: the new benchmark for managing financial risk*. New York: McGraw-Hill, 2000). Turning to the semi-parametric approach of Hull and White (Journal of Risk 1: 5–19, 1998), before performing the traditional historical simulation, the raw return series is scaled by a volatility ratio where the volatility is estimated by the same procedure of parametric approach. Empirical results show that the kind of VaR approaches is more influential than that of return distribution settings on VaR estimate. Moreover, under the same return distributional setting, the HW-based models have the better VaR forecasting performance as compared with the GARCH-based models. Furthermore, irrespective of whether the GARCH-based model or HW-based model is employed, the SGT has the best VaR forecasting performance followed by student's t, while the normal owns the worst VaR forecasting performance. In addition, all models tend to underestimate the real market risk in most cases, but the non-normal distributions (student's t and SGT) and the semi-parametric approach try to reverse the trend of underestimating.

Keywords

Value-at-Risk • Semi-parametric approach • Parametric approach • Generalized autoregressive conditional heteroskedasticity • Skewed generalized student's t • Composite trapezoid rule • Method of maximum likelihood • Unconditional coverage test • Loss function

51.1 Introduction

Over the last two decades, a number of global and national financial disasters have occurred due to failures in risk management procedures. For instance, US Savings and Loan crisis of 1989–1991, Japanese asset price bubble collapse of 1990, Black Wednesday of 1992–1993, 1994 economic crisis in Mexico, 1997 Asian Financial Crisis, 1998 Russian financial crisis, financial crisis of 2007–2010, followed by the late 2000s recession, and the 2010 European sovereign debt crisis. The crises caused many enterprises to be liquidated and many countries to face near depressions in their economies. These painful experiences once again underline the importance of accurately measuring financial risks and implementing sound risk management policies. Hence, Value-at-Risk (VaR) is a widely used risk measure of the risk of loss on a specific portfolio of financial assets because it is an attempt to summarize the total risk with a single number. For example, if a portfolio of stocks has a 1-day 99 % VaR of US$1,000, there is a 1 % probability that the portfolio will fall in value by more than US$1,000 over a 1-day period. In other words, we are 99 % certain that we will not lose more than US$1,000 in the next 1 day, where 1 day is the time horizon, 99 % is the confidence level, and the US$1,000 is the VaR of the portfolio.

VaR estimates are currently based on either of three main approaches: the historical simulation, the parametric method, and the Monte Carlo simulation. The Monte Carlo simulation is a class of computational algorithms that rely on repeated random sampling to compute their results. That is, this approach allows for an infinite number of possible scenarios you are exposing yourself to huge model risks in determining the likelihood of any given path. In addition, as you had more and more variables that could possibly alter your return paths, model complexity and model risks also increase in scale. Like historical simulation, however, this methodology removes any assumption of normality and thus, if modeled accurately, probably would give the most accurate measure of the portfolio's true VaR. Besides, little research such as Vlaar (2000) had applied this approach to estimate the VaR. The parametric method is also known as variance/covariance approach. This method is popular because the only variables you need to do the calculation are the mean and standard deviation of the portfolio, indicating the simplicity of the calculations. The parametric method assumes that the returns of the portfolios are normally distributed and serially independent. In practice, this assumption of return normality has proven to be extremely risky. Indeed, this was the biggest mistake that LTCM made gravely underestimating their portfolio risks. Another weakness with this method is the stability of the standard deviation through time as well as the stability of the variance/covariance matrix in your portfolio. However, it is easy to depict how correlations have changed over time particularly in emerging markets and through contagion in times of financial crisis. Additionally, numerous studies focused on the parametric approach of generalized autoregressive conditional heteroskedasticity (GARCH) family variance specifications (i.e., risk metrics, asymmetric power ARCH (APARCH), exponential GARCH (EGARCH), threshold GARCH (TGARCH), integrated GARCH (IGARCH), and fractional IGARCH (FIGARCH)) to estimate the VaR (see Vlaar (2000), Giot and Laurent (2003a, b), Gencay et al. (2003), Cabedo and Moya (2003), Angelidis et al. (2004), Huang and Lin (2004), Hartz et al. (2006), So and Yu (2006), Sadeghi and Shavvalpour (2006), Bali and Theodossiou (2007), Bhattacharyya et al. (2008), Lee et al. (2008), Lu et al. (2009), Lee and Su (2011), and so on). Lately, in the empirical study of parametric VaR approach, several researches have utilized the other type of volatility specifications besides GARCH family such as the ARJI-GARCH-based model (hereafter ARJI) of Chan and Maheu (2002) which combines the GARCH specification of volatility and autoregressive jump intensity (ARJI) in jump intensity (see Su and Hung (2011) Chang et al. (2011), and so on). Moreover, the other types of long memory volatility specifications such as fractional integrated APARCH (FIAPARCH) and hyperbolic

GARCH (HYGARCH) besides FIGARCH mentioned above are also used to estimate the VaR (see Aloui and Mabrouk (2010), Degiannakis et al. (2012)). As to distribution setting, some special distributions like the Weibull distribution (see Gebizlioglu et al. (2011)), the asymmetric Laplace distribution (see Chen et al. (2012)), and the Pearson type-IV distribution (see Stavroyiannis et al. (2012)) are also employed to estimate VaR.

The historical simulation assumes that the past will exactly replicate the future. The VaR calculation of this approach is literally ranking all of your past historical returns in terms of lowest to highest and computing with a predetermined confidence rate what your lowest return historically has been.[1] In addition, several studies such as Vlaar (2000), Gencay et al. (2003), Cabedo and Moya (2003), and Lu et al. (2009) had applied this approach to estimate the VaR. Even though it is relatively easy to implement, there is a couple of shortcomings of this approach, and first of all is that it imposes a restriction on the estimation assuming asset returns are independent and identically distributed (iid) which is not the case. From empirical evidence, it is known that asset returns are clearly not independent as they exhibit volatility clustering.[2] Therefore, it can be unrealistic to assume iid asset returns. Second restriction relates to time. Historical simulation applies equal weight to all returns of the whole period, and this is inconsistent with the nature where there is diminishing predictability of data that are further away from the present.

These two shortcomings of historical simulation lead this paper to use the approach proposed by Hull and White (1998) (hereafter, HW method) as a representative of the semi-parametric approach. This semi-parametric approach combines the abovementioned parametric approach of GARCH-based variance specification with the weighted historical simulation. The weighted historical simulation applies decreasing weights to returns that are further away from the present, which overcomes the inconsistency of historical simulation with diminishing predictability of data that are further away from the present. Hence, this study utilizes the parametric approach (GARCH-N, GARCH-T, and GARCH-SGT models) and the semi-parametric approach of Hull and White (1998) (HW-N, HW-T, and HW-SGT models), totaling six models, to estimate the VaR for the eight stock indices in Europe and Asia stock markets, then uses three accuracy measures: one likelihood ratio test (the unconditional coverage test (LR_{uc}) of Kupiec (1995)) and two loss functions (the average quadratic loss function (AQLF) of Lopez (1999) and the unexpected loss (UL)) to compare the forecasting ability of the aforementioned models in terms of VaR.

Our results show that the kind of VaR approaches is more influential than that of return distribution settings on VaR estimate. Moreover, under the same return distributional setting, the HW-based models have the better VaR forecasting

[1]This means if you had 200 past returns and you wanted to know with 99 % confidence what's the worst you can do, you would go to the 2nd data point on your ranked series and know that 99 % of the time you will do no worse than this amount.

[2]Large changes tend to be followed by large changes, of either sign, and small changes tend to be followed by small changes.

performance as compared with the GARCH-based models. Furthermore, irrespective of whether the GARCH-based model or HW-based model is employed, the skewed generalized student's t (SGT) has the best VaR forecasting performance followed by student's t, while the normal owns the worst VaR forecasting performance. In addition, all models tend to underestimate the real market risk in most cases, but the non-normal distributions (student's t and SGT) and the semi-parametric approach try to reverse the trend of underestimating.

The remainder of this paper is organized as follows. Section 51.2 describes the methodology of two dissimilar VaR approaches (the parametric and semi-parametric approaches) and the VaR calculations using these approaches. Section 51.3 provides criteria for evaluating risk management, and Sect. 51.4 reports on and analyzes the empirical results of the out-of-sample VaR forecasting performance. The final section makes some concluding remarks.

51.2 Empirical Methodology

In this paper, there are two approaches of calculating VaR to be introduced, that is, the parametric method and the semi-parametric approach. Here, we use the GARCH(1,1) model with three conditional distributions, namely, the normal, student's t, and SGT distributions, to estimate the corresponding volatility in terms of different stock indices then employ the framework of Jorion (2000) to evaluate the VaR of parametric approach whereas utilizing the weighting scheme of volatility proposed by Hull and White (1998) (hereafter, HW method) which is a straightforward extension of traditional historical simulation to calculate the VaR of semi-parametric VaR.

51.2.1 Parametric Method

Many time series data of financial assets appear to exhibit autocorrelated and volatility clustering. Bollerslev et al. (1992) showed that the GARCH(1,1) specification works well in most applied situations. Furthermore, the unconditional distribution of those returns displays leptokurtosis and a moderate amount of skewness. Hence, this study thus considers the applicability of the GARCH(1,1) model with three conditional distributions, namely, the normal, student's t, and SGT distributions, to estimate the corresponding volatility in terms of different stock indices and use the GARCH model as an official delegate of the VaR model.

51.2.1.1 GARCH Model with Normal Distribution

Let $r_t = (\ln P_t - \ln P_{t-1}) \times 100$, where P_t denotes the stock price and r_t denotes the continuously compounded daily returns of the underlying assets on time t. The GARCH (1,1) model with SGT distribution (GARCH-SGT) can be expressed as follows:

$$r_t = \mu + e_t, \quad e_t = \varepsilon_t \sigma_t, \quad \cdot\, \varepsilon_t \sim \text{IID} \;\; \text{SGT}(0, 1; \kappa, \lambda, n) \qquad (51.1)$$

$$\sigma_t^2 = \omega + \alpha e_{t-1}^2 + \beta\sigma_{t-1}^2 \tag{51.2}$$

where e_t is the current error and μ and $\sigma_t{}^2$ are the conditional mean and variance of return, respectively. Moreover, the variance parameters ω, α, and β are the parameters to be estimated and obey the constraints ω, α, $\beta > 0$ and $\alpha + \beta < 1$. IID denotes that the standardized errors ε_t are independent and identically distributed. Since ε_t is drawn from the standard normal distribution, the probability density function for ε_t is

$$f(\varepsilon_t) = \frac{1}{\sqrt{2\pi}}\exp\left(-\frac{\varepsilon_t^2}{2}\right), \tag{51.3}$$

and the log-likelihood function of GARCH-N model thus can be written as

$$L(\psi) = \ln f(r_t|\Omega_{t-1};\psi) = -0.5\left(\ln\ 2\pi + \ln\ \sigma_t^2 + (r_t - \mu)^2/\sigma_t^2\right) \tag{51.4}$$

where $\psi = [\mu, \omega, \alpha, \beta]$ is the vector of parameters to be estimated and Ω_{t-1} denotes the information set of all observed returns up to time $t - 1$. Under the framework of the parametric techniques (Jorion 2000), the 1-day-ahead VaR based on GARCH-N model can be calculated as

$$VaR_{t+1|t}^N = \mu + F_c(\varepsilon_t)\cdot\hat{\sigma}_{t+1|t} \tag{51.5}$$

where $F_c(\varepsilon_t)$ is the left-tailed quantile at c% for the standardized normal distribution. $\hat{\sigma}_{t+1|t}$ is the one-step-ahead forecasts of the standard deviation of the returns conditional on all information upon the time t.

51.2.1.2 GARCH Model with Student's t Distribution

Since the characteristics of many financial data are non-normal, the student's t distribution is most commonly employed to capture the fat-tailed properties of their empirical distributions. Moreover, Bollerslev (1986) argued that using the student's t distribution as the conditional distribution for GARCH model is more satisfactory since it exhibits thicker tail and larger kurtosis than normal distribution. Under the same specifications of mean and variance equation as the GARCH-N model, the probability density function for the standardized student's t distribution can be represented as follows:

$$f(\varepsilon_t) = \frac{\Gamma(0.5(n+1))}{\Gamma(0.5\ n)\sqrt{\pi(n-2)}}\left\{1 + \frac{\varepsilon_t^2}{n-2}\right\}^{-\frac{n+1}{2}} \tag{51.6}$$

where $\Gamma(\bullet)$ is the gamma function and n is the shape parameter. Hence, the log-likelihood function of the GARCH-T model can be expressed as

$$
\begin{aligned}
L(\psi) &= \ln f(r_t|\Omega_{t-1};\psi) = \ln\left[\frac{\Gamma(0.5(n+1))}{\Gamma(0.5n)\sqrt{\pi(n-2)}}\right] \\
&\quad -\ln\sigma_t - \frac{n+1}{2}\ln\left[1+\left(\frac{r_t-\mu}{\sigma_t}\right)^2(n-2)^{-1}\right]
\end{aligned}
\tag{51.7}
$$

where $\psi = [\mu, \omega, \alpha, \beta, n]$ is the vector of parameters to be estimated. The 1-day-ahead VaR based on GARCH-T model can be obtained as

$$
\mathrm{VaR}^{T}_{t+1|t} = \mu + F_c(\varepsilon_t; n)\cdot\hat{\sigma}_{t+1|t} \tag{51.8}
$$

where $F_c(\varepsilon_t;\ n)$ denotes the left-tailed quantile at c% for standardized student's t distribution with shape parameter n.

51.2.1.3 GARCH Model with Skewed Generalized Student's t Distribution

This study also employs the SGT distribution of Theodossiou (1998) which allows return innovation to follow a flexible treatment of both skewness and excess kurtosis in the conditional distribution of returns. Under the same specifications of mean and variance as the GARCH-N model, the probability density function for the standardized SGT distribution is derived by Lee and Su (2011) and can be represented as follows:

$$
f(\varepsilon_t) = C\left\{1+\frac{|\varepsilon_t+\delta|^{\kappa}}{[1+\mathrm{sign}\,(\varepsilon_t+\delta)\lambda]^{\kappa}\theta^{\kappa}}\right\}^{-\frac{n+1}{\kappa}} \tag{51.9}
$$

where $\theta = \frac{1}{S(\lambda)}B\left(\frac{1}{\kappa},\frac{n}{\kappa}\right)^{\frac{1}{2}}B\left(\frac{3}{\kappa},\frac{n-2}{\kappa}\right)^{-\frac{1}{2}}, S(\lambda) = \sqrt{1+3\lambda^2-4A^2\lambda^2},$

$$
A = B\left(\tfrac{2}{\kappa},\tfrac{n-1}{\kappa}\right)B\left(\tfrac{1}{\kappa},\tfrac{n}{\kappa}\right)^{-0.5}B\left(\tfrac{3}{\kappa},\tfrac{n-2}{\kappa}\right)^{-0.5},\ \delta = \tfrac{2\lambda A}{S(\lambda)},\ C = \tfrac{\kappa}{2\theta}B\left(\tfrac{1}{\kappa},\tfrac{n}{\kappa}\right)^{-1}
$$

where κ, n, and λ are scaling parameters and C and θ are normalizing constants ensuring that $f(\bullet)$ is a proper p.d.f. The parameters κ and n control the height and tails of density with constraints $\kappa > 0$ and $n > 2$, respectively. The skewness parameter λ controls the rate of descent of the density around the mode of ε_t with $-1 < \lambda < 1$. In the case of positive (resp. negative) skewness, the density function skews toward the right (resp. left). Sign is the sign function, and $B(\bullet)$ is the beta function. The parameter n has the degrees of freedom interpretation in case $\lambda = 0$ and $\kappa = 2$. The log-likelihood function of the GARCH-SGT model thus can be written as

$$
\begin{aligned}
L(\psi) = \ln f(r_t|\Omega_{t-1};\psi) &= \ln C - \ln\sigma_t - \frac{n+1}{\kappa}\ln\left\{1+\left|\frac{r_t-\mu}{\sigma_t}+\delta\right|^{\kappa}\right. \\
&\qquad \left.\left[1+\mathrm{sign}\left(\frac{r_t-\mu}{\sigma_t}+\delta\right)\lambda\right]^{-\kappa}\theta^{-\kappa}\right\}
\end{aligned}
\tag{51.10}
$$

where $\psi = [\mu, \omega, \alpha, \beta, \kappa, \lambda, n]$ is the vector of parameters to be estimated, and Ω_{t-1} denotes the information set of all observed returns up to time $t - 1$.

Under the framework of the parametric techniques (Jorion 2000), the 1-day-ahead VaR based on GARCH-SGT model can be calculated as

$$\mathrm{VaR}^{\mathrm{SGT}}_{t+1|t} = \mu + F_c(\varepsilon_t; \kappa, \lambda, n) \cdot \hat{\sigma}_{t+1|t} \tag{51.11}$$

where $F_c(\varepsilon_t; \kappa, \lambda, n)$ denotes the left-tailed quantile at c% for standardized SGT distribution with shape parameters κ, λ, and n and can be evaluated by a numerical integral method (composite trapezoid rule).[3] Particularly, the SGT distribution generates the student's t distribution for $\lambda = 0$ and $\kappa = 2$. Moreover, the SGT distribution generates the normal distribution for $\lambda = 0$, $\kappa = 2$, and $n = \infty$.

51.2.2 Semi-parametric Method

In this paper, we use the approach proposed by Hull and White (1998) (hereafter, HW method) as a representative of the semi-parametric approach. The HW method is a straightforward extension of traditional historical simulation. Instead of using the actual historical percentage changes in market variables for the purposes of calculating VaR, we use historical changes that have been adjusted to reflect the ratio of the current daily volatility to the daily volatility at the time of the observation and assume that the variance of each market variable during the period covered by the historical data is monitored using a GARCH model. The methodology is explained in the following three steps: ***First***, use a raw return series, $\{r_1, r_2, r_3, \ldots\ldots, r_{t=T}\}$, to fit the GARCH(1,1) models with alternative distributions expressed as in Sect. 51.2.1. Thus, a series of daily volatility estimates, $\{\sigma_1, \sigma_2, \sigma_3, \ldots\ldots, \sigma_{t=T}\}$, are obtained where T is the number of estimated samples. ***Second***, the modified return series are obtained by the raw return series multiplied by the ratio of the current daily volatility to the daily volatility at the time of the observation, σ_T/σ_i. That is, the modified return series are expressed as $\{r_1^*, r_2^*, r_3^*, \ldots\ldots, r_{t=T}^*\}$, where $r_i^* = r_i(\sigma_T/\sigma_i)$. ***Finally***, sort the returns ascendingly to achieve the empirical distribution. Thus, VaR is the percentile that corresponds to the specified confidence level.

The HW-GARCH-SGT model (simply called HW-SGT) implies that the standardized residual return of the GARCH-SGT model is applied by the HW approach to estimate the VaR so are HW-N and HW-T models.

51.3 Evaluation Methods of Model-Based VaR

Many financial institutions have been required to hold capital against their market risk exposure, while the market risk capital requirements are based on the VaR estimates

[3] See Faires and Burden (2003) for more details.

generated by the financial institutions' own risk management models. Explicitly, the accuracy of these VaR estimates is of concern to both financial institutions and their regulators. Hence, model accuracy is important to all VaR model users. To compare the forecasting ability of the aforementioned models in terms of VaR, this study considers three accuracy measures: the unconditional coverage test of Kupiec (1995) which are quite standard in the literatures. Moreover, the quadratic loss function and the unexpected loss are introduced and used for determining the accuracy of model-based VaR measurements.

51.3.1 Log-Likelihood Ratio Test

Before performance competition of alternative VaR models, with regard to two models, we can use the log-likelihood ratio test to compare which one model has the better matching ability of between actual data and empirical model. This can be regarded as the preliminary analysis. The log-likelihood ratio test is a statistical test used to compare the fit of two models, one of which, the null model, is a special case of the other, the alternative model. The test is based on the likelihood ratio, which expresses how many times more likely the data are under one model than the other. This log-likelihood ratio can then be used to compute a p-value, or compared to a critical value, to decide whether to reject the null model in favor of the alternative model.

The log-likelihood ratio test LR_N (LR_T), used to test the null hypothesis that log-returns are normally (student's t) distributed against the alternative hypothesis, is given by

$$LR_N \text{ or } LR_T = -2(LR_r - LR_u) \sim \chi^2(m) \tag{51.12}$$

where LR_r and LR_u are, respectively, the maximum value of the log-likelihood values under the null hypothesis of the restricted model and the alternative hypothesis of the unrestricted model and m is the number of the restricted parameters in the restricted model. For example, LR_N for GARCH-SGT model could be used to test the null hypothesis that log-returns are normally distributed against the alternative hypothesis that they are SGT distributed. The null hypothesis for testing normality is $H_0{:}\kappa = 2$, $\lambda = 0$ and $n \to \infty$, and the alternative hypothesis is $H_1{:}\kappa \in R^+$, $n > 2$ and $|\lambda| < 1$. Restate, $LR_N = -2(LR_r - LR_u) \sim \chi^2(3)$ where LR_r and LR_u are, respectively, the maximum value of the log-likelihood values under the null hypothesis of restricted model (GARCH-N model) and the alternative hypothesis of unrestricted model (GARCH-SGT model) and m is the number of the restricted parameters in the restricted model ($\kappa = 2$, $\lambda = 0$ and $n \to \infty$) and equal to 3 in this case. At the same inference, LR_N for GARCH-T model follows the $\chi^2(1)$ distribution with one degree of freedom. Moreover, LR_T for GARCH-SGT model follows the $\chi^2(2)$ distribution with two degrees of freedom.

51.3.2 Binary Loss Function or Failure Rate

If the predicted VaR is not able to cover the realized loss, this is termed a violation. A binary loss function (BLF) is merely the reflection of the LR test of unconditional coverage test and gives a penalty of one to each exception of the VaR. The BLF for long position can be defined as follows:

$$BL_{t+1} = \begin{cases} 1 & \text{if } r_{t+1} < VaR_{t+1|t}, \\ 0 & \text{if } r_{t+1} \geq VaR_{t+1|t}. \end{cases} \tag{51.13}$$

where BL_{t+1} represents the 1-day-ahead BLF for long position. If a VaR model truly provides the level of coverage defined by its confidence level, then the average binary loss function (ABLF) or the failure rate over the full sample will equal c for the $(1-c)$th percentile VaR.

51.3.3 Quadratic Loss Function

The quadratic loss function (QLF) of Lopez (1999) penalizes violations differently from the binary loss function and pays attention to the magnitude of the violation. The QLF for long position can be expressed as

$$QL_{t+1} = \begin{cases} 1 + \left(r_{t+1} - VaR_{t+1|t}\right)^2 & \text{if } r_{t+1} < VaR_{t+1|t}, \\ 0 & \text{if } r_{t+1} \geq VaR_{t+1|t}. \end{cases} \tag{51.14}$$

where QL_{t+1} represents the 1-day-ahead QLF for long position. The quadratic term in Eq. 51.14 ensures that large violations are penalized more than the small violations which provides a more powerful measure of model accuracy than the binary loss function.

51.3.4 The Unconditional Coverage Test

Kupiec (1995) proposes the unconditional coverage test which is a likelihood ratio test for testing the model accuracy which is identical to a test of the null hypothesis that the probability of failure for each trial $(\hat{\pi})$ equals the specified model probability (p). The likelihood ratio test statistics is given by

$$LR_{uc} = -2\ln\left(p^{n_1}(1-p)^{n_0}\hat{\pi}^{-n_1}(1-\hat{\pi})^{-n_0}\right) \sim \chi^2(1) \tag{51.15}$$

where $\hat{\pi} = \frac{n_1}{n_0+n_1}$ is the maximum likelihood estimate of p, n_1 denotes a Bernoulli random variable representing the total number of VaR violations, and $n_0 + n_1$

represents the full sample size. The LR_{uc} test can be employed to test whether the sample point estimate is statistically consistent with the VaR model's prescribed confidence level or not.

51.3.5 Unexpected Loss

The unexpected loss (UL) will equal the average magnitude of the violation over the full sample. The magnitude of the violation for long position is given by

$$L_{t+1} = \begin{cases} r_{t+1} - VaR_{t+1|t} & \text{if } r_{t+1} < VaR_{t+1|t}, \\ 0 & \text{if } r_{t+1} \geq VaR_{t+1|t}. \end{cases} \tag{51.16}$$

where L_{t+1} is the 1-day-ahead magnitude of the violation for long position.

51.4 Empirical Results

The study data comprises daily prices of the following eight stock indices: the Austria ATX (6/29/1999–8/10/2009), the Belgium Brussels (10/19/1999–8/10/2009), the France CAC40 (10/22/1999–8/10/2009) and the Switzerland Swiss (9/8/1999–8/10/2009) in Europe, the India Bombay (7/8/1999–8/10/2009), the Malaysia KLSE (6/23/1999–8/10/2009), the South Korea KOSPI (6/21/1999–8/10/2009), and the Singapore STRAITS (8/24/1999–8/10/2009) in Asia, where the numbers in parentheses are the start and end dates for our sample. Daily closing spot prices for the study period, totaling 2,500 observations, were obtained from http://finance.yahoo.com. The stock returns are defined as the first difference in the logarithms of daily stock prices then multiplied by 100.

51.4.1 Data Preliminary Analysis

Table 51.1 summarizes the basic statistical characteristics of return series for both the estimation and forecast periods. Notably, the average daily returns are all negative (resp. positive) for forecast (resp. estimation) period and very small compared with the variable standard deviation, indicating high volatility. Except the Brussels of estimation period and the CAC40, Swiss and Bombay of forecast period, all returns series almost exhibit negative skewness for both the estimation and forecast periods. The excess kurtosis all significantly exceeds zero at the 1 % level, indicating a leptokurtic characteristic. Furthermore, J-B normality test statistics are all significant at the 1 % level and thus reject the hypothesis of normality and confirm that neither return series is normally distributed. Moreover, the Ljung-Box $Q^2(20)$ statistics for the squared returns are all significant at the 1 %

Notes: 1. [a], [b], and [c] denote significantly at the 10 %, 5 %, and 1 % levels, respectively. 2. J-B statistics are based on Jarque and Bera (1987) and are asymptotically chi-squared distributed with 2 degrees of freedom. 3. $Q^2(20)$ statistics are asymptotically chi-squared distributed with 20 degrees of freedom

level and thus indicate that the return series exhibit linear dependence and strong ARCH effects. Therefore, the preliminary analysis of the data suggests the use of a GARCH model to capture the fat-tails and time-varying volatility found in these stock indices return series.

Descriptive graphs (levels of spot prices, density of the daily returns against normal distribution) for each stock index are illustrated in Fig. 51.1a–h. As shown in Fig. 51.1, all stock indices have experienced a severe slide in price levels and display pictures of volatile bear markets for forecast period. Moreover, comparing density graphs against the normal distribution shows that each return distribution of data employed exhibits non-normal characteristics. This provides evidence in favor of some of skewed, leptokurtic, and fat-tailed return distributions. These results are in line with those of Table 51.1.

51.4.2 Estimation Results for Alternate VaR Models

This section estimates the GARCH(1,1) model with alternative distributions (normal, student's t, and SGT) for performing VaR analysis. For each data series, three GARCH models are estimated with a sample of 2,000 daily returns, and the estimation period is then rolled forwards by adding one new day and dropping the

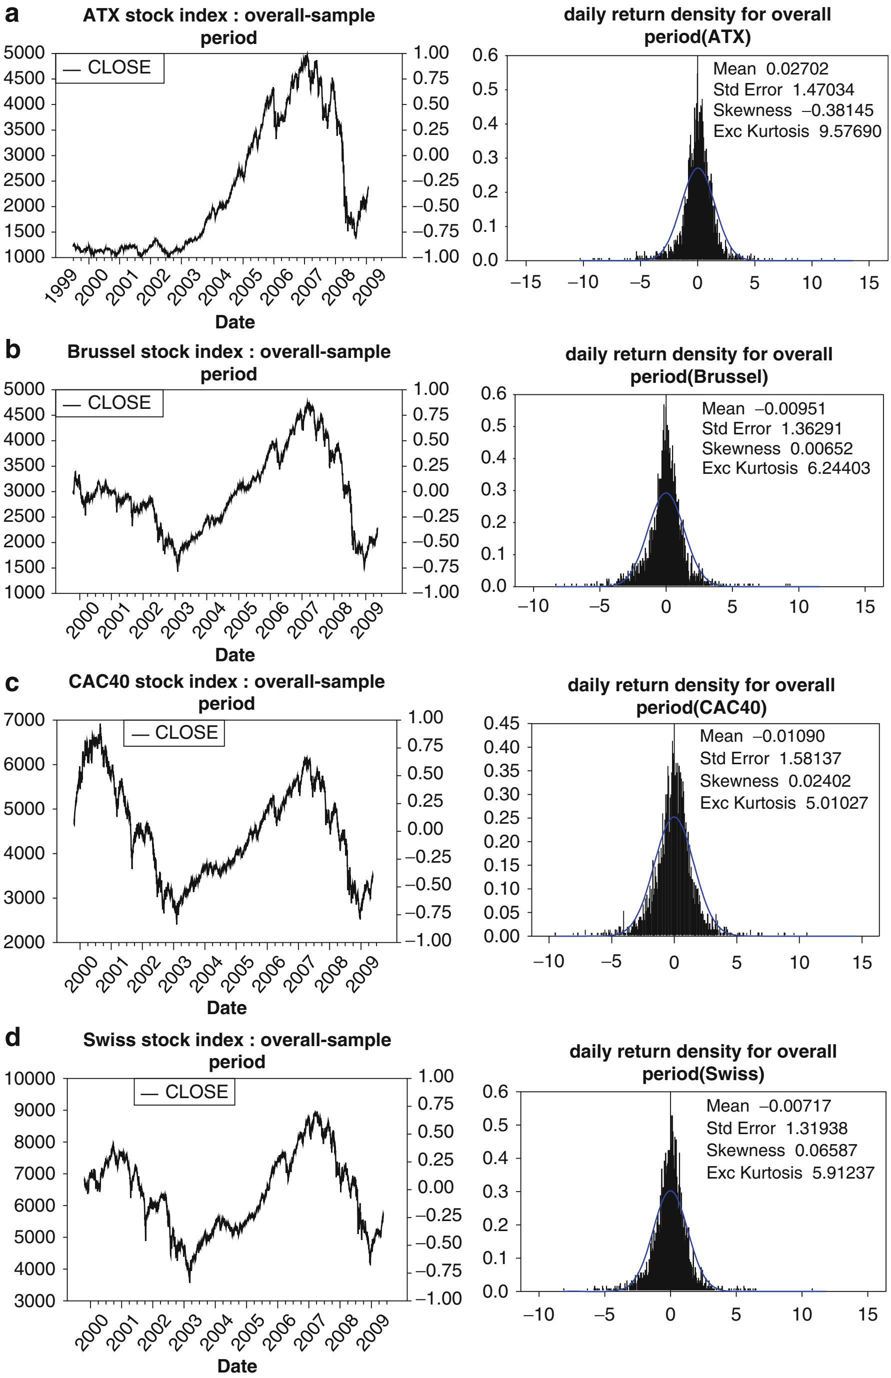

Fig. 51.1 (continued)

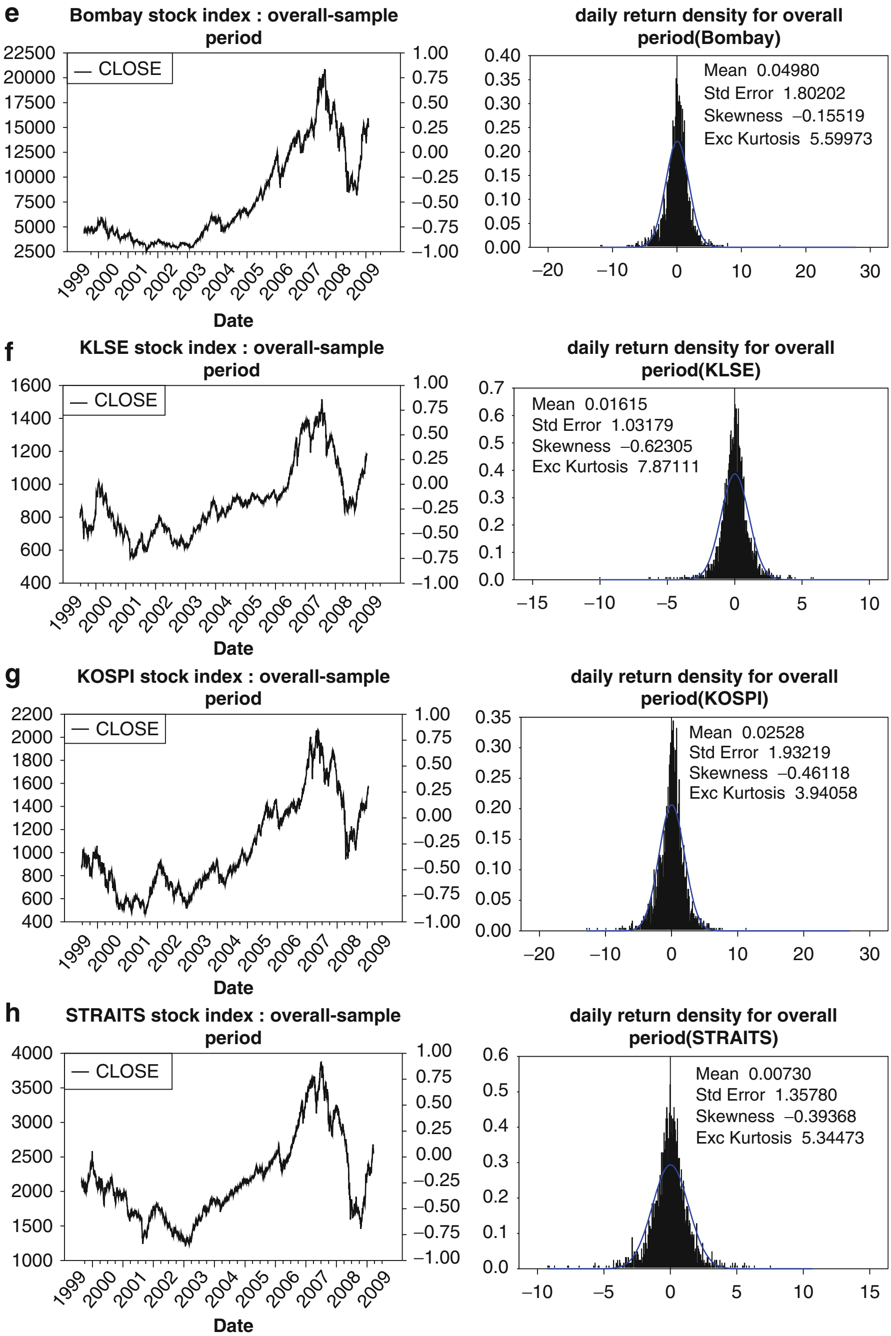

Fig. 51.1 The stock index in level and daily return density (versus normal) for whole sample (**a**) ATX, (**b**) Brussels, (**c**) CAC40, (**d**) Swiss, (**e**) Bombay, (**f**) KLSE, (**g**) KOSPI, (**h**) STRAITS stock indices

most distant day. In this procedure, according to the theory of Sect. 51.2, the out-of-sample VaR is computed for the next 500 days.

Table 51.2 lists the estimation results[4] of the GARCH-N, GARCH-T, and GARCH-SGT models for the ATX, Brussels, CAC40, and Swiss stock indices in Europe and the Bombay, KLSE, STRAITS, and KOSPI stock indices in Asia during the first in-sample period. The variance coefficients ω, α, and β are all positive and significant almost at the 1 % level. Furthermore, the sums of parameters α and β for these three models are less than one thus ensuring that the conditions for stationary covariance hold. As to the fat-tail parameters in student's t distribution, the fat-tail parameter (n) ranges from 4.9906 (KLSE) to 14.9758 (CAC40) for GARCH-T model. All these shape parameters are all significant at 1 % level and obey the constraint $n > 2$ and thereby implying that the distribution of returns has larger, thicker tails than the normal distribution. Turning to the shape parameters in SGT distribution, the fat-tail parameter (n) ranges from 4.9846 (KLSE) to 21.4744 (KOSPI), and the fat-tail parameter (κ) is between 1.5399 (KOSPI) and 2.3917 (Bombay). The skewness parameter (λ) ranges from -0.1560 (Bombay) to -0.0044(KLSE). Moreover, these three coefficients are almost significant at the 1 % level and thereby these negative skewness parameters imply that the distribution of returns has a leftward tail. Therefore, both fat-tails and skewness cannot be ignored in modeling these stock indices returns. The Ljung-Box $Q^2(20)$ statistics for the squared returns are all not significant at the 10 % level and thus indicate that serial correlation does not exist in standard residuals, confirming that the GARCH (1,1) specification in these models is sufficient to correct the serial correlation of these eight return series in the conditional variance equation.

Moreover, as shown in Table 51.2, the LR_N statistics for both GARCH-T and GARCH-SGT models are all significant at the 1 % level, indicating that the null hypothesis of normality for either stock index is rejected. These results thus imply that both the student's t and SGT distributions closely approximate the empirical return series as compared with the normal distribution. Furthermore, except for ATX and KLSE stock indices, the LR_T statistics of GARCH-SGT model are all significant, implying that the SGT distribution more closely approximates the empirical return series than the student's t does. To sum up, the SGT distribution closely approximates the empirical return series followed by student's t and normal distributions.

51.4.3 The Results of VaR Performance Assessment

In this paper, we utilize the parametric approach (GARCH-N, GARCH-T, and GARCH-SGT models) and the semi-parametric approach (HW-N, HW-T, and HW-SGT models), totaling six models, to estimate the VaR.; thereafter, it was compared with the observed return, and both results were recorded. This section

[4]The parameters are estimated by QMLE (quasi-maximum likelihood estimation; QMLE) and the BFGS optimization algorithm, using the econometric package of WinRATS 6.1.

Notes: 1.$^{a, b}$ and^c denote significantly at the 10 %, 5 %, and 1 % levels, respectively. 2. Numbers in parentheses are standard errors. 3. LL indicates the log-likelihood value. 4. The critical value of the LR_N test statistics at the 1 % significance level is 6.635 for GARCH-T and 11.345 for GARCH-SGT model. 5. The critical value of the LR_T test statistics at the 10 %, 5 %, and 1 % significance level is 4.605, 5.991, and 9.210 for GARCH-SGT model, respectively. 6. $Q^2(20)$ statistics are asymptotically chi-squared distributed with 20 degrees of freedom

then uses three accuracy measures: one likelihood ratio test (the unconditional coverage test (LR_{uc}) of Kupiec (1995)) and two loss functions (the average quadratic loss function (AQLF) of Lopez (1999) and the unexpected loss (UL)) to compare the forecasting ability of the aforementioned models in terms of VaR.

Figure 51.2 graphically illustrates the long VaR forecasts of the GARCH-N, GARCH-T, and GARCH-SGT models at alternate levels (95 %, 99 %, and 99.5 %) for all stock indices. Tables 51.3, 51.4 and 51.5 provide the failure rates and the results of the prior three accuracy evaluation tests (LR_{uc}, AQLF, and UL) for the aforementioned six models at the 95 %, 99 %, and 99.5 % confidence levels, respectively. As observed in Tables 51.3, 51.4 and 51.5, we find that, except for a few cases at the 99 % and 99.5 % confidence levels, all models tend to underestimate real market risk because the empirical failure rate is higher than the theoretical failure rate in most cases. The abovementioned exceptional cases emerge at the GARCH-SGT model of 99 % level (CAC40); both the GARCH-T and GARCH-SGT models of 99.5 % level (KLSE and STRAITS); the HW-N (KLSE), HW-T (KLSE), and HW-SGT (KLSE and STRAITS) models of 99 % level; and the HW-N (STRAITS), HW-T (ATX and STRAITS), and HW-SGT (ATX, KLSE, and STRAITS) models of 99.5 % level, where the stock indices in parentheses behind the models are the exceptional cases. Moreover, the empirical failure rate of the above exceptional cases is lower than the theoretical failure rate, indicating that the non-normal distributions (student's t and SGT) and the semi-parametric approach try to reverse the trend of underestimating real market risk, especially at the 99.5 % level.

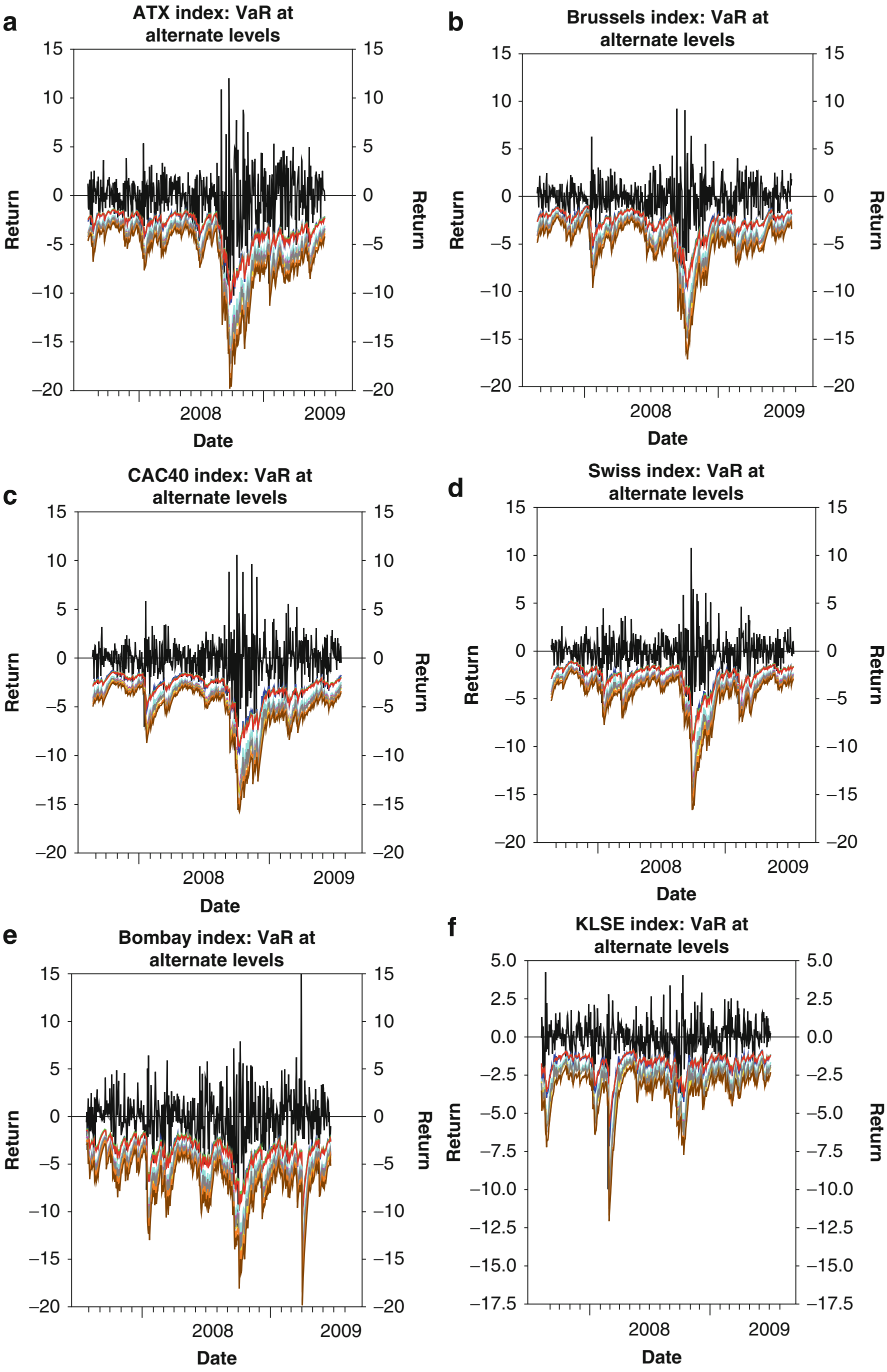

Fig. 51.2 (continued)

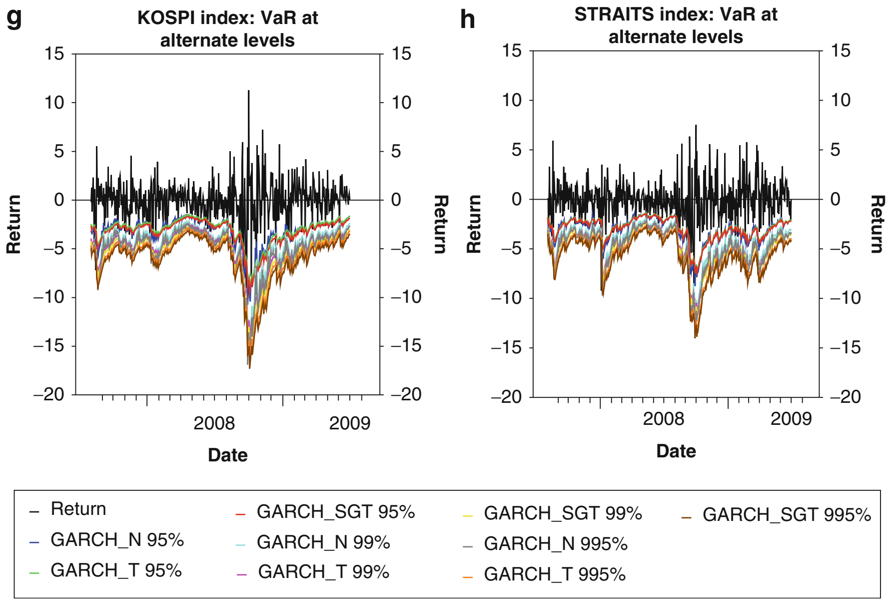

Fig. 51.2 Long VaR forecasts at alternative level for the normal, student's t, and SGT distribution. (**a**) ATX, (**b**) Brussels, (**c**) CAC40, (**d**) Swiss, (**e**) Bombay, (**f**) KLSE, (**g**) KOSPI, (**h**) STRAITS stock indices

As to the back-testing, the back-testing is a specific type of historical testing that determines the performance of the strategy if it had actually been employed during the past periods and market conditions. In this paper, the unconditional coverage tests (LR_{uc}) proposed by Kupiec (1995) is employed to test whether the unconditional coverage rate is statistically consistent with the VaR model's prescribed confidence level and thus is applied as the back-testing to measure the accuracy performance of these six VaR models. To interpret the result of accepting back-testing in Tables 51.3, 51.4 and 51.5, there is an illustration in the following. In Table 51.3, the VaR estimates based on GARCH-N, GARCH-T, and GARCH-SGT models, respectively, have a total of 2 (KLSE and STRAITS), 2 (KLSE and STRAITS), and 5 (Brussels, Bombay, KLSE, STRAITS, and KOSPI) acceptances for the LR_{uc} test when applying to all stock indices returns under 95 % confidence level, where the stock indices in parentheses behind the number are the acceptance cases. For 99 % confidence level, Table 51.4 shows that the GARCH-N, GARCH-T, and GARCH-SGT models pass the LR_{uc} tests with a total of 1, 5, and 8 stock indices, respectively; for 99.5 % confidence level, Table 51.5 gives that the GARCH-N, GARCH-T, and GARCH-SGT models pass the LR_{uc} tests with a total of 3, 7, and 7 stock indices, respectively. Hence, under all confidence levels, there is a total of 6, 14, and 20 acceptances for GARCH-N, GARCH-T, and GARCH-SGT models (the parametric approach), respectively. On the contrary, for 95 % confidence

Note: 1. *Indicates that the model passes the unconditional coverage test at the 5 % significance level and the critical value of the LR_{uc} test statistics at the 5 % significance level is 3.84. 2. The *red* (resp. *blue*) *font* represents the lowest (resp. highest) AQLF and unexpected loss when the predictive accuracies of three different innovations with the same VaR method are compared. 3. The *delete-line font* represents the lowest AQLF and unexpected loss when the predictive accuracies of two different VaR methods with the same innovation are compared. 4. The model acronyms stand for the following methods: *HW-GARCH* non-parametric method proposed by Hull and White (1998), *GARCH* parametric method of GARCH model, *N* the standard normal distribution, *T* the standardized student's t distribution, *SGT* the standardized SGT distribution proposed by Theodossiou (1998) level, Table 51.3 describes that the HW-N, HW-T, and HW-SGT models pass the LR_{uc} tests with a total of 5, 5, and 6 stock indices, respectively. Moreover, for 99 % confidence level, Table 51.4 depicts that the HW-N, HW-T, and HW-SGT models pass the LR_{uc} tests with a total of 7, 8, and 8 stock indices, respectively; for 99.5 % confidence level, Table 51.5 illustrates that the HW-N, HW-T, and HW-SGT models pass the LR_{uc} tests with a total of 7, 8, and 8 stock indices, respectively. Hence, under all confidence levels, there is a total of 19, 21, and 22 acceptances for HW-N, HW-T, and HW-SGT models (the semi-parametric approach), respectively.

From the abovementioned results, we can find the following two important phenomena: First, under the same return distributional setting, the number of acceptance of the HW-based models is greater or equal than those of the GARCH-based models, irrespective of whether the case of individual level (95 %, 99 %, or 99.5 %) or all levels (95 %, 99 %, and 99.5 %) is considered. For example, with regard to all levels, the number of acceptance of the HW-N model (19) is greater than those of the GARCH-N models (6). These results reveal that the HW-based models (semi-parametric approach) have the better VaR forecasting performance as compared with GARCH-based models (parametric approach). Second, the number of acceptance of the SGT distribution is the greatest followed by the student's t and normal distributions, irrespective of whether the GARCH-based model (parametric) or HW-based model (semi-parametric approach) is employed. For instance, with regard to all levels, the number of acceptance of the GARCH-SGT model (20) is the greatest followed by the GARCH-T model (14) and GARCH-N model (6). These results indicate that the SGT has the best VaR forecasting performance followed by student's t while the normal owns the worst VaR forecasting performance.

Turning to the other two accuracy measures (i.e., AQLF and UL), the two loss functions (the average quadratic loss function (AQLF) and the unexpected loss (UL)) reflect the magnitude of the violation which occur as the observed return exceeds the VaR estimation. The smaller the AQLF and UL are generated, the better the forecasting performance of the models is. As observed in Tables 51.3, 51.4 and 51.5, we can also find the following two important phenomena which are similar as those of the back-testing as was mentioned above: First, under the same return distributional setting, the AQLF and UL generated by the HW-based models are smaller than those generated by the GARCH-based models, irrespective of whether the 95 %, 99 %, or 99.5 % level is considered. These results reveal that the HW-based models (semi-parametric approach) significantly have the better VaR forecasting performance as compared with GARCH-based models (parametric approach), which is in line with the results of the back-testing. Second, for all confidence levels, the GARCH-SGT model yields the lowest AQLF and UL for most of the stock indices. Moreover, for most of the stock indices, the GARCH-N model produces the highest AQLF and UL for both 99 % and 99.5 % levels, while the GARCH-T model gives the highest AQLF and UL for 95 % level. These results indicate that the GARCH-SGT model significantly owns the best out-of-sample VaR performance, while the GARCH-N model appears to have the worst out-of-sample VaR performance. On the contrary, for all confidence levels, the HW-N model bears the highest AQLF and UL for most of the stock indices, while the HW-SGT model gives the lowest AQLF and UL for half of the stock indices, indicating that the HW-N model significantly owns the worst out-of-sample VaR performance, while the HW-SGT model appears to bear the highest out-of-sample VaR performance. Consequently, it seems reasonable to conclude that the SGT has the best VaR forecasting performance followed by student's t, while the normal owns the worst VaR forecasting performance, which appears to be consistent with the results of back-testing.

To sum up, according to the three accuracy measures, the HW-based models (semi-parametric approach) have the better VaR forecasting performance as compared with GARCH-based models (parametric approach), and the SGT has the best VaR forecasting performance followed by student's t, while the normal owns the worst VaR forecasting performance. In addition, the kind of VaR approach is more influential than that of return distribution setting on VaR estimate.

51.5 Conclusion

This study utilizes the parametric approach (GARCH-N, GARCH-T, and GARCH-SGT models) and the semi-parametric approach of Hull and White (1998) (HW-N, HW-T, and HW-SGT models), totaling six models, to estimate the VaR for the eight stock indices in Europe and Asia stock markets, then uses three accuracy measures: one likelihood ratio test (the unconditional coverage test (LR_{uc}) of Kupiec (1995)) and two loss functions (the average quadratic loss function (AQLF) of Lopez (1999) and the unexpected loss (UL)) to compare the forecasting ability of the aforementioned models in terms of VaR.

The empirical findings can be summarized as follows. First, according to the results of the log-likelihood ratio test, the SGT distribution closely approximates the empirical return series followed by student's t and normal distributions. Second, in terms of the failure rate, all models tend to underestimate the real market risk in most cases, but the non-normal distributions (student's t and SGT) and the semi-parametric approach try to reverse the trend of underestimating real market risk, especially at the 99.5 % level. Third, the kind of VaR approaches is more influential than that of return distribution settings on VaR estimate. Moreover, under the same return distributional setting, the HW-based models (semi-parametric approach) have the better VaR forecasting performance as compared with the GARCH-based models (parametric approach). Finally, irrespective of whether the GARCH-based model (parametric) or HW-based model (semi-parametric approach) is employed, the SGT has the best VaR forecasting performance followed by student's t, while the normal owns the worst VaR forecasting performance.

Appendix 1: The Left-Tailed Quantiles of the Standardized SGT

The standardized SGT distribution was derived by Lee and Su (2011) and expressed as follows:

$$f(\varepsilon_t) = C\left\{1 + \frac{|\varepsilon_t + \delta|^\kappa}{[1 + \mathrm{sign}(\varepsilon_t + \delta)\lambda]^\kappa \theta^\kappa}\right\}^{-\frac{n+1}{\kappa}} \tag{51.17}$$

where $\theta = \frac{1}{S(\lambda)} B\left(\frac{1}{\kappa}, \frac{n}{\kappa}\right)^{\frac{1}{2}} B\left(\frac{3}{\kappa}, \frac{n-2}{\kappa}\right)^{-\frac{1}{2}}, S(\lambda) = \sqrt{1 + 3\lambda^2 - 4A^2\lambda^2},$

$$A = B\left(\frac{2}{\kappa}, \frac{n-1}{\kappa}\right) B\left(\frac{1}{\kappa}, \frac{n}{\kappa}\right)^{-0.5} B\left(\frac{3}{\kappa}, \frac{n-2}{\kappa}\right)^{-0.5}, \ \delta = \frac{2\lambda A}{S(\lambda)}, \ C = \frac{\kappa}{2\theta} B\left(\frac{1}{\kappa}, \frac{n}{\kappa}\right)^{-1}$$

where κ, n, and λ are scaling parameters and C and θ are normalizing constants ensuring that f(•) is a proper p.d.f. The parameters κ and n control the height and tails of density with constraints $\kappa > 0$ and $n > 2$, respectively. The skewness parameter λ controls the rate of descent of the density around the mode of ε_t with $-1 < \lambda < 1$. In the case of positive (resp. negative) skewness, the density function skews toward the right (resp. left). Sign is the sign function, and B(•) is the beta function. The parameter n has the degrees of freedom interpretation in case $\lambda = 0$ and $\kappa = 2$. Particularly, the SGT distribution generates the student's t distribution for $\lambda = 0$ and $\kappa = 2$. Moreover, the SGT distribution generates the normal distribution for $\lambda = 0$, $\kappa = 2$, and $n = \infty$.

As observed from Table 51.2, the shape parameters in SGT distribution, the fat-tail parameter (n) ranges from 4.9846 (KLSE) to 21.4744 (KOSPI), and the fat-tail parameter (κ) is between 1.5399 (KOSPI) and 2.3917 (Bombay). The skewness parameter (λ) ranges from −0.1560 (Bombay) to −0.0044 (KLSE). Therefore, the left-tailed quantiles of the SGT distribution with various combinations of shape parameters ($-0.15 \le \lambda \le 0.05$; $1.0 \le \kappa \le 2.0$; $n = 10$) at alternate levels are obtained by the composite trapezoid rule and are listed in Table 51.6. Moreover, Fig. 51.3 depicts the left-tailed quantiles surface of SGT (versus normal) distribution with various combinations of shape parameters ($-0.25 \le \lambda \le 0.25$; $0.8 \le \kappa \le 2.0$; $n = 10$ and 20) at 10 %, 5 %, 1 %, and 0.5 % levels. Notably, $F_c(\varepsilon_t; \kappa = 2, \lambda = 0, n = \infty)$ where c = 0.1, 0.05, 0.01, and 0.005 in Fig. 51.3 represents the left-tailed quantiles of normal distribution at 10 %, 5 %, 1 %, and 0.5 % levels, which is −1.28155, −1.64486, −2.32638, and −2.57613, respectively.

Appendix 2: The Procedure of Parametric VaR Approach

The parametric method is very popular because the only variables you need to do the calculation are the mean and standard deviation of the portfolio, indicating the simplicity of the calculations. Moreover, from the literatures' review mentioned above, numerous studies focused on the parametric approach of the GARCH family

variance specifications to estimate the VaR. Furthermore, numerous time series data of financial assets appear to exhibit autocorrelated and volatility clustering, and the unconditional distribution of those returns displays leptokurtosis and a moderate amount of skewness. This study thus considers the applicability of the GARCH(1,1) model with three conditional distributions (the normal, student's t, and SGT distributions) to estimate the corresponding volatility in terms of different stock indices, then employs the framework of Jorion (2000) to evaluate the VaR of parametric approach. We take an example of the GARCH-SGT model. The methodology of parametric VaR approach is based on a rolling window procedure. The window size is fixed at 2,000 observations. More specifically, the procedure is conducted in the following manner:

Step 1: For each data series, using the econometric package of WinRATS 6.1, the parameters are estimated with a sample of 2,000 daily returns by quasi-maximum likelihood estimation (QMLE) of log-likelihood function such as Eq. 51.10 and by the BFGS optimization algorithm. Thus, with $\psi = [\mu, \omega, \alpha, \beta, \kappa, \lambda, n]$, the vector of parameters is estimated. The empirical results of GARCH-SGT model are listed in Table 51.2 for all stock indices surveyed in this paper. As to the empirical results of GARCH-N and GARCH-T models, they are also provided by the same approach.

Step 2: Based on the framework of the parametric techniques (Jorion 2000), the 1-day-ahead VaR based on GARCH-SGT model can be calculated by Eq. 51.11. Then the one-step-ahead VaR forecasts are compared with the observed returns, and the comparative results are recorded for subsequent evaluation using statistical tests.

Step 3: The estimation period is then rolled forwards by adding one new day and dropping the most distant day. By replicating step 1 and step 2, the vector of parameters is estimated, and then the 1-day-ahead VaR can be calculated for the next 500 days.

Step 4: For the out-sample period (500 days), via the comparable results between the one-step-ahead VaR forecasts and the observed returns, the 1-day-ahead BLF, QLF, and UL can be calculated by using Eqs. 51.13, 51.14 and 51.16. On the other hand, the unconditional coverage test, LR_{uc}, is evaluated by employing Eq. 51.15. Thereafter, with regard to the GARCH-based models with alternate distributions (GARCH-N, GARCH-T, and GARCH-SGT), the unconditional coverage test (LR_{uc}) and three loss functions (failure rate, AQLF, and UL) are obtained and are reported in the left panel of Tables 51.3, 51.4 and 51.5 for 95 %, 99 %, and 99.5 % levels.

Appendix 3: The Procedure of Semi-parametric VaR Approach

In this paper, we use the approach proposed by Hull and White (1998) as a representative of the semi-parametric approach. This method mainly couples a weighting scheme of volatility with the traditional historical simulation. Hence, it can be regarded as a straightforward extension of traditional historical simulation. The weighting scheme of volatility is expressed as follows. Instead of using the actual historical percentage changes in market variables for the purposes of calculating VaR, we use historical changes that have been adjusted to reflect the ratio of the current daily volatility to the daily volatility at the time of the observation and assume that the variance of each market variable during the period covered by the historical data is monitored using a GARCH-based models. We take an example of the HW-SGT model. This methodology is explained in the following five steps:

Step 1: For each data series, using the econometric package of WinRATS 6.1, the parameters are estimated with a sample of 2,000 daily returns by quasi-maximum likelihood estimation (QMLE) of log-likelihood function such as Eq. 51.10 and by the BFGS optimization algorithm. Thus, with $\psi = [\mu, \omega, \alpha, \beta, \kappa, \lambda, n]$, the vector of parameters is estimated. This step is the same as the first step of parametric approach. Consequently, a series of daily volatility estimates, $\{\sigma_1, \sigma_2, \sigma_3, \ldots\ldots, \sigma_{t=T}\}$, are obtained where T is the number of estimated samples and equals 2,000 in this study.

Step 2: The modified return series are obtained by the raw return series multiplied by the ratio of the current daily volatility to the daily volatility at the time of the observation, σ_T/σ_i. That is, the modified return series are expressed as $\{r_1^*, r_2^*, r_3^*, \ldots\ldots, r_{t=T}^*\}$, where $r_i^* = r_i(\sigma_T/\sigma_i)$.

Step 3: Resort this modified return series ascendingly to achieve the empirical distribution. Thus, VaR is the percentile that corresponds to the specified confidence level. Then the one-step-ahead VaR forecasts are compared with the observed returns, and the comparative results are recorded for subsequent evaluation using statistical tests.

Step 4: The estimation period is then rolled forwards by adding one new day and dropping the most distant day. By replicating steps 1–3, the vector of parameters is estimated, and then the 1-day-ahead VaR can be calculated for the next 500 days. This step is the same as the third step of parametric approach.

Step 5: For the out-sample period (500 days), via the comparable results between the one-step-ahead VaR forecasts and the observed returns, the 1-day-ahead BLF, QLF, and UL can be calculated by using Eqs. 51.13, 51.14, and 51.16. On the other hand, the unconditional coverage test, LR_{uc}, is evaluated by employing Eq. 51.15. Thereafter, with regard to HW-based models with alternate distributions (HW-N, HW-T, and HW-SGT), the unconditional coverage test (LR_{uc}) and three loss functions (failure rate, AQLF, and UL) are obtained and are reported in the right panel of Tables 51.3, 51.4 and 51.5 for 95 %, 99 %, and 99.5 % levels.

Modeling Multiple Asset Returns by a Time-Varying *t* Copula Model

52

Long Kang

Contents

Abstract

We illustrate a framework to model joint distributions of multiple asset returns using a time-varying Student's *t* copula model. We model marginal distributions of individual asset returns by a variant of GARCH models and then use a Student's *t* copula to connect all the margins. To build a time-varying structure for the correlation matrix of *t* copula, we employ a dynamic conditional correlation (DCC) specification. We illustrate the two-stage estimation procedures for the model and apply the model to 45 major US stocks returns selected from nine

sectors. As it is quite challenging to find a copula function with very flexible parameter structure to account for difference dependence features among all pairs of random variables, our time-varying *t* copula model tends to be a good working tool to model multiple asset returns for risk management and asset allocation purposes. Our model can capture time-varying conditional correlation and some degree of tail dependence, while it also has limitations of featuring symmetric dependence and inability of generating high tail dependence when being used to model a large number of asset returns.

Keywords

Student's *t* copula • GARCH models • Asset returns • US stocks • Maximum likelihood • Two-stage estimation • Tail dependence • Exceedance correlation • Dynamic conditional correlation • Asymmetric dependence

52.1 Introduction

There have been a large number of applications of copula theory in financial modeling. The popularity of copula mainly results from its capability of decomposing joint distributions of random variables into marginal distributions of individual variables and the copula which links the margins. Then the task of finding a proper joint distribution becomes to find a copula form which features a proper dependence structure given that marginal distributions of individual variables are properly specified. Among many copula functions, Student's *t* copula is a good choice, though not perfect, for modeling multivariate financial data as an alternative to a normal copula, especially for a very large number of assets. The *t* copula models are very useful tools to describe joint distributions of multiple assets for risk management and asset allocation purposes. In this chapter, we illustrate how to model the joint distribution of multiple asset returns under a Copula-GARCH framework. In particular, we show how we can build and estimate a time-varying *t* copula model for a large number of asset returns and how well the time-varying *t* copula accounts for some dependence features of real data.

There are still two challenging issues when applying copula theory to multiple time series. The first is how to choose a copula that best describes the data. Different copulas feature different dependence structure between random variables. Some copulas may fit one particular aspect of the data very well but do not have a very good overall fit, while others may have the opposite performance. What criteria to use when we choose from copula candidates is a major question remaining to be fully addressed. Secondly, how to build a multivariate copula which is sufficiently flexible to simultaneously account for the dependence structure for each pair of random variables in joint distributions is still quite challenging. We hope to shed some light on those issues by working through our time-varying *t* copula model.

Under a Copula-GARCH framework, we first model each asset return with a variant of GARCH specification. Based on different properties of asset returns, we choose a proper GARCH specification to formulate conditional distributions of each return. Then, we choose a proper copula function to link marginal distributions of each return to form the joint distribution. As in marginal distributions of each return, the copula parameters can also be specified as being dependent on previous observations to make the copula structure time varying for a better fit of data. In this chapter, we have an AR(1) process for the conditional mean and a GJR-GARCH (1,1) specification for the conditional volatility for each return. We employ a Student's *t* copula with a time-varying correlation matrix (by a DCC specification) to link marginal distributions. Usually the specified multivariate model contains a huge number of parameters, and the estimation by maximum likelihood estimator (MLE) can be quite challenging. Therefore, we pursue a two-stage procedure, where all the GARCH models for each return are estimated individually first and copula parameters are estimated in the second stage with estimated cumulative distribution functions from the first stage.

We apply our model to modeling log returns of 45 major US stocks selected from nine sectors with a time span ranging from January 3, 2000 to November 29, 2011. Our estimation results show that AR(1) and GJR-GARCH(1,1) can reasonably well capture empirical properties of individual returns. The stock returns possess fat tails and leverage effects. We plot the estimated conditional volatility on selected stocks and volatility spikes which happened during the "Internet Bubbles" in the early 2000s and the financial crisis in 2008. We estimate a DCC specification for the time-varying *t* copula and also a normal copula for comparison purposes. The parameter estimates for time-varying *t* copula are statistically significant, which indicates a significant time-varying property of the dependence structure. The time-varying *t* copula yields significantly higher log-likelihood than normal copula. This improvement of data fitness results from flexibility of *t* copula (relative to normal copula) and its time-varying correlation structure.

We plot the time-varying correlation parameter for selected pairs of stocks under the time-varying *t* copula model. The correlation parameters fluctuate around certain averages, and they spike during the 2008 crisis for some pairs. For 45 asset returns, the estimated degree-of-freedom (DoF) parameter of the *t* copula is around 25. Together with the estimated correlation matrix of the *t* copula, this DoF leads to quite low values of tail dependence coefficients (TDCs). This may indicate the limitation of *t* copulas in capturing possibly large tail dependence behavior for some asset pairs when being used to model a large number of asset returns. Nevertheless, the time-varying Student's *t* copula model has a relatively flexible parameter structure to account for the dependence among multiple asset returns and is a very effective tool to model the dynamics of a large number of asset returns in practice.

This chapter is organized as follows. Section 52.2 gives a short literature review on recent applications of copulas to modeling financial time series. Section 52.3 introduces our copula model where we introduce copula theory, Copula-GARCH framework, and estimation procedures. In particular, we elaborate on how to construct and estimate a time-varying *t* copula model. Section 52.4 documents the data source and descriptive statistics for the data set we use. Section 52.5 reports estimation results and Sect. 52.6 concludes.

52.2 Literature Review

Copula-GARCH models were previously proposed by Jondeau and Rockinger (2002) and Patton (2004, 2006a).[1] To measure time-varying conditional dependence between time series, the former authors use copula functions with time-varying parameters as functions of predetermined variables and model marginal distributions with an autoregressive version of Hansen's (1994) GARCH-type model with time-varying skewness and kurtosis. They show for many market indices, dependency increases after large movements and for some cases it increases after extreme downturns. Patton (2006a) applies the Copula-GARCH model to modeling the conditional dependence between exchange rates. He finds that mark-dollar and yen-dollar exchange rates are more correlated during depreciation against dollar than during appreciation periods. By a similar approach, Patton (2004) models the asymmetric dependence between "large cap" and "small cap" indices and examines the economic and statistical significance of the asymmetries for asset allocations in an out-of-sample setting. As in above literature, copulas are mostly used in capturing asymmetric dependence and tail dependence between times series. Among copula candidates, Gumbel's copula features higher dependence (correlation) at upper side with positive upper tail dependence, and rotated Gumbel's copula features higher dependence (correlation) at lower side with positive lower tail dependence. Hu (2006) studies the dependence structure between a number of pairs of major market indices by a mixed copula approach. Her copula is constructed by a weighted sum of three copulas–normal, Gumbel's, and rotated Gumbel's copulas. Jondeau and Rockinger (2006) model the bivariate dependence between major stock indices by a Student's *t* copula where the parameters are assumed to be modeled by a two-state Markov process.

The task of flexibly modeling dependence structure becomes more challenging for n-dimensional distributions. Tsafack and Garcia (2011) build up a complex multivariate copula to model four international assets (two international equities and two bonds). In his model, he assumes that the copula form has a regime-switching setup where in one regime he uses an n-dimensional normal copula and in the other he uses a mixed copula of which each copula component features the dependence structure of two pairs of variables. Savu and Trede (2010) develop a hierarchical Archimedean copula which renders more flexible parameters to characterize dependency between each pair of variables. In their model, each pair of closely related random variables is modeled by a copula of a particular Archimedean class, and then these pairs are nested by copulas as well. The nice property of Archimedean family easily leads to the validity of the

[1]Alternative approaches are also developed, such as in Ang and Bekaert (2002), Goeij and Marquering (2004), and Lee and Long (2009), to address non-normal joint distributions of asset returns.

joint distribution constructed by this hierarchical structure. (Trivedi and Zimmer 2006) apply trivariate hierarchical Archimedean copulas to model sample selection and treatment effects with applications to the family health-care demand.

Statistical goodness-of-fit tests can provide some guidance for selecting copula models. Chen et al. (2004) propose two simple goodness-of-fit tests for multivariate copula models, both of which are based on multivariate probability integral transform and kernel density estimation. One test is consistent but requires the estimation of the multivariate density function and hence is suitable for a small number of random variables, while the other may not be consistent but requires only kernel estimation of a univariate density function and hence is suitable for a large number of assets. Berg and Bakken (2006) propose a consistent goodness-of-fit test for copulas based on the probability integral transform, and they incorporate in their test a weighting functionality which can increase influence of some specific areas of copulas.

Due to their parameter structure, the estimation of Copula-GARCH models also suffers from "the curse of dimensionality".[2] The exact maximum likelihood estimator (MLE) works in theory.[3] In practice, however, as the number of time series being modeled increases, the numerical optimization problem in MLE will become formidable. Joe and Xu (1996) propose a two-stage procedure, where in the first stage only parameters in marginal distributions are estimated by MLE and then the copula parameters are estimated by MLE in the second stage. This two-stage method is called inference for the margins (IFM) method. Joe (1997) shows that under regular conditions the IFM estimator is consistent and has the property of asymptotic normality and Patton (2006b) also shows similar estimator properties for the two-stage method. Instead of estimating parametric marginal distributions in the IFM method, we can estimate the margins by using empirical distributions, which can avoid the problem of mis-specifying marginal distributions. This method is called canonical maximum likelihood (CML) method by Cherubini et al. (2004). Hu (2006) uses this method and she names it as a semi-parametric method. Based on Genest et al. (1995), she shows that CML estimator is consistent and has asymptotical normality. Moreover, copula models can also be estimated under a nonparametric framework. Deheuvels (1981) introduces the notion of empirical copula and shows that the empirical copula converges uniformly to the underlying true copula. Finally, Xu (2004) shows how the copula models can be estimated with a Bayesian approach. The author shows how a Bayesian approach can be used to account for estimation uncertainty in portfolio optimization based on a Copula-GARCH model, and she proposes to use a Bayesian MCMC algorithm to jointly estimate the copula models.

[2]For a detailed survey on the estimation of Copula-GARCH model, see Chap. 5 of Cherubini et al. (2004).

[3]See Hamilton (1994) and Greene (2003) for more details on maximum likelihood estimation.

52.3 The Model

52.3.1 Copula

We introduce our Copula-GARCH model framework by first introducing the concept of copula. A copula is a multivariate distribution function with uniform marginal distributions as its arguments, and its functional form links all the margins to form a joint distribution of multiple random variables.[4] Copula theory is mainly based on the work of Sklar (1959), and we state the Sklar's theorem for continuous marginal distributions as follows.

Theorem 52.1 *Let $F_1(x_1), \ldots, F_n(x_n)$ be given marginal distribution functions and continuous in $x_1, \ldots, x_n$, respectively. Let H be the joint distribution of $(x_1, \ldots, x_n)$. Then there exists a unique copula C such that*

$$H(x_1, \ldots, x_n) = C(F_1(x_1), \ldots, F_n(x_n)), \quad \forall (x_1, \ldots, x_n) \in \overline{\mathbb{R}}^n. \tag{52.1}$$

Conversely, if we let $F_1(x_1), \ldots, F_n(x_n)$ be continuous marginal distribution functions and C be a copula, then the function H defined by Eq. 52.1 is a joint distribution function with marginal distributions $F_1(x_1), \ldots, F_n(x_n)$.

The above theory allows us to decompose a multivariate distribution function into marginal distributions of each random variable and the copula form linking the margins. Conversely, it also implies that to construct a multivariate distribution, we can first find a proper marginal distribution for each random variable and then obtain a proper copula form to link the margins. Depending on which dependence measure used, the copula function mainly, not exclusively, governs the dependence structure between individual variables. Hence, after specifying marginal distributions of each variable, the task of building a multivariate distribution solely becomes to choose a proper copula form which best describes the dependence structure between variables.

Differentiating Eq. 52.1 with respect to $(x_1, \ldots, x_n)$ leads to the joint density function of random variables in terms of copula density. It is given as

$$h(x_1, \ldots, x_n) = c((F_1(x_1), \ldots, F_n(x_n))\prod_{i=1}^{n} f_i(x_i), \quad \forall (x_1, \ldots, x_n) \in \overline{\mathbb{R}}^n, \tag{52.2}$$

where $c(F_1(x_1), \ldots, F_n(x_n))$ is the copula density and $f_i(x_i)$ is the density function for variable i. Equation 52.2 implies that the log-likelihood of the joint density can be decomposed into components which only involve each marginal density and a component which involves copula parameters. It provides a convenient structure for a two-stage estimation, which will be illustrated in details in the following sections.

[4] See Nelsen (1998) and Joe (1997) for a formal treatment of copula theory, and Bouye et al. (2000), Cherubini et al. (2004), and Embrechts et al. (2002) for applications of copula theory in finance.

To better fit the data, we usually assume the moments of distributions of random variables are time varying and depend on past variables. Therefore, the distribution of random variables at time t becomes a conditional one, and then the above copula theory needs to be extended to a conditional case. It is given as follows.[5]

Theorem 52.2 *Let Ω_{t-1} be the information set up to time t, and let $F_1(x_{1,t}|\Omega_{t-1})$, …, $F_n(x_{n,t}|\Omega_{t-1})$ be continuous marginal distribution functions conditional on Ω_{t-1}. Let H be the joint distribution of $(x_1, \ldots, x_n)$ conditional on Ω_{t-1}. Then there exists a unique copula C such that*

$$H\left(x_1, \ldots, x_n|\Omega_{t-1}\right) = C\left(F_1\left(x_1|\Omega_{t-1}\right), \ldots, F_n\left(x_n|\Omega_{t-1}\right)|\Omega_{t-1}\right), \ \ \forall(x_1, \ldots, x_n) \in \overline{\mathbb{R}}^n. \tag{52.3}$$

Conversely, if we let $F_1(x_{1,t}|\Omega_{t-1})$, …, $F_n(x_{n,t}|\Omega_{t-1})$ be continuous conditional marginal distribution functions and C be a copula, then the function H defined by Eq. 52.3 is a conditional joint distribution function with conditional marginal distributions $F_1(x_{1,t}|\Omega_{t-1})$, …, $F_n(x_{n,t}|\Omega_{t-1})$.

It is worth noting that for the above theorem to hold, the information set Ω_{t-1} has to be the same for the copulas and all the marginal distributions. If different information sets are used, the conditional copula form on the right side of Eq. 52.3 may not be a valid distribution. Generally, the same information set used may not be relevant for each marginal distributions and the copula. For example, the marginal distributions or the copula may be only conditional on a subset of the universally used information set. At the very beginning of estimation of the conditional distributions, however, we should use the same information set based on which we can test for insignificant explanatory variables so as to stick to a relevant subset for each marginal distribution or the copula.

52.3.2 Modeling Marginal Distributions

Before building a copula model, we need to find a proper specification for marginal distributions of individual asset returns, as mis-specified marginal distributions automatically lead to a mis-specified joint distribution. Let $x_{i,t}$ be asset i return at time t, and its conditional mean and variance are modeled as follows:

$$x_{i,t} = \alpha_{0,i} + \alpha_{1,i}x_{i,t-1} + \varepsilon_{i,t}, \tag{52.4}$$

$$\varepsilon_{i,t} = \sqrt{h_{i,t}}\eta_{i,t}, \tag{52.5}$$

$$h_{i,t} = \beta_{0,i} + \beta_{1,i}h_{i,t-1} + \beta_{2,i}\varepsilon^2_{i,t-1} + \beta_{3,i}\varepsilon^2_{i,t-1}1\left(\varepsilon_{i,t-1} < 0\right). \tag{52.6}$$

[5]See Patton (2004).

As shown in Eqs. 52.4, 52.5 and 52.6, we model the conditional mean as an AR(1) process and the conditional variance as a GJR(1,1) specification.[6] We have parameter restrictions as $\beta_{0,i} > 0$, $\beta_{1,i} \geq 0$, $\beta_{2,i} \geq 0$, $\beta_{2,i} + \beta_{3,i} \geq 0$, and $\beta_{1,i} + \beta_{2,i} + \frac{1}{2}\beta_{3,i} < 1$. $1(\varepsilon_{i,t-1} < 0)$ is an indicator function, which equals one when $\varepsilon_{i,t-1} < 0$ and zero otherwise. We believe that our model specifications can capture the features of the individual stock returns reasonably well. It is worth noting that Eqs. 52.4, 52.5 and 52.6 can include more exogenous variables to better describe the data. Alternative GARCH specifications can be used to describe the time-varying conditional volatility. We assume $\eta_{i,t}$ is *i.i.d.* across time and follows a Student's *t* distribution with DoF v_i.

Alternatively, to model the conditional higher moments of the series, we can follow Hansen (1994) and Jondeau and Rockinger (2003) who assume a skewed *t* distribution for the innovation terms of GARCH specifications and find that the skewed *t* distribution fits financial time series better than normal distribution. Accordingly, we can assume $\eta_{i,t} \sim Skewed\,T(\eta_{i,t}|v_{i,t},\lambda_{i,t})$ with zero mean and unitary variance where $v_{i,t}$ is DoF parameter and $\lambda_{i,t}$ is skewness parameter. The two parameters are time varying and depend on lagged values of explanatory variables in a nonlinear form. For illustration purposes, however, we will only use Student's *t* distribution for $\eta_{i,t}$ in this chapter.

52.3.3 Modeling Dependence Structure

Normal copula and Student's *t* copula are two copula functions from elliptical families, which are frequently used in modeling joint distributions of random variables. In this chapter, we also estimate a normal copula model for comparison purposes. Let Φ^{-1} denote the inverse of the standard normal distribution Φ and $\Phi_{\sum,n}$ be *n*-dimensional normal distribution with correlation matrix $\sum$. Hence, the *n*-dimensional normal copula is

$$C(\mathbf{u};\Sigma) = \Phi_{\Sigma,N}\left(\Phi^{-1}(u_1), \ldots, \Phi^{-1}(u_n)\right), \tag{52.7}$$

and its density form is

$$c(\mathbf{u};\Sigma) = \frac{\phi_{\Sigma,n}\left(\Phi^{-1}(u_1), \ldots, \Phi^{-1}(u_n)\right)}{\prod_{i=1}^{n}\phi\left(\Phi^{-1}(u_i)\right)}, \tag{52.8}$$

where ϕ and $\phi_{\sum,n}$ are the probability density functions (*pdf*s) of Φ and $\Phi_{\sum,n}$, respectively. It can be shown via Sklar's theorem that normal copula generates standard joint normal distribution if and only if the margins are standard normal.

[6]See Glosten et al. (1993).

On the other hand, let T_v^{-1} be the inverse of standard Student's t distribution T_v with DoF parameter[7] $v > 2$ and $T_{R,v}$ be n-dimensional Student's t distribution with correlation matrix R and DoF parameter v. Then n-dimensional Student's t copula is

$$C(\mathbf{u};R,v) = T_{R,v}\left(T_v^{-1}(u_1),\ \ldots, T_v^{-1}(u_n)\right), \tag{52.9}$$

and its density function is

$$c(u_1,\ldots,u_n) = \frac{t_{R,v}\left(T_v^{-1}(u_1),\ \ldots, T_v^{-1}(u_n)\right)}{\prod_{i=1}^{n} t_v\left(T_v^{-1}(u_i)\right)},$$

where t_v and $t_{R,v}$ are the *pdf*s of T_v and $T_{R,v}$, respectively.

Borrowing from the dynamic conditional correlation (DCC) structure of multivariate GARCH models, we can specify a time-varying parameter structure in the t copula as follows.[8] For a t copula, the time-varying correlation matrix is governed by

$$Q_t = (1-\alpha-\beta)S + \alpha\left(\varsigma_{t-1}\varsigma_{t-1}'\right) + \beta Q_{t-1}, \tag{52.10}$$

where S is the unconditional covariance matrix of $\varsigma_t = (T_v^{-1}(u_{1,t}), \ldots, T_v^{-1}(u_{n,t}))'$ and α and β are nonnegative and satisfy the condition $\alpha + \beta < 1$. We assign $Q_0 = S$ and the dynamics of Q_t is given by Eq. 52.10. Let $q_{i,j,t}$ be the i,j element of the matrix Q_t, and the i,j element of the conditional correlation matrix R_t can be calculated as

$$\rho_{i,j,t} = \frac{q_{i,j,t}}{\sqrt{q_{i,i,t}q_{j,j,t}}}. \tag{52.11}$$

Moreover, the specification of Eq. 52.10 guarantees that the conditional correlation matrix R_t is positive definite.

Proposition 52.1 *In Eqs.* 52.10 and 52.11, *if*

(a) $\alpha \geq 0$ and $\beta \geq 0$,
(b) $\alpha + \beta < 1$,
(c) *All eigenvalues of S are strictly positive, then the correlation matrix R_t is positive definite.*

[7]In contrast to the previous standardized Student's t distribution, the standard Student's t distribution here has variance as $v/(v-2)$.

[8]Please see Engle and Sheppard (2001) and Engle (2002) for details on the multivariate DCC-GARCH models.

Proof *First, (a) and (b) guarantee the system for $\varsigma_t\varsigma_t'$ is stationary and S exists. With $Q_0 = S$, (c) guarantees Q_0 is positive definite. With (a) to (c), Q_t is the sum of a positive definite matrix, a positive semi-definite matrix, and a positive definite matrix both with nonnegative coefficients and then is positive definite for all t. Based on the proposition Eq.* 52.1 *in Engle and Sheppard* (2001), *we prove that R_t is positive definite.*

52.3.4 Estimation

We illustrate the estimation procedure by writing out the log-likelihoods for observations. Let $\Theta = \{\theta, \gamma_1, \ldots, \gamma_n\}$ be the set of parameters in the joint distribution where θ is the set of parameters in the copula and γ_t is the set of parameters in marginal distributions for asset *i*. Then the conditional cumulative distribution function (*cdf*) of *n* asset returns at time *t* is given as

$$F\left(x_{1,t}, \ldots, x_{n,t} \middle| \underline{X}_{t-1}, \Theta\right) = C\left(u_{1,t}, \ldots, u_{n,t} \middle| \underline{X}_{t-1}, \theta\right) \tag{52.12}$$

where $\underline{X}_{t-1}$ is a vector of previous observations, $C(\cdot|\underline{X}_{t-1}, \theta)$ is the conditional copula, and $u_{i,t} = F_i(x_{i,t}|X_{t-1}, \gamma_i)$ is the conditional *cdf* of the margins. Differentiating both sides with respect to $x_{1t}, \ldots, x_{n,t}$ leads to the density function as

$$f\left(x_{1,t}, \ldots, x_{n,t} \middle| \underline{X}_{t-1}, \Theta\right) = c\left(u_{1,t}, \ldots, u_{n,t} \middle| \underline{X}_{t-1}, \theta\right) \prod_{i=1}^{n} f_i\left(x_{i,t} \middle| \underline{X}_{t-1}, \gamma_i\right), \tag{52.13}$$

where $c(\cdot|\underline{X}_{t-1}, \theta)$ is the density of the conditional copula and $f_i(x_{i,t}|\underline{X}_{t-1}, \gamma_i)$ is the conditional density of the margins. Accordingly, the log-likelihood of the sample is given by

$$L(\Theta) = \sum_{t=1}^{T} \log f\left(x_{1,t}, \ldots, x_{n,t} \middle| \underline{X}_{t-1}, \Theta\right). \tag{52.14}$$

With Eq. 52.13, the log-likelihood can be written as

$$L(\theta, \gamma_1, \ldots, \gamma_n) = \sum_{t=1}^{T} \log c\left(u_{1,t}, \ldots, u_{n,t} \middle| \underline{X}_{t-1}, \theta\right) + \sum_{t=1}^{T} \sum_{i=1}^{n} f_i\left(x_{i,t} \middle| \underline{X}_{t-1}, \gamma_i\right). \tag{52.15}$$

From Eq. 52.15, we observe that the copula and marginal distributions are additively separate. Therefore, we can estimate the model by a two-stage MLE procedure. In the first stage, the marginal distribution parameters for each asset are estimated by MLE, and then with estimated *cdf* of each asset, we estimate the copula parameters by MLE. Based on Joe (1997) and Patton (2006b), this two-stage estimator is consistent and asymptotically normal.

With our model specifications, we first estimate the univariate GJR-GARCH (1,1) with an AR(1) conditional mean and Student's t distribution by MLE. In the second stage, we need to estimate the parameters for the constant normal copula and the time-varying Student's t copula. Let $\mathbf{x}_t = (\Phi^{-1}(u_{1,t}), \ldots, \Phi^{-1}(u_{n,t}))'$, and we can analytically derive the correlation matrix estimator $\hat{\Sigma}$ which maximizes the log-likelihood of the normal copula density as

$$\hat{\Sigma} = \frac{1}{T}\sum_{t=1}^{T} \mathbf{x}_t \mathbf{x}_t'. \tag{52.16}$$

As there is no analytical solution for MLE of Student's t copula, the numerical maximization problem is quite challenging. Following Chen et al. (2004), however, with $\varsigma_t = (T_v^{-1}(u_{1,t}), \ldots, T_v^{-1}(u_{n,t}))'$, we can calculate the sample covariance matrix of ς_t as $\hat{S}$, which is a function of DoF parameter v. By setting $Q_0 = \hat{S}$, we can express Q_t and R_t for all t in terms of α, β, and v using Eq. 52.10. Then we can estimate α, β, and v by maximizing the log-likelihood of t copula density. In the following sections, we apply our estimation procedure to the joint distribution of 45 selected major US stock returns.

52.4 Data

We apply our model to modeling log returns of 45 major US stocks from nine sectors: Consumer Discretionary, Consumer Staples, Energy, Financials, Health Care, Industrials, Technology, Materials, and Utilities. Table 52.1 shows stock symbols and company names of the selected 45 companies. We select five major companies from each sector to form the stock group. The time span ranges from January 3, 2000 to November 29, 2011 with 2990 observations. We download data from yahoo finance (http://finance.yahoo.com/). The log returns are calculated from daily close stock prices adjusted for dividends and splits.

To save space, we only plot and calculate descriptive statistics of nine stocks with each from one sector. Figure 52.1 plots the log returns of those nine selected stocks, and there are two periods of volatility clusterings due to "Internet Bubbles" in the early 2000s and the financial crisis in 2008, respectively. We observe that during the financial crisis in 2008, major banks, such as Citigroup, incurred huge negative and positive daily returns. Table 52.2 shows the calculated mean, standard deviation, skewness, and kurtosis for the nine stocks. The average returns for the nine stocks are close to zero. Major banks, represented by Citigroup, have significantly higher volatility. Most of the stocks are slightly positively skewed, and only two have slight negative skewness. All the stocks have kurtosis greater than three indicating fat tails, and again major banks have significantly fatter tails. All the descriptive statistics indicate that the data property of individual returns needs to be captured by a variant of GARCH specification.

52.5 Empirical Results

52.5.1 Marginal Distributions

We briefly report estimation results for marginal distributions of 45 stock returns. For convenience, we only show the estimates and standard errors (in brackets) for nine selected stocks with each from one sector in Table 52.3. The star indicates statistical significance at a 5 % level. Consistent with our observations in Table 52.2, all the nine stocks have low values of DoF indicating fat tails. The parameter $\beta_{3,i}$ is

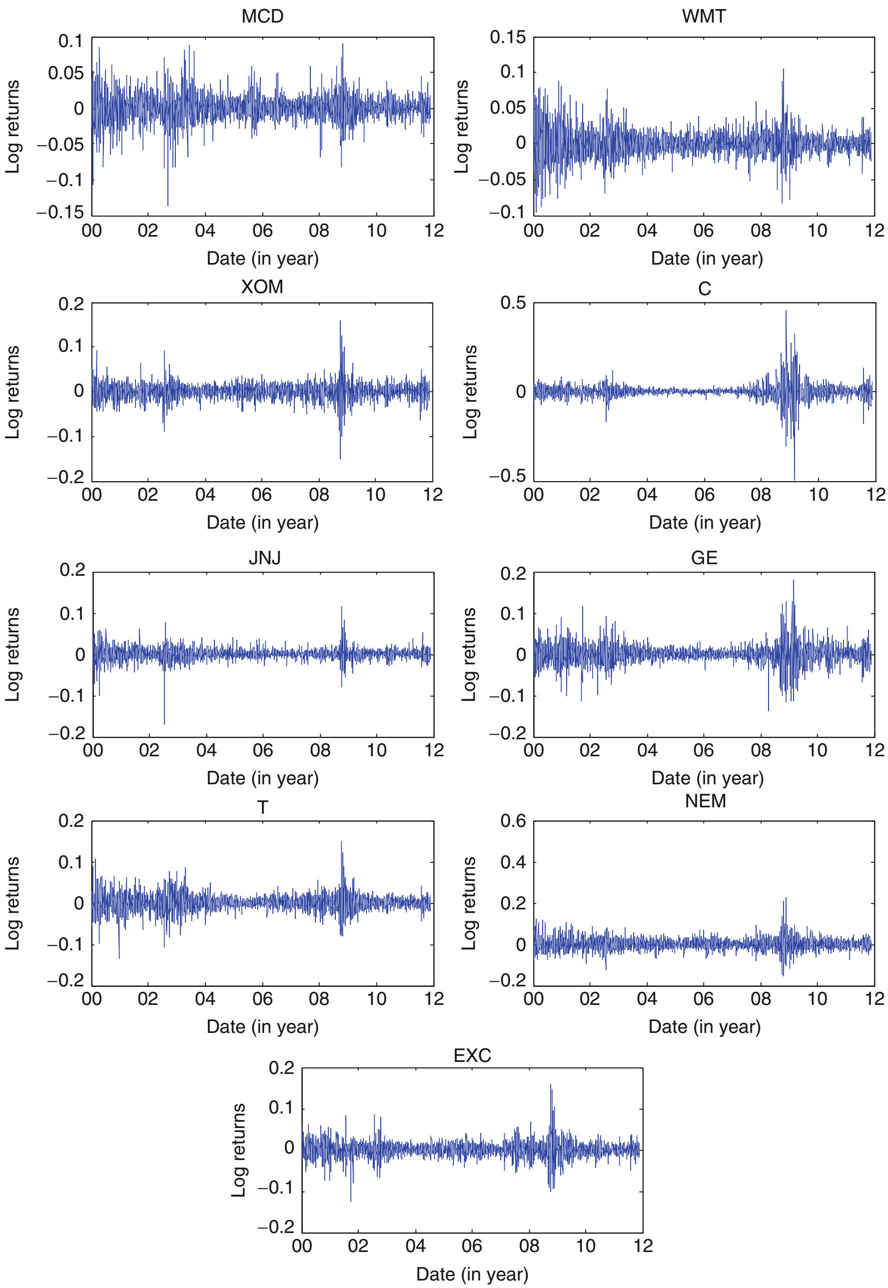

Fig. 52.1 The log returns of the nine of our 45 selected stocks with each from one sector have been plotted

Kurtosis	8.25	7.72	12.52	35.55	17.83	9.99	8.68	8.22	10.58
# obs.	2,990	2,990	2,990	2,990	2,990	2,990	2,990	2,990	2,990

statistically significant at a 5 % level for eight of the nine stocks indicating significant leverage effects for stock returns. The parameters in conditional mean are statistically significant for some stocks and not for others. In Fig. 52.2, we plot estimated conditional volatility for the stocks MCD, WMT, XOM, and C. Consistent with Fig. 52.1, we observe MCD and WMT have significant high volatility in the early 2000s and 2008, while XOM and C have their volatility hikes mainly in 2008 with C, representing Citigroup, having the highest conditional volatility during the 2008 crisis.

52.5.2 Copulas

We report estimation results for the time-varying *t* copula parameters in Table 52.4. All the three parameters α, β, and v are statistically significant. The estimate α is close to zero and the estimate for β is close to one. The estimate for v is about 25. As our estimation is carried out on the joint distribution of 45 stock returns, the estimate for v shed some light on how much Student's *t* copula can capture tail dependence when used to fit a relatively large number of variables. We also report the log-likelihood for time-varying Student's *t* copula and normal copula in Table 52.4. As the correlation matrix in normal copula is estimated by its sample correlation, we did not report it here. We find that time-varying *t* copula has significantly higher log-likelihood than normal copula, which results from the more flexible parameter structure of *t* copula and the time-varying parameter structure.

52.5.3 Time-Varying Dependence

Our time-varying *t* copula features a time-varying dependence structure among all the variables. The DoF parameter, together with the correlation parameters, governs the tail dependence behavior of multiple variables. We plot the estimated

conditional correlation parameters of t copula for four selected pairs of stock returns in Fig. 52.3. For those four pairs, the conditional correlation parameter fluctuates around certain positive averages. The two pairs, MCD-WMT and NEM-EXC, experienced apparent correlation spikes during the 2008 financial crisis. Moreover, Fig. 52.4 shows the estimated TDCs for the four pairs. We find that with the DoF around 25, the TDCs for those pairs of stock returns are very low, though some pairs do exhibit TDC spikes during the 2008 crisis. The low values of TDCs indicate possible limitations of t copula to account for tail dependence when being used to model a large number of variables.

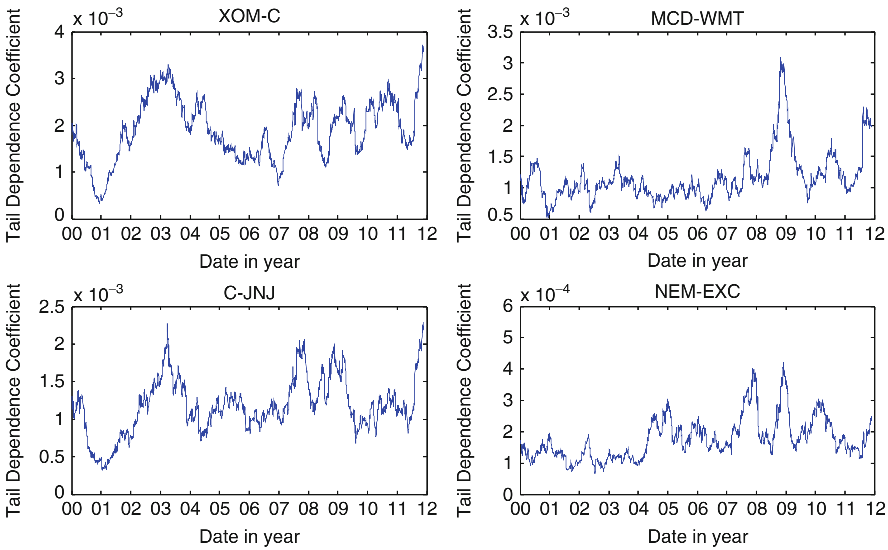

Fig. 52.4 The time-varying tail dependence coefficient (*TDC*) for the four selected pairs of stock returns has been plotted

52.6 Conclusion

We illustrate an effective approach (Copula-GARCH models) to model the dynamics of a large number of multiple asset returns by constructing a time-varying Student's *t* copula model. Under a general Copula-GARCH framework, we specify a proper GARCH model for individual asset returns and use a copula to link the margins to build the joint distribution of returns. We apply our time-varying Student's *t* copula model to 45 major US stock returns, where each stock return is modeled by an AR(1) and GJR-GARCH(1,1) specification and a Student's *t* copula with a DCC dependence structure is used to link all the returns. We illustrate how the model can be effectively estimated by a two-stage MLE procedure, and our estimation results show time-varying *t* copula model has significant better fitness of data than normal copula models.

As it is quite challenging to find a copula function with very flexible parameter structure to account for difference dependence features among all pairs of random variables, our time-varying *t* copula model tends to be a good working tool to model multiple asset returns for risk management and asset allocation purposes. Our model can capture time-varying conditional correlation and some degree of tail dependence, while it also has limitations of featuring symmetric dependence and inability of generating high tail dependence when being used to model a large number of asset returns. Nevertheless, we hope that this chapter provides researchers and financial practitioners with a good introduction on the Copula-GARCH models and a detailed illustration on constructing joint distributions of multiple asset returns using a time-varying Student's *t* copula model.

Abstract

To evaluate the performance of the prospects X and Y, financial professionals are interested in testing the equality of their Sharpe ratios (SRs), the ratios of the excess expected returns to their standard deviations. Bai et al. (Statistics and Probability Letters 81, 1078–1085, 2011d) have developed the mean-variance-ratio (MVR) statistic to test the equality of their MVRs, the ratios of the excess expected returns to its variances. They have also provided theoretical reasoning to use MVR and proved that their proposed statistic is uniformly most powerful unbiased. Rejecting the null hypothesis infers that X will have either smaller

variance or larger excess mean return or both leading to the conclusion that X is the better investment. In this paper, we illustrate the superiority of the MVR test over the traditional SR test by applying both tests to analyze the performance of the S&P 500 index and the NASDAQ 100 index after the bursting of the Internet bubble in the 2000s. Our findings show that while the traditional SR test concludes the two indices being analyzed to be indistinguishable in their performance, the MVR test statistic shows that the NASDAQ 100 index underperformed the S&P 500 index, which is the real situation after the bursting of the Internet bubble in the 2000s. This shows the superiority of the MVR test statistic in revealing short-term performance and, in turn, enables investors to make better decisions in their investments.

53.1 Introduction

Internet stocks obtained huge gains in the late 1990s, followed by huge losses from early 2000. In just 2 years from 1998 to early March 2000, prices of Internet stocks rose by sixfold and outperformed the S&P 500 by 482 %. Technology stocks generally showed a similar trend based on the fact that NASDAQ 100 index quadrupled in value over the same period and outperformed the S&P 500 index by 268 %. On the other hand, NASDAQ 100 index dropped by 64.28 % in value during the Internet bubble crash and underperformed the S&P 500 index by 173.87 %.

The spectacular rise and fall of Internet stocks in the late 1990s has stimulated research into the causes of the Internet stock bubble. Theories had been developed to explain the Internet bubble. For example, Baker and Stein (2004) develop a model of market sentiment with irrationally overconfident investors and short-sale constraints. Ofek and Richardson (2003) provide circumstantial evidence that Internet stocks attract mostly retail investors who are more prone to be overconfident about their ability to predict future stock prices than institutional investors. Perkins and Perkins (1999) suggest that during the Internet boom, investors were confidently betting on the continued rise of Internet stocks because they knew that high demand and limited equity float implies substantial upside returns. Moreover, Ofek and Richardson (2003) provide indirect evidence that Internet stock prices were supported by a combination of factors such as limited float, short-sale constraints, and aggressive trend chased by retail investors, whereas Statman (2002) shows that this asymmetric payoff must have made Internet stocks appear to be an extremely attractive gamble for risk seekers. On the other hand, Fong et al. (2008) use stochastic dominance methodology (Fong et al. 2005; Broll et al. 2006; Chan et al. 2012; Lean et al. 2012) to identify dominant types of risk preferences in the Internet bull and bear markets. They conclude that investor risk preferences (Wong and Li 1999; Wong and Chan 2008) have changed over this cycle, and the change is related to utility theory (Wong 2007; Sriboonchitta et al. 2009) and behavioral finance (Lam et al. 2010, 2012).

In this paper, we apply both the mean-variance ratio (MVR) test and the Sharpe ratio (SR) test to examine the performance of the NASDAQ 100 index and the S&P 500 index during the bursting of the Internet bubble in the 2000s. The tests are relied on the theory of the mean-variance (MV) portfolio optimization (Markowitz 1952; Bai et al. 2009a, b). The Markowitz efficient frontier also provides the basis for many important financial economics advances, including the Sharpe-Lintner capital asset pricing model (CAPM, Sharpe 1964; Lintner 1965) and the well-known optimal one-fund theorem (Tobin 1958). Originally motivated by the MV analysis, the optimal one-fund theorem, and the CAPM model, the Sharpe ratio, the ratio of the excess expected return to its volatility or standard deviation, is one of the most commonly used statistics in the MV framework. The SR is now widely used in many different areas in Finance and Economics, from the evaluation of portfolio performance to market efficiency tests (see, e.g., Ofek and Richardson 2003).

Jobson and Korkie (1981) develop a SR statistic to test for the equality of two SRs. The test statistic has been modified and improved by Cadsby (1986) and Memmel (2003). Lo (2002) carries out a more thorough study of the statistical property of the SR estimator. Using standard econometric methods with several different sets of assumptions imposed on the statistical behavior of the returns series, Lo derives the asymptotic statistical distribution for the SR estimator and shows that confidence intervals, standard errors, and hypothesis tests can be computed for the estimated SRs in much the same way as regression coefficients such as portfolio alphas and betas are computed.

The SR test statistic developed by Jobson and Korkie (1981) and others provides a formal statistical comparison of performance among portfolios. One deficiency of the SR statistic is that it has only an asymptotic distribution. Hence, the SR test has its statistical properties only for large samples, but not for small samples. Nevertheless, the performance of assets is often compared by using small samples, especially when markets undergo substantial changes resulting from changes in short-term factors and momentum. Under these circumstances, it is more meaningful to use limited data to predict the assets' future performance. In addition, it is not meaningful to measure SRs for extended periods when the means and standard deviations of the underlying assets are found empirically to be nonstationary and/or to possess structural breaks. For small samples, the main difficulty in developing the SR test is that it is impossible to obtain a uniformly most powerful unbiased (UMPU) test to check for the equality of SRs. To circumvent this problem, Bai et al. (2011d) propose to use an alternative statistic, the MVR tests to compare performance of assets. They also discuss the evaluation of the performance of assets for small samples by providing a theoretical framework and then invoking both one-sided and two-sided UMPU MVR tests. Moreover, Bai et al. (2012) further extend the MVR statistics to compare the performance of prospects after the effect of the background risk has been mitigated.

Applying the traditional SR test, we fail to reject the possibility of having any significant difference between the performance of the S&P 500 index and the NASDAQ 100 index during the bursting of the Internet bubble in the 2000s. This finding implies that the two indices being analyzed could be indistinguishable in their performance during the period under the study. However, we conjecture that this conclusion is most likely to be inaccurate as the lack of sensitivity of the SR test in analyzing small samples. Thus, we propose to use the MVR test in the analysis. As expected, the MVR test shows that the MVR of the weekly return on S&P 500 index is different from that on the NASDAQ 100 index. We conclude that the NASDAQ 100 index underperformed the S&P 500 index during the period under the study. The proposed MVR test can discern the performance of the two indices and hence is more informative than tests using the SR statistics for investors to decide on their investments.

The rest of the paper is organized as follows: Section 53.2 discusses the data while Sect. 53.3 provides the theoretical framework and discusses the theory for both one-sided and two-sided MVR tests. In Sect. 53.4, we demonstrate the superiority of the MVR tests over the traditional SR tests by applying both tests to analyze the performance of the S&P 500 index and the NASDAQ 100 index during the bursting of the Internet bubble in the 2000s. This is followed by Sect. 53.4 which summarizes our conclusions and shares our insights.

53.2 Data

The data used in this study consists of weekly returns on two stock indices: the S&P 500 and the NASDAQ 100 index. We use the S&P 500 index to represent non-technology or "old economy" firms. Our proxy for the Internet and technology sectors is the NASDAQ 100 index. Firms represented in the NASDAQ 100 include those in the computer hardware and software, telecommunications, and biotechnology sectors. The NASDAQ 100 index is value weighted.

Our sample period is from January 1, 2000 to December 31, 2002, to study the effect of the crash in the Internet bubble. Before 2000, there is a clear upward trend in technology stock prices emerging from around that period and this period spans a period of intense IPO and secondary market activities for Internet stocks. Schultz and Zaman (2001) report that 321 Internet firms went public between January 1999 and March 2000, accounting for 76 % of all new Internet issues since the first wave of Internet IPOs began in 1996. Ofek and Richardson (2003) find that the extraordinary high valuations of Internet stocks between the early 1998 and February 2000 were accompanied by very high trading volume and liquidity. The unusually high volatility of technology stocks is only partially explained by the rise in the overall market volatility. Our interest centers on the bear market from January 1, 2000 to December 31, 2002. All data for this study are from datastream.

53.3 Methodology

Let X_i and Y_i ($i = 1, 2, \cdots, n$) be independent excess returns drawn from the corresponding normal distributions $N(\mu, \sigma^2)$ and $N(\eta, \tau^2)$ with joint density $p(x, y)$ such that

$$p(x,y) = k \times \exp\left(\frac{\mu}{\sigma^2}\sum x_i - \frac{1}{2\sigma^2}\sum x_i^2 + \frac{\eta}{\tau^2}\sum y_i - \frac{1}{2\tau^2}\sum y_i^2\right) \qquad (53.1)$$

Where $k = (2\pi\sigma^2)^{-n/2}(2\pi\tau^2)^{-n/2}\exp\left(-\frac{n\mu^2}{2\sigma^2}\right)\exp\left(-\frac{n\eta^2}{2\tau^2}\right)$

To evaluate the performance of the prospects X and Y, financial professionals are interested in testing the hypotheses

$$H_0^* : \frac{\mu}{\sigma} \le \frac{\eta}{\tau} \text{ versus } H_1^* : \frac{\mu}{\sigma} > \frac{\eta}{\tau} \qquad (53.2)$$

to compare the performance of their corresponding SRs, $\frac{\mu}{\sigma}$ and $\frac{\eta}{\tau}$, the ratios of the excess expected returns to their standard deviations.

If the hypothesis H_0^* is rejected, it infers that X is the better investment prospect with larger SR because X has either larger excess mean return or smaller standard deviation or both. Jobson and Korkie (1981) and Memmel (2003) develop test statistics to test the hypotheses in Eq. 53.2 for large samples but their tests would not be appropriate for testing small samples as the distribution of their test statistics is only valid asymptotically but not valid for small samples. However, it is especially relevant in investment decisions to test the hypotheses in Eq. 53.2 for small samples to provide useful investment information to investors. Furthermore, as it is impossible to obtain any UMPU test statistic to test the inequality of the SRs in Eq. 53.2 for small samples, Bai et al. (2011d) propose to use the following hypothesis to test for the inequality of the MVRs:

$$H_{01} : \frac{\mu}{\sigma^2} \le \frac{\eta}{\tau^2} \quad \text{versus} \quad H_{11} : \frac{\mu}{\sigma^2} > \frac{\eta}{\tau^2}. \qquad (53.3)$$

In addition, they develop the UMPU test statistic to test the above hypotheses. Rejecting the hypothesis H_0 infers that X will have either smaller variance or larger excess mean return or both leading to the conclusion that X is the better investment. As sometimes investors conduct the two-sided test to compare the MVRs, the following hypotheses are included in our study:

$$H_{02} : \frac{\mu}{\sigma^2} = \frac{\eta}{\tau^2} \quad \text{versus} \quad H_{12} : \frac{\mu}{\sigma^2} \neq \frac{\eta}{\tau^2}. \tag{53.4}$$

One may argue that the MVR test is that SR test is scale invariant, whereas the MV ratio test is not. To support the MVR test to be an acceptable alternative test statistic, Bai et al. (2011d) show the theoretical justification for the use of the MVR test statistic in the following remark:

Remark 53.1 *One may think that the MVR can be less favorable than the SR as the former is not scale invariant while the latter is. However, in some financial processes, the mean change in a short period of time is proportional to its variance change. For example, many financial processes can be characterized by the following diffusion process for stock prices formulated as*

$$dY_t = \mu^P(Y_t)dt + \sigma(Y_t)dW_t^P,$$

where μ^P is an N-dimensional function, σ is an $N \times N$ matrix and W_t^P is an N-dimensional standard Brownian motion under the objective probability measure P. Under this model, the conditional mean of the increment dY_t given Y_t is $\mu^P(Y_t)dt$ and the covariance matrix is $\sigma(Y_t)\sigma^T(Y_t)dt$. When $N = 1$, the SR will be close to 0 while the MVR will be independent of dt. Thus, when the time period dt is small, the MVR will be advantageous over the SR.

To further support for the use of MVR, Bai et al. (2011d) document the MVR in the context of Markowitz MV optimization theory as follows: suppose that there is p-branch of assets $\mathbf{S} = (s_1,\cdots, s_p)^T$ whose returns are denoted by $\mathbf{r} = (r_1,\cdots, r_p)^T$ with mean $\boldsymbol{\mu} = (\mu_1,\cdots, \mu_p)^T$ and covariance matrix $\Sigma = (\sigma_{ij})$. In addition, we suppose that investors will invest capital C on the p-branch of securities $\mathbf{S}$ such that they solve for their optimal investment plans $\mathbf{c} = (c_1,\cdots, c_p)^T$ to allocate their investable wealth on the p-branch of securities to obtain maximize return subject at a given level of risk.

The above maximization problem can be formulated as the following optimization problem:

$$\max R = \mathrm{c}^T\boldsymbol{\mu}, \text{ subject to } \mathrm{c}^T\Sigma\mathrm{c} \leq \sigma_0^2 \tag{53.5}$$

where σ_0^2 is a given risk level. We call R satisfying Eq. 53.5 the optimal return and $\mathbf{c}$ be its corresponding allocation plan. One could easily extend the separation theorem and the mutual fund theorem to obtain the solution of Eq. 53.5[1] from the following lemma:

[1]We note that Bai et al. (2009a, b, 2011c) have also used the same framework as in 53.5.

Lemma 53.1 *For the optimization setting displayed in* Eq. 53.5, *the optimal return, R, and its corresponding investment plan, c, are obtained as follows*:

$$R = \sigma_0 \sqrt{\boldsymbol{\mu}^T \Sigma^{-1} \boldsymbol{\mu}}$$

and

$$c = \frac{\sigma_0}{\sqrt{\boldsymbol{\mu}^T \Sigma^{-1} \boldsymbol{\mu}}} \Sigma^{-1} \boldsymbol{\mu}. \tag{53.6}$$

From Lemma 53.1, the investment plan, **c**, is proportional to the MVR when Σ is a diagonal matrix. Hence, when the asset is concluded as superior in performance utilizing the MVR test, its corresponding weight could then be computed based on the corresponding MVR test value. Thus, another advantage of using the MVR test over the SR test is that it not only allows investors to compare the performance of different assets, but it also provides investors with information of the assets weight. The MVR test enables investors to compute the corresponding allocation for the assets. On the other hand, as the SR is not proportional to the weight of the corresponding asset, an asset with the highest SR would not infer that one should put highest weight on this asset as compared with our MVR. In this sense, the test proposed by Bai et al. (2011d) is superior to the SR test.

Bai et al. (2011d) have also developed both one-sided UMPU test and two-sided UMPU test of equality of the MVRs in comparing the performances of different prospects with hypotheses stated in Eqs. 53.3 and 53.4, respectively. We first state the one-sided UMPU test for the MVRs as follows:

Theorem 53.1 *Let X_i and Y_i $(i = 1, 2, \cdots, n)$ be independent random variables with joint distribution function defined in* Eq. 53.1. *For the hypotheses setup in* Eq. 53.3, *there exists a UMPU level-α test with the critical function $\phi(u, t)$ such that*

$$\phi(u,t) \begin{cases} 1, & \text{when } u \geq C_0(t) \\ 0, & \text{when } u < C_0(t) \end{cases} \tag{53.7}$$

where C_0 is determined by

$$\int_{C_0}^{\infty} f_{n,t}^{*}(u) \ du = K_1; \tag{53.8}$$

with

$$f_{n,t}^{*}(u) = \left(t_2 - \frac{u^2}{n}\right)^{\frac{n-1}{2} - 1} \left(t_3 - \frac{(t_1 - u)^2}{n}\right)^{\frac{n-1}{2} - 1},$$
$$K_1 = \alpha \int_{\Omega} f_{n,t}^{*}(u) \ du;$$

in which

$$U = \sum_{i=1}^{n} X_i, \quad T_1 = \sum_{i=1}^{n} X_i + \sum_{i=1}^{n} Y_i,$$
$$T_2 = \sum_{i=1}^{n} X_i^2, \quad T_3 = \sum_{i=1}^{n} Y_i^2, \quad T = (T_1, T_2, T_3);$$

with $\Omega = \{u | \max(-\sqrt{nt_2}, t_1 - \sqrt{nt_3}) \leq u \leq \min(\sqrt{nt_2}, t_1 + \sqrt{nt_3})\}$ *to be the support of the joint density function of* (U, T).

We call the statistic U in Theorem 53.1 the one-sided MVR test statistic or simply the MVR test statistic for the hypotheses setup in Eq. 53.3 if no confusion arises. In addition, Bai et al. (2011d) have introduced the two-sided UMPU test statistic as stated in the following theorem to test for the equality of the MVRs listed in Eq. 53.4:

Theorem 53.2 *Let* X_i *and* Y_i $(i = 1, 2, \cdots, n)$ *be independent random variables with joint distribution function defined in* Eq. 53.1. *Then, for the hypotheses setup in* Eq. 53.4, *there exists a UMPU level-*α *test with critical function*

$$\phi(u,t) = \begin{cases} 1, & \text{when } u \leq C_1(t) \text{ or } \geq C_2(t) \\ 0, & \text{when } C_1(t) < u < C_2(t) \end{cases} \tag{53.9}$$

in which C_1 *and* C_2 *satisfy*

$$\begin{cases} \int_{C_1}^{C_2} f_{n,t}^*(u)\, du = K_2 \\ \int_{C_1}^{C_2} u f_{n,t}^*(u)\, du = K_3 \end{cases}, \tag{53.10}$$

where

$$K_2 = (1-\alpha)\int_{\Omega} f_{n,t}^*(u)\, du,$$
$$K_3 = (1-\alpha)\int_{\Omega} u f_{n,t}^*(u)\, du.$$

The terms $f_{n,t}^*(u)$, T_i $(i = 1, 2, 3)$ *and* T *are defined in* Theorem 53.1.

We call the statistic U in Theorem 53.2 the two-sided MVR test statistic or simply the MVR test statistic for the hypotheses setup in Eq. 53.4 if no confusion arises. To obtain the critical values C_1 and C_2 for the test, readers may refer to Bai et al. (2011d, 2012).

53.4 Illustration

In this section, we demonstrate the superiority of the MVR tests over the traditional SR tests by illustrating the applicability of the MVR tests to examine the Internet bubble during January 2000 and December 2002. For simplicity, we only demonstrate the two-sided UMPU test.[2] The data for this study consists of weekly returns on two stock indices: the S&P 500 and the NASDAQ 100 index. The sample period covers from January 2000 to December 2002 in which the data from the first week of November 2000 to the last week of January 2001 (3 months) are used to compute the MVR in January 2001, while the data from the first week of December 2000 to the last week of February 2001 are used to compute the MVR in February 2001, and so on. However, if the period used to compute the SRs is too short, the result would not be meaningful as discussed in our previous sections. Thus, we utilize a longer period from the first week of February 2000 to the last week of January 2001 (12 months) to compute the SR ratio in January 2001, from the first week of March 2000 to the last week of February 2001 to compute the SR ratio in February 2001, and so on.

Let X with mean μ_X and variance σ_X^2 be the weekly return on S&P 500 while Y with mean μ_Y and variance σ_Y^2 be the weekly return on the NASDAQ 100 index. We test the following hypotheses:

$$H_0 : \frac{\mu_X}{\sigma_X^2} = \frac{\mu_Y}{\sigma_Y^2} \quad \text{versus} \quad H_1 : \frac{\mu_X}{\sigma_X^2} \neq \frac{\mu_Y}{\sigma_Y^2}. \tag{53.11}$$

To test the hypotheses in Eq. 53.11, we first compute the values of the test function U for the MVR statistic shown in Eq. 53.9, then compute the critical values C_1 and C_2 under the test level of 5 % for the pair of indices and display the values in Table 53.1.

For comparison, we also compute the corresponding SR statistic developed by Jobson and Korkie (1981) and Memmel (2003) such that

$$z = \frac{\hat{\sigma}_Y \hat{\mu}_X - \hat{\sigma}_X \hat{\mu}_Y}{\sqrt{\hat{\theta}}}, \tag{53.12}$$

which follows standard normal distribution asymptotically with

$$\theta = \frac{1}{T}\left(2\sigma_X^2\sigma_Y^2 - 2\sigma_X\sigma_Y\sigma_{X,Y} + \frac{1}{2}\mu_X^2\sigma_Y^2 + \frac{1}{2}\mu_Y^2\sigma_X^2 - \frac{\mu_X\mu_Y}{\sigma_X\sigma_Y}\sigma_{X,Y}^2\right)$$

to test for the equality of the SRs for the funds by setting the following hypotheses such that

$$H_0^* : \frac{\mu_X}{\sigma_X} = \frac{\mu_Y}{\sigma_Y} \quad \text{versus} \quad H_1^* : \frac{\mu_X}{\sigma_X} \neq \frac{\mu_Y}{\sigma_Y}. \tag{53.13}$$

[2]The results of the one-sided test which draw a similar conclusion are available on request.

Note: The MVR test statistic U is defined in Eq. 53.9 and its critical values C_1 and C_2 are defined in Eqs. 53.10, respectively. The SR test statistic Z is defined in Eq. 53.12. The level is $\alpha = 0.05$, and "*" means significant at levels 5 %. Here, the sample size of the MVR test is 3 months, while the sample size of the SR test 12 months. Recall that $\pm z_{0.025} \approx \pm 1.96$

Instead of using a 2-month data to compute the values of our proposed statistic, we use the overlapping 12-month data to compute the SR statistic. The results are also reported in Table 53.1.

The limitation of applying the SR test is that it would usually conclude indistinguishable performances between the indices, which may not be the situation in reality. In this aspect, looking for a statistic to evaluate the difference between indices for short periods is essential. The situation in reality is that the Internet stocks registered large gains in the late 1990s, followed by large losses from 2000. As we mentioned before, the NASDAQ 100 index comprises 100 of the largest domestic and international technology firms including those in the computer hardware and software, telecommunications, and biotechnology sectors, while the S&P

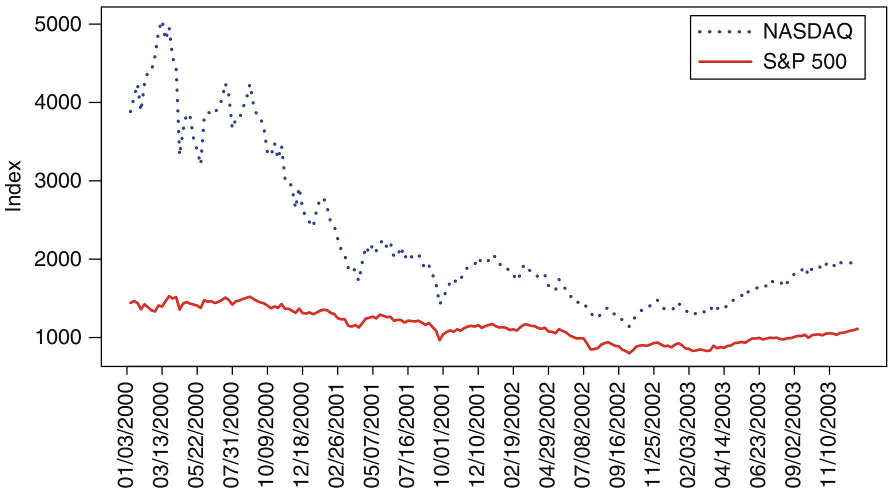

Fig. 53.1 Weekly indices of *NASDAQ* and S&P 500 from January 3, 2000 to December 31, 2003

500 index represents non-technology or "old economy" firms. After the bursting of the Internet bubble in the 2000s, as shown in Fig. 53.1, the NASDAQ 100 declined much more and underperformed the S&P 500. From Table 53.1, we find that the MVR test statistic does not disappoint us in that it does pick up significant differences in performances between the S&P 500 and the NASDAQ 100 index in September 2001, July 2002, August 2002, and September 2002, but SR test does not conclude any distinguishable performances between the indices. Further to say, from Table 53.1, we observe that $\hat{\mu}_X > \hat{\mu}_Y$ in September 2001, July 2002, August 2002, and September 2002. This infers that the MVR test statistics can detect the real situation that the NASDAQ 100 index underperformed the S&P 500 index, but the traditional SR test cannot detect any difference. Thus, we conclude that investors could be able to profiteer from the Internet bubble if they apply the MVR test.

53.5 Concluding Remarks

In this paper, we employ the MVR test statistics developed by Bai et al. (2011d) to examine the performances between the S&P 500 index and the NASDAQ 100 index during Internet bubble from January 2000 to December 2002. We illustrate the superiority of the MVR test over the traditional SR test by applying both tests to analyze the performance of the S&P 500 index and the NASDAQ 100 index after the bursting of the Internet bubble in the 2000s. Our findings show that while the traditional SR test concludes the two indices being analyzed to be indistinguishable in their performance, the MVR test statistic shows that the NASDAQ 100 index underperformed the S&P 500 index, which is the real situation after the bursting of the Internet bubble in the 2000s. This shows the superiority of the MVR test statistic in revealing short-term performance and, in turn, enables the investors to make better decisions about their investments.

There are two basic approaches to the problem of portfolio selection under uncertainty. One approach is based on the concept of utility theory (Gasbarro et al. 2007; Wong et al. 2006, 2008). Several stochastic dominance (SD) test statistics have been developed; see, for example, Bai et al. (2011a) and the references therein for more information. This approach offers a mathematically rigorous treatment for portfolio selection, but it is not popular among investors since investors would have to specify their utility functions and choose a distributional assumption for the returns before making their investment decisions.

The other approach is the mean-risk (MR) analysis that has been discussed in this paper. In this approach, the portfolio choice is made with respect to two measures – the expected portfolio mean return and portfolio risk. A portfolio is preferred if it has higher expected return and smaller risk. These are convenient computational recipes and they provide geometric interpretations for the trade-off between the two measures. A disadvantage of the latter approach is that it is derived by assuming the Von Neumann-Morgenstern quadratic utility function and that returns are normally distributed (Hanoch and Levy 1969). Thus, it cannot capture the richness of the former approach. Among the MR analyses, the most popular measure is the SR introduced by Sharpe (1966). As the SR requires strong assumptions that the returns of assets being analyzed have to be iid, various measures for MR analysis have been developed to improve the SR, including the Sortino ratio (Sortino and van der Meer 1991), the conditional SR (Agarwal and Naik 2004), the modified SR (Gregoriou and Gueyie 2003), value at risk (Ma and Wong 2010), expected shortfall (Chen 2008), and the mixed Sharpe ratio (Wong et al. 2012). However, most of the empirical studies, see, for example, Eling and Schuhmacher (2007), find that the conclusions drawn by using these ratios are basically the same as that drawn by the SR. Nonetheless, Leung and Wong (2008) have developed a multiple SR statistic and find that the results drawn from the multiple Sharpe ratio statistic can be different from its counterpart pair-wise SR statistic comparison, indicating that there are some relationships among the assets that have not being revealed using the pair-wise SR statistics. The MVR test could be the right candidate to reveal these relationships.

One may claim that the limitation of the MVR test statistic is that it can only draw conclusion for investors with quadratic utility functions and for normal-distributed assets. Wong (2006), Wong and Ma (2008), and others have shown that the conclusion drawn from the MR comparison is equivalent to the comparison of expected utility maximization for any risk-averse investor, not necessarily with only quadratic utility function, and for assets with any distribution, not necessarily normal distribution, if the assets being examined belong to the same location-scale family. In addition, one can also apply the results from Li and Wong (1999) and Egozcue and Wong (2010) to generalize the result so that it will be valid for any risk-averse investor and for portfolios with any distribution if the portfolios being examined belong to the same convex combinations of (same or different) location-scale families. The location-scale family can be very large, containing normal distributions as well as t-distributions, gamma distributions, etc. The stock returns could be expressed as convex combinations of normal distributions, t-distributions, and other location-scale families; see, for example, Wong and Bian (2000) and the references therein for more information. Thus, the conclusions drawn from the MVR test statistics are valid for most of the stationary data including most, if not all, of the returns of different portfolios.

Last, we note that to improve the effectiveness of applying the MVR test in evaluating financial assets performance, one may incorporate other techniques/ approaches/models, for example, fundamental analysis (Wong and Chan 2004), technical analysis (Wong et al. 2001, 2003), behavioral finance (Matsumura et al. 1990), prospect theory (Broll et al. 2010; Egozcue et al. 2011), and advanced econometrics (Wong and Miller 1990; Bai et al. 2010, 2011b), to measure the performance of different financial assets and assist investors to make wiser decisions.

Quantile Regression in Risk Calibration

Abstract

Financial risk control has always been challenging and becomes now an even harder problem as joint extreme events occur more frequently. For decision makers and government regulators, it is therefore important to obtain accurate

information on the interdependency of risk factors. Given a stressful situation for one market participant, one likes to measure how this stress affects other factors. The CoVaR (Conditional VaR) framework has been developed for this purpose. The basic technical elements of CoVaR estimation are two levels of quantile regression: one on market risk factors; another on individual risk factor.

Tests on the functional form of the two-level quantile regression reject the linearity. A flexible semiparametric modeling framework for CoVaR is proposed. A partial linear model (PLM) is analyzed. In applying the technology to stock data covering the crisis period, the PLM outperforms in the crisis time, with the justification of the backtesting procedures. Moreover, using the data on global stock markets indices, the analysis on marginal contribution of risk (MCR) defined as the local first order derivative of the quantile curve sheds some light on the source of the global market risk.

CoVaR • Value-at-Risk • Quantile regression • Locally linear quantile regression • Partial linear model • Semiparametric model

54.1 Introduction

Sufficiently accurate risk measures are needed not only in crisis times. In the last two decades, the world has gone through several financial turmoils, and the financial market is getting riskier and the scale of loss soars. Beside marginal extremes that can shock even a well-diversified portfolio, the focus of intensified research in the recent years has been on understanding the interdependence of risk factors and their conditional structure.

The most popular risk measure is the Value-at-Risk (VaR), which is defined as the τ-quantile of the return distribution at time $t + d$ conditioned on the information set $\mathcal{F}_t$:

$$VaR^{\tau}_{t+d} \overset{\text{def}}{=} \inf\{x \in \mathbb{R} : \mathrm{P}(X_{t+d} \le x|\mathcal{F}_t) \ge \tau\}. \tag{54.1}$$

Here X_t denotes the asset return and τ is taking values such as 0.05, 0.01 or 0.001 to reflect negative extreme risk.

Extracting information in economic variables to predict VaR brings quantile regression into play here, since VaR is the quantile of the conditional asset return distribution. Engle and Manganelli (2004) propose the nonlinear Conditional Autoregressive Value-at-Risk (CaViaR) model, which uses (lag) VaR and lag returns. Chernozhukov and Umantsev (2001) propose linear and quadratic time series models for VaR prediction. Kuan et al. (2009) propose the Conditional AutoRegressive Expectile (CARE) model, and argue that expectiles are more sensitive to the scale of losses. These studies and many others apply quantile regression in a prespecified, often linear functional form. In a more nonparametric context, Cai and Wang (2008) estimate the conditioned cdf by a double kernel local linear estimator and find the quantile by inverting the cdf. Schaumburg (2011) uses the same technique together with extreme value theory for VaR prediction. Taylor (2008) proposes Exponentially Weighted Quantile Regression (EWQR) for estimating VaR time series.

The aforementioned studies focus mainly on the VaR estimation for single assets and do not directly take into account the escalated spillover effect in crisis periods. This risk of joint tail events of asset returns has been identified and studied. Further, Brunnermeier and Pedersen (2008) show that the negative feedback effect of a "loss spiral" and a "margin spiral" leads to the joint depreciation of assets prices. It is therefore important to develop risk measures which can quantify the contagion effects of negative extreme event.

Acharya et al. (2010) propose the concept of marginal expected shortfall (MES), which measures the contribution of individual assets to the portfolio expected shortfall. Via an equilibrium argument, the MES is shown to be a predictor to a financial institution's risk contribution. Brownlees and Engle (2012) demonstrate that the MES can be written as a function of volatility, correlation, and expectation conditional on tail events. Huang et al. (2012) propose the distress insurance premium (DIP), a measure similar to MES but computed under the risk-neutral probability. This measure can therefore be viewed as the market insurance premium against the event that the portfolio loss exceeds a low level. Adams et al. (2012) construct financial indices on return of insurance companies, commercial banks, investment banks, and hedge funds, and use a linear model for the VaRs of the four financial indices to forecast the state-dependent sensitivity VaR (SDSVaR). The risk measures proposed above have some shortcomings though: The computation of DIP is demanding since this involves the simulation of rare events. MES suffers from the scarcity of data because it conditions on a rare event.

In Adrian and Brunnermeier (2011) (henceforth AB), the CoVaR concept of conditional VaR is proposed, which controls the effect of the negative extreme event of some systemically risky financial institutions. Formally, let $C(X_{i,t})$ be some event of a asset i return $X_{i,t}$ at time t and take $X_{j,t}$ as another asset return (e.g., the market index). The $\mathrm{CoVaR}^{\tau}_{j|i,t}$ is defined as the τ-quantile of the conditional probability distribution:

$$\mathrm{P}\left\{X_{j,t} \leq \mathrm{CoVa}R^{\tau}_{j|i,t} \middle| C\left(X_{i,t}\right), M_t\right\} = \tau, \tag{54.2}$$

where M_t is a vector of market variables defined in Sect. 54.2.1. The standard CoVaR approach is to set $C\left(X_{i,t}\right) = \left\{X_{i,t} = VaR^{\tau}_{X_{i,t}}\right\}$. In AB, $X_{j,t}$ is the weekly return which is constructed from a vast data set comprised of all publicly traded commercial banks, broker dealers, insurance companies, and real estate companies in the USA. Further, AB propose ΔCoVaR (measure of marinal risk contribution) as the difference between $CoVaR^{\tau_1}_{j|i,t}$ and $CoVaR^{\tau_2}_{j|i,t}$, where $\tau_1 = 0.5$ is associated with the normal state and $\tau_2 = 0.05$ is associated with the financial distress state.

The formulation of this conditional risk measure has several advantages. First, the cloning property: After dividing a systemically risky firm into several clones, the value of CoVaR conditioned on the entire firm does not differ from the one conditioned on one of the clones. Second, the conservativeness. The CoVaR value is more conservative than VaR, because it conditions on an extreme event. Third, CoVaR is endogenously generated and adapted to the varying environment of the market.

The recipe of AB for CoVaR construction is as follows: In the first step, one predicts the VaR of an individual asset $X_{i,t}$ through a linear model on market variables:

$$X_{i,t} = \alpha_i + \gamma_i^{\mathrm{T}} M_{t-1} + \varepsilon_{i,t}, \tag{54.3}$$

where γ_i^{T} means the transpose of γ_i and M_t is a vector of the state variables (see Sect. 54.2.1). This model is estimated with quantile regression of Koenker and Bassett (1978) to get the coefficients $(\hat{\alpha}_i, \hat{\gamma}_i)$ with $F_{\varepsilon_{i,t}}^{-1}(\tau|M_{t-1}) = 0$. The VaR of asset i is predicted by

$$\widehat{VaR}_{i,t} = \hat{\alpha}_i + \hat{\gamma}_i^{\mathrm{T}} M_{t-1}. \tag{54.4}$$

In the second step, one models the asset j return as a linear function of asset return i and market variables M_t:

$$X_{j,t} = \alpha_{j|i} + \beta_{j|i} X_{i,t} + \gamma_{j|i}^{\mathrm{T}} M_{t-1} + \varepsilon_{j,t}, \tag{54.5}$$

Again one employs quantile regression and obtains coefficients $\left(\hat{\alpha}_{j|i}, \hat{\beta}_{j|i}, \hat{\gamma}_{j|i}\right)$. The CoVaR is finally calculated as:

$$\widehat{CoVaR}_{j|i,t}^{AB} = \hat{\alpha}_{j|i} + \hat{\beta}_{j|i} \widehat{VaR}_{i,t} + \hat{\gamma}_{j|i}^{\mathrm{T}} M_{t-1}. \tag{54.6}$$

In Eq. 54.5, the variable $X_{i,t}$ influences the return $X_{j,t}$ in a linear fashion. However, the linear parametric model may not be flexible enough to capture the tail dependence between i and j. The linearity of the conditioned quantile curves of X_j on X_i is challenged by the confidence bands of the nonparametric quantile curves, as shown in Fig. 54.1. The left tail quantile from linear parametric quantile regression (red) lies well outside the confidence band (gray dashed curve) of Hardle and Song (2010). This motivates empirically that a linear model is not flexible enough for the CoVaR question at hand.

Nonparametric models can be used to account for the nonlinear structure of the conditional quantile, but the challenge for using such models is the curse of dimensionality, as the quantile regression in CoVaR modeling often involves many variables. Thus, we resort to semiparametric partial linear model (PLM) which preserves some flexibility of the nonparametric model while suffers little from the curse of dimensionality.

As an illustration, the VaR/CoVaR of Goldman Sachs (GS) returns are shown, given the returns of Citigroup (C) and S&P500 (SP). S&P500 index return is used as a proxy for the market portfolio return.

Choosing market variables is crucial for the VaR/CoVaR estimation. For the variables representing market states, we follow the most popular choices such as VIX, short-term liquidity spread, etc. In particular, the variable we use for real estate companies is the Dow Jones U.S. real estate index. The daily data date from August 4, 2006 to August 4, 2011.

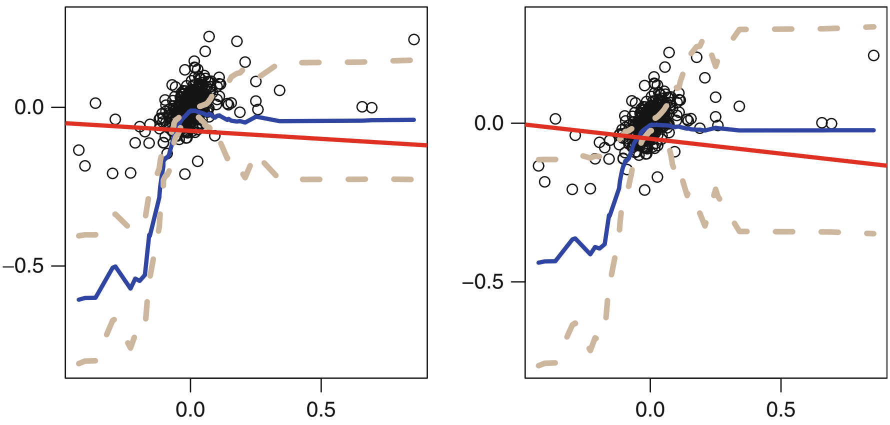

Fig. 54.1 Goldman Sachs (*GS*) and Citigroup (*C*) weekly returns 0.05(*left*) and 0.1(*right*) quantile functions. The *y*-axis is GS daily returns and the *x*-axis is the C daily returns. The *blue curve* are the locally linear quantile regression curves (see Appendix 1). The locally linear quantile regression bandwidth are 0.1026 and 0.0942. The *red lines* are the linear parametric quantile regression line. The antique *white dashed curves* are the asymptotic confidence band (see Appendix 2) with significance level 0.05. The sample size $N = 546$

To see if the estimated VaRs/CoVaRs are accurate, we utilize the backtesting procedures described in Berkowitz et al. (2011). We compare three (Co)VaR estimating methods in this study: VaR computed by linear quantile regression on market variables; CoVaR; PLM CoVaR proposed here. The VaR is one-sided interval prediction, the violations (the asset return exceeds estimated VaR/CoVaR) should happen unpredictably if the VaR algorithm is accurate. In other words, the null hypothesis is that the series of violations of VaR is a martingale difference, given all the past information. Furthermore, if the time series is autocorrelated, we can reject the null hypothesis of martingale difference right away; therefore, autocorrelation tests can be utilized in this context. The Ljung-Box test is not the most appropriate approach here since it has a too strong null hypothesis (i.i.d. sequence). Thus, we additionally apply the Lobato test. The CaViaR test, which is inspired by the CaViaR model, is proposed and shown to have the best overall performance by Berkowitz et al. (2011) among other alternative tests with an exclusive desk-level data set. To illustrate the VaR/CoVaR performances in the crisis time, we separately apply the CaViaR test to the violations of the whole sample period and to the financial crisis period.

The results show that during the financial crisis period from mid-2008 to mid-2009, the PLM CoVaR of GS given C performs better than that constructed from the technique of AB and the PLM CoVaR given SP. In particular, these results suggest that with appropriate modeling techniques (accounting for nonlinearity), the CoVaR of GS calculated from conditioning on C reflects some structurally risk which is not reflected from conditioning on market returns such as SP during financial crisis.

In contrast to ΔCoVaR, we use a mathematically more intuitive way to analyze the marginal effect by taking the first order derivative of the quantile function.

We call it "marginal contribution of risk" (MCR). Bae et al. (2003) and many others have pointed out the phenomenon of financial contagion across national borders. This motivates us to consider the stock indices of a few developed markets and explore their risk contribution to the global stock market. MCR results show that when the global market condition varies, the source of global market risk can be different. To be more specific, when the global market return is bad, the risk contribution from the USA is the largest. On the other hand, during financially stable periods, Hong Kong and Japan are more significant risk contributors than the USA to the global market.

This study is organized as follows: Sect. 54.2 introduces the construction and the estimation of the PLM model of CoVaR. The backtesting methods and our risk contribution measure are also introduced in this section. Section 54.3 presents the Goldman Sachs CoVaR time series and the backtesting procedure results. Section 54.4 presents the conclusion and possible further studies. Appendices describe the detailed estimation and statistical inference procedures used in this study.

54.2 Methodology

Quantile regression is a well-established technique to estimate the conditional quantile function. Koenker and Bassett (1978) focus on the linear functional form. An extension of linear quantile regression is the PLM quantile regression. A partial linear model for the dynamics of assets return quantile is constructed in this section. The construction is justified by a linearity test based on a conservative uniform confidence band proposed in Hardle and Song (2010). For more details on semiparametric modeling and PLM, we refer to Härdle et al. (2004) and Härdle et al. (2000).

The backtesting procedure is done via the CaViaR test. Finally, the methodology of MCR is introduced, which is an intuitive marginal risk contribution measure. We will apply the method to a data set of global market indices in developed countries.

54.2.1 Constructing Partial Linear Model (PLM) for CoVaR

Recall how the CoVaR is constructed:

$$\widehat{VaR}i,t = \hat{\alpha}_i + \hat{\gamma}_i M_{t-1},$$
$$\widehat{CoVaR}^{AB}_{j|i,t} = \hat{\alpha}_{j|i} + \hat{\beta}_{j|i}\widehat{VaR}_{i,t} + \hat{\gamma}^{\mathrm{T}}_{j|i} M_{t-1}.$$

where $(\hat{\alpha}_i, \hat{\gamma}_i)$ and $\left(\hat{\alpha}_{j|i}, \hat{\beta}_{j|i}, \hat{\gamma}_{j|i}\right)$ are estimated from a linear model using standard linear quantile regression.

We have motivated the need for more general functional forms for the quantile curve. We therefore relax the model to a non- or semiparametric model. The market variable M_t is multidimensional, and the data frequency here is daily. The following key variables are entering our analysis:

1. VIX: Measuring the model-free implied volatility of the market. This index is known as the "fear gauge" of investors. The historical data can be found in the Chicago Board Options Exchange's website.
2. Short-term liquidity spread: Measuring short-term liquidity risk by the difference between the 3-month treasury repo rate and the 3-month treasury bill rate. The repo data is from the Bloomberg database and the treasury bill rate data is from the Federal Reserve Board H.15.
3. The daily change in the 3-month treasury bill rate: AB find that the changes have better explanatory power than the levels for the negative tail behavior of asset returns.
4. The change in the slope of the yield curve: The slope is defined by the difference of the 10-year treasury rate and the 3-month treasury bill rate.
5. The change in the credit spread between 10 years BAA-rated bonds and the 10 years treasury rate.
6. The daily Dow Jones U.S. Real Estate index returns: The index reflects the information of lease rates, vacancies, property development, and transactions of real estates in the USA.
7. The daily S&P500 index returns: The approximate of the theoretical market portfolio returns.

The variables 3, 4, 5 are from the Federal Reserve Board H.15 and the data of 6 and 7 are from Yahoo Finance.

First we conduct a statistical check of the linearity between GS return and the market variables using the confidence band as constructed in Appendix 2. As shown in Fig. 54.2, except for some ignorable outsiders, the linear quantile regression line lies in the LLQR asymptotic confidence band.

On the other hand, there is nonlinearity between two individual assets X_i and X_j. To illustrate this, we regress X_j on M_t, and then take the residuals and regress them on X_i. Again the $X_{j,t}$ is GS daily return and X_i is C daily return. The result is shown in Fig. 54.3. The linear QR line (red) lies well outside the LLQR confidence band (magenta) when the C return is negative. The linear quantile regression line is fairly flat. The risk of using a linear model is obvious in this figure: The linear regression can "average out" the humped relation of the underlying structure (blue), and therefore imply a model risk in estimation.

Based on the results of the linearity tests above, we construct a PLM model:

$$X_{i,t} = \alpha_i + \gamma_i^{\mathrm{T}} M_{t-1} + \varepsilon_{i,t}, \tag{54.7}$$

$$X_{j,t} = \hat{\alpha}_{j|i} + \hat{\beta}_{j|i}^{\mathrm{T}} M_{t-1} + l_{j|i}\left(X_{i,t}\right) + \varepsilon_{j,t}, \tag{54.8}$$

where $X_{i,t}, X_{j,t}$ are asset returns of i, j firms. M_t is a vector of market variables at time t as introduced before. If i = S&P500, M_t is set to consist of the first 6 market variables only. Notice the variable $X_{i,t}$ enter the Eq. 54.8 nonlinearly.

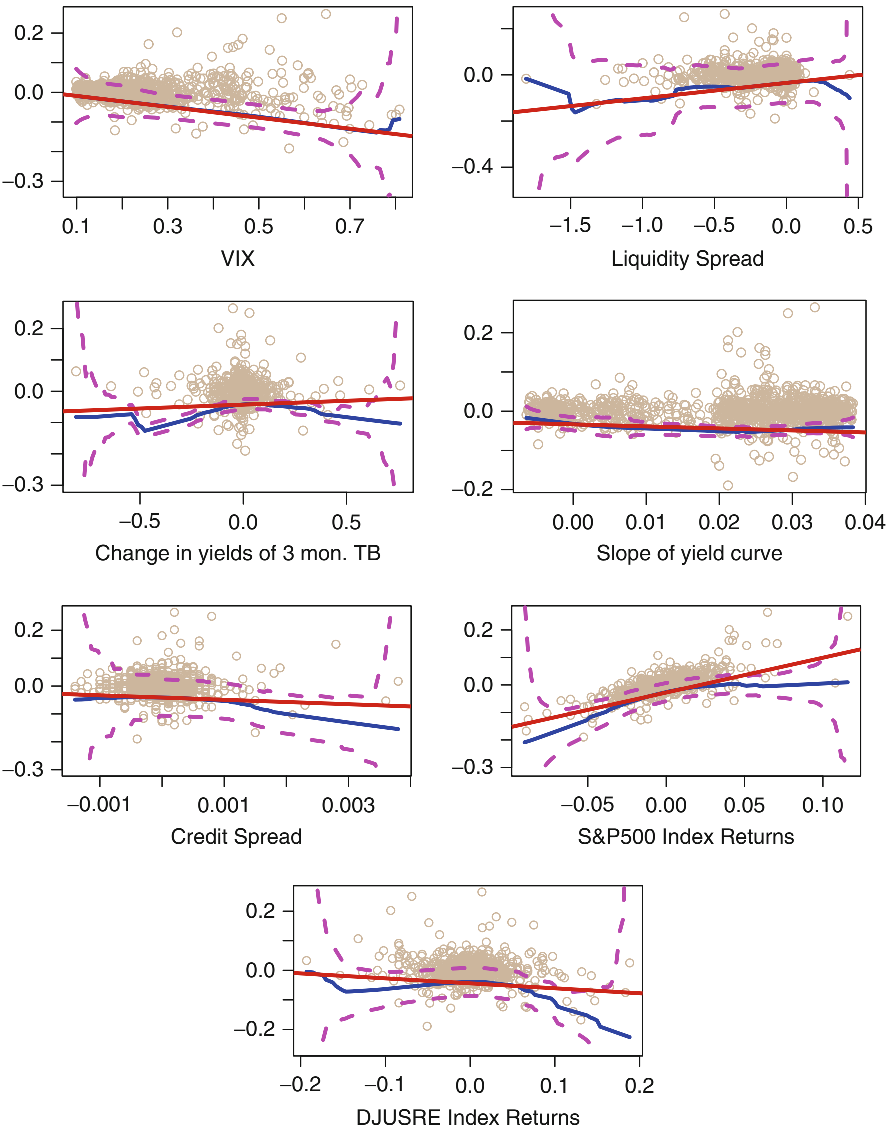

Fig. 54.2 The scatter plots of GS daily returns to the seven market variables with the LLQR curves. The bandwidths are selected by the method described in Appendix 1. The LLQR bandwidths are 0.1101, 0.1668, 0.2449, 0.0053, 0.0088, 0.0295 and 0.0569. The data period is from August 4, 2006, to August 4, 2011. $N = 1260$. $\tau = 0.05$

Applying the algorithm of Koenker and Bassett (1978) to Eq. 54.7 and the process described in Appendix 3 to Eq. 54.8, we get $\{\hat{\alpha}_i, \hat{\gamma}_i\}$ and $\left\{\hat{\alpha}_{j|i}, \hat{\beta}_i, \hat{l}(\cdot)\right\}$ with $F^{-1}_{\varepsilon_{i,t}}(\tau|M_{t-1}) = 0$ for Eq. 54.7 and $F^{-1}_{\varepsilon_{i,t}}\left(\tau|M_{t-1}, X_{i,t}\right) = 0$ for Eq. 54.8. Finally, we estimate the PLM $CoVaR_{j|i,t}$ by

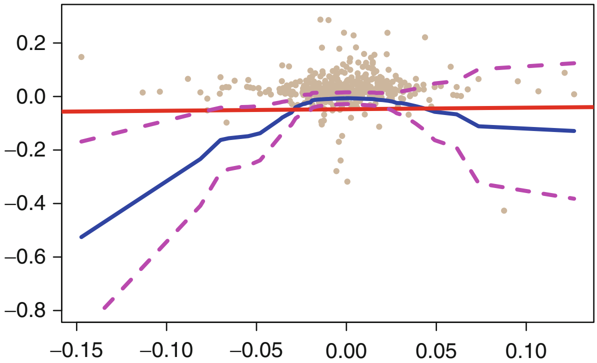

Fig. 54.3 The nonparametric part $\hat{l}_{GS|C}(\cdot)$ of the PLM estimation. The y-axis is the GS daily returns. The x-axis is the C daily returns. The *blue curve* is the LLQR quantile curve. The *red line* is the linear parametric quantile line. The *magenta dashed curves* are the asymptotic confidence band with significance level 0.05. The data is from June 25, 2008, to December 23, 2009. 378 observations. Bandwidth = 0.1255. $\tau = 0.05$

$$\widehat{VaR}_{i,t} = \hat{\alpha}_i + \hat{\gamma}_i^{\mathrm{T}} M_{t-1}, \tag{54.9}$$

$$\widehat{CoVaR}_{j|i,t}^{PLM} = \hat{\tilde{\alpha}}_{j|i} + \hat{\tilde{\beta}}_j^{\mathrm{T}} M_{t-1} + \hat{l}_{j|i}\left(\widehat{VaR}_{i,t}\right). \tag{54.10}$$

54.2.2 Backtesting

The goal of the backtesting procedure is to check if the VaR/CoVaR is accurate enough so that managerial decisions can be made based on them. The VaR forecast is a (one-sided) interval forecast. If the VaR algorithm is correct, then the violations should be unpredictable, after using all the past information. Formally, if we define the violation time series as

$$I_t = \begin{cases} 1, & \text{if } X_t < \widehat{VaR}_t^{\tau}; \\ 0, & \text{otherwise.} \end{cases}$$

where $\widehat{VaR}_t^{\tau}$ can be replaced by $\widehat{CoVaR}_t^{\tau}$ in the case of CoVaR. I_t should form a sequence of martingale difference.

There is a large literature on martingale difference tests. We adopt Ljung-Box test, Lobato test, and the CaViaR test. The Ljung-Box test and Lobato test aim to check whether the time series is autocorrelated. If the time series is autocorrelated, then we reject of course the hypothesis that the time series is a martingale difference.

Particularly, let $\hat{\rho}_k$ be the estimated autocorrelation of lag k of the sequence of violation $\{I_t\}$ and n be the length of the time series. The Ljung-Box test statistics is

$$\mathrm{LB}(m) = n(n+2)\sum_{k=1}^{m} \frac{\hat{\rho}_k^2}{n-k} \xrightarrow{\mathcal{L}} \chi(m), \tag{54.11}$$

as $n \to \infty$.

This test is too strong though in the sense that the asymptotic distribution is derived based on the i.i.d. assumption. A modified Box-Pierce test is proposed by Lobato et al. (2001), who also consider the test of no autocorrelation, but their test is more robust to the correlation of higher (greater than the first) moments. (Autocorrelation in higher moments does not contradict with the martingale difference hypothesis.) The test statistics is given by

$$\mathrm{L}(m) = n\sum_{k=1}^{m} \frac{\hat{\rho}_k^2}{\hat{v}_{kk}} \xrightarrow{\mathcal{L}} \chi(m),$$

as $n \to \infty$, where

$$\hat{v}_{kk} = \frac{\frac{1}{n}\sum_{i=1}^{n-k} (y_i - \overline{y})^2 (y_{i+k} - \overline{y})^2}{\left\{\frac{1}{N}\sum_{i=1}^{n} (y_i - \overline{y})^2\right\}^2}.$$

The CaViaR test, proposed by Berkowitz et al. (2011), is based on the idea that if the sequence of violation is a martingale difference, there ought to be no correlation between any function of the past variables and the current violation. One way to test this uncorrelatedness is through a linear model. The model is

$$I_t = \alpha + \beta_1 I_{t-1} + \beta_2 VaR_t + u_t,$$

where VaR_t can be replaced by $CoVaR_t$ in the case of conditional VaR. The residual u_t follows a Logistic distribution since I_t is binary. We get the estimates of the coefficients $\left(\hat{\beta}_1, \hat{\beta}_2\right)^{\mathrm{T}}$. Therefore, the null hypothesis is $\hat{\beta}_1 = \hat{\beta}_2 = 0$. This hypothesis can be tested by Wald's test.

We set $m = 1$ or 5 for the Ljung-Box and Lobato tests. For the CaViaR test, two data periods are considered separately. The first is the overall data from August 4, 2006, to August 4, 2011. The second is the data from August 4, 2008, to August 4, 2009, the period when the financial market reached its bottom. By separately testing the two periods, we can gain more insights into the PLM model.

54.2.3 Risk Contribution Measure

The risk contribution of one firm to the market is one of the top concerns among central bankers. The regulator can restrict the risky behaviors of the financial institution with high-risk contribution to the market, and reduce the institution's incentive to take more risk. AB propose the idea of ΔCoVaR, which is defined by

$$\Delta CoVaR^{\tau}_{j|i,t} = CoVaR^{\tau}_{j|i,t} - CoVaR^{0.5}_{j|i,t}. \tag{54.12}$$

where $\mathrm{CoVaR}^{\tau}_{j|i,t}$ is defined as in the introduction. j, i represent the financial system and an individual asset. $\tau = 0.5$ corresponds to the normal state of the individual asset i. This is essentially a sensitivity measure quantifying the effect to the financial system from the occurrence of a tail event of asset X_i.

In this study, we adopt a mathematically intuitive way to measure the marginal effect by searching the first order derivative of the quantile function. Because the spillover effect from stock market to stock market has already got much attention, it is important to investigate the risk contribution of a local market to the global stock market. The estimation is conducted as follows:

First, one estimates the following model nonparametrically:

$$X_{j,t} = f_j^{0.05}(X_t) + \varepsilon_j, \tag{54.13}$$

The quantile function $f_j^{0.05}(\cdot)$ is estimated with local linear quantile regression with $\tau = 0.05$, described with more details in Appendix 1. X_j is the weekly return of the stock index of an individual country and X is the weekly return of the global stock market.

Second, with $\hat{f}_j^{0.05}(\cdot)$, we compute the "marginal contribution of risk" (MCR) of institution j by

$$MCR_j^{\tau} = \left.\frac{\partial \hat{f}_j^{0.05}(x)}{\partial x}\right|_{x = \hat{F}_x^{-1}(\tau_k)}, \tag{54.14}$$

where $\hat{F}^{-1}(\tau_k)$ is a consistent estimator of the τ_k quantile of the global market return, and it can be estimated by regressing X_t on the time trend. We put $k = 1, 2$ with $\tau_1 = 0.5$ and $\tau_2 = 0.05$. The quantity Eq. 54.14 is similar to the MES proposed by Acharya et al. (2010) in the sense that the conditioned event belongs to the information set of the market return, but we reformulate it in the VaR framework instead of the expected shortfall framework.

There are some properties of the *MCR* to be described further. First, τ_k determines the condition of the global stock market. This allows us to explore the risk contribution from the index j to the global market, given different global market status. Second, the higher the value of MCR, the more risk factor j imposes on the market in terms of risk. Third, since the function $f_j^{0.05}(\cdot)$ is estimated by LLQR, the quantile curve is locally linear, and therefore, the local first order derivative is straightforward to compute.

We choose indices $j =$ S&P500, NIKKEI225, FTSE100, DAX30, CAC40, Hang Seng as the approximate of the market returns of each developed country or market. The global market is approximated by the MSCI World (developed countries) market index. The data is weekly from April 11, 2004, to April 11, 2011, and $\tau = 0.05$.

54.3 Results

54.3.1 CoVaR Estimation

The estimation results of VaR/CoVaR are shown in this section. We compute three types of VaR/CoVaR of GS, with a moving window size of 126 business days and $\tau = 0.05$.

First, the VaR of GS is estimated using linear quantile regression:

$$\widehat{VaR}_{GS,t} = \hat{\alpha}_{GS} + \hat{\gamma}_{GS}^{\mathrm{T}} M_{t-1}, \tag{54.15}$$

$M_t \in \mathbb{R}^7$ is introduced in Sect. 54.2.1.

Second, the CoVaR of GS given C returns is estimated:

$$\widehat{VaR}_{C,t} = \hat{\alpha}_C + \hat{\gamma}_C^{\mathrm{T}} M_{t-1}; \tag{54.16}$$

$$\widehat{CoVaR}^{AB}_{GS|C,t} = \hat{\alpha}_{GS|C} + \hat{\beta}_{GS|C} \widehat{VaR}_{C,t} + \hat{\gamma}_{GS|C}^{\mathrm{T}} M_{t-1}. \tag{54.17}$$

If the SP replaces C, the estimates are generated from

$$\widehat{VaR}_{SP,t} = \hat{\alpha}_{SP} + \hat{\gamma}_{SP}^{\mathrm{T}} \widetilde{M}_{t-1}; \tag{54.18}$$

$$\widehat{CoVaR}^{AB}_{GS|SP,t} = \hat{\alpha}_{GS|SP} + \hat{\beta}_{GS|SP} \widehat{VaR}_{SP,t} + \hat{\gamma}_{GS|SP}^{\mathrm{T}} \widetilde{M}_{t-1}, \tag{54.19}$$

where $\widetilde{M}_t \in \mathbb{R}^6$ is the vector of market variables without the market portfolio return.

Third, the PLM CoVaR is generated:

$$\widehat{VaR}_{C,t} = \hat{\alpha}_C + \hat{\gamma}_C^{\mathrm{T}} M_{t-1}; \tag{54.20}$$

$$\widehat{CoVaR}^{PLM}_{GS|C,t} = \hat{\hat{\alpha}}_{GS|C} + \hat{\hat{\beta}}_{GS|C}^{\mathrm{T}} M_{t-1} + \hat{l}_{GS|C}\left(\widehat{VaR}_{C,t}\right). \tag{54.21}$$

If SP replaces C:

$$\widehat{VaR}_{SP,t} = \hat{\alpha}_{SP} + \hat{\gamma}_{SP}^{\mathrm{T}} \widetilde{M}_{t-1}; \tag{54.22}$$

$$\widehat{CoVaR}^{PLM}_{GS|SP,t} = \hat{\hat{\alpha}}_{GS|SP} + \hat{\hat{\beta}}_{GS|SP}^{\mathrm{T}} \widetilde{M}_{t-1} + \hat{l}_{GS|SP}\left(\widehat{VaR}_{SP,t}\right). \tag{54.23}$$

The coefficients in Eqs. 54.15–54.20, and 54.22 are estimated from the linear quantile regression and those in Eqs. 54.21 and 54.23 are estimated from the method described in Appendix 3.

Figure 54.4 shows the $\widehat{VaR}_{GS,t}$ sequence. The VaR forecasts (red) seem to form a lower cover of the GS returns (blue). This suggests that the market variables M_t

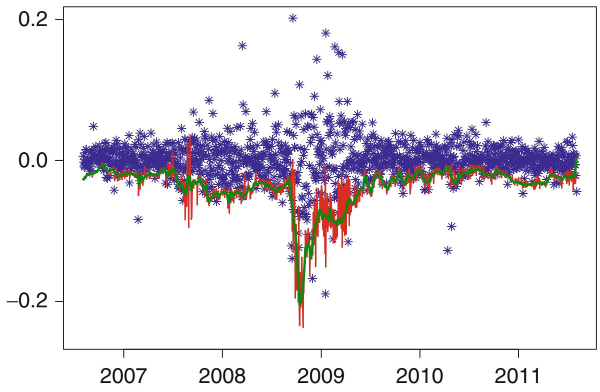

Fig. 54.4 The $\widehat{VaR}_{GS,t}$. The *red line* is the $\widehat{VaR}_{GS,t}$ and *blue stars* are daily returns of GS. The *dark green curve* is the median smoother of the $\widehat{VaR}_{GS,t}$ curve with $h = 2.75$. $\tau = 0.05$. The window size is 252 days

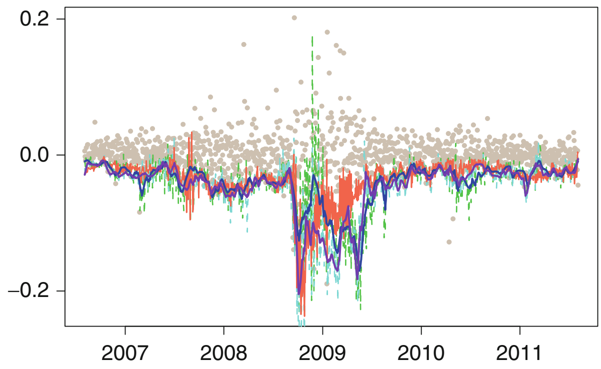

Fig. 54.5 The CoVaR of GS given the VaR of C. The *gray dots* mark the daily returns of GS. The *light green dashed curve* is the $\widehat{CoVaR}^{PLM}_{GS|C,t}$. The *dark blue curve* is the median LLQR smoother of the *light green dashed curve* with $h = 3.19$. The *cyan dashed curve* is the $\widehat{CoVaR}^{AB}_{GS|C,t}$. The *purple curve* is the median LLQR smoother of the *cyan dashed curve* with $h = 3.90$. The *red curve* is the $\widehat{VaR}_{GS,t}$. $\tau = 0.05$. The moving window size is 126 days

have some predictive power for the left tail quantile of the GS return distribution. Figure 54.5 shows the sequences $\widehat{CoVaR}^{AB}_{GS|SP,t}$ (cyan) and $\widehat{CoVaR}^{PLM}_{GS|C,t}$ (light green). As the time series of the estimates is too volatile, we smooth it further by the median LLQR. The two estimates are similar as the market state is stable, but during the period of financial instability (from mid-2008 to mid-2009), the two estimates have different behavior. The performances of these estimates are evaluated by backtesting procedure in Sect. 54.3.2.

Table 54.1 shows the summary statistics of the VaR/CoVaR estimates. The first three rows show the summary statistics of $\widehat{VaR}_{GS,t}$, $\widehat{VaR}_{C,t}$, and $\widehat{VaR}_{SP,t}$. The $\widehat{VaR}_{GS,t}$ has lower mean and higher standard deviation than the other two. Particularly during 2008–2009, the standard deviation of the GS VaR is twice as much as the other two. The mean and standard deviation of the $\widehat{VaR}_{C,t}$ and $\widehat{VaR}_{SP,t}$ are rather similar. The last four rows show the summary statistics of $\widehat{CoVaR}^{PLM}_{GS|C,t}$,

Table 54.1 VaR/CoVaR summary statistics. The overall period is from August 4, 2006, to August 4, 2011. The crisis period is from August 4, 2008, to August 4, 2009. The numbers in the table are scaled up by 10^2

	mean-overall	sd-overall	mean-crisis	sd-crisis
$\widehat{VaR}_{GS,t}$	−3.66	3.08	−7.43	4.76
$\widehat{VaR}_{C,t}$	−2.63	1.67	−4.62	2.25
$\widehat{VaR}_{SP,t}$	−2.09	1.57	−3.88	2.24
$\widehat{CoVaR}^{PLM}_{GS\|C,t}$	−4.26	3.84	−8.79	5.97
$\widehat{CoVaR}^{AB}_{GS\|C,t}$	−4.60	4.30	−10.36	6.32
$\widehat{CoVaR}^{PLM}_{GS\|SP,t}$	−3.86	3.30	−8.20	4.69
$\widehat{CoVaR}^{AB}_{GS\|SP,t}$	−5.81	4.56	−12.65	5.56

$\widehat{CoVaR}^{AB}_{GS|C,t}$, $\widehat{CoVaR}^{PLM}_{GS|SP,t}$, and $\widehat{CoVaR}^{AB}_{GS|SP,t}$. This shows that the CoVaR obtaining from the AB model has smaller mean and greater standard deviation than the CoVaR obtaining from PLM model.

Figure 54.6 shows the bandwidth sequence of the nonparametric part of the PLM estimation. The bandwidth varies with time. Before mid-2007, the bandwidth sequence is stably jumping around 0.2. After that the sequence becomes very volatile. This may have something to do with the rising systemic risk.

54.3.2 Backtesting

For the evaluation of the CoVaR models, we resort to the backtesting procedure described in Sect. 54.2.2. In order to perform the backtesting procedure, the sequences $\{I_t\}$ (defined in Sect. 54.2.2) have to be computed for all VaR/CoVaR estimates. Figure 54.7 shows the timings of the violations $\{t : I_t = 1\}$ of $\widehat{CoVaR}^{PLM}_{GS|C,t}$, $\widehat{CoVaR}^{AB}_{GS|C,t}$ and $\widehat{VaR}_{GS,t}$. This figure shows the total number of violations of PLM CoVaR and CoVaR is similar, while $\widehat{VaR}_{GS,t}$ has more violations than the both. The $\widehat{VaR}_{GS,t}$ has a few clusters of violations in both financial stable and unstable periods. This may result from the failure $\widehat{VaR}_{GS,t}$ to adapt for the negative shocks. The violations of $\widehat{CoVaR}^{PLM}_{GS|C,t}$ are more evenly distributed. The violations of $\widehat{CoVaR}^{AB}_{GS|C,t}$ have large clusters during financially stable period, while the violation during financial crisis period is meager. This contrast suggests that $\widehat{CoVaR}^{AB}_{GS|C,t}$ tend to overreact, as it is slack during the stable period but is too tight during the unstable period.

Figure 54.8 shows the timings of the violations $\{t : I_t = 1\}$ of $\widehat{CoVaR}^{PLM}_{GS|SP,t}$, $\widehat{CoVaR}^{AB}_{GS|SP,t}$, and $\widehat{VaR}_{GS,t}$. The overall number of violations of $\widehat{CoVaR}^{PLM}_{GS|SP,t}$ is more than that of $\widehat{VaR}_{GS,t}$, and it has many clusters. $\widehat{CoVaR}^{PLM}_{GS|SP,t}$ behaves differently from $\widehat{CoVaR}^{PLM}_{GS|C,t}$. The SP may not be more informative than C, though

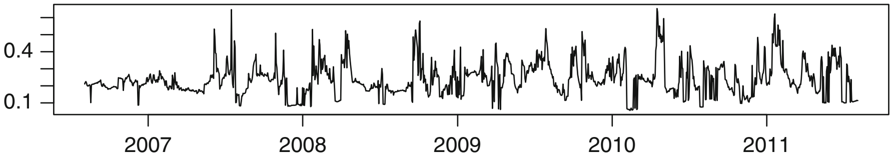

Fig. 54.6 LLQR bandwidth in the daily estimation of $\widehat{CoVaR}^{PLM}_{GS|C,t}$. The average bandwidth is 0.24

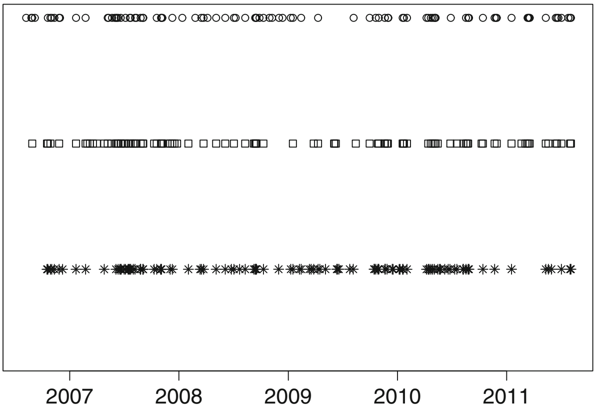

Fig. 54.7 The timings of violations $\{t : I_t = 1\}$. The *top circles* are the violations of the $\widehat{CoVaR}^{PLM}_{GS|C,t}$, totally 95 violations. The *middle squares* are the violations of $\widehat{CoVaR}^{AB}_{GS|C,t}$, totally 98 violations. The *bottom stars* are the violations of $\widehat{VaR}_{GS,t}$, totally 109 violations. Overall data $N = 1260$

the efficient market hypothesis suggests so. The violation of $\widehat{CoVaR}^{AB}_{GS|SP,t}$ is fewer than the other two measures, and the clustering is not significant.

The backtesting procedure is performed separately for each sequence of $\{I_t\}$. The null hypothesis is that each sequence of $\{I_t\}$ forms a series of martingale difference. Six different tests are applied for each $\{I_t\}$: Ljung-Box tests with lags 1 and 5, Lobato test with lags 1 and 5, and finally the CaViaR test with two data periods: overall and crisis period.

The result is shown in Table 54.2. First, in Panel 1 of Table 54.2, the $\widehat{VaR}_{GS,t}$ is rejected by the LB(5) test and the two CaViaR tests. This shows that a linear quantile regression on the seven market variables may not give accurate estimates, in the sense that the violation $\{I_t\}$ of $\widehat{VaR}_{GS,t}$ does not form a martingale sequence. Next we turn to the $\widehat{CoVaR}^{AB}_{GS|SP,t}$ and $\widehat{CoVaR}^{PLM}_{GS|SP,t}$. In Panel 2, the low p-values of the two CaViaR tests show that both the AB model and PLM model conditioned on SP are rejected, though the p-value of the AB model almost reaches the 5 % significant level. In particular, the $\widehat{CoVaR}^{PLM}_{GS|SP,t}$ is rejected by the L(5) and LB (5) tests. Both the parametric and semiparametric models fail with this choice of variable. This suggests that the market return does not provide enough information in risk measurement.

We therefore need more informative variables. Panel 3 of Table 54.2 illustrates this by using C daily returns, which may contain information not revealed in the

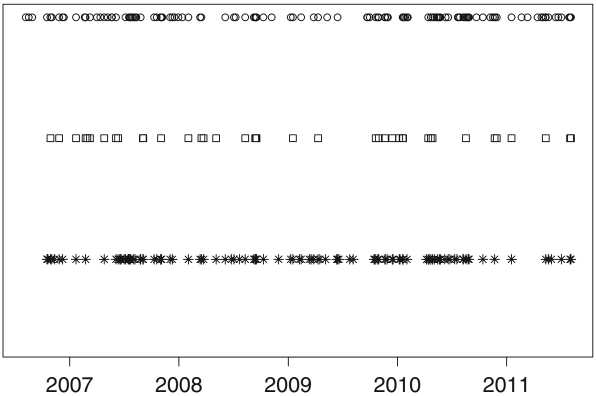

Fig. 54.8 The timings of violations $\{t : I_t = 1\}$. The *top circles* are the violations of $\widehat{CoVaR}^{PLM}_{GS|SP,t}$, totally 123 violations. The *middle squares* are the violations of $\widehat{CoVaR}^{AB}_{GS|SP,t}$, totally 39 violations. The *bottom stars* are the violations of $\widehat{VaR}_{GS,t}$, totally 109 violations. Overall data $N = 1{,}260$

Table 54.2 Goldman Sachs VaR/CoVaR backtesting p-values. The overall period is from August 4, 2006, to August 4, 2011. The crisis period is from August 4, 2008, to August 4, 2009. LB(1) and LB(5) are the Ljung-Box tests of lags 1 and 5. L(1) and L(5) are the Lobato tests of lags 1 and 5. CaViaR-overall and CaViaR-crisis are two CaViaR tests described in Sect. 2.2 applied on the two data periods

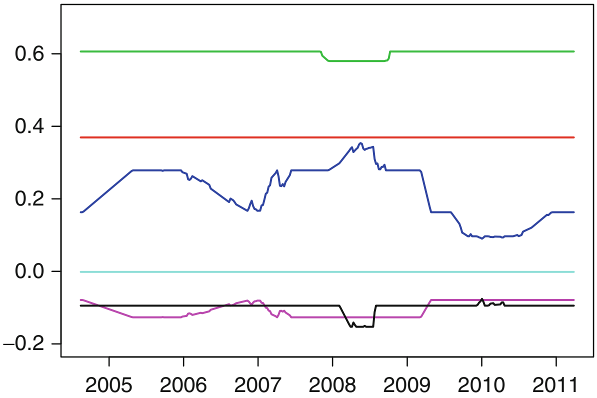
market and improve the performance of the estimates. The $\widehat{CoVaR}^{AB}_{GS|C,t}$ is rejected by the two CaViaR tests and the LB(1) test with 0.1 % and 5 % significant level. However, $\widehat{CoVaR}^{PLM}_{GS|C,t}$ is not rejected by the CaViaR-crisis test. This implies that the nonparametric part in the PLM model captures the nonlinear effect of C returns to GS returns, which can lead to better risk-measuring performance.

54.3.3 Global Risk Contribution

In this section, we present the *MCR* (defined in Sect. 54.2.3), which measures the marginal risk contribution of risk factors. We choose $\tau_1 = 0.5$, associated to the

Fig. 54.9 The $MCR_j^{\tau_1}$, $\tau = 0.5$. j:CAC, FTSE, DAX, Hang Seng, S&P500 and NIKKEI225. The global market return is approximated by MSCI World



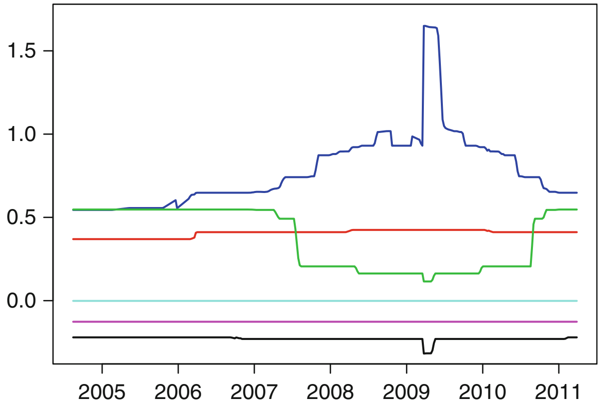


Fig. 54.10 The $MCR_j^{\tau_2}$, $\tau = 0.05$. j:CAC, FTSE, DAX, Hang Seng, S&P500 and NIKKEI225. The global market return is approximated by MSCI World

normal (median) state and $\tau_2 = 0.05$, associated to an negative extreme state. Figure 54.9 shows the $MCR_j^{\tau_1}$ from local markets j to the global market. When the MSCI World is at its normal state, the Hang Seng index in normal times contributes the most risk to the MSCI World at all times. The NIKKEI225 places second; the contribution from S&P500 varies most with the time; the risk contribution from DAX30 is nearly zero. The contributions from CAC40 and FTSE100 are negative.

Assuming that the MSCI World is at its bad state ($\tau_2 = 0.05$), the $MCR_j^{\tau_2}$ differs from $MCR_j^{\tau_1}$, see Fig. 54.10. One sees that the S&P500 imposes more pressure on the world economy than the other countries, especially during the financial crisis of 2008 and 2009. The contribution from Hang Seng is no longer of the same significance. The three European markets are relatively stable.

This analysis suggests that the risk contribution from individual stock market varies a lot with the state of global economy.

54.4 Conclusion

In this study, we construct a PLM model for the CoVaR, and we compare it to the AB model by backtesting. Results show that PLM CoVaR is preferable, especially during a crisis period. The study of the MCR reveals the fact that the risk from each country can vary with the state of global economy.

As an illustration, we only study the Goldman Sachs conditional VaR with Citigroup and S&P500 as conditioned risk sources. In practice, we need to choose variables. In Hautsch et al. (2011), the Least Absolute Shrinkage and Selection Operator (LASSO) techniques are used to determine the most relevant systemic risk sources from a pool of financial institutions. A VAR (Vector Autoregression) model may be also suitable for capturing the asset dynamics, but the estimation may be more involved. We may include other firm-specific variables such as corporate bond yields as these variables can bear other information which is not included in the stock returns or stock indices.

Appendix 1: Local Linear Quantile Regression (LLQR)

Let $\{(X_i, Y_i)\}_{i=1}^n \subset \mathbb{R}^2$ be independently and identically distributed (i.i.d.) bivariate random variables. Denote by $F_{Y|x}(u)$ the conditional cumulative distribution function (cdf) and $l(x) = F_{Y|x}^{-1}(\tau)$ the conditional quantile curve to level τ, given observations $\{(x_i, y_i)\}_{i=1}^n$, one may write this as

$$y_i = l(x_i) + \varepsilon_i,$$

with $F_{\varepsilon|x}^{-1}(\tau) = 0$. A locally linear kernel quantile estimator (LLQR) is estimated as $\hat{l}(x_0) = \hat{a}_0$ from:

$$\left(\hat{a}_0, \hat{b}_0\right) = \underset{\{a_0, b_0\}}{\text{argmin}} \sum_{i=1}^{n} K\left(\frac{x_i - x_0}{h}\right) \tag{54.24}$$

$$\rho_\tau\{y_i - a_0 - b_0(x_i - x_0)\}, \tag{54.25}$$

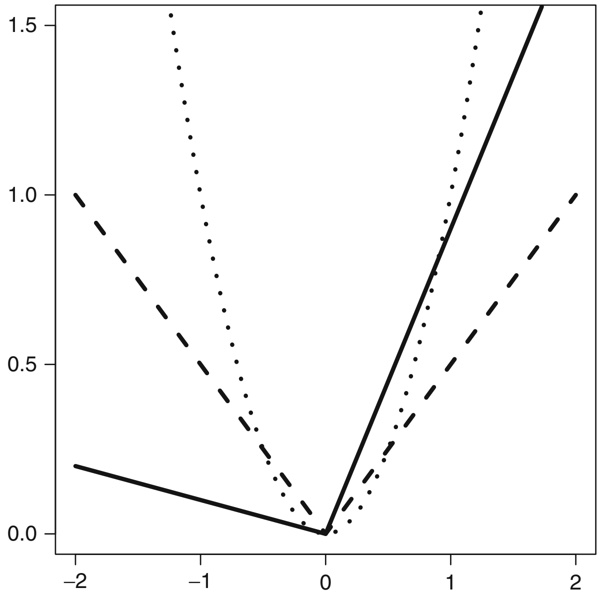
where h is the bandwidth, $K(\cdot)$ is a kernel, and $\rho_\tau(\cdot)$ is the check function given by

$$\rho_\tau(u) = \left(\tau - 1_{\{u<0\}}\right)u \tag{54.26}$$

Figure 54.11 illustrates the check functions. Different loss functions give different estimates. u^2 corresponds to the conditional mean. $\rho_\tau(u)$ corresponds to the conditional τth quantile.

It is shown by Fan et al. (1994) that the locally linear kernel estimator is asymptotically efficient in a minimax sense. It also possesses good finite sampling property which is adaptive to a variety of empirical density $g(x)$ and has good boundary property.

Fig. 54.11 This figure presents the check function. The *dotted line* is u^2. The *dashed and solid lines* are check functions $\rho_\tau(u)$ with $\tau = 0.5$ and 0.9 respectively



Next, we describe the method to compute the bandwidths. The approach used here follows Yu and Jones (1998). The bandwidth is chosen by

$$h_\tau = h_{mean}\left[\tau(1-\tau)\varphi\left\{\Phi^{-1}(\tau)\right\}^{-2}\right]^{1/5}, \tag{54.27}$$

where h_{mean} is the locally linear mean regression bandwidth, which can be computed by the algorithm described in Ruppert and Wand (1995) or Ruppert et al. (1995). $\varphi(\cdot)$ and $\Phi(\cdot)$ are the pdf and cdf of the standard normal distribution. Since we discuss the case for VaR, τ is usually small. h_τ needs to be enlarged to allow for more smoothing (usually taking $1.5h_\tau$ or $2h_\tau$).

The approach is acceptable but not so flexible, because it is based on assuming the quantile functions are parallel. A more flexible approach was developed by Spokoiny et al. (2011). In order to stabilize the bandwidth choice, we first regress y_i on the rank of the corresponding x_i and then rescale the resulted estimated values to the original x space. Carroll and Hardle (1989) show that this local bandwidth estimator and the global bandwidth estimator are asymptotically equivalent.

Appendix 2: Confidence Band for Nonparametric Quantile Estimator

The uniform confidence band of the quantile estimator is based on the Theorem 2.2 and Corollary 2.1 presented in Hardle and Song (2010). The details are as follows.

Let $\{(X_i, Y_i)\}_{i=1}^{n}$ be as in Appendix 1. Define $K_h(u) = h^{-1} K(u/h)$ and similar to Eq. 54.25 let $l_n(x)$ and $l(x)$ are zeros (w.r.t. θ) of the functions:

$$\widetilde{H}_n(\theta, x) \stackrel{\text{def}}{=} n^{-1} \sum_{i=1}^{n} K_h(x - X_i)\rho_\tau(Y_i - \theta);$$

$$\widetilde{H}(\theta, x) \stackrel{\text{def}}{=} \int_{\mathbb{R}} f(x, y)\rho_\tau(y - \theta)dy,$$

where $\rho_\tau(\cdot)$ is the check function defined as Eq. 54.26.

Theorem 1 *Let* $h = n^{-\delta}$, $\frac{1}{5} < \delta < \frac{1}{3}$, $\lambda(K) = \int_{-A}^{A} K^2(u)du$, *where* $K(\cdot)$ *is supported on* $[-A, A]$. $J = [0, 1]$. *Define* $c_1(K) = \{K^2(A) + K^2(-A)\}/2\lambda(K)$, $c_2(K) = \int_{-A}^{A}\{K'(u)\}^2 du/2\lambda(K)$ *and*

$$d_n = \begin{cases} (2\delta \log n)^{1/2} + (2\delta \log n)^{-1/2}\left[\frac{\log\{c_1(K)\}}{\pi^{1/2}}\right\} + \frac{1}{2}\{\log\delta + \log\log n\}], \\ \text{if } \ c_1(K) > 0; \\ (2\delta \log n)^{1/2} + (2\delta \log n)^{-1/2 \frac{\log\{c_2(K)\}}{2\pi}}\}, \quad \text{otherwise.} \end{cases}$$

Then

$$\mathrm{P}\left[(2\delta \log n)^{1/2}\left\{\sup_{x \in J} r(x)\frac{|l_n(x) - l(x)|}{\lambda(K)^{1/2}} - d_n\right\} < z\right] \\ \to \exp\{-2\exp(-z)\},$$

as $n \to \infty$, *with*

$$r(x) = (nh)^{1/2} f\{l(x)|x\}\{f_X(x)/\tau(1 - \tau)\}^{1/2},$$

where $f_X(\cdot)$ *is the marginal pdf for X and* $f(\cdot|x)$ *is the conditional pdf of Y on* $X = x$.

The corollary followed by the theorem explicitly indicates how a uniform confidence interval can be constructed.

Corollary 1 *An approximate* $(1 - \alpha) \times 100\ \%$ *confidence band is*

$$l_n \pm (nh)^{-1/2}\left\{\tau(1 - \tau)\lambda(K)/\hat{f}_X(t)\right\}^{1/2} \hat{f}^{-1}\{l(t)|t\} \times \left\{d_n + c(\alpha)(2\delta \log n)^{-1/2}\right\},$$

where $c(\alpha) = \log 2 - \log|\log(1 - \alpha)|$ *and* $\hat{f}_X(t), \hat{f}\{l(t)|t\}$ *are consistent estimates for* $f_X(t), f\{l(t)|t\}$.

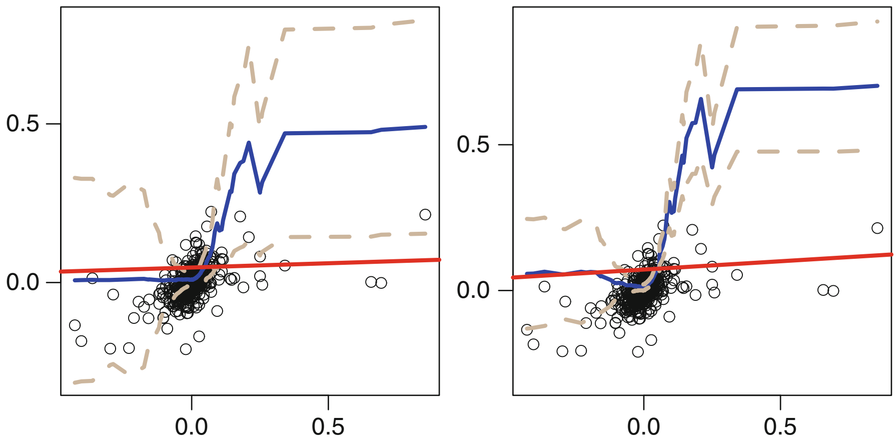


Fig. 54.12 GS and C weekly returns 0.90(*left*) and 0.95(*right*) quantile functions. The y-axis is GS daily returns and the x-axis is the C daily returns. The *blue curves* are the LLQR curves (see Appendix 1). The LLQR bandwidths are 0.0942 and 0.1026. The *red lines* are the linear parametric quantile regression line. The *antique white curves* are the asymptotic confidence band (see Appendix 2) with significance level 0.05. $N = 546$

Figure 54.1 is done by the techniques introduced in Appendices 1 and 2. Another illustration with right tail quantiles is in Fig. 54.12. We plot the LLQR curve for 0.9 and 0.95 quantile. Both the two linear quantile regression lines lie outside the LLQR confidence band as the Citigroup returns are positive.

Appendix 3: PLM Model Estimation

For the PLM estimation, we adopt the algorithm described in Song et al. (2012). Given data $\{(X_t, Y_n)\}_{n=1}^{T}$ bivariate and $\{M_t\}_{n=1}^{T}$ multivariate random variables. The PLM is:

$$Y_t = \alpha + \beta^{\mathrm{T}} M_{t-1} + l(X_t) + \varepsilon_t.$$

Let a_n denote an increasing sequence of positive integers and set $b_n = a_n^{-1}$. For given n, dividing the interval [0, 1] into a_n subintervals I_{nt}, $t = 1, \ldots, a_n$ with equal length b_n. On each I_{nt}, $l(\cdot)$ can approximately be taken as a constant.

The PLM estimation procedure is:

1. Inside each partition I_{nt}, a linear quantile regression is performed to get $\hat{\beta}_i$, then their weighted mean gives $\hat{\beta}$. Formally, let $\rho_\tau(\cdot)$ be the check function defined as Eq. 54.26, $l_1, \ldots, l_{a_n}$ are constants,

$$\hat{\beta} = \underset{\beta}{\operatorname{argmin}} \min_{l_1, \ldots, l_{a_n}} \sum_{t=1}^{n} \rho_\tau \left\{ X_{j,t} - \alpha - \beta^{\mathrm{T}} M_{t-1} - \sum_{m=1}^{a_n} l_m 1\left(X_{i,t} \in I_{nt}\right) \right\}$$

2. Computing the LLQR nonparametric quantile estimates of $l(\cdot)$ as outlined in Appendix 1 from $\left\{ \left(X_{i,t}, X_{j,t} - \hat{\alpha} - \hat{\beta}^{\mathrm{T}} M_{t-1} \right) \right\}_{t=1}^{n}$.

Strike Prices of Options for Overconfident Executives

55

Oded Palmon and Itzhak Venezia

Contents

Abstract

We explore via simulations the impacts of managerial overconfidence on the optimal strike prices of executive incentive options. Although it has been shown that, optimally, managerial incentive options should be awarded in-the-money, in practice most firms award them at-the-money. We show that the optimal strike prices of options granted to overconfident executive are directly related to their overconfidence level and that this bias brings the optimal strike prices closer to the institutionally prevalent at-the-money prices. Our results thus support the viability of the common practice of awarding managers with at-the-money incentive options. We also show that overoptimistic CEOs receive lower compensation than their realistic counterparts and that the stockholders benefit from

their managers bias. The combined welfare of the firm's stakeholders is, however, positively related to managerial overconfidence.

The Monte Carlo simulation procedure described in Sect. 55.3 uses a Mathematica program to find the optimal effort by managers and the optimal (for stockholders) contract parameters. An expanded discussion of the simulations, including the choice of the functional forms and the calibration of the parameters, is provided in Appendix 1.

Keywords

Overconfidence • Managerial effort • Incentive options • Strike price • Simulations • Behavioral finance • Executive compensation schemes • Mathematica optimization • Risk aversion • Effort aversion

55.1 Introduction

The optimal structure of executive compensation has intrigued academic researchers as well as practitioners for a long time. Most principal-agent models dealing with this issue yield rather complex payment schedules, making it quite challenging to test their predictions. In practice there is a widespread use of simple compensation schemes such as linear or piecewise linear (stock option) contracts. An important question that arises in this case is what are the optimal parameters for these simple schemes? In particular what are the optimal strike prices for incentive option schemes? Unfortunately, this important issue has received only little attention. Institutional and tax factors could be to blame for this neglect. Before the 2006 changes in the US tax rules, the "intrinsic value" of executive options was taxed, and this discouraged firms from granting their executives in-the-money options. Granting out-of-the-money options seemed unfair and there is no empirical or theoretical evidence for advantages to such practice (Mahajan 2002). Indeed, only a very small fraction of firms used such strike prices.[1] The virtual monopoly of at-the-money strike prices, their institutional appeal, or some other unknown factors might have discouraged academics from studying the merits and demerits of this practice.

In their landmark paper, Hall and Murphy (2000, 2002) attribute the pervasiveness of granting at-the-money options to their property of being the most sensitive to changes in the stock price. Palmon et al. (2008), however, have shown that issuing the most sensitive options is not necessarily optimal when managers are risk and effort averse.[2] Within a model explicitly considering the choice of the contract parameters by stockholders and the resulting effort chosen by risk-averse and effort-averse managers, they show for a wide range of parameters that well describe

[1]According to Mahajan (2002), less than 1 % of firms used out-of-the-money strike prices. Furthermore, in his study firms did not benefit from awarding such options to their managers.

[2]Hall and Murphy (2000) did not show that at-the-money strike prices are optimal, just that they possess the highest sensitivity to stock prices. They did not assume effort aversion by managers either.

managers' risk and effort aversion, that in-the-money options provide are optimal. Such options provide managers a better risk-return trade-off and ultimately constitute a better form of compensation than either out-of-the-money or at-the-money options.[3] Palmon et al. further argue that the asymmetric tax treatment of options under the old (prior to 2006) tax system, which penalized the issuance of in-the-money options, may have driven firms to use at-the-money options.

Whereas most studies of the issue of optimal incentive contracts assumed that managers as well as stockholders are rational, there exists extensive literature that documents that managers often are overconfident. Of the few studies that explore the effect of cognitive biases on managerial compensation, none however explores the effect of overconfidence on the optimal strike prices for the incentive options. Gervais et al. (2011) investigate the optimal form of managerial compensation under overconfidence but define overconfidence in the sense of too-high-precision-of-estimates (calibration), and the managers in their model exert effort to obtain better information on the investment parameters. There is an abundant literature however that indicates the pervasiveness of overconfidence in the optimism or "better than average" sense rather than in the calibration interpretation (see, e.g., Malmendier and Tate 2005a, b, 2008; Roll 1986; Suntheim 2012).[4] Oyer and Schaefer (2005) and Bergman and Jenter (2007) also consider the effect of optimism, and other sentiments, on managerial compensation, but they do not consider the effect of these sentiments on the optimal strike prices or on the managers' effort.

In this paper we investigate the hitherto unexplored question of the effect of overconfidence on the optimal strike prices for risk-averse and effort-averse managers. We show that overconfidence leads to higher optimal strike prices of managerial incentive schemes, and that awarding overconfident CEOs at-the-money options mitigates the stockholders' vs. managers' agency problem, leading to higher managers' productivity. Our results thus provide support for the viability of the ubiquitous yet seemingly unoptimal practice of awarding CEOs with at-the-money incentive options.

Whereas the main focus of the paper is the interaction between overconfidence and the strike prices of managerial incentive options, it also sheds light on the effect of overconfidence on the firm's stakeholders (stockholders and managers). We predict, as empirically shown by Otto (2011), that overoptimistic CEOs receive lower compensation than their realistic counterparts. However, the stockholders benefit from their managers bias since they pay less and enjoy the productivity of the higher effort the overconfident manager exerts. We construct a measure of the combined welfare of managers and stockholders and demonstrate that it is

[3]Dittman et al. (2010) found that for a range of parameterizations, a principal-agent model with loss-averse agents generates convex compensation contract but did not investigate the parameters of the options to be used in the compensation package. Recently, however, Dittman and Yu (2011) found that in-the-money options are optimal.

[4]Glaser and Weber (2007) note that only overconfidence in the better than average sense affects trading.

positively related to managerial overconfidence, a result helping explain the persistence of this bias.[5]

The paper is constructed as follows. In Sect. 55.2 we present the model. In Sect. 55.3 we explain the simulation method, and in Sect. 55.4 we present the simulations' results. Section 55.5 concludes.

55.2 Overconfidence and the Optimal Exercise Prices of Executive Incentive Options

We consider a one-period Holmstrom (1979)-type model where a risk-neutral firm employs an overconfident, risk-averse, and effort-averse manager.[6] The cash flows, X, of the firm depend on the manager's effort and on exogenous stochastic factors. The manager is assumed to provide some effort which is the minimum necessary to run the firm and hence may be considered observable, but can provide also unobservable extra effort. The more extra effort the manager exerts, the higher will be the expected cash flows. Because stockholders cannot observe managers' extra effort, managerial compensation may depend on the firm's cash flows (which depend on effort), but cannot be determined directly based on extra effort.

We assume that the cash flows of the firm, X, are lognormally distributed with the following distribution function:

$$f(X) = \exp\left\{-0.5\{[\log(X) - \mu(Y)]/\sigma\}^2\right\}/\left(X\sigma\sqrt{2\pi}\right) \tag{55.1}$$

where Y denotes the managerial extra effort (a managerial choice variable) and $\mu(Y)$ and σ denote, respectively, the mean and the standard deviation of the underlying normal distribution of the natural logarithm of X. We assume that managerial effort increases cash flows and that overconfident managers overestimate the impact of their effort on cash flows. Formally, we use the following specification:

$$\mu(Y) = \mathrm{Ln}(\mu_0 + 500\lambda Y) - \sigma^2/2, \tag{55.2}$$

where λ denotes the degree of overconfidence. We assume that stockholders have realistic expectations, which are represented by $\lambda = 1$, and that managers use $\lambda > 1$ to form their expectations. Thus, f(X) can be written as f(X, λ), where f(X, $\lambda = 1$) represents the realistic cash flow distribution, while f(X, $\lambda > 1$)

[5] Palmon and Venezia (2012) explore the effect of managerial overconfidence on the firm's stockholders and show that overconfidence may improve welfare. However, that study does not investigate the optimal strike price of managerial incentive options.

[6] In our model we assume symmetry of information between the manager and the firm regarding the distribution of cash flows of the firm except for the different view of the effect of the manager's effort on cash flows.

represents the cash flow distribution as viewed by overconfident managers. For notation brevity, we suppress the λ in $f(X, \lambda)$. By the known properties of the lognormal distribution, the mean and variance of X equal $e^{\left[\mu(Y)+0.5\sigma^2\right]}$ and $\left[e^{\left[2\mu(Y)+\sigma^2\right]}\left(e^{\sigma^2}-1\right)\right]$, respectively. Thus, it follows from Eq. 55.2 that a person with a λ overconfidence measure believes that the mean of the cash flows X is $e^{\mu(Y)+0.5\sigma^2} = \mu_0 + 500\lambda Y$ and that their coefficient of variation is approximately σ.[7] Since managers and stockholders differ in their perception of the distributions of cash flows, one must be careful in their use. In what follows we refer to the distribution of cash flows as seen by stockholders as the realistic distribution, and will make a special note whenever the manager's overconfident beliefs are used.

Except for her overconfidence, the manager is assumed to be rational and to choose her extra effort so as to maximize the expected value of the following utility function which exhibits constant relative risk aversion (CRRA) with respect to compensation:

$$U(I, Y) = \frac{1}{1-\gamma} NY^{\beta} + \frac{1}{1-\gamma} I^{1-\gamma} \tag{55.3}$$

In Eq. 55.3, I denotes the manager's monetary income, γ denotes the constant relative risk aversion measure, N is a scaling constant representing the importance of effort relative to monetary income in the manager's preferences, and the positive parameter β is related to the convexity of the disutility of effort.

Since stockholders cannot observe the manager's extra effort, they propose compensation schemes that depend on the observed cash flows, but not on Y. Stockholders, which we assume to be risk neutral, strive to make the compensation performance sensitive in order to better align the manager's incentives with their own. Stockholders offer the manager a compensation package that includes two components: a fixed wage (W) that she will receive regardless of her extra effort and of the resulting cash flows and options with a strike price (K) for a fraction (s) of the equity of the firm. We assume that stockholders offer the contract that maximizes the value of their equity.

The following timeline of decisions is assumed. At the beginning of the period, the firm chooses the parameters of the compensation contract (K, W, and s) and offers this contract to the manager. Observing the contract parameters, and taking into account the effects of her endeavors on firm cash flows and hence on her compensation, the manager determines the extra-effort level Y that maximizes her expected utility. At the end of the period, X is revealed, and the firm distributes the cash flows to the manager and to the stockholders and then dissolves. The priority of payments is as follows. The firm first pays the wages or only part of them if the cash flows do not suffice. If the cash flows exceed the wage, W, but not (K + W), then the

[7] More precisely the square of the coefficient of variation is $\left[e^{\sigma^2}-1\right]$ which can be approximated by σ^2 since for any small z, e^z-1 is close to z.

managers just receive their fixed wage. The managers are paid the value of the options s(X − K − W), in addition to W if X exceeds K + W. The manager therefore receives the cash flows I(X) defined by

$$I(x) = \begin{Bmatrix} X \\ W \\ W + s(X - W - K) \end{Bmatrix} \quad \text{when} \quad \begin{Bmatrix} X \le W \\ W \le X \le W + K \\ W + K \le X \end{Bmatrix} \tag{55.4}$$

The shareholders get the residual cash flows.

In the above cash flow formula, the first range covers the case where cash flows do not suffice to pay the entire wage. The second range covers the case where the options expire out-of-the-money, and the manager gets the promised wage. The third range represents cash flows that are large enough so that the options expire in-the-money. In addition to the wage, the manager receives a proportion, s, of the value of the firm above the threshold value of K. The expected utility of the manager E{U[I(X),Y]} which governs her behavior, and her expected compensation E[I(X)], can be obtained by integrating her utility U[I(X),Y] given in Eq. 55.3 and her compensation I(X), given in Eq. 55.4, respectively. We note that the manager chooses the effort level so as to maximize the expected utility using her perception of the distribution of the firm's final cash flows, while stockholders choose the parameters of the compensation contract using the realistic cash flow distribution to calculate the expected cash flows and managerial compensation.

Shareholders receive all cash flows that are not received by the manager. Since stockholders are risk neutral and rational, stockholders' equity value (SEV) is the expected value of these payments, using the realistic distribution function, and hence,[8]

$$SEV = E(Cashflows) - E[I(X)] = \int_0^\infty Xf(X)dX - E[I(X)] \tag{55.5}$$

While the derivation of the optimal contract for any set of exogenous parameters is conceptually straightforward, unfortunately, closed form solutions cannot be obtained in our integrative model. Hence, following Hall and Murphy (2000), we resort to simulations to evaluate the optimal contracts and analyze their properties. In addition, we cannot use the Black-Scholes model to evaluate the executive stock options since this model takes the values of the underlying asset as given, whereas a crucial aspect of the managerial incentive scheme of our model is that managerial extra effort and firm value are endogenously determined. We therefore introduce a model that simultaneously simulates the manager's optimal extra-effort level as well as the expected values of the executive stock options and shareholders' equity

[8]Discounting the cash flows by an appropriate risk-adjusted discount rate would yield a linear transformation of equity values. To simplify the presentation, and as is common in the literature, we abstract from that.

for each compensation package. We check the robustness of our results by using alternative parameters for the manager's utility function and the distribution functions of the cash flows.

55.3 The Simulation Procedures

We assume that managers have external employment opportunities and that stockholders offer managerial compensation packages that provide the managers with a comparable expected utility.[9] Without loss of generality (i.e., by an appropriate definition of the wage units), we assume that these external employment opportunities provide the manager an expected utility that equals the level of utility that is obtained from a fixed compensation of 100 in the absence of any extra effort. Thus, in all the simulations, we set the manager's expected utility to correspond to the level obtained from a fixed compensation of 100 (wage = 100 and no option grants) and no extra effort (which is the optimal extra-effort choice when no options are granted).[10] We then search over a grid of strike prices (using four-digit accuracy) and find for each strike price the percentage of options that should be awarded so that the manager's expected utility equals the expected utility target when the manager chooses the optimal extra-effort level. We identify the strike price that is associated with the highest equity level and refer to this contract as the optimal contract for the given set of parameters.

In calibrating the other parameters for the simulations, we try to approximately conform to Hall and Murphy (2000) and Hall and Liebman (1998); to studies that simulate decisions with effort aversion, such as Bitler et al. (2005); and to studies that explore the effect of overconfidence on corporate decisions, such as Malmendier and Tate (2005a, b, 2008).[11] Accordingly, we set the parameters in our base case as follows. The coefficient of variation, σ, equals 0.3, and thus, the standard deviation is 0.3E(X). Since the expected cash flows serve as numeraire, the volatility is determined solely by the coefficient of variation. In our base case, we set the managerial wage to equal 50.[12] The expected cash flows as viewed by an overconfident manager with an overconfidence measure of λ are $E(X) = 45{,}000 + 500\lambda Y$ (i.e., $\mu_0 = 45{,}000$). The risk aversion and effort aversion parameters are $\gamma = 4$ and $\beta = 3$, respectively.

[9] See Appendix 1 for more details.

[10] When the manager is overconfident, this expected utility is calculated according to the manager's expectations.

[11] See Appendix 1 for the explanation for the calibration of our model. To be on the safe side and in stride with explanations for the risk premium puzzle, we use higher values for the risk aversion parameter.

[12] It should be noted that although the wage level in our base case equals half of the fixed compensation that corresponds to the utility target, it equals only about 11 % of the expected compensation under the optimal contract when managers are realistic. When managers are overconfident, a wage of 50 consists of less than 11 % of total compensation according to the manager's expectations but more than 11 % according to the realistic expectations.

We consider overconfidence levels between $\lambda = 1$ (no overconfidence) and $\lambda = 2.5$ in 0.5 increments.

We examine the robustness of the results to deviations from the base case combination of parameters by simulating with several alternative sets of exogenous parameters. We repeat the analysis for many alternative sets of the exogenous parameters: the manager's risk and extra-effort aversion, γ and β, as well as the volatility measure of cash flows, σ.[13]

55.4 Results and Discussion

In Table 55.1 we present the impact of overconfidence on the strike price that stockholders choose to offer: the moneyness, the percentage of the firm given as options, the effort choice of managers, the stockholders' equity value, and the expected managerial compensation. The expected compensation is calculated both under the realistic distribution and under the subjective distribution of the manager.

One observes from Table 55.1 that the strike price, the options' moneyness, the optimal managerial effort, the value of the stockholders' equity, and the expected compensation according to the managers' expectations are directly related to overconfidence. The optimal strike price (in thousands of dollars; strike prices will be denoted in thousands of dollars in the rest of the study) for a rational manager is 40.71, with a 0.60 moneyness (which can be described as deep-in-the-money), but it rises to 63.74 with a 0.89 moneyness (closer to at-the-money) when $\lambda = 2.5$.[14] Managers also work harder the more overconfident they are (Y increases from around 47 when they are realistic to around 52 when $\lambda = 2.5$). Consequently, in order to hold the managers' expected utility fixed, their subjective expected monetary compensation must increase with overconfidence to compensate for the extra risk resulting from the higher strike price and for the additional effort they exert. The expected compensation the stockholders perceive they pay according to the realistic expectation, however, is inversely related to the overconfidence measure as they take advantage of managers' unrealistic expectations. The SEVs of the optimal contracts increase as managerial overconfidence increases (see column 5, the SEV rises from 68,099 when $\lambda = 1$ to 70,958 when $\lambda = 2.5$, an increase of about 6 %). That is, the stockholders benefit from the managers overestimating their powers.

This analysis suggests that stockholders are able to induce overconfident managers to exert higher effort levels even though the objective contract parameters they offer them are less favorable (the managers work harder but receive lower

[13]Because of scaling there is no need to conduct robustness checks for the expected cash flows.

[14]The moneyness measure depends on the strike price and the value of equity, which in turn depends on effort. Thus, the moneyness measure varies with overconfidence because effort varies with overconfidence, even when the strike price remains constant.

Table 55.1 Stockholders' equity values (SEV), strike prices (K), moneyness (K/S), effort levels (Y), and other parameters of interest. Base case: $\gamma = 4$ $\beta = 3$, $\sigma = 0.3$, wage $= 50$, $N = 4{,}000$

Overconfidence measure, λ	Strike price (K) in 1000s	Moneyness (K/S)	Percentage of firm given as options, (s)	Effort (Y)	Stockholders Equity Value (SEV)	Expected compensation, realistic valuation	Expected compensation, managers valuation	Sum of SEV and realistic expected compensation
	1	2	3	4	5	6	7	8
1	40.71	0.5944	1.40%	47.083	68099.42	441.89	441.89	68541.31
1.5	48.16	0.6891	1.35%	49.867	69580.04	353.41	513.34	69933.45
2	55.88	0.7910	1.35%	51.393	70417.74	278.65	598.49	70696.39
2.5	63.74	0.8962	1.38%	52.351	70958.63	217.12	698.06	71175.75

expected compensation). In particular the optimal strike prices of the options that stockholders award overconfident managers are increasing with their overconfidence. While realistic managers estimate that there is a substantial probability that options with an at-the-money strike price will be worthless regardless of their effort, overconfident managers may believe that their efforts will enhance the values of such options making them valuable.

In practice executive options usually are provided with at-the-money strike prices. When overconfidence or some other behavioral biases are not present, theory has shown (see, e.g., Dittmann et al. 2010; Dittmann and Yu 2011; Palmon et al. 2008), contrary to Hall and Murphy, that at-the-money prices are not optimal. Hall and Murphy argue that at-the-money prices are optimal because they provide maximum sensitivity to stock prices, but their argument does not hold when the managers are risk averse and effort averse. Managers must be adequately compensated for their efforts and for risk taking, and a balance must be reached between their efforts, risk taking, and their pay. As Palmon et al. have shown, the optimal balance is reached by issuing in-the-money options which do not necessarily provide maximum sensitivity to stock prices. If managers are overconfident, however, that makes them more amenable for stock price sensitivity, and hence, they will prefer higher strike prices which are closer to the at-the-money options usually awarded in practice.

We also note in Table 55.1 that managerial overconfidence increases stockholders' equity value. Given that the compensation is determined so as to equate the manager's expected utility to the target expected utility, it follows from Table 55.1 that consistent with the results of Palmon and Venezia (2012), the total welfare of both the managers and the stockholders improves with increased managerial overconfidence. The fixed-level expected utility of the manager is determined according to their subjective, overoptimistic perception. However, when evaluated according to the realistic view, expected managerial compensation falls with overconfidence. We note that, nonetheless, the difference between the monetary expected compensations according to the overoptimistic and realistic expectations is smaller than the monetary gains to stockholders from overconfidence, so that the sum of realistic compensation and SEV rises with overconfidence (see column 8). Thus, also in terms of realistic monetary values, the welfare of the stakeholders (stockholders and managers) increases with overconfidence.

In Table 55.2 we provide sensitivity analysis examining the effect of each of the parameters on the behavior of stockholders and managers. We present the results of only one or two changes in each of the exogenous parameters, but we conduct many other simulations, and all provide the same qualitative results.[15] In all the panels, higher overconfidence measure is associated with higher strike prices, moneyness levels, optimal managerial effort, value of the stockholders' equity, and expected compensation according to the managers' expectations. They also are associated

[15]The results of these simulations can be obtained from the authors upon request.

with lower expected managerial compensation according to the realistic expectation. This indicates that the qualitative results obtained from the base case prevail also for a host of other parameters.

In panels A and B, we examine the effect of the fixed wages on the results. A higher wage level implies a lower value for the option component of the compensation. Imposing the use of lower-valued options, stockholders choose options that are more responsive to cash flow changes. This is obtained by an increase in the ownership percentage and in the strike price. In panels C and D, we set the coefficient of variation, σ, which equals 0.3 in the base case, to 0.2 and 0.4, respectively. We observe in panel D that facing a higher coefficient of variation, managers prefer a compensation that is less sensitive to firm cash flows, which is achieved by selecting a contract specifying a smaller ownership fraction and a lower strike price. Finally, in panels E and F, we observe the effects of varying risk aversion and in panels G and H those of varying effort aversion. Overall, higher risk aversion levels are associated with less risky compensations as they induce optimal contracts with a smaller option ownership percentage and a lower strike price. Higher effort aversion results in lower SEV and also in lower total monetary welfare.

The above sensitivity analysis shows that the effect of changing the parameters quite conforms to intuition, adding to the robustness of our results. We also note that regardless of the parameters considered, the effect of overconfidence on the qualitative behavior is the same as that observed from the base case. In particular, the higher the overconfidence, the higher the optimal strike prices and the closer they are to the at-the-money levels.

55.5 Conclusion

Our study suggests an explanation for the puzzling questions of why most incentive stock options are issued with at-the-money strike prices. This practice seems arbitrary and beyond its institutional appeal and its expired tax advantages; its main theoretical backing is that it provides the highest sensitivity to stock price. Several studies however have shown that in many cases it is inferior to awarding in-the-money options. Our analysis demonstrates that the optimal strike prices of incentive stock options when managers are overconfident are higher than the corresponding strike prices when managers are realistic, and are closer to the at-the-money strike prices awarded in practice. This makes at-the-money options more attractive to overconfident managers, and hence, given the ubiquity of overconfident managers, it provides support for the popularity of awarding such options. We also show that overoptimistic CEOs receive lower compensation than their realistic counterparts and that the stockholders benefit from their managers' bias. The combined welfare of the firm's stakeholders however is positively related to managerial overconfidence, hence providing support to the survival of managerial overconfidence.

Assef and Santos (2005) interpret the strike price as an intermediate instrument (between wages and stocks) in the incentive schemes for managers. Similarly one can interpret an in-the-money strike price as an intermediate instrument between a stock (zero strike price) and an at-the-money option. Since in practice, because of institutional reasons or inertia, firms are constrained to choose options with at-the-money strike price, they achieve their instrumental in-the-money strike price by choosing an appropriate weight of options relative to stock grants in their compensation contract. According to such an interpretation and from our results showing that higher overconfidence implies higher strike prices, it follows that the observable weight of options in the compensation contract may serve as a proxy for an unobservable degree of confidence.

Appendix 1

In this appendix we expand on the simulations we conduct. These simulations are intended to identify the contracts that yield the highest stockholders' equity value subject to manager's incentive compatibility and participation constraints. That is, the managers choose their effort optimally, and their resulting expected utility equals a predetermined level representing their alternative opportunities. Because we are studying the impact of overconfidence on the strike price, our calculations focus on the trade-off between the strike price and the fraction of the company that is awarded as options. For simplicity, we consider contracts that include only a fixed wage and options.

The first step in our simulation is the selection of the appropriate distribution of the company's cash flow as a function of managerial effort and the manager's utility as a function of managerial effort and compensation. In accordance with conventional assumptions in the options literature, we assume that the firms' cash flows, X, are lognormally distributed with the distribution function (55.1) where Y denotes the managerial extra effort (a managerial choice variable) and $\mu(Y)$ and σ denote, respectively, the mean and the standard deviation of the underlying normal distribution of the natural logarithm of X. We assume that managerial effort increases cash flows, that overconfident managers overestimate the impact of their effort on cash flows, and that the impact of effort on the mean of the natural logarithm of X is presented in Eq. 55.2.

We refer to Hek (1999) and Bitler et al. (2005) for the choice of the parameters and the shape of the manager's utility function that depends also on leisure.[16] We start with a base case of parameters and repeat the analysis for a large set of parameters around the base case. We chose the base case so that these parameters and the deviations around them that we also analyze cover the equivalent parameters used in similar studies. These simulations help verify that our results are robust to the choice of parameter values. They also are used to examine to what

[16]We found additional estimates of effort disutility (leisure utility) in the following papers: Dowell (1985), Kiker and Mendes de Oliveira (1990), and Prasch (2001). These estimates varied in the functional form as well as in the level of effort aversion.

extent the effects of changes in the parameter values on the outcomes coincide with economic intuition.

The parameter μ_0 serves as a numeraire for the other cash flows related parameters, and is chosen, without loss of generality, to equal 45,000. That, in the absence of managerial extra effort, the expected value of the company's cash flows is 45,000. Since the expected cash flows serve as numeraire, the ratio of the standard deviation of the cash flows per share to their expected value is a surrogate for the standard deviation of stock returns. Since Hall and Murphy (2000) used a standard deviation of 0.3, we chose this value also for our base case coefficient of variation.

The appropriate measure of risk aversion is harder to agree upon. Early estimates of risk aversion put this variable at around two (see, e.g., Mehra and Prescott 1985), but they are based on aggregate data and not on CEO compensation data.[17] In our study, in line with more advanced econometric methods (see, e.g., Campbell et al. 1996), we prefer using a base case risk aversion measure of four, slightly higher than the measure of three suggested by Malmendier and Tate (2008) and Hall and Liebman (1998). Our simulations (see, e.g., Glasserman 2003) and sensitivity analysis, of course, cover these parameters as well.

The next step in the simulation process is to identify, for each overconfidence level, the executive options' strike price that is optimal for stockholders. All the simulations were conducted using Mathematica. Because it is not possible to express the equity value as an explicit function of the strike price, we search for the optimal strike price by calculating the equity values that are associated with a set of discrete strike prices. Our search was facilitated by assuming that the stockholders know the manager's reservation expected utility. We assume that reservation utility to equal the utility obtained from a fixed salary of 100 with no extra effort.

For any given wage, the strike price and the fraction of the company awarded to the manager (which is a continuous variable representing the number of options the manager receives; we will henceforth use the latter expression) determine the value of the options to the managers and their cost to the stockholders. For each strike price and number of options, we then find the effort that the manager chooses to apply in order to maximize his/her expected utility Eq. 55.3. For each given strike price, the stockholders, well aware of the managers' reactions, will offer them the number of options that yield their reservation utility. We calculate the value of the stockholders' equity for each strike price (in thousands of dollars, using two digits beyond the decimal point) and identify the strike price that yields a maximum for stockholders' equity.

For each set of parameters for the cash flow distribution function and the managerial utility function, as well as for the several values of fixed salary (50 for the base case, 25 and 75 for the presented robustness simulations), we obtain the optimal effort, stockholders' equity value, and the expected managerial

[17] Similar estimates are provided in other contexts by Carpenter (2000), Constantinides et al. (2002), Epstein and Zin (1991), Friend and Blume (1975), and Levy (1994).

compensation according to the manager's overconfident view and the stockholders' realistic expectations. We repeat these simulations for several values of the overconfidence measure λ. Presented here however are just four such values: 1 for the realistic expectations and 1.5, 2, and 2.5 for increasing levels of overconfidence. We used quite a few simulations but choose to present a subset of the results as all showed the same qualitative results. In addition to verifying the robustness of the results to the choice of the parameter values, they also help examine to what extent the effects of changes in the parameter values on the outcomes coincide with economic intuition.

Acknowledgment We thank Darius Palia, Orly Sade, and seminar participants at Rutgers University and the Universitat Pompeu Fabra for helpful comments and suggestions. Contents

Abstract

The technique of using densities and conditional distributions to carry out consistent specification testing and model selection amongst multiple diffusion processes has received considerable attention from both financial theoreticians and empirical econometricians over the last two decades. In this chapter, we discuss advances to this literature introduced by Corradi and Swanson (J Econom 124:117–148, 2005), who compare the cumulative distribution (marginal or joint) implied by a hypothesized null model with corresponding empirical distributions of observed data. We also outline and expand upon

further testing results from Bhardwaj et al. (J Bus Econ Stat 26:176–193, 2008) and Corradi and Swanson (J Econom 161:304–324, 2011). In particular, parametric specification tests in the spirit of the conditional Kolmogorov test of Andrews (Econometrica 65:1097–1128, 1997) that rely on block bootstrap resampling methods in order to construct test critical values are first discussed. Thereafter, extensions due to Bhardwaj et al. (J Bus Econ Stat 26:176–193, 2008) for cases where the functional form of the conditional density is unknown are introduced, and related continuous time simulation methods are introduced. Finally, we broaden our discussion from single process specification testing to multiple process model selection by discussing how to construct predictive densities and how to compare the accuracy of predictive densities derived from alternative (possibly misspecified) diffusion models. In particular, we generalize simulation steps outlined in Cai and Swanson (J Empir Financ 18:743–764, 2011) to multifactor models where the number of latent variables is larger than three. We finish the chapter with an empirical illustration of model selection amongst alternative short-term interest rate models.

Multifactor diffusion process • Specification test • Out-of-sample forecasts • Conditional distribution • Model selection • Block bootstrap • Jump process

56.1 Introduction

The last three decades have provided a unique opportunity to observe numerous interesting developments in finance, financial econometrics, and statistics. For example, although starting as a narrow subfield, financial econometrics has recently transformed itself into an important discipline, equipping financial economic researchers and industry practitioners with immensely helpful tools for estimation, testing, and forecasting. One of these developments has involved the development of "state-of-the-art" consistent specification tests for continuous time models, including not only the geometric Brownian motion process used to describe the dynamics of asset returns (Merton (1973)) but also a myriad of other diffusion models used in finance, such as the Ornstein-Uhlenbeck process introduced by Vasicek (1977); the constant elastic volatility process applied by Beckers (1980); the square root process due to Cox et al. (1985); the so-called CKLS model by Chan et al. (1992); various three-factor models proposed Chen (1996); stochastic volatility processes such as generalized CIR of Andersen and Lund (1997); and the generic class of affine jump diffusion processes discussed in Duffle et al. (2000).[1]

The plethora of available diffusion models allow decision makers to be flexible when choosing a specification to be subsequently used in contexts ranging from equity and option pricing, to term structure modeling and risk management.

[1]For complete details, see Sect. 56.2.2.

Moreover, the use of high-frequency data when estimating such model, in continuous time contexts, allows investors to continuously update their dynamic trading strategies in real time.[2] However, for statisticians and econometricians, the vast number of available models has important implications for formalizing model selection and specification testing methods. This has led to several key papers that have recently been published in the area of parametric and nonparametric specification testing. Most of the papers focus on the ongoing "search" for correct Markov and stationary models that "fit" historical data and associated dynamics. In this literature, it is important to note that correct specification of a joint distribution is not the same as that of a conditional distribution, and hence the recent focus on conditional distributions, given that most models have an interpretation as conditional models. In summary, the key issue in the construction of model selection and specification tests of conditional distributions is the fact that knowledge of the transition density (or conditional distribution) in general cannot be inferred from knowledge of the drift and variance terms of a diffusion model. If the functional form of the density is available parametrically, though, one can test the hypothesis of correct specification of a diffusion via the probability integral transform approach of Diebold et al. (1998); the cross-spectrum approach of Hong (2001), Hong and Li (2005), and Hong et al. (2007); the martingalization-type Kolmogorov test of Bai (2003); or the normality transformation approaches of Bontemps and Meddahi (2005) and Duan (2003). Furthermore, if the transition density is unknown, one can construct a nonparametric test by comparing a kernel density estimator of the actual and simulated data, for example, as in Altissimo and Mele (2009) and Thompson (2008), or by comparing the conditional distribution of the simulated and the historical data, as in Bhardwaj et al. (2008). One can also use the methods of Aït-Sahalia (2002) and Aït-Sahalia et al. (2009), in which they compare closed form approximations of conditional densities under the null, using data-driven kernel density estimates.

For clarity and ease of presentation, we categorize the above literature into two areas. The first area, initiated by the seminal work of Aït-Sahalia (1996) and later followed by Pritsker (1998) and Jiang (1998), breaks new ground in the continuous time specification testing literature by comparing marginal densities implied by hypothesized null models with nonparametric estimates thereof. These sorts of tests examine one-factor specifications. The second area of testing, as initiated in Corradi and Swanson (2005), does not look at densities. Instead, they compare cumulative distributions (marginal, joint, or conditional) implied by a hypothesized null model with corresponding empirical distributions. A natural extension of these sorts of tests involves model selection amongst alternative predictive densities associated with competing models. While Corradi and Swanson (2005) focus on cases where the functional form of the conditional density is known, Bhardwaj et al. (2008) use simulation methods to examine testing in cases where the functional form of the conditional density is unknown. Corradi and Swanson (2011) and

[2]For further discussion, see Duong and Swanson (2010, 2011).

Cai and Swanson (2011) take the analysis of Bhardwaj et al. (2008) on Step further and focus on the comparison of out-of-sample predictive accuracy of possibly misspecified diffusion models, when the conditional distribution is not known in closed form (i.e., they "choose" amongst competing models based on predictive density model performance). The "best" model is selected by constructing tests that compare both predictive densities and predictive conditional confidence intervals associated with alternative models.

In this chapter, we primarily focus our attention on the second area of the model selection and testing literature.[3] One feature of all the tests that we shall discuss is that, given that they are based on the comparison of CDFs, they obtain parametric rates. Moreover, the tests can be used to evaluate single and multiple factor and dimensional models, regardless of whether or not the functional form of the conditional distribution is known.

In addition to discussing simple diffusion process specification tests of Corradi and Swanson (2005), we discuss tests discussed in Bhardwaj et al. (2008) and Corradi and Swanson (2011) and provide some generalizations and additional results. In particular, parametric specification tests in the spirit of the conditional Kolmogorov test of Andrews (1997) that rely on block bootstrap resampling methods in order to construct test critical values are first discussed. Thereafter, extensions due to Bhardwaj et al. (2008) for cases where the functional form of the conditional density is unknown are introduced, and related continuous time simulation methods are introduced. Finally, we broaden our discussion from single dimensional specification testing to multiple dimensional selection by discussing how to construct predictive densities and how to compare the accuracy of predictive densities derived from alternative (possibly misspecified) diffusion models as in Corradi and Swanson (2011). In addition, we generalize simulation and testing procedures introduced in Cai and Swanson (2011) to more complicated multifactor and multidimensional models where the number of latent variables is larger than three. These final tests can be thought of as continuous time generalizations of the discrete time "reality check" test statistics of White (2000), which are widely used in empirical finance (see, e.g., Sullivan et al. (1999, 2001)). We finish the chapter with an empirical illustration of model selection amongst alternative short-term interest rate models, drawing on Bhardwaj et al. (2008), Corradi and Swanson (2011) and Cai and Swanson (2011).

Of the final note is that the test statistics discussed here are implemented via use of simple bootstrap methods for critical value simulation. We use the bootstrap because the covariance kernels of the (Gaussian) asymptotic limiting distributions of the test statistics are shown to contain terms deriving from both the contribution of recursive parameter estimation error (PEE) and the time dependence of data. Asymptotic critical value thus cannot be tabulated in a usual way. Several methods can easily be implemented in this context. First one can use block bootstrapping procedures, as discussed below. Second one can use the conditional p-value

[3]For a recent survey on results in the first area of this literature, see Aït-Sahalia (2007).

approach of Corradi and Swanson (2002) which extends the work of Hansen (1996) and Inoue (2001) to the case of nonvanishing parameter estimation error. Third is the subsampling method of Politis et al. (1999), which has clear efficiency "costs," but is easy to implement. Use of the latter two methods yields simulated (or subsample based) critical values that diverge at rate equivalent to the block size length under the alternative. This is the main drawback to their use in our context. We therefore focus on use of a block bootstrap that mimics the contribution of parameter estimation error in a recursive setting and in the context of time series data. In general, use of the block bootstrap approach is made feasible by establishing consistency and asymptotic normality of both simulated generalized method of moments (SGMM) and nonparametric simulated quasi-maximum likelihood (NPSQML) estimators of (possibly misspecified) diffusion models, in a recursive setting, and by establishing the first-order validity of their bootstrap analogs.

The rest of the paper is organized as follows. In Sect. 56.2, we present our setup and discuss various diffusion models used in finance and financial econometrics. Section 56.3 outlines the specification testing hypotheses, presents the cumulative distribution-based test statistics for one-factor and multiple-factor models, discusses relevant procedures for simulation and estimation, and outlines bootstrap techniques that can be used for critical value tabulation. In Sect. 56.4, we present a small empirical illustration. Section 56.5 summarizes and concludes.

56.2 Setup

56.2.1 Diffusion Models in Finance and Financial Econometrics

For the past two decades, continuous time models have taken center stage in the field of financial econometrics, particularly in the context of structural modeling, option pricing, risk management, and volatility forecasting. One key advantage of continuous time models is that they allow financial econometricians to use the full information set that is available. With the availability of high-frequency data and current computation capability, one can update information, model estimates, and predictions in milliseconds. In this section, we will summarize some of the standard models that have been used in asset pricing as well as term structure modeling. Generally, assume that financial asset returns follow Ito-semimartingale processes with jumps, which are the solution to the following stochastic differential equation system:

$$\begin{aligned} X(t_-) = &\int_0^t b(X(s_-), \theta_0)ds - \lambda_0 t \int_Y y\phi(y)dy \\ &+ \int_0^t \sigma(X(s_-), \theta_0)dW(s) + \sum_{j=1}^{J_t} y_j, \end{aligned} \tag{56.1}$$

where $X(t_{-})$ is a cadlag process (right continuous with left limit) for $t \in \Re^{+}$ and is an N-dimensional vector of variables, $W(t)$ is an N-dimensional Brownian motion, $b(\cdot)$ is N-dimensional function of $X(t_{-})$, and $\sigma(\cdot)$ is an $N \times N$ matrix-valued function of $X(t_{-})$, where θ_0 is an unknown true parameter. J_t is a Poisson process with intensity parameter λ_0, λ_0 finite, and the N-dimensional jump size, y_j, is i.i.d. with marginal distribution given by ϕ. Both J_t and y_j are assumed to be independent of the driving Brownian motion, $W(t)$.[4] Also, note that $\int_Y y\phi(y)dy$ denotes the mean jump size, hereafter denoted by μ_0. Over a unit time interval, there are on average λ_0 jumps, so that over the time span $[0, t]$, there are on average $\lambda_0 t$ jumps. The dynamics of $X(t_{-})$ is then given by

$$\begin{aligned} dX(t) = {} & \big(b(X(t_{-}), \theta_0) - \lambda_0 \mu_{y,0}\big)dt \\ & + \sigma(X(t_{-}), \theta_0)dW(t) + \int_Y yp(dy, dt), \end{aligned} \tag{56.2}$$

where $p(dy, dt)$ is a random Poisson measure giving point mass at y if a jump occurs in the interval dt and $b(\cdot)$, $\sigma(\cdot)$ are the "drift" and "volatility" functions defining the parametric specification of the model. Hereafter, the same (or similar) notation is used throughout when models are specified.

Through not an exhaustive list, we review some popular models. Models are presented with the "true" parameters.

56.2.1.1 Diffusion Models Without Jumps

Geometric Brownian Motion (Log Normal Model)

In this setup, $b(X(t_{-}), \theta_0) = b_0 X(t)$ and $\sigma(X(t_{-}), \theta_0) = \sigma_0 X(t)$.

$$dX(t) = b_0 X(t)dt + \sigma_0 X(t)dW(t),$$

where b_0 and σ_0 are constants and $W(t)$ is a one-dimensional standard Brownian motion. (Below, other constants such as α_0, β_0, λ_0, γ_0, δ_0, η_0, κ_0, and Ω_0 are also used in model specifications.)

This model is popular in the asset pricing literature. For example, one can model equity prices according to this process, especially in the Black-Scholes option setup or in structured corporate finance.[5] The main drawback of this model is that the return process (log(price)) has constant volatility and is not time varying. However, it is widely used as a convenient "first" econometric model.

Vasicek (1977) and *Ornstein-Uhlenbeck Process*: The process is used to model asset prices, specifically in term structure modeling, and the specification is

$$dX(t) = (\alpha_0 + \beta_0 X(t))dt + \sigma_0 dW(t),$$

[4] Hereafter, $X(t_{-})$ denotes the cadlag, while X_t denotes discrete skeleton for $t = 1, 2, \ldots$.

[5] See Black and Scholes (1973) for details.

where $W(t)$ is a standard Brownian motion and α_0, β_0, and σ_0 are constants. β_0 is negative to ensure the mean reversion of $X(t)$.

Cox et al. (1985) use the following square root process to model the term structure of interest rates:

$$dX(t) = \kappa(\alpha_0 - X(t))dt + \sigma_0\sqrt{X(t)}dW(t),$$

where $W(t)$ is a standard Brownian motion, α_0 is the long-run mean of $X(t)$, κ measures the speed of mean reversion, and σ_0 is a standard deviation parameter and is assumed to be fixed. Also, non-negativity of the process is imposed, as $2\kappa\beta_0 > \sigma_0^2$.

Wong (1964) points out that in the CIR model, $X(t)$ with the dynamics evolving according to

$$dX(t) = ((\alpha_0 - \lambda_0) - X(t))dt + \sqrt{\alpha_0 X(t)}dW(t), \tag{56.3}$$

$$\alpha_0 > 0 \text{ and } \alpha_0 - \lambda_0 > 0,$$

belongs to the linear exponential (or Pearson) family with a closed form cumulative distribution. α_0 and λ_0 are fixed parameters of the model.

The constant elasticity of variance or CEV model is specified as follows:

$$dX(t) = \alpha_0 X(t)dt + \sigma_0 X(t)^{\beta_0/2}dW(t),$$

where $W(t)$ is a standard Brownian motion and α_0, σ_0, and β_0 are fixed constants.

Of note is that the interpretation of this model depends on β_0, i.e., in the case of stock prices, if $\beta_0 = 2$, then the price process $X(t)$ follows a lognormal diffusion; if $\beta_0 < 2$, then the model captures exactly the leverage effect as price and volatility are inversely correlated.

Amongst other authors, Beckers (1980) used this CEV model for stocks, Marsh and Rosenfeld (1983) apply a CEV parametrization to interest rates, and Emanuel and Macbeth (1982) utilize this setup for option pricing.

The *generalized constant elasticity of variance model is defined as follows*:

$$dX(t) = \left(\alpha_0 X(t)^{-(1-\beta_0)} + \lambda_0 X(t)\right)dt + \sigma_0 X(t)^{\beta_0/2}dW(t),$$

where the notation follows the CEV case. λ_0 is another parameter of the model. This process nests log diffusion when $\beta_0 = 2$ and nests square root diffusion when $\beta_0 = 1$.

Brennan and Schwartz (1979) and Courtadon (1982) analyze the model:

$$dX(t) = (\alpha_0 + \beta_0 X(t))dt + \sigma_0 X(t)^2 dW(t),$$

where α_0, β_0, σ_0 are fixed constants and $W(t)$ is a standard Brownian motion.

Duffie and Kan (1996) study the specification:

$$dX(t) = (\alpha_0 + X(t))dt + \sqrt{\beta_0 + \gamma_0 X(t)}dW(t),$$

where $W(t)$ is a standard Brownian motion and α_0, β_0, and γ_0 are fixed parameters.

Aït-Sahalia (1996) looks at a general case with general drift and CEV diffusion:

$$dX(t) = \left(\alpha_0 + \beta_0 X(t) + \gamma_0 X(t)^2 + \eta_0/X(t)\right)dt + \sigma_0 X(t)^{\beta_0/2}dW(t).$$

In the above expression, α_0, β_0, γ_0, η_0, σ_0, and β_0 are fixed constants and $W(t)$ is again a standard Brownian motion.

56.2.1.2 Diffusion Models with Jumps

For term structure modeling in empirical finance, the most widely studied class of models is the family of affine processes, including diffusion processes that incorporate jumps.

Affine Jumps Diffusion Model: $X(t_{-})$ is defined to follow an affine jump diffusion if

$$dX(t) = \kappa_0(\alpha_0 \pm X(t))dt + \Omega_0\sqrt{D(t)}dW(t) + dJ(t),$$

where $X(t_{-})$ is an N-dimensional vector of variables of interest and is a cadlag process, $W(t)$ is an N-dimensional independent standard Brownian motion, κ_0 and Ω_0 are square $N \times N$ matrices, α_0 is a fixed long-run mean, and $D(t)$ is a diagonal matrix with ith diagonal element given by

$$d_{ii}(t) = \theta_{0i} + \delta'_{0i}X(t).$$

In the above expressions, θ_{0i} and $\delta\prime_{0i}$ are constants. The jump intensity is assumed to be a positive, affine function of $X(t)$, and the jump size distribution is assumed to be determined by its conditional characteristic function. The attractive feature of this class of affine jump diffusions is that, as shown in Duffie et al. (2000), it has an exponential affine structure that can be derived in closed form, i.e.,

$$\Phi(X(t)) = \exp\left(a(t) + b(t)'X(t)\right),$$

where the functions $a(t)$ and $b(t)$ can be derived from Riccati equations.[6] Given a known characteristic function, one can use either GMM to estimate the

[6]For details, see Singleton (2006), p. 102.

parameters of this jump diffusion, or one can used quasi-maximum likelihood (QML), once the first two moments are obtained. In the univariate case without jumps, as a special case, this corresponds to the above general CIR model with jumps.

56.2.1.3 Multifactor and Stochastic Volatility Model

Multifactor models have been widely used in the literature, particularly in option pricing, term structure, and asset pricing. One general setup has $(X(t), V(t))' = (X(t), V^1(t), \ldots, V^d(t))'$ where only the first element, the diffusion process X_t, is observed while $V(t) = (V^1(t), \ldots, V^d(t))'_{d\times 1}$ is latent. In addition, $X(t)$ can be dependent on $V(t)$. For instance, in empirical finance, the most well-known class of the multifactor models is the stochastic volatility model expressed as

$$\begin{pmatrix} dX(t) \\ dV(t) \end{pmatrix} = \begin{pmatrix} b_1(X(t), \theta_0) \\ b_2(V(t), \theta_0) \end{pmatrix} dt + \begin{pmatrix} \sigma_{11}(V(t), \theta_0) \\ 0 \end{pmatrix} dW_1(t) + \begin{pmatrix} \sigma_{12}(V(t), \theta_0) \\ \sigma_{22}(V(t), \theta_0) \end{pmatrix} dW_2(t), \tag{56.4}$$

where $W_1(t)_{1\times 1}$ and $W_2(t)_{1\times 1}$ are independent standard Brownian motions and $V(t)$ is latent volatility process. $b_1(\cdot)$ is a function of $X(t)$ and $b_2(\cdot)$, $\sigma_{11}(\cdot)$, $\sigma_{22}(\cdot)$, and $\sigma_{22}(\cdot)$ are general functions of $V(t)$, such that system of Eq. 56.4 is well defined. Popular specifications are the square root model of Heston (1993), the GARCH diffusion model of Nelson (1990), lognormal model of Hull and White (1987), and the eigenfunction models of Meddahi (2001). Note that in this stochastic volatility case, the dimension of volatility is $d = 1$. More general setup can involve d driving Brownian motions in $V(t)$ equation.

As an example, Andersen and Lund (1997) study the generalized CIR model with stochastic volatility, specifically

$$dX(t) = \kappa_{x0}(\overline{x}_0 - X(t))dt + \sqrt{V(t)}dW_1(t),$$

$$dX(t) = \kappa_{v0}(\overline{v}_0 - V(t))dt + \sigma_{v0}\sqrt{V(t)}dW_2(t),$$

where $X(t)$ and $V(t)$ are price and volatility processes, respectively, $\kappa_{x0}, \kappa_{v0} > 0$ to ensure stationarity, $\overline{x}_0$ is the long-run mean of (log) price process, and $\overline{v}_0$ and σ_{v0} are constants. $W_1(t)$ and $W_2(t)$ are scalar Brownian motions. However, $W_1(t)$ and $W_2(t)$ are correlated such that $dW_1(t)dW_2(t) = \rho dt$ where the correlation ρ is some constant $\rho \in [-1, 1]$. Finally, note that volatility is a square root diffusion process, which requires that $\kappa_{v0}\overline{v}_0 > \sigma_{v0}^2$.

Stochastic Volatility Model with Jumps (*SVJ*): A standard specification is

$$dX(t) = \kappa_{x0}\left(\overline{x}_0 - X(t)\right)dt + \sqrt{V(t)}dW_1(t) + J_u dq_u - J_d dq_d,$$

$$dV(t) = \kappa_{v0}(\overline{v}_0 - V(t))dt + \sigma_{v0}\sqrt{V(t)}dW_2(t),$$

where q_u and q_d are Poisson processes with jump intensity parameters λ_u and $\lambda_{d,}$ respectively, and are independent of the Brownian motions $W_1(t)$ and $W_2(t)$. In particular, λ_u is the probability of a jump-up, $\Pr(dq_u\,(t) = 1) = \lambda_u$, and λ_d is the probability of a jump-down, $\Pr(dq_d(t) = 1) = \lambda_d$. J_u and J_d are jump-up and jump-down sizes and have exponential distributions: $f(J_u) = \frac{1}{\varsigma_u}\exp\left(-\frac{J_u}{\varsigma_u}\right)$ and $f(J_d) = \frac{1}{\varsigma_d}\exp\left(-\frac{J_d}{\varsigma_d}\right)$, where ς_u, $\varsigma_d > 0$ are the jump magnitudes, which are the means of the jumps, J_u and J_d.

Three-Factor Model (*CHEN*): The three-factor model combines various features of the above models, by considering a version of the oft examined three-factor model due to Chan et al. (1992), which is discussed in detail in Dai and Singleton (2000). In particular,

$$\begin{aligned} dX(t) &= \kappa_{x0}(\theta(t) - X(t))dt + \sqrt{V(t)}dW_1(t), \\ dV(t) &= \kappa_{v0}(\overline{v} - V(t))dt + \sigma_{v0}\sqrt{V(t)}dW_2(t), \\ d\theta(t) &= \kappa_{\theta 0}\left(\overline{\theta}(t) - \theta(t)\right)dt + \sigma_{\theta 0}\sqrt{\theta(t)}dW_3(t), \end{aligned} \tag{56.5}$$

where $W_1(t)$, $W_2(t)$ $W_3(t)$ are independent Brownian motions and V and θ are the stochastic volatility and stochastic mean of $X(t)$, respectively. κ_{x0}, κ_{v0}, $\kappa_{\theta 0}$, $\overline{v_0}$, $\overline{\theta_0}$, σ_{v0}, $\sigma_{\theta 0}$ are constants. As discussed above, non-negativity for $V(t)$ and $\theta(t)$ requires that $2\kappa_{v0}\overline{v}_0 > \sigma_{v0}^2$ and $2\kappa_{\theta 0}\overline{\theta}_0 > \sigma_{\theta 0}^2$.

Three-Factor Jump Diffusion Model (*CHENJ*): Andersen et al. (2004) extend the three-factor Chen (1996) model by incorporating jumps in the short rate process, hence improving the ability of the model to capture the effect of outliers and to address the finding by Piazzesi (2004, 2005) that violent discontinuous movements in underlying measures may arise from monetary policy regime changes. The model is defined as follows:

$$\begin{aligned} dX(t) &= \kappa_{x0}(\theta(t) - X(t))dt + \sqrt{V(t)}dW_1(t) + J_u dq_u - J_d dq_d, \\ dV(t) &= \kappa_{v0}\Big(\overline{v}_0 - V(t))dt + \sigma_{v0}\sqrt{V(t)}dW_2(t), \\ d\theta(t) &= \kappa_{\theta 0}\Big(\overline{\theta}_0 - \theta(t))dt + \sigma_{\theta 0}\sqrt{\theta(t)}dW_3(t) \end{aligned} \tag{56.6}$$

where all parameters are similar as in Eq. 56.5; $W_1(t)$, $W_2(t)$, and $W_3(t)$ are independent Brownian motions; and q_u and q_d are Poisson processes with jump intensities λ_{u0} and λ_{d0}, respectively, and are independent of the Brownian motions $W_r(t)$, $W_v(t)$, and $W_\theta(t)$. In particular, λ_{u0} is the probability of a jump-up, $\Pr(dq_u(t) = 1) = \lambda_{u0}$, and λ_{d0} is the probability of a jump-down, $\Pr(dq_d(t) = 1) = \lambda_{d0}$. J_u and J_d are jump-up and jump-down sizes and have exponential distributions $f(J_u) = \frac{1}{\varsigma_{u0}} \exp\left(-\frac{J_u}{\varsigma_{u0}}\right)$ and $f(J_d) = \frac{1}{\varsigma_{d0}} \exp\left(-\frac{J_d}{\varsigma_{d0}}\right)$, where $\varsigma_{u0}, \varsigma_{d0} > 0$ are the jump magnitudes, which are the means of the jumps J_u and J_d.

56.2.2 Overview on Specification Tests and Model Selection

The focus in this chapter is specification testing and model selection. The "tools" used in this literature have been long established. Several key classical contributions include the Kolmogorov-Smirnov test (see, e.g., Kolmogorov (1933) and Smirnov (1939)), various results on empirical processes (see, e.g., Andrews (1993) and the discussion in Chap. 19 of van der Vaart (1998) on the contributions of Glivenko, Cantelli, Doob, Donsker, and others), the probability integral transform (see, e.g., Rosenblatt (1952)), and the Kullback–Leibler information criterion (see, e.g., White (1982) and Vuong (1989)). For illustration, the empirical distribution mentioned above is crucial in our discussion of predictive densities because it is useful in estimation, testing, and model evaluation. Let Y_t is a variable of interest with distribution F and parameter θ_0. The theory of empirical distributions provides a result that

$$\frac{1}{\sqrt{T}} \sum_{t=1}^{T} (1\{Y_t \leq u\} - F(u|\theta_0))$$

satisfies a central limit theorem (with a parametric rate) if T is large (i.e., asymptotically). In the above expression, $1\{Y_t \leq u\}$ is the indicator function which takes value 1 if $Y_t \leq u$ and 0 otherwise. In the case where there is parameter estimation error, we can use more general results in Chap. 19 of van der Vaart (1998). Define

$$P_T(f) = \frac{1}{T} \sum_{i=1}^{T} f(Y_i) \text{ and } P(f) = \int f dP,$$

where P is a probability measure associated with F. Here, $P_n(f)$ converges to $P(f)$ almost surely for all the measurable functions f for which $P(f)$ is defined. Suppose one wants to test the null hypothesis that P belongs to a certain family $\{P_{\theta_0} : \theta_0 \in \Theta\}$, where θ_0 is unknown; it is natural to use a measure of the discrepancy between P_n and $P_{\hat{\theta}}$ for a reasonable estimator $\hat{\theta}_t$ of θ_0. In particular, if $\hat{\theta}_t$ converges to θ_0 at a root-T rate, $\frac{1}{\sqrt{T}} \left(P_T - P_{\hat{\theta}t}\right)$ has been shown to satisfy a central limit theorem.[7]

With regard to dynamic misspecification and parameter estimation error, the approach discussed for the class of tests in this chapter allows for the construction

[7]See Theorem 19.23 in van der Vaart (1998) for details.

of statistics that admit for dynamic misspecification under both hypotheses. This differs from other classes of tests such as the framework used by Diebold et al. (1998), Hong (2001), and Bai (2003) in which correction dynamic specification under the null hypothesis is assumed. In particular, DGT use the probability integral transform to show that $F_t(Y_t|\Im_{t-1},\theta_0) = \int_{-\infty}^{Y_t} f_t(y|\Im_{t-1},\theta_0)dy$ is identically and independently distributed as a uniform random variable on [0; 1], where $F_t(\cdot)$ and $f_t(\cdot)$ are a parametric distribution and density with underlying parameter θ_0, Y_t is again our random variable of interest, and $\Im_t$ is the information set containing all "relevant" past information. They thus suggest using the difference between the empirical distribution of $F_t\left(Y_t\middle|\Im_{t-1},\hat{\theta}_t.\right)$ and the 45° line as a measure of "goodness of fit," where $\hat{\theta}_t$ is some estimator of θ_0. This approach has been shown to be very useful for financial risk management (see, e.g., Diebold et al. (1999)), as well as for macroeconomic forecasting (see, e.g., Diebold et al. (1998) and Clements and Smith (2000, 2002)). Similarly, Bai (2003) develops a Kolmogorov-type test of $F_t(Y_t|\Im_{t-1},\theta_0)$ on the basis of the discrepancy between $F_t\left(Y_t\middle|\Im_{t-1},\hat{\theta}_t.\right)$ and the CDF of a uniform on [0; 1]. As the test involves estimator $\hat{\theta}_t$, the limiting distribution reflects the contribution of parameter estimation error and is not nuisance parameter-free. To overcome this problem, Bai (2003) proposes a novel approach based on a martingalization argument to construct a modified Kolmogorov test which has a nuisance parameter-free limiting distribution. This test has power against violations of uniformity but not against violations of independence. Hong (2001) proposes another related interesting test, based on the generalized spectrum, which has power against both uniformity and independence violations, for the case in which the contribution of parameter estimation error vanishes asymptotically. If the null is rejected, Hong (2001) also proposes a test for uniformity robust to nonindependence, which is based on the comparison between a kernel density estimator and the uniform density. Two features differentiate the tests surveyed in this chapter from the tests outlined in the other papers mentioned above. First, the tests discussed here assume strict stationarity. Second, they allow for dynamic misspecification under the null hypothesis. The second feature allows us to obtain asymptotically valid critical values even when the conditioning information set does not contain all of the relevant past history. More precisely, assume that we are interested in testing for correct specification, given a particular information set which may or may not contain all of the relevant past information. This is important when a Kolmogorov test is constructed, as one is generally faced with the problem of defining $\Im_{t-1}$. If enough history is not included, then there may be dynamic misspecification. Additionally, finding out how much information (e.g., how many lags) to include may involve pre-testing, hence leading to a form of sequential test bias. By allowing for dynamic misspecification, such pre-testing is not required. Also note that critical values derived under correct specification given $\Im_{t-1}$ are not in general valid in the case of correct specification given a subset of $\Im_{t-1}$. Consider the following example. Assume that we are interested in testing whether the conditional distribution of $Y_t|Y_{t-1}$ follows normal distribution $N(\alpha_1 Y_{t-1}, \sigma_1)$. Suppose also that in actual fact the "relevant" information set has $\Im_{t-1}$ including both Y_{t-1} and Y_{t-2}, so that the true conditional model is $Y_t|\Im_{t-1} = Y_t|Y_{t-1}, Y_{t-2} = N(\alpha_1 Y_{t-1} + \alpha_2 Y_{t-2}, \sigma_2)$. In this case, correct specification holds with respect to the information contained in X_{t-1}; but there is dynamic misspecification with respect to Y_{t-1} and Y_{t-2}. Even without taking account of parameter estimation error, the critical values obtained assuming correct dynamic specification are invalid, thus leading to invalid inference. Stated differently, tests that are designed to have power against both uniformity and independence violations (i.e., tests that assume correct dynamic specification under the null) will reject an inference which is incorrect, at least in the sense that the "normality" assumption is not false. In summary, if one is interested in the particular problem of testing for correct specification for a given information set, then the approach of tests in this chapter is appropriate.

56.3 Consistent Distribution-Based Specification Tests and Predictive Density-Type Model Selection for Diffusion Processes

56.3.1 One-Factor Models

In this section, we outline the setup for the general class of one-factor jump diffusion specifications. All analyses carry through to the more complicated case of multifactor stochastic volatility models which we will elaborate upon in the next subsection. In the presentation of the tests, we follow a view that all candidate models, either single or multiple dimensional ones, are approximations of reality and can thus be misspecified. The issue of correct specification (or misspecification) of a single model and the model selection test for choosing amongst multiple competing models allow for this feature.

To begin, fix the time interval $[0, T]$ and consider a given single one-factor candidate model the same as Eq. 56.1, with the true parameters θ_0, λ_0, μ_0 to be replaced by its pseudo true analogs $\theta^{\dagger}$, λ, μ, respectively, and $0 \leq t \leq T$:

$$X(t_-) = \int_0^t b\left(X(s_-), \theta^{\dagger}\right) ds - \lambda t \int_Y y\phi(y) dy + \int_0^t \sigma\left(X(s_-), \theta^{\dagger}\right) dW(s) + \sum_{j=1}^{J_t} y_j,$$

or

$$\begin{aligned} dX(t-) = {} & \left(b\left(X(t-), \theta^{\dagger}\right) - \lambda\mu\right) dt. \\ & + \sigma\left(X(t-), \theta^{\dagger}\right) dW(t) + \int_Y y p(dy, dt), \end{aligned} \tag{56.7}$$

where variables are defined the same as in Eqs. 56.1 and 56.2. Note that as the above model is the one-factor version of Eqs. 56.1 and 56.2 where the dimension of $X(t_-)$ is 1×1, $W(t)$ is a one-dimensional standard Brownian motion and jump size, and y_j

is one-dimensional variable for all j. Also note both J_t and y_j are assumed to be independent of the driving Brownian motion.

If the single model is correctly specified, then $b(X(t-),\theta^{\dagger}) = b_0(X(t-),\theta_0)$, $\sigma(X(t-),\theta^{\dagger}) = \sigma_0(X(t-),\theta_0)$, $\lambda = \lambda_0$, $\mu = \mu_0$, and $\phi = \phi_0$ where $b_0(X(t-),\theta_0)$, $\sigma_0(X(t-),\theta_0)$, λ_0, μ_0, ϕ_0 are unknown and belong to the true specification.

Now consider a different case (not a single model) where m candidate models are involved. For model k with $1 \le k \le m$, denote its corresponding specification to be $(b_k(X(t_-),\theta_k^{\dagger}), \sigma_k(X(t_-),\theta_k^{\dagger}), \lambda_k, \mu_k, \phi_k)$. Two scenarios immediate arise. Firstly, if the model k is correctly specified, then $b_k(X(t_-),\theta_k^{\dagger}) = b_0(X(t_-),\theta_0)$, $\sigma_k(X(t_-),\theta_k^{\dagger}) = \sigma_0(X(t_-),\theta_0)$, $\lambda_k = \lambda_0$, $\mu_k = \mu_0$, and $\phi_k = \phi_0$ which are similar to the case of a single model. In the second scenario, all the models are likely to be misspecified and modelers are faced with the choice of selecting the "best" one. This type of problem is well fitted into the class of accuracy assessment tests initiated earlier by Diebold and Mariano (1995) or White (2000).

The tests discussed hereafter are Kolmogorov-type tests based on the construction of cumulative distribution functions (CDFs). In a few cases, the CDF is known in closed form. For instance, for the simplified version of the CIR model as in Eq. 56.3, $X(t)$ belongs to the linear exponential (or Pearson) family with the gamma CDF of the form[8]

$$F(u,\alpha,\lambda) = \frac{\int_0^u \left(\frac{\lambda}{2}\right)^{-2(1-\alpha/\lambda)-1} \exp\left(-x/\left(\frac{\lambda}{2}\right)\right)dx}{\Gamma(2(1-\alpha/\lambda))} \tag{56.8}$$

where $\Gamma(x) = \int_0^{\infty} t^x \exp(-t)dt$, and α, λ are constants.

Furthermore, if we look at the pure diffusion process without jumps

$$dX(t) = b\left(X(t),\theta^{\dagger}\right)dt + \sigma\left(X(t),\theta^{\dagger}\right)dW(t), \tag{56.9}$$

where $b(\cdot)$ and $\sigma = \sigma(\cdot)$ are drift and volatility functions, it is known that the stationary density, say $f(x,\theta^{\dagger})$, associated with the invariant probability measure can be expressed explicitly as[9]

$$f\left(x,\theta^{\dagger}\right) = \frac{c\left(\theta^{\dagger}\right)}{\sigma^2\left(x,\theta^{\dagger}\right)}\exp\left(\int^x \frac{2b\left(u,\theta^{\dagger}\right)}{\sigma^2\left(u,\theta^{\dagger}\right)}du\right),$$

where $c(\theta^{\dagger})$ is a constant ensuring that f integrates to one. The CDF, say $F(u,\theta^{\dagger}) = \int^u f(x,\theta^{\dagger})\, dx$, can then be obtained using available numerical integration procedures.

However, in most cases, it is impossible to derive the CDFs in closed form. To obtain a CDF in such cases, a more general approach is to use simulation. Instead of

[8]See Wong (1964) for details.

[9]See Karlin and Taylor (1981) for details.

estimating the CDF directly, simulation techniques estimate the CDF indirectly utilizing its generated sample paths and the theory of empirical distributions. The specification of a specific diffusion process will dictate the sample paths and thereby corresponding test outcomes.

Note that in the historical context, many early papers in this literature are probability density based. For example, in a seminal paper, Ait-Sahalia (1996) compares the marginal densities implied by hypothesized null models with nonparametric estimates thereof. Following the same framework of correct specification tests, Corradi and Swanson (2005) and Bhardwaj et al. (2008), however, do not look at densities. Instead, they compare the cumulative distribution (marginal or joint) implied by a hypothesized null model with the corresponding empirical distribution. While Corradi and Swanson (2005) focus on the known unconditional distribution, Bhardwaj et al. (2008) look at the conditional simulated distributions. Corradi and Swanson (2011) make extensions to multiple models in the context of out-of-sample accuracy assessment tests. This approach is somewhat novel to this continuous time model testing literature.

Now suppose we observe a discrete sample path $X_1, X_2, \ldots, X_T$ (also referred as skeletons).[10] The corresponding hypotheses can be set up as follows:

Hypothesis 1 Unconditional Distribution Specification Test of a Single Model

$H_0 : F(u,\theta^\dagger) = F_0(u,\theta_0)$, for all u, a.s.

$H_A : \Pr(F(u,\theta^\dagger) - F_0(u,\theta_0) \neq 0) > 0$, for some $u \in U$, with nonzero Lebesgue measure.

where $F_0(u, \theta_0)$ is the true cumulative distribution implied by the above density, i.e., $F_0(u,\theta_0) = \Pr(X_t \leq u)$. $F\left(u, \theta^\dagger\right) = \Pr\left(X_t^{\theta^\dagger} \leq u\right)$ is the cumulative distribution of the proposed model. $X_t^{\theta^\dagger}$ is a skeleton implied by model (56.7).

Hypothesis 2 Conditional Distribution Specification Test of a Single Model

$H_0 : F_\tau(u|X_t, \theta^\dagger) = F_{0,\tau}(u|X_t, \theta_0)$, for all u, a.s.

$H_A : \Pr(F_\tau(u|X_t, \theta^\dagger) - F_{0,\tau}(u|X_t, \theta_0) \neq 0) > 0$, for some $u \in U$, with nonzero Lebesgue measure.

where $F_\tau\left(u|X_t, \theta^\dagger\right) = \Pr\left(X_{t+\tau}^{\theta^\dagger} \leq u \middle| X_t^{\theta^\dagger} = X_t\right)$ is τ-step ahead conditional distributions and $t = 1, \ldots, T - \tau$. $F_{0,\tau}(u|X_t, \theta_0)$ is τ-step ahead true conditional distributions.

Hypothesis 3 Predictive Density Test for Choosing Amongst Multiple Competing Models

The null hypothesis is that no model can outperform model 1 which is the benchmark model.[11]

[10] As mentioned earlier, we follow Corradi and Swanson (2005) by using notation $X(\cdot)$ when defining continuous time processes and X_t for a skeleton.

[11] See White (2000) for a discussion of a discrete time series analog to this case, whereby point rather than density-based loss is considered; Corradi and Swanson (2007b) for an extension of White (2000) that allows for parameter estimation error; and Corradi and Swanson (2006) for an extension of Corradi and Swanson (2007b) that allows for the comparison of conditional distributions and densities in a discrete time series context.

H_0:

$$\max_{k=2,\ldots,m} E_X\left(\left(F_{X_{1,t+\tau}^{\theta_1^\dagger}(X_t)}(u_2) - F_{X_{1,t+\tau}^{\theta_1^\dagger}(X_t)}(u_1)\right)\right.$$
$$\left. -(F_0(u_2|X_t) - F_0(u_1|X_t))\right)^2$$
$$- E_X\left(\left(F_{X_{k,t+\tau}^{\theta_k^\dagger}(X_t)}(u_2) - F_{X_{k,t+\tau}^{\theta_k^\dagger}(X_t)}(u_1)\right)\right.$$
$$\left. -(F_0(u_2|X_t) - F_0(u_1|X_t))\right)^2 .$$

H_A: negation of H_0
where

$$F_{X_{k,t+\tau}^{\theta_k^\dagger}(X_t)}(u) = F_k^\tau\left(u\middle|X_t, \theta_k^\dagger\right) = P_{\theta_k^\dagger}^\tau\left(X_{k,t+\tau}^{\theta_k^\dagger} \le u\middle|X_t^{\theta_k^\dagger} = X_t\right),$$

which is the conditional distribution of $X_{t+\tau}$, given X_t, and evaluated at u under the probability law generated by model k. $X_{k,t+\tau}^{\theta_k^\dagger}(X_t)$ with $1 \le \tau \le T - t$ is the skeleton implied by model k, parameter $\theta_k^\dagger$, and initial value X_t. Analogously, define $F_0^\tau(u|X_t, \theta_0) = P_{\theta_0}^\tau(X_{t+\tau} \le u|X_t)$ to be the "true" conditional distribution.

Note that the three hypotheses expressed above apply exactly the same to the case of multifactor diffusions. Now, before moving to the statistics description section, we briefly explain the intuitions in facilitating construction of the tests.

In the first case (Hypothesis 1), Corradi and Swanson (2005) construct a Kolmogorov-type test based on comparison of the empirical distribution and the unconditional CDF implied by the specification of the drift, variance, and jumps. Specifically, one can look at the scaled difference between

$$F\left(u, \theta^\dagger\right) = \Pr\left(X_t^{\theta^\dagger} \le u\right) = \int^u f\left(x, \theta^\dagger\right)dx$$

and estimator of the true $F_0(u|X_t, \theta_0)$, the empirical distribution of X_t defined as

$$\frac{1}{T}\sum_{t=1}^{T} 1\{X_t \le u\},$$

where $1\{Y_t \le u\}$ is indicator function which takes value 1 if $Y_t \le u$ and 0 otherwise.

Similarly for the second case of conditional distribution (Hypothesis 2), the test statistic V_T can be a measure of the distance between the τ-*step* ahead conditional distribution of $X_{t+\tau}^{\theta^\dagger}$, given $X_t^{\theta^\dagger} = X_t$, as

$$F_\tau\left(u\middle|X_t,\theta^\dagger\right) = \Pr\left(X_{t+\tau}^{\theta^\dagger} \le u\middle|X_t^{\theta^\dagger} = X_t\right),$$

to an estimator of the true $F_{0,\tau}(u|X_t,\theta_0)$, the conditional empirical distribution of $X_{t+\tau}$ conditional on the initial value X_t defined as

$$\frac{1}{T-\tau}\sum_{t=1}^{T-\tau} 1\{X_{t+\tau} \le u\},$$

In the third case (Hypothesis 3), model accuracy is measured in terms of a distributional analog of mean square error. As is commonplace in the out-of-sample evaluation literature, the sample of T observations is divided into two subsamples, such that $T = R + P$, where only the last P observations are used for predictive evaluation. A τ-step ahead prediction error under model k is $1\{u_1 \le X_{t+\tau} \le u_2\} - (F_k^\tau(u_2|X_t,\ \theta_k^\dagger) - F_k^\tau(u_1|X_t,\ \theta_k^\dagger))$ where $2 \le k \le m$ and similarly for model 1 by replacing index k with index 1. Suppose we can simulate $P - \tau$ paths of τ-step ahead skeleton[12] using X_t as starting values where $t = R, \ldots, R + P - \tau$, from which we can construct a sample of $P - \tau$ prediction errors. Then, these prediction errors can be used to construct a test statistic for model comparison. In particular, model 1 is defined to be more accurate than model k if

$$\begin{aligned} &F\left(\left(\begin{array}{c}\left(F_1^\tau\left(u_2\middle|X_t,\theta_1^\dagger\right) - F_1^\tau\left(u_1\middle|X_t,\theta_1^\dagger\right)\right)\\ -\left(F_1^\tau(u_2|X_t,\theta_0) - F_1^\tau(u_1|X_t,\theta_0)\right)\end{array}\right)^2\right)\\ &\quad < E\left(\left(\begin{array}{c}\left(F_k^\tau\left(u_2^\tau\middle|X_t,\theta_1^\dagger\right) - F_k^\tau\left(u_1^\tau\middle|X_t,\theta_k^\dagger\right)\right)\\ -\left(F_0^\tau(u_2|X_t,\theta_0) - F_0^\tau(u_1|X_t,\theta_0)\right)\end{array}\right)^2\right),\end{aligned}$$

where $E(\cdot)$ is an expectation operator and $E(1\{u_1 \le X_{t+\tau} \le u_2\}|X_t) = F_0^\tau(u_2|X_t,\theta_0) - F_0^\tau(u_1|X_t,\theta_0)$. Concretely, model k is worse than model 1 if on average τ-step ahead prediction errors under model k is larger than that of model 1.

Finally, it is important to point out some main features characterized by all the three test statistics. Processes $X(t)$ hereafter are required to satisfy the regular conditions, i.e., assumptions A1–A8 in Corradi and Swanson (2011). Regarding model estimation (in Sect. 56.3.3), $\theta^\dagger$ and $\theta_k^\dagger$ are unobserved and need to be estimated. While Corradi and Swanson (2005) and Bhardwaj et al. (2008) utilize (recursive) simulated generalized method of moments (SGMM), Corradi and Swanson (2011) make extension to (recursive) nonparametric simulated

[12]See Sect. 56.3.3.1 for model simulation details.

quasi-maximum likelihood (NPSQML). For the unknown distribution and conditional distribution, it will be pointed out in Sect. 56.3.3.2 that $F(u,\theta^{\dagger})$, $F_{\tau}(u|X_t, \theta^{\dagger})$, and $F_{X_{k,t+\tau}^{\theta_k^{\dagger}}(X_t)}(u)$ can be replaced by their simulated counterparts using the (recursive) SGMM and NPSQML parameter estimators. In addition, test statistics converge to functional of Gaussian processes with covariance kernels that reflect time dependence of the data and the contribution of parameter estimation error (PEE). Limiting distributions are not nuisance parameter-free, and critical values thereby cannot be tabulated by the standard approach. All the tests discussed in this chapter rely on the bootstrap procedures for obtaining the asymptotically valid critical values, which we will describe in Sect. 56.3.4.

56.3.1.1 Unconditional Distribution Tests

For one-factor diffusions, we outline the construction of unconditional test statistics in the context where CDF is known in closed form. In order to test the **Hypothesis 1**, consider the following statistic:

$$V_{T,N,h}^2 = \int_U V_{T,N,h}^2(u)\pi(u),$$

where

$$V_{T,N,h} = \frac{1}{\sqrt{T}}\sum_{t=1}^{T}\left(1\{X_t \le u\} - F\left(u, \hat{\theta}_{T,N,h}\right)\right).$$

In the above expression, U is a compact interval and $\int_U \pi(u)du = 1, 1\{X_t \le u\}$ is again the indicator function which returns value 1 if $X_t \le u$ and 0 otherwise. Further, as defined in Sect. 56.3.3, $\hat{\theta}_{T,N,h}$ hereafter is a simulated estimator where T is sample size and h is the discretization interval used in simulation. In addition, with the abuse of notation, N is a generic notation throughout this chapter, i.e., $N = L$, the length of each simulation path for (recursive) SGMM, and $N = M$, the number of random draws (simulated paths) for (recursive) NPQML estimator.[13] Also note in our notation that as the above test is in sample specification test, the estimator and the statistics are constructed using the entire sample, i.e., $\hat{\theta}_{T,N,h}$.

It has been shown in Corradi and Swanson (2005) that under regular conditions and if the estimator is estimated by SGMM, the above statistics converges to a functional of Gaussian process.[14] In particular, pick the choice T, $N \to \infty$, $h \to 0$, $T/N \to 0$, and $Th^2 \to 0$.

[13] M is often chosen to coincide with S, the number of simulated paths used when simulating distributions.

[14] For details and the proof, see Theorem 1 in Corradi and Swanson (2005).

Under the null,

$$V_{T,N,h}^2 \to \int_U Z^2(u)\pi(u),$$

where Z is a Gaussian process with covariance kernel. Hence, the limiting distribution of $V_{T,N,h}^2$ is a functional of a Gaussian process with a covariance kernel that reflects both PEE and the time series nature of the data. As $\hat{\theta}_{T,N,h}$ is root-T consistent, PEE does not disappear in the asymptotic covariance kernel.

Under H_A, there exists an $\varepsilon > 0$ such that

$$\lim_{T\to\infty} \Pr\left(\frac{1}{T}V_{T,N,h}^2 > \varepsilon\right) = 1.$$

For the asymptotic critical value tabulation, we use the bootstrap procedure. In order to establish validity of the block bootstrap under SGMM with the presence of PEE, the simulated sample size should be chosen to grow at a faster rate than the historical sample, i.e., $T/N \to 0$.

Thus, we can follow the steps in appropriate bootstrap procedure in Sect. 56.3.4. For instance, if the SGMM estimator is used, the bootstrap statistic is

$$V_{T,N,h}^{2*} = \int\limits_U V_{T,N,h}^{2*}(u)\pi(u)du,$$

where

$$V_{T,N,h}^{2*} = \frac{1}{\sqrt{T}}\sum_{t=1}^{T}\Big(\left(1\left\{X_t^* \le u\right\} - 1\{X_t \le u\}\right)$$
$$-\left(F\left(u, \hat{\theta}_{T,N,h}^*\right) - F\left(u, \hat{\theta}_{T,N,h}\right)\right)\Big).$$

In the above expression, $\hat{\theta}_{T,N,h}^*$ is the bootstrap analog of $\hat{\theta}_{T,N,h}^*$ and is estimated by the bootstrap sample $X_1^*, \ldots, X_T^*$ (see Sect. 56.3.4). With appropriate conditions, Corradi and Swanson (2005) show that under the null, $V_{T,N,h}^{2*}$ has a well-defined limiting distribution which coincides with that of $V_{T,N,h.}^2$ We then can straightforwardly derive the bootstrap critical value by following Steps 1–5 in Sect. 56.3.4. In particular, in Step 5, the idea is to perform B bootstrap replications (B large) and compute the percentiles of the empirical distribution of the B bootstrap statistics. Reject H_0 if $V_{T,N,h}^2$ is greater than the $(1-\alpha)$th percentile of this empirical distribution. Otherwise, do not reject H_0.

56.3.1.2 Conditional Distribution Tests

Hypothesis 2 tests correct specification of the conditional distribution, implied by a proposed diffusion model. In practice, the difficulty arises from the fact that the functional form of neither τ-step ahead conditional distributions $F_\tau(u|X_t, \theta^\dagger)$ nor $F_{0,\tau}(u|X_t, \theta_0)$ is unknown in most cases. Therefore, Bhardwaj et al. (2008) develop bootstrap specification test on the basis of simulated distribution using the SGMM estimator.[15] With the important inputs leading to the test such as simulated estimator, distribution simulation, and bootstrap procedures to be presented in the next section,[16] the test statistic is defined as

$$Z_T = \sup_{u\times v\in U\times V} |Z_T(u, v)|,$$

where

$$Z_T(u, v) = \frac{1}{\sqrt{T-\tau}} \sum_{t=1}^{T-\tau} \left(\begin{array}{c} \frac{1}{S}\sum_{s=1}^{S} 1\left\{X_{s,t+\tau}^{\hat{\theta}_{T,N,h}} \le u\right\} \\ -(1\{X_{t+\tau} \le u\}) \end{array} \right),$$

with U and V compact sets on the real line. $\hat{\theta}_{T,N,h}$ is the simulated estimator using entire sample $X_1, \ldots, X_T$, and S is the number of simulated replications used in the estimation of conditional distributions as described in Sect. 56.3.3. If SGMM estimator is used (similar to unconditional distribution case and the same as in Bhardwaj et al. (2008)), then $N = L$, where L is the simulation length used in parameter estimation.

The above statistic is a simulation-based version of the conditional Kolmogorov test of Andrews (1997), which compare the joint empirical distribution:

$$\frac{1}{\sqrt{T-\tau}} \sum_{t=1}^{T-\tau} 1\{X_{t+\tau} \le u\} 1\{X_t \le v\},$$

with its semi-empirical/semi-parametric analog given by the product of

$$\frac{1}{\sqrt{T-\tau}} \sum_{t=1}^{T-\tau} F_{0,\tau}(u|X_t, \theta_0) 1\{X_t \le v\}.$$

Intuitively, if the null is not rejected, the metric distance between the two should asymptotically disappear. In the simulation context with parameter estimation error, the asymptotic limit of Z_T however is a nontrivial one. Bhardwaj et al. (2008) show that with the proper choice of T, N, S, h, i.e., T, N, S, $T^2/S \to \infty$ and h, T/N, T/S, Nh, $h^2T \to 0$, then

$$Z_T \xrightarrow{d} \sup_{u\times v\in U\times V} |Z(u, v)|,$$

where $Z(u, v)$ is a Gaussian process with a covariance kernel that characterizes (1) long-run variance we would have if we knew $F_{0,\tau}(u|X_t, \theta_0)$), (2) the contribution

[15] In this chapter, we assume that $X(\cdot)$ satisfies the regularity conditions stated in Corradi and Swanson (2011), i.e., assumptions A1–A8. Those conditions also reflect requirements A1–A2 in Bhardwaj et al. (2008). Note that the SGMM estimator used in Bhardwaj et al. (2008) satisfies the root-N consistency condition that Corradi and Swanson (2011) impose on their parameter estimator (see Assumption 4).

[16] See Sects. 56.3.3 and 56.3.4 for further details.

of parameter estimation error, and (3) The correlation between the first two.

Furthermore, under H_A, there exists some $\varepsilon > 0$ such that

$$\lim_{P\to\infty} \Pr\left(\frac{1}{\sqrt{T}} Z_T > \varepsilon\right) = 1.$$

As $T/S \to 0$, the contribution of simulation error is asymptotically negligible. The limiting distribution is not nuisance parameter-free and hence critical values cannot be tabulated directly from it. The appropriate bootstrap statistic in this context is

$$Z_T^* = \sup_{u\times v\in U\times V} \left|Z_T^*(u,v)\right|,$$

where

$$\begin{aligned} Z_T^* = (u,v) = {} & \frac{1}{\sqrt{T-\tau}} \sum_{t=1}^{T-\tau} 1\left\{X_t^* \le v\right\} \\ & \times \left(\frac{1}{S}\sum_{s=1}^{S} 1\left\{X_{s,t+\tau}^{\hat{\theta}^*_{T,N,h}} \le u\right\} - 1\left\{X_{t+\tau}^* \le u\right\}\right) \\ & - \frac{1}{\sqrt{T-\tau}} \sum_{t=1}^{T-\tau} 1\{X_t \le v\} \\ & \times \left(\frac{1}{S}\sum_{s=1}^{S} 1\left\{X_{s,t+\tau}^{\hat{\theta}^*_{T,N,h}} \le u\right\} - 1\{X_{t+\tau} \le u\}\right). \end{aligned}$$

In the above expression, $\hat{\theta}^*{}_{T,N,h}$ is the bootstrap parameter estimated using the resampled data X_t^* for $t = 1, \ldots, T-\tau$. $X_{s,t+\tau}^{\hat{\theta}^*_{T,N,h}}$, $s = 1, \ldots, S$ and $t = 1, \ldots, T-\tau$ is the simulated date under $\hat{\theta}^*_{T,N,h}$ and X_t^*; $t = 1, \ldots, T-\tau$ is a resampled series constructed using standard block bootstrap methods as described in Sect. 56.3.4. Note that in the original paper, Bhardwaj et al. (2008) propose bootstrap SGMM estimator for conditional distribution of diffusion processes. Corradi and Swanson (2011) extend the test to the case of simulated recursive NPSQML estimator. Regarding the generation of the empirical distribution of Z_T^* (asthmatically the same as Z_T), follow Steps 1–5 in the bootstrap procedure in Sect. 56.3.4. This yields B bootstrap replications (B large) of Z_T^*. One can then compare Z_T with the percentiles of the empirical distribution of Z_T^*, and reject H_0 if Z_T is greater than the $(1-\alpha)$th percentile. Otherwise, do not reject H_0. Tests carried out in this manner are correctly asymptotically sized and have unit asymptotic power.

56.3.1.3 Predictive Density Tests for Multiple Competing Models

In many circumstances, one might want to compare one (benchmark) model (model 1) against multiple competing models (models k, $2 \le k \le m$). In this case, recall in the null in **Hypothesis 3** that no model can outperform the benchmark model. In testing the null, we first choose a particular interval, i.e., $(u_1, u_2) \in U \times U$, where U is a compact set so that the objective is evaluation of predictive densities for a given range of values. In addition, in the recursive setting (not full sample is used to estimate parameters), if we use the recursive NPSQML estimator, say $\hat{\theta}_{1.t,N,h}$ and $\hat{\theta}_{k.t,N,h}$, for models 1 and k, respectively, then the test statistic is defined as

$$D^{Max}_{k,P,S}(u_1,u_2) = \max_{k=2,\ldots,m} D_{k,P,S}(u_1,u_2),$$

where

$$\begin{aligned} D_{k,P,S}(u_1,u_2) = \frac{1}{\sqrt{P}} \sum_{t=R}^{T-\tau} \Bigg(\Bigg[\frac{1}{S} \sum_{i=1}^{S} 1\left\{ u_1 \le X^{\hat{\theta}_{1,t,N,h}}_{1,i,t+\tau}(X_t) \le u_2 \right\} \\ - 1\{u_1 \le X_{t+\tau} \le u_2\} \Bigg]^2 \\ - \Bigg(\Bigg[\frac{1}{S} \sum_{i=1}^{S} 1\left\{ u_1 \le X^{\hat{\theta}_{k,t,N,h}}_{k,i,t+\tau}(X_t) \le u_2 \right\} \\ - \{u_1 \le X_{t+\tau} \le u_2\} \Bigg]^2 \Bigg). \end{aligned}$$

All notations are consistent with previous sections where S is the number of simulated replications used in the estimation of conditional distributions. $X^{\hat{\theta}_{1,t,N,h}}_{1,i,t+\tau}(X_t)$ and $X^{\hat{\theta}_{k,t,N,h}}_{k,i,t+\tau}$, $i = 1, \ldots, S$, $t = 1, \ldots, T-\tau$, are the ith simulated path under $\hat{\theta}_{1,t,N,h}$ and $\hat{\theta}_{k,t,N,h}$. If models 1 and k are nonnested for at least one, $k = 2, \ldots, m$. Under regular conditions and if P, R, S, h are chosen such as $P, R, N \to \infty$ and h, P/N, $h^2P \to 0$, $P/R \to \pi$ where π is finite then

$$\max_{k=2,\ldots,m} \left(D_{k,P,N}(u_1,u_2) - \mu_k(u_1,u_2) \right) \to \max_{k=2,\ldots,m} Z_k(u_1,u_2).$$

where, with an abuse of notation, $\mu_k(u_1, u_2) = \mu_1(u_1, u_2) - \mu_k(u_1, u_2)$, and

$$\mu_j(u_1,u_2) = E\left(\left(\begin{pmatrix} F_{X^{\theta_j^\dagger}_{j,t+\tau}(X_t)}(u_2) - F_{X^{\theta_j^\dagger}_{j,t+\tau}(X_t)}(u_1) \\ -(F_0(u_2|X_t) - F_0(u_1|X_t)) \end{pmatrix} \right)^2 \right),$$

for $j = 1,\ldots, m$, and where $(Z_1(u_1, u_2), \ldots, Z_m(u_1, u_2))$ is an m-dimensional Gaussian random variable the covariance kernels that involves error in parameter estimation. Bootstrap statistics are therefore required to reflect this parameter estimation error issue.[17]

In the implementation, we can obtain the asymptotic critical value using a recursive version of the block bootstrap. The idea is that when forming block

[17]See Corradi and Swanson (2011) for further discussion.

bootstrap samples in the recursive setting, observations at the beginning of the sample are used more frequently than observations at the end of the sample. We can replicate Steps 1–5 in bootstrap procedure in Sect. 56.3.4. It should be stressed that the resampling in the Step 1 is the recursive one. Specifically, begin by resampling b blocks of length l from the full sample, with $lb = T$. For any given τ, it is necessary to jointly resample $X_t, X_{t+1}, \ldots, X_{t+\tau}$. More precisely, let $Z^{t,\tau} = (X_t, X_{t+1}, \ldots, X_{t+\tau})$, $t = 1, \ldots, T-\tau$. Now, resample b overlapping blocks of length l from $Z^{t,\tau}$. This yields $Z^{t,*} = \left(X_t^*, X_{t+1}^*, \ldots, X_{t+\tau}^*\right)$, $t = 1, \ldots, T-\tau$. Use these data to construct bootstrap estimator $\hat{\theta}_{k,t,N,h}$. Recall that N is chosen in Corradi and Swanson (2011) as the number of simulated series used to estimate the parameters ($N = M = S$) and such as N/R, $N/P \to \infty$. Under this condition, simulation error vanishes and there is no need to resample the simulated series.

Corradi and Swanson (2011) show that

$$\frac{1}{\sqrt{P}}\sum_{t=R}^{T}\left(\hat{\theta}^*_{k,t,N,h} - \hat{\theta}_{k,t,N,h}\right)$$

has the same limiting distribution as

$$\frac{1}{\sqrt{P}}\sum_{t=R}^{T}\left(\hat{\theta}_{k,t,N,h} - \theta_k^\dagger\right),$$

conditional on all samples except a set with probability measure approaching zero. Given this, the appropriate bootstrap statistic is

$$\begin{aligned}
D^*_{k,P,S}(u_1,u_2) = \frac{1}{\sqrt{P}}\sum_{t=R}^{T-\tau}\Bigg\{ & \Bigg(\Bigg[\frac{1}{S}\sum_{i=1}^{S} 1\left\{u_1 \le X_{1,i,t+\tau}^{\hat{\theta}_{1,t,N,h}}\left(X_t^*\right) \le u_2\right\} \\
& - 1\left\{u_1 \le X^*_{t+\tau} \le u_2\right\}\Bigg]^2 \\
& - \left(\frac{1}{T}\sum_{j=1}^{T}\left[\frac{1}{S}\sum_{i=1}^{S} 1\left\{u_1 \le X_{1,i,t+\tau}^{\hat{\theta}_{1,t,N,h}}\left(X_j^*\right) \le u_2\right\}\right.\right. \\
& \left.\left. - 1\left\{u_1 \le X_{j+\tau} \le u_2\right\}\right]^2\right. \\
& - \Bigg(\Bigg[\frac{1}{S}\sum_{i=1}^{S} 1\left\{u_1 \le X_{k,i,t+\tau}^{\hat{\theta}_{k,t,N,h}}\left(X_t^*\right) \le u_2\right\} \\
& - 1\left\{u_1 \le X^*_{t+\tau} \le u_2\right\}\Bigg]^2 \\
& - \left(\frac{1}{S}\sum_{i=1}^{S}\left[\frac{1}{S}\sum_{i=1}^{S} 1\left\{u_1 \le X_{k,i,t+\tau}^{\hat{\theta}_{k,t,N,h}}\left(X_j\right) \le u_2\right\}\right.\right. \\
& -1\left\{u_1 \le X_{j+\tau} \le u_2\right\}\Bigg]^2\Bigg)\Bigg)\Bigg\}.
\end{aligned}$$

As the bootstrap statistic is calculated from the last P resampled observations, it is necessary to have each bootstrap term recentered around the (full) sample mean. This is true even in the case there is no need to mimic PEE, i.e., the choice of P, R is such that $P/R \to 0$. In such a case, above statistic can be formed using $\hat{\theta}_{k,t,N,h}$ rather than $\hat{\theta}^*_{k,t,N,h}$.

For any bootstrap replication, repeat B times (B large) bootstrap replications which yield B bootstrap statistics $D^*_{k,P,S}$. Reject H_0 if $D_{k,P,S}$ is greater than the $(1 - \alpha)$th percentile of the bootstrap empirical distribution. For numerical implementation, it is of importance to note that in the case where $P/R \to 0, P, T, R \to \infty$, there is no need to re-estimate $\hat{\theta}^*_{1,t,N,h}\left(\hat{\theta}^*_{k,t,N,h}\right)$. Namely, $\hat{\theta}_{1,t,N,h}\left(\hat{\theta}_{k,t,N,h}\right)$ can be used in all bootstrap experiments.

Of course, the above framework can also be applied using entire simulated distributions rather than predictive densities, by simply estimating parameters once, using the entire sample, as opposed to using recursive estimation techniques, say, as when forming predictions and associated predictive densities.

56.3.2 Multifactor Models

Now, let us turn our attention to multifactor diffusion models of the form $(X(t), V(t))' = (X(t), V^1(t), \ldots, V^d(t))'$, where only the first element, the diffusion process X_t, is observed while $V(t) = (V^1(t), \ldots, V^d(t))'$ is latent. The most popular class of the multifactor models is stochastic volatility model expressed as below:

$$\begin{pmatrix} dX(t) \\ dV(t) \end{pmatrix} = \begin{pmatrix} b_1\left(X(t), \theta^\dagger\right) \\ b_2\left(V(t), \theta^\dagger\right) \end{pmatrix} dt + \begin{pmatrix} \sigma_{11}\left(V(t), \theta^\dagger\right) \\ 0 \end{pmatrix} dW_1(t) + \begin{pmatrix} \sigma_{12}\left(V(t), \theta^\dagger\right) \\ \sigma_{22}\left(V(t), \theta^\dagger\right) \end{pmatrix} dW_2(t), \tag{56.10}$$

where $W_1(t)_{1\times1}$ and $W_2(t)_{1\times1}$ are independent Brownian motions.[18] For instance, many term structure models require the multifactor specification of the above form (see Dai and Singleton (2000)). In a more complicated case, the drift function can also be specified to be a stochastic process which poses even more challenges to testing. As mentioned earlier, the hypotheses (**Hypothesis 1**, **2**, **3**) and the test

[18]Note that the dimension of $X(\cdot)$ can be higher and we can add jumps to the above specification such that it satisfies the regularity conditions outlined in the one-factor case. In addition, Corradi and Swanson (2005) provide a detailed discussion of approximation schemes in the context of stochastic volatility models.

construction strategy for multifactor models are the same as for one-factor model. All theory essentially applies immediately to multifactor cases. In implementation, the key difference is in the simulated approximation scheme facilitating parameter and CDF estimation. $X(t)$ cannot simply be expressed as a function of $d + 1$ driving Brownian motions but instead involves a function of $(W_{jt}, \int_0^t W_{js} dW_{is})$, $i, j = 1, \ldots, d + 1$ (see, e.g., Pardoux and Talay (1985, pp. 30–32) and Corradi and Swanson (2005)).

For illustration, we hereafter focus on the analysis of a stochastic volatility model (56.10) where drift and diffusion coefficients can be written as

$$
\begin{aligned}
b &= \begin{pmatrix} b_1\left(X(t), \theta^\dagger\right) \\ b_2\left(V(t), \theta^\dagger\right) \end{pmatrix} \\
\sigma &= \begin{pmatrix} \sigma_{11}\left(V(t), \theta^\dagger\right) & \sigma_{12}\left(V(t), \theta^\dagger\right) \\ 0 & \sigma_{22}\left(V(t), \theta^\dagger\right) \end{pmatrix}
\end{aligned}
$$

We also examine a three-factor model (i.e., the Chen model as in Eq. 56.5) and a three-factor model with jumps (i.e., CHENJ as in Eq. 56.6). By presenting two- and three-factor models as an extension of our above discussion, we make it clear that specification tests of multiple factor diffusions with $d \geq 3$ can be easily constructed in similar manner.

In distribution estimation, the important challenge for multifactor models lies in the missing variable issue. In particular, for simulation of X_t, one needs initial values of the latent processes $V_1, \ldots, V_d$, which are unobserved. To overcome this problem, it suffices to simulate the process using different random initial values for the volatility process; then construct the simulated distribution using those initial values and average them out. This allows one to integrate out the effect of a particular choice of volatility initial value.

For clarity of exposition, we sketch out a simulation strategy for a general model of d latent variables in Sect. 56.3.3. This generalizes the simulation scheme of three-factor models in Cai and Swanson (2011). As a final remark before moving to the statistic presentation, note that the class of multifactor diffusion processes considered in this chapter is required to match the regular conditions as in previous section (assumption from A1 to A8 in Corradi and Swanson (2011) with A4 being replaced by A4′).

56.3.2.1 Unconditional Distribution Tests

Following the above discussion on test construction, we specialize to the case of two-factor stochastic volatility models. Extension to general multidimensional and multifactor models follows similarly. As the CDF is rarely known in closed form for stochastic volatility models, we rely on simulation technique. With the simulation scheme, estimators, simulated distribution, and bootstrap procedures to be presented in the next sections (see Sects. 56.3.3 and 56.3.4), the test statistics for **Hypothesis 1** turns out to be

$$SV_{T,S,h} = \frac{1}{\sqrt{T}}\sum_{t=1}^{T}\left(1\{X_t \le u\} - \frac{1}{S}\sum_{t=1}^{S}1\left(X_{t,h}^{\hat{\theta}_{T,N,L,h}} \le u\right)\right).$$

In the above expression, recall that S is the number of simulation paths used in distribution simulation; $\hat{\theta}_{T,N,L,h}$ is a simulated estimator (see Sect. 56.3.3). N is a generic notation throughout this chapter, i.e., $N = L$, the length of each simulation path for SGMM, and $N = M$, the number of random draws (simulated paths) for NPQML estimator. h is the discretization interval used in simulation. Note that $\hat{\theta}_{T,N,L,h}$ is chosen in Corradi and Swanson (2005) to be SGMM estimator using full sample and therefore $N = L = S$.[19] To put it simply, one can write $\hat{\theta}_{T,S,h} = \hat{\theta}_{T,N,L,h}$.

Under the null, choose T, S to satisfy $T, S \to \infty$, $Sh \to 0$, $T/S \to 0$, then

$$SV_{T,S,h}^2 \to \int_U SV^2(u)\pi(u),$$

where Z is a Gaussian process with covariance kernel that reflects both PEE and the time-dependent nature of the data. The relevant bootstrap statistic is

$$\begin{aligned} SV_{T,S,h}^{2*} = &\frac{1}{\sqrt{T}}\sum_{t=1}^{T}\left(1\{X_t^* \le u\} - 1\{X_t \le u\}\right) \\ &- \frac{1}{\sqrt{T}}\sum_{t=1}^{T}\frac{1}{S}\sum_{t=1}^{S}\left(1\left(X_{t,h}^{\hat{\theta}_{T,N,L,h}} \le u\right) - 1\left(X_{t,h}^{\hat{\theta}_{T,N,L,h}} \le u\right)\right), \end{aligned}$$

where $\hat{\theta}^*_{T,S,h}$ is the bootstrap analog of $\hat{\theta}_{T,S,h}$. Repeat Steps 1–5 in the bootstrap procedure in Sect. 56.3.4 to obtain critical values which are the percentiles of the empirical distribution of Z_T^*. Compare $SV_{T,S,h}$ with the percentiles of the empirical distribution of the bootstrap statistic and reject H_0 if $SV_{T,S,h}$ is greater than the $(1-\alpha)$th percentile thereof. Otherwise, do not reject H_0.

56.3.2.2 Conditional Distribution Tests

To test **Hypothesis 2** for the multifactor models, first we present the test statistic for the case of the stochastic volatility model (X_t, V_t) in Eq. 56.10 (i.e., for two-factor diffusion), and then we discuss testing with the three-factor model (X_t, V_t^1, V_t^2) as in Eq. 56.5. Other multiple factor models can be tested analogously.

[19] As seen in assumption A4′ in Corradi and Swanson (2011) and Sect. 56.3.3 of this chapter, $\hat{\theta}_{T,N,L,h}$ can be other estimators such as the NPSQML estimator. Importantly, $\hat{\theta}_{T,N,L,h}$ satisfies condition A4′ in Corradi and Swanson (2011).

Note that for illustration, we again assume use of the SGMM estimator $\hat{\theta}_{T,N,L,h}$, as in the original work of Bhardwaj et al. (2008) (namely, $\hat{\theta}_{T,N,L,h}$ is the simulated estimator described in Sect. 56.3.3). Specifically, N is chosen as the length of sample path L used in parameter estimation. The associated test statistic is

$$\begin{aligned} SZ_T &= \sup_{u\times v\in U\times V} |SZ_T(u,v)| \\ SZ_T(u,v) &= \frac{1}{\sqrt{T-\tau}}\sum_{t=1}^{T-\tau} 1\{X_t \le v\} \\ &\quad \times \left(\frac{1}{NS}\sum_{j=1}^{N}\sum_{i=1}^{S} 1\left\{X_{j,i,t+\tau}^{\hat{\theta}_{T,N,L,h}} \le u\right\} - 1\{X_{t+\tau} \le u\}\right), \end{aligned}$$

where $X_{j,i,t+\tau}^{\hat{\theta}_{T,N,L,h}}$ is τ-step ahead simulated skeleton obtained by simulation procedure for multifactor model in Sect. 56.3.3.1.

In a similar manner, the bootstrap statistic analogous to SZ_T is

$$\begin{aligned} SZ_T^* &= \sup_{u\times v\in U\times V} \left|SZ_T^*(u,v)\right|, \\ SZ_T^*(u,v) &= \frac{1}{\sqrt{T-\tau}}\sum_{t=1}^{T-\tau} 1\left\{X_t^* \le v\right\} \\ &\quad \times \left(\frac{1}{NS}\sum_{j=1}^{N}\sum_{i=1}^{S} 1\left\{X_{j,i,t+\tau}^{\hat{\theta}^*_{T,N,L,h}} \le u\right\} - 1\left\{X_{t+\tau}^* \le u\right\}\right) \\ &\quad - \frac{1}{\sqrt{T-\tau}}\sum_{t=1}^{T-\tau} 1\{X_t \le v\} \\ &\quad \left(\frac{1}{NS}\sum_{j=1}^{N}\sum_{i=1}^{S} 1\left\{X_{j,i,t+\tau}^{\hat{\theta}_{T,N,L,h}} \le u\right\} - 1\{X_{t+\tau} \le u\}\right) \end{aligned}$$

where $\hat{\theta}^*_{T,N,L,h}$ is the bootstrap estimator described in Sect. 56.3.4. For the three-factor model, the test statistic is defined as

$$\begin{aligned} MZ_T &= \sup_{u\times v\in U\times V} |MZ_T(u,v)|, \\ MZ_T(u,v) &= \frac{1}{\sqrt{T-\tau}}\sum_{t=1}^{T-\tau} 1\{X_t \le v\} \\ &\quad \times \left(\frac{1}{L^2 S}\sum_{j=1}^{L}\sum_{k=1}^{L}\sum_{i=1}^{S} 1\left\{X_{s,t+\tau}^{\hat{\theta}_{T,N,L,h}} \le u\right\} - 1\{X_{t+\tau} \le u\}\right), \end{aligned}$$

and bootstrap statistics is

$$\begin{aligned}MZ_T^*(u,v) &= \frac{1}{\sqrt{T-\tau}}\sum_{t=1}^{T-\tau}1\{X_t \le v\} \\ &\quad \times\left(\frac{1}{L^2S}\sum_{j=1}^{L}\sum_{k=1}^{L}\sum_{i=1}^{S}1\left\{X_{s,t+\tau}^{\hat{\theta}^*_{t,N,L,h}} \le u\right\} - 1\{X^*_{t+\tau} \le u\}\right) \\ &\quad - \frac{1}{\sqrt{T-\tau}}\sum_{t=1}^{T-\tau}1\{X_t \le v\} \\ &\quad \times\left(\frac{1}{L^2S}\sum_{j=1}^{L}\sum_{k=1}^{L}\sum_{i=1}^{S}1\left\{X_{s,t+\tau}^{\hat{\theta}_{t,N,L,h}} \le u\right\} - 1\{X_{t+\tau} \le u\}\right)\end{aligned}$$

where $X_{s,t+\tau}^{\hat{\theta}_{T,N,L,h}} = X_{s,t+\tau}^{\hat{\theta}_{T,N,L,h}}\left(X_t, V_j^{1,\hat{\theta}_{T,N,L,h}}, V_k^{2,\hat{\theta}_{T,N,L,h}}\right)$ and $X_{s,t+\tau}^{\hat{\theta}^*_{t,N,L,h}} = X_{s,t+\tau}^{\hat{\theta}^*_{t,N,L,h}}\left(X_t, V_j^{1,\hat{\theta}^*_{t,N,L,h}}, V_k^{2,\hat{\theta}^*_{t,N,L,h}}\right)$.

The first-order asymptotic validity of inference carried out using bootstrap statistics formed as outlined above follows immediately from Bhardwaj et al. (2008). For testing decision, one compares the test statistics $SZ_{T,S,h}$ and $MZ_{T,S,h}$ with the percentiles or the empirical distributions of SZ_T^* and $MZ_{T,S,h}^*$, respectively. Then, reject H_0 if the actual statistic is greater than the $(1-\alpha)$th percentile of the empirical distribution of the bootstrap statistic, as in Sect. 56.3.4. Otherwise, do not reject H_0.

56.3.2.3 Predictive Density Tests for Multiple Competing Models

For illustration, we present the test for the stochastic volatility model (two-factor model). Again, note that extension to other multifactor models follows immediately. In particular, all steps in the construction of the test in the one-factor model case carry through immediately to the stochastic volatility case with the statistic defined as

$$DV_{P,L,S} = \max_{k=2,\dots,m} DV_{k,P,L,S}(u_1,u_2),$$

where

$$\begin{aligned}DV_{k,P,L,S}(u_1,u_2) &= \frac{1}{\sqrt{P}}\sum_{t=R}^{T-\tau} \\ &\left(\left(\frac{1}{SL}\sum_{j=1}^{L}\sum_{i=1}^{S}1\left\{u_1 \le X_{1,t+\tau,i,j}^{\hat{\theta}_{1,t,N,L,h}}\left(X_t, V_{1,j}^{\hat{\theta}_{1,t,N,L,h}}\right) \le u_2\right\} - 1\{u_1 \le X_{t+\tau} \le u_2\}\right)^2\right. \\ &\left. - \left(\frac{1}{SL}\sum_{j=1}^{L}\sum_{i=1}^{S}1\left\{u_1 \le X_{k,t+\tau,i,j}^{\hat{\theta}_{k,t,N,L,h}}\left(X_t, V_{k,j}^{\hat{\theta}_{k,t,N,L,h}}\right) \le u_2\right\} - 1\{u_1 \le X_{t+\tau} \le u_2\}\right)^2\right).\end{aligned}$$

Critical values for these tests can be obtained using a recursive version of the block bootstrap. The corresponding bootstrap test statistic is

$$DV^*_{P,L,S} = \max_{k=2,\ldots,m} DV^*_{k,P,L,S}(u_1, u_2)$$

where

$$\begin{aligned}
DV^*_{k,P,L,S}(u_1,u_2) &= \frac{1}{\sqrt{P}}\sum_{t=R}^{T-\tau} \\
&\Bigg\{\Bigg(\left[\frac{1}{SL}\sum_{j=1}^{L}\sum_{i=1}^{S}1\left\{u_1 \le X_{1,t+\tau,i,j}^{\hat{\theta}^*_{1,t,N,L,h}}\left(X_t^*, V_{1,j}^{\hat{\theta}^*_{1,t,N,L,h}}\right) \le u_2\right\} - 1\left\{u_1 \le X^*_{t+\tau} \le u_2\right\}\right]^2 \\
&-\frac{1}{T}\sum_{l=1}^{T}\left[\frac{1}{SL}\sum_{j=1}^{L}\sum_{i=1}^{S}1\left\{u_1 < X_{1,t+\tau,i,j}^{\hat{\theta}_{1,t,N,L,h}}\left(X_l, V_{1,j}^{\hat{\theta}_{1,t,N,L,h}}\right) \le u_2\right\} - 1\{u_1 \le X_{l+\tau} \le u_2\}\right]^2\Bigg) \\
&-\Bigg(\left[\frac{1}{SL}\sum_{j=1}^{L}\sum_{i=1}^{S}1\left\{u_1 \le X_{k,t+\tau,i,j}^{\hat{\theta}^*_{k,t,N,L,h}}\left(X_t^*, V_{k,j}^{\hat{\theta}^*_{k,t,N,L,h}}\right) \le u_2\right\} - 1\left\{u_1 \le X^*_{t+\tau} \le u_2\right\}\right]^2 \\
&-\frac{1}{T}\sum_{l=1}^{T}\left[\frac{1}{SL}\sum_{j=1}^{L}\sum_{i=1}^{S}1\left\{u_1 \le X_{k,t+\tau,i,j}^{\hat{\theta}_{k,t,N,L,h}}\left(X_l, V_{k,j}^{\hat{\theta}_{k,t,N,L,h}}\right) \le u_2\right\} - 1\{u_1 \le X_{l+\tau} \le u_2\}\right]^2\Bigg)\Bigg\}
\end{aligned}$$

Of note is that we follow Cai and Swanson (2011) by adopting the recursive NPSQML estimator $\hat{\theta}_{1,t,N,L,h}$ and $\hat{\theta}_{k,t,N,L,h}$ for model 1 and k, respectively, as introduced in Sect. 56.3.3.4 with the choice $N = M = S$. $\hat{\theta}^*_{1,t,N,L,h}$ and $\hat{\theta}^*_{k,t,N,L,h}$ are bootstrap analogs of $\hat{\theta}_{1,t,N,L,h}$ and $\hat{\theta}_{k,t,N,L,h}$, respectively (see Sect. 56.3.4). In addition, we do not need to resample the volatility process, although volatility is simulated under both $\hat{\theta}_{k,t,N,L,h}$ and $\hat{\theta}^*_{k,t,N,L,h}$, $k = 1, \ldots, m$.

Repeat Steps 1–5 in the bootstrap procedure in Sect. 56.3.4 to obtain critical values. Compare $DV_{P,\ L,\ S}$ with the percentiles of the empirical distribution of $DV^*_{P,\ L,\ S}$, and reject H_0 if $DV_{P,\ L,\ S}$ is greater than the $(1 - \alpha)$th percentile. Otherwise, do not reject H_0. Again, in implementation, there is no need to re-estimate $\hat{\theta}^*_{k,t,N,L,h}$ for each bootstrap replication if $P/R \to 0$, $P, T, R \to \infty$, *as* parameter estimation error vanishes asymptotically in this case.

56.3.3 Model Simulation and Estimation

56.3.3.1 Simulating Data

Approximation schemes are used to obtain simulated distributions and simulated parameter estimators, which are needed in order to construct the test statistics outlined in previous sections. We therefore devote the first part of this section to a discussion of the Milstein approximation schemes that have been used in Corradi and Swanson (2005), Bhardwaj et al. (2008), and Corradi and Swanson (2011). Let L be the length of each simulation path and h be the discretization interval, $L = Qh$, and θ be a generic parameter in simulation expression. We consider three cases:

The pure diffusion process as in Eq. 56.9:

$$X^{\theta}_{qh} - X^{\theta}_{(q-1)h} = b\left(X^{\theta}_{(q-1)h}, \theta\right)h + \sigma\left(X^{\theta}_{(q-1)h}, \theta\right)\epsilon_{qh} - \frac{1}{2}\sigma\left(X^{\theta}_{(q-1)h}, \theta\right)'\sigma\left(X^{\theta}_{(q-1)h}, \theta\right)h$$
$$+\frac{1}{2}\sigma\left(X^{\theta}_{(q-1)h}, \theta\right)'\sigma\left(X^{\theta}_{(q-1)h}, \theta\right)\epsilon^{2}_{qh},$$

where

$$\left(W_{qh} - W_{(q-1)h}\right) = \epsilon_{qh} \overset{iid}{\sim} N(0, h),$$

$q = 1, \ldots, Q$, *with* $\epsilon_{qh} \sim^{iid} N(0, h)$, and where σ' is the derivative of $\sigma(\cdot)$ *with* respect to its first argument. Hereafter, X^{θ}_{qh} denotes the values of the diffusion at time qh, simulated under generic θ, and with a discrete interval equal to h, and so is a fine-grain analog of $X^{\theta}_{t,h}$.

The pure jump diffusion process without stochastic volatility as in Eq. 56.1:

$$\begin{aligned} X^{\theta}_{(q+1)h} - X^{\theta}_{qh} = {} & b\left(X^{\theta}_{qh}, \theta\right)h + \sigma\left(X^{\theta}_{qh}, \theta\right)\epsilon_{(q+1)h} - \frac{1}{2}\sigma\left(X^{\theta}_{qh}, \theta\right)'\sigma\left(X^{\theta}_{qh}, \theta\right)h \\ & + \frac{1}{2}\sigma\left(X^{\theta}_{qh}, \theta\right)'\sigma\left(X^{\theta}_{qh}, \theta\right)\epsilon^{2}_{(q+1)h} - \lambda\mu_y h \\ & + \sum_{j=1}^{\mathcal{J}} y_j 1\left\{qh \le \mathcal{U}_j \le (q+1)h\right\}. \end{aligned} \tag{56.11}$$

The only difference between this approximation and that used for the pure diffusion is the jump part. Note that the last term on the right-hand side (RHS) of Eq. 56.11 is nonzero whenever we have one (or more) jump realization(s) in the interval $[(q-1)h, qh]$. Moreover, as neither the intensity nor the jump size is state dependent, the jump component can be simulated without any discretization error, as follows. Begin by making a draw from a Poisson distribution with intensity parameter $\hat{\lambda}_{\tau}$, say $\mathcal{J}$. This gives a realization for the number of jumps over the simulation time span. Then draw $\mathcal{J}$ uniform random variables over $[0, L]$, and sort them in ascending order so that $\mathcal{U}_1 \le \mathcal{U}_2 \le \ldots \le \mathcal{U}_{\mathcal{J}}$. These provide realizations for the $\mathcal{J}$ independent draws from ϕ, say $y_1, \ldots, y_{\mathcal{J}}$.

SV models without jumps as in Eq. 56.4 (using a generalized Milstein scheme):

$$
\begin{aligned}
X^{\theta}_{(q+1)h} &= X^{\theta}_{qh} + \widetilde{b}_1\left(X^{\theta}_{qh}, \theta\right)h + \sigma_{11}\left(V^{\theta}_{qh}, \theta\right)\epsilon_{1,(q+1)h} + \sigma_{12}\left(V^{\theta}_{qh}, \theta\right)\epsilon_{2,(q+1)h} \\
&\quad + \frac{1}{2}\sigma_{22}\left(V^{\theta}_{qh}, \theta\right)\frac{\partial\sigma_{12,k}\left(V^{\theta}_{qh}, \theta\right)}{\partial V}\epsilon^2_{2,(q+1)h} + \sigma_{22}\left(V^{\theta}_{qh}, \theta\right)\frac{\partial\sigma_{11}\left(V^{\theta}_{qh}, \theta\right)}{\partial V} \\
&\quad \times \int_{qh}^{(q+1)h}\left(\int_{qh}^{s} dW_{1,\tau}\right)dW_{2.s},
\end{aligned}
\tag{56.12}
$$

$$
\begin{aligned}
V^{\theta}_{(q+1)h} &= V^{\theta}_{qh} + \widetilde{b}_2\left(V^{\theta}_{qh}, \theta\right)h + \sigma_{22}\left(V^{\theta}_{qh}, \theta\right)\epsilon_{2,(q+1)h} \\
&\quad + \frac{1}{2}\sigma_{22}\left(V^{\theta}_{qh}, \theta\right)\frac{\partial\sigma_{22}\left(V^{\theta}_{qh}, \theta\right)}{\partial V}\epsilon^2_{2,(q+1)h},
\end{aligned}
\tag{56.13}
$$

where $h^{-1/2}\epsilon_{i,qh} \sim N(0,1)$, $i = 1, 2, E\left(\epsilon_{1,qh}\epsilon_{2,q'h}\right) = 0$ for all $q \neq q'$, and

$$
\widetilde{b}(V, \theta) = \begin{pmatrix} \widetilde{b}_1(V, \theta) \\ \widetilde{b}_2(V, \theta) \end{pmatrix} = \begin{pmatrix} b_1(V, \theta) - \frac{1}{2}\sigma_{22}(V, \theta)\frac{\partial\sigma_{12}(V, \theta)}{\partial V} \\ b_2(V, \theta) - \frac{1}{2}\sigma_{22}(V, \theta)\frac{\partial\sigma_{22}(V, \theta)}{\partial V} \end{pmatrix}.
$$

The last terms on the RHS of Eq. 56.12 involve stochastic integrals and cannot be explicitly computed. However, they can be approximated up to an error of order $o(h)$ by (see, e.g., Eq. 3.7, pp. 347 in Kloeden and Platen (1999))

$$
\begin{aligned}
&\int_{qh}^{(q+1)h}\left(\int_{qh}^{s} dW_{1,\tau}\right)dW_{2,s} \approx h\left(\frac{1}{2}\xi_1\xi_2 + \sqrt{\rho_p}\left(\mu_{1,p}\xi_2 - \mu_{2,p}\xi_1\right)\right) \\
&+ \frac{h}{2\pi}\sum_{r=1}^{p}\frac{1}{r}\left(\varsigma_{1,r}\left(\sqrt{2}\xi_2 + \eta_{2,r}\right) - \varsigma_{2,r}\left(\sqrt{2}\xi_1 + \eta_{1,r}\right)\right),
\end{aligned}
$$

where for $j = 1, 2$, ξ_j, $\mu_{j,p}$, $\varsigma_{j,r}$, $\eta_{j,r}$ are i.i.d. $N(0, 1)$ random variables, $\rho_p = \frac{1}{12} - \frac{1}{2\pi^2}\sum_{r=1}^{p}\frac{1}{r^2}$, and p is such that as $h \to 0$, $p \to \infty$.

Stochastic Volatility with Jumps

Simulation of sample paths of diffusion processes with stochastic volatility and jumps follows straightforwardly from the previous two cases. Whenever both intensity and jump size are not state dependent, a jump component can be simulated and added to either $X(t)$ or the $V(t)$ in the same manner as above. Extension to general multidimensional and multifactor models both with and without jumps also follows directly.

56.3.3.2 Simulating Distributions

In this section, we sketch out methods used to construct τ-step ahead simulated conditional distributions using simulated data. In applications, simulation techniques are needed when the functional form conditional distribution is unknown. We first illustrate the technique for one-factor models and then discuss multifactor models.

One-factor Models

Consider the one-factor model as in Eq. 56.7. To estimate the simulated CDFs:

Step 1: Obtain $\hat{\theta}_{T,N,h}$ (using the entire sample) or $\hat{\theta}_{t,N,h}$ (recursive estimator) where $\hat{\theta}_{T,N,h}$ and $\hat{\theta}_{t,N,h}$ are estimators as discussed in Sects. 56.3.3.3 and 56.3.3.4.

Step 2: Under $\hat{\theta}_{T,N,h}$ or $\hat{\theta}_{t,N,h},$[20] simulate S paths of length τ, all having the same starting value, X_t. In particular, for each path $i = 1, \ldots, S$ of length τ, generate $X_{i,t+\tau}^{\hat{\theta}_{T,N,h}}(X_t)$ according to a Milstein schemes detailed in previous section, with $\theta = \hat{\theta}_{T,N,h}$ or $\hat{\theta}_{t,N,h}$. The errors used in simulation are $\varepsilon_{qh} \overset{iid}{\sim} N(0,h)$, and $Qh = \tau$. ε_{qh} is assumed to be independent across simulations, so that $E(\varepsilon_{i,qh}\varepsilon_{j,qh}) = 0$, for all $i \neq j$ and $E(\varepsilon_{i,qh}\varepsilon_{i,qh}) = h$, for any i, j. In addition, as the simulated diffusion is ergodic, the effect of the starting value approaches zero at an exponential rate, as $\tau \to \infty$.

Step 3: If $\hat{\theta}_{T,N,h}\left(\hat{\theta}_{t,N,h}\right)$ is used, an estimate for the distribution, at time $t + \tau$, conditional on X_t, with estimator $\hat{\theta}_{T,N,h}\left(\hat{\theta}_{t,N,h}\right)$, is defined as

$$\hat{F}_\tau\left(u \middle| X_t, \hat{\theta}_{T,N,h}\right) = \frac{1}{S}\sum_{i=1}^{S} 1\left\{X_{i,t+\tau}^{\hat{\theta}_{T,N,h}}(X_t) \leq u\right\}.$$

Bhardwaj et al. (2008) show that if the model is correctly specified, then $\frac{1}{S}\sum_{i=1}^{S} 1\left\{X_{i+t+\tau}^{\hat{\theta}_{T,N,h}}(X_t) \leq u\right\}$ provides a consistent of the conditional distribution $F_\tau(u|X_t, \theta^\dagger) = \Pr(X_{t+\tau}^{\theta\dagger} \leq u|X_t^{\theta\dagger} = X_t)$.

Specifically, assume that $T, N, S \to \infty$. Then, for the case of SGMM estimator, if $h \to 0$, $T/N \to 0$, and $h^2T \to 0$, $T^2/S \to \infty$, the following result holds for any Xt, $t \geq 1$, uniformly in u

$$\hat{F}_\tau\left(u \middle| X_t, \hat{\theta}_{T,N,h}\right) - F_\tau\left(u|X_t, \theta^\dagger\right) \xrightarrow{pr} 0,$$

[20] Note that $N = L$ for the SGMM estimator while $N = M = S$ for NSQML estimator.

In addition, if the model is correctly specified (i.e., if $\mu(,) = \mu_0(,)$ and $\sigma(,) = \sigma_0(,)$), then

$$\hat{F}_\tau\left(u\middle|X_t, \hat{\theta}_{T,N,h}\right) - F_{0,\tau}(u|X_t, \theta_0) \xrightarrow{pr} 0.$$

Step 4: Repeat Steps 1–3 for $t = 1, \ldots,$ T $-$ τ. This yields T $-$ τ conditional distributions that are τ-steps ahead which will be used in the construction of the specification tests.

The CDF simulation in the case selection test of multiple models with recursive estimator is similar. For model k, let $\hat{\theta}_{k,t,N,h}$ be the recursive estimator of "pseudo true" $\theta_k^\dagger$ computed using all observations up to varying time t. Then, $X_{k,i,t+\tau}^{\hat{\theta}_{k,t,N,h}}(X_t)$ is generated according to a Milstein schemes as in Sect. 56.3.3.1, with $\theta = \hat{\theta}_{k,t,N,h}$ and the initial value X_t, $Qh = \tau$. The corresponding empirical distribution of the simulated series $X_{k,i,t+\tau}^{\hat{\theta}_{k,t,N,h}}X(t)$ can then be constructed. Under some regularity conditions,

$$\frac{1}{S}\sum_{i=1}^{S} 1\left\{u_1 \le X_{k,i,t+\tau}^{\hat{\theta}_{k,t,N,h}}(X_t) \le u_2\right\} \xrightarrow{pr} F_{X_{k,t+\tau}^{\theta_k^\dagger}(X_t)}(u_2) - F_{X_{k,t+\tau}^{\theta_k^\dagger}(X_t)}(u_1), t = R, \ldots, T-\tau,$$

where $F_{X_{k,t+\tau}^{\theta_k^\dagger}(X_t)}(u)$ is the marginal distribution of $X_{t+\tau}^{\theta_k^\dagger}(X_t)$ implied by k model (i.e., by the model used to simulate the series), conditional on the (simulation) starting value X_t. Furthermore, the marginal distribution of $X_{t+\tau}^{\theta^\dagger}(X_t)$ is the distribution of $X_{t+\tau}$ conditional on the values observed at time t. Thus, $F_{X_{k+t+\tau}^{\theta^\dagger}(X_t)}(u) = F_k^T\left(u\middle|X_t, \theta_k^\dagger\right)$.

Of important note is that in the simulation of $X_{k,i,t+\tau}^{\hat{\theta}_{k,t,N,h}}(X_t)$, $i = 1, \ldots, S$, for each t, $t = R, \ldots, T - \tau$, we must use the same set of randomly drawn errors and similarly the same draws for numbers of jumps, jump times, and jump sizes. Thus, we only allow for the starting value to change. In particular, for each $i = 1, \ldots, S$, we generate $X_{k,i,R+\tau}^{\hat{\theta}_{k,R,N,h}}(X_R), \ldots, X_{k,i,t}^{\hat{\theta}_{k,T-\tau,N,h}}(X_{T-\tau})$. This yields an $S \times P$ matrix of simulated values, where $P = T - R - \tau + 1$ refers to the length of the out-of-sample period. $X_{k,i,R+j+\tau}^{\hat{\theta}_{k,R+j,N,h}}(X_{R+j})$ (at time $R + j + \tau$) can be seen as τ periods ahead value "predicted" by model k using all available information up to time $R + j_{R+j}$, $j = 1, \ldots, P$ (the initial value X_{R+j} and $\hat{\theta}_{k,R+j,N,h}$ estimated using $X_1, \ldots, X_{R+j}$). The key feature of this setup is that it enables us to compare "predicted" τ periods ahead values (i.e., $X_{k,i,R+j+\tau}^{\hat{\theta}_{k,R+j,N,h}}(X_{R+j})$) with actual values that are τ periods ahead (i.e., $X_{R+j+\tau}$), for $j = 1, \ldots, P$. In this manner, simulation-based tests under *ex-ante* predictive density comparison framework can be constructed.

Multifactor Model

Consider the multifactor model with a skeleton $(X_t, V_t^1, \ldots, V_t^d)'$ (e.g., stochastic mean, stochastic volatility models, stochastic volatility of volatility) where only the first element X_t is observed. For simulation of the CDF, the difficulty arises as we do not know the initial values of latent variables $(V_t^1, \ldots, V_t^d)'$ at each point in time. We generalize the simulation plan of Bhardwaj et al. (2008) and Cai and Swanson (2011) to the case of d dimensions. Specifically, to overcome the initial value difficulty, a natural strategy is to simulate a long path of length L for each latent variable $V_t^1, \ldots, V_t^d$ and use them to construct $X_{t+\tau}$ and the corresponding simulated CDF of $X_{t+\tau}$; and finally, we average out the volatility values. Note that there are L^d combinations of the initial values $V_t^1, \ldots, V_t^d$. For illustration, consider the case of stochastic volatility ($d = 1$) and the Chen three-factor model as in Eq. 56.5 ($d = 2$), using recursive estimators.

For the case of stochastic volatility ($d = 1$), i.e., $(X_t, V_t)'$, the steps are as follows:

Step 1: Estimate $\hat{\theta}_{t,N,L,h}$ using recursive SGMM or NSQML estimation methods.

Step 2: Using the scheme in Eq. 56.13 with $\theta = \hat{\theta}_{t,N,L,h}$, generate the path $V_{qh}^{\hat{\theta}_{t,N,L,h}}$ for $q = 1/h, \ldots, Qh$ with $Qh = L$ and hence obtain $V_j^{\hat{\theta}_{t,N,L,h}} j = 1, \ldots L$.

Step 3: Using schemes in Eqs. 56.12, 56.13, simulate $L \times S$ paths of length τ, setting the initial value for the observable state variable to be X_t. For the initial values of unobserved volatility, use $V_{j,qh}^{\hat{\theta}_{t,N,L,h}}$ $j = 1, \ldots, L$ as retrieved in Step 2. Also, keep the simulated random innovations (i.e., $\varepsilon_{1,qh}$, $\varepsilon_{1,qh}$, $\int_{qh}^{(q+1)h}(\int_{qh}^{s} dW_{1,\tau})dW_{2,s}$) to be constant across each j and t. Hence, for each replication i, using initial values X_t and $V_{j,qh}^{\hat{\theta}_{T,N,h}}$, we obtain $X_{j,i,t+\tau}^{\theta_{t,N,L,h}}(X_t)$ which is a τ-step ahead simulated value.

Step 4: Now the estimator of $F_\tau(u|X_t,\theta^\dagger)$ is defined as

$$\hat{F}_\tau\left(u\middle|X_t, \hat{\theta}_{t,N,L,h}\right) = \frac{1}{LS}\sum_{j=1}^{L}\sum_{i=1}^{S} 1\left\{X_{j,i,t+\tau}^{\hat{\theta}_{t,N,h}}(X_t) \le u\right\}.$$

Note that by averaging over the initial value of the volatility process, we have integrated out its effect. In other words, $\frac{1}{S}\sum_{i=1}^{S} 1\left\{X_{j,i,t+\tau}^{\theta_{t,N,h}}(X_t) \le u\right\}$ is an estimate *of* $F_\tau\left(u\middle|X_t, V_{j,h}^{\hat{\theta}_{t,N,h}}, \theta^\dagger\right)$.

Step 5: Repeat Steps 1–4 for $t = 1, \ldots, T - \tau$. This yields $T - \tau$ conditional distributions that are τ-steps ahead which will be used in the construction of the specification tests.

For three-factor model ($d = 2$), i.e., (X_t, V_t^1, V_t^2), consider model (56.5), where $W_t = (W_t^1, W_t^2, W_t^3)$ are mutually independent standard Brownian motions.

Step 1: Estimate $\hat{\theta}_{t,N,L,h}$ using SGMM or NSQML estimation methods.

Step 2: Given the estimated parameter $\hat{\theta}_{t,N,L,h}$, generate the paths $V_{qh}^{1,\hat{\theta}_{t,N,L,h}}$ and $V_{ph}^{2,\hat{\theta}_{t,N,L,h}}$ for q, $p = 1/h, \ldots, Qh$ with $Qh = L$, and hence, obtain $V_j^{1,\hat{\theta}_{T,N,L,h}}$, $V_k^{2,\hat{\theta}_{T,N,L,h}j}$, $k = 1, \ldots, L$.

Step 3: Given the observable X_t and the $L \times L$ simulated latent paths ($V_j^{1,\hat{\theta}_{t,N,L,h}}$ and $V_k^{2,\hat{\theta}_{t,N,L,h}}j$, $k = 1, \ldots, L$) as the start values, we simulate τ-step ahead $X_{t+\tau}^{\hat{\theta}_{t,N,L,h}}\left(X_t, V_j^{1,\hat{\theta}_{t,N,L,h}}, V_k^{2,\hat{\theta}_{t,N,L,h}}\right)$. Since the start values for the two latent variables are $L \times L$ length, so for each X_t we have N^2 path. Now to integrate out the initial effect of latent variables, form the estimate of conditional distribution as

$$\hat{F}_{\tau,s}\left(u\middle|X_t\hat{\theta}\right) = \frac{1}{L^2}\sum_{j=1}^{L}\sum_{k=1}^{L} 1\left\{X_{s,t+\tau}^{\hat{\theta}_{t,N,L,h}}\left(X_t, V_j^{1,\hat{\theta}_{t,N,L,h}}, V_k^{2,\hat{\theta}_{t,N,L,h}}\right) \le u\right\},$$

where s denotes the sth simulation.

Step 4: Simulate $X_{s,t+\tau}^{\hat{\theta}_{t,N,L,h}}$ S times, that is, repeat Step 3 S times, i.e., $s = 1, \ldots, S$. The estimate of $F_\tau(u|X_t,\theta^\dagger)$ is

$$\hat{F}_\tau\left(u\middle|X_t\hat{\theta}\right) = \frac{1}{S}\sum_{i=1}^{S}\hat{F}_{\tau,s}\left(u\middle|X_t, \hat{\theta}_{T,N,h}\right).$$

Step 5: Repeat Steps 1–4 for $t = 1, \ldots, T - \tau$. This yields $T - \tau$ conditional distributions that are t-steps ahead which will be used in the construction of the specification tests.

As a final remark, for the case of multiple competing models, we can proceed similarly. In addition, in the next two subsections, we present the exactly identified simulated (recursive) general method of moments and recursive nonparametric simulated quasi-maximum likelihood estimators that can be used in simulating distributions as well as constructing test statistics described in Sect. 56.3.2. The bootstrap analogs of those estimators will be discussed in Sect. 56.3.4.

56.3.3.3 Estimation: (Recursive) Simulated Generalized Method of Moments (SGMM) Estimators

Suppose that we observe a discrete sample (skeleton) of T observations, say $(X_1, X_2, \ldots, X_T)'$, from the underlying diffusion in Eq. 56.7. The (recursive) SGMM estimator $\hat{\theta}_{t,L,h}$ with $1 \le t \le T$ is specified as

$$\begin{aligned}\hat{\theta}_{t,L,h} &= \arg\min_{\theta\in\Theta}\left(\frac{1}{t}\sum_{j=1}^{t}g(X_j)-\frac{1}{L}\sum_{j=1}^{L}g\left(X_{j,h}^{\theta}\right)\right)'\\ &\quad\times W_t^{-1}\left(\frac{1}{t}\sum_{j=1}^{t}g(X_j)-\frac{1}{L}\sum_{j=1}^{L}g\left(X_{j,h}^{\theta}\right)\right)\\ &= \arg\min_{\theta\in\Theta}G_{t,L,h}(\theta)'W_tG_{t,L,h}(\theta),\end{aligned} \tag{56.14}$$

where g is a vector of p moment conditions, $\Theta \subset \Re^p$ (so that we have as many moment conditions as parameters), and $X_{j,h}^{\theta} = X_{[Qjh/L]}^{\theta}$, with $L = Qh$ is the simulated path under generic parameter θ and with discrete interval h. $X_{j,h}^{\theta}$ is simulated using the Milstein schemes.

Note that in the above expression, in the context of the specification test, $\hat{\theta}_{t,L,h}$ is estimated using the whole sample, i.e., $t = T$. In the out-of-sample context, the recursive SGMM estimator $\hat{\theta}_{t,L,h}$ is estimated recursively using the using sample from 1 up to t.

Typically, the p moment conditions are based on the difference between sample moments of historical and simulated data or between sample moments and model implied moments, whenever the latter are known in closed form. Finally, W_t is the heteroskedasticity and autocorrelation (HAC) robust covariance matrix estimator, defined as

$$W_t^{-1} = \frac{1}{t}\sum_{v=-l_t}^{l_t}w_v\sum_{j=v+1+lt}^{t-l_t}\left(g(X_j)-\frac{1}{t}\sum_{j=1}^{t}g(X_j)\right)\left(g(X_{j-v})-\frac{1}{t}\sum_{j=1}^{t}g(X_j)\right)', \tag{56.15}$$

where $w_v = 1 - v/(l_T + 1)$. Further, the pseudo true value, $\theta^{\dagger}$, is defined to be

$$\theta^{\dagger} = \arg\min_{\theta\in\Theta}G_{\infty}(\theta)'W_0G_{\infty}(\theta),$$

where

$$G_{\infty}(\theta)'W_0G_{\infty}(\theta) = p\lim_{L,T\to\infty,h\to 0}G_{T,L,h}(\theta)'W_TG_{T,L,h}(\theta),$$

and where $\theta^{\dagger} = \theta_0$ if the model is correctly specified.

In the above setup, the exactly identified case is considered rather than the overidentified SGMM. This choice guarantees that $G_{\infty}(\theta^{\dagger}) = 0$ even under misspecification, in the sense that the model differs from the underlying DGP. As pointed out by Hall and Inoue (2003), the root-N consistency does not hold for overidentified SGMM estimators of misspecified models. In addition,

$$\nabla_\theta G_\infty\left(\theta^\dagger\right)' W^\dagger G_\infty\left(\theta^\dagger\right) = 0.$$

However, in the case for which the number of parameters and the number of moment conditions are the same, $\nabla_\theta G_\infty(\theta^\dagger)' W^\dagger$ is invertible, and so the first-order conditions also imply that $G_\infty(\theta^\dagger) = 0$.

Also note that other available estimation methods using moments include the efficient method of moments (EMM) estimator as proposed by Gallant and Tauchen (1996, 1997), which calculates moment functions by simulating the expected value of the score implied by an auxiliary model. In their setup, parameters are then computed by minimizing a chi-square criterion function.

56.3.3.4 Estimation: Recursive Nonparametric Simulated Quasi-maximum Likelihood Estimators

In this section, we outline a recursive version of the NPSQML estimator of Fermanian and Salanié (2004), proposed by Corradi and Swanson (2011). The bootstrap counterpart of the recursive NPSQML estimator will be presented in the next section.

One-Factor Models

Hereafter, let $f(X_t|X_{t-1}, \theta^\dagger)$ be the conditional density associated with the above jump diffusion. If f is known in closed form, we can just estimate $\theta^\dagger$ recursively, using standard QML as[21]

$$\hat{\theta}_t = \arg\max_{\theta \in \Theta} \frac{1}{t} \sum_{j=2}^{t} \ln f\left(X_j \middle| X_{j-1}, \theta\right), t = R, \ldots R + P - 1. \tag{56.16}$$

Note that, similarly to the case of SGMM, the pseudo true value $\theta^\dagger$ is optimal in the sense:

$$\theta^\dagger = \arg\max_{\theta \in \Theta} E(\ln f(X_t|X_{t-1}, \theta)). \tag{56.17}$$

For the case f is not known in closed form, we can follow Kristensen and Shin (2008) and Cai and Swanson (2011) to construct the simulated analog $\hat{f}$ of f and then use it to estimate $\theta^\dagger$. $\hat{f}$ is estimated as function of the simulated sample paths $X^\theta_{t,i}(X_{t-1})$, for $t = 2, \ldots, T-1$, $i = 1, \ldots, M$. First, generate $T-1$ paths of length one for each simulation replication, using X_{t-1} with $t = 1, \ldots, T$ as starting values. Hence, at time t and simulation replication i, we obtain skeletons $X^\theta_{t,i}(X_{t-1})$, for $t = 2, \ldots, T-1$; $i = 1, \ldots M$ where M is the number of simulation paths (number of random draws or $X^\theta_{t,j}(X_{t-1})$ and $X^\theta_{t,l}(X_{t-1})$ are i.i.d.) for each simulation replication.

[21]Note that as model k is, in general, misspecified, $\sum_{t=1}^{T-1} f_k(X_t|X_{t-1},\theta_k)$ is a quasi-likelihood and $f_k(X_t|X_{t-1},\theta_k^\dagger)$ is not necessarily a martingale difference sequence.

M is fixed across all initial values. Then the recursive NPSQML estimator is defined as follows:

$$\hat{\theta}_{t,M,h} = \arg\max_{\theta\in\Theta} \frac{1}{t}\sum_{i=2}^{t} \left(\ln\hat{f}_{M,h}(X_i|X_{i-1},\theta)\tau_M \times \hat{f}_{M,h}(X_i|X_{i-1},\theta)\right), t \geq R,$$

where

$$\hat{f}_{M,h}(X_t|X_{t-1},\theta) = \frac{1}{M\xi_M}\sum_{i=1}^{M} K\left(\frac{X^{\theta}_{t,i,h}(X_{t-1}) - X_t}{\xi_M}\right).$$

Note that with abuse of notation, we define $\hat{\theta}_{t,L,h}$ for SGMM and $\hat{\theta}_{t,M,h}$ for NPSQML estimators where L and M have different interpretations (L is the length of each simulation path and M is number of random draws).

The function $\tau_M\left(\hat{f}_{M,h}(X_t|X_{t-1},\theta)\right)$ is a trimming function. It has some characteristics such as positive and increasing, $\tau_M\left(\hat{f}_{M,h}(X_t,X_{t-1},\theta)\right) = 0$, if $\hat{f}_{M,h}(X_t,X_{t-1},\theta) < \xi_M^{\delta}$ and $\tau_M\left(\hat{f}_{M,h}(X_t,X_{t-1},\theta)\right) = 1$ if $\hat{f}_{M,h}(X_t,X_{t-1},\theta) > 2\xi_M^{\delta}$, for some $\delta > 0$.[22] Note that when the log density is close to zero, the derivative tends to infinity and thus even very tiny simulation errors can have a large impact on the likelihood. The introduction of the trimming parameter into the optimization function ensures the impact of this case to be minimal asymptotically.

Multifactor Models

Since volatility is not observable, we cannot proceed as in the single-factor case when estimating the SV model using NPSQML estimator. Instead, let V_j^{θ} be generated according to Eq. 56.13, setting $qh = j$, and $j = 1, \ldots, L$. The idea is to simulate L different starting values for unobservable volatility, construct the simulated likelihood functions accordingly, and then average them out. For each simulation replication at time t, we simulate L different values of $X_t(X_{t-1}, V_j^{\theta})$ by generating L paths of length one, using fixed observable X_{t-1} and unobservable V_j^{θ}, $j = 1, \ldots, L$ as starting values. Repeat this procedure for any $t = 1, \ldots, T-1$ and for any set $j, j = 1, \ldots, L$ of random errors $\varepsilon_{1,t+(q+1)h,j}$ and $\varepsilon_{2,t+(q+1)h,j}$, $q = 1, \ldots, 1/h$. Note that it is important to use the same set of random errors $\varepsilon_{1,t+(q+1)h,j}$ and $\varepsilon_{2,t+(q+1)h,j}$ across different initial values for volatility. Denote the simulated value

[22] Fermanian and Salanie (2004) suggest using the following trimming function:

$$\tau_N(x) = \frac{4(x-a_N)^3}{a_N^3} - \frac{3(x-a_N)4}{a_N^4},$$

for $a_N \leq x \leq 2a_N$.

at time t and simulation replication i, under generic parameter θ, using X_{t-1}, V_j^θ as starting values as $X_{t,i,h}^\theta(X_{t-1}, V_j^\theta)$. Then

$$\hat{f}_{M,L,h}(X_t|X_{t-1},\theta) = \frac{1}{L}\sum_{j=1}^{L}\frac{1}{M\xi_M}\sum_{i=1}^{M}K\left(\frac{X_{t,i,h}^\theta\left(X_{t-1},V_j^\theta\right) - X_t}{\xi_M}\right),$$

and note that by averaging over the initial values for the unobservable volatility, its effect is integrated out. Finally, define[23]

$$\hat{\theta}_{t,M,L,h} = \arg\min_{\theta\in\Theta}\frac{1}{t}\sum_{s=2}^{t}\left(\ln \hat{f}_{M,L,h}(X_s|X_{s-1},\theta)\tau_M \times \hat{f}_{M,L,h}(X_s|X_{s-1},\theta)\right), t \geq R.$$

Note that in this case, X_t is no longer Markov (i.e., X_t and V_t are jointly Markovian, but X_t is not). Therefore, even in the case of true data generating process, the joint likelihood cannot be expressed as the product of the conditional and marginal distributions. Thus, $\hat{\theta}_{t,M,L,h}$ is necessarily a QML estimator. Furthermore, note that $\nabla_\theta f(X_t|X_{t-1},\theta^\dagger)$ is no longer a martingale difference sequence; therefore, we need to use HAC robust covariance matrix estimators, regardless of whether the model is the "correct" model or not.

56.3.4 Bootstrap Critical Value Procedures

The test statistics presented in Sects. 56.3.1 and 56.3.2 are implemented using critical values constructed via the bootstrap. As mentioned earlier, motivation for using the bootstrap is clear. The covariance kernel of the statistic limiting distributions contains both parameter estimation error and the data-related time-dependence components. Asymptotic critical value cannot thus be tabulated in a usual way. Several methods have been proposed to tackle this issue. One is the block bootstrap procedures which we discuss. Others have been mentioned above.

With regard to the validity of the bootstrap, note that, in the case of dependent observations without PEE, we can tabulate valid critical value using a simple empirical version of the Künsch (1989) block bootstrap. Now, the difficulty in our context lies in accounting for parameter estimation error. Goncalves and White (2002) establish the first-order validity of the block bootstrap for QMLE (or m-estimator) for dependent and heterogeneous data. This is an important result

[23]For discussion of asymptotic properties of $\hat{\theta}_{k,t,M,L,h}$, as well as of regularity conditions, see Corradi and Swanson (2011).

for the class of SGMM and NSQML estimators surveyed in this chapter and allows Corradi and Swanson in CS (2011) and elsewhere to develop asymptotically valid version of the bootstrap that can be applied under generic model misspecification, as assumed throughout this chapter.

For the SGMM estimator, as shown in Corradi and Swanson (2005), the first-order validity of the block bootstrap is valid in the exact identification case, and when $T/S \to 0$. In this case, SGMM is asymptotically equivalent to GMM, and consequently, there is no need to bootstrap the simulated series. In addition, in the exact identification case, GMM estimators can be treated the same way that QMLE estimators are treated. For the NSQML estimator, Corradi and Swanson (2011) point out that the NPSQML estimator is asymptotically equivalent to the QML estimator. Thus, we do not need to resample the simulated observations as the negligible contribution of simulation errors.

Also note that critical values for these tests can be obtained using a recursive version of the block bootstrap. When forming block bootstrap samples in the recursive case, observations at the beginning of the sample are used more frequently than observations at the end of the sample. This introduces a location bias to the usual block bootstrap, as under standard resampling with replacement, all blocks from the original sample have the same probability of being selected. Also, the bias term varies across samples and can be either positive or negative, depending on the specific sample. A first-order valid bootstrap procedure for nonsimulation-based m-estimators constructed using a recursive estimation scheme is outlined in Corradi and Swanson (2007a). Here we extend the results of Corradi and Swanson (2007a) by establishing asymptotic results for cases in which simulation-based estimators are bootstrapped in a recursive setting.

Now the details of bootstrap procedure for critical value tabulation can be outlined in 5 steps as follows:

Step 1: Let $T = bl$, where b denotes the number of blocks and l denotes the length of each block. We first draw a discrete uniform random variable, I_1, that can take values $0, 1, \ldots, T - l$ with probability $1/(T - l + 1)$. The first block is given by $X_{I_1+1}, \ldots, X_{I_1+l}$. We then draw another discrete uniform random variable, say I_2, and a second block of length l is formed, say $X_{I_2+1}, \ldots, X_{I_2+l}$. Continue in the same manner, until you draw the last discrete uniform, say I_b, and so the last block is $X_{I_b+1}, \ldots, X_{I_b+l}$. Let's call the X_t^* the resampled series, and note that $X_1^*, X_2^*, \ldots, X_T^*$ corresponds to $X_{I_1+1}, X_{I_1+2}, \ldots, X_{I_b+l}$. Thus, conditional on the sample, the only random element is the beginning of each block. In particular,

$$X_1^*, \ldots, X_l^*, X_{l+1}^*, \ldots, X_{2l}^*, X_{T-l+1}^*, \ldots, X_T^*,$$

conditional on the sample, can be treated as b i.i.d. blocks of discrete uniform random variables. Note that it can be shown that except a set of probability measure approaching zero,

$$E^*\left(\frac{1}{T}\sum_{t=1}^{T}X_t^*\right)=\frac{1}{T}\sum_{t=1}^{T}X_t+O_P^*(l/T) \tag{56.18}$$

$$Var*\left(\frac{1}{T^{1/2}}\sum_{t=1}^{T}X_t^*\right)=\frac{1}{T}\sum_{t=l}^{T-l}\sum_{i=-l}^{l}\left(X_t-\frac{1}{T}\sum_{t=1}^{T}X_t\right)\left(X_{t+i}-\frac{1}{T}\sum_{t=1}^{T}X_t\right)+O_{P*}\left(l^2/T\right), \tag{56.19}$$

where E^* and Var^* denote the expectation and the variance operators with respect to P^* (the probability law governing the resampled series or the probability law governing the i.i.d. uniform random variables, conditional on the sample) and where $O_{P^*}(l/T)(O_{P^*}(l^2/T))$ denotes a term converging in probability P^* to zero, as $l/T \to 0(l^2/T \to 0)$.

In the case of recursive estimators, we proceed the bootstrap similarly as follows. Begin by resampling b blocks of length l from the full sample, with $lb = T$. For any given τ, it is necessary to jointly resample $X_t, X_{t+1}, \ldots, X_{t+\tau}$. More precisely, let $Z^{t,\tau} = (X_t, X_{t+1}, \ldots, X_{t+\tau})$, $t = 1,\ldots, T - \tau$. Now, resample b overlapping blocks of length l from $Z^{t,\tau}$. This yields $Z^{t,*} = (X_t^*, X_{t+1}^*, \ldots, X_{t+\tau}^*)$, $t = 1, \ldots, T - \tau$.

Step 2: Re-estimate $\hat{\theta}^*_{t,N,h}\left(\hat{\theta}^*_{T,N,L,h}\right)$ using the bootstrap sample $Z^{t,*} = (X_t^*, X_{t+1}^*, \ldots, X_{t+\tau}^*)$, $t = 1, \ldots, T - \tau$ (or full sample $X_1^*, X_2^*, \ldots, X_T^*$). Recall that if we use the entire sample for the estimation, as the specification test in Corradi and Swanson (2005) and Bhardwaj et al. (2008), then $\hat{\theta}^*_{t,N,h}$ is denoted as $\hat{\theta}^*_{T,N,h}$. The bootstrap estimators for SGMM and NPSQML are presented below:

Bootstrap (Recursive) SGMM Estimators

If the full sample is used in the specification test as in Corradi and Swanson (2005) and Bhardwaj et al. (2008), the bootstrap estimator is constructed straightforward as

$$\begin{aligned}\hat{\theta}^*_{T,N,h} = \arg\min_{\theta\in\Theta}&\left(\frac{1}{T}\sum_{j=1}^{T}g\left(X_j^*\right)-\frac{1}{L}\sum_{i=1}^{L}g\left(X_{j,h}^{\theta}\right)\right)'\\ &\times W_T^{*-1}\left(\frac{1}{T}\sum_{j=1}^{T}g\left(X_j^*\right)-\frac{1}{L}\sum_{i=1}^{L}g\left(X_{j,h}^{\theta}\right)\right),\end{aligned}$$

where W_T^{-1} and $g(.)$ are defined in Eq. 56.15 and L is the length of each simulation path.

Note that it is convenient not to resample the simulated series as the simulation error vanishes asymptotically. In implementation, we do not mimic its contribution to the covariate kernel.

In the case of predictive density-type model selection where recursive estimators are needed, define the bootstrap analog as

$$
\begin{aligned}
\hat{\theta}^*_{t,L,h} = \arg\min_{\theta\in\Theta} & \left(\frac{1}{t}\sum_{j=1}^{t}\left(\left(g\left(X_j^*\right) - \frac{1}{T}\sum_{j'=1}^{T} g\left(X_{j'}\right)\right)\right.\right. \\
& \left.\left.- \left(\frac{1}{L}\sum_{i=1}^{L} g\left(X_{j,h}^{\theta}\right) - \frac{1}{L}\sum_{i=1}^{L} g\left(X_{j,h}^{\hat{\theta}_{t,L,h}}\right)\right)\right)\right)' \\
& \times \Omega_t^{*-1}\left(\frac{1}{t}\sum_{j=1}^{t}\left(\left(g\left(X_j^*\right) - \frac{1}{T}\sum_{j'=1}^{T} g\left(X_{j'}\right)\right)\right.\right. \\
& \left.\left.- \left(\frac{1}{L}\sum_{i=1}^{L} g\left(X_{j,h}^{\theta}\right) - \frac{1}{L}\sum_{i=1}^{L} g\left(X_{j,h}^{\hat{\theta}_{t,L,h}}\right)\right)\right)\right) \\
= \arg\min_{\theta\in\Theta} & \, G^*_{t,L,h}(\theta)'\Omega_t^{*-1} G^*_{t,L,h}(\theta),
\end{aligned}
$$

where

$$
\Omega_t^{*-1} = \frac{1}{t}\sum_{v=-l_t}^{l_t} w_{v,t} \sum_{j=v+1+l_t}^{t-l_t}\left[g\left(X_j^*\right) - \frac{1}{T}\sum_{j'=1}^{T} g\left(X_{j'}\right)\right]\left[g\left(X_{j-v}^*\right) - \frac{1}{T}\sum_{j'=1}^{T} g\left(X_{j'}\right)\right].
$$

Note that each bootstrap term is recentered around the (full) sample mean. The intuition behind the particular recentering in bootstrap recursive SGMM estimator is that it ensures that the mean of the bootstrap moment conditions, evaluated at $\hat{\theta}_{t,L,h}$, is zero, up to a negligible term. Specifically, we have

$$
\begin{aligned}
& E*\left(\frac{1}{t}\sum_{j=1}^{t}\left(g\left(X_j^*\right) - \frac{1}{T}\sum_{j'=1}^{T} g\left(X_{j'}\right)\right)\right. \\
& \left.- \left(\frac{1}{L}\sum_{i=1}^{L} g\left(X_{j,h}^{\hat{\theta}^*_{t,L,h}}\right) - \frac{1}{L}\sum_{i=1}^{L} g\left(X_{j,h}^{\hat{\theta}_{t,L,h}}\right)\right)\right) \\
& = E*\left(g\left(X_j^*\right)\right) - \frac{1}{T}\sum_{j'=1}^{T} g\left(X_{j'}\right) \\
& = O(l/T), \text{with}\, l = o\left(T^{1/2}\right),
\end{aligned}
$$

where the $O(l/T)$ term is due to the end block effect (see Corradi and Swanson (2007b) for further discussion).

Bootstrap Recursive NPSQML Estimators

Let $Z^{t,*} = (X_t^*, X_{t+1}^*, \ldots, X_{t+\tau}^*)$, $t = 1, \ldots, T - \tau$. For each simulation replication, generate $T - 1$ paths of length one, using $X_1^*, \ldots, X_{T-1}^*$ as starting values, and so obtaining $X_{t,j}^{\theta}(X_{t-1}^*)$ for $t = 2, \ldots, T - 1$, $i = 1,.., M$. Further, let:

$$\hat{f}^*_{M,h}\left(X_t^* \middle| X_{t-1}^*, \theta\right) = \frac{1}{M\xi_M} \sum_{i=1}^{M} K\left(\frac{X_{t,i,h}^{\theta}\left(X_{t-1}^*\right) - X_t^*}{\xi_M}\right),$$

Now, for $t = R, \ldots, R + P - 1$, define

$$\begin{aligned}
\hat{\theta}^*_{t,M,h} = \arg\max_{\theta \in \Theta} \frac{1}{t} \sum_{l=2}^{t} & \ln \hat{f}_{M,h}\left(X_l^* \middle| X_{l-1}^*, \theta\right) \tau_M \\
& \times \left(\hat{f}_{M,h}\left(X_l^* \middle| X_{l-1}^*, \theta\right)\right) \\
& -\theta' \left(\frac{1}{T} \sum_{l'=2}^{T} \frac{\nabla_\theta \hat{f}_{M,h}(X_{l'} | X_{l'-1}, \theta)}{\hat{f}_{M,h}\left(X_{l'}^* | X_{t-l'}^* \theta\right)} \bigg|_{\theta = \hat{\theta}_{t,M,h}} \right. \\
& \times \tau_M \left(\hat{f}_{M,h}\left(X_{l'} \middle| X_{l'-1}, \hat{\theta}_{t,M,h}\right)\right) \\
& + \tau'_M \left(\hat{f}_{M,h}\left(X_{l'} \middle| X_{l'-1}, \hat{\theta}_{t,M,h}\right)\right) \\
& \times \nabla_\theta \hat{f}_{M,h}(X_{l'} | X_{l'-1}, \theta) \Big|_{\hat{\theta}_{t,M,h}} \\
& \left. \times \ln \hat{f}_{M,h}(X_{l'} | X_{l'-1} \hat{\theta}_{t,M,h}) \right),
\end{aligned}$$

where $\tau'_M(\cdot)$ denotes the derivative of $\tau_M(\cdot)$ with respect to its argument. Note that each term in the simulated likelihood is recentered around the (full) sample mean of the score, evaluated at $\hat{\theta}_{t,M,h}$. This ensures that the bootstrap score has mean zero, conditional on the sample. The recentering term requires computation of $\nabla_\theta \hat{f}_{M,h}\left(X_{l'} \middle| X_{l'-1}, \hat{\theta}_{t,M,h}\right)$, which is not known in closed form. Nevertheless, it can be computed numerically, by simply taking the numerical derivative of the simulated likelihood.

Bootstrap Estimators for Multifactor Model

The SGMM and the bootstrap SGMM estimators in the case of multifactor model are similar as in one-factor model. The difference is that the simulation schemes (56.12) and (56.13) are used instead of Eq. 56.11.

For recursive NPSQML estimators, to construct the bootstrap counterpart $\hat{\theta}^*_{t,M,L,h}$ of $\hat{\theta}_{t,M,L,h}$, since $M/T \to \infty$ and $L/T \to \infty$, the contribution of simulation error is asymptotically negligible. Hence, there is no need to resample the simulated observations or the simulated initial values for volatility. Define

$$\hat{f}_{M,L,h}\left(X_t^*\middle|X_{t-1}^*,\theta\right) = \frac{1}{L}\sum_{j=1}^{L}\frac{1}{M\xi_M}\sum_{i=1}^{M}K\left(\frac{X_{t,i,h}^{\theta}\left(X_{t-1}^*,V_j^{\theta}\right)-X_t^*}{\xi_M}\right).$$

Now, for $t = R, \ldots, R + P - 1$, define

$$\begin{aligned}\hat{\theta}^*_{t,M,L,h} = \arg\max_{\theta\in\Theta}\frac{1}{t}\sum_{l=2}^{t} & \\ & \left(\log\hat{f}_{t,M,L,h}\left(X_l^*\middle|X_{l-1}^*,\theta\right)\tau_M\left(\hat{f}_{t,M,L,h}\left(X_l^*\middle|X_{l-1}^*,\theta\right)\right)\right. \\ & -\theta'\left(\frac{1}{T}\sum_{l'=2}^{T}\frac{\nabla_\theta\hat{f}_{t,M,L,h}(X_{l'}|X_{l'-1},\theta)}{\hat{f}_{t,M,L,h}\left(X_{l'}^*\middle|X_{t-l'}^*,\theta\right)}\Big|_{\theta_{t,M,L,h}}\right. \\ & \times\tau_M = \left(\hat{f}_{t,M,L,h}\left(X_{l'}\middle|X_{l'-1},\hat{\theta}_{t,M,L,h}\right)\right) \\ & +\tau'_M\left(\hat{f}_{t,M,L,h}\left(X_{l'}\middle|X_{l'-1},\hat{\theta}_{t,M,L,h}\right)\right) \\ & \times\nabla_\theta\hat{f}_{t,M,L,h}(X_{l'}|X_{l'-1},\theta)\Big|_{\hat{\theta}_{t,M,L,h}} \\ & \left.\left.\times\ln\hat{f}_{t,M,L,h}(X_{l'}|X_{l'-1},\hat{\theta}_{t,M,L,h})\right)\right),\end{aligned}$$

where $\tau_M'(\cdot)$ denotes the derivative with respect to its argument.

Of note is that each bootstrap term is recentered around the (full) sample mean. This is necessary because the bootstrap statistic is constructed using the last P resampled observations, which in turn have been resampled from the full sample. In particular, this is necessary regardless of the ratio, P/R. In addition, in the case $P/R \to 0$, so that there is no need to mimic parameter estimation error, the bootstrap statistics can be constructed using $\hat{\theta}_{t,M,L,h}$ instead of $\hat{\theta}^*_{t,M,L,h}$.

Step 3: Using the same set of random variables used in the construction of the actual statistics, construct $X_{i,t+\tau,*}^{\hat{\theta}^*_{t,N,h}}$ or $X_{k,i,t+\tau,*}^{\hat{\theta}^*_{t,N,h}}$, $i = 1, \ldots, S$ and $t = 1,\ldots, T - \tau$. Note that we do not need resample the simulated series (as $L/T \to \infty$, simulation error is asymptotically negligible). Instead, simulate the series using bootstrap estimators and using bootstrapped values as starting values.

Step 4: Corresponding bootstrap statistics $V_{T,N,h}^{2*}$ (or $Z_{T,N,h}^*$, $D_{k,P,S}^*$, $SV_{T,N,h}^{2\,*}$, $SZ_{T,N,h}^*$, $SD_{k,P,S}^*$ depending on the types of tests) which are built on $\hat{\theta}^*_{t,N,h}\left(\hat{\theta}^*_{t,N,L,h}\right)$ then are followed correspondingly. For the numerical implementation, again, of important note is that in the case where we pick the choice $P/R \to 0$, P, T,

$R \to \infty$, there is no need to re-estimate $\hat{\theta}^*_{t,N,h}\left(\hat{\theta}^*_{t,N,L,h}\right)$. $\hat{\theta}^*_{t,N,h}\left(\hat{\theta}^*_{t,N,L,h}\right)$ can be used in all the bootstrap replications.

Step 5: Repeat the bootstrap Steps 1–4 B times, and generate the empirical distribution of the B bootstrap statistics.

56.4 Summary of Empirical Applications of the Tests

In this section, we briefly review some empirical applications of the methods discussed above. We start with unconditional distribution test, as in Corradi and Swanson (2005) and then give a specific empirical example using the conditional distribution test from Bhardwaj et al. (2008). Finally, we briefly discuss on conditional distribution specification test applied to multiple competing models. The list of the diffusion models considered is provided in Table 56.1.

Note that specification testing of the first model – a simplified version of the CIR model (we refer to this model as Wong) – is carried out using the unconditional distribution test. With the cumulative distribution function known in closed form as in Eq. 56.8, the test statistic can be straightforwardly calculated. It is also convenient to use GMM estimation in this case as the first two moments are known in closed form, i.e., $\alpha - \lambda$ and $\alpha/2(\alpha - \beta)$, respectively. Corradi and Swanson (2005) examine Hypothesis 1 using simulated data. Their Monte Carlo experiments suggest that the test is useful, even for samples as small as 400 observations.

Hypothesis 2 is tested in Bhardwaj et al. (2008) and Cai and Swanson (2011). For illustration, we focus on the results in Bhardwaj et al. (2008) where CIR, SV, and SVJ models are empirically tested using the 1-month Eurodollar deposit rate (as a proxy for short rate) for the sample period January 6, 1971–September 30, 2005, which yields 1,813 weekly observations. Note that one might apply these tests to other datasets including the monthly federal funds rate, the weekly 3-month T-bill rate, the weekly US dollar swap rate, the monthly yield on zero-coupon bonds with different maturities, and the 6-month LIBOR. Some of these variables have been examined elsewhere, for example, in Ait-Sahalia (1999), Andersen et al. (2004), Dai and Singleton (2000), Diebold and Li (2006), and Piazzesi (2001).

The statistic needed to apply the test discussed in Sect. 56.3.1.2 is

$$Z_T = \sup_{v \in V} |Z_T(v)|,$$

Table 56.1 Specification test hypotheses of continuous time spot rate process[a]

Model	Specification	Reference and data	Hypothesis
Wong	$dr(t) = (\alpha - \lambda - r(t))dt + \sqrt{\alpha r(t)}dW_r(t)$	Corradi and Swanson (2005)	H1
		Simulated data	
		Bhardwaj et al. (2008)	
		Eurodollar rate	H2
		(1971–2005)	
CIR	$dr(t) = k_r(\bar{r} - r(t))dt + \sqrt{V(t)}dW_r(t),$	Cai and Swanson (2011)	
		Eurodollar Rate	H2, H3
		(1971–2008)	
		Cai and Swanson (2011)	
CEV	$dr(t) = k_r(\bar{r} - r(t))dt + \sigma_r r(t)^{\rho}dW_r(t)$	Eurodollar rate	H2, H3
		(1971–2008)	
SV	$dr(t) = k_r(\bar{r} - r(t))dt + \sqrt{V(t)}dW_r(t),$	Bhardwaj et al. (2008)	H2
	$dV(t) = k_r(\bar{v} - V(t))dt + \sigma_v\sqrt{V(t)}dW_v(t),$	Cai and Swanson (2011)	H2, H3
SVJ	$dr(t) = k_r(\bar{r} - r(t))dt + \sqrt{V(t)}dW_r(t) + J_u dq_u - J_d dq_d,$	Bhardwaj et al. (2008)	H2
	$dV(t) = k_v(\bar{v} - V(t))dt + \sigma_v\sqrt{V(t)}dW_v(t),$	Cai and Swanson (2011)	H2, H3
CHEN	$dr(t) = \kappa_r(\theta(t) - r(t))dt + \sqrt{V(t)}dW_r,$	Cai and Swanson (2011)	
	$dV(t) = \kappa_v(\bar{v} - V(t))dt + \sigma_v\sqrt{V(t)}dW_v(t),$	Eurodollar rate	H2, H3
	$d\theta(t) = \kappa_\theta\left(\bar{\theta} - \theta(t)\right)dt + \sigma_\theta\sqrt{\theta(t)}dW_\theta(t),$	(1971–2008)	
CHENJ	$dr(t) = \kappa_r(\theta(t) - r(t))dt + \sqrt{V(t)}dW_r(t) + J_u dq_u - J_d dq_d,$	Cai and Swanson (2011)	
	$dV(t) = \kappa_v(\bar{v} - V(t))dt + \sigma_v\sqrt{V(t)}dW_v(t),$	Eurodollar rate	H2, H3
	$d\theta(t) = \kappa_\theta\left(\bar{\theta} - \theta(t)\right)dt + \sigma_\theta\sqrt{\theta(t)}dW_\theta(t),$	(1971–2008)	

[a]Note that the third column, "Reference and data," provides the referenced papers and data used in empirical applications. In the fourth column, H1, H2, and H3 denote Hypothesis 1, Hypothesis 2, and Hypothesis 3, respectively. The hypotheses are presented corresponding to the references in the third column. For example, for CIR model, H2 corresponds to Bhardwaj et al. (2008) and H2 and H3 correspond to Cai and Swanson (2011)

where

$$
\begin{aligned}
Z_T(v) = {} & \frac{1}{\sqrt{T-\tau}}\sum_{t=1}^{T-\tau} 1\{X_t \le v\} \\
& \times \left(\frac{1}{S}\sum_{s=1}^{S} 1\left\{\underline{u} \le X_{s,t+\tau}^{\hat{\theta}_{T,N,h}} \le \overline{u}\right\} - 1\left\{\underline{u} \le X_{t+\tau} \le \overline{u}\right\}\right),
\end{aligned}
$$

and

$$Z_T^* = \sup_{v \in V} \left| Z_T^*(v) \right|,$$

Where

$$\begin{aligned} Z_T^*(v) = & \frac{1}{\sqrt{T-\tau}} \sum_{t=1}^{T-\tau} 1\left\{ X_t^* \leq v \right\} \\ & \times \left(\frac{1}{S} \sum_{s=1}^{S} 1\left\{ \underline{u} \leq X_{s,t+\tau,*}^{\hat{\theta}_{T,N,h}^*} \leq \overline{u} \right\} - 1\left\{ \underline{u} \leq X_{t+\tau}^* \leq \overline{u} \right\} \right) \\ & - \frac{1}{\sqrt{T-\tau}} \sum_{t=1}^{T-\tau} 1\{ X_t \leq v \}. \\ & \times \left(\frac{1}{S} \sum_{s=1}^{S} 1\left\{ \underline{u} \leq X_{s,t+\tau}^{\hat{\theta}_{T,N,h}} \leq \overline{u} \right\} - 1\left\{ \underline{u} \leq X_{t+\tau} \leq \overline{u} \right\} \right). \end{aligned}$$

For the case of stochastic volatility models, similarly we have

$$SZ_T = \sup_{v \in V} |SZ_T(v)|,$$

where

$$\begin{aligned} SZ_T(v) = & \frac{1}{\sqrt{T-\tau}} \sum_{t=1}^{T-\tau} 1\{ X_t \leq v \} \\ & \times \left(\frac{1}{LS} \sum_{j=1}^{L} \sum_{s=1}^{S} 1\left\{ \underline{u} \leq X_{j,s,t+\tau}^{\hat{\theta}_{T,N,h}} \leq \overline{u} \right\} - 1\left\{ \underline{u} \leq X_{t+\tau} \leq \overline{u} \right\} \right), \end{aligned}$$

and its bootstrap analog

$$SZ_T^* = \sup_{v \in V} \left| SZ_T^*(v) \right|,$$

where

$$\begin{aligned} SZ_T^*(v) = & \frac{1}{\sqrt{T-\tau}} \sum_{t=1}^{T-\tau} 1\left\{ X_t^* \leq v \right\} \times \left(\frac{1}{LS} \sum_{j=1}^{L} \sum_{s=1}^{S} 1\left\{ \underline{u} \leq X_{j,s,t+\tau,*}^{\hat{\theta}_{i,T,N,h}^*} \leq \overline{u} \right\} \right. \\ & \left. - 1\left\{ \underline{u} \leq X_{t+\tau}^* \leq \overline{u} \right\} \right) - \frac{1}{\sqrt{T-\tau}} \sum_{t=1}^{T-\tau} 1\{ X_t \leq v \} \\ & \times \left(\frac{1}{LS} \sum_{j=1}^{L} \sum_{s=1}^{S} 1\left\{ \underline{u} \leq X_{j,s,t+\tau}^{\hat{\theta}_{i,T,N,h}} \leq \overline{u} \right\} - 1\left\{ \underline{u} \leq X_{t+\tau} \leq \overline{u} \right\} \right). \end{aligned}$$

Bhardwaj et al. (2008) carry out these tests using τ-*step* ahead confidence intervals. They set $\tau = \{1, 2, 4, 12\}$ which corresponds to 1-week, 2-week, 1-month, and one-quarter ahead intervals and set $\left(\underline{u}\overline{u}\right) = \left(\overline{X} \pm 0.5\sigma_X, \overline{X} \pm \sigma_X\right)$, covering 46.3 % and 72.4 % coverage, respectively. $\overline{X}$ and σ_X are the mean and variance of an initial sample of data. In addition, $S = \{10T, 20T\}$ and $l = \{5, 10, 20, 50\}$.

For illustrative purposes, we report one case from Bhardwaj et al. (2008). The test is implemented by setting $S = 10T$ and $l = 25$ for the calculation of both Z_T and SZ_T. In Table 56.2, single, double, and triple starred entries represent rejection using 20 %, 10 %, and 5 % size tests, respectively. Not surprisingly, the findings are consistent with some other papers in the specification test literature such as Aït-Sahalia (1996) and Bandi (2002). Namely, the CIR model is rejected using 5 % size tests in almost all cases. When considering SV and SVJ models, smaller confidence intervals appear to lead to more model rejections. Moreover, results are somewhat mixed when evaluating the SVJ model, with a slightly higher frequency of rejection than in the case of SV models.

Finally, turning to **Hypothesis 3**, Cai and Swanson (2011) use an extended version of the above dataset, i.e., the 1-month Eurodollar deposit rate from January 1971 to April 2008 (1,996 weekly observations). Specifically, they examine whether the Chen model is the "best" model amongst multiple alternative models including those outlined in Table 56.1. The answer is "yes." In this example, the test was implemented using $D_{k,p,N}(u1,\ u2)$, as described in Sects. 56.3.1 and 56.3.2, where $P = T/2$ and predictions are constructed using recursively estimated models and the simulation sample length used to address latent variable initial values is set at $L = 10T$. The choice of other inputs to the test such as τ and interval $\left(\underline{u}, \overline{u}\right)$ is the same as in Bhardwaj et al. (2008). The number of replications S, the block length l, and number of bootstrap replications are $S = 10T$, $l = 20$, and $B = 100$.

Cai and Swanson (2011) also compare the Chen model with the so-called smooth transition autoregression (STAR) model defined as follows:

$$r_t = (\theta_1 + \beta_1 r_{t-1})G(\gamma, z_t, c) + (\theta_1 + \beta_2 r_{t-1})(1 - G(\gamma, z_t, c)) + u_t,$$

where u_t is a disturbance term; θ_1, β_1, γ, β_2, and c are constants; $G(\cdot)$ is the logistic CDF $\left(\text{i.e.}, G, (\gamma, z_t, c), =, \frac{1}{1+\exp(\gamma(z_t - c))}\right)$ and the number of lags; and p is selected via the use of Schwarz information criterion. Test statistics and predictive density-type "mean square forecast error" (MSFEs) values are again calculated as in Sects. 56.3.1 and 56.3.2.[24] Their results indicate that at a 90 % level of confidence, one cannot reject the null hypothesis that the Chen model generates predictive densities at least as accurate as the STAR model, regardless of forecast horizon and confidence interval width. Moreover, in almost all cases, the Chen model has lower MSFE, and the magnitude of the MSFE differential between the Chen model and STAR model rises as the forecast horizon increases. This confirms their in-sample findings that the Chen model also wins when carrying out in-sample tests.

[24]See Table 6 in Cai and Swanson (2011) for complete details.

Table 56.2 Empirical illustration of specification testing – *CIR*, *SV*, *SVJ* models[a]

	$(\underline{u}, \overline{u})$	CIR			SV			SVJ

[a]Tabulated entries are test statistics and 5 %, 10 %, and 20 % level critical values. Test intervals are given in the second column of the table, for $\tau = 1, 2, 4, 12$. All tests are carried out using historical 1-month Eurodollar deposit rate data for the period January 1971–September 2005, measured at a weekly frequency. *, **, and *** denote rejection at the 20 %, 10 %, and 5 % levels, respectively. Additionally, $\overline{X}$ and σ_X are the mean and standard deviation of the historical data. See above for complete details

56.5 Conclusion

This chapter reviews a class of specification and model selection-type tests developed by Corradi and Swanson (2005), Bhardwaj et al. (2008), and Corradi and Swanson (2011) for continuous time models. We begin with outlining the setup used to specify the types of diffusion models considered in this chapter. Thereafter, diffusion models in finance are discussed, and testing procedures are outlined. Related testing procedures are also discussed, both in contexts where models are assumed to be either correctly specified under the null hypothesis or generically misspecified under both the null and alternative test hypotheses. In addition to discussing tests of correct specification and test for selecting amongst alternative competing models, using both in-sample methods and via comparison of predictive accuracy, methodology is outlined allowing for parameter estimation, model and data simulation, and bootstrap critical value construction.

Several extensions that are left to future research are as follows. First, it remains to construct specification tests that do not integrate out the effects of latent factors. Additionally, it remains to examine the finite sample properties of the estimators and bootstrap methods discussed in this chapter.

Acknowledgments The authors thank the editor, Cheng-Few Lee, for many useful suggestions given during the writing of this chapter. Duong and Swanson would like to thank the Research Council at Rutgers University for research support.

Abstract

We describe different procedures to deal with measurement error in linear models and assess their performance in finite samples using Monte Carlo simulations and data on corporate investment. We consider the standard instrumental variable approach proposed by Griliches and Hausman (Journal of Econometrics 31:93–118, 1986) as extended by Biorn (Econometric Reviews 19:391–424, 2000) [OLS-IV], the Arellano and Bond (Review of Economic Studies 58:277–297, 1991) instrumental variable estimator, and the higher-order moment estimator proposed by Erickson and Whited (Journal of Political Economy 108:1027–1057, 2000, Econometric Theory 18:776–799, 2002). Our analysis focuses on characterizing the conditions under which each of these estimators produce unbiased and efficient estimates in a standard "errors-in-variables" setting. In the presence of fixed effects, under heteroscedasticity, or in the absence of a very high degree of skewness in the data, the EW estimator is inefficient and returns biased estimates for mismeasured and perfectly measured regressors. In contrast to the EW estimator, IV-type estimators (OLS-IV and AB-GMM) easily handle individual effects, heteroscedastic errors, and different degrees of data skewness. The IV approach, however, requires assumptions about the autocorrelation structure of the mismeasured regressor and the measurement error. We illustrate the application of the different estimators using empirical investment models. Our results show that the EW estimator produces inconsistent results when applied to real-world investment data, while the IV estimators tend to return results that are consistent with theoretical priors.

57.1 Introduction

OLS estimators are the workhorse of empirical research in many fields in applied economics. Researchers see a number of advantages in these estimators. Most notably, they are easy to implement and the results they generate are easy to replicate. Another appealing feature of OLS estimators is that they easily accommodate the inclusion of individual (e.g., firm and time) idiosyncratic effects. Despite their popularity, however, OLS estimators are weak in dealing with the problem of errors in variables. When the independent (right-hand side) variables of an empirical model are mismeasured, coefficients estimated via standard OLS are inconsistent (*attenuation bias*). This poses a problem since, in practice, it is hard to think of any empirical proxies in applied research whose measurement is not a concern.

In this chapter, we describe three estimators that deal with the problem of mismeasurement, namely, the standard instrumental variable approach extended by Biorn (2000) [OLS-IV], the Arellano and Bond (1991) instrumental variable estimator [AB-GMM], and the higher-order moment estimator proposed by Erickson and Whited (2000, 2002) [henceforth, EW]. We also assess the performance of these estimators in finite samples using Monte Carlo simulations and illustrate their application using data on corporate investment.

While we provide a formal presentation in the next section, it is useful to discuss the intuition behind the estimation approaches we analyze. All approaches share the attractive property that they do not require the researcher to look for instruments outside the model being considered.[1] They differ, however, on how identification is achieved.

Both instrumental variable approaches rely on assumptions about the serial correlation of the latent variable and the innovations of the model (the model's disturbances and the measurement error). There are two conditions that must hold to ensure identification. First, the true value of the mismeasured regressor must have some degree of autocorrelation. In this case, lags of the mismeasured regressor are natural candidates for the instrumental set since they contain information about the current value of the mismeasured regressor.[2] This condition is akin to the standard requirement that the instrument be correlated with the variable of interest. The other necessary condition is associated with the *exclusion restriction* that is standard in IV methods and relates to the degree of serial correlation of the innovations. A standard assumption guaranteeing identification is that the measurement-error process is independently and identically distributed. This condition ensures that past values of the observed variables are uncorrelated with the current value of the measurement error, validating the use of lags of observed variables as instruments. Under certain conditions, one can also allow for autocorrelation in the measurement error. Examples in which identification works are when autocorrelation is constant over time or when it evolves according to a moving average process.[3] The first assumption ensures identification because it means that while lagged values of the measurement error are correlated with its current value, any past shocks to the measurement-error process do not persist over time. The moving average assumption allows for shocks to persist over time, but it imposes restrictions on the instrumental set. In particular, as we show below, it precludes the

[1]Naturally, if extraneous instruments are available, they can help solve the identification problem. See Rauh (2006) for the use of discontinuities in pension contributions as a source of variation in cash flows in an investment model. Bond and Cummins (2000) use information contained in financial analysts' forecasts to instrument for investment demand.

[2]Lags of the well-measured variable may also be included in the instrument set if they are believed to also contain information about the mismeasured one.

[3]See, among others, Biorn (2000), Wansbeek (2001), and Xiao et al. (2008).

use of shorter lags of observed variables in the instrument set, as the information contained in short lags may be correlated with the current value of the measurement error.

The EW estimator is based on high-order moments of residuals obtained by "partialling out" perfectly measured regressors from the dependent, observed mismeasured, and latent variables, as well as high-order moments of the innovations of the model. The key idea is to create a set of auxiliary equations as a function of these moments and cross-moments. Implementation then requires a high degree of skewness in the distribution of the partialled out latent variable. Our analysis also shows that the presence of individual fixed effects and heteroscedasticity also impacts the performance of the EW estimator, particularly so if they are both present in the data process.

We perform a series of Monte Carlo simulations to compare the performance of the EW and IV estimators in finite samples. Emulating the types of environments commonly found by empirical researchers, we set up a panel data model with individual fixed effects and potential heteroscedasticity in the errors. Monte Carlo experiments enable us to study those estimators in a "controlled environment," where we can investigate the role played by each element (or assumption) of an estimator in evaluating its performance. Our simulations compare the EW and IV (OLS-IV and AB-GMM) estimators in terms of bias and root mean squared error (RMSE), a standard measure of efficiency.

We consider several distributional assumptions to generate observations and errors. Experimenting with multiple distributions is important because researchers often find a variety of distributions in real-world applications and because one ultimately does not observe the distribution of the mismeasurement term. Since the EW estimator is built around the notion of skewness of the relevant distributions, we experiment with three skewed distributions (lognormal, chi-square, and F-distribution), using the standard normal (non-skewed) as a benchmark. The simulations also allow for significant correlation between mismeasured and well-measured regressors (as in Erickson and Whited 2000, 2002), so that the attenuation bias of the mismeasured regressor affects the coefficient of the well-measured regressor.

Our simulation results can be summarized as follows. First, we examine the identification test proposed by Erickson and Whited (2002). This is a test that the data contain a sufficiently high degree of skewness to allow for the identification of their model. We study the *power* of the EW identification test by generating data that *do not* satisfy its null hypothesis of non-skewness. In this case, even for the most skewed distribution (lognormal), the test rejects the null hypothesis only 47 % of the time – this is far less than desirable, given that the null is false. The power of the test becomes even weaker after we treat the data for the presence of fixed effects in the true model ("within transformation"). In this case, the rejection rate under the lognormal distribution drops to 43 %. The test's power declines even further when we consider alternative skewed distributions (chi-square and F-distributions). The upshot of this first set of experiments is that the EW model too often rejects data that are generated to fit its identifying assumptions. These findings may help explain some of the difficulties previous researchers have reported when attempting to implement the EW estimator.

We then study the bias and efficiency of the EW and IV estimators. Given that the true model contains fixed effects, it is appropriate to apply the within transformation to the data. However, because most empirical implementations of the EW estimator have used data in "level form" (i.e., not treated for the presence of fixed effects),[4] we also experiment with cases in which we do not apply the within transformation. EW propose three estimators that differ according to the number of moments used: GMM3, GMM4, and GMM5. We consider all of them in our experiments.

In a first round of simulations, we impose error homoscedasticity. When we implement the EW estimator with the data in level form, we find that the coefficients returned are significantly biased even when the data have a high degree of skewness (i.e., under the lognormal case, which is EW's preferred case). Indeed, for the mismeasured regressors the EW biases are in excess of 100 % of their true value. As should be expected, the performance of the EW estimator improves once the within transformation is used. In the case of the lognormal distribution, the EW estimator bias is relatively small. In addition, deviations from the lognormal assumption tend to generate significant biases for the EW estimator.

In a second round of simulations, we allow for heteroscedasticity in the data. We focus our attention on simulations that use data that are generated using a lognormal distribution after applying the within transformation (the best case scenario for the EW estimator). Heteroscedasticity introduces heterogeneity to the model and consequently to the distribution of the partialled out dependent variable, compromising identification in the EW framework. The simulations show that the EW estimator is biased and inefficient for both the mismeasured and well-measured regressors. In fact, biases emerge even for very small amounts of heteroscedasticity, where we find biases of approximately 40 % for the mismeasured regressor. Paradoxically, biases "switch signs" depending on the degree of heteroscedasticity that is allowed for in the model. For instance, for small amounts of heteroscedasticity, the bias of the mismeasured regressor is negative (i.e., the coefficient is biased downwards). However, the bias turns positive for a higher degree of heteroscedasticity. Since heteroscedasticity is a naturally occurring phenomenon in corporate data, our simulations imply that empirical researchers might face serious drawbacks when using the EW estimator.

Our simulations also show that, in contrast to the EW estimator, the bias in the IV estimates is small and insensitive to the degree of skewness and heteroscedasticity in the data. Focusing on the OLS-IV estimator, we consider the case of time-invariant correlation in the error structure and use the second lag of the

[4]Examples are Whited (2001, 2006), Hennessy (2004), and Colak and Whited (2007).

observed mismeasured variable as an instrument for its current (differenced) value.[5] We also allow the true value of the mismeasured regressor to have a moderate degree of autocorrelation. Our results suggest that the OLS-IV estimator renders fairly unbiased estimates. In general, that estimator is also distinctly more efficient than the EW estimator.

We also examine the OLS-IV estimator's sensitivity to the autocorrelation structures of the mismeasured regressor and the measurement error. First, we consider variations in the degree of autocorrelation in the process for the true value of the mismeasured regressor. Our simulations show that the IV bias is largely insensitive to variations in the autoregressive (AR) coefficient (except for extreme values of the AR coefficient). Second, we replace the assumption of time-invariant autocorrelation in the measurement error with a moving average (MA) structure. Our simulations show that the OLS-IV bias remains small if one uses long enough lags of the observable variables as instruments. In addition, provided that the instrument set contains suitably long lags, the results are robust to variations in the degree of correlation in the MA process. As we discuss below, understanding these features (and limitations) of the IV approach is important given that the researcher will be unable to pin down the process followed by the measurement-error process.

To illustrate the performance of these alternative estimators on real data, in the final part of our analysis, we estimate empirical investment models under the EW and IV frameworks. Concerns about measurement errors have been emphasized in the context of the empirical investment model introduced by Fazzari et al. (1988), where a firm's investment is regressed on a proxy for investment demand (Tobin's q) and cash flows. Theory suggests that the correct proxy for a firm's investment demand is captured by *marginal* q, but this quantity is unobservable and researchers use instead its measurable proxy, *average* q. Since the two variables are not the same, a measurement problem naturally arises (Hayashi 1982; Poterba 1988). Following Fazzari et al. (1988), investment-cash flow sensitivities became a standard metric in the literature that examines the impact of financing imperfections on corporate investment (Stein 2003). These empirical sensitivities are also used for drawing inferences about efficiency in internal capital markets (Lamont 1997; Shin and Stulz 1998), the effect of agency on corporate spending (Hadlock 1998; Bertrand and Mullainathan 2005), the role of business groups in capital allocation (Hoshi et al. 1991), and the effect of managerial characteristics on corporate policies (Bertrand and Schoar 2003; Malmendier and Tate 2005).

Theory does not pin down exact values for the expected coefficients on q and cash flow in an investment model. However, two conditions would seem reasonable in practice. First, given that the estimator is addressing measurement error in q that may be "picked up" by cash flow (joint effects of attenuation bias and regressor

[5]The results for the Arellano–Bond GMM estimator are similar to those of the OLS-IV estimator. To save space and because the OLS-IV estimator is easier to implement, we focus on this estimator.

covariance), we should expect the q coefficient to go up and the cash flow coefficient to go down, when compared to standard (likely biased) OLS estimates. Second, we would expect the q and cash flow coefficients to be nonnegative after addressing the problem of mismeasurement. If the original q-theory of investment holds and the estimator does a good job of addressing mismeasurement, then the cash flow coefficient would be zero. Alternatively, the cash flow coefficient could be positive because of financing frictions.[6]

Using data from Compustat from 1970 to 2005, we estimate investment equations in which investment is regressed on proxies for q and cash flow. Before doing so, we perform standard tests to check for the presence of individual fixed effects and heteroscedasticity in the data. In addition, we perform the EW identification test to check whether the data contain a sufficiently high degree of skewness.

Our results are as follows. First, our tests reject the hypotheses that the data do not contain firm-fixed effects and that errors are homoscedastic. Second, the EW identification tests indicate that the data fail to display sufficiently high skewness. These initial tests suggest that the EW estimator is not suitable for standard investment equation applications. In fact, we find that, when applied to the data, the EW estimator returns coefficients for q and cash flow that are highly unstable across different years. Moreover, following the EW procedure for panel models (which comprises combining yearly cross-sectional coefficients into single estimates), we obtain estimates for q and cash flow that do not satisfy the conditions discussed above. In particular, EW estimators do not reduce the cash flow coefficient relative to that obtained by standard OLS, while the q coefficient is never statistically significant. In addition, those estimates are not robust with respect to the number of moments used: EW's GMM3, GMM4, and GMM5 models procedure results that are inconsistent with one another. These results suggest that the presence of heteroscedasticity and fixed effects in real-world investment data hampers identification when using the EW estimator.

In contrast to EW, the OLS-IV procedure yields estimates that are fairly sensible. The q coefficient goes up by a factor of 3–5, depending on the set of instruments used. At the same time, the cash flow coefficient goes down by about two-thirds of the standard OLS value. Similar conclusions apply to the AB-GMM estimator. We also examine the robustness of the OLS-IV to variations in the set of instruments used in the estimation, including sets that feature only longer lags of the variables in the model. The OLS-IV coefficients remain fairly stable after such changes. These results suggest that real-world investment data likely satisfies the assumptions that are required for identification of IV estimators.

The remainder of the chapter is structured as follows. We start the next section discussing in detail the EW estimator, clarifying the assumptions that are needed for its implementation. Subsequently, we show how alternative IV models deal with

[6]See Hubbard (1998) and Stein (2003) for comprehensive reviews. We note that the presence of financing frictions does not necessarily imply that the cash flow coefficient should be positive. See Chirinko (1993) and Gomes (2001) for arguments suggesting that financing frictions are not sufficient to generate positive cash flow coefficients.

the errors-in-variables problem. In Sect. 57.3, we use Monte Carlo simulations to examine the performance of alternative estimators in small samples and when we relax the assumptions that are required for identification. In Sect. 57.4, we take our investigation to actual data, estimating investment regressions under the EW and IV frameworks. Section 57.5 concludes the chapter.

57.2 Dealing with Mismeasurement: Alternative Estimators

57.2.1 The Erickson–Whited Estimator

In this section, we discuss the estimator proposed in companion papers by Erickson and Whited (2000, 2002). Those authors present a two-step generalized method of moments (GMM) estimator that exploits information contained in the high-order moments of residuals obtained from perfectly measured regressors (similar to Cragg 1997). We follow EW and present the estimator using notation of cross-section estimation. Let (y_i, z_i, x_i), $i = 1,\ldots,n$, be a sequence of observable vectors, where $x_i \equiv (x_{i1},\ldots,x_{iJ})$ and $z_i \equiv (1, z_{i1},\ldots, z_{iL})$. Let $(u_i, \chi_i, \varepsilon_i)$ be a sequence of unobservable vectors, where $\chi_i \equiv (\chi_{i1},\ldots,\chi_{iJ})$ and $\varepsilon_i \equiv (\varepsilon_{i1},\ldots,\varepsilon_{iJ})$. Consider the following model:

$$y_i = z_i a + \chi_i \beta + u_i \tag{57.1}$$

where y_i is the dependent variable, z_i is a perfectly measured regressor, χ_i is a mismeasured regressor, u_i is the innovation of the model, and $\alpha \equiv (\alpha_0, \alpha_i, \ldots,\alpha_L)'$ and $\beta \equiv (\beta_1, \ldots,\beta_J)'$. The measurement error is assumed to be additive such that

$$x_i = \chi_i + \varepsilon_i \tag{57.2}$$

where x_i is the observed variable and ε_i is the measurement error. The observed variables are y_i, z_i, and x_i; and by substituting Eq. 57.2 in Eq. 57.1, we have

$$y_i = z_i \alpha + x_i \beta + v_i,$$

where $v_i = u_i - \varepsilon_i \beta$. In the new regression, the observable variable x_i is correlated with the innovation term v_i, causing the coefficient of interest, β, to be biased.

To compute the EW estimator, it is necessary to first partial out the effect of the well-measured variable, z_i, in Eqs. 57.1 and 57.2 and rewrite the resulting expressions in terms of residual populations:

$$y_i - z_i \mu_y = \eta_i \beta + u_i \tag{57.3}$$

$$x_i - z_i \mu_x = \eta_i + \varepsilon_i, \tag{57.4}$$

where $(\mu_y, \mu_x, \mu_\chi) = [E(z_i'z_i)]^{-1}E[z_i'(y_i, x_i, \chi_i)]$ and $\eta_i \equiv \chi_i - z_i\mu_\chi$. For the details of this derivation, see Erickson and Whited (2002, p. 779). One can then consider a two-step estimation approach, where the first step is to substitute least squares estimates $(\hat{\mu}_y, \hat{\mu}_x) \equiv \left(\sum_{i=1}^{n} z_i'z_i\right)^{-1}\sum_{i=1}^{n} z_i'(y_i, x_i)$ into Eqs. 57.3 and 57.4 to obtain a lower dimensional errors-in-variables model. The second step consists of estimating β using GMM using high-order sample moments of $y_i - z_i\hat{\mu}_y$ and $x_i - z_i\hat{\mu}_x$. Estimates of α are then recovered via $\mu_y = \alpha + \mu_x\beta$. Thus, the estimators are based on equations giving the moments of $y_i - z_i\mu_y$ and $x_i - z_i\mu_x$ as functions of β and the moments of $(u_i, \varepsilon_i, \eta_i)$.

To give a concrete example of how the EW estimator works, we explore the case of $J = 1$. The more general case is discussed below. By substituting

$$\hat{\mu}_y, \hat{\mu}_x \equiv \left(\sum_{i=1}^{n} z_i'z_i\right)^{-1}\sum_{i=1}^{n} z_i{}'(y_i, x_i)$$

into Eqs. 57.1 and 57.2, one can estimate β, $E(u_i^2)$, $E(\varepsilon_i^2)$, and $E(\eta_i^2)$ via GMM. Estimates of the lth element of a are obtained by substituting the estimate of β and the lth elements of $\hat{\mu}_y$ and $\hat{\mu}_x$ into

$$\alpha_l = \mu_{yl} - \mu_{xl}\beta, \quad l \neq 0.$$

There are three second-order moment equations:

$$E\left[\left(y_i - z_i\mu_y\right)^2\right] = \beta^2 E\left(\eta_i^2\right) + E\left(u_i^2\right) \tag{57.5}$$

$$E\left[\left(y_i - z_i\mu_y\right)(x_i - z_i\mu_x)\right] = \beta E\left(\eta_i^2\right) \tag{57.6}$$

$$E\left[(x_i - z_i\mu_x)^2\right] = E\left(\eta_i^2\right) + E\left(\varepsilon_1^2\right). \tag{57.7}$$

The left-hand side quantities are consistently estimable, but there are only three equations with which to estimate four unknown parameters on the right-hand side. The third-order product moment equations, however, consist of two equations in two unknowns:

$$E\left[\left(y_i - z_i\mu_y\right)^2(x_i - z_i\mu_x)\right] = \beta^2 E\left(\eta_i^3\right), \tag{57.8}$$

$$E\left[\left(y_i - z_i\mu_y\right)(x_i - z_i\mu_x)^2\right] = \beta E\left(\eta_i^3\right). \tag{57.9}$$

It is possible to solve these two equations for β. Crucially, a solution exists if the identifying assumptions $\beta \neq 0$ and $E(\eta_i^3) \neq 0$ are true, and one can test the contrary hypothesis (i.e., $\beta \neq 0$ and/or $E(\eta_i^3) = 0$) by testing whether their sample counterparts are significatively different from zero.

Given β, Eqs. 57.5, 57.6, 57.7, and 57.9 can be solved for the remaining right-hand side quantities. One obtains an overidentified equation system by combining Eqs. 57.5, 57.6, 57.7, 57.8, and 57.9 with the fourth-order product moment equations, which introduce only one new quantity, $E(\eta_i^4)$:

$$E\left[\left(y_i - z_i\mu_y\right)^3\left(x_i - z_i\mu_x\right)\right] = \beta^3 E\left(\eta_i^4\right) + 3E\left(\eta_i^2\right)E\left(u_i^2\right), \tag{57.10}$$

$$\begin{aligned} E\left[\left(y_i - z_i\mu_y\right)^2\left(x_i - z_i\mu_x\right)^2\right] = \beta^2\left[E\left(\eta_i^4\right) + E\left(\eta_i^2\right)E\left(u_i^2\right)\right] \\ + E\left(u_i^2\right)\left[E\left(\eta_i^2\right) + E\left(\varepsilon_i^2\right)\right], \end{aligned} \tag{57.11}$$

$$E\left[\left(y_i - z_i\mu_y\right)\left(x_i - z_i\mu_x\right)^3\right] = \beta\left[E\left(\eta_i^4\right) + 3E\left(\eta_i^2\right)E\left(\varepsilon_i^2\right)\right]. \tag{57.12}$$

The resulting eight-equation system Eqs. 57.5, 57.6, 57.7, 57.8, 57.9, 57.10, 57.11, and 57.12 contains the six unknowns (β, $E(u_i^2)$, $E(\varepsilon_i^2)$, $E(\eta_i^2)$, $E(\eta_i^3)$, $E(\eta_i^4)$). It is possible to estimate this vector by numerically minimizing a quadratic form that minimizes asymptotic variance.

The conditions imposed by EW imply restrictions on the residual moments of the observable variables. Such restrictions can be tested using the corresponding sample moments. EW also propose a test for residual moments that is based on several assumptions.[7] These assumptions imply testable restrictions on the residuals from the population regression of the dependent and proxy variables on the perfectly measured regressors. Accordingly, one can develop Wald-type partially adjusted statistics and asymptotic null distributions for the test. Empirically, one can use the Wald test statistic and critical values from a chi-square distribution to test whether the last moments are equal to zero. This is an identification test, and if in a particular application one cannot reject the null hypothesis, then the model is unidentified and the EW estimator may not be used. We study the finite sample performance of this test and its sensitivity to different data-generating processes in the next section.

It is possible to derive more general forms of the EW estimator. In particular, the EW estimators are based on the equations for the moments of $y_i - z_i\mu_y$ and $x_i - z_i\mu_x$ as functions of β and the moments u_i, ε_i, and η_i. To derive these equations, write Eq. 57.3 as $y_i - z_i\mu_y = \sum_{j=1}^{J} \eta_{ij}\beta_j + u_i$, where J is the number of well-measured regressors and the jth equation in Eq. 57.4 as $x_{ij} - z_i\mu_{xj} = \eta_{ij} + \varepsilon_{ij}$, where μ_{xj} is the jth column of and μ_x and $(\eta_{ij}, \varepsilon_{ij})$ is the jth row of $(\eta_{ij}', \varepsilon_{ij}')$. Next write

[7] First, the measurement errors, the equation error, and all regressors have finite moments of sufficiently high order. Second, the regression error and the measurement error must be independent of each other and of all regressors. Third, the residuals from the population regression of the unobservable regressors on the perfectly measured regressors must have a nonnormal distribution.

$$E\left[\left(y_i - z_i\mu_y\right)^{r_0}\prod_{j=1}^{J}\left(x_i - z_i\mu_x\right)^{r_j}\right] = E\left[\left(\sum_{j=1}^{J}\eta_i\beta + u_i\right)^{r_0}\prod_{j=1}^{J}\left(\eta_i + \varepsilon_i\right)^{r_j}\right], \tag{57.13}$$

where $(r_0, r_1,\ldots, r_J)$ are nonnegative integers. After expanding the right-hand side of Eq. 57.13, using the multinomial theorem, it is possible to write the above moment condition as

$$E[g_i(\mu)] = c(\theta),$$

where $\mu = vec(\mu_y, \mu_x)$, $g_i(\mu)$ is a vector of distinct elements of the form $\left(y_i - z_i\mu_y\right)^{r_0}\prod_{j=1}^{J}\left(x_i - z_i\mu_x\right)^{r_j}$, $c(\theta)$ contains the corresponding expanded version of the right-hand side of Eq. 57.13, and θ is a vector containing the elements of β and the moments of $(u_i, \varepsilon_i, \eta_i)$. The GMM estimator θ is defined as

$$\hat{\theta} = \arg \min_{t\in\Theta} \left(\overline{g}_i(\hat{\mu}) - c(t)\right)'\hat{W}\left(\overline{g}_i(\hat{\mu}) - c(t)\right),$$

where $\bar{g}_i(s) \equiv \sum_{t=1}^{n} g_i(s)$ for all s, and $\hat{W}$ is a positive definite matrix. Assuming a number of regularity conditions,[8] the estimator is consistent and asymptotically normal.

It is important to notice that the estimator proposed by Erickson and Whited (2002) was originally designed for cross-sectional data. To accommodate a panel-like structure, Erickson and Whited (2000) propose transforming the data before the estimation using the within transformation or differencing. To mimic a panel structure, the authors propose the idea of combining different cross-sectional GMM estimates using a minimum distance estimator (MDE).

The MDE estimator is derived by minimizing the distance between the auxiliary parameter vectors under the following restrictions:

$$f\left(\beta, \hat{\theta}\right) = H\beta - \hat{\theta} = 0,$$

where the $R \cdot K \times K$ matrix H imposes $(R - 1) \cdot K$ restrictions on θ. The $R\,K \times 1$ vector $\hat{\theta}$ contains the R stacked auxiliary parameter vectors, and β is the parameter of interest. Moreover, H is defined by an $R \cdot K \times K$ – dimensional stacked identity matrix.

---

[8] More specifically, these conditions are as follows: $(z_i, \chi_i, u_i, \varepsilon_i)$ is an independent and identically distributed sequence; u_i and the elements of z_i, χ_i, and ε_i, have finite moments of every order; (u_i, ε_i) is independent of (z_i, χ_i), and the individual elements in (u_i, ε_i) are independent of each other; $E(u_i) = 0$ and $E(\varepsilon_i) = 0$; $E[(z_i, \chi_i)'(z_i, \chi_i)]$ is positive definite; every element of β is nonzero; and the distribution of η satisfies $E[(\eta_i c)^3] \neq 0$ for every vector of constants $c = (c_1,\cdots,c_J)$ having at least one nonzero element.

The MDE is given by the minimization of

$$D(\beta) = f\left(\beta, \hat{\theta}\right)' \hat{V}\left[\hat{\theta}\right]^{-1} f\left(\beta, \hat{\theta}\right), \tag{57.14}$$

where $\hat{V}[\hat{\theta}]$ is the common estimated variance–covariance matrix of the auxiliary parameter vectors.

In order to implement the MDE, it is necessary to determine the covariances between the cross-sections being pooled. EW propose to estimate the covariance by using the covariance between the estimators' respective influence functions.[9] The procedure requires that each cross-section have the same sample size, that is, the panel needs to be balanced.

Thus, minimization of D in Eq. 57.14 leads to

$$\hat{\beta} = \left(H' \hat{V}\left[\hat{\theta}\right]^{-1} H\right)^{-1} H' \hat{V}\left[\hat{\theta}\right]^{-1} \hat{\theta},$$

with variance–covariance matrix:

$$\hat{V}\left[\hat{\beta}\right] = \left(H' \hat{V}\left[\hat{\theta}\right]^{-1} H\right)^{-1}.$$

H is a vector in which R is the number of GMM estimates available (for each time period) and $K = 1$, $\hat{\theta}$ is a vector containing all the EW estimates for each period, and β is the MDE of interest. In addition, $V\left[\hat{\theta}\right]$ is a matrix carrying the estimated variance–covariance matrices of the GMM parameter vectors.

57.2.2 An OLS-IV Framework

In this section, we revisit the work of Griliches and Hausman (1986) and Biorn (2000) to discuss a class of OLS-IV estimators that can help address the errors-in-variables problem.

Consider the following single-equation model:

$$y_{it} = \gamma_i + \chi_{it}\beta + u_{it}, \quad i = 1, \ldots N, \quad t = 1, \ldots, T, \tag{57.15}$$

where u_{it} is independently and identically distributed, with mean zero and variance σ_u^2, and $\text{Cov}(\chi_{it}, u_{is}) = \text{Cov}(\gamma_i, u_{is}) = 0$ for any t and s, but $\text{Cov}(\gamma_i, \chi_{it}) \neq 0$, y is an observable scalar, χ is a $1 \times K$ vector, and β is $K \times 1$ vector. Suppose we do not observe χ_{it} itself, but rather the error-ridden measure:

[9] See Erickson and Whited (2002) Lemma 1 for the definition of their proposed influence function.

$$x_{it} = \chi_{it} + \varepsilon_{it}, \tag{57.16}$$

where $\mathrm{Cov}(\chi_{it}, \varepsilon_{it}) = \mathrm{Cov}(\gamma_i, \varepsilon_{it}) = \mathrm{Cov}(u_{is}, \varepsilon_{it}) = 0$, $\mathrm{Var}(\varepsilon_{it}) = \sigma_\varepsilon^2$, $\mathrm{Cov}(\varepsilon_{it}, \varepsilon_{it-1}) = \gamma_\varepsilon \sigma_\varepsilon^2$, and ε is a $1 \times K$ vector. If we have a panel data with $T > 3$, by substituting Eq. 57.16 in Eq. 57.15, we can take first differences of the data to eliminate the individual effects γ_i and obtain

$$y_{it} - y_{it-1} = (x_{it} - x_{it-1})\beta + [(u_{it} - \varepsilon_{it}\beta) - (u_{it-1} - \varepsilon_{it-1}\beta)] \tag{57.17}$$

Because of the correlation between the mismeasured variable and the innovations, the coefficient of interest is known to be biased.

Griliches and Hausman (1986) propose an instrumental variable approach to reduce the bias. If the measurement error ε_{it} is i.i.d. across i and t, and x is serially correlated, then, for example, x_{it-2}, x_{it-3}, or $(x_{it-2} - x_{it-3})$ are valid as instruments for $(x_{it} - x_{it-1})$. The resulting instrumental variable estimator is consistent even though T is finite and N might tend to infinity.

As emphasized by Erickson and Whited (2000), for some applications, the assumption of i.i.d. measurement error can be seen as too strong. Nonetheless, it is possible to relax this assumption to allow for autocorrelation in the measurement errors. While other alternatives are available, here we follow the approach suggested by Biorn (2000).[10]

Biorn (2000) relaxes the i.i.d. condition for innovations in the mismeasured equation and proposes alternative assumptions under which consistent IV estimators of the coefficient of the mismeasured regressor exists. Under those assumptions, as we will show, one can use the lags of the variables already included in the model as instruments. A notable point is that the consistency of these estimators is robust to potential correlation between individual heterogeneity and the latent regressor.

Formally, consider the model described in Eqs. 57.15 and 57.16 and assume that $(\chi_{it}, u_{it}, \varepsilon_{it}, \gamma_i)$ are independent across individuals. For the necessary orthogonality assumptions, we refer the reader to Biorn (2000), since these are quite standard. More interesting are the assumptions about the measurement errors and disturbances. The standard Griliche–Hausman's assumptions are
(A1) $E(\varepsilon'_{it}\varepsilon_{i\theta}) = 0_{KK}$, $t \neq \theta$,
(A2) $E(u_{it}u_{i\theta}) = 0$, $t \neq \theta$
which impose non-autocorrelation on innovations. It is possible to relax these assumptions in different ways. For example, we can replace (A1) and (A2) with
(B1) $E(\varepsilon'_{it}\varepsilon_{i\theta}) = 0_{KK}$, $|t - \theta| > \tau$,
(B2) $E(u_{it}u_{i\theta}) = 0$, $|t - \theta| > \tau$,

[10] A more recent paper by Xiao et al. (2008) also shows how to relax the classical Griliches–Hausman assumptions for measurement error models.

This set of assumptions is weaker since (B1) and (B2) allow for a vector moving average (MA) structure up to order τ ($\geq$1) for the innovations. Alternatively, one can use the following assumptions:

(C1) $E(\varepsilon_{it}'\varepsilon_{t\theta})$ is invariant to t, θ, $t \neq \theta$.

(C2) $E(u_{it}u_{i\theta})$ is invariant to t, θ, $t \neq \theta$.

Assumptions (C1) and (C2) allow for a different type of autocorrelation, more specifically they allow for any amount of autocorrelation that is time invariant. Assumptions (C1) and (C2) will be satisfied if the measurement errors and the disturbances have individual components, say $\varepsilon_{it} = \varepsilon_{1i} + \varepsilon_{2it}$, $u_{it} = u_{1i} + u_{2it}$, where ε_{1i}, ε_{2it}, u_{1i}, u_{2it} i.i.d. Homoscedasticity of ε_{it} and/or u_{it} across i and t need not be assumed; the model accommodates various forms of heteroscedasticity.

Biorn also considers assumptions related to the distribution of the latent regressor vector χ_{it}:

(D1) $\mathrm{E}(\chi_{it})$ is invariant to t.

(D2) $\mathrm{E}(\gamma_i\chi_{it})$ is invariant to t.

Assumptions (D1) and (D2) hold when χ_{it} is stationary. Note that χ_{it} and i need not be uncorrelated.

To ensure identification of the slope coefficient vector when panel data are available, it is necessary to impose restrictions on the second-order moments of the variables (χ_{it}, u_{it}, ε_{it}, γ_i). For simplicity, Biorn assumes that this distribution is the same across individuals and that the moments are finite. More specifically, $C(\chi_{it}, \chi_{it}) = \sum_{t\theta}^{\chi\chi}$, $E(\chi_{it}\eta_i) = \sum_t^{\chi n}$, $E(\varepsilon_{it}'\varepsilon_{it}) = \sum_{t\theta}^{\varepsilon\varepsilon}$, $E(u_{it}u_{it}) = \sigma_{t\theta}^{uu}$, $E(\eta_i^2) = \sigma^{\eta\eta}$, where C denotes the covariance matrix operator. Then, it is possible to derive the second-order moments of the observable variables and show that they only depend on these matrices and the coefficient β.[11] In this framework, there is no need to use assumptions based on higher-order moments.

Biorn proposes several strategies to estimate the slope parameter of interest. Under the OLS-IV framework, he proposes estimation procedures of two kinds:

- *OLS-IV A*: The equation is transformed to differences to remove individual heterogeneity and is estimated by OLS-IV. Admissible instruments for this case are the level values of the regressors and/or regressands for other periods.
- *OLS-IV B*: The equation is kept in level form and is estimated by OLS-IV. Admissible instruments for this case are differenced values of the regressors and/or regressands for other periods.

Using moment conditions from the OLS-IV framework, one can define the estimators just described. In particular, using the mean counterpart and the moment conditions, one can formally define the *OLS-IV A* and *OLS-IV B* estimators.

[11]Formally, one can show that $C(x_{it}, x_{i\theta}) = \sum_{t\theta}^{\chi\chi} + \sum_{t\theta}^{\varepsilon\varepsilon}$, $E(x_{it}, y_{i\theta}) = \sum_{t\theta}^{\chi\chi}\beta + \sum_t^{\chi\eta}$, and $E(y_{it}, y_{i\theta}) = \beta' \sum_{t\theta}^{\chi\chi}\beta + \sum_t^{xn}\beta + \beta^{H\prime}(\sum_\theta^{xn})' + \sigma_{t\theta}^{uu} + \sigma^{\eta\eta}$.

In particular, the estimator for *OLS-IV A* can be defined as

$$\hat{\beta}_{xp(t\theta)} = \left[\sum_{i=1}^{N} x'_{ip}(\Delta x_{it\theta})\right]^{-1}\left[\sum_{i=1}^{N} x'_{ip}(\Delta y_{it\theta})\right],$$

where (t, θ, p) are indices. Let the dimension of β be defined by K. If $K = 1$, it is possible to define the following estimator for a given (t, θ, p):

$$\hat{\beta}_{yp(t\theta)} = \left[\sum_{i=1}^{N} y_{ip}(\Delta x_{it\theta})\right]^{-1}\left[\sum_{i=1}^{N} y_{ip}(\Delta y_{it\theta})\right].$$

If $K > 1$, the latter estimator is infeasible, but it is possible to modify the former estimator by replacing one element in x'_{ip} by y_{ip}.

The estimator for *OLS-IV B* (equation in level and instruments in difference) can be defined as

$$\hat{\beta}_{x(pq)t} = \left[\sum_{i=1}^{N} (\Delta x_{ipq})' x_{it}\right]^{-1}\left[\sum_{i=1}^{N} (\Delta x_{ipq})' y_{it}\right].$$

As in the previous case, if the dimension of β, K is equal to 1, it is possible to define the following estimator for (t, p, q):

$$\hat{\beta}_{y(pq)t} = \left[\sum_{i=1}^{N} (\Delta y_{ipq}) x_{it}\right]^{-1}\left[\sum_{i=1}^{N} (\Delta y_{ipq}) y_{it}\right].$$

If $K > 1$, the latter estimator is infeasible, but it is possible to modify the former estimator by replacing one element in Δx_{ip} by Δy_{ip}.

For some applications, it might be useful to impose weaker conditions on the autocorrelation of measurement errors and disturbances. In this case, it is necessary to restrict slightly further the conditions on the instrumental variables. More formally, if one replaces assumptions (A1) and (A2), or (C1) and (C2), by the weaker assumptions (B1) and (B2), then it is necessary to ensure that the IV set has a lag of at least $\tau - 2$ and/or lead of at least $\tau + 1$ periods of the regressor in order to "clear" the τ period memory of the MA process. Consistency of these estimators is discussed in Biorn (2000).[12]

To sum up, there are two simple ways to relax the standard assumption of i.i.d. measurement errors. Under the assumption of time-invariant autocorrelation, the set of instruments can contain the same variables used under Griliches–Hausman.

[12]In particular, if $|t - p|$, $|\theta - p| > \tau$, then (B1) and rank $(E[\chi'_{ip}(\Delta\chi_{it\theta})]) = K$ for some $p \neq t \neq 0$ ensure consistency of *OLS–IV B*, $\hat{\beta}_{xp(t\theta)}$, and (B2) and the same rank condition ensure consistency of $\hat{\beta}_{xy(t\theta)}$. In the same way, if $|p - t|$, $q - t > \tau$, (B1), (D1), (D2), and rank $(E[(\Delta\chi_{ipq})'\chi_{it})]) = K$ for some $p \neq q \neq t$ ensure consistency of *OLS-IV B*, $\hat{\beta}_{x(pq)t}$, and (B2), (D1), (D2), and the same rank condition ensure consistency of $\hat{\beta}_{y(pq)t}$.

For example, if one uses the *OLS-IV A* estimator (equation in differences and instruments in levels), then twice-lagged levels of the observable variables can be used as instruments. Under a moving average structure for the innovations in the measurement error [assumptions (B1) and (B2)], identification requires the researcher to use longer lags of the observable variables as instruments. For example, if the innovations follow an MA(1) structure, then consistency of the *OLS-IV A* estimator requires the use of instruments that are lagged three periods and longer. Finally, identification requires the latent regressor to have some degree of autocorrelation (since lagged values are used as instruments). Our Monte Carlo simulations will illustrate the importance of these assumptions and will evaluate the performance of the OLS-IV estimator under different sets of assumptions about the structure of the errors.

57.2.3 GMM Estimator

Within the broader instrumental variable approach, we also consider an entire class of GMM estimators that deal with mismeasurement. These GMM estimators are close to the OLS-IV estimator discussed above but may attain appreciable gains in efficiency by combining numerous orthogonality conditions [see Biorn (2000) for a detailed discussion]. GMM estimators that use all the available lags at each period as instruments for equations in first differences were proposed by Holtz-Eakin et al. (1988) and Arellano and Bond (1991). We provide a brief discussion in turn.

In the context of a standard investment model, Blundell et al. (1992) use GMM allowing for correlated firm-specific effects, as well as endogeneity (mismeasurement) of q. The authors use an instrumental variable approach on a first-differenced model in which the instruments are weighted optimally so as to form the GMM estimator. In particular, they use q_{it-2} and twice-lagged investments as instruments for the first-differenced equation for firm i in period t. The Blundell, Bond, Devereux, and Schiantarelli estimators can be seen as an application of the GMM instrumental approach proposed by Arellano and Bond (1991), which was originally applied to a dynamic panel.

A GMM estimator for the errors-in-variables model of Eq. 57.17 based on IV moment conditions takes the form

$$\hat{\beta} = \left[\left(\Delta x' Z\right) V_N^{-1} \left(Z' \Delta x\right)\right]^{-1} \left(\Delta x' Z\right) V_N^{-1} \left(Z' \Delta y\right),$$

where Δx is the stacked vector of observations on the first difference of the mismeasured variable and Δy is the stacked vector of observations on the first difference of the dependent variable. As in Blundell et al. (1992), the instrument matrix Z has the following form[13]:

[13] In models with exogenous explanatory variables, Z_i may consist of sub-matrices with the block diagonal (exploiting all or part of the moment restrictions), concatenated to straightforward one-column instruments.

$$Z_i = \begin{pmatrix} x_1 & 0 & 0 & \cdots & 0 & \cdots & 0 \\ 0 & x_1 & x_2 & \cdots & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & x_1 & \cdots & x_{T-2} \end{pmatrix}.$$

According to standard GMM theory, an optimal choice of the inverse weight matrix V_N is a consistent estimate of the covariance matrix of the orthogonality conditions $E(Z_i'\Delta v_i \Delta v_i' Z_i)$, where Δv_i are the first-differenced residuals of each individual. Accordingly, a one-step GMM estimator uses $\hat{V} = \sum_{i-1}^{N} Z_i' DD' Z_i$, where D is the first-difference matrix operator. A two-step GMM estimator uses a robust choice $\widetilde{V} = \sum_{i=1}^{N} Z\Delta\hat{v}_i \Delta\hat{v}_i{\prime} Z_i$ where $\Delta\hat{v}_i$ are one-step GMM residuals.

Biorn (2000) proposes estimation of linear, static regression equations from panel data models with measurement errors in the regressors, showing that if the latent regressor is autocorrelated or nonstationary, several consistent OLS-IV and GMM estimators exist, provided some structure is imposed on the disturbances and measurement errors. He considers alternative GMM estimations that combine all essential orthogonality conditions. The procedures are very similar to the one described just above under non-autocorrelation in the disturbances. In particular, the required assumptions when allowing autocorrelation in the errors are very similar to those discussed in the previous section. For instance, when one allows for an MA(τ) structure in the measurement error, for instance, one must ensure that the variables in the IV matrix have a lead or lag of at least $\tau + 1$ periods to the regressor.

We briefly discuss the GMM estimators proposed by Biorn (2000). First, consider estimation using the equation in differences and instrumental variables in levels. After taking differences of the model, there are $(T-1)+(T+1)$ equations that can be stacked for individual i as

$$\begin{bmatrix} \Delta y_{i21} \\ \Delta y_{i32} \\ \vdots \\ \Delta y_i, T, T-1 \\ \Delta y_{i31} \\ \Delta y_{i42} \\ \vdots \\ \Delta y_i, T, T-2 \end{bmatrix} = \begin{bmatrix} \Delta x_{i21} \\ \Delta x_{i32} \\ \vdots \\ \Delta x_i T, T-1 \\ \Delta x_{i31} \\ \Delta x_{i42} \\ \vdots \\ \Delta x_i, T, T-2 \end{bmatrix} \beta + \begin{bmatrix} \Delta\varepsilon_{i21} \\ \Delta\varepsilon_{i32} \\ \vdots \\ \Delta\varepsilon_i, T, T-1 \\ \Delta\varepsilon_{i31} \\ \Delta\varepsilon_{i42} \\ \vdots \\ \Delta\varepsilon_i, T, T-2 \end{bmatrix},$$

or compactly

$$\Delta y_i = \Delta X_i \beta + \Delta \in_i.$$

The IV matrix is the $((2T - 3) \times KT(T - 2))$ diagonal matrix with the instruments in the diagonal defined by Z. Let

$$\Delta y = \left[(\Delta y_1)', \ldots, (\Delta y_N)'\right]', \Delta \in = \left[(\Delta \in_1)', \ldots, (\Delta \in_N)'\right]'$$

$$\Delta X = \left[(\Delta X_1)', \ldots, (\Delta X_N)'\right]', \quad Z = \left[Z_1', \ldots, Z_N'\right]'.$$

The GMM estimator that minimizes $[N^{-1}(\Delta\in)'Z](N^{-2}V)^{-1}[N^{-1}Z'(\Delta\in)]$ for $V = Z'Z$ can be written as

$$\hat{\beta}_{Dx} = \left[\left[\sum_i (\Delta X_i)' Z_i\right]\left[\sum_i Z_i' Z_i\right]^{-1}\left[\sum_i Z_i'(\Delta X_i)\right]\right]^{-1} \times \left[\left[\sum_i (\Delta X_i)' Z_i\right]\left[\sum_i Z_i' Z_i\right]^{-1}\left[\sum_i Z_i'(\Delta y_i)\right]\right].$$

If $\Delta\in$ has a non-scalar covariance matrix, a more efficient GMM estimator, $\widetilde{\beta}_{Dx}$, can be obtained setting $V = V_{Z(\Delta\in)} = E[Z'(\Delta\in)(\Delta\in)'Z]$ and estimating $\hat{V}_{z(\Delta\in)}$ by

$$\frac{\hat{V}_{Z(\Delta\in)}}{N} = \frac{1}{N}\sum_i Z'\left(\widehat{\Delta\in}\right)\left(\widehat{\Delta\in}\right)'Z,$$

where $\widehat{\Delta\in}_i = \Delta y_i - (\Delta X_i)\hat{\beta}_{Dx}$. This procedure assumes that (A1) and (A2) are satisfied. However, as Biorn (2000) argues, one can replace them by (B1) or (B2) and then ensure that the variables in the IV matrix have a lead or lag of at least $\tau + 1$ periods to the regressor, to "get clear of" the t period memory of the MA(τ) process. The procedure described below is also based on the same set of assumptions and can be extended similarly.[14]

The procedure for estimation using equation in levels and IVs in difference is similar. Consider the T stacked level equations for individual i:

$$\begin{bmatrix} y_{i1} \\ \vdots \\ y_{iT} \end{bmatrix} = \begin{bmatrix} c \\ \vdots \\ c \end{bmatrix} + \begin{bmatrix} x_{i1} \\ \vdots \\ x_{iT} \end{bmatrix}\beta + \begin{bmatrix} \in_{i1} \\ \vdots \\ \in_{iT} \end{bmatrix},$$

or more compactly,

$$y_i = e_T c + X_i\beta + \in,$$

where e_T denotes a $(T \times 1)$ vector of ones. Let the $(T \times T(T-2)K)$ diagonal matrix of instrument be denoted by ΔZ_i. This matrix has the instruments in difference in the main diagonal. In addition,

[14]See Propositions 1* and 2* in Biorn (2000) for a formal treatment of the conditions.

define:

$$y = \left[y_1', \ldots, y_N'\right]', \in = \left[\in_1', \ldots, \in_N'\right]'$$
$$X = \left[X_1', \ldots, X_N'\right]', \Delta Z = \left[(\Delta Z_1)', \ldots, (\Delta Z_N)'\right]'.$$

The GMM estimator that minimizes $[N^{-1}\in'(\Delta Z_i)']|(N^{-2}V_\Delta)^{-1}[N^{-1}(\Delta Z)'\in]$ for $V_\Delta = (\Delta Z)'(\Delta Z)$ is

$$\begin{aligned}\hat{\beta}_{Lx} &= \left[\left[\sum_i X_i'(\Delta Z_i)\right]\left[\sum_i (\Delta Z_i)'\Delta Z_i\right]^{-1}\left[\sum_i (\Delta Z_i)'X_i\right]\right]^{-1}\\ &\times\left[\left[\sum_i X_i{}'(\Delta Z_i)\right]\left[\sum_i (\Delta Z_i)'\Delta Z_i\right]^{-1}\left[\sum_i (\Delta Z_i)'y_i\right]\right].\end{aligned}$$

If $\in$ has a non-scalar covariance matrix, a more efficient GMM estimator, $\widetilde{\beta}_{Lx}$, can be obtained setting $V_\Delta = V_{(\Delta Z)\in} = E[(\Delta Z)\in\in'(\Delta Z)]$ and estimating $\hat{V}_{(\Delta Z)\in}$ by

$$\frac{\hat{V}_{(\Delta Z)\in}}{N} = \frac{1}{N}\sum_i (\Delta Z)'\hat{\in}\hat{\in}'(\Delta Z),$$

where $\hat{\in} = y_i - X_i\hat{\beta}_{Lx}$.

Finally, let us briefly contrast the OLS-IV and AB-GMM estimators. The advantages of GMM over IV are clear: if heteroscedasticity is present, the GMM estimator is more efficient than the IV estimator, while if heteroscedasticity is not present, the GMM estimator is no worse asymptotically than the IV. Implementing the GMM estimator, however, usually comes with a high price. The main problem, as Hayashi (2000, p. 215) points out, concerns the estimation of the optimal weighting matrix that is at the core of the GMM approach. This matrix is a function of fourth moments, and obtaining reasonable estimates of fourth moments requires very large sample sizes. Problems also arise when the number of moment conditions is high, that is, when there are "too many instruments." This latter problem affects squarely the implementation of the AB-GMM, since it relies on large numbers of lags (especially in long panels). The upshot is that the efficient GMM estimator can have poor small sample properties [see Baum et al. (2003) for a discussion]. These problems are well documented and remedies have been proposed by, among others, Altonji and Segal (1996) and Doran and Schmidt (2006).

57.3 Monte Carlo Analysis

We use Monte Carlo simulations to assess the finite sample performance of the EW and IV estimators discussed in Sect. 57.2. Monte Carlo simulations are an ideal experimental tool because they enable us to study those two estimators in a controlled setting, where we can assess and compare the importance of elements that are key to estimation performance. Our simulations use several distributions to generate observations. This is important because researchers will often find a variety of distributions in real-world applications and because one ultimately does not see the distribution of the mismeasurement term. Our Monte Carlos compare the EW, OLS-IV, and AB-GMM estimators presented in Sect. 57.2 in terms of bias and RMSE.[15] We also investigate the properties of the EW identification test, focusing on the empirical size and power of this test.

57.3.1 Monte Carlo Design

A critical feature of panel data models is the observation of multiple data points from the same individuals over time. It is natural to consider that repeat samples are particularly useful in that individual idiosyncrasies are likely to contain information that might influence the error structure of the data-generating process.

We consider a simple data-generating process to study the finite sample performance of the EW and OLS-IV estimators. The response variable y_{it} is generated according to the following model:

$$y_{it} = \gamma_i + \beta\chi_{it} + z_{it}'\alpha(1 + \rho w_{it})u_{it}, \tag{57.18}$$

where γ_i captures the individual-specific intercepts, β is a scalar coefficient associated with the mismeasured variable χ_{it}, $\alpha = (\alpha_1,\alpha_2,\alpha_3)'$ is 3×1 vector of coefficients associated with the 3×1 vector of perfectly measured variables $z_{it} = (z_{it1}, z_{it2}, z_{it3})$, u_{it} is the error in the model, and ρ modulates the amount of heteroscedasticity in the model. When $\rho = 0$, the innovations are homoscedastic. When $\rho > 0$, there is heteroscedasticity associated with the variable w_{it}, and this correlation is stronger as the coefficient gets larger. The model in Eq. 57.18 is flexible enough to allow us to consider two different variables as w_{it}: (1) the individual-specific intercept γ_i and (2) the well-measured regressor z_{it}.

We consider a standard additive measurement error

$$x_{it} = \chi_{it} + v_{it}, \tag{57.19}$$

where χ_{it} follows an AR(1) process:

[15]The mean squared error (MSE) of an estimator $\hat{\theta}$ incorporates a component measuring the variability of the estimator (precision) and another measuring its bias (accuracy). An estimator with good MSE properties has small combined variance and bias. The MSE of $\hat{\theta}$ can be defined as $\mathrm{Var}\left(\hat{\theta}\right) + \left[\mathrm{Bias}\left(\hat{\theta}\right)\right]^2$. The root mean squared error (RMSE) is simply the square root of the MSE. This is an easily interpretable statistic, since it has the same unit as the estimator $\hat{\theta}$. For an approximately unbiased estimator, the RMSE is just the square root of the variance, that is, the standard error.

$$(1 - \phi L)\chi_{it} = \in_{it}. \tag{57.20}$$

In all simulations, we set $\chi^{*}_{i,-50} = 0$ and generate χ_{it} for $t = -49, -48, \ldots, T$, such that we drop the first 50 observations. This ensures that the results are not unduly influenced by the initial values of the χ_{it} process.

Following Biorn (2000), we relax the assumption of i.i.d. measurement error. Our benchmark simulations will use the assumption of time-invariant autocorrelation [(C1) and (C2)]. In particular, we assume that $u_{it} = u_{1i} + u_{2it}$ and $v_{it} = v_{1i} + v_{2it}$. We draw all the innovations (u_{1i},u_{2it},v_{1i},v_{2it},) from a lognormal distribution; that is, we exponentiate two normal distributions and standardize the resulting variables to have unit variances and zero means (this follows the approach used by EW). In Sect. 57.3.6, we analyze the alternative case in which the innovations follow an MA structure.

The perfectly measured regressor is generated according to

$$z_{it} = \mu_i + \in_{it}. \tag{57.21}$$

And the fixed effects, μ_i and γ_i, are generated as

$$\begin{aligned} \mu_i &= e_{1i} \\ \gamma_i &= e_{2i} + \frac{1}{\sqrt{T}}\sum_{t=1}^{T} W_{it}, \end{aligned} \tag{57.22}$$

where W_{it} is the sum of the explanatory variables. Our method of generating μ_i and γ_i ensures that the usual random effects estimators are inconsistent because of the correlation that exists between the individual effects and the error term or the explanatory variables. The variables (e_{1i}, e_{2i}) are fixed as standard normal distributions.[16]

We employ four different schemes to generate the disturbances ($\in_{it}$, ε_{it}). Under Scheme 1, we generate them under a normal distribution, $N(0,\sigma_u^2)$. Under Scheme 2, we generate them from a lognormal distribution, $LN(0,\sigma_u^2)$. Under Scheme 3, we use a chi-square with 5 degrees of freedom, χ^2_5. Under Scheme 4, we generate the innovations from a $F_{m,n}$-distribution with $m = 10$ and $n = 40$. The latter three distributions are right-skewed so as to capture the key distributional assumptions behind the EW estimator. We use the normal (non-skewed) distribution as a benchmark.

Naturally, in practice, one cannot determine how skewed – if at all – is the distribution of the partially out latent variable. One of our goals is to check how this assumption affects the properties of the estimators we consider. Figure 57.1 provides a visual illustration of the distributions we employ. By inspection, at least, the three skewed distributions we study appear to be plausible candidates for the distribution governing mismeasurement, assuming EW's prior that measurement error must be markedly rightly skewed.

[16] Robustness checks show that the choice of a standard normal does not influence our results.

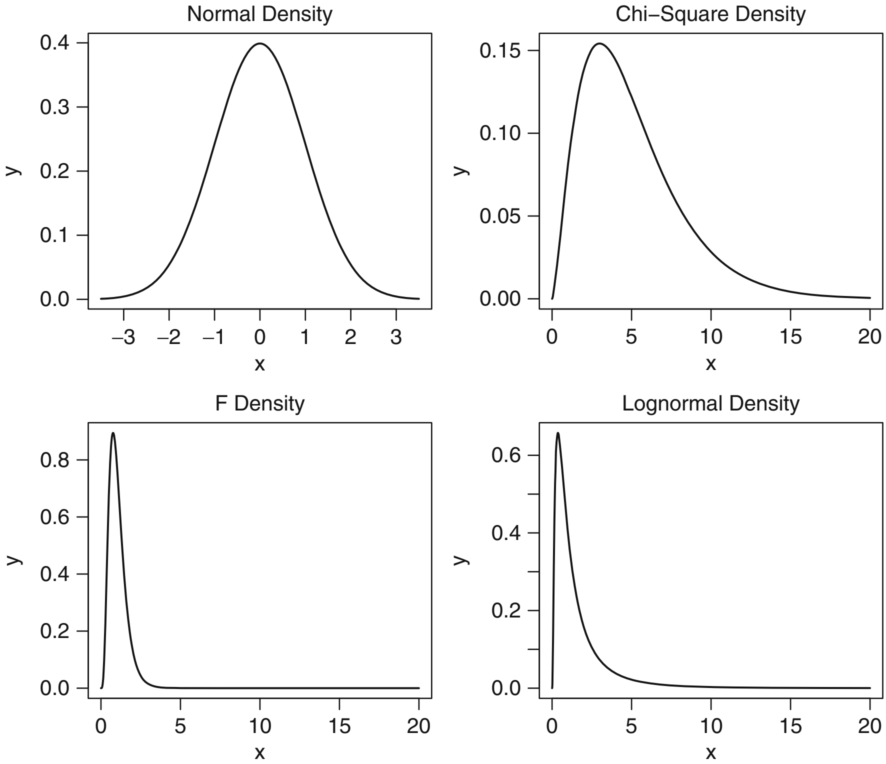

Fig. 57.1

As in Erickson and Whited (2002), our simulations allow for cross-sectional correlation among the variables in the model. We do so because this correlation may aggravate the consequences of mismeasurement of one regressor on the estimated slope coefficients of the well-measured regressors. Notably, this source of correlation is emphasized by EW in their argument that the inferences of Fazzari et al. (1988) are flawed in part due to the correlation between q and cash flows. To introduce this correlation in our application, for each period in the panel, we generate $(\chi_i, z_{i1}, z_{i2}, z_{i3})$ using the correspondent error distribution and then multiply the resulting vector by $[\mathrm{var}(\chi_i, z_{i1}, z_{i2}, z_{i3})]^{1/2}$ with diagonal elements equal to 1 and off-diagonal elements equal to 0.5.

In the simulations, we experiment with $T = 10$ and $N = 1{,}000$. We set the number of replications to 5,000 and consider the following values for the remaining parameters:

$$(\beta, \alpha_1, \alpha_2, \alpha_3) = (1, -1, 1, -1)$$
$$\phi = 0.6, \sigma_u^2 = \sigma_{e1}^2 = \sigma_{e2}^2 = 1,$$

where the set of slope coefficients β, α_i is set similarly to EW.

Notice that the parameter ϕ controls the amount of autocorrelation of the latent regressor. As explained above, this autocorrelation is an important requirement for the identification of the IV estimator. While we set $\phi = 0.6$ in the following experiments, we also conduct simulations in which we check the robustness of the results with respect to variations in ϕ between 0 and 1 (see Sect. 57.3.6).

57.3.2 The EW Identification Test

We study the EW identification test in a simple panel data setup. In the panel context, it is important to consider individual fixed effects. If the data contain fixed effects, according to Erickson and Whited (2000), a possible strategy is to transform the data first and then apply their high-order GMM estimator. Accordingly, throughout this section, our estimations consider data presented in two forms: "level" and "within." The first refers to data in their original format, without the use of any transformation; estimations in level form ignore the presence of fixed effects.[17] The second applies the within transformation to the data – eliminating fixed effects – before the model estimation.

We first compute the empirical size and power of the test. Note that the null hypothesis is that the model is incorrectly specified, such that $\beta = 0$ and/or $E[\eta_i^3] = 0$. The *empirical size* is defined as the number of rejections of the null hypothesis when the null is true – ideally, this should hover around 5 %. In our case, the empirical size is given when we draw the innovations $(\in_{it}, \varepsilon_{it})$ from a non-skewed distribution, which is the normal distribution since it generates $E[\eta_i^3] = 0$. The empirical power is the number of rejections when the null hypothesis is false – ideally, this should happen with very high probability. In the present case, the empirical power is given when we use skewed distributions: lognormal, chi-square, and F-distribution.

Our purpose is to investigate the validity of the skewness assumption once we are setting $\beta \neq 0$. Erickson and Whited (2002) also restrict every element of β to be nonzero. We conduct a Monte Carlo experiment to quantify the second part of this assumption. It is important to note that we can compute the $E[(\eta_i)^3]$ since, in our controlled experiment, we generate χ_i and therefore observe it.

Since the EW test is originally designed for cross-sectional data, the first difficulty the researcher faces when implementing a panel test is aggregation. Following EW, our test is computed for each year separately. We report the average of empirical rejections over the years.[18] To illustrate the size and power of the test for the panel data case, we set the time series dimension of the

[17]To our knowledge, all but one of the empirical applications of the EW model use the data in level form. In other words, firm-fixed effects are ignored outright in panel setting estimations of parameters influencing firm behavior.

[18]The results using the median are similar.

Table 57.1 The performance of the EW identification test

Distribution	Null is	Data form	Frequency of rejection
Normal	True	Level	0.05
		Within	0.05
Lognormal	False	Level	0.47
		Within	0.43
χ_3^2	False	Level	0.14
		Within	0.28
$F_{10,\,40}$	False	Level	0.17
		Within	0.28

This table shows the performance of the EW identification test for different distributional assumptions displayed in column 1. The tests are computed for the data in levels and after applying a within transformation. Column 4 shows the frequencies at which the null hypothesis that the model is not identified is rejected at the 5 % level of significance

panel to $T = 10$. Our tests are performed over 5,000 samples of cross-sectional size equal to 1,000. We use a simple homoscedastic model with $\rho = 0$, with the other model parameters given as above.

Table 57.1 reports the empirical size and power of the statistic proposed by EW for testing the null hypothesis $H_0 : E(\dot{y}_i^2 \dot{x}_i) = E(\dot{y}_i \dot{x}_i^2) = 0$. This hypothesis is equivalent to testing $H_0 : \beta = 0$ and/or $E(\eta_i^3) = 0$. Table 57.1 reports the frequencies at which the statistic of test is rejected at the 5 % level of significance for, respectively, the normal, lognormal, chi-square, and F-distributions of the data-generating process. Recall that when the null hypothesis is true, we have the size of the test, and when the null is false, we have the power of the test.

The results reported in Table 57.1 imply an average size of approximately 5 % for the test. In particular, the first two rows in the table show the results in the case of a normal distribution for the residuals (implying that we are operating under the null hypothesis). For both the level and within cases, the empirical sizes match the target significance level of 5 %.

When we move to the case of skewed distributions (lognormal, chi-square, and F), the null hypothesis is not satisfied by design, and the number of rejections delivers the empirical power of the test. In the case when the data is presented in levels and innovations are drawn from a lognormal distribution (see row 2), the test rejects about 47 % of the time the null hypothesis of no skewness. Using within data, the test rejects the null hypothesis 43 % of the time. Not only are these frequencies low, but comparing these results, one can see that the within transformation slightly reduces the power of the test.

The results associated with the identification test are more disappointing when we consider other skewed distributions. For example, for the F-distribution, we obtain only 17 % of rejections of the null hypothesis in the level case and only 28 % for the within case. Similarly, poor statistical properties for the model identification test are observed in the chi-square case.

57.3.3 Bias and Efficiency of the EW, OLS-IV, and AB-GMM Estimators

In this section we present simulation results that assess the finite sample performance of the estimators discussed in Sect. 57.2. The simulations compare the estimators in terms of bias and efficiency under several distributional assumptions. In the next subsection, we consider the cross-sectional setting, focusing on the properties of the EW estimator. Subsequently, we examine the panel case in detail, comparing the performance of the EW, OLS-IV, and AB-GMM estimators in terms of bias and efficiency.

57.3.3.1 The Cross-Sectional case

We generate data using a simple model as in Eqs. 57.18, and 57.19 with $T = 1$, such that there are no fixed effects, no autocorrelation($\phi = 0$), and no heteroscedasticity ($\rho = 0$). The other parameters are $(\beta, \alpha_1, \alpha_2, \alpha_3) = (1, -1, 1, -1)$. Table 57.2 shows the results for bias and RMSE for four different distributions: lognormal, chi-square, F-distribution, and standard normal. For each distribution we estimate the model using three different EW estimators: EW-GMM3, EW-GMM4, and EW-GMM5. These estimators are based on the respective third, fourth, and fifth moment conditions. By combining the estimation of 4 parameters, under 4 different distributions, for all 3 EW estimators – a total of 48 estimates – we aim at establishing robust conclusions about the bias and efficiency of the EW approach.

Panel A of Table 57.2 presents the results for bias and RMSE when we use the lognormal distribution to generate innovations ($\in_i$ ε_i) that produce χ_i and z_i. Under this particular scenario, point estimates are approximately unbiased, and the small RMSEs indicate that coefficients are relatively efficiently estimated.

Panels B and C of Table 57.2 present the results for the chi-square and F-distribution, respectively. The experiments show that coefficient estimates produced by the EW approach are generally very biased. For example, Panel B shows that the β coefficient returned for the EW-GMM4 and EW-GMM5 estimators is biased downwards by approximately 35 %. Panel C shows that for EW-GMM3, the β coefficient is biased upwards about 35 %. Paradoxically, for EW-GMM4 and EW-GMM5, the coefficients are biased downwards by approximately 25 %. The coefficients returned for the perfectly measured regressors are also noticeably biased. And they, too, switch bias signs in several cases. Panels B and C show that the EW RMSEs are very high. Notably, the RMSE for EW-GMM4 under the chi-square distribution is 12.23, and under F-distribution, it is 90.91. These RMSE results highlight the lack of efficiency of the EW estimator. Finally, Panel D presents the results for the normal distribution case, which has zero skewness. In this case, the EW estimates are severely biased and the RMSEs are extremely high. The estimated coefficient for the mismeasured variable using EW-GMM3 has a bias of 1.91 (about three times larger than its true value) and an RMSE of 2305.

These results reveal that the EW estimators only have acceptable performance in the case of very strong skewness (lognormal distribution). They relate to the last section in highlighting the poor identification of the EW framework, even in the

Table 57.2 The EW estimator: cross-sectional data

		β	α_1	α_2	α_3

Panel D. Normal distribution					
EW-GMM3	Bias	1.9179	−0.6397	−0.5073	−0.3512
	RMSE	2305.0309	596.1859	608.2098	542.2125
EW-GMM4	Bias	−1.0743	0.3012	0.2543	0.2640
	RMSE	425.5931	111.8306	116.2705	101.4492
EW-GMM5	Bias	3.1066	−1.0649	−0.9050	−0.5483
	RMSE	239.0734	60.3093	65.5883	58.3686

This table shows the bias and the RMSE associated with the estimation of the model in Eqs. 57.17, 57.18, 57.19, 57.20, and 57.21 using the EW estimator in simulated cross-sectional data. β is the coefficient on the mismeasured regressor, and α_1 to α_3 are the coefficients on the perfectly measured regressors. The table shows the results associated with GMM3, GMM4, and GMM5 for all the alternative distributions. These estimators are based on the respective third, fourth, and fifth moment conditions

most basic cross-sectional setup. Crucially, for the other skewed distributions we study, the EW estimator is significantly biased for both the mismeasured and the well-measured variables. In addition, the RMSEs are quite high, indicating low efficiency.

57.3.3.2 The Panel Case

We argue that a major drawback of the EW estimator is its limited ability to handle individual heterogeneity – fixed effects and error heteroscedasticity – in panel data. This section compares the impact of individual heterogeneity on the EW, OLS-IV, and AB-GMM estimators in a panel setting. In the first round of experiments, we assume error homoscedasticity by setting the parameter ρ in Eq. 57.18 equal to zero. We shall later allow for changes in this parameter.

Although the EW estimations are performed on a period-by-period basis, one generally wants a single coefficient for each of the variables in an empirical model. To combine the various (time-specific) estimates, EW suggest the minimum distance estimator (MDE) described below. Accordingly, the results presented in this section are for the MDE that combines the estimates obtained from each of the ten time periods considered. For example, EW-GMM3 is the MDE that combines the ten different cross-sectional EW-GMM3 estimates in our panel.

The OLS-IV is computed after differencing the model and using the second lag of the observed mismeasured variable x, x_{t-2}, as an instrument for Δx_t. The AB-GMM estimates (Arellano and Bond 1991) use all the orthogonality conditions, with all available lags of x's as instrumental variables. We also concatenate the well-measured variables z's in the instruments' matrix. The AB-GMM estimator is also computed after differencing Eq. 57.18. To highlight the gains of these various estimators vis-à-vis the standard (biased) OLS estimator, we also report the results of simulations for OLS models using equation in first difference without instruments.

We first estimate the model using data in level form. While the true model contains fixed effects (and thus it is appropriate to use the within transformation), it is interesting to see what happens in this case since most applications of the EW estimator use data in level form, and as shown previously, the EW identification test performs slightly better using data in this form.

The results are presented in Table 57.3. The table makes it clear that the EW method delivers remarkably biased results when ignoring the presence of fixed effects. Panel A of Table 57.3 reports the results for the model estimated with the data under strong skewness (lognormal). In this case, the coefficients for the mismeasured regressor are very biased, with biases well in excess of 100 % of the true coefficient for the EW-GMM3, EW-GMM4, and EW-GMM5 estimators. The biases for the well-measured regressors are also very strong, all exceeding 200 % of the estimates' true value. Panels B and C report results for models under chi-square and F-distributions, respectively. The EW method continues to deliver very biased results for all of the estimates considered. For example, the EW-GMM3 estimates that are returned for the mismeasured regressors are biased downwardly by about 100 % of their true values – those regressors are deemed irrelevant when they are not. Estimates for the well-measured regressors are positively biased by approximately 200 % – they are inflated by a factor of 3. The RMSEs reported in Panels A, B, and C show that the EW methodology produces very inefficient estimates even when one assumes pronounced skewness in the data. Finally, Panel D reports the results for the normal distribution. For the non-skewed data case, the EW framework can produce estimates for the mismeasured regressor that are downwardly biased by about 90 % of their true parameter values for all models. At the same time, that estimator induces an upward bias of larger than 200 % for the well-measured regressors.

Table 57.3 The EW estimator: panel data in levels

		β	α_1	α_2	α_3

	RMSE	0.9846	2.2316	2.2279	2.2269

This table shows the bias and the RMSE associated with the estimation of the model in Eqs. 57.17, 57.18, 57.19, 57.20, and 57.21 using the EW estimator in simulated panel data. The table reports results from data in levels (i.e., without applying the within transformation). β is the coefficient on the mismeasured regressor, and α_1, α_2, α_3 are the coefficients on the perfectly measured regressors. The table shows the results for the EW estimator associated with EW-GMM3, EW-GMM4, and EW-GMM5 for all the alternative distributions. These estimators are based on the respective third, fourth, and fifth moment conditions

Table 57.4 reports results for the case in which we apply the within transformation to the data. Here, we introduce the OLS, OLS-IV, and AB-GMM estimators. We first present the results associated with the set up that is most favorable for the EW estimations, which is the lognormal case in Panel A. The EW estimates for the lognormal case are relatively unbiased for the well-measured regressors (between 4 % and 7 % deviation from true parameter values). The same applies for the mismeasured regressors. Regarding the OLS-IV, Panel A shows that coefficient estimates are unbiased in all models considered. AB-GMM estimates are also approximately

This table shows the bias and the RMSE associated with the estimation of the model in Eqs. 57.17, 57.18, 57.19, 57.20, 57.21 using the OLS, OLS-IV, AB-GMM, and EW estimators in simulated panel data. The table reports results from the estimators on the data after applying the within transformation. β is the coefficient on the mismeasured regressor, and α_1, α_2, α_3 are the coefficients on the perfectly measured regressors. The table shows the results for the EW estimator associated with EW-GMM3, EW-GMM4, and EW-GMM5 for all the alternative distributions. These estimators are based on the respective third, fourth, and fifth moment conditions

unbiased, while standard OLS estimates are very biased. In terms of efficiency, the RMSEs of the EW-GMM3 are somewhat smaller than those of the OLS-IV and AB-GMM for the well-measured and mismeasured regressors. However, for the mismeasured regressor, both OLS-IV and AB-GMM have smaller RMSEs than EW-GMM4 and EW-GMM5.

Panel B of Table 57.4 presents the results for the chi-square distribution. One can see that the EW yields markedly biased estimates in this case. The bias in the mismeasured regressor is approximately 38 % (downwards), and the coefficients for the well-measured variable are also biased (upwards). In contrast, the OLS-IV and AB-GMM estimates for both well-measured and mismeasured regressors are approximately unbiased. In terms of efficiency, as expected, the AB-GMM presents slightly smaller RMSEs than the OLS-IV estimator. These IV estimators' RMSEs are much smaller than those associated with the EW estimators.

Panels C and D of Table 57.4 show the results for the F and standard normal distributions, respectively. The results for the F-distribution in Panel C are essentially similar to those in Panel B: the instrumental variable estimators are approximately unbiased while the EW estimators are very biased. Finally, Panel D shows that deviations from a strongly skewed distribution are very costly in terms of bias for the EW estimator, since the bias for the mismeasured regressor is larger than 70 %, while for the well measured, it is around 20 %. A comparison of RMSEs shows that the IV estimators are more efficient in both the F and normal cases. In all, our simulations show that standard IV methods almost universally dominate the EW estimator in terms of bias and efficiency.

We reiterate that the bias and RMSE of the IV estimators in Table 57.4 are all relatively invariant to the distributional assumptions, while the EW estimators are all very sensitive to those assumptions. In short, this happens because the EW relies on the high-order moment conditions as opposed to the OLS and IV estimators.

57.3.4 Heteroscedasticity

One way in which individual heterogeneity may manifest itself in the data is via error heteroscedasticity. Up to this point, we have disregarded the case in which the data has a heteroscedastic error structure. However, most empirical applications in corporate finance entail the use of data for which heteroscedasticity might be relevant. It is important that we examine how the EW and the IV estimators are affected by heteroscedasticity.[19]

The presence of heteroscedasticity introduces heterogeneity in the model and consequently in the distribution of the partialled out dependent variable. This compromises identification in the EW framework. Since the EW estimator is based on equations giving the moments of $(y_i - z_i\mu_y)$ and $(y_i - z_i\mu_\chi)$ as functions of β and moments of $(u_i, \varepsilon_i, \eta_i)$, the heteroscedasticity associated with the fixed effects (α_i) or with the perfectly measured regressor (z_{it}) distorts the required moment conditions associated with $(y_i - z_i\mu_y)$, yielding biased estimates. These inaccurate estimates enter the minimum distance estimator equation and consequently produce incorrect weights for each estimate along the time dimension. As our simulations of this section demonstrate, this leads to biased MDE estimates, where the bias is a function of the amount of heteroscedasticity.

We examine the biases imputed by heteroscedasticity by way of graphical analysis. The graphs we present below are useful in that they synthesize the outputs of numerous tables and provide a fuller visualization of the contrasts we draw between the EW and OLS-IV estimators. The graphs depict the sensitivity of those two estimators with respect to heteroscedasticity as we perturb the coefficient p in Eq. 57.18.

In our simulations, we alternatively set $w_{it} = \gamma_i$ or $w_{it} = z_{it}$. In the first case, heteroscedasticity is associated with the individual effects. In the second, heteroscedasticity is associated with the well-measured regressor. Each of our figures describes the biases associated with the mismeasured and the well-measured regressors for each of the OLS-IV, EW-GMM3, EW-GMM4, and EW-GMM5 estimators.[20] In order to narrow our discussion, we only present results for the highly skewed distribution case (lognormal distribution) and for data that is treated for fixed effects using the within transformation. As Sect. 57.3.3 shows, this is the only case in which the EW estimator returns relatively unbiased estimators for the parameters of interest. In all the other cases (data in levels and for data generated by

[19]We focus on the OLS-IV estimator hereinafter for the purpose of comparison with the EW estimator.

[20]Since estimation biases have the same features across all well-measured regressors of a model, we restrict attention to the first well-measured regressor of each of the estimated models.

chi-square, F, and normal distributions), the estimates are strongly biased even under the assumption of homoscedasticity.[21]

Figure 57.2 presents the simulation results under the assumption that $w_{it} = \gamma_i$ as we vary the amount of heteroscedasticity by changing the parameter ρ,[22] the results for the mismeasured coefficients show that biases in the EW estimators are generally small for ρ equal to zero (this is the result reported in Sect. 57.3.3). However, as this coefficient increases, the bias quickly becomes large. For example, for $\rho = 0.45$, the biases in the coefficient of the mismeasured variable are, respectively, -11 %, -20 %, and -43 %, for the EW-GMM3, EW-GMM4, and EW-GMM5 estimators. Notably, those biases, which are initially negative, turn positive for moderate values of ρ. As heteroscedasticity increases, some of the biases diverge to positive infinite. The variance of the biases of the EW estimators is also large. The results regarding the well-measured variables using EW estimators are analogous to those for the mismeasured one. Biases are substantial even for small amounts of heteroscedasticity, they switch signs for some level of heteroscedasticity, and their variances are large. In sharp contrast, the same simulation exercises show that the OLS-IV estimates are approximately unbiased even under heteroscedasticity. While the EW estimator may potentially allow for some forms of heteroscedasticity, it is clear that it is not well equipped to deal with this problem in more general settings.

57.3.5 Identification of the EW Estimator in Panel Data

Our Monte Carlo experiments show that the EW estimator has a poor handle of individual fixed effects and that biases arise for deviations from the assumption of strict lognormality. Biases in the EW framework are further magnified if one allows for heteroscedasticity in the data (even under lognormality). The biases arising from the EW framework are hard to measure and sign, ultimately implying that it can be very difficult to replicate the results one obtains under that framework.

To better understand these results, we now discuss in more mathematical details the identification of the EW estimator for the panel data case for both the model in level and after the within transformation. Extending the EW estimator to panel data seems to be a nontrivial task. EW have proposed to break the problem for each time series, estimate a cross-section model for each t, and after that combine the estimates using a minimum distance estimator. In what follows we show that this procedure might affect the identification condition.

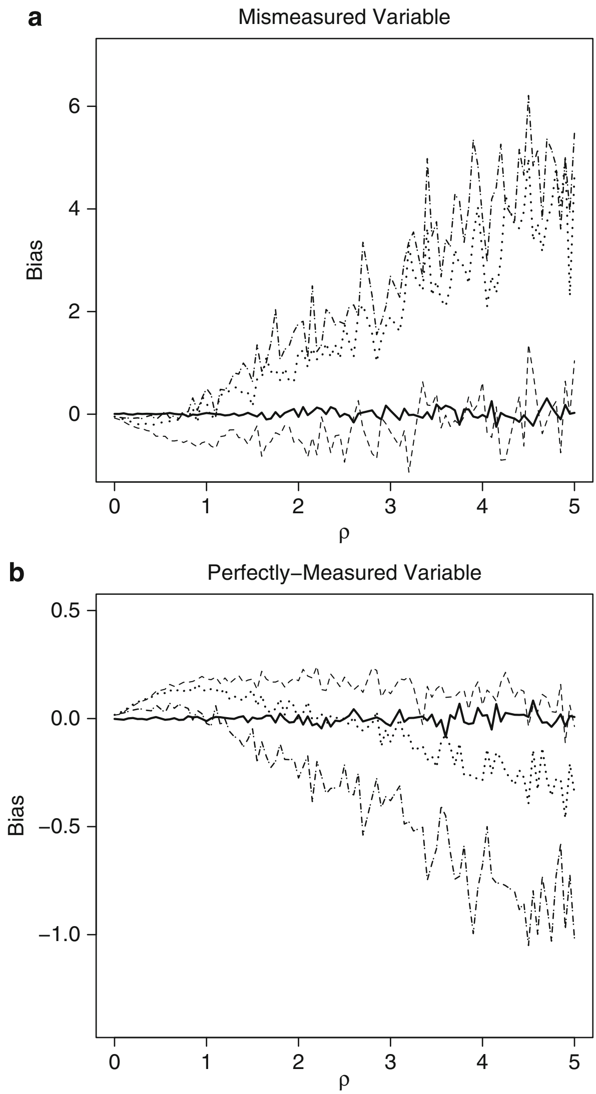
Consider the following model:

$$y_{it} = \alpha_i + \beta \chi_{it} + u_{it}, \quad i = 1, \ldots, N; t = 1, \ldots, T, \tag{57.23}$$

[21]Our simulation results (available upon request) suggest that introducing heteroscedasticity makes the performance of the EW estimator even worse in these cases.

[22]The results for $w_{it} = z_{it}$ are quite similar to those we get from setting $w_{it} = \gamma_i$. We report only one set of graphs to save space.

Fig. 57.2



where u_{it} is independent and identically distributed, with mean zero and variance σ_u^2. Assume that the $\mathrm{Var}(x_{it}) = \sigma_\chi^2$. The independent variable and unobserved effects are exogenous, that is, $\mathrm{Cov}(\chi_{it}, u_{is}) = \mathrm{Cov}(\alpha_i, u_{it}) = 0$ for any t and s. However, $\mathrm{Cov}(\alpha_i, \chi_{it}) \neq 0$. Now, assume that we do not observe the true variable χ_{it}, but rather a mismeasured variable, that is, you observe the following variable with an error:

$$x_{it} = \chi_{it} + e_{it}, \quad i = 1, \ldots, N \ldots, N; t = 1, \ldots T, \tag{57.24}$$

where $\mathrm{Cov}(x_{it}, e_{is}) = \mathrm{Cov}(\alpha_i, e_{is}) = \mathrm{Cov}(u_{it}, e_{is}) = 0$, and $\mathrm{Var}(e_{it}) = \sigma_e^2$, $\mathrm{Cov}(e_{it}, e_{it-1}) = \gamma\sigma_e^2$.

In addition, assume here that there is no variable z_{it} ($\alpha = 0$ in Eq. 57.18) to simplify the argument.

57.3.5.1 Model in Level

As mentioned before, EW propose to fix a particular time series and estimate the model using the cross-section data. Without loss for generality, fix $T = 1$. Thus, Eqs. 57.23 and 57.24 become

$$y_{i1} = \alpha_i + \beta\chi_{i1} + u_{i1}, \quad i = 1, \ldots, N, \tag{57.25}$$

and

$$x_{i1} = \chi_{i1} + e_{i1}, \quad i = 1, \ldots, N. \tag{57.26}$$

However, the unobserved individual-specific intercepts, α_i, are still present in Eq. 57.25 and in addition $\mathrm{Cov}(\alpha_i, \chi_{i1}) \neq 0$. Therefore, one can see that it is impossible to estimate β consistently since α_i's are unobserved. This argument is easily extended for every $t = 1, \ldots, T$. Thus, the estimator for each fixed t is inconsistent, and consequently the minimum distance estimator is inconsistent by construction. Therefore, we conclude that the EW minimum distance estimator produces inconsistent estimates for panel data model with fixed effects.

57.3.5.2 Model After Within Transformation

Given the inconsistency of the model in levels presented in the last section, one strategy is to previously transform the data to eliminate the fixed effects. One suggestion is to use the within transformation in the data before estimation.

In order to analyze the model after the transformation, let's assume that $T = 2$ for simplification. Using the within transformation in Eqs. 57.23 and 57.24, we obtain

$$y_{it} - \overline{y}_{it} = \beta(\chi_{it} - \overline{\chi}_i) + (u_{it} - \overline{u}_i),$$

and

$$x_{it} - \overline{x}_i = (\chi_{it} - \overline{\chi}_i) + (e_{it} - \overline{e}_i),$$

where $\bar{y}_i = \frac{1}{2}(y_{i1} + y_{i2})$, $\bar{\chi}_i = \frac{1}{2}(\chi_{i1} + \chi_{i2})$, and so on.

Now, again EW propose to use a particular time series and estimate the model using the cross-section data. Let's use $t = 1$ for ease of exposition. The model can be written as

$$y_{il} - \overline{y}_i = \beta(\chi_{i1} - \overline{\chi}_i) + (u_{i1} - \overline{u}_i)$$

and

$$x_{i1} - \overline{x}_i = (\chi_{i1} - \overline{\chi}_i) + (e_{it} - \overline{e}_i).$$

Now substituting the definition of the deviations and rearranging, we have

$$y_{i1} - \frac{1}{2}(y_{i1} + y_{i2}) = \beta\left(\chi_{i1} - \frac{1}{2}(\chi_{i1} + \chi_{i2})\right) + \left(u_{i1} - \frac{1}{2}(u_{i1} + u_{i2})\right),$$
$$y_{il} + y_{i2} = \beta(\chi_{i1} + \chi_{i2}) + (u_{i1} + u_{i2}),$$

and

$$x_{i1} - \frac{1}{2}(x_{i1} + x_{i2}) = \left(\chi_{i1} - \frac{1}{2}(\chi_{i1} + \chi_{i2})\right) + \left(e_{i1} - \frac{1}{2}(e_{i1} + e_{i2})\right),$$
$$x_{i1} + x_{i2} = (\chi_{i1} + \chi_{i2}) + (e_{i1} + e_{i2}).$$

Finally, our model can be described as

$$y_{i1} + y_{i2} = \beta(\chi_{i1} + \chi_{i2}) + (u_{i1} + u_{i2}),$$

and

$$x_{i1} + x_{i2} = (\chi_{i1} + \chi_{i2}) + (e_{i1} + e_{i2}).$$

Let's now define $Y_i = y_{i1} + y_{i2}$, $X_i = x_{i1} + x_{i2}$, $U_i = u_{i1} + u_{i2}$, $v_i = \chi_{i1} + \chi_{i2}$, and $E_i = e_{i1} + e_{i2}$. So, the model could be rewritten as

$$Y_i = \beta v_i + U_i$$

and

$$X_i = v_i + E_i.$$

Notice that the requirements for identification now are on the high-order moments of (v, U, E). However, note that $v_i = \chi_{i1} + \chi_{i2}$, which is a sum of two random variables. As it is well known from the econometrics literature, convolution of random variables is in general a nontrivial object.

One example of why the identification condition may worsen considerably is the following. Consider a model where χ_{i1} and χ_{i2} are independent chi-square distributions with 2 degrees of freedom. The skewness of the chi-square with k degrees of freedom is $\sqrt{8/k}$. Note that the sum of two independent chi-squares with k degrees of freedom is a chi-square with $2k$ degrees of freedom. Therefore, the skewness of the $v_i = \chi_{i1} + \chi_{i2}$ drops from two for the model using one distribution to 1.41 for the model using the summation of both χ_{i1} and χ_{i2}.

From this simple analysis one could conclude that the identification conditions required for EW estimator can deteriorate considerably when using the within transformation to eliminate the fixed effects in panel data. Thus, the required conditions to achieve unbiased estimates with EW are very strong.

57.3.6 Revisiting the OLS-IV Assumptions

Our Monte Carlo simulations show that the OLS-IV estimator is consistent even when one allows for autocorrelation in the measurement-error structure. We have assumed, however, some structure on the processes governing innovations. In this section, we examine the sensitivity of the OLS-IV results with respect to our assumptions about measurement-error correlation and the amount of autocorrelation in the latent regressor. These assumptions can affect the quality of the instruments and therefore should be examined in some detail.

We first examine conditions regarding the correlation of the measurement errors and disturbances. The assumption of time-invariant autocorrelation for measurement errors and disturbances implies that past shocks to measurement errors do not affect the current level of the measurement error. One way to relax this assumption is to allow for the measurement-error process to have a moving average structure. This structure satisfies Biorn's assumptions (B1) and (B2). In this case, Proposition 1 in Biorn (2000) shows that for an MA(τ), the instruments should be of order of at most $t - \tau - 2$. Intuitively, the set of instruments must be "older" than the memory of the measurement-error process. For example, if the measurement error is MA(1), then one must use third- and longer-lagged instruments to identify the model.

To analyze this case, we conduct Monte Carlo simulations in which we replace the time-invariant assumption for innovation u_{it} and v_{it} with an MA(1) structure for the measurement-error process. The degree of correlation in the MA process is set to $\theta = 0.4$. Thus, the innovation in Eqs. 57.18 and 57.19 has the following structure:

$$u_{it} = u_{1it} - \theta u_{1it-1} \;\text{ and }\; v_{it} = v_{1it} = v_{1it} - \theta v_{1it-1},$$

with $|\theta| \leq 1$, and u_{1it} and v_{1it} are i.i.d. lognormal distributions. The other parameters in the simulation remain the same.

The results are presented in Table 57.5. Using MA(1) in the innovations and the third lag of the latent regressor as an instrument (either on its own or in combination with the fourth lag), the bias of the OLS estimator is very small (approximately 2–3 %). The bias increases somewhat when we use only the fourth lag. While the fourth is an admissible instrument in this case, using longer lags decreases the implied autocorrelation in the latent regressor [which follows an

AR(1) process by Eq. 57.20]. This effect decreases somewhat the quality of the instruments. Notice also that when we do not eliminate short lags from the instrument set, the identification fails. For example, the bias is 60 % when we use the second lag as an instrument. These results thus underscore the importance of using long enough lags in this MA case. Table 57.5 also reports results based on an MA (2) structure. The results are qualitatively identical to those shown in the MA (1) case. Once again, the important condition for identification is to use long enough lags (no less than four lags in this case).[23]

The second condition underlying the use of the OLS-IV is that the latent regressor is not time invariant. Accordingly, the degree of autocorrelation in the process for the latent regressor is an important element of the identification strategy. We assess the sensitivity of the OLS-IV results to this condition by varying the degree of autocorrelation through the autoregressive coefficient in the AR(1) process for the latent regressor. In these simulations, we use a time-invariant autocorrelation condition for the measurement error, but the results are very similar for the MA case.

Figure 57.3 shows the results for the bias in the coefficients of interest for the well-measured and mismeasured variables, using the second lag of the mismeasured variable as an instrument. The results show that the OLS-IV estimator performs well for a large range of the autoregressive coefficient. However, as expected, when the ϕ coefficient is very close to zero or one, we have evidence of a weak instrument problem. For example, when $\phi = 1$, then $\Delta\chi_{it}$ is uncorrelated with any variable dated at time $t-2$ or earlier. These simulations show that, provided that one uses adequately lagged instruments, the exact amount of autocorrelation in the latent variable is not a critical aspect of the estimation.

The simulations of this section show how the performance of the OLS-IV estimator is affected by changes in assumptions concerning measurement errors and latent regressors. In practical applications, it is important to verify whether the results obtained with OLS-IV estimators are robust to the elimination of short lags from the instrumental set. This robustness check is particularly important given that the researcher will be unable to pin down the process followed by the measurement error. Our empirical application below incorporates this suggestion. In addition, identification relies on some degree of autocorrelation in the process for the latent regressor. While this condition cannot be directly verified, we can perform standard tests of instrument adequacy that rely on "first-stage" test statistics calculated from the processes for the observable variables in the model.

Another important assumption in the OLS is non-autocorrelation in both u_{it} and v_{it}. For example, these innovations cannot follow an autoregressive process.

[23]We note that if the instrument set uses suitably long lags, then the OLS-IV results are robust to variations in the degree of correlation in the MA process. In unreported simulations under MA(1), we show that the OLS bias is nearly invariant to the parameter θ.

Table 57.5 Moving average structures for the measurement-error process

Instrument	MA(1)	MA(2)
X_{it-2}	−0.593	−0.368
	(0.60)	(0.38)
X_{it-3}	0.028	−0.707
	(0.30)	(0.71)
X_{it-3}, X_{it-4}	0.025	0.077
	(0.63)	(1.01)
$X_{it-3}, X_{it-4}, X_{it-5}$	−0.011	−0.759
	(0.30)	(0.76)
X_{it-4}	−0.107	−0.144
	(1.62)	(2.01)
X_{it-4}, X_{it-5}	−0.113	−0.140
	(0.58)	(0.59)
X_{it-5}	−0.076	−0.758
	(0.31)	(0.76)

This table shows the bias in the well-measured coefficient for OLS-IV using moving average structure for the measurement-error process. Numbers in parentheses are the RMSE

When this is the case, the IV strategy of using lags of mismeasured variable as valid instruments is invalid (see Biorn 2000).

57.3.7 Distributional Properties of the EW and OLS-IV Estimators

A natural question is whether our simulation results are rooted in the lack of accuracy of the asymptotic approximation of the EW method. Inference in models with mismeasured regressors is based on asymptotic approximations; hence inference based on estimators with poor approximations might lead to wrong inference procedures. For instance, we might select wrong critical values for a test under poor asymptotic approximations and make inaccurate statements under such circumstances. In this section, we use the panel data simulation procedure of Sect. 3.3.2 to study and compare the accuracy of the asymptotic approximation of the EW and IV methods. To save space, we restrict our attention to the mismeasured regressor coefficient for the EW-GMM5 and OLS-IV cases. We present results where we draw the data from the lognormal, chi-square, and F-distributions. The EW-GMM5 estimator is computed after the within transformation and the OLS-IV uses second lags as instruments.

One should expect both the IV and EW estimators to have asymptotically normal representations, such that when we normalize the estimator by subtracting the true parameter and divide by the standard deviation, this quantity behaves asymptotically as a normal distribution. Accordingly, we compute the empirical density and the distribution functions of the normalized sample estimators and their normal approximations. These functions are plotted in Fig. 57.4. The true normal density

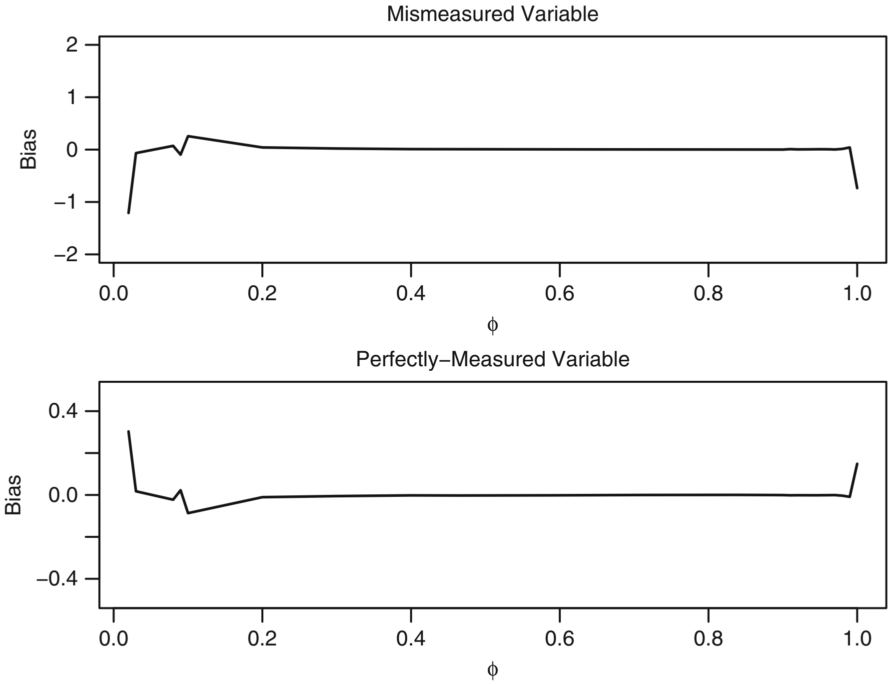


Fig. 57.3

and distribution functions (drawn in red) serve as benchmarks. The graphs in Fig. 57.4 depict the accuracy of the approximation. We calculate the density of the estimators using a simple Gaussian Kernel estimator and also estimate the empirical cumulative distribution function.[24]

Consider the lognormal distribution (first panel). In that case, the OLS-IV (black line) displays a very precise approximation to the normal curve in terms of both density and distribution. The result for the OLS-IV is robust across all of the distributions considered (lognormal, chi-square, and F). These results are in sharp contrast to those associated with the EW-GMM5 estimator. This estimator presents a poor asymptotic approximation for all distributions examined. For the lognormal case, the density is not quite centered at zero, and its shape does not fit the normal distribution. For the chi-square and F-distributions, Fig. 57.4 shows that the shapes of the density and distribution functions are very unlike the normal case, with the center of the distribution located far away from zero. These results imply that inference procedures using the EW estimator might be asymptotically invalid in simple panel data with fixed effects, even when the relevant distributions present high skewness.

[24]The empirical cumulative distribution function F_n is a step function with jumps i/n at observation values, where i is the number of tied observations at that value.

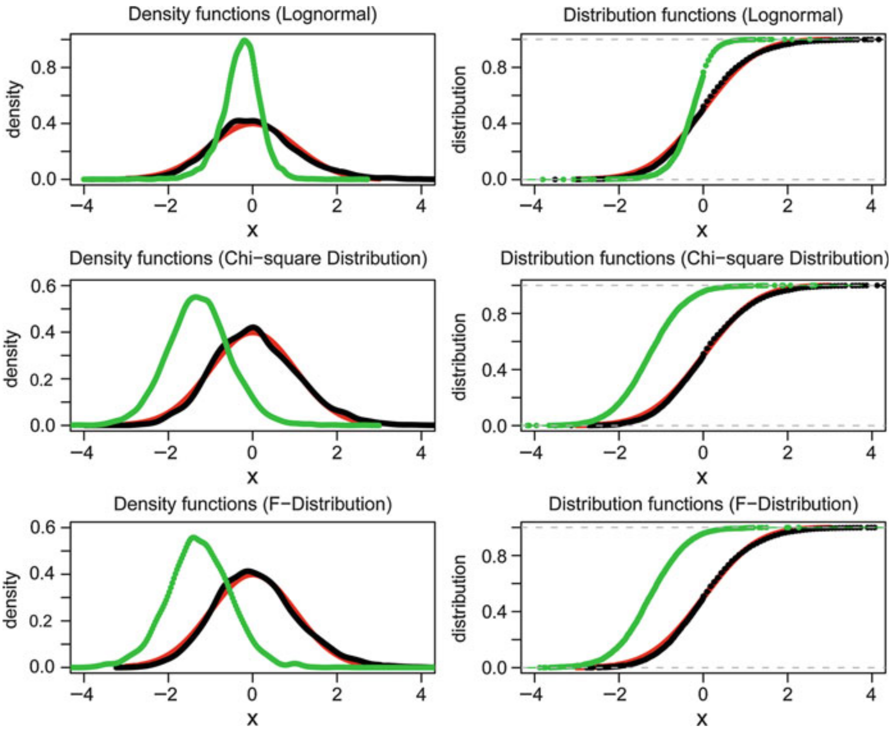

Fig. 57.4

57.4 Empirical Application

We apply the EW and OLS-IV estimators to Fazzari et al. (1988) investment equation. This is the most well-known model in the corporate investment literature, and we use this application as a way to illustrate our Monte Carlo-based results. In the Fazzari, Hubbard, and Petersen model, a firm's investment spending is regressed on a proxy for investment demand (Tobin's q) and the firm's cash flow. Theory suggests that the correct proxy for the firm's investment demand is *marginal* q, but this quantity is unobservable and researchers use instead its measurable proxy, *average* q. Because average q measures marginal q imperfectly, a measurement problem naturally arises. Erickson and Whited (2002) uses the Fazzari, Hubbard, and Petersen model to motivate the adoption of their estimator in applied work in panel data.

A review of the corporate investment literature shows that virtually all empirical work in the area considers panel data models with firm-fixed effects (Kaplan and Zingales 1997; Rauh 2006; Almeida and Campello 2007). From an estimation point of view, there are distinct advantages in exploiting repeated observations from individuals to identify the model (Blundell et al. 1992). In an investment model setting, exploiting firm effects contributes to estimation precision and allows for model consistency in the presence of unobserved idiosyncrasies that may be simultaneously correlated with investment and q. The baseline model in this literature has the form

$$I_{it}/K_{it} = \eta_i + \beta q^*_{it} + \alpha CF_{it}/K_{it} + u_{it}, \tag{57.27}$$

where I denotes investment, K capital stock, q* is marginal q, CF cash flow, η is the firm-specific effect, and u is the innovation term.

As mentioned earlier, if q* is measured with error, OLS estimates of β will be biased downwards. In addition, given that q and cash flow are likely to be positively correlated, the coefficient α is likely to be biased upwards in OLS estimations. In expectation, these biases should be reduced by the use of estimators like the ones discussed in the previous section.

57.4.1 Theoretical Expectations

In order to better evaluate the performance of the two alternative estimators, we develop some hypotheses about the effects of measurement-error correction on the estimated coefficients β and α from Eq. 57.27. Theory does not pin down the exact values that these coefficients should take. Nevertheless, one could argue that the two following conditions should be reasonable.

First, an estimator that addresses measurement error in q in a standard investment equation should return a higher estimate for β and a lower estimate for α when compared with standard OLS estimates. Recall that measurement error causes an attenuation bias on the estimate for the coefficient β. In addition, since q and cash flow are likely to be positively correlated, measurement error should cause an upward bias on the empirical estimate returned under the standard OLS estimation. Accordingly, if one denotes the OLS and the measurement-error consistent estimates, respectively, by (β^{OLS}, α^{OLS}) and (β^{MEC}, α^{MEC}), one should expect:

Condition 1. $\beta^{OLS} < \beta^{MEC}$ *and* $\alpha^{OLS} > \alpha^{MEC}$. Second, one would expect the coefficients for q and the cash flow to be nonnegative after treating the data for measurement error. The q-theory of investment predicts a positive correlation between investment and q (e.g., Hayashi 1982). If the theory holds and the estimator does a good job of adjusting for measurement error, then the cash flow coefficient should be zero ("neoclassical view"). However, the cash flow coefficient could be positive either because of the presence of financing frictions (as posited by Fazzari et al. 1988)[25] or

[25]However, financial constraints are not sufficient to generate a strictly positive cash flow coefficient because the effect of financial constraints is capitalized in stock prices and may thus be captured by variations in q (Chirinko 1993; Gomes 2001).

due to fact that cash flow picks up variation in investment opportunities even after we apply a correction for mismeasurement in q. Accordingly, one should observe:

Condition 2. $\beta^{MEC} \geq 0$ *and* $\alpha^{MEC} \geq 0$. Notice that these conditions are fairly weak. If a particular measurement-error consistent estimator does not deliver these basic results, one should have reasons to question the usefulness of that estimator in applied work.

57.4.2 Data Description

Our data collection process follows that of Almeida and Campello (2007). We consider a sample of manufacturing firms over the 1970–2005 period with data available from Compustat. Following those authors, we eliminate firm years displaying asset or sales growth exceeding 100 %, or for which the stock of fixed capital (the denominator of the investment and cash flow variables) is less than \$5 million (in 1976 dollars). Our raw sample consists of 31,278 observations from 3,084 individual firms. Summary statistics for investment, q, and cash flow are presented in Table 57.6. These statistics are similar to those reported by Almeida and Campello, among other papers. To save space we omit the discussion of these descriptive statistics.

57.4.3 Testing for the Presence of Fixed Effects and Heteroscedasticity

Before estimating our investment models, we conduct a series of tests for the presence of firm-fixed effects and heteroscedasticity in our data. As a general rule, these phenomena might arise naturally in panel data applications and should not be ignored. Importantly, whether they appear in the data can have concrete implications for the results generated by different estimators.

We first perform a couple of tests for the presence of firm-fixed effects. We allow for individual firm intercepts in Eq. 57.27 and test the null hypothesis that the coefficients associated with those firm effects are jointly equal to zero (Baltagi 2005). Table 57.7 shows that the F-statistic for this test is 4.4 (the associated p-value is 0.000). Next, we contrast the random effects OLS and the fixed effects OLS estimators to test again for the presence of fixed effects. The Hausman test statistic reported in Table 57.7 rejects the null hypothesis that the random effects model is appropriate with a test statistic of 8.2 (p-value of 0.017). In sum, standard tests strongly reject the hypothesis that fixed effects can be ignored.

We test for homoscedasticity using two different panel data-based methods. First, we compute the residuals from the least squares dummy variables estimator and regress the squared residuals on a function of the independent variables [see Frees (2004) for additional details]. We use two different combinations of independent regressors – (q_{it}, CF_{it}) and (q_{it}, q_{it}^2, CF_{it}, CF_{it}, CF_{it}^2) – and both of them robustly reject the null hypothesis of homoscedasticity. We report the results for the

Table 57.6 Descriptive statistics

Variable	Obs.	Mean	Std. dev.	Median	Skewness
Investment	22,556	0.2004	0.1311	0.17423	2.6871
q	22,556	1.4081	0.9331	1.1453	4.5378
Cash flow	22,556	0.3179	0.3252	0.27845	−2.2411

This table shows the basic descriptive statistics for q, cash flow, and investment. The data are taken from the annual Compustat industrial files over the 1970–2005 period. See text for details

Table 57.7 Diagnosis tests

Test	Test statistic	p-value
Pooling test	4.397	0.0000
Random effects vs. fixed effects	8.17	0.0169
Homoscedasticity 1	55.19	0.0000
Homoscedasticity 2	7,396.21	0.0000

This table reports results for specification tests. Hausman test for fixed effects models considers fixed effects models against the simple pooled OLS and the random effects model. A homoscedasticity test for the innovations is also reported. The data are taken from the annual Compustat industrial files over the 1970–2005 period. See text for details

first combination in Table 57.7, which yields a test statistic of 55.2 (p-value of 0.000). Our second approach for testing the null of homoscedasticity is the standard random effects Breusch-Pagan test. Table 57.7 shows that the Breusch-Pagan test yields a statistic of 7,396.2 (p-value of 0.000). Our tests hence show that the data strongly reject the hypothesis of error homoscedasticity.

57.4.4 Implementing the EW Identification Test

Our preliminary tests show that one should control for fixed effects when estimating investment models using real data. In the context of the EW estimator, it is thus appropriate to apply the within transformation before the estimation. However, in this section, we also present results for the data in level form to illustrate the point made in Sect. 57.3.2 that applying the within transformation compromises identification in the EW context. Prior papers adopting the EW estimator have ignored (or simply dismissed) the importance of fixed effects (e.g., Whited 2001, 2006).

We present the results for EW's identification test in Table 57.8. Using the data in level form, we reject the hypothesis of no identification in 12 out of 30 years (or 36 % rejection). For data that is transformed to accommodate fixed effects (within transformation), we find that in only 7 out of 33 (or 21 %) of the years between 1973 and 2005, one can reject the null hypothesis that the model is not identified at the usual 5 % level of significance. These results suggest that the power of the test is low and decreases further after applying the within transformation to the data. These results are consistent with Almeida and Campello's (2007) use of the EW estimator. Working with a 15-year Compustat panel, those authors report that they could only find a maximum of 3 years of data passing the EW identification test.

The results in Table 57.8 reinforce the notion that it is quite difficult to operationalize the EW estimator in real-world applications, particularly in situations in which the within transformation is appropriate due to the presence of fixed effects. We recognize that the EW identification test rejects the model for most of the data at hand. However, recall from Sect. 57.3.2 that the test itself is likely to be misleading ("over-rejecting" the data). In the next section, we take the EW estimator to the data (a standard Compustat sample extract) to illustrate the issues applied researchers face when using that estimator, contrasting it to an easy-to-implement alternative.

57.4.5 Estimation Results

We estimate Eq. 57.27 using the EW, OLS-IV, and AB-GMM estimators. For comparison purposes, we also estimate the investment equation using standard OLS and OLS with fixed effects (OLS-FE). The estimates for the standard OLS are likely to be biased, providing a benchmark to evaluate the performance of the other estimators. As discussed in Sect. 57.4.1, we expect estimators that improve upon the problem of mismeasurement to deliver results that satisfy Conditions 1 and 2 above.

As is standard in the empirical literature, we use an unbalanced panel in our estimations. Erickson and Whited (2000) propose a minimum distance estimator (MDE) to aggregate the cross-sectional estimates obtained for each sample year, but their proposed MDE is designed for balanced panel data. Following Riddick and Whited (2009), we use a Fama–MacBeth procedure to aggregate the yearly EW estimations.[26]

To implement our OLS-IV estimators, we first take differences of the model in Eq. 57.27. We then employ the estimator denoted by *OLS-IV A* from Sect. 57.2.2, using lagged levels of q and cash flow as instruments for (differenced) q_{it}. Our Monte Carlos suggest that identification in this context may require the use of longer lags of the model variables. Accordingly, we experiment with specifications that use progressively longer lags of q and cash flow to verify the robustness of our results.

Table 57.9 reports our findings. The OLS and OLS-FE estimates, reported in columns (1) and (2), respectively, disregard the presence of measurement error in q. The EW-GMM3, EW-GMM4, and EW-GMM5 estimates are reported in columns (3), (4), and (5). For the OLS-IV estimates reported in column (6), we use q_{t-2} as an instrument.[27] The AB-GMM estimator, reported in column (7), uses lags of q as instruments. Given our data structure, this implies using a total of 465 instruments. We account for firm-fixed effects by transforming the data.

[26]Fama–MacBeth estimates are computed as a simple standard errors for yearly estimates. An alternative approach could use the Hall–Horowitz bootstrap. For completeness, we present in the appendix the actual yearly EW estimates.

[27]In the next section, we examine the robustness of the results with respect to variation in the instrument set.

This table shows the test statistic and its *p*-value for the EW identification test, which tests the null hypothesis that the model is not identified. The tests are performed on a yearly basis. In the last columns, we collect the number of years in which the null hypothesis is rejected (sum) and compute the percentage of years in which the null is rejected. The data are taken from the annual Compustat industrial files over the 1970–2005 period. See text for details

Table 57.9 EW, GMM, and OLS-IV coefficients, real-world data

Variables	OLS	OLS-FE	EW-GMM3	EW-GMM4	EW-GMM5	OLS-IV	AB-GMM

Observations	22,556	22,556	22,556	22,556	22,556	17,348	19,748
F-stat *p*-value (first step)	–	–	–	–	–	0.000	–

This table shows the coefficients and standard deviations that we obtain when we use the OLS, EW, and the GMM estimators in Eq. 57.22. The table also displays the standard OLS-FE coefficients (after applying the differencing transformation to treat the fixed effects) in column (2) and OLS-IV in the last column. Robust standard errors in parentheses for OLS and GMM and clustered in firms for OLS-FE and OLS-IV. Each EW coefficient is an average of the yearly coefficients reported in Table 57.11 and the standard error for these coefficients is a Fama–MacBeth standard error. The table shows the EW coefficients for the data after applying the within transformation. The data are taken from the annual Compustat industrial files over the 1970–2005 period. See text for details. *, **, and *** represent statistical significance at the 10 %, 5 %, and 1 % levels, respectively

When using OLS and OLS-FE, we obtain the standard result in the literature that both q and cash flow attract positive coefficients [see columns (1) and (2)]. In the OLS-FE specification, for example, we obtain a q coefficient of 0.025 and a cash flow coefficient of 0.121. Columns (3), (4), and (5) show that the EW estimator does not deliver robust inferences about the correlations between investment, cash flow, and q. The q coefficient estimate varies significantly with the set of moment conditions used, even flipping signs. In addition, none of the q coefficients is statistically significant. The cash flow coefficient is highly inflated under EW, and in the case of the EW-GMM4 estimator, it is more than three times larger than the (supposedly biased) OLS coefficient. These results are inconsistent with Conditions 1 and 2 above. These findings agree with the Monte Carlo simulations of Sect. 57.3.3, which also point to a very poor performance of the EW estimator in cases in which fixed effects and heteroscedasticity are present.

By comparison, the OLS-IV delivers results that are consistent with Conditions 1 and 2. In particular, the q coefficient increases from 0.025 to 0.063, while the cash flow coefficient drops from 0.131 to 0.043. These results suggest that the proposed OLS-IV estimator does a fairly reasonable job at addressing the measurement-error problem. This conclusion is consistent with the Monte Carlo simulations reported above, which show that the OLS-IV procedure is robust to the presence of fixed effects and heteroscedasticity in simulated data. The AB-GMM results also generally satisfy Conditions 1 and 2. Notice, however, that the observed changes in the q and *cash flow* coefficients ("corrections" relative to the simple, biased OLS estimator) are less significant than those obtained under the OLS-IV estimation.

57.4.6 Robustness of the Empirical OLS-IV Estimator

It is worth demonstrating that the OLS-IV we consider is robust to variations in the set of instruments that is used for identification. While the OLS-IV delivered results that are consistent with our priors, note that we examined a just-identified model, for which tests of instrument quality are not available. As we have discussed previously, OLS-IV estimators should be used with care in this setting, since the underlying structure of the error in the latent variable is unknown. In particular, the Monte Carlo simulations suggest that it is important to show that the results remain when we use longer lags to identify the model.

We present the results from our robustness checks in Table 57.10. We start by adding one more lag of q (i.e., q_{t-3}) to the instrumental set. The associated estimates are in the first column of Table 57.10. One can observe that the slope coefficient associated with q increases even more with the new instrument (up to 0.090), while that of the cash flow variable declines further (down to 0.038). One problem with this estimation, however, is the associated J-statistic. If we consider a 5 % hurdle rule, the J-statistic of 4.92 implies that, with this particular instrumental set, we reject the null hypothesis that the identification restrictions are met (p-value of 3 %). As we have discussed, this could be expected if, for example, the measurement-error process has an MA structure.

Table 57.10 OLS-IV coefficients, robustness tests

Variables	(1)	(2)	(3)	(4)	(5)	(6)	(7)
q	0.0901***	0.0652***	0.0394***	0.0559***	0.0906***	0.0660***	0.0718***
	(0.014)	(0.014)	(0.015)	(0.012)	(0.033)	(0.024)	(0.026)
Cash flow	0.0383***	0.0455***	0.0434***	0.0449***	0.0421***	0.0450***	0.0444***
	(0.007)	(0.011)	(0.011)	(0.010)	(0.008)	(0.012)	(0.012)
Observations	15,264	11,890	12,000	13,448	12,000	10,524	10,524
F-stat p-value (first step)	0.000	0.000	0.000	0.000	0.001	0.000	0.000
J-stat	4.918	3.119	0.122	0.00698	0.497	8.955	5.271
J-stat p-value	0.0266	0.210	0.727	0.933	0.481	0.111	0.261

This table shows the results of varying the set of instruments that are used when applying the OLS-IV estimator to Eq. 57.22. In the first column we use the second and third lags of q as instruments for current (differenced) q, as in Table 57.6. In column (2), we use third, fourth, and fifth lags of q as instruments. In column (3), we use the fourth and fifth lags of q and the first lag of cash flow as instruments. In column (4), we use the third lag of q and fourth lag of cash flow as instruments. In column (5), we use the fourth and fifth lags of cash flow as instruments. In column (6), we use $\{q_{t-4}, q_{t-5}, q_{t-6}, CF_{t-3}, CF_{t-4}, CF_{t-5}\}$ as instruments. Finally, in column (7) $\{q_{t-5},q_{t-6},CF_{t-3},CF_{t-4},CF_{t-5}\}$ as instruments. The estimations correct the errors for heteroscedasticity and firm-clustering. The data are taken from the annual Compustat industrial files over the 1970–2005 period. See text for details. *, **, and *** represent statistical significance at the 10 %, 5 %, and 1 % levels, respectively

This suggests that the researcher should look for longer lagging schemes, lags that "erase" the MA memory of the error structure.

Our next set of estimations use longer lagging structures for our proposed instruments and even an instrumental set with only lags of cash flow, the exogenous regressors in the model. We use combinations of longer lags of q (such as the fourth and fifth lags) and longer lags of cash flow (fourth and fifth lags). This set of tests yields estimates that more clearly meet standard tests for instrument validity.[28] Specifically, the J-statistics now indicate we do not reject the hypothesis that the exclusion restrictions are met. The results reported in columns (2) through (7) of Table 57.10 also remain consistent with Conditions 1 and 2. In particular, the q coefficient varies from approximately 0.040 to 0.091, while the cash flow coefficient varies roughly from 0.044 to 0.046. These results are consistent with our simulations, which suggest that these longer lag structures should deliver relatively consistent, stable estimates of the coefficients for q and cash flow in standard investment regressions.

57.5 Concluding Remarks

OLS estimators have been used as a reference in empirical work in financial economics. Despite their popularity, those estimators perform poorly when dealing with the problem of errors in variables. This is a serious problem since in most empirical applications, one might raise concerns about issues such as data quality and measurement errors.

This chapter uses Monte Carlo simulations and real data to assess the performance of different estimators that deal with measurement error, including EW's higher-order moment estimator and alternative instrumental variable-type approaches. We show that in the presence of individual fixed effects, under heteroscedasticity, or in the absence of high degree of skewness in the data, the EW estimator returns biased coefficients for both mismeasured and perfectly measured regressors. The IV estimator requires assumptions about the autocorrelation structure of the measurement error, which we characterize and discuss in the chapter.

We also estimate empirical investment models using the two methods. Because real-world investment data contain firm-fixed effects and heteroscedasticity, the EW estimator delivers coefficients that are unstable across different specifications and not economically meaningful. In contrast, a simple OLS-IV estimator yields results that conform to theoretical expectations. We conclude that real-world investment data is likely to satisfy the assumptions that are required for identification of OLS-IV but that the presence of heteroscedasticity and fixed effects causes the EW estimator to return biased coefficients.

[28] All of the F-statistics associated with the first-stage regressions have p-values that are close to zero. These statistics (reported in Table 57.10) suggest that we do not incur a weak instrument problem when we use longer lags in our instrumental set.

Table 57.11 EW coefficients for real data (within transformation)

q coefficient				Cash flow coefficient

This table shows the coefficients and standard deviations that we obtain when we use the EW estimator in Eq. 57.22, estimated year by year. The table also shows the results for the EW estimator associated with GMM3, GMM4, and GMM5. The table also shows the EW coefficients for the data that is treated for fixed effects via the within transformation. The data are taken from the annual Compustat industrial files over the 1970–2005 period. See text for details

58 Realized Distributions of Dynamic Conditional Correlation and Volatility Thresholds in the Crude Oil, Gold, and Dollar/Pound Currency Markets

Tung-Li Shih, Hai-Chin Yu, Der-Tzon Hsieh, and Chia-Ju Lee

Contents

Abstract

This chapter proposes a modeling framework for the study of co-movements in price changes among crude oil, gold, and dollar/pound currencies that are conditional on volatility regimes. Methodologically, we extend the dynamic

conditional correlation (DCC) multivariate GARCH model to examine the volatility and correlation dynamics depending on the variances of price returns involving a threshold structure. The results indicate that the periods of market turbulence are associated with an increase in co-movements in commodity (gold and oil) prices. By contrast, high market volatility is associated with a decrease in co-movements between gold and the dollar/pound or oil and the dollar/pound. The results imply that gold may act as a safe haven against major currencies when investors face market turmoil. By looking at different subperiods based on the estimated thresholds, we find that the investors' behavior changes in different subperiods. Our model presents a useful tool for market participants to engage in better portfolio allocation and risk management.

Keywords

Dynamic conditional correlation • Volatility threshold • Realized distribution • Currency market • Gold • Oil

58.1 Introduction

Commodity markets in recent years have experienced dramatic growth in trading volume as well as widespread price volatility. With few exceptions, most of the commodities have experienced an impressive bull run and have generally outperformed traditional investments. For example, the prices of commodities such as crude oil have risen dramatically, and the crude oil price almost reached a new high of US$200 per barrel in 2011. In the meantime, the price of gold hit a new high of US$1,700 in 2011. These price surprises have influenced not only the commodity markets but also the currency markets and the international parity of foreign exchange. By the fall of 2007, the increasing speculation in commodity markets was associated with the devaluation of the US dollar.

Among these commodities, gold appears to have exhibited a more stable price trend than crude oil. From the beginning of the financial crisis in 1997 up until 2011, the price of gold has risen by almost 42 %. For many years, gold has been viewed as a safe haven from market turbulence. However, very few empirical studies have examined the role of gold as a safe-haven asset and even fewer have examined gold's safe-haven role with respect to major currency exchange rates, especially those of the two major currencies – the US dollar and the British pound.

The reason why we choose exchange rates as a comparative baseline is that, for commodities that are traded continuously in organized markets, a change in a major currency exchange rate will result in an instant adjustment in the prices of commodities in at least one currency and perhaps in both currencies if both countries are "large." For instance, when the dollar depreciates against the pound, the dollar prices of commodities tend to rise (and pound prices fall) even though the fundamentals of the markets remain unchanged.

This widely expanded and complex volatility in commodity prices increases the importance of modeling real volatility and correlation, because a good estimate helps facilitate portfolio optimization, risk management, and hedging activities. Although some of the literature assumes volatility and correlation to be constant in the past years, it is widely recognized that they indeed vary over time. This recognition has spurred a vibrant body of work regarding the dynamic properties of market volatility. To date, very little is known about the volatility dynamics between the commodity and currency markets, for instance, in the case of gold and its possible correlations with oil and major currencies. This chapter intends to address this gap.

The main purpose of this study is to examine the dynamic relationships among gold, oil, and the dollar/pound to further understand the hedging ability of gold relative to another commodity or currency. That is to say, if gold acts as a financial safe haven against the dollar (or oil), it allows for systematic feedback between changes in the price of gold, oil, and the dollar/pound exchange rate. Specifically, this chapter asks, does gold act as a safe haven against the dollar/pound, as a hedge, or as neither? Are gold and oil highly correlated with each other? Movements in the price of gold, oil, and the dollar/pound are analyzed using a model of dynamic conditional correlation covering 20 years of daily data.

Studies related to this issue are few. Capie et al. (2005) point out that gold acts as an effective hedge against the US dollar by estimating elasticity relative to changes in the exchange rate. However, their approach involves the use of a single-equation model in which the exchange rate is assumed to be unaffected by the time of the dependent variable, the price of gold. Our chapter improves their work by employing a dynamic model of conditional correlations in which all variables are treated symmetrically. Besides, although Baur and Lucey (2010) find evidence in support of gold providing a haven from losses incurred in the bond and stock markets, they neglect the interactions with the currency market and, like Capie et al. (2005), do not consider feedback in their model of returns. Nikos (2006) uses correlation analysis to estimate the correlation of returns between gold and the dollar and shows that the correlation between the dollar and gold is −0.19 and −0.51 for two different periods. These findings imply that gold is a contemporaneous safe haven in extreme currency market conditions. Steinitz (2006) utilizes the same method to estimate the correlations of weekly returns between gold and Brent oil for two periods of 1 year and 5 years, respectively, and shows that the correlations between gold and Brent oil are 0.310 and 0.117, respectively. Boyer and Fillion (2007) report on the financial determination of Canadian oil and gas stock returns and conclude that a weakening of the Canadian dollar against the US dollar has a negative impact on stock returns.

If correlations and volatilities vary over time, the hedge ratio should be adjusted to account for the new information. Other work, such as Baur and McDermott (2010), similarly neglects feedback in its regression model. Further studies investigate the concept of a safe-haven asset without reference to gold. For example, Ranaldo and Soderlind (2009) and Kaul and Sapp (2006) examine safe-haven currencies, while Upper (2000) examines German government bonds as safe-haven instruments. Andersen et al. (2007) show that exchange rate volatility outstrips bond volatility in the US, British, and German markets. Thus, currency risk is worth exploring and being hedged.

As a general rule, commodities are priced in US dollars. Since the US currency has weakened that a bull run of commodity prices appeared, the question arises as to which the increases in commodity prices have been a product of the depreciation in the US dollar. Furthermore, it would be interesting to examine how to provide a hedge against the dollar that varies across different commodities. It also needs to be asked which investment instruments are more suitable for diversification purposes to protect against changes in the US currency.

This chapter investigates the following issues. First, how do the time-varying correlations and associated distributions appear in the crude oil, gold, and dollar/pound markets? Second, what is the shape of each separate distribution of various volatility levels among the crude oil, gold, and dollar/pound markets? Third, by employing the volatility threshold DCC model put forward by Kasch and Caporin (2012), is the high volatility (exceeding a specified threshold) of the assets associated with an increasing degree of correlation?

We find that the volatility thresholds of oil and gold correspond to two major events – *the First Gulf War in 1990 and the 911 event in 2001*. We also find that the increase in commodity (crude oil and gold) prices was a reflection of the falling US dollar, especially after the 911 event. The evidence shows that the DCC between crude oil and gold was 0.1168, while those for the gold/dollar/pound and oil/dollar/pound markets were −0.2826 and −0.0369, respectively, with the latter being significantly higher than in the other subperiods.

This remainder of this chapter is organized as follows. Section 58.2 provides a review of the literature. Section 58.3 describes the data and summary statistics for crude oil, gold, and the dollar/pound exchange rate. Section 58.4 presents the dynamic conditional correlation model and reports the results of its volatility threshold. And also provides the results for subperiods separated by the thresholds found. Finally, Sect. 58.5 discusses the results and concludes.

58.2 Literature Review

Engle et al. (1994) investigate how the returns and volatilities of stock indices between Tokyo and New York are correlated and find that, except for a lagged return spillover from New York to Tokyo after the crash, there was no significant lagged spillover in returns or in volatilities. Ng (2000) examines the size and the impact of volatility spillover from Japan and the USA to six Pacific Basin equity markets. Using four different specifications of correlation by constructing volatility spillover models, he distinguishes the volatility between local idiosyncratic shock, regional shock from Japan, and global shock from the USA and finds significant spillover effects from regional to Pacific Basin economies. Andersen et al. (2001a) find strong evidence that volatilities and correlations move together in a manner broadly consistent with the latent factor structure. Andersen et al. (2001b) found that volatility movements are highly correlated across the deutsche mark and yen against the US dollar. Furthermore, the correlation between the two exchange rates increases with volatility. Engle (2002) finds that the breakdown of the correlations between the deutsche mark and the pound and lira in August 1992 is very apparent. In addition, after the euro is launched, the estimated currency correlation essentially moves to 1.

Recently, Doong et al. (2005) examined the dynamic relationship and pricing between stocks and exchange rates for six Asian emerging markets. They found that the currency depreciation is accompanied by a fall in stock prices. The conditional variance-covariance process of changes in stock prices and exchange rates is time varying. Lanza et al. (2006) estimate the dynamic conditional correlations in the daily returns for West Texas Intermediate (WTI) oil forward and future prices from January 3, 1985 to January 16, 2004, and find that the dynamic conditional correlations vary dramatically. Chiang et al. (2009) investigate the probability distribution properties, autocorrelations, dynamic conditional correlations, and scaling analysis of Dow-Jones and NASDAQ Intraday returns from August 1, 1997 to December 31, 2003. They find the correlations to be positive and to mostly fluctuate in the range of 0.6–0.8. Furthermore, the variance of the correlation coefficients has been declining and appears to be stable during the post-2001 period. Pérez-Rodríguez (2006) applies a multivariate DCC-GARCH technique to examine the structure of the short-run dynamics of volatility returns on the euro, yen, and British pound against the US dollar over the period from 1999 to 2004 and finds strong dynamic relationships between currencies. Tastan (2006) applies multivariate GARCH to capture the time-varying variance-covariance matrix for stock market returns (Dow-Jones Industrial Average Index and S&P500 Index) and changes in exchange rates (euro/dollar exchange rates). He also plots news impact surfaces for variances, covariances, and correlation coefficients to sort out the effects of shocks. Chiang et al. (2007a) apply a dynamic conditional correlation model to nine Asian daily stock-return series from 1990 to 2003 and find evidence of a contagion effect and herding behavior. Chiang et al. (2007b) examine A-share and B-share market segmentation conditions by employing a dynamic multivariate GARCH model and show that stock returns in both A- and B-shares are positively correlated with the daily change in trading volume or abnormal volume.

58.3 Data

Our data consist of the daily prices of crude oil and gold, and the US dollar/British pound exchange rate, and are obtained from the *AREMOS* database over the period from January 1, 1986 to December 31, 2007 for a total of 5,165 observations. The West Texas Intermediate crude oil price is chosen to represent the oil spot market, and the price of 99.5 % fine gold, the London afternoon fixing,

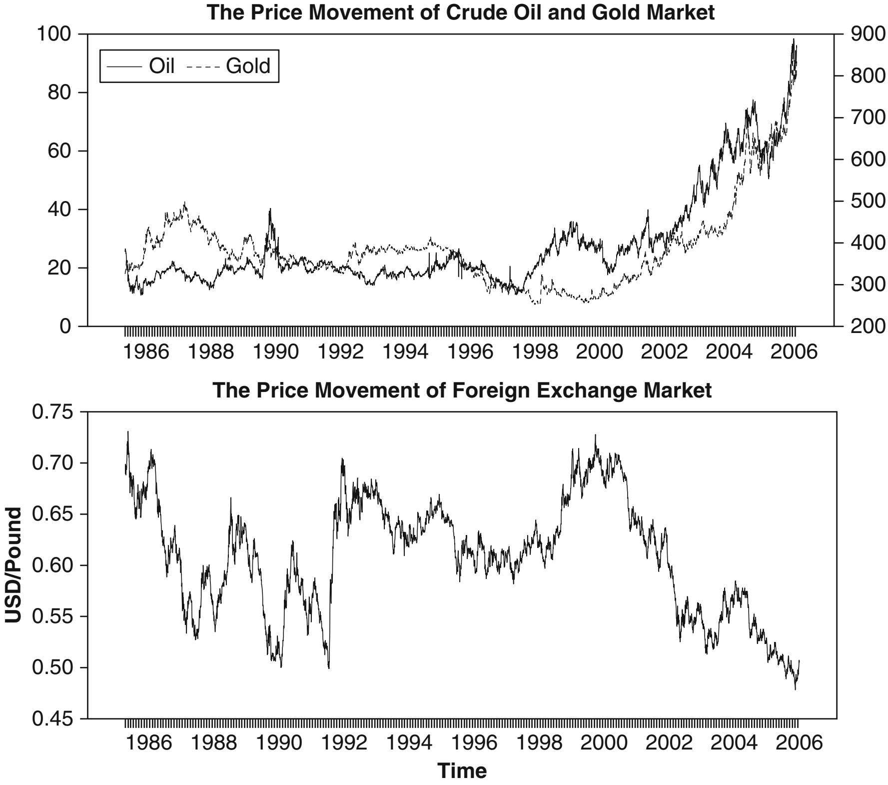

Fig. 58.1 The price movement for the sampled markets from January 1, 1986 to December 31, 2007, for a total of 5,405 observations

is chosen to represent the gold spot market. The daily dollar/pound exchange rate, which represents the major currencies, is selected to estimate the volatility of the FX market.

In our sample period, the crude oil price was testing the $100 per barrel threshold by November 2007. Meanwhile, the price of gold was relatively stable varying between $415 and $440 per ounce from January to September 2005. However, in the fourth quarter of 2005, the gold price jumped dramatically and hit $500 per ounce. In April 2006, the gold price broke through the $640 level. 2007 was a strong year, with the price steadily rising from $640 on January 2 with a closing London fixed price of over $836 on December 31, 2007. Since then, prices have continued to increase to reach new record highs of over $1,700 in 2011.

Figure 58.1 displays the price movements for oil, gold, and the dollar/pound over the sample period. As shown in Fig. 58.1, gold traded between a low of $252 (August 1999) and a high of $836 (December 31, 2007) per ounce at the fixing, while oil traded between a low of $10 (in late 1998, in the wake of the Asian

[a]The table summarizes the daily returns of estimates for the West Texas Intermediate crude oil, gold, and dollar/pound markets. The sample covers the period from January 1, 1986 through December 31, 2007 for a total of 5,405 observations
[b]The three markets are far away from the skewness and kurtosis of 0 and 3, respectively, implying that the three markets are not normally distributed
[c]Jarque-Bera is the Jarque-Bera test statistic, distributed χ^2_2
**Denotes significance at the 0.05 level

Financial Crisis and the United Nations' oil-for-food program) and a high of $99.3 (November 2007) per barrel. These large variations in the price of both gold and oil indicate that the DCC and realized distribution are better approaches for detecting the trading pattern of investors.

Table 58.1 reports the statistics of daily returns for crude oil, gold, and the dollar/pound exchange rate. The daily returns are calculated as the first differences of the natural log of the prices times 100. The results show that the crude oil has the highest return, followed by gold and the dollar/pound.

58.4 Dynamic Conditional Correlation

58.4.1 Dynamic Conditional Correlation Between Gold, Oil, and the Dollar/Pound

It is generally recognized that financial markets are highly integrated in terms of price movements, since prices soaring in one market can spill over to another market instantly. One simple method to explore the relationship between the two markets is to calculate the correlation coefficient. We then specify a multivariate model, which is capable of computing the dynamic conditional correlation (DCC) that is capable of capturing ongoing market elements and shocks. The DCC model is specified as Eq. 58.1.

Table 58.2 The correlation among crude oil, gold, and FX of dollar/pound (January 1, 1986 to December 31, 2007)

	Oil	Gold	FX
Oil	1		
Gold	0.7488	1	
FX	−0.5592	−0.6260	1

$$\rho_{ij,t} = \frac{E_{t-1}\left(r_{i,t} r_{j,t}\right)}{\sqrt{E_{t-1}\left(r_{i,t}^2\right) E_{t-1}\left(r_{j,t}^2\right)}} \tag{58.1}$$

where the conditional correlation $\rho_{ij,t}$ is based on information known in the previous period E_{t-1} and i, j represent the three markets 1, 2, and 3. Based on the laws of probability, all correlations defined in this way must lie within the interval [−1, 1]. This is different from the constant correlation we have usually used and assumed throughout a given period. To clarify the relationship between the conditional correlations and conditional variances, it is convenient to express the returns as the conditional standard deviation times the standardized disturbance as suggested by Engle (2002) in Eq. 58.2 below:

$$h_{i,t} = E_{t-1}\left(r_{i,t}^2\right), \quad r_{i,t} = \sqrt{h_{i,t}\varepsilon_{i,t}}, \qquad i = 1, 2, 3 \tag{58.2}$$

Since the correlation coefficients among crude oil, gold, and dollar/pound FX markets provide useful measures of the long-term relationship between each pair of markets, Table 58.2 presents a simple correlation matrix in which the calculation is based on the constant coefficient given by Eq. 58.1. Some preliminary information is obtained below. First, the crude oil and gold are highly correlated with a coefficient of 0.7488, a result that is in line with Steinitz (2006). Secondly, both gold and crude oil are highly negatively related to the dollar/pound with coefficients of −0.6260 and −0.5592, respectively, which is consistent with the report of Nikos (2006).

As the autoregressive conditional heteroskedasticity (ARCH) model has become the most useful model in investigating the conditional volatility since Engle (1982), we then follow this model in our analysis. The ARCH model adopts the effect of past residuals that helps explain the phenomenon of volatility clustering. Bollerslev (1986) proposed the generalized autoregressive conditional heteroskedasticity (GARCH) model, which has created a new field in the research on volatility and is widely used in financial and economic time series. Some of his research attempts to discuss the effects of more than one variable simultaneously. For instance, Bollerslev (1990) proposed the constant conditional correlation (CCC) model which makes a strong assumption, namely, that the correlation among the variables remains constant in order to simplify the estimation. Engle (2002) later proposed a dynamic conditional correlation (DCC) model, which allows the correlation to be time varying and, by involving fewer complicated calculations, is capable of dealing with numerous variables.

In this chapter, we follow the Engle (2002) approach, which has clear computational advantages over multivariate GARCH models in that the number of parameters to be estimated remains constant and loosens the assumptions of the multivariate conditional correlations, in order to develop the dynamic conditional correlation (DCC) model. The DCC model can be viewed as a generalization of the Bollerslev (1990) constant conditional correlation (CCC) estimator. It differs only in that it allows the correlation to be time varying, which parameterizes the conditional correlations directly. The estimation takes place in two steps, in that a series of univariate GARCH estimates are first obtained followed by the correlation coefficients. The characteristics of the DCC model are that the multivariate conditional correlations are dynamic and not constant and confirm that the real conditional correlations of financial assets in general and the time-varying covariance matrices can be estimated. This model involves a less complicated calculation without losing too much generality and is able to deal with numerous variables.

Following Engle (2002) and Chiang et al. (2009), the mean equation is assumed to be represented by Eq. 58.1, where the multivariate conditional variance is given by

$$H_{\tau,t} = D_{\tau,t} V_{\tau,t} D_{\tau,t}, \tag{58.3}$$

where τ is a time interval, which can be a day, an hour, or 1 min. Here τ is a daily interval. $V_{\tau,t}$ is a symmetric conditional correlation matrix of ε_t and $D_{\tau,t}$ is a (2×2) matrix with the conditional variances $h_{\tau,ii,t}$ for two stock returns (where i = gold, oil, or the dollar/pound exchange rate) on the diagonal. That is, $D_{\tau,t} = diag\left[\sqrt{\sigma^2_{\tau,ii,t}}\right]_{(2,2)}$. Equation 58.3 suggests that the dynamic properties of the covariance matrix $H_{\tau,t}$ are determined by $D_{\tau,t}$ and $V_{\tau,t}$ for a given τ, a time interval that can be 1 min, 1 day, or 1 week and so on. The DCC model proposed by Engle (2002) involves a two-stage estimation of the conditional covariance matrix H_t in Eq. 58.3. In the first stage, univariate volatility models are fitted for each of the returns, and estimates of $\sqrt{\sigma^2_{\tau,ii,t}}$ $(i = 1, 2, \text{ and } 3)$ are obtained by using Eq. 58.4. In the second stage, return residuals are transformed by their estimated standard deviations from the first stage. That is $\eta_{\tau,i,t} = \varepsilon_{\tau,i,t}/\sqrt{\sigma^2_{\tau,ii,t}}$, where $\eta_{\tau,i,t}$ is used to estimate the parameters of the conditional correlation. The evolution of the correlation in the DCC model is given by Eq. 58.5:

$$\sigma^2_{\tau,ii,t} = c_{\tau,i} + \alpha_{\tau,i}\varepsilon^2_{\tau,i,t-1} + \beta_{\tau,i}\sigma^2_{\tau,ii,t-1}, \quad i = 1, 2 \tag{58.4}$$

$$Q_{\tau,t} = \left(1 - \alpha_{\tau,i} - \beta_{\tau,i}\right)\overline{Q}_\tau + \alpha_{\tau,i}\, \eta_{\tau,i,t-1}\eta'_{\tau,i,t-1} + \beta_{\tau,i} Q_{\tau,t-1}, \tag{58.5}$$

where $Q_{\tau,t} = (q_{\tau,ij,t})$ is the 2 × 2 time-varying covariance matrix of $\eta_{\tau,i,t}, \overline{Q}_\tau = E\left[\eta_{\tau,i,t}\eta'_{\tau,i,t}\right]$ is the 2 × 2 unconditional variance matrix of $\eta_{\tau,i,t}$, and $a_{\tau,i}$ and $\beta_{\tau,i}$ are non-negative scalar parameters satisfying $(\alpha_{\tau,i} + \beta_{\tau,i}) < 1$. Since Q_t does not generally have ones on its diagonal, we scale it to obtain a proper correlation matrix $V_{\tau,t}$ Thus,

$$V_{\tau,t} = \left(diag\left(Q_{\tau,t}\right)\right)^{-1/2} Q_{\tau,t}\left(diag\left(Q_{\tau,t}\right)\right)^{-1/2}, \tag{58.6}$$

where $\left(diag\left(Q_{\tau,t}\right)\right)^{-1/2} = diag\left(1/\sqrt{q_{\tau,11,t}},\quad 1/\sqrt{q_{\tau,22,t}}\right)$.

Here $V_{\tau,t}$ in Eq. 58.6 is a correlation matrix with ones on the diagonal and off-diagonal elements of less than one in absolute value terms, as long as $Q_{\tau,t}$ is positive definite. A typical element of $V_{\tau,t}$ takes the form:

$$\rho_{\tau,12,t} = q_{\tau,12,t} / \sqrt{q_{\tau,11,t} q_{\tau,22,t}} \tag{58.7}$$

The dynamic correlation coefficient, $\rho_{\tau,12,t}$, can be obtained by using the element of $Q_{\tau,t}$ in Eq. 58.5, which is given by Eq. 58.8 below:

$$q_{\tau,ij,t} = \left(1 - a_{\tau,i} - b_{\tau,i}\right)\overline{\rho}_{\tau,ij} + a_{\tau,i}\, \eta_{\tau,i,t-1}\eta'_{\tau,j,t-1} + b_{\tau,i} q_{\tau,ij,t-1}, \tag{58.8}$$

The mean reversion requires that $(a_{\tau,i} + b_{\tau,i}) < 1$. In general terms, the essence of this concept is the assumption that both an asset's high and low prices are temporary and that the asset's price will tend to move toward the average price over time. Besides, the estimates of the dynamic correlation coefficients, $\rho_{ij,t}$, between each pair of the three markets have been specified as in Eq. 58.1.

58.4.2 Empirical Results of Dynamic Conditional Correlation

In this section, we present the estimation results of the models outlined above. The estimation results are presented in Table 58.1, which provides the dynamic correlations of returns across crude oil, gold, and the dollar/pound foreign exchange rate with each other. The estimated a and β for three markets are listed in Tables 58.3 and 58.4. The likelihood ratio does not support the rejection of the null hypothesis of the scalar dynamic conditional correlation. It can be seen that the sum of the estimated coefficients in the variance equations $(\alpha + \beta)$ is close to 1 for all of the cases, implying that the volatility appears to be highly persistent. As for the Ljung-Box Q-statistic of the serial correlation of the residuals, the results show that that the serial correlations in the error series are regarded as adequate.

Calvert et al. (2006) observed that through the dynamic conditional correlation distribution, we can more fully understand the real impacts in international markets.

**Denotes significance at the 0.05 level

It can also help with portfolio selection and risk management. In Fig. 58.2, which reports the results of the dynamic conditional correlation, the estimated correlation coefficients are time varying, reflecting some sort of portfolio shift between each two items.

The correlation between crude oil and gold was estimated using the DCC integrated method, and the results, shown in Fig. 58.2a, are quite interesting. The correlations are found to be generally positive around 0.2 except for mid-1990 which turns out to be highly correlated with a correlation of around 0.6605. The possible interpretation for the high correlation is due to the Iraqi invasion of Kuwait and the Gulf War. The crude oil price jumped from about $15 to over $33 per barrel during that time, so that investors channeled their money into the gold market because of their fear of inflation. This fact accords with the “flight to quality” concept, which represents the action of investors moving their capital away from riskier or more volatile assets to the ones considered to be safer and less volatile. The correlation between gold and the dollar/pound exchange rate is shown in Fig. 58.2b for the integrated DCC in the last 20 years. Whereas for most of the period the correlations were between −0.1 and −0.3, there were two notable drops, where the stock market crashed in October 1987 and in late 2002, and we also find two peaks, one in the middle of 1990 and the other in late 1998 where the gold price dropped to $252 per ounce. Fig. 58.2c shows the correlation between crude oil and

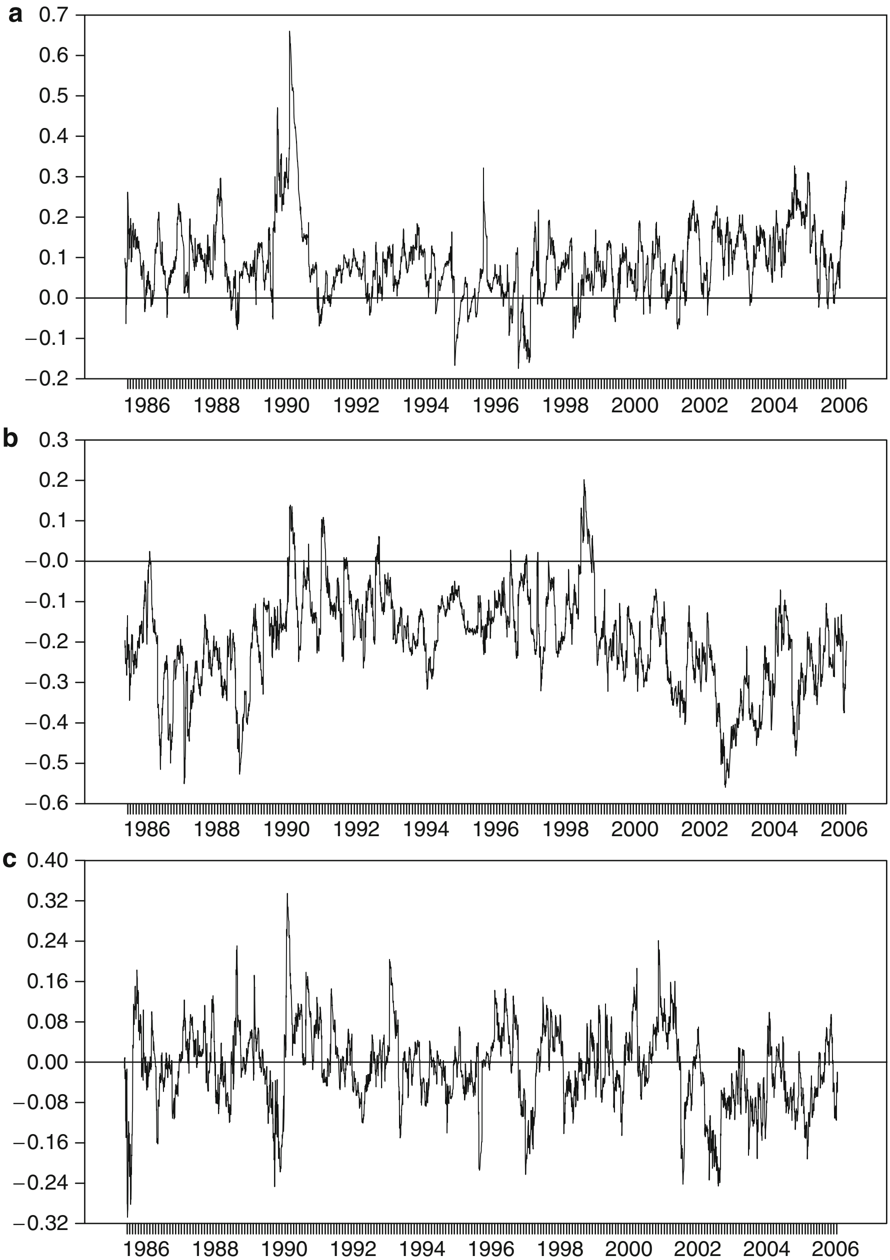

Fig. 58.2 The time series of dynamic conditional correlations (DCC) among each pair of three markets: (**a**) daily DCC between crude oil and gold, (**b**) daily DCC between gold and dollar/pound, and (**c**) daily DCC between crude oil and dollar/pound

the dollar/pound that was estimated using the DCC integrated method. Except in the mid-1990s when they are highly correlated with a coefficient of 0.32, the correlation between crude oil and the dollar/pound is generally negative (with a coefficient of −0.08 at the beginning of 1986 and a coefficient of −0.16 at the beginning of 2003, respectively).

Key issues relevant in financial economic applications include, for example, whether and how volatility and correlation move together. It is widely recognized among both finance academics and practitioners that they vary importantly over time (Andersen et al. 2001a, b; Engle 2002; Kasch and Caporin 2012). Such questions are difficult to answer using conventional volatility models, and so we wish to use the dynamic conditional correlation model to explain the phenomenon. From Fig. 58.3, the bivariate scatter plots of volatilities and correlations, it is hard to tell if there is a strong positive association between each of the two markets sampled. The correlation between two financial assets will affect the diversification of the portfolio. If two financial assets are highly negatively correlated, the effect of diversification will be significant, meaning that the portfolio can balance the returns. This is the so-called idea of not putting all one's eggs in the same basket.

According to the empirical data, the dynamic conditional correlation for the overall gold and dollar/pound (at −0.1986) or the overall oil and dollar/pound (at −0.0116) can moderately diversify investment risks and can thereby increase the rate of return. Investors can add commodities and their related derivatives to portfolios, in an effort to diversify away from traditional investments and assets. These results are in line with Capie et al. (2005) who found a negative relationship between the gold price and the sterling/dollar and yen/dollar foreign exchange rates and Nikos (2006) who found that the correlation between the dollar and gold is significantly negative. The conclusion we can draw from the results is that gold is by far the most relevant commodity in hedging against the US dollar. Capie et al. (2005) observed that gold has served as a hedge against fluctuations in the foreign exchange value of the dollar. Secondly, gold has become particularly relevant during times of US dollar weakness. In addition to that, the dynamic conditional correlation for the overall crude oil and gold markets is 0.0889, and a similar correlation was documented for the Brent crude oil and gold markets by Steinitz (2006).

To characterize the distributions of dynamic conditional correlation among the sampled markets, the summary statistics of the probability distributions for DCC are shown in Table 58.5, and the associated distributions of DCC for the sampled markets are shown in Fig. 58.4. We can find that the average DCC between the crude oil and gold markets is 0.0889 with a standard deviation of 0.0916. The distribution of the daily DCC between the crude oil and gold markets reflects a slightly right-skewed (at 1.2021) and leptokurtic distribution (at 4.6799), implying that a positive DCC occurs more often than a negative DCC between the crude oil and gold markets. Furthermore, the average DCC between the gold and

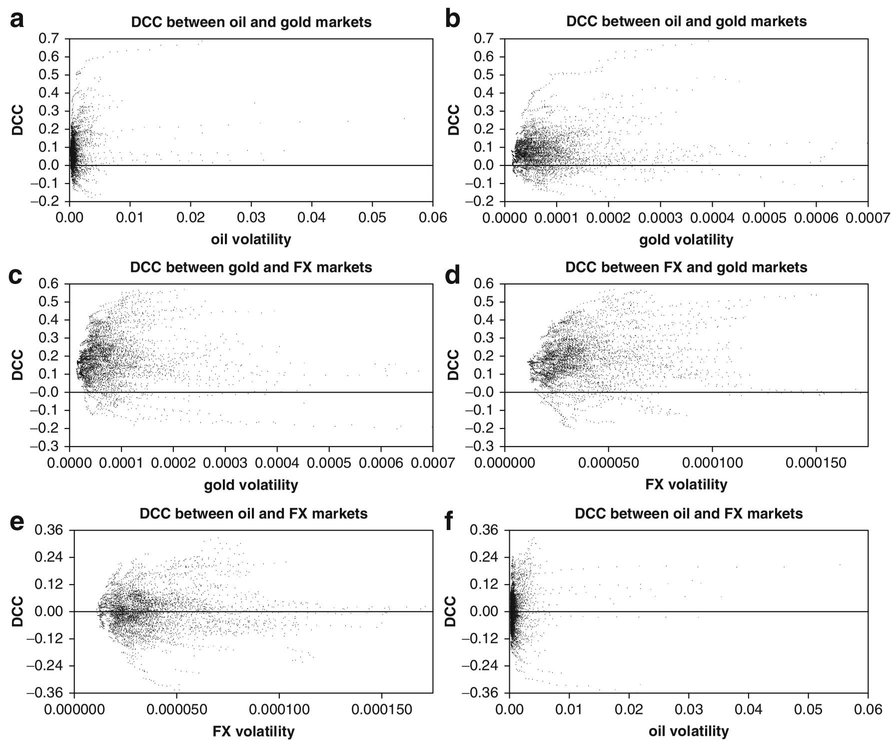

Fig. 58.3 Bivariate scatter plots of volatilities and correlations. The scatter plots of the daily DCC between (**a**) crude oil and gold and (**b**) crude oil and dollar/pound against the crude oil volatility; the daily DCC between (**c**) gold and crude oil and (**d**) gold and dollar/pound against the gold volatility; and the daily DCC between (**e**) dollar/pound and crude oil and (**f**) dollar/pound and gold against the dollar/pound volatility have been shown

Table 58.5 Summary statistics of probability distributions of DCC for each pair of oil, gold, and FX

	Mean	Standard dev.	Max	Min	Skewness	Kurtosis
DCC between oil and gold	0.1168	0.0758	0.3270	−0.0772	−0.0521	−0.4706
DCC between gold and FX	−0.2826	0.1003	−0.0688	−0.5596	−0.2534	−0.4195
DCC between FX and oil	−0.0369	0.0832	0.2413	−0.2459	0.1549	−0.0225

dollar/pound markets is −0.1986 with a standard deviation of 0.1197. The distribution of the daily DCC between the gold and dollar/British pound markets reflects a slightly left-skewed (at −0.1529) and platykurtic distribution (at 0.3304), implying that a negative DCC occurs more often than a positive DCC between gold and the dollar/pound. Moreover, the average DCC between the dollar/pound and crude oil is −0.0116 with a standard deviation of 0.0799. The distribution of daily DCCs between the dollar/pound and crude oil markets reflects a slightly left-skewed (at −0.0201) and platykurtic distribution (at 0.8678), implying that negative DCCs occur more often than positive DCCs between the dollar/pound and crude oil markets.

According to the empirical results, we rank the sequence of the volatility in order to analyze the volatility effect in the correlation. We show the panel of volatility and dynamic conditional correlation in Tables 58.6, 58.7, and 58.8. We can clearly realize from the sample mean, from the daily DCC between the crude oil and gold markets, that higher volatility can accompany the larger DCC. However, the higher volatility can also accompany the smaller DCC between the gold and dollar/pound markets and the crude oil and dollar/pound markets. This is because the correlations between these markets are negative.

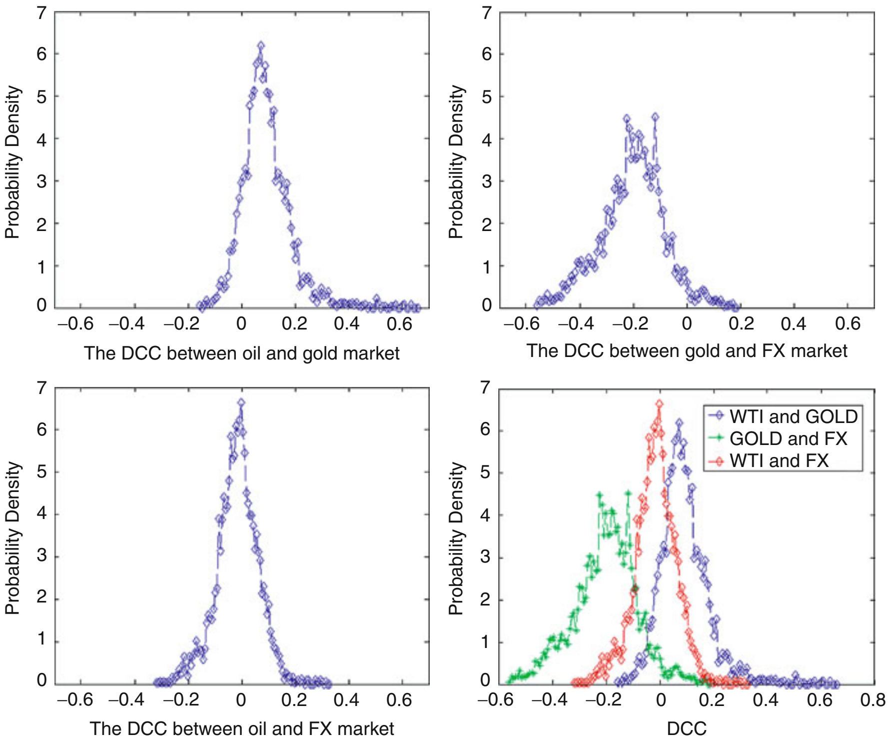

Fig. 58.4 The distributions of dynamic conditional correlations among gold, oil, and FX from 1986 to 2007

To further quantify this volatility effect in correlation, we classify the volatility into two categories, low volatility days and high volatility days,[1] and according to the results, we rank the sequence of the volatility. The group of low volatility days means that the volatility is less than the 10th percentile value and the group of high volatility days means that the volatility is greater than the 90th percentile value. The results are shown in Fig. 58.5a–c that reports the DCC distributions for low volatility days and high volatility days.

It is found that some special characteristics of DCC exist among the oil, gold, and FX markets. First, distributions for low volatility days are obviously different from those for high volatility days. Those for low volatility days approximate leptokurtic distributions, whereas those for high volatility days approximate

[1]Following Andersen et al. (2001b), the authors classify the days into two groups: low volatility days and high volatility days. The empirical results show that the distribution of correlations shifts rightward when volatility increases.

platykurtic distributions. Secondly, the average DCCs of the high volatility days are greater than the average DCCs of the low volatility days for the DCCs between crude oil and gold, implying that the correlation between gold and oil increases with volatility. Furthermore, the distribution of DCCs shifts rightward when volatility increases. Similar results are found for equity returns as reported by Sonlinik et al. (1996) and in realized exchange rate returns by Andersen et al. (2001b). Thirdly, the average DCCs for the high volatility days are smaller than the average DCCs for lower volatility days across gold and the dollar/pound, and oil and the dollar/pound. This implies that the correlation between gold (oil) and foreign exchange rates decreases with volatility, and the distribution of DCCs shifts leftward when volatility increases. Finally, the standard deviations of the distributions for high volatility days are obviously greater than the standard deviations of the distributions for low volatility days.

58.4.3 Volatility Threshold Dynamic Conditional Correlation

To further check if different subperiods have various patterns, we utilize the volatility threshold model addressed by Kasch and Caporin (2012)[2] to examine whether increasing volatility (exceeding a specified threshold) is associated with an increasing correlation. The volatility threshold DCC model is specified as Eq. 58.9:

$$q_{ij,t} = \left(1 - \alpha^2 - \beta^2\right)\overline{q_{ij}} - \gamma_i\gamma_j\overline{v_{ij}} + \alpha^2\varepsilon_{i,t-1}\varepsilon_{j,t-1} + \beta^2 q_{ij,t-1} + \gamma_i\gamma_j v_{ij,t} \tag{58.9}$$

[2]Kasch and Caporin (2012) extended the multivariate GARCH dynamic conditional correlation of Engle to analyze the relationship between the volatilities and correlations. The empirical results indicated that high volatility levels significantly affect the correlations of the developed markets, while high volatility does not seem to have a direct impact on the correlations of the transition blue chip indices with the rest of the markets. It is easy to see that the volatility and correlation move together.

where v_t is a dummy variables matrix defined as

$$v_{ij,t} = \begin{cases} 1 \ \text{if} \ \ h_{i,t} > fh_i(k) \ \ \text{or} \ \ h_{j,t} > fh_j(k) \\ 0 \ \text{otherwise} \end{cases} \tag{58.10}$$

where $fh_i(k)$ is the kth fractional of the volatility series $h_{i,t}$.

When thresholds are found, the whole period will be divided into various sub-periods based on these thresholds. This separation helps detect any changes in investor behavior after crucial events. It is then known whether a time horizon is a key factor influencing the patterns of return and volatility.

Table 58.9 presents the estimation results of the volatility threshold DCC models. The estimation was based on various volatility threshold levels at 50 %, 75 %, 90 %, and 95 %. The results in Table 58.9 show that the correlation between the oil and gold prices is significantly affected by the volatility of oil at the 50 %, 75 %, and 90 %

(with the exception of 95 %) thresholds. Interestingly, these estimated thresholds were quite consistent with the real events of *the First Gulf War in 1990 and the 911 attack in 2001*. We then separate the period into three subperiods to further examine whether the investors' behaviors change after the events.

[a]This table presents the quasi-maximum likelihood estimates of volatility threshold of dynamic conditional correlation. The t-statistics are given in parentheses

58.4.4 Does Investors' Behavior Change over Subperiods?

The three subperiods based on our estimated thresholds are before the first Gulf War (January 1, 1986 to July 31, 1990), after the first Gulf War up to the 911 attack (August 1, 1990 to August 31, 2001), and after the 911 attack (September 1, 2001 to December 1, 2007). We then examine the dynamic co-movement in each pair of markets in various subperiods (Rigobon and Sack 2005; Guidi et al. 2007[3]).

Our sampled period covers economic hardship and soaring energy prices. Soaring energy prices make gold an attractive hedging asset against inflation in that a positive correlation with oil is expected over time, especially after the 911 event. The evidence in Table 58.10 shows that oil and gold are highly

[3]Guidi et al. (2007) examined the impact of relevant US decisions on oil spot price movements from January 1986 to December 2005. They identified the following conflict periods: the Iran-Iraq conflict, January 1985 until July 1988; Iraq's invasion of Kuwait, August 1990 until February 1991; and the US-led forces' invasion of Iraq, March 2003 until December 2005.

Table 58.10 Simple correlation matrix of oil, gold, and dollar/pound markets among the three subperiods

	Oil	Gold	FX
Panel A The correlation coefficients between crude oil, gold, and dollar/pound markets from January 1, 1986 through July 31, 1990			
	Oil	Gold	FX
Oil	1		
Gold	0.1648	1	
FX	−0.1517	−0.5228	1
Panel B The correlation coefficients between crude oil, gold, and dollar/pound markets from August 1, 1990 through August 31, 2001			
	Oil	Gold	FX
Oil	1		
Gold	−0.2465	1	
FX	0.0628	−0.2096	1
Panel C The correlation coefficients between crude oil, gold, and dollar/pound markets from September 1, 2001 through December 31, 2007			
	Oil	Gold	FX
Oil	1		
Gold	0.9264	1	
FX	−0.8124	−0.8142	1

correlated with a high coefficient of 0.9264 between September 1, 2001 and December 31, 2007 (after the 911 event). In the meantime, the correlation between gold and the dollar/pound is −0.8142, and between oil and the dollar/pound is −0.8124, showing the fears of a depreciation in the US dollar push commodity prices up significantly.

The results of Panels B, C, and D in Table 58.5 along with Figs. 58.6 and 58.7 show that the DCCs between oil and gold are all positive in the three subperiods (with coefficients of 0.0910, 0.0720, and 0.1168, respectively). Obviously, higher oil prices spark inflationary concerns and make gold a value reserve for wealth. By contrast, the correlation between oil and the dollar/pound has been negative, and a DCC of −0.0369 is shown after the 911 attack. In this period, the oil price increased from a low of US$19 per barrel in late January 2002 to US$96 per barrel in late December 2007. Meanwhile, the dollar conversely tumbled 29 % from US$0.7 to a US$0.5 per pound.

Historical data also show that the prices of oil and gold are rising over time. The increase in the prices of gold was a reflection of the falling US dollar. The evidence confirms that the DCCs between gold and the dollar/pound in the three subperiods are all negative (with average DCC of −0.2567, −0.1258, and −0.2826 in the first, second, and third periods, respectively). Generally speaking, during the subperiods of market crises, increasingly high correlations in commodity prices were observed, with oil and gold moving in the same direction and the dollar/pound moving in opposite directions.

58.5 Conclusions and Implications

Using the dynamic conditional correlation model, we have estimated the cross correlation and volatility among crude oil, gold, and dollar/pound currencies from 1986 to 2007. After exploring the time-varying correlations and realized distributions, several regularities have been found that help illustrate the characteristics of the crude oil, gold, and currency markets.

First, the correlation coefficients between each pair of the three assets are found to be time varying instead of constant. As such, besides considering the mean and standard deviation of the underlying assets, investors need to follow the co-movement in the relevant assets in order to make better portfolio hedging and risk management decisions across these assets. The results of the dynamic correlation coefficients between the gold and dollar/pound show that gold is by far the most relevant commodity in terms of serving as a hedge against the US dollar. These results are in line with the reports suggested by Nikos (2006) and Capie et al. (2005). Our findings are helpful in terms of arriving at a more optimal allocation of assets based on their multivariate returns and associated risks.

Besides, the distributions of low volatility days are found to approximate leptokurtic distributions in the gold, oil, and dollar/pound markets, whereas the high volatility days approximate platykurtic distributions. Furthermore, the DCC between oil and gold is increasing with volatility, indicating that the distribution of DCC shifts rightward when volatility increases. By contrast, the DCCs between gold and the dollar/pound and crude oil and the dollar/pound are decreasing with the volatility. Our findings in terms of oil and gold are consistent with the reports of Sonlinik et al. (1996) and Andersen et al. (2001b) who use different approaches.

Moreover, by estimating the volatility threshold dynamic conditional correlation model addressed by Kasch and Caporin (2012), we find that high volatility values (exceeding some specified thresholds) are associated with an increase in correlation values in various subperiods. Remarkably, investors' behaviors are seen to have changed in different subperiods. During periods of market turmoil, such as the First Gulf War in 1990 and the 911 terror attack in 2001, an increase in correlation between the prices of oil and gold, as well as a decrease in correlation between the oil (gold) and dollar/pound currencies, is observed. These behaviors make gold an attractive asset against major currencies for value-preserving purposes. For market participants from long-term hedging perspective, our results provide useful information on asset allocation across commodity and currency markets during market turmoil.

Abstract

We estimate two SVECM (structural vector error correction) models for the Turkish economy based on imposing short-run and long-run restrictions that account for examining the behavior of the real sphere in the pre-IT policy (before inflation-targeting adoption) and post-IT policy (after inflation-targeting adoption).

Responses reveal that an expansionary interest policy shock leads to a decrease in price level, a fall in output, an appreciation in the exchange rate, and an improvement in the share prices in the very short run for the most of pre-IT period.

Central Bank of the Republic of Turkey (CBT) stabilizes output fluctuations in the short run while maintaining a very medium-run inflation target since January 2006. One of the most important results of this study is that the impact of a monetary policy shock on the real sphere is insignificant during the post-IT policy.

Keywords

SVECM models • Turkish economy • Pre-IT policy • Post-IT policy • Real sphere

59.1 Introduction

The effectiveness of inflation targeting on the real sphere has recently been the subject of a vast and ever-growing literature. Being well defined in theory, we can say that there is a lack especially in the identification of the repercussion of inflation-targeting framework on macroeconomic variables. This is one of the most interesting subjects that merit to be watched nowadays. This chapter will be a new contribution to the empirical literature.

We are going to present the eligible method that allows us to discover the relation between the inflation targeting and the real sphere in Turkey.

Due to the successful experience in some neighboring countries with the adopting of inflation-targeting regime, the Turkish economy was encouraged to adopt such a monetary policy to overcome one of the deepest crises of Turkish economy in 2001 especially when the Central Bank of the Republic of Turkey was obliged to observe floating its currency.

In this study, we analyze the following research questions: “How can the real sphere react to a pre-inflation-targeting regime?” “Does inflation targeting enhance output growth?” “Are we going to find similar results regarding the effectiveness of pre-IT policy and IT policy?”

To deal with our objective, we investigate a structural vector error correction model (SVECM) analysis with long-run and short-run restrictions for IT policy and pre-IT policy to extract conclusions through examining the responses of macroeconomic data, respectively, to a monetary policy shock. Monetary transmission mechanisms based on a structural vector error correction model were studied by King et al. (1991), Ehrmann (1998), Lütkepohl et al. (1998), Ramaswamy and Sloek (1998), Cecchetti (1995), Debondt (2000), Clements et al. (2001), Kakes and Sturm (2002), Nadenichek (2006), Hachicha and Chaabane (2007), Ivrendi and Guloglu (2010), Lucke (2010), and Bhuiyan (2012).

The structure of this chapter is as follows: Sect. 59.2 provides the empirical methodology and outlines the SVECM technique. Section 59.3 defines the data. Section 59.4 presents long-run and short-run matrices estimation of the SVECM technique before and after IT adoption. Section 59.5 highlights a comparative analysis for the empirical results studying the impact of an interest rate shock on the output, inflation rate, share prices, and exchange rates in the pre-IT and post-IT policy. Section 59.6 makes some concluding remarks.

59.2 Empirical Methodology

Searching for an answer to my problematic, we resort to a structural vector error correction model (SVECM) technique with contemporaneous and long-run restrictions developed by Breitung et al. (2004). The main advantage of adopting a structural vector error correction model instead of a structural vector autoregressive model is that it gives us the opportunity to use cointegration restrictions which implement constraints on the long-run effects of the permanent shocks (Lutkepohl 2005). In what follows, we explore the SVEC model and forecasting technique.

59.2.1 SVEC Model and Forecasting Technique

$$\Delta y_t = \alpha\beta^{*\prime}\begin{pmatrix} y_{t-1} \\ D^{\infty}_{t-1} \end{pmatrix} + \Gamma_1\Delta y_{t-1} + \ldots + \Gamma_p\Delta y_{t-p} + CD_t + u_t \tag{59.1}$$

where $y_t = (y_{1t}, \ldots y_{kt})\,'$ is a vector of K endogenous variables, D^{∞}_{t-1} contains all deterministic terms included in the cointegration relations, and D_t contains all remaining deterministic variables (constant, seasonal dummy). The residual vector u_t is assumed to be a K-dimensional process and unobservable zero means white noise process with positive definite covariance matrix $E(u\,u\,') = \Sigma_u$.

The parameter matrices α and β have dimensions (K × r) and they have to have rank r. They specify the long-run part of the model with β containing the cointegrating relations and α representing the loading coefficients. The column dimension of η is also r and its row dimension corresponds to the dimension of D^{∞}_{t-1}. The notation $\beta^* = \begin{pmatrix} \beta \\ \eta \end{pmatrix}$ will be used in the following and the row dimension of β^* will be denoted by K^*. Hence, β^* is a (K × r) matrix. The cointegrating rank has to be in the range $1 \leq r \leq k - 1$.

SVEC (structural vector correction) is a model that can identify the shocks to be traced in an impulse response analysis by imposing restrictions on the matrix of long-run effects of shocks and the matrix B of contemporaneous effects of the shocks.

59.2.2 Matrix B Definition

According to the theorem of Johansen (1995), the VEC model has the following moving average representation:

$$y_t = \Xi \sum_{i=1}^{t} u_i + \Xi^*(L)u_t + y_0^* \tag{59.2}$$

where $y_t = (y_{1t}, \ldots y_{kt})'$ is a vector of K observable series and y_0^* contains the initial values. The long-run effects of shocks are represented by the first term in Eq. 59.2, $\Xi \sum_{i=1}^{t} u_i$, which captures the common stochastic trends from time (1) till time (t). The matrix B is defined such that $u_t = B\varepsilon_t$, and assuming that it is in reduced form, the matrix of long-run effects of the u_t residuals is

$$\Xi = \beta\perp \left(\alpha\perp' \left(I_k - \sum_{i=1}^{p-1} \Gamma_i \right) \beta\perp \right)^{-1} \alpha'\perp \tag{59.3}$$

Hence the long-run effects of ε shocks are given by ΞB. $rk(\Xi) = K - r$ and it follows that ΞB has rank $K - r$. Thus the matrix ΞB can have at most r columns of zero.

On that account, there can be at most r shock with transitory effect andis at least $(k - r)$ shocks have permanent effects. Due to the reduced rank of the matrix, each column of zeros stands for only $(k - r)$ independent restrictions. $(K - r)(K - r - 1)/2$ additional restrictions are needed to exactly identify the permanent shocks and $r(r - 1)/2$ additional contemporaneous restrictions identify the transitory shocks.

59.2.3 The Confidence Interval

The impulse responses are computed from the estimated VAR coefficients, and the Hall percentile interval is chosen to build confidence intervals (CI) that reflect the estimation's unpredictability:

$$CI = \left[\phi_1 - t^*_{(1-\gamma/2)}, \phi_2 - t^*_{(\gamma/2)} \right] \tag{59.4}$$

According to Hall (1992), $t^*_{\gamma/2}$ and t^* $(1 - \gamma/2)$ are the $\gamma/2$ and the $(1 - \gamma/2)$ quantiles of the distribution of $CI = \langle \phi_1 - \phi_2 \rangle$, respectively.

59.2.4 Forecasting with SVEC Processes

According to Pfaff (2008), forecasting is based on h-step at time T:

$$y_{T+h/T} = A_1 y_{T+h-1/T} + \ldots + A_p y_{T+h-p/T} + B_0 x_{T+h} + \ldots + B_q x_{T+h-q} + CD_{T+h} \tag{59.5}$$

The forecasts are computed recursively for h $\geq$ 1 of an empirical VECM (p) process according to

$$y_{T+h/T} = A_1 y_T + \ldots + A_p y_{T+h-p} + B_0 x_{T+h} + \ldots + B_q x_{T+1-q} + CD_{T+h} \tag{59.6}$$

The forecasting errors are

$$y_{T+h} - y_{T+h/T} = u_{T+h} + \Phi_1 u_{T+h-1} + \ldots + \phi_{h-1} u_{T+1}, \tag{59.7}$$

With $\Phi_0 = I_k$ and Φ_s can be computed recursively according to

$$\Phi_s = \sum_{i=1}^{s} \Phi_{s-j} A_j, \quad s = 1, 2 \ldots \tag{59.8}$$

According to Lütkepohl (1991), $\Phi_0 = I_k$ and $A_j = 0$ for $j \rangle p$. Appendix 1 explores

the forecast error covariance matrix, presents forecasting series estimations (Tables 59.1 and 59.2), and plots figures (Figs. 59.1 and 59.2).

59.3 Data Definition

The dataset consists of monthly observations from January 2000 up to November 2011 divided into two periods, i.e., the inflation-targeting framework was adopted in Turkey in January 2006. The first period named "**Pre-IT**" treats the case before the adoption of inflation-targeting policy and starts from 2000 M1.

The second period called "**Post-IT**" takes into consideration the adoption of inflation-targeting policy and starts from 2006 M1. This division highlights the importance of the topic treated in our paper and does not affect our estimation results. We choose deliberately monthly frequency to maximize the number of observations to get a robust estimation of each period.

The empirical models are estimated separately for each period. The interest rate (R) is measured by the log of money market rate (MMR); the price level (P) is measured by the log of consumer prices (2005=100); the real output (Y) is measured by the log of industrial production index (2005=100);

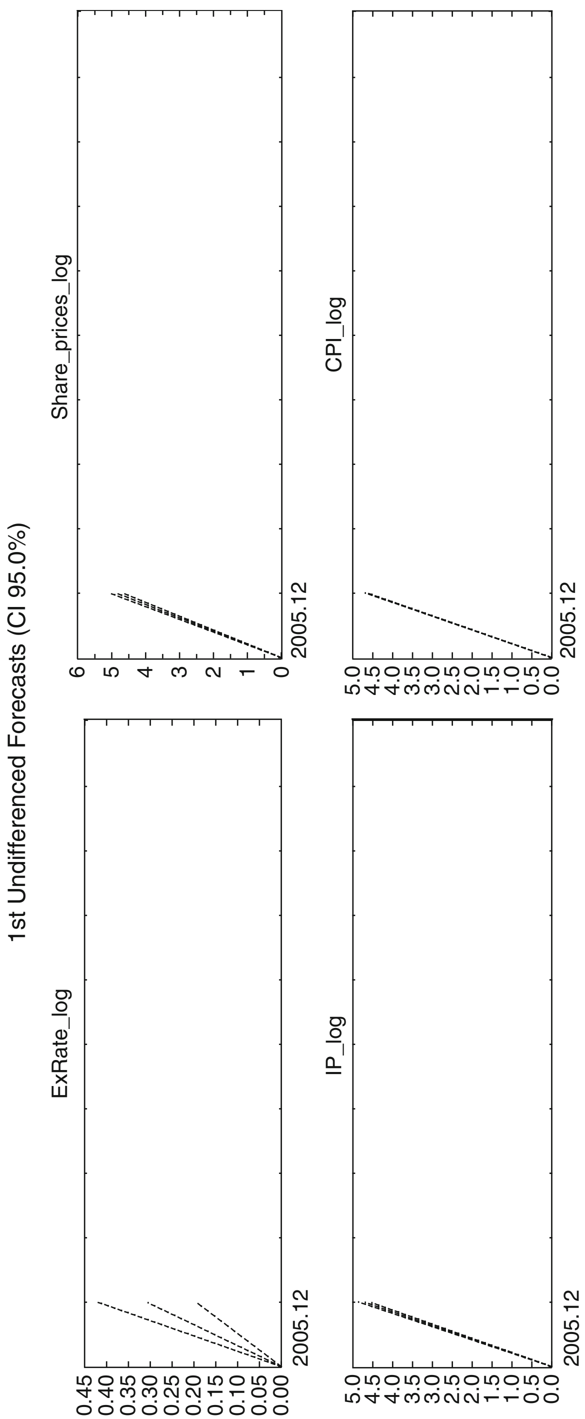

Fig. 59.1 Time series forecasts (2000 M1–2005 M12)

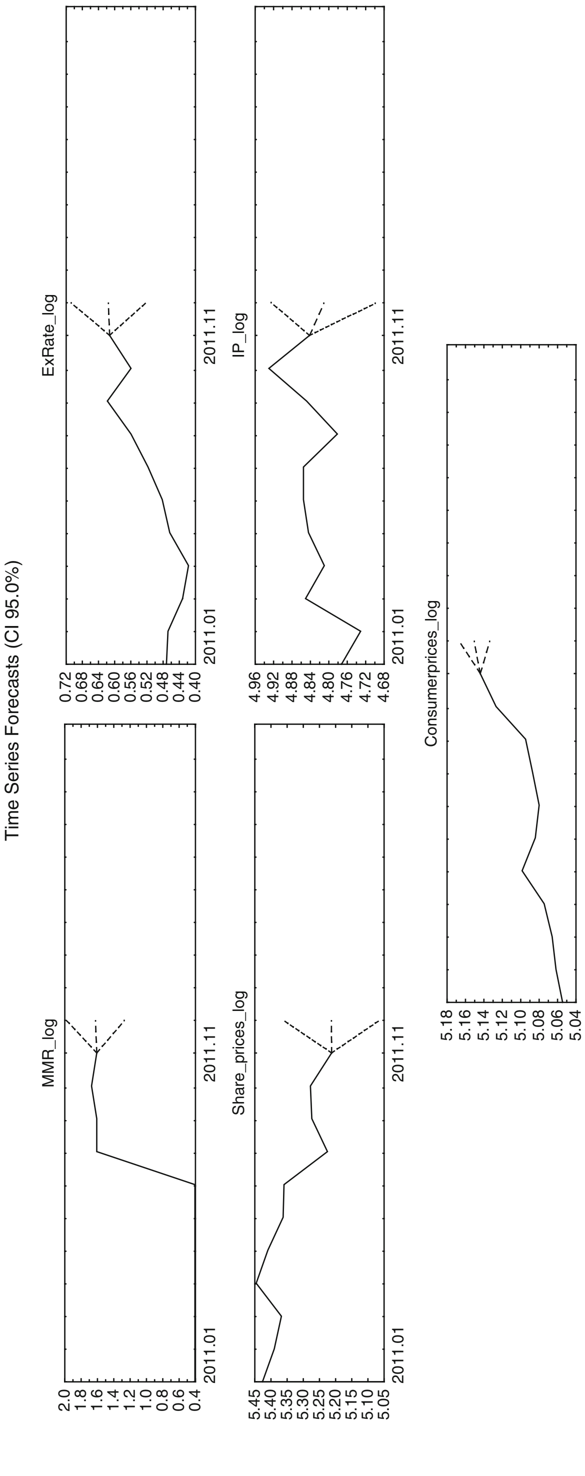

Fig. 59.2 Time series forecasts (2006 M1–2011 M11)

the real exchange rate (REXR) is measured by the log of (EXR). Due to lack of adequate data for the Tobin's Q, the share prices index (share prices) is taken as a proxy for wealth channel, and it is measured by the log of share prices.

The main source of data is IMF's International Financial Statistics and the Central Bank of the Republic of Turkey.

59.4 Empirical Analysis

We start our empirical analysis by investigating the univariate time series properties of the variables. Secondly, we use the AIC information criteria to determine the lag length of the VECM process. It suggests a lag length of $P = 11$ when maximum lag length is $pmax = 11$. This lag length is also confirmed with the same information criteria for $p = 12$ (Lütkepohl 1991). Then, we test the number of cointegration relation for each system before and after IT adoption, separately. We use Johansen's (1988, 1995) approach to test for the existence of a cointegrating relationship among the variables.

The maximum eigenvalue (λmax) and the trace tests for each model suggest one or two cointegration relations among five variables. In Appendix 2, we show results of Johansen cointegration test for the two systems. Specifically in Tables 59.3 and 59.4, we report cointegration results of the estimated parameters for the whole SVECM systems.

The structural shocks being identified, the VECM model is transformed into a VMA model (moving average) which makes it possible to compute the dynamics of the various endogenous variables following a structural shock due to

the Johansen procedure which supposes the ignorance of restrictions on beta. Then, we introduce restrictions in matrices of the long and short run. In addition, we know from the common trends literature that in a five-dimensional system with two cointegration relations determined previously, only three shocks can have permanent effect. We impose over identifying restrictions on the cointegrating vectors using the ML method proposed by Johansen (1995).

The identified cointegration relations can be used to set up a full VECM, where no further restrictions are imposed to form an estimate for Σ_u. Moreover, long-run and contemporaneous identifying restrictions derived from the theory are used to form estimates for matrix B or A. We know from the previous results that we need K (K − 1)/2 = 5(5 − 1)/2 = 10 additional linearly independent restrictions coming from economic theory to exactly identify the structural shocks.

$$\mathrm{A} = \mathrm{C}(1)\mathrm{B} = \begin{pmatrix} * & * & * & * & * \\ 0 & 0 & * & * & * \\ * & * & * & * & * \\ * & * & * & 0 & * \\ * & 0 & * & * & * \end{pmatrix}$$

While

$$\mathrm{B} = \begin{pmatrix} * & 0 & 0 & 0 & 0 \\ * & * & 0 & * & 0 \\ * & * & * & 0 & 0 \\ * & * & * & * & 0 \\ * & * & * & * & 0 \end{pmatrix}$$

Then, we estimate the standard VECM with identifying restrictions explained above for the first non-inflation-targeting period and reestimate a second model for the second inflation-targeting period. The zeros represent the restricted elements and the asterisks denote unrestricted elements.

The bootstrap estimation allows us to determine unknown values of the short and long-run matrix for two periods.

59.4.1 Pre-IT (Before IT Adoption)

$$\text{Matrix A} = \mathrm{C}(1)\mathrm{B}$$
$$= \begin{pmatrix} 0.134 & 0.0125 & -0.1012 & -0.0668 & -0.00587 \\ 0 & 0 & 0.004 & 0.0649 & 0.0427 \\ -0.0644 & 0.0609 & 0.0622 & -0.0068 & 0.0068 \\ -0.0362 & -0.0602 & 0.0289 & 0 & 0.0325 \\ 0.0139 & 0 & 0.0112 & 0.0064 & 0.0325 \end{pmatrix}$$

While

$$\text{Matrix B} = \begin{pmatrix} 0.3601 & 0 & 0 & 0 & 0 \\ -0.0089 & 0.0005 & 0 & 0.0622 & 0 \\ -0.0415 & 0.0596 & 0.0725 & 0 & 0 \\ -0.0156 & -0.0613 & 0.0382 & 0.0061 & 0 \\ 0.0018 & 0.0007 & 0.0057 & 0.0028 & 0 \end{pmatrix}$$

59.4.2 Post-IT (After IT Adoption)

$$\text{Matrix A} = \mathrm{C}(1)\mathrm{B} = \begin{pmatrix} 0.1815 & 0.029 & 0.0428 & 0.0113 & 0.0123 \\ 0 & 0 & -0.003 & -0.0479 & -0.0324 \\ -0.0134 & -0.0784 & 0.02134 & -0.0011 & -0.0214 \\ 0.0012 & -0.0211 & 0.0012 & 0 & 0.0213 \\ 0.0011 & 0 & 0.0007 & 0.001 & 0.0012 \end{pmatrix}$$

While

$$\text{Matrix B} = \begin{pmatrix} 0.1851 & 0 & 0 & 0 & 0 \\ -0.0003 & 0.002 & 0 & -0.0471 & 0 \\ -0.0138 & -0.0756 & 0.0041 & 0 & 0 \\ -0.0035 & 0.0168 & 0.0571 & 0.0148 & 0 \\ 0.001 & 0.0003 & 0.0011 & 0.0011 & 0 \end{pmatrix}$$

To investigate the impulse response analysis, we compute impulse responses from the full SVECM, and we try to benefit from the important number of series

Table 59.5 Selected impulse responses: "impulse variable −> response variable" related to Appendix 3. Selected confidence interval (CI): (a) 95 % Hall percentile CI ($B = 100$ $h = 20$)
