$$C_1 = C_2 - e^{-r\tau}N\left(\ln(S/K_2e^{-r\tau})/\left(\sigma\sqrt{\tau}\right) - \sigma\sqrt{\tau}/2\right)(K_1-K_2)+\varepsilon_1, \tag{90.12}$$

$$C_2 = C_1 - e^{-r\tau}N\left(\ln(S/K_1e^{-r\tau})/\left(\sigma\sqrt{\tau}\right) - \sigma\sqrt{\tau}/2\right)(K_2-K_1)+\varepsilon_2. \tag{90.13}$$

Here ε_1 and ε_2 are the remainder terms of C_1 at K_2 and C_2 at K_1 from Eq. 90.1. Dividing both sides of Eqs. 90.12 and 90.13 by $e^{-r\tau}$ (K_2-K_1) and simple manipulations produce the same left-hand side of $(C_1–C_2)/e^{-r\tau}(K_2-K_1)$.

Then applying the inverse function of cumulative normal function on both sides and after using the Taylor's formula yields the following equations:

$$N^{-1}[(C_1-C_2)/e^{-r\tau}(K_2-K_1)] = \ln(S/K_1e^{-r\tau})/\left(\sigma\sqrt{\tau}\right) - \sigma\sqrt{\tau}/2+\eta_1, \tag{90.14}$$

$$N^{-1}[(C_1-C_2)/e^{-r\tau}(K_2-K_1)] = 1\mathrm{n}(S/K_2e^{-r\tau})/\left(\sigma\sqrt{\tau}\right) - \sigma\sqrt{\tau}/2+\eta_2, \tag{90.15}$$

where η_1 and η_2 are the remainder terms of Taylor's formulas derived from Eqs. 90.12 and 90.13, respectively. After combining Eqs. 90.14 and 90.15 and dropping the remainder terms (η_1 + η_2), the quadratic function of $\sigma\sqrt{\tau}$ can be shown as

[1]The details of the derivation of Eq. 90.10 can be found in Ang et al. (2012) paper.

$$\left(\sigma\sqrt{\tau}\right)^2 + 2N^{-1}[(C_1 - C_2)/e^{-r\tau}(K_2 - K_1)]\left(\sigma\sqrt{\tau}\right) - \ln\left[S^2/\left(e^{-2r\tau}K_1K_2\right)\right] = 0. \quad (90.16)$$

Thus, the ISD can be solved as

$$\sigma\sqrt{T} = \begin{cases} -N^{-1}[(C_1 - C_2)/e^{-r\tau}(K_2 - K_1)] + \sqrt{\zeta} & \text{when } \mathrm{S} > \mathrm{K}_1 \\ -N^{-1}[(C_1 - C_2)/e^{-r\tau}(K_2 - K_1)] - \sqrt{\zeta} & \text{when } \mathrm{S} \le \mathrm{K}_1 \le \mathrm{K}_2 \end{cases}$$
$$\zeta = \left[N^{-1}((C_1 - C_2)/e^{-r\tau}(K_2 - K_1))\right]^2 + \ln\left(S^2/e^{-2r\tau}K_1K_2\right). \quad (90.17)$$

It is clear that if stock price is less than the lower exercise K_1 (i.e., then both call options are out of the money), and if we had chosen the value with the plus sign of $\sqrt{\zeta}$ in Eq. 90.17, ISD calculated by Eq. 90.17 will be overstated. The advantage of this formula is that a sufficient condition to calculate ISD by Eq. 90.17 only requires that there existed any two consecutive call option values with different exercise prices. But, the accuracy of this formula will depend on the magnitude of the deviation between these two exercise prices.

Ang et al. (2012) further extend this approach to include a third option to derive the third formula. Similar to Eq. 90.16, if there is a third call option C_3 with the exercise price K_3, then the following Eq. 90.18 must hold for K_2, K_3 and C_2, C_3.

$$\left(\sigma\sqrt{\tau}\right)^2 + 2N^{-1}[(C_2 - C_3)/e^{-r\tau}(K_3 - K_2)]\left(\sigma\sqrt{\tau}\right) - \ln\left[S^2/\left(e^{-2r\tau}K_2K_3\right)\right] = 0. \quad (90.18)$$

Given the constant variance assumption in Black and Scholes option model, the following Eq. 90.19 is thus derived by subtracting Eq. 90.18 from Eq. 90.16 as follows:

$$\sigma\sqrt{\tau} = \ln(K_3/K_1)/\left[2\left(N^{-1}((C_1 - C_2)/e^{-r\tau}(K_2 - K_1)) - N^{-1}((C_2 - C_3)/e^{-r\tau}(K_3 - K_2))\right)\right]. \quad (90.19)$$

An advantage of using Eq. 90.19 rather than Eq. 90.17 to estimate the ISD is to circumvent the sign issue that appears in Eq. 90.17. However, a drawback of using Eq. 90.19 is that there must exist at least three instead of two call options for Eq. 90.17. Equation 90.19 provides a simple formula to calculate ISD because all option values and exercise price are given and the inverse function of the standard cumulative normal function also available in the Excel spreadsheet. Ang et al. (2012) state that this third formula in Eq. 90.19 is more accurate method for estimating ISD based on their simulation results.

90.4 Illustration of Estimating Implied Standard Deviation by MATLAB

The data for this study for estimating ISD include the call options on the S&P 500 index futures which are traded at the Chicago Mercantile Exchange (CME).[2] According to Eq. 90.6, we need the information of market call option price on S&P 500 index, the annualized risk-free rate, S&P 500 index futures price, exercise price, and maturity date on the contracts as input variables to calculate the ISD of call option on S&P 500 index futures. Daily closed-price data of S&P 500 index futures and options on S&P 500 index futures was gathered from Datastream for two periods of time: the options expired on March, June, and September, 2010; options expired on March, June, and September, 2011; and the S&P 500 index future from October 1, 2008, to November 4, 2011. The S&P 500 spot price is based on the closed price of S&P 500 index on Yahoo! Finance[3] during the same period of S&P 500 index future data. The risk-free rate used in Black model is based on 3-month Treasury bill from Federal Reserve Bank of St. Louis.[4] The selection of these futures option contracts is based on the length of trading days. The futures options expired on March, June, September, and December have over 1 year trading date (above 252 observations), and other options only have more or less 100 observations. Therefore, we only choose the futures options with longer trading period to investigate the distributional statistics of these ISD series. Studying two different time periods (2010 and 2011) of call options on S&P 500 index futures will allow the examination of ISD characteristics and movements over time as well as the effects of different market climates.

The tolerance level used is the same formula as shown in Eq. 90.5, and let the tolerance level Q equal to 0.000001 as follows:

$$\left| \frac{\sigma_1 - \sigma_0}{\sigma_0} \right| < .000001$$

This chapter utilized financial toolbox in MATLAB to calculate the implied volatility for futures option that the code of function is as follows[5]:

$$\text{Volatility} = \text{blsimpv}(\text{Price},\ \ \text{Strike},\ \ \text{Rate},\ \ \text{Time}, \text{Value}, \text{Limit},\ \ \text{Tolerance},\ \ \text{Class})$$

[2]Nowadays Chicago Mercantile Exchange (CME), Chicago Board of Trade (CBOT), New York Mercantile Exchange (NYMEX), and Commodity Exchange (COMEX) are merged and operate as designated contract markets (DCM) of the CME Group which is the world's leading and most diverse derivatives marketplace. Website of CME group: http://www.cmegroup.com/

[3]Website of Yahoo! Finance is as follows: http://finance.yahoo.com

[4]Website of Federal Reserve Bank of St. Louis: http://research.stlouisfed.org/

[5]The syntax and the code from m-file source of MATLAB for Implied Volatility Function of Futures Options are represented in Appendix 1. The detailed information of the function and example of calculating the implied volatility for futures option also can be referred on MathWorks website: http://www.mathworks.com/help/toolbox/finance/blkimpv.html

where the blsimpv is the function name in MATLAB; Price, Strike, Rate, Time, Value, Limit, Tolerance, and Class are input variables; Volatility is the annualized ISD (also called implied volatility). The advantages of this function are the allowance of the upper bound of implied volatility (Limit variable) and the adjustment of the implied volatility termination tolerance (Tolerance variable), in general, equal to 0.000001.

A summary of the ISD distributional statistics for S&P 500 index futures call options in 2010 and 2011 appears in Table 90.1. The most noteworthy feature from this table is the significantly different mean values of the ISD that occur for different exercise prices. The means and variability of the ISD in 2010 and 2011 appear to be inversely related to the exercise price. Comparing the mean ISDs across time periods, it is quite evident that the ISDs in 2011 are significantly smaller. Also, the time-to-maturity effect observed by Park and Sears (1985) can be identified. The September options in 2011 possess higher mean value of the ISD than those maturing in June and March with the same strike price.

The other statistical measures listed in Table 90.1 are the relative skewness and relative kurtosis of the ISD series, along with the studentized range. Skewness measures lopsidedness in the distribution and might be considered indicative of a series of large outliers at some point in the time series of the ISDs. Kurtosis measures the peakedness of the distribution relative to the normal and has been found to affect the stability of variance (see Lee and Wu 1985). The studentized range gives an overall indication as to whether the measured degrees of skewness and kurtosis have significantly deviated from the levels implied by a normality assumption for the ISD series.

Although an interpretation of the effects of skewness and kurtosis on the ISD series needs more accurate analysis, a few general observations are warranted at this point. Both 2010 and 2011 ISD's statistics present a very different view of normal distribution, certainly challenging any assumptions concerning normality in Black–Scholes option pricing model framework. Using significance tests on the results of Table 90.1 in accordance with Jarque–Bera test, the 2010 and 2011 skewness and kurtosis measures indicate a higher proportion of statistical significance. We also utilize simple back-of-the-envelope test based on the studentized range to identify whether the individual ISD series approximate a normal distribution. The studentized range larger than 4 in both 2010 and 2011 indicates that a normal distribution significantly understates the maximum magnitude of deviation in individual ISD series.

As a final point to this brief examination of the ISD skewness and kurtosis, note the statistics for MAR10 1075, MAR11 1200, and MAR11 1250 contracts. The relative size of these contract's skewness and kurtosis measures reflect the high degree of instability that its ISD exhibited during the last 10 days of the contract's life. Such instability is consistent across contracts. However, these distortions remain in the computed skewness and kurtosis measures only for these particular contracts to emphasize how a few large outliers can magnify the size of these statistics. For example, the evidence that S&P 500 future price jumped on

Table 90.1 Distributional statistics for the ISD series of call options on S&P 500 index futures

Option series[a]	Mean	Std. dev.	CV[b]	Skewness	Kurtosis	Studentized range[c]	Observations
Call futures options in 2010							
MAR10 1075 (C070WC)	0.230	0.032	0.141	2.908	14.898	10.336	251
JUN10 1050 (B243UE)	0.263	0.050	0.191	0.987	0.943	6.729	434
JUN10 1100 (B243UF)	0.247	0.047	0.189	0.718	−0.569	4.299	434
SEP10 1100 (C9210T)	0.216	0.024	0.111	0.928	1.539	6.092	259
SEP10 1200 (C9210U)	0.191	0.022	0.117	0.982	2.194	6.178	257
Call futures options in 2011							
MAR11 1200 (D039NR)	0.206	0.040	0.195	5.108	36.483	10.190	384
MAR11 1250 (D1843V)	0.188	0.027	0.145	3.739	25.527	10.636	324
MAR11 1300 (D039NT)	0.176	0.021	0.118	1.104	4.787	8.588	384
JUN11 1325 (B513XF)	0.165	0.016	0.095	−1.831	12.656	10.103	200
JUN11 1350 (A850CJ)	0.161	0.018	0.113	−0.228	1.856	8.653	234
SEP11 1250 (B9370T)	0.200	0.031	0.152	2.274	6.875	7.562	248
SEP11 1300 (B778PK)	0.185	0.024	0.131	2.279	6.861	7.399	253
SEP11 1350 (B9370V)	0.170	0.025	0.147	2.212	5.848	6.040	470

[a]Option series contain the name and code of futures options with information of the strike price and the expired month, for example, SEP11 1350 (B9370V) represents that the futures call option is expired on September 2011 with the strike price $1,350, and the parentheses is the code of this futures option in Datastream

[b]CV represents the coefficient of variation that is standard deviation of option series divided by their mean value

[c]Studentized range is the difference of the maximum and minimum of the observations divided by the standard deviation of the sample

January 18, 2010, and plunged on February 2, 2011, causes the ISD of these particular contracts sharply increasing on that dates. Thus, while still of interest, any skewness and kurtosis measures must be calculated and interpreted with caution.

One difficulty in discerning the correct value for the volatility parameter in the option pricing model is due to its fluctuation over time. Therefore, since an accurate estimate of this variable is essential for correctly pricing an option, it would seem that time series and cross-sectional analysis of this variable would be as important as the conventional study of security price movements. Moreover, by examining the ISD series of each call options on S&P 500 index futures over time as well as within different time sets, the unique relationships between the underlying stochastic process and the pricing influences of differing exercise prices, maturity dates, and market sentiment (and, indirectly, volume), might be revealed in a way that could be modeled more efficiently. Therefore, we should consider autoregressive–moving-average (ARMA) models or cross-sectional time series regression models to analyze the ISD series and forecast the price of call options on S&P 500 index futures by predicting the future ISD of these options.

90.5 Summary and Concluding Remarks

The research in estimation of the implied volatility becomes the one of most important topics in option pricing research because the standard deviation of the underlying asset return, which is the important factor in Black–Scholes' option pricing model, cannot be observed directly. The purpose of this chapter is to review the different theoretical methods used to estimate implied standard deviation and to show how the implied volatility can be estimated in empirical work. We review the OLS method and a Taylor series expansion method for estimating the ISD in previous literature. Three formulas for the estimation of the ISD by applying a Taylor series expansion method to Black–Scholes option pricing model can be derived from one, two, and three options, respectively. Regarding to these formulas with the remainder terms in a Taylor series expansion method, the accuracy of these formulas depends on how an underlying asset is close to the present value of exercise price in an option.

In empirical work, we illustrate how MATLAB can be used to deal with the issue of estimating implied volatility for call options on S&P 500 index futures in 2010 and 2011. The results show that the time series of implied volatility significantly violate the assumption of constant volatility in Black–Scholes option pricing model. The skewness and kurtosis measures reflect the instability and fluctuation of the ISD series over time. Therefore, in the future research in the ISD, we should consider autoregressive–moving-average (ARMA) models or cross-sectional time series regression models to analyze and predict the ISD series to forecast the future price of call options on S&P 500 index futures.

Appendix 1: The Syntax and Code for Implied Volatility Function of Futures Options in MATLAB

The function name of estimating implied volatility for European call options on index futures in this chapter are as below:

Syntax

$$\text{Volatility} = \text{blsimpv}(\text{Price}, \text{Strike}, \text{Rate}, \text{Time}, \text{Value}, \text{Limit}, \ldots \text{Tolerance}, \text{Class})$$

The input variables that can be a scalar, vector, or matrix in the function of estimating implied volatility are described in Table 90.2

The code from m-file source of MATLAB for implied volatility function of futures options is shown as below:

```
function volatility = blkimpv(F, X, r, T, value, varargin)
% BLKIMPV Implied volatility from Black's model for futures options.
% Compute the implied volatility of a futures price from the market
% value of European futures options using Black's model.
%
% Volatility = blkimpv(Price, Strike, Rate, Time, Value)
% Volatility = blkimpv(Price, Strike, Rate, Time, Value, Limit, ...
% Tolerance, Class)
%
% Optional Inputs: Limit, Tolerance, Class.
%
% Inputs:
% Price - Current price of the underlying asset (i.e., a futures contract).
%
```

Table 90.2 The description of input variables used in blsimpv function in MATLAB

Price	Current price of the underlying asset (a futures contract)
Strike	Exercise price of the futures option
Rate	Annualized, continuously compounded risk-free rate of return over the life of the option, expressed as a positive decimal number
Time	Time to expiration of the option, expressed in years
Value	Price of a European futures option from which the implied volatility of the underlying asset is derived
Limit (optional)	Positive scalar representing the upper bound of the implied volatility search interval. If Limit is empty or unspecified, the default = 10, or 1,000 % per annum
Tolerance (optional)	Implied volatility termination tolerance. A positive scalar. Default = 1e-6
Class (optional)	Option class (call or put) indicating the option type from which the implied volatility is derived. May be either a logical indicator or a cell array of characters. To specify call options, set Class = true or Class = {'call'}; to specify put options, set Class = false or Class = {'put'}. If Class is empty or unspecified, the default is a call option

```
% Strike - Strike (i.e., exercise) price of the futures option.
%
% Rate - Annualized continuously compounded risk-free rate of return
% over the life of the option, expressed as a positive decimal number.
%
% Time - Time to expiration of the option, expressed in years.
%
% Value - Price (i.e., value) of a European futures option from which
% the implied volatility is derived.
%
% Optional Inputs:
% Limit - Positive scalar representing the upper bound of the implied
% volatility search interval. If empty or missing, the default is 10,
% or 1000% per annum.
%
% Tolerance - Positive scalar implied volatility termination tolerance.
% If empty or missing, the default is 1e-6.
%
% Class - Option class (i.e., whether a call or put) indicating the
% option type from which the implied volatility is derived. This may
% be either a logical indicator or a cell array of characters. To
% specify call options, set Class = true or Class = {'call'}; to specify
% put options, set Class = false or Class = {'put'}. If empty or missing,
% the default is a call option.
%
% Output:
% Volatility - Implied volatility derived from European futures option
% prices, expressed as a decimal number. If no solution is found, a
% NaN (i.e., Not-a-Number) is returned.
```

```
%
% Example:
% Consider a European call futures option trading at
$1.1166, with an
% exercise prices of $20 that expires in 4 months. Assume
the current
% underlying futures price is also $20 and that the risk-
free rate is 9%
% per annum. Furthermore, assume we are interested in
implied volatilities
% no greater than 0.5 (i.e., 50% per annum). Under these
conditions, any
% of the following commands
%
% Volatility = blkimpv(20, 20, 0.09, 4/12, 1.1166, 0.5)
% Volatility = blkimpv(20, 20, 0.09, 4/12, 1.1166, 0.5,
[], {'Call'})
% Volatility = blkimpv(20, 20, 0.09, 4/12, 1.1166, 0.5,
[], true)
%
% return an implied volatility of 0.25, or 25%, per annum.
%
% Notes:
% (1) The input arguments Price, Strike, Rate, Time, Value,
and Class may be
% scalars, vectors, or matrices. If scalars, then that
value is used to
% compute the implied volatility from all options. If more
than one of
% these inputs is a vector or matrix, then the dimensions of
all
% non-scalar inputs must be the same.
% (2) Ensure that Rate and Time are expressed in consistent
units of time.

Measuring Credit Risk in a Factor Copula Model

91

Jow-Ran Chang and An-Chi Chen

Contents

Abstract

In this chapter, we provide a new approach to estimate future credit risk on target portfolio based on the framework of CreditMetrics™ by J.P. Morgan. However, we adopt the perspective of factor copula and then bring the principal component analysis concept into factor structure to construct a more appropriate dependence structure among credits.

In order to examine the proposed method, we use real market data instead of virtual one. We also develop a tool for risk analysis which is convenient to use, especially for banking loan businesses. The results show the fact that people assume dependence structures are normally distributed will indeed lead to risk

underestimation. On the other hand, our proposed method captures better features of risks and shows the fat-tail effects conspicuously even though assuming the factors are normally distributed.

91.1 Introduction

Credit risk is a risk that generally refers to counterparty failure to fulfill its contractual obligations. The history of financial institutions has shown that many banking association failures were due to credit risk. For the integrity and regularity, financial institutions attempt to quantify credit risk as well as market risk. Credit risk has great influence on all financial institutions as long as they have contractual agreements. The evolution of measuring credit risk has been progressed for a long time. Many credit risk measure models were published, such as CreditMetrics by J.P. Morgan and CreditRisk + by Credit Suisse. On the other side, New Basel Accords (Basel II Accords) which are the recommendation on banking laws and regulations construct a standard to promote greater stability in financial system. Basel II Accords allowed banks to estimate credit risk by using either a standardized model or an internal model approach, based on their own risk management system. The former approach is based on external credit ratings provided by external credit assessment institutions. It describes the weights, which fall into five categories for banks and sovereigns and four categories for corporations. The latter approach allows banks to use their internal estimation of creditworthiness, subject to regulatory. How to build a credit risk measurement model after banking has constructed internal customer credit rating? How to estimate their default probability and default correlations? This thesis attempts to implement a credit risk model tool which links to internal banking database and gives the relevant reports automatically. The developed model facilitates banks to boost their risk management capability.

The dispersion of the credit losses, however, critically depends on the correlations between default events. Several factors such as industry sectors and corporation sizes will affect correlations between every two default events. The CreditMetrics™ model (1997) issued from J.P. Morgan proposed a binomial normal distribution to describe the correlations (dependence structures). In order to describe the dependence structure between two default events in detail, we adopt copula function instead of binomial normal distribution to express the dependence structure.

When estimating credit portfolio losses, both the individual default rates of each firm and joint default probabilities across all firms need to be considered. These features are similar to the valuation process of collateralized debt obligation (CDO). A CDO is a way of creating securities with widely different risk characteristics from a portfolio of debt instrument. The estimating process is almost the same between our goal and CDO pricing. We focus on how to estimate risks. Most CDO pricing literature adopted copula functions to capture the default correlations. Li (2000) extended Sklar's issue (1959) that a copula function can be applied to solve financial problems of default correlation. Li (2000) pointed out that if the dependence structure were assumed to be normally distributed through binomial normal probability density function, the joint transformation probability would be consistent with the result from using a normal copula function. But this assumption is too strong. It has been discovered that most financial data have skew or fat-tail phenomenon. Bouye et al. (2000) and Embrechts et al. (1999) pointed out that the estimating VaR would be underestimated if the dependence structure were described by normal copula comparing to actual data. Hull and White (2004) combined factor analysis and copula functions as a factor copula concept to investigate reasonable spread of CDO. How to find a suitable correlation to describe the dependence structure between every two default events and to speed up the computational complexity is our main object. Bielecki et al. (2012) apply the Markov copula approach to model joint default between counterparty and the reference name in a CDS contract.

This chapter aims to:

1. Construct an efficient model to describe the dependence structure
2. Use this constructed model to analyze overall credit, marginal, and industrial risks
3. Build up an automatic tool for banking system to analyze its internal credit risks

91.2 Methodology

91.2.1 CreditMetrics

Gupton et al. (1997) adopt the main framework of CreditMetrics and calculate credit risks by using real commercial bank loans. The calculating dataset for this chapter is derived from a certain commercial bank in Taiwan. Although there may be some conditions which are different from the situations proposed by CreditMetrics, the calculating process by CreditMetrics can still be appropriately applied to this chapter. For instance, the number of rating degrees in CreditMetrics adopted in S&P's rating category is 7, i.e., AAA to C, but in this loan dataset, there are 9° instead. The following is the introduction to CreditMetrics model framework.

This model can be roughly divided into three components, i.e., value at risk due to credit, exposures, and correlations, respectively, as shown in Fig. 91.1. In this section, these three components and how does this model work out on credit risk valuation will be briefly introduced. Further details could be referred to CreditMetrics technical document.

91.2.1.1 Value at Risk Due to Credit

The process of valuing value at risk due to credit can be decomposed into three steps. For simplicity, we assumed there is only one stand-alone instrument which is

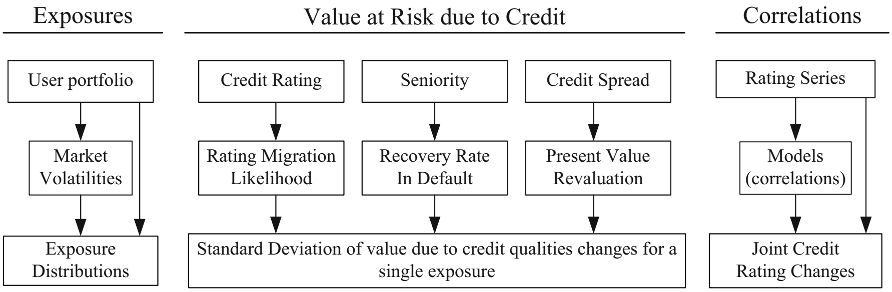

Fig. 91.1 Structure of CreditMetrics model

Table 91.1 One-year transition matrix

	Rating at year-end (%)							
Initial rating	AAA	AA	A	BBB	BB	B	CCC	D
AAA	90.81	8.33	0.68	0.06	0.12	0	0	0
AA	0.70	90.65	7.79	0.64	0.06	0.14	0.02	0
A	0.09	2.27	91.05	5.52	0.74	0.26	0.01	0.06
BBB	0.02	0.33	5.95	86.93	5.30	1.17	0.12	0.18
BB	0.03	0.14	0.67	7.73	80.53	8.84	1.00	1.06
B	0	0.11	0.24	0.91	6.48	83.46	4.07	5.20
CCC	0.22	0	0.22	1.30	2.38	11.24	64.86	19.79

Source: J.P. Morgan's CreditMetrics – technical document (1997)

a corporation bond. (The bond property is similar to loan as they both receive certain amount of cash flow every period and principal at the maturity.) This bond has 5-year maturity and pays an annual coupon at the rate of 5 % to express the calculation process if necessary. Some modifications to fit real situations will be considered later. In Step 1, CreditMetrics assumed that all risks of one portfolio are due to credit rating changes, no matter defaulting or rating migrating. It is significant to estimate not only the likelihood of default but also the chance of migration to move toward any possible credit quality state at the risk horizon. Therefore, a standard system that evaluated "rating changing" under a certain horizon of time is necessary. This information is represented more concisely in transition matrix. Transition matrix can be calculated by observing the historical pattern of rating change and default. They have been published by S&P and Moody's rating agencies or calculated by private banking internal rating systems. Besides, the transition matrix should be estimated for the same time interval (risk horizon) which can be defined by user demand, usually in 1-year period. Table 91.1 is an example to represent 1-year transition matrix.

In the transition matrix table, AAA level is the highest credit rating, and D is the lowest; D also represents that default occurs. According to the above transition matrix table, a company which stays in AA level at the beginning of the year has the probability of 0.64 % to go down to BBB level at the end of the year. By the same

Table 91.2 Recovery rates by seniority class

Class		Recovery rate of Taiwan debt business research using TEJ data	
		Mean (%)	Standard deviation (%)
Loan	Secured	55.38	35.26
	Unsecured	33.27	30.29
Corporation bond	Secured	67.99	26.13
	Unsecured	36.15	37.17

Source: Da-Bai Shen et al. (2003), Research of Taiwan recovery rate with TEJ Data Bank

way, a company which stays in CCC level at the beginning of the year has the probability of 2.38 % to go up to BB level at the end of the year. In this chapter, the transition matrix is to be seen as an external data.[1]

In Step 1, we describe the likelihood of migration to move to any possible quality states (AAA to CCC) at the risk horizon. Step 2 is valuation. The value at the risk horizon must be determined. According to different states, the valuation falls into two categories. First, in the event of a default, recovery rate of different seniority class is needed. Second, in the event of up (down) grades, the change in credit spread that results from the rating migration must be estimated, too.

In default category, Table 91.2 shows the recovery rates by seniority class which this chapter adopts to revaluate instruments. For instance, if the holding bond (5-year maturity that pays an annual coupon at the rate of 5 %) is unsecured and the default occurs, the recovery value will be estimated using its mean value which is 36.15 %.

In rating migration category, the action of revaluation is to determine the cash flows which result from holding the instrument (corporation bond position). Assuming a face value of $100, the bond pays $5 (an annual coupon at the rate of 5 %) each at the end of the next 4 years. Now, the calculating process to describe the value V of the bond assuming the bond upgrades to level A by the formula below:

$$V = 5 + \frac{5}{(1 + 3.72\%)} + \frac{5}{(1 + 4.32\%)^2} + \frac{5}{(1 + 4.93\%)^3} + \frac{105}{(1 + 5.32)^4} = 108.66$$

The discount rate in the above formula comes from the forward zero curves shown in Table 91.3, which is derived from CreditMetrics technical document. This chapter does not focus on how to calculate forward zero curves. It is also seen as an external input data.

Step 3 is to estimate the volatility of value due to credit quality changes for this stand-alone exposure (level A, corporation bond). From step 1 and step 2, the likelihood of all possible outcomes and distribution of values within each outcome are known. CreditMetrics used two measures to calculate the risk estimate:

[1]We do not focus on how to model probability of default (PD) but focus on how to establish the dependence structure. The 1-year transition matrix is a necessary input to our model.

Table 91.3 One-year forward zero curves by credit rating category

Category	Year 1	Year 2	Year 3	Year 4
AAA	3.60	4.17	4.73	5.12
AA	3.65	4.22	4.78	5.17
A	3.72	4.32	4.93	5.32
BBB	4.10	4.67	5.25	5.63
BB	5.55	6.02	6.78	7.27
B	6.05	7.02	8.03	8.52
CCC	15.05	15.02	14.03	13.52

Source: J.P. Morgan's CreditMetrics – technical document (1997)

One is standard deviation, and the other is percentile level. Besides these two measures, this chapter also embraces marginal VaR which denotes the increment VaR due to adding one new instrument in the portfolio.

91.2.1.2 Exposures

As discussed above, the instrument is limited to corporation bonds. CreditMetrics has allowed the following generic exposure types:

1. Non-interest bearing receivables
2. Bonds and loans
3. Commitments to lend
4. Financial letters of credit
5. Market-driven instruments (swap, forwards, etc.)

The exposure type this chapter aims at is loans. The credit risk calculation process of loans is similar to bonds as previous example. The only difference is that loans do not pay coupons. Instead, loans receive interests. But the CreditMetrics model can definitely fit the goal of this chapter to estimate credit risks on banking loan business.

91.2.1.3 Correlations

In most circumstances, there is usually more than one instrument in a target portfolio. Now, multiple exposures are taken into consideration. In order to extend the methodology to a portfolio of multiple exposures, estimating the contribution to risk brought by the effect of nonzero credit quality correlations is necessary. Thus, the estimation of joint likelihood in the credit quality co-movement is the next problem to be resolved. There are many academic papers which address the problems of estimating correlations within a credit portfolio. For example, Gollinger and Morgan (1993) used time series of default likelihood to correlate default likelihood, and Stevenson and Fadil (1995) correlated the default experience across 33 industry groups. On the other hand, CreditMetrics proposed a method to estimate default correlation. They have several assumptions:

(A) A firm's asset value is the process which drives its credit rating changes and default.
(B) The asset returns are normally distributed.
(C) Two asset returns are correlated and bivariate normally distributed, and multiple asset returns are correlated and multivariate normally distributed.

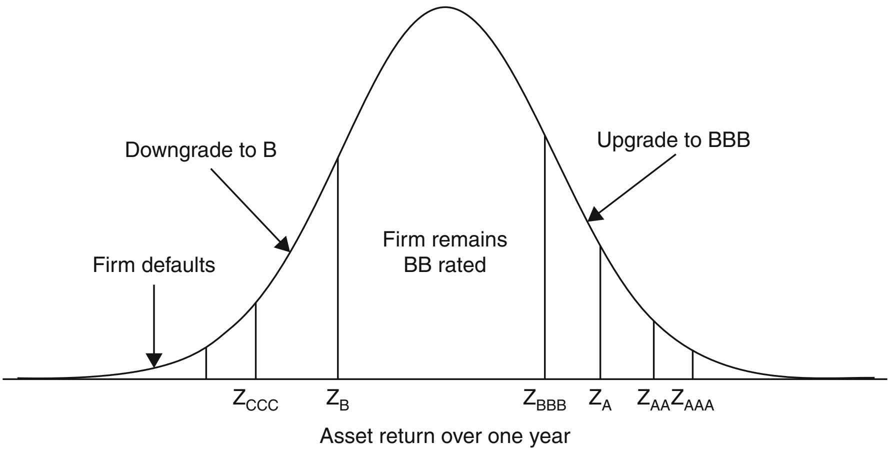

Fig. 91.2 Distribution of asset returns with rating change thresholds

According to assumption A, individual threshold of one firm can be calculated. For a two-exposure portfolio, which credit ratings are level B and level AA and standard deviations of returns are σ and σ′, respectively, it only remains to specify the correlation ρ between two asset returns. The covariance matrix for the bivariate normal distribution is

$$\Sigma = \begin{pmatrix} \sigma^2 & \rho\sigma\sigma' \\ \rho\sigma\sigma' & \sigma'2 \end{pmatrix}$$

Then the joint probability of co-movement that both two firms stay in the same credit rating can be described by the following formula:

$$\Pr\{Z_{BB} < R_1 < Z_B, Z'_{AAA} < R_2 < Z'_{AA}\} = \int_{Z_{BB}}^{Z_B} \int_{Z'_{AAA}}^{Z'_{AA}} f(r, r'; \Sigma)(dr')dr$$

where Z_{BB}, Z_B, Z'_{AAA}, Z'_{AA} are the thresholds. Figure 91.2 gives a concept of the probability calculation. These three assumptions regarding estimating the default correlation are too strong, especially assuming the multiple asset returns are multinormally distributed. In the next section, a better way of using copula to examine the default correlation is proposed.

91.2.2 Copula Function

Consider a portfolio consists of *m* credits. The marginal distribution of each individual credit risks (defaults occur) can be constructed by using either the historical approach or the market implicit approach (derived credit curve from market information). But the question is: how to describe the joint distribution or co-movement between these risks (default correlation)? In a sense, every joint distribution function for a vector of risk factors implicitly contains both a description of the marginal behavior of individual risk factors and a description of their dependence structure. The simplest assumption of dependence structure is mutual independence among the credit risks. However, the independent assumption of the credit risks is obviously not realistic. Undoubtedly, the default rate for a group of credits tends to be higher when the economy is in a recession and lower in a booming. This implies that each credit is subject to the same factors from macroeconomic environment and that there exists some form of dependence among the credits. The copula approach provides a way of isolating the description of the dependence structure. That is, the copula provides a solution to specify a joint distribution of risks, with given marginal distributions. Of course, this problem has no unique solution. There are many different techniques in statistics which can specify a joint distribution with given marginal distributions and a correlation structure. In the following section, the copula function is briefly introduced.

91.2.2.1 Copula Function

An m-dimensional copula is a distribution function on $[0,1]^m$ with standard uniform marginal distributions:

$$C(u) = C(u_1, u_2, \ldots, u_m) \tag{91.1}$$

C is called a copula function.

The copula function C is a mapping of the form C:$[0, 1]^m \rightarrow [0, 1]$, i.e., a mapping of the m-dimensional unit cube $[0, 1]^m$ such that every marginal distribution is uniform on the interval [0, 1]. The following two properties must hold:

1. $C(u_1, u_2, \ldots, u_m, \Sigma)$ is increasing in each component u_i.
2. $C(1, \ldots, 1, u_i, 1, \ldots, 1, \Sigma) = u_i$ for all $i \in \{1, \ldots, m\}$, $u_i \in [0, 1]$.

91.2.2.2 Sklar's Theorem

Sklar (1959) underlined the applications of the copula. Let $F(\bullet)$ be an m-dimensional joint distribution function with marginal distribution $F_1, F_2, \ldots, F_m$. There exist a copula C: $[0, 1]^m \rightarrow [0, 1]$ such that

$$F(x_1, x_2, \ldots, x_m) = C(F_1(x_1), F_2(x_2), \ldots, F_m(x_m)) \tag{91.2}$$

If the margins are continuous, then C is unique.

For any $x_1, \ldots, x_m$ in $\Re = [-\infty, \infty]$ and X has joint distribution function F, then

$$F(x_1, x_2, \ldots, x_m) = \Pr[F_1(X_1) \le F_1(x_1), F_2(X_2) \le F_2(x_2), \ldots, F_m(X_m) \le F_m(x_m)] \tag{91.3}$$

According to Eq. 91.2, the distribution function of $(F_1(X_1), F_2(X_2), \ldots, F_m(X_m))$ is a copula. Let $x_i = F_i^{-1}(u_i)$, then

$$C(u_1, u_2, \ldots, u_m) = F\left(F_1^{-1}(u_1), F_2^{-1}(u_2), \ldots, F_m^{-1}(u_m)\right) \tag{91.4}$$

This gives an explicit representation of C in terms of F and its margins.

91.2.2.3 Copula of F

Li (2000) used the copula function conversely. The copula function links univariate marginals to their full multivariate distribution. For m uniform random variables, U_1, U_2, ..., U_m, the joint distribution function C is defined as

$$C(u_1, u_2, \ldots, u_m, \Sigma) = \Pr[U_1 \leq u_1, U_2 \leq u_2, \ldots, U_m \leq u_m] \tag{91.5}$$

where Σ is correlation matrix of U_1, U_2, ..., U_m.

For given univariate marginal distribution functions $F_1(x_1)$, $F_2(x_2)$, ..., $F_\mathrm{m}(x_\mathrm{m})$. $x_i = F_i^{-1}(u_i)$, the joint distribution function F can be described as follows:

$$F(x_1, x_2, \ldots, x_m) = C(F_1(x_1), F_2(x_2), \ldots, F_m(x_m), \Sigma) \tag{91.6}$$

The joint distribution function F is defined by using a copula.

The property can be easily shown as follows:

$$\begin{aligned}
\mathrm{C}(F_1(x_1), F_2(x_2), \ldots, F_\mathrm{m}(x_\mathrm{m}), \Sigma) &= \Pr[U_1 \leq F_1(x_1), U_2 \leq F_2(x_2), \ldots, U_m \leq F_m(x_m)] \\
&= \Pr\left[F_1^{-1}(U_1) \leq x_1, F_2^{-1}(U_2) \leq x_2, \ldots, F_m^{-1}(U_m) \leq x_m\right] \\
&= \Pr[X_1 \leq x_1, X_2 \leq x_2, \ldots, X_m \leq x_m] \\
&= F(x_1, x_2, \ldots, x_m)
\end{aligned}$$

The marginal distribution of $\mathrm{X_i}$ is

$$\begin{aligned}
&C(F_1(+\infty), F_2(+\infty), \ldots, F_i(x_i), \ldots, F_m(+\infty), \Sigma) \\
&= \Pr[X_1 \leq +\infty, X_2 \leq +\infty, \ldots, X_i \leq x_i, \ldots, X_m \leq +\infty] \\
&= \Pr[X_i \leq x_i] \\
&= F_i(x_i)
\end{aligned} \tag{91.7}$$

Li showed that with given marginal functions, we can construct the joint distribution through some copulas accordingly. But what kind of copula should be chosen corresponding to the realistic joint distribution of a portfolio? For example, the CreditMetrics chose Gaussian copula to construct multivariate distribution.

By Eq. 91.6, this Gaussian copula is given by

$$\begin{aligned}
C^{Ga}(u, \Sigma) &= \Pr(\Phi(X_1) \leq u_1, \Phi(X_2) \leq u_2, \ldots, \Phi(X_m) \leq u_m, \Sigma) \\
&= \Phi_\Sigma\left(\Phi^{-1}(u_1), \Phi^{-1}(u_2), \ldots, \Phi^{-1}(u_m)\right)
\end{aligned} \tag{91.8}$$

where Φ denotes the standard univariate normal distribution, Φ^{-1} denotes the inverse of a univariate normal distribution, and Φ_Σ denotes multivariate normal distribution. In order to easily describe the construction process, we only discuss two random variables u_1 and u_2 to demonstrate the Gaussian copula:

$$C^{Ga}(u_1, u_2, \rho) = \int_{-\infty}^{\Phi^{-1}(u_1)} \int_{-\infty}^{\Phi^{-1}(u_2)} \frac{1}{2\pi\sqrt{(1-\rho^2)}} \exp\left\{-\frac{v_1^2 - 2\rho v_1 v_2 + v_2^2}{2(1-\rho^2)}\right\} dv_2 dv_1 \tag{91.9}$$

where ρ denotes the correlation of u_1 and u_2.

Equation 91.9 is also equivalent to the bivariate normal copula which can be written as follows:

$$C(u_1, u_2, \rho) = \Phi_2\left(\Phi^{-1}(u_1), \Phi^{-1}(u_2)\right) \tag{91.10}$$

Thus, with given individual distribution (e.g., credit migration over 1-year horizon) of each credit asset within a portfolio, we can obtain the joint distribution and default correlation of this portfolio through copula function. In our methodology, we do not use copula function directly. In the next section, we bring in the concept of factor copula for further improvement to form the default correlation. Using factor copula has two advantages. One is to avoid constructing a high-dimensional correlation matrix. If there are more and more instruments ($N > 1{,}000$) in our portfolio, we need to store N-by-N correlation matrix; scalability is one problem. The other advantage is to speed up the computation time because of the lower dimension.

91.2.3 Factor Copula Model

In this section, copula models that have a factor structure will be introduced. It is called factor copula because this model describes dependence structure between random variables not from the perspective of a certain copula form, such as Gaussian copula, but from the factors model. Factor copula models have been broadly used to assess price of collateralized debt obligation (CDO) and credit default swap (CDS). The main concept of factor copula model is that under a certain macro environment, credit default events are independent to each other. And the main causes that affect default events come from potential market economic conditions. This model provides another way to avoid dealing with multivariate normal distribution (high-dimensional) simulation problem.

Continuing the above example, a portfolio is consisted of m credits. In the first we consider the simplest example which contains only one factor and define V_i as the asset value of ith credit under single factor copula model. Then this ith credit asset value can be expressed by one factor M (mutual factor) chosen from macroeconomic factors and one error term ε_i:

$$V_i = r_i M + \sqrt{1 - r_i^2}\varepsilon_i \tag{91.11}$$

where r_{i} is weight of M, and the mutual factor M is independent of ε_i.

Let the marginal distribution of $V_1, V_2, \ldots, V_{\mathrm{m}}$ are F_{i}, $\mathrm{i} = 1, 2, \ldots, m$. Then the m-dimensional copula function can be written as

$$\begin{aligned} C(u_1, u_2, \ldots, u_m) &= F\left(F_1^{-1}(u_1), F_2^{-1}(u_2), \ldots, F_m^{-1}(u_m)\right) \\ &= \Pr\left(V_1 \le F_1^{-1}(u_1), V_2 \le F_2^{-1}(u_2), \ldots, V_m \le F_m^{-1}(u_m)\right) \end{aligned} \tag{91.12}$$

where F is the joint cumulative distribution function of $V_1, V_2, \ldots, V_{\mathrm{m}}$.

It has been known that M and ε_i are independent of each other, according to iterated expectation theorem; Eq. 91.12 can be written as

$$\begin{aligned} C(u_1, u_2, \ldots, u_m) &= E\left\{\Pr\left(V_1 \le F_1^{-1}(u_1), V_2 \le F_2^{-1}(u_2), \ldots, V_m \le F_m^{-1}(u_n)\right)|M\right\} \\ &= E\left\{\prod_{i=1}^{m} \Pr\left(r_i M + \sqrt{1 - r_i^2}\varepsilon_i \le F_i^{-1}(u_i)\right)|M\right\} \\ &= E\left\{\prod_{i=1}^{m} F_{\varepsilon, i}\left(\frac{F_i^{-1}(u_i) - r_i M}{\sqrt{1 - r_i^2}}\right)|M\right\} \\ &= \int\left(\prod_{i=1}^{m} F_{\varepsilon, i}\left(\frac{F_i^{-1}(u_i) - r_i M}{\sqrt{1 - r_i^2}}\right)\right) g(M) dM \end{aligned} \tag{91.13}$$

Using the above formula, the m-dimensional copula function can be derived. Moreover, according to Eq. 91.13, the joint cumulative distribution F can also be derived:

$$F(t_1, t_2, \ldots, t_m) = \int\left(\prod_{i=1}^{m} F_{\varepsilon, i}\left(\frac{\left(F_i^{-1}\left(F_{T,i}(t_i)\right) - r_i M\right)}{\sqrt{1 - r_i^2}}\right)\right) g(M) dM \tag{91.14}$$

Let $F_i(t_i) = \Pr(T_i \le t_i)$ represents i credit default probability (default occurs before time $\mathrm{t_i}$), where F_i is the marginal cumulative distribution. We note here that CDX pricing cares about when the default time $\mathrm{T_i}$ occurs. Under the same environment (systematic factor M) (Andersen and Sidenius (2004)), the default probability $\Pr(T_i \le t_i)$ will be equal to $\Pr(V_i \le c_i)$, which represent that the probability asset value V_{i} is below its threshold c_{i}. Then joint default probability of these m credits can be described as follows:

$$F(c_1, c_2, \ldots, c_m) = \Pr(V_1 \le c_1, V_2 \le c_2, \ldots, V_m \le c_m)$$

Now, we bring the concept of principal component analysis (PCA). People use PCA to reduce the high-dimensional or multivariable problems. If someone would like to explain one thing (or some movement of random variables), he/she has to

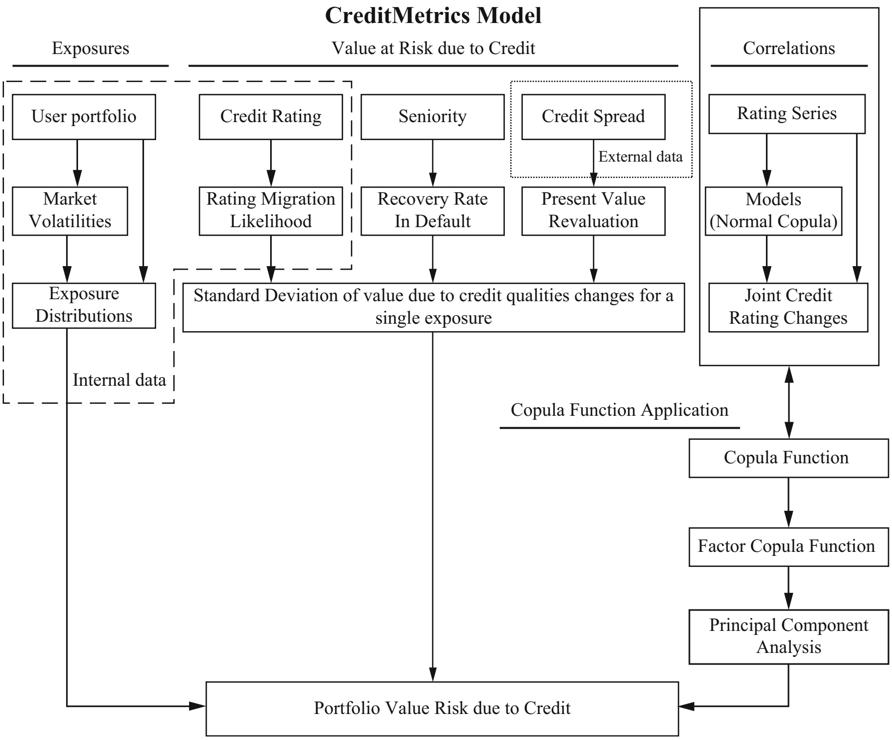

Fig. 91.3 Architecture of proposed model

gather interpreting variables related to those variable movements or their correlation. Once the kinds of interpreting variables are too huge or complicated, it becomes harder to explain those random variables and will produce complex problems. Principal component analysis provides a way to extract approximate interpreting variables to cover maximum variance of variables. Those representative variables may not be "real" variables. Virtual variables are allowed and depend on the explaining meaning. We do not talk about PCA calculation processes; further detail could be referred to Jorion (2000). Based on factor model, the asset value of m credits with covariance matrix Σ can be described as follows:

$$V_i = r_{i1}y_1 + r_{i2}y_2 + \ldots + r_{im}y_m + \varepsilon_i \tag{91.15}$$

where y_i are common factors between these m credits and r_{ij} is the weight (factor loading) of each factor. The factors are independent of each other. The question is: how to determinate those y_i factors and their loading? We use PCA to derive the factor loading. Factor loadings are based on listed price of those companies in the portfolio to calculate their dependence structure. The experimental results will be shown in the next section. We note here that the dependence structure among assets have been absorbed into factor loadings (Fig. 91.3).

91.3 Experimental Results

The purpose of this chapter is to estimate credit risk by using principal component analysis to construct dependence structure without giving any assumptions to specify formulas of copula. In other words, the data were based on itself to describe the dependence structure.

91.3.1 Data

In order to analyze credit VaR empirically through proposed method, this investigation adopts the internal loan account data, loan application data, and customer information data from a commercial bank on current market in Taiwan. For reliability of data authenticities, all the data are in Taiwan stock market instead of virtual one. This also means now the portfolio pool contains only the loans of listed companies and does not contain the loan of unlisted companies. According to the period of these data, we can estimate two future portfolio values. They are values on 2003 and 2004, respectively.

All requirement data are downloaded automatically from database system to workspace for computations. Before going to the detail of the experiments, the relevant data and experimental environment are introduced as follows.

91.3.1.1 Requirements of Data Input

1. Commercial bank internal data: This internal data contains nearly 40,000 entries of customer's data, 50,000 entries of loan data, and 3,000 entries of application data. These data contain maturity dates, outstanding amount, credit ratings, interest rate for lending, market type, etc. up to December 31, 2004.
2. One-year period transition matrix: The data was extracted from Yang (2005), who used the same commercial bank history data to estimate a transition matrix which obeyed Markov chain (Table 91.4).
3. Zero forward rate: Refer to Yang (2005), based on computed transition matrix to estimate the term structure of credit spreads. Furthermore, they added corresponding risk-free interest rate to calculate zero forward rates from discounting zero spot rates (Table 91.5).
4. Listed share prices at exchange market and over-the-counter market: We collected weekly listed share prices of all companies at exchange and over-the-counter markets in Taiwan from January 1, 2000, to December 31, 2003, in total 3 years' data, through Taiwan Economic Journal Data Bank (TEJ).

91.3.2 Simulation

In this section, the simulation procedure of analyzing banking VaR is briefly introduced. There are two main methods of experiments: A and B. A is the method that this chapter proposed which uses factor analysis to explain the dependence

structure and to simulate the distribution of future values. B is the contrast set which are used traditionally and popularly in most applications such as CreditMetrics. We call it the multi-normal (normal/Gaussian copula) simulation method.

Both of these two methods need three input data tables: credit transition matrix, forward zero curves, and share prices of each corporation in the portfolio pool. The detail of normal copula method procedure is not mentioned here; readers can refer to technical documentation of CreditMetrics. Now, the process of factor analysis method is shown as follows:

1. Extract the data entries that do not mature under given date, from database system including credit ratings, outstanding amounts, and interest rates.
2. According to the input transition matrix, we can calculate standardized thresholds for each credit rating.
3. Use the share prices of those corporations in the portfolio pool to calculate equities correlations.

4. Use principal component analysis to obtain each factor loadings for all factors under the assumption that these factors obey some distributions (e.g., standard normal distribution) to simulate their future asset value and future possible credit ratings.
5. According to possible credit ratings, discount the outstanding amounts by their own forward zero curves to evaluate future value distributions.
6. Display the analysis results.

91.3.3 Discussion

91.3.3.1 Tools and Interfaces Preview

For facility and convenience, this chapter uses MATLAB and MySQL to construct an application tool to help tool users analyze future portfolio value more efficiently. Following is this tool's interactive interfaces:

Basic Information of Experimental Data: (Pie Chart)

The non-computing data and pie charts give user the basic view of loan information. These charts present the proportion of each composition of three key elements: loan amount of companies, industry, and credit rating. To assist user, construct an overview of concerned portfolio (Fig. 91.4).

Pie chart of loan amount weight in terms of enterprise, industry, and credit rating.

Information According to Experimental data: (Statistic Numbers)

Besides graphic charts, the second part demonstrates a numerical analysis. The first part is the extraction of the company data which has maturity more than the given months, and the second part is the extraction of the essential data of top weighted companies. Parts I and II extract data without any computation; the only thing has been done is to sort or remove some useless data (Figs. 91.5 and 91.6).

Set Criteria and Derive Fundamental Experimental Result

This portion is the core of proposed tool; it provides several functions of computations. Here are the parameters that users must decide themselves:

1. Estimated year.
2. Confidence level.
3. Simulation times. Of course, the more simulation time user chooses, the more computational time will need.
4. Percentage of explained factors which is defined for PCA method. Using the eigenvalues of given normalized assets (equities) values, we can determinate the explained percentage.
5. This function gives user the option to estimate all or portion of the companies of portfolio pool. The portion part is sorted according to the loan amount of each enterprise. User can choose multiple companies they are most concerned. The computational result is written to a text file for further analysis.

6. Distribution of factors. This is defined for PCA method, too. There are two distributions that user can choose: standard normal distribution or Student's t-distribution. The default freedom of Student's t-distribution is set as one (Fig. 91.7).

Report of Overall VaR Contributor

User may be more interested in the detail of risk profile at various levels. In this part, industries are discriminated from 19 sections, and credits are discriminated from nine levels. This allow user to see where the risk is concentrated visually (Fig. 91.8).

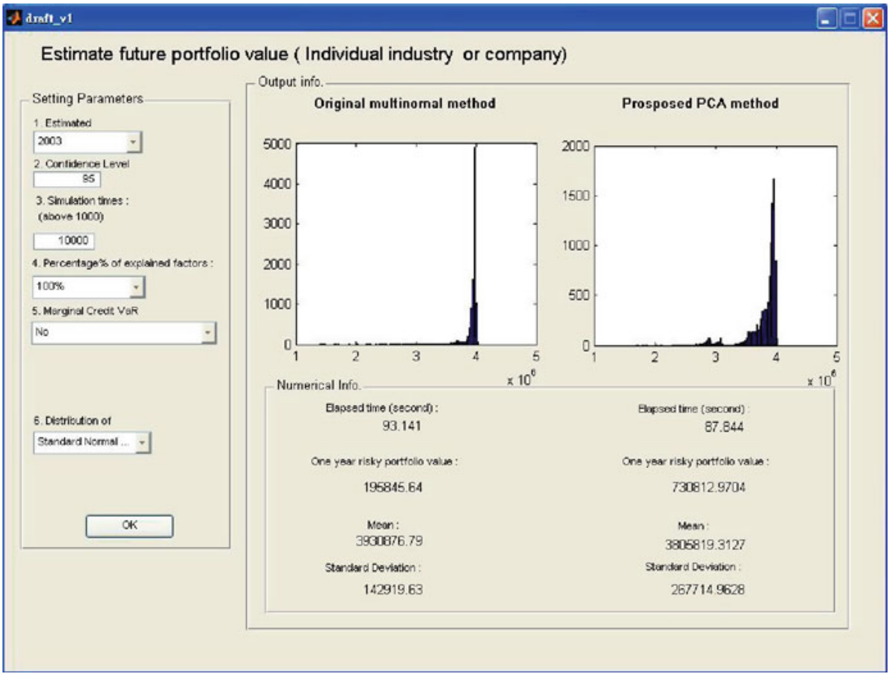

Fig. 91.7 Interface of part III

91.3.3.2 Experimental Result and Discussion

Table 91.6 represents the experimental results. For objectivity, all simulation times are set to 100,000 times which is large enough to obtain stable numerical results.[2] Based on the provided data, the 1-year future portfolio value of listed corporations on 2003 and 2004 can be estimated. In other words, standing on January 1, 2002, we can estimate the portfolio value on December 31, 2003. Or standing on January 1, 2003, we can estimate the portfolio value on December 31, 2004. The following tables listed the experimental results of factor copula methods of different factor distributions and compared with multi-normal method by CreditMetrics. The head of the tables are parameter setting, and the remained fields are experimental results. We note here the formula Eq. 91.15

$$V_i = r_{i1}y_1 + r_{i2}y_2 + \ldots + r_{im}y_m + \varepsilon_i$$

where the distribution of factors $y_1, y_2 \ldots y_m$ listed in the following table is standard normally distributed and Student t-distributed (assumes freedoms are 2, 5, and 10).

[2]We have examine the simulation times; 100,000 times is enough to have a stable computational result.

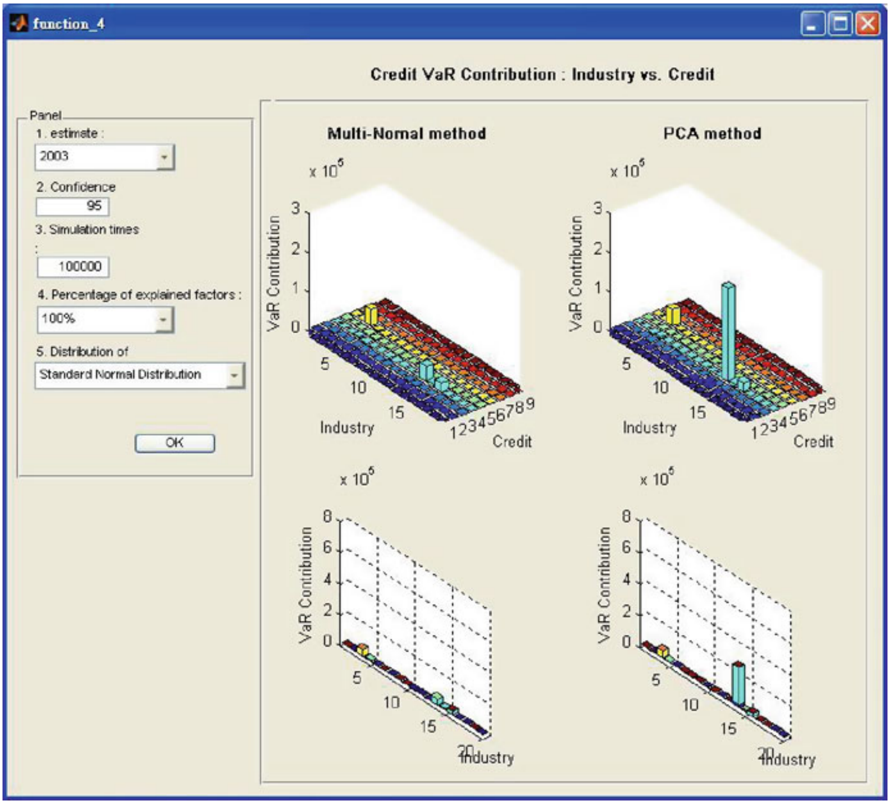

Fig. 91.8 VaR contribution of individual credits and industries

There are some messages that can be derived from the above table. First, obviously, risk of future portfolio value by multi-normal method is less than by proposed method. The risk amount of proposed method is 3–5 times over multi-normal method. This result corresponds to most research that copula function can capture the fat-tail phenomenon which prevails over practical market more adequately. Second, the distribution of future portfolio value by proposed method is more diversified than multi-normal method which concentrated on nearly 400,000 with 50,000 times while proposed method with 17,000 times. Third, it is very clear to see that risks with factors using Student's t-distribution to simulate are more than with normal distribution, and the risk amount tends toward the same while the degree of freedom becomes larger. Fourth, the mean of portfolio of proposed method is smaller than that of multi-normal method, but the standard deviation of proposed method is much more than multi-normal method. It shows that the overall possible portfolio values by proposed method have the trend to become less worth and also fluctuate more rapidly.

The above discrepancies between two methods give us some inferences. First, the proposed method provides another way to estimate more actual credit risks of

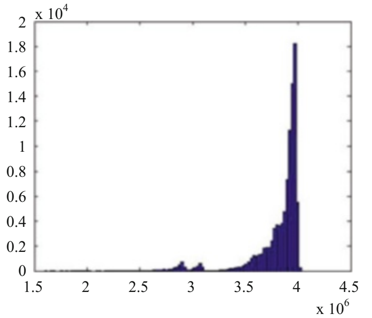
Multi-Normal method



PCA method

Table 91.7 CPU time for factor computation (simulation time: 100,000 year: 2003)

	Explained ratio (s)				
Method	100 %	90~95 %	80~85 %	70~80 %	Below 60 %
Multi-normal	2.5470	2.6090	2.2350	2.2500	2.3444
PCA	1.2030	0.7810	0.7030	0.6720	0.6090

portfolio containing risky credits through market data, and this method captures fat-tail event more notably. Second, the computation time of proposed method is shorter than multi-normal method. In Table 91.7, when using fully explained factors, computation time by proposed method is still faster than by multi-normal method. The computation time decreases as the required explained ratio is set lower.

Table 91.8 Individual credit VaR of top 5 industries

	Credit VaR	
Industry	Multi-normal method	PCA method
(No. 1) Electronics	40,341	252,980
(No. 2) Plastic	42,259	42,049
(No. 3) Transportation	22,752	22,391
(No. 4) Construction	7,011	7,007
(No. 5) Textile	2,884	2,765

Table 91.9 Estimate portfolio value at the end of 2004 with different explained level

95 % confidence level, F ~ (0,1)					
	100 %	90~95 %	80~85 %	70~80 %	60~70 %
Multi-normal	208,329.40	208,684.38	209,079.72	208,686.22	207,710.63
PCA	699,892.33	237,612.60	200,057.74	187,717.73	183,894.91

This means less numbers of factors are used for the expected explained level. Third, Table 91.8 which retrieves individual credit VaR contribution to whole portfolio from 19 industries shows that the main risk comes from electronics industry. Based on the commercial data, we find out that among its loan account entries, the electronics industry customers have the proportion of exceeding half of loan entries (63/119). The credit VaR of electronics industry computed by proposed method is six times more than by multi-normal method. This effect reveals that the multi-normal method lacks the ability to catch concentrative risks. On the contrary, based on factor structure, the mutual factor loadings extracted by the correlation among companies express more actual risks. Fourth, for finite degree of freedom, the t-distribution has fatter tails than Gaussian distribution and is known to generate tail dependence in the joint distribution.

Table 91.9 shows the impact on risk amount by using different factor numbers. According to Table 91.9, the risks decrease as the explained level decreases; this is a trade-off between time-consuming and afforded risk amount. Most research and reports say 80 % explained level is large enough to be accepted.

91.4 Conclusion

Credit risk and default correlation issues have been probed in recent research, and many solutions have been proposed. We take another view to examine credit risks and derivative tasks. On our perspective, the loan credits in target portfolio like the widely different risk characteristics from a portfolio of debt instruments and their properties and behavior are the same in the main.

In this chapter, we propose a new approach which connects the principal component analysis and copula functions to estimate credit risks of bank loan businesses. The advantage of this approach is that we do not need to specify particular copula functions to describe dependence structure among credits. On the contrary, we use a factor structure which covers market factor and idiosyncratic factor, and the computed risks have heavy-tail phenomenon. Another benefit is that it reduces the difficulties to estimate parameters which copula functions will use. This approach provides another way and has better performance than conventional method such as assume the dependence structures are normally distributed.

In order to describe the risk features and other messages that bank policymakers may like to know, we wrote a tool for risk estimation and results display. It contains basic data information preview which just downloads data from database and does some statistic analyses. It also provides different parameter settings and uses Monte Carlo simulation to calculate credit VaR and finally gives an overview of individual credit VaR contributions. The experimental results are consistent with previous studies that the risk will be underestimated compared with real risks if people assume dependence structure are normally distributed. In addition, the aforementioned approach and tool still have some rooms to be improved such as recovery rate estimations, how to chose distributions of factors, and more friendly user interface.

Instantaneous Volatility Estimation by Nonparametric Fourier Transform Methods

92

Chuan-Hsiang Han

Contents

Abstract

Malliavin and Mancino (2009) proposed a nonparametric Fourier transform method to estimate the instantaneous volatility under the assumption that the underlying asset price process is a semi-martingale. Based on this theoretical result, this chapter first conducts some simulation tests to justify the effective-ness of the Fourier transform method. Two correction schemes are proposed to improve the accuracy of volatility estimation. By means of these Fourier transform methods, some documented phenomena such as volatility daily

effect and multiple risk factors of volatility can be observed. Then, a linear hypothesis between the instantaneous volatility and VIX derived from Zhang and Zhu (2006) is investigated. We extend their result and adopt a general linear test for empirical analysis.

92.1 Introduction

Volatility estimation has been recognized as a core problem along the development of modern financial markets. There are enormous literatures devoted to this subject. The concept of "information content" is introduced to categorize a huge amount of studies. More precisely, backward and forward information contents of volatility are used and distinguished by time.

For any given time point, the backward information refers to the usage of a set of past information. A segment of historical data of an underlying risky asset, such as historical stock prices, is a typical example. In contrast, the forward information refers to the usage of financial data that contain risk exposure in the future. Financial derivatives such as futures and options are typical examples.

The backward information content of volatility is extensively investigated in the fields of financial statistics and econometrics. See Tsai (2005), Engle (2009), and references therein. The forward information content of volatility is almost exclusively studied in the field of mathematical finance and financial engineering. Within all these academic fields, parametric models play the key role to analyze financial data such as stocks and options because certain mathematical structures allow for analytic or computational assessments to relevant estimation procedures.

Relatively few results on nonparametric models can be found to analyze volatility. Dupire formula and VIX Gatheral (2006) are frontiers to compute some kinds of volatility using traded option data. Of course, these volatilities contain forward information. In the context of backward information, the dual concept of VIX, i.e., the integrated variance, is the historical volatility squared, which is defined as the variance of the standardized returns and easy to calculate. The instantaneous volatility, denoted by σ_t, can be viewed as the dual concept of Dupire formula, in which the volatility $\sigma(T, K)$ depends on the maturity T and the strike price K. Unfortunately, estimation of the instantaneous volatility is hard.

One accessible way to estimate the instantaneous volatility is taken directly from the result of a differentiation on the quadratic variation $\langle \cdot, \cdot \rangle_t$ of the underlying price process S. That is, for small $\Delta > 0$,

$$\sigma_t \approx \frac{\langle S, S\rangle_{t+\Delta} - \langle S, S\rangle_t}{\Delta}$$

This approximation is theoretically consistent but not plausible for practical implementation. One main reason is that the differentiation is sensitive to data frequency as seen from the above approximation. See Zhang and Mykland (2005) for improved methods on this direction.

Not until recently, Malliavin and Mancino (2009) proposed a Fourier transform method for estimation of the instantaneous volatility. This alternative approach is integral based, not differentiable based, as the aforementioned difference approximation. The authors claim that this approach is particularly suitable for the analysis of high-frequency time series and for the computation of cross volatilities.

However, Reno (2008) alerts that the Fourier algorithm performs badly near boundaries of estimated volatility time series data, i.e., estimated volatility of the first and last 1 % time series is not accurate enough. The author recommends discarding those volatility estimates near the boundary. Yet, this compromise may constitute a drawback in estimation. One example is that, when exclusively following Reno (2008), dropping the most recent 1 % volatility estimates will distort the prediction of a short-time volatility, say 1-day volatility.

To avoid this "boundary effect" pitfall, price correction schemes by matching the estimated volatility with observed price returns have been proposed in Han et al. (2014) and Han (2014). These schemes only require solving some regression equations derived from the maximum likelihood method so they are easy to implement. Additional advantages include (i) no loss of data observations and (ii) reduction of the volatility bias generated from the Fourier transform method.

Based on those developed Fourier transform methods to estimate the instantaneous volatility, this chapter further conducts two empirical studies as applications. The first empirical study investigates dynamic behaviors of volatility under three different sampling frequencies: high, medium, and low. In particular, the daily effect, a U shape of volatility, and evidence of multiple risk factors of volatility are observed. These observations are consistent with empirical findings in financial literatures. The second empirical study reveals the linear relationship between VIX and the instantaneous volatility. We derive a theoretical result and apply a general linear test to justify the linearity. Two datasets are used for empirical examination. They include TAIEX (January 2001–March, 2011) and S&P 500 index and its VIX (January 1990–January 2011). Data period covers both tranquil and turbulent times.

The organization of this chapter is as follows. Section 92.2 reviews the Fourier transform method and two price correction schemes, including a linear and a nonlinear correction method. Section 92.3 conducts some simulation tests for typical local and stochastic volatility models. Section 92.4 investigates the dynamic behavior of volatility under different sampling frequencies. Section 92.5 conducts a linear test for the instantaneous volatility and its VIX. Section 92.6 concludes this chapter.

92.2 Volatility Estimation: Introduction to Fourier Transform Method

Fourier transform method (Malliavin and Mancino (2009)) is a nonparametric method to estimate multivariate volatility process. Its main idea is to reconstruct volatility as time series in terms of sine and cosine basis under the following continuous semi-martingale assumption. Let u_t be the log-price of an underlying asset S at time t, i.e., $u_t = 1\text{n}\, S_t$, and follow a diffusion process

$$du_t = \mu_t dt + \sigma_t dW_t, \tag{92.1}$$

where μ_t is the instantaneous growth rate and W_t is a one-dimensional standard Brownian motion. One can estimate the time series volatility σ_t with the following steps.

- Step 1: Compute the Fourier coefficients of the underlying u_t as follows:

$$a_0(du) = \frac{1}{2\pi}\int_0^{2\pi} du_t, \tag{92.2}$$

$$a_k(du) = \frac{1}{\pi}\int_0^{2\pi} \cos(kt) du_t, \tag{92.3}$$

$$b_k(du) = \frac{1}{\pi}\int_0^{2\pi} \sin(kt) du_t, \tag{92.4}$$

  for any $k \geq 1$, so that $u(t) = a_0 + \sum_{k=1}^{\infty}\left[-\frac{b_k(du)}{k}\cos(kt) + \frac{a_k(du)}{k}\sin(kt)\right]$. Note that the original time interval [0, T] can always be rescaled to $[0, 2\pi]$ as shown in above integrals.
- Step 2: Compute the Fourier coefficients of variance σ_{t}^2 as follows:

$$a_k(\sigma^2) = \lim_{N\to\infty} \frac{\pi}{2N+1}\sum_{S=-N}^{N-k}\left[a_s^*(du)a_{s+k}^*(du) + b_s^*(du)b_{s+k}^*(du)\right] \tag{92.5}$$

$$b_k(\sigma^2) = \lim_{N\to\infty} \frac{\pi}{2N+1}\sum_{S=-N}^{N-k}\left[a_s^*(du)b_{s+k}^*(du) - b_s^*(du)a_{s+k}^*(du)\right], \tag{92.6}$$

  for $k \geq 0$, in which $a_s^*(du)$ and $b_s^*(du)$ are defined by

$$a_s^*(du) = \begin{cases} a_s(du), & if\, s > 0 \\ 0, & if\, s = 0 \\ a_{-s}(du), & if\, s < 0 \end{cases} \quad and \quad b_s^*(du) = \begin{cases} b_s(du), & if\, s > 0 \\ 0, & if\, s = 0 \\ -b_{-s}(du), & if\, s < 0. \end{cases}$$

- Step 3: Reconstruct the time series of variance σ_t^2 by

$$\sigma_t^2 = \lim_{N\to\infty} \sum_{k=0}^{N} \varphi(\delta k)\left[a_k\left(\sigma^2\right)\cos(kt) + b_k\left(\sigma^2\right)\sin(kt)\right], \tag{92.7}$$

where $\varphi(x) = \frac{\sin^2(x)}{x^2}$ is a smooth function with the initial condition $\varphi(0) = 1$ and δ is a smooth parameter typically specified as $\delta = \frac{1}{50}$ (Reno 2008).

From Eqs. 92.2, 92.3, and 92.4, it is observed that the integration error of Fourier coefficients is adversely proportional to data frequency. That is, when the data frequency gets higher, each integral becomes more accurate.

This Fourier transform method is easy to implement because, as shown in Eqs. 92.5 and 92.6, Fourier coefficients of the variance time series can be approximated by a finite sum of multiplications of a^* and b^*. This integration method can accordingly avoid drawbacks inherited from those traditional methods based on the differentiation of quadratic variation.

92.2.1 Price Correction Schemes: Bias Reduction

It is documented that this Fourier transform method incurs a "boundary effect." Reno (2008) notes that Fourier algorithm provides inaccurate estimate for volatility time series near the boundary of simulated data. He suggests that all the time series of estimated volatility near the first and last 1 % should be discarded for the purpose of better estimation. This compromise is in contrast to the Markov property, which is a key assumption in the stochastic financial theory Shreve (2000). For example, when one is about to compute the value at risk, evaluate option prices, or hedge financial derivatives, he or she may need the most updated volatility for computational tasks. Two correction schemes to remedy this boundary deficit are reviewed as follows.

Recall that u_t defined in Eq. 92.1 is the natural logarithm of asset price. Based on the Euler discretization, the increment of log-price u_t can be approximated by $\sigma_t\sqrt{\Delta_t \varepsilon_t}$. That is,

$$\Delta u_t \approx \sigma_t \sqrt{\Delta_t \varepsilon_t,} \tag{92.8}$$

where Δ_t denotes a small discretized time interval and ε_t denotes a sequence of i.i.d. standard normal random variables. This approximation is derived from neglecting the drift term of small order Δ_t and using the increment distribution of Brownian motion $\Delta W_t = \sqrt{\Delta_t \varepsilon_t,}$. Given a set of discrete observations of log returns, let $\hat{\sigma}_t$ denote the volatility time series estimated from the original Fourier transform method. Two correction schemes including nonlinear and linear correction methods have been proposed in Han et al. (2014) and Han (2014), respectively. These Fourier transform methods are effective to reduce bias of volatility estimation, known as the boundary effect.

1. **Nonlinear Correction Method**: This method consists of a linear transformation on the natural logarithm of estimated variance process $\hat{\sigma}_t^2$ in order to guarantee the positiveness of estimated volatility. That is, we transform $\hat{Y}_t = 2\ln\hat{\sigma}_t$ to $a + b\hat{Y}_t$ so that the corrected volatility $\sigma_t = \exp\left(\left(a + b\hat{Y}_t\right)/2\right) > 0$ satisfies $\Delta u_t \approx \exp\left(\left(a + b\hat{Y}_t\right)/2\right)\sqrt{\Delta_t \varepsilon_t}$, where $\Delta u_t = u_{t+1} - u_t$, and a and b denote the correction variables. This linear transformation on $\hat{Y}_t$ can be understood as the first-order approximation to a possible nonlinear transformation on estimated volatility $\hat{\sigma}_t$. Then, we can use the maximum likelihood method to regress out correction variables via the relationship between logarithm of squared standardized return $\Delta u_t/\sqrt{\Delta_t}$ and the driving volatility process $a + b\hat{Y}_t$:

$$\ln\left(\frac{\Delta u_t}{\sqrt{\Delta_t}}\right)^2 = a + b\hat{Y}_t + \ln\varepsilon_t^2. \tag{92.9}$$

2. **Linear Correction Method**: This method directly applies a linear transformation on the estimated volatility as

$$\sigma_t = a + b\hat{\sigma}_t. \tag{92.10}$$

Substituting this corrected volatility σ_t into Eq. 92.8, $\Delta u_t \approx \left(a + b\hat{\sigma}_t\right)\sqrt{\Delta t \varepsilon_t}$ is obtained. For regression purpose, we take squares on both sides, then a natural logarithm to obtain the following nonlinear equation:

$$\ln\left(\Delta u_t/\sqrt{\Delta_t}\right)^2 \approx \ln\left(a + b\hat{\sigma}_t\right)^2 + \ln{\varepsilon_t}^2.$$

We remark that there is no guarantee that the corrected volatility estimation defined in Eq. 92.10 remains positive. This is a disadvantage compared with the previous nonlinear correction method.

Note that these correction methods do not involve any model parameters, so they retain the spirit of non-parameterization.

92.3 Simulation Tests

In this section, two well-known volatility models including a local volatility model and a stochastic volatility model are considered for simulation studies in order to justify effectiveness of these Fourier transform methods.

92.3.1 Case I: Local Volatility Model

A local volatility model of the following form

$$dS_t = \alpha(m - S_t)dt + \beta S_t^{\gamma} dw_t$$

is employed. Model parameters are taken from Jiang (1998) based on the following estimation result: $\alpha = 0.093$, $m = 0.079$, $\beta = 0.794$, and $\gamma = 1.474$. A simulation procedure is used to generate sample processes of the price S_t and its volatility $\sigma_t = \beta S_t^{\gamma}$. This simulation is done by the Euler discretization with time step size $\Delta_t = 1/250$, and the total sample number is 5,000.

Based on the original Fourier transform method and two proposed price correction schemes, three volatility time series can be estimated. These are compared with the actual volatility series generated from the local volatility model. Criteria for error measurements include mean squared error (MSE) and maximum absolute error (MAE). Comparison results are shown below:

1. MSE: 7.52E-04 (original Fourier method), 1.19E-05 (nonlinear correction method), and 7.61E-06 (linear correction method)
2. MAE: 0.04 (original Fourier method), 0.02 (nonlinear correction method), and 0.01 (linear correction method)

Price correction methods are effective to reduce both error criteria at least by half in this simulated example. Other vast simulation studies also show similar results of bias reduction.

92.3.2 Case II: Stochastic Volatility Model

Stochastic volatility models often possess the mean-reverting property. Among various models, the Ornstein-Uhlenbeck process is often taken as the driving one-factor volatility model, which is also known as the exp-OU model in finance. It is defined as

$$\left\{ \begin{array}{c} dS_t = \mu S_t dt + \exp(Y_t/2) S_t dW_{1t}, \\ dY_t = \alpha(m - Y_t)dt + \beta dW_{2t}, \end{array} \right\} \tag{92.11}$$

where S_t denotes the underlying risky asset price, μ the return rate, and W_{1t} and W_{2t} are two correlated Brownian motions. The volatility process σ_t is defined as $\exp(Y_t/2)$, m denotes the long-run mean, α denotes the rate of mean reversion, β denotes the vol-vol (volatility of volatility), and Y_t denotes the Ornstein-Uhlenbeck process. Model parameters are set as follows: $\mu = 0.01$, $S_0 = 50$, $Y_0 = -2$, $m = -2$, $\alpha = 5$, $\beta = 1$, and $\rho = 0$. To simulate sample processes, the time discretization is set as $\Delta_t = 1/5{,}000$ and the total number of samples is 5,000.

The procedure to conduct our simulation study is as follows. First, time series of volatility $\sigma_t = \exp(Y_t/2)$ and the asset price S_t are simulated. Using the original Fourier transform method and the nonlinear correction method, two volatility time series are estimated to compare with the true volatility time series. Comparison results are as follows:

1. Mean squared error: 0.0324 (original FTM), 0.0025 (corrected FTM)
2. Maximum absolute error: 0.3504 (original FTM), 0.1563 (corrected FTM)

From these simulated results, over a half of errors are reduced by the corrected FTM. Similar reduction can also be found among a vast of simulations. It is worth noting that the employed nonlinear correction method is based on the maximum likelihood method, which is fairly easy to compute numerically.

This section conducted simulation tests for two corrected Fourier transform methods for the instantaneous volatility estimation. It is observed that those methods can effectively reduce bias generated from the truncation errors of the original Fourier transform method. Next, we apply these methods to analyze volatility of indices such as S&P 500 in the USA and TAIEX (Taiwan Stock Exchange Capitalization Weighted Stock Index) in Taiwan.

92.4 Volatility Estimation Under Different Sampling Frequencies

92.4.1 Volatility Daily Effect

It is well documented that volatility demonstrates a daily effect under the high sampling frequency. This effect causes a pattern of U shape on volatility, which is often observed from intraday data. TAIEX, complied by Taiwan Stock Exchange, is updated every 15 s and publically available. Such easy access to the data enables an exploration of the daily effect. The sampled data period is from February 10 to 15 for four consecutive trading days in 2011. In Fig. 92.1, the bottom line, labeled as vol with magnitude on the left Y-axis, shows four U shapes of the instantaneous volatility. Using an average-type deseasoning technique, see Wild and Seber (1999), time series of deseasoned volatility, labeled as Vol_Deseasoned with magnitude on the right Y-axis, is shown in the middle part of that figure. This deseasoned volatility is often used to measure the actual activity of volatility.

92.4.2 Multiple Risk Factors of Volatility

From the statistical point of view, volatility is a latent variable, and its estimation causes a lot of attentions during the last two decades. See review papers of Broto and Ruiz (2004), Molina et al. (2010), Yu (2010), and references therein.

In virtue of the nonparametric Fourier transform method, volatility is represented as a Fourier transformation of the underlying asset prices, which can be calculated but is subject to some truncation errors. Then given such estimation modified by our correction schemes, one can further investigate parameters given a prescribed model. Therefore, a new approach to estimate the exp-OU stochastic volatility model parameters can be given as follows:

Step 1: Use a corrected Fourier transform method to estimate the instantaneous volatility $\hat{\sigma}_t$. By taking a natural logarithm $\hat{Y}_t = 2\ln\hat{\sigma}_t$, the time series of the driving volatility OU becomes available.

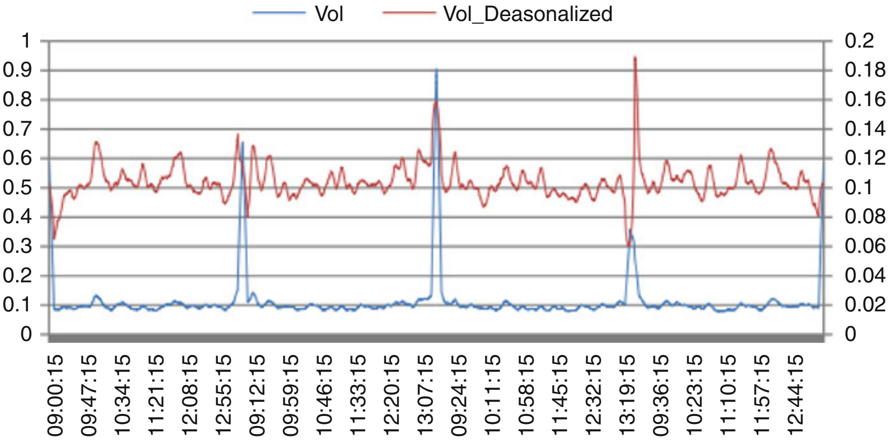

Fig. 92.1 2011/02/10~2011/02/15 TAIEX's estimated Ivol (every 15 s)

Step 2: Discretize the OU process and use the maximum likelihood method to estimate three parameters with the OU process. Detailed description can be found in Han et al. (2014), but estimators for parameters defined in Eq. 92.11 are given below:

$$\hat{\alpha} = \frac{1}{\Delta_t}\left[1 - \frac{\left(\sum_{t=2}^{N}\hat{Y}_t\right)\left(\sum_{t=1}^{N-1}\hat{Y}_t\right) - (N-1)\left(\sum_{t=1}^{N-1}\hat{Y}_t\hat{Y}_{t+1}\right)}{\left(\sum_{t=1}^{N-1}\hat{Y}_t\right)^2 - (N-1)\left(\sum_{t=1}^{N-1}\hat{Y}_t^2\right)}\right],$$

$$\hat{\beta} = \sqrt{\frac{1}{(N-1)\Delta_t}\sum_{t=1}^{N-1}\left[\hat{Y}_{t+1} - \left(\hat{\alpha}\, m\Delta_t + (1-\hat{\alpha}\,\Delta_t)\hat{Y}_t\right)\right]^2},$$

$$\hat{m} = \frac{-1}{\hat{\alpha}\Delta_t}\left[\frac{\left(\sum_{t=2}^{N}\hat{Y}_t\right)\left(\sum_{t=1}^{N-1}\hat{Y}_t^2\right) - \left(\sum_{t=1}^{N-1}\hat{Y}_t\right)\left(\sum_{t=1}^{N-1}\hat{Y}_t\hat{Y}_{t+1}\right)}{\left(\sum_{t=1}^{N-1}\hat{Y}_t\right)^2 - (N-1)\left(\sum_{t=1}^{N-1}\hat{Y}_t^2\right)}\right].$$

These estimators are employed to estimate model parameters under three different sampling frequencies, i.e., high (5 months_1 day, 5-min data for one trading day), medium (1 day_2 years, daily data for 2 years), and low (1 week_10 years, weekly data for 10 years). Parameter m, the long-run mean, is referred as the risk level of volatility. Figure 92.2 illustrates its estimation from January 3 to March 31 of 2011. To be more precise, for any given date, we use historical data of 1 day, 2 years, and 10 years separately, then adopt the M estimator for parameter m under

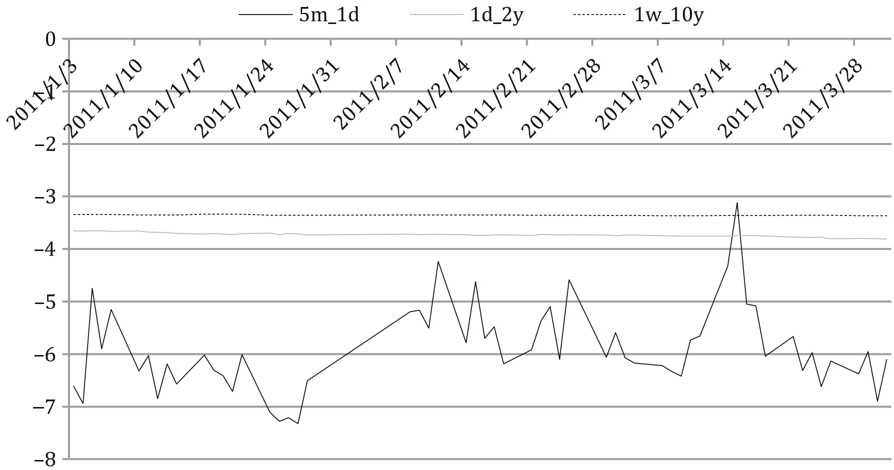

Fig. 92.2 2011/01/03~2011/03/31 long-run mean (m) of the exp-OU stochastic volatility model

these three different frequencies. Our dataset is TAIEX and the data resource is from Taiwan Stock Exchange.

Two other model parameters which include rate of mean reversion α and vol-vol β are related to invariance property of time scales. See Fouque et al. (2000) for detailed discussions.

From Table 92.1, both mean-reverting rate α and vol-vol β are proportional to data sampling frequency. That is, the higher the data frequency, the larger those parameter sizes are. Note that those parameters are well separated, especially the rate of mean reversion. These estimations show a strong evidence of multiple time scales on volatility.

92.5 Hypothesis of Linearity Between the Instantaneous Volatility and VIX

VIX (Volatility Index) is complied by Chicago Board Options Exchange (CBOE). Its formula is mainly based on out-of-money S&P 500 index options with weights depending on the corresponding strike prices. The full definition and formula can be found on Hull (2008) or the VIX white paper published by CBOE.[1] VIX is often used to measure an aggregated risk exposure in the next 30 calendar days. Hence, the information content of VIX is forward, as opposed to its dual backward information content of volatility, i.e., the 30-day historical volatility.

[1]www.cboe.com/micro/vix/vixwhite.pdf

Table 92.1 Model parameter estimations under different data frequencies

	α	(α _ std)	β	(β _ std)
5 months_1 day	11,661.39	(2,681.39)	114.83	(14.70)
1 day _ 2 years	23.81	(2.08)	6.29	(0.27)
1 week _ 10 years	2.62	(0.17)	2.18	(0.07)

In addition, due to a strong negative correlation with the S&P 500 index, VIX is popularly used as a fear gauge.

92.5.1 Theoretical Result

Zhang and Zhu (2006) obtained a linear relationship between the VIX squared and the square of the instantaneous volatility under the Heston model Heston (1993). This result is based on the following derivation. Under a risk-neutral probability measure, the instantaneous variance V_s is assumed to follow a square root process

$$dV_s = [\alpha m - (\alpha + \lambda)V_s]dt + \beta\sqrt{V_s dW_s},$$

where m denotes the long-run mean, α the rate of mean reversion, β the variance of variance, W_s the standard Brownian motion, and λ the volatility risk premium under the probability measure change. Taking mathematical expectations to the previous stochastic differential equation on both sides, we obtain

$$dE_t[V_s] = \alpha m - (\alpha + \lambda)E_t[V_s]dt. \tag{92.12}$$

This is because an exchange of integral and differential is assumed, and the expectation (conditioned at time t) over the Brownian motion term is zero. The notation $E_t[.]$ means a conditional expectation given the filtration at time t under a risk-neutral probability measure.

Equation 92.10 is a linear ordinary equation, and its solution is given as

$$E_t[V_s] = \frac{\alpha m}{\alpha + \lambda} + \left(V_t - \frac{\alpha m}{\alpha + \lambda}\right)e^{-(\alpha+\lambda)(s-t)}.$$

Since VIX^2 can also be defined as a variance swap rate Hull (2008), one can evaluate it by its definition

$$\begin{aligned} VIX_t^2 &= E_t\left[\frac{1}{\tau_0}\int_t^{t+\tau_0} V_s ds\right] \\ &= \frac{1}{\tau_0}\int_t^{t+\tau_0} E_t(V_s)ds, \end{aligned}$$

where τ_0 is defined by $\frac{30}{365}$. In summary, under the Heston model, a linear relationship between VIX^2 and the instantaneous variance V_t is deduced by

$$VIX_t^2 = A + BV_t,$$

where constant coefficients are

$$A = \frac{\alpha\, m}{\alpha+\lambda}\left[1 - \frac{1-e^{-(\alpha+\lambda)\tau_0}}{(\alpha+\lambda)\tau_0}\right], \quad B = \frac{1-e^{-(\alpha+\lambda)\tau_0}}{(\alpha+\lambda)\tau_0}.$$

Next, we generalize this result to a more general class of models, within which the long-run mean m and vol-vol β can be time dependent but deterministic. Even under his larger model class, we still can derive and obtain a linear relationship between VIX square and the instantaneous variance.

Theorem 1 Assume that the instantaneous variance σ_t follows a mean-reverting process

$$d\sigma_t = \alpha(m(t) - \sigma_t)dt + g(\sigma_t)dW_t, \tag{92.13}$$

where functions m and g exist such that the classical assumption of stochastic differential equations (see Oksendal (1998)) is satisfied. A linear relationship between VIX square and the instantaneous variance

$$VIX_t^2 = A + B\sigma_t^2,$$

where $A = -\frac{1}{\tau}\int_0^\tau\int_0^t e^{2\alpha(s-t)}h(s)dsdt$ and $B = \frac{1}{2\alpha\tau}\left(e^{2\alpha\tau} - 1\right)$.

Proof Apply Ito's Lemma to σ_t^2 to obtain

$$d\sigma_t^2 = \left(2\alpha m(t)\sigma_t - 2\alpha\sigma_t^2 + g^2(\sigma_t)\right)dt + 2\sigma_t g(\sigma_t)dW_t.$$

Then, take a mathematical expectation over both sides

$$dE\left[\sigma_t^2\right] = \left(-2\alpha E\left[\sigma_t^2\right] + h(t)\right)dt, \tag{92.14}$$

where $h(t) = E\lfloor 2\alpha m(t)\sigma_t + g^2(\sigma_t)\rfloor$ is a time-dependent deterministic function. This equation is known as the linear ordinary differential equation with an inhomogeneous term. The unique solution is given by

$$E\left[\sigma_t^2\right] = \sigma_0^2 e^{2\alpha t} - \int_0^t e^{2\alpha(s-t)}h(s)ds,$$

and VIX^2 defined as $VIX_0^2 = \frac{1}{\tau}\int_0^\tau E\sigma_t^2 dt = A + B\sigma_0^2$. Coefficients are $A = -\frac{1}{\tau}\int_0^\tau\int_0^t e^{2\alpha(s-t)}h(s)dsdt$ and $B = \frac{1}{2\alpha\tau}\left(e^{2\alpha\tau} - 1\right)$.

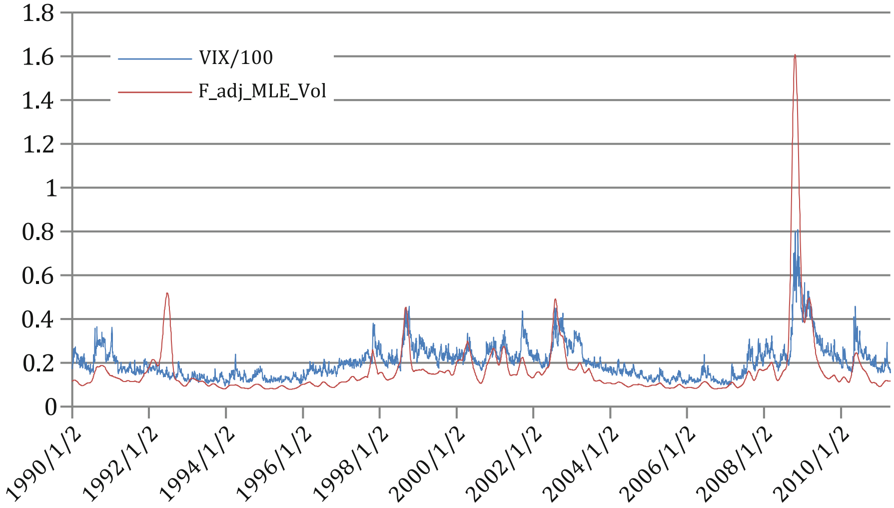

Fig. 92.3 Daily VIX, denoted by VIX/100, and the estimated instantaneous volatility, denoted by F_adj_MLE_Vol, of S&P 500 index within the time period from January 2, 1990, to January 31, 2011

92.5.2 Empirical Results

The previous theorem advocates a linear relationship between the VIX squared and the instantaneous variance. No empirical analysis on this theoretical result is found to our best knowledge. The reason may come from the fact that estimation for the instantaneous variance was difficult. In virtue of the corrected Fourier transform methods, one can estimate time series σ_t^2. Daily VIX and the estimated instantaneous volatility of S&P 500 index within the time period from January 2, 1990, to January 31, 2011, are shown in Fig. 92.3. Our data resource is from Yahoo! Finance.

We adopt the general linear test approach, see Kutner et al. (2005), to examine the linear relationship between VIX^2 and the instantaneous variance σ^2. Assuming that the null hypothesis is

$$\begin{cases} H_0 : \beta_1 = 0, \\ H_1 : \beta_1 \neq 0. \end{cases}$$

and the alternative is $Y_i = \beta_0 + \beta_1 X_i + \varepsilon_i$, one can use the least squares method to obtain the sum of squared errors, denoted by $SSE(F)$, which is chi-square distributed with the degree of freedom (n-2) and denoted by df_F. Similarly under the null hypothesis, the model is assumed to be $Y_i = \beta_O + \varepsilon_i$, and the sum of squared errors, denoted by $SSE(R)$, which is also chi-square distributed with the degree of freedom (n-1), denoted by df_R. The F statistic is defined by

$$F^* = \frac{\frac{SSE(R)-SSE(F)}{df_R - df_F}}{\frac{SSE(F)}{df_F}} \sim F(1-\alpha, df_R - df_F, df_F),$$

where the confidence level is $(1 - \alpha)$. Our data size is $n = 1{,}091$ and estimated linear equation is

$$\text{VIX\_2} = 0.039342 + 0.180687\text{V}.$$

Given the significance level alpha = 1 %, the value of F statistic is equal to 6192.8 > F(0.99, 1, n − 2) = 6.639621 so that the null is rejected.

92.6 Concluding Remarks and Future Works

This chapter presents methods of nonparametric Fourier transform for estimating the instantaneous volatility in one dimension. Based on these results, we conduct simulation tests for a local model and a stochastic volatility model and two empirical studies. They include (1) volatility behaviors under different sampling frequencies and (2) linear hypothesis between the instantaneous volatility and VIX.

As a matter of fact, this method can be used for high-dimensional case. That allows for estimating dynamic volatility matrices. As a result, this whole approach may be suitable to study subjects of portfolio risk management, systemic risk analysis, etc. We leave these as future works.

Abstract

Breeden (1979) and Grinols (1984) and Cox et al. (1985) have described the importance of supply side for the capital asset pricing. Black (1976) derives a dynamic, multiperiod CAPM, integrating endogenous demand and supply. However, Black's theoretically elegant model has never been empirically tested for its implications in dynamic asset pricing. We first theoretically extend Black's CAPM. Then, we use price, dividend per share, and earnings per share to test the existence of supply effect with US equity data. We find the supply effect is important in US domestic stock markets. This finding holds as we break the companies listed in the S&P 500 into ten portfolios by different level of payout ratio. It also holds consistently if we use individual stock data.

A simultaneous equation system is constructed through a standard structural form of a multiperiod equation to represent the dynamic relationship between supply and demand for capital assets. The equation system is exactly identified under our specification. Then, two hypotheses related to supply effect are tested regarding the parameters in the reduced form system. The equation system is estimated by the seemingly unrelated regression (SUR) method, since SUR allow one to estimate the presented system simultaneously while accounting for the correlated errors.

CAPM • Asset • Endogenous supply • Simultaneous equations • Reduced form • Seemingly unrelated regression (SUR) • Exactly identified • Cost of capital • Quadratic cost • Partial adjustment

93.1 Introduction

Breeden (1979) and Grinols (1984) and Cox et al. (1985) have described the importance of supply side for the capital asset pricing. Cox et al. (1985) study a restricted technology to allow them to explicitly solve their model for reduced form. Grinols (1984) focuses on describing market optimality and supply decisions which guide firms in incomplete markets in the absence of investor unanimity. Black (1976) extends the static CAPM by Sharpe (1964), Litner (1965), and Mossin (1966) explicitly allowing for the endogenous supply effect of risky securities to derive the dynamic asset pricing model.[1] Black modifies the static model by explicitly allowing for the existence of the supply effect of risky securities. In addition, the demand side for the risky securities is derived from a negative exponential function for the investor's utility of wealth. Black finds that the static

[1]This dynamic asset pricing model is different from Merton's (1973) intertemporal asset pricing model in two key aspects. First, Black's model is derived in the form of simultaneous equations. Second, Black's model is derived in terms of price change, and Merton's model is derived in terms of rates of return.

CAPM is unnecessarily restrictive in its neglect of the supply side and proposes that his dynamic generalization of the static CAPM can provide the basis for many empirical tests, particularly with regard to the intertemporal aspects and the role of the endogenous supply side. Assuming that there is a quadratic cost structure of retiring or issuing securities and that the demand for securities may deviate from supply due to anticipated and unanticipated random shocks, Black concludes that if the supply of a risky asset is responsive to its price, large price changes will be spread over time as specified by the dynamic capital asset pricing model. One important implication in Black's model is that the efficient market hypothesis holds only if the supply of securities is fixed and independent of current prices. In short, Black's dynamic generalization model of static wealth-based CAPM adopts an endogenous supply side of risky securities by setting equal quantity demanded and supplied of risky securities. Lee and Gweon (1986) extend Black's framework to allow time-varying dividend payments and then test the existence of supply effect in the situation of market equilibrium. Their results reject the null hypothesis of no supply effect in the US domestic stock market. The rejection seems to imply a violation of efficient market hypothesis in the US stock market.

It is worth noting that some recent studies also relate return on portfolio to trading volume (e.g., Campbell et al. 1993; Lo and Wang 2000). Surveying the relationship between aggregate stock market trading volume and the serial correlation of daily stock returns, (Campbell et al. 1993) suggest that a stock price decline on a high-volume day is more likely than a stock price decline on a low-volume day. They propose an explanation that trading volume occurs when random shifts in the stock demand of non-informational traders are accommodated by the risk-averse market makers. Lo and Wang (2000) also examine the CAPM in the intertemporal setting. They derive an intertemporal CAPM (ICAPM) by defining preference for wealth instead of consumption, by introducing three state variables into the exponential types of investor's preference as we do in this paper. This state-dependent utility function allows one to capture the dynamic nature of the investment problem without explicitly solving a dynamic optimization problem. Thus, the marginal utility of wealth depends not only on the dividend of the portfolio but also on future state variables. This dependence introduces dynamic hedging motives in the investors' portfolio choices. That is, this dependence induces investors to care about future market conditions when choosing their portfolio. In equilibrium, this model also implies that an investor's utility depends not only on his wealth but also on the stock payoffs directly. This "market spirit," in their terminology, affects investor's demand for the stocks. In other words, for even the investor who holds no stocks, his utility fluctuates with the payoffs of the stock index.

Black (1976), Lee and Gweon (1986), and Lo and Wang (2000) develop models by using either outstanding shares or trading volumes as variables to connect the decisions in two different periods, unlike consumption-based CAPM which uses consumption or macroeconomic information. Black (1976) and Lee and Gweon (1986) both derive the dynamic generalization models from the wealth-based CAPM by adopting an endogenous supply schedule of risky securities.[2] Thus, the information of quantities demanded and supplied can now play a role in determining the asset price. This proposes a wealth-based model as an alternative method to investigate intertemporal CAPM.

In this chapter, we first theoretically extend the Black's dynamic, simultaneous CAPM to be able to test the existence of the supply effect in the asset pricing determination process. We use two datasets of price per share and dividend per share to test the existence of supply effect with US equity data. The first dataset consists most companies listing in the S&P 500 of the US stock market. The second dataset is the companies listed in the Dow Jones Index. In this study, we find the supply effect is important in the US stock market. This finding holds as we break the companies listed in the S&P 500 into ten portfolios. It also holds if we use individual stock data. For example, the existence of supply effect holds consistently in most portfolios if we test the hypotheses by using individual stock as many as 30 companies in one group. We also find that one cannot reject the existence of supply effect by using the stocks listed in the Dow Jones Index.

This chapter is structured as follows. In Sect. 93.2, a simultaneous equation system of asset pricing is constructed through a standard structural form of a multiperiod equation to represent the dynamic relationship between supply and demand for capital assets. The hypotheses implied by the model are also presented in this section. Section 93.3 describes the two sets of data used in this paper. The empirical finding for the hypotheses and tests constructed in previous section is then presented. Our summary is presented in Sect. 93.4.

93.2 Development of Multiperiod Asset Pricing Model with Supply Effect

Based on the framework of Black (1976), we derive a multiperiod equilibrium asset pricing model in this section. Black modifies the static wealth-based CAPM by explicitly allowing for the endogenous supply effect of risky securities. The demand for securities is based on the well-known model of James Tobin (1958) and Harry Markowitz (1959). However, Black further assumes a quadratic cost function of changing short-term capital structure under long-run optimality condition. He also assumes that the demand for security may deviate from supply due to anticipated and unanticipated random shocks.

Lee and Gweon (1986) modify and extend Black's framework to allow time-varying dividends and then test the existence of supply effect. In Lee and Gweon's model, two major differing assumptions from Black's model are: (1) the model allows for time-varying dividends, unlike Black's assumption constant dividends,

[2]It should be noted that Lo and Wang's model did not explicitly introduce the supply equation in asset pricing determination. Also, one can identify the hedging portfolio using volume data in the Lo and Wang model setting.

and (2) there is only one random, unanticipated shock in the supply side instead of two shocks, anticipated and unanticipated shocks, as in Black's model. We follow the Lee and Gweon set of assumptions. In this section, we develop a simultaneous equation asset pricing model. First, we derive the demand function for capital assets, then we derive the supply function of securities. Next, we derive the multiperiod equilibrium model. Thirdly, the simultaneous equation system is developed for testing the existence of supply effects. Finally, the hypotheses of testing supply effect are developed.

93.2.1 The Demand Function for Capital Assets

The demand equation for the assets is derived under the standard assumptions of the CAPM.[3] An investor's objective is to maximize their expected utility function. A negative exponential function for the investor's utility of wealth is assumed:

$$U = a - h \times e^{\{-bW_{t+1}\}}, \tag{93.1}$$

where the terminal wealth $W_{t+1} = W_t(1 + R_t)$; W_t is initial wealth; and R_t is the rate of return on the portfolio. The parameters a, b, and h are assumed to be constants.

The dollar returns on N marketable risky securities can be represented by

$$X_{j,\ t+1} = P_{j,\ t+1} - P_{j,\ t} + D_{j,\ t+1},\ j = 1, \ldots, N, \tag{93.2}$$

where
$P_{j,\ t+1}$ = (random) price of security j at time t + 1
$P_{j,\ t}$ = price of security j at time t
$D_{j,\ t+1}$ = (random) dividend or coupon on security at time t + 1

These three variables are assumed to be jointly normally distributed. After taking the expected value of Eq. 93.2 at time t, the expected returns for each security, $x_{j,\ t+1}$, can be rewritten as

$$x_{j,t+1} = E_t X_{j,t+1} = E_t P_{j,t+1} - P_{j,t} + E_t D_{j,t+1}, \quad j = 1, \ldots, N, \tag{93.3}$$

where

$$\begin{aligned} E_t P_{j,t+1} &= E\left(P_{j,t+1} | \Omega_t\right) \\ E_t D_{j,t+1} &= E\left(D_{j,t+1} | \Omega_t\right) \\ E_t X_{j,t+1} &= E\left(X_{j,t+1} | \Omega_t\right) \end{aligned}$$

Ω_t is the given information available at time t.

[3]The basic assumptions are as follows: (1) a single period moving horizon for all investors; (2) no transaction costs or taxes on individuals; (3) the existence of a risk-free asset with rate of return, r*; (4) evaluation of the uncertain returns from investments in terms of expected return and variance of end-of-period wealth; and (5) unlimited short sales or borrowing of the risk-free asset.

Then, a typical investor's expected value of end-of-period wealth is

$$w_{t+1} = E_t W_{t+1} = W_t + r^* \left(W_t - q_{t+1}{}' P_t \right) + q_{t+1}{}' x_{t+1}, \tag{93.4}$$

where
$P_t = (P_{1,\,t}, P_{2,\,t}, P_{3,\,t}, \ldots, P_{N,\,t})'$
$x_{t+1} = (x_{1,\,t+1}, x_{2,\,t+1}, x_{3,\,t+1}, \ldots, x_{N,\,t+1})' = E_t P_{t+1} - P_t + E_t D_{t+1}$
$q_{t+1} = (q_{1,\,t+1}, q_{2,\,t+1}, q_{3,\,t+1}, \ldots, q_{N,\,t+1})'$
$q_{j,t+1}$ = number of units of security j after reconstruction of his portfolio
r^* = risk-free rate

In Eq. 93.4, the first term on the right hand side is the initial wealth, the second term is the return on the risk-free investment, and the last term is the return on the portfolio of risky securities. The variance of W_{t+1} can be written as

$$V(W_{t+1}) = E(W_{t+1} - w_{t+1})(W_{t+1} - w_{t+1})' = q_{t+1}{}' S q_{,\,t+1}, \tag{93.5}$$

where $S = E(X_{t+1} - x_{t+1})(X_{t+1} - x_{t+1})'$ = the covariance matrix of returns of risky securities.

Maximization of the expected utility of W_{t+1} is equivalent to:

$$\text{Max } w_{t+1} - \frac{b}{2} V(W_{t+1}), \tag{93.6}$$

By substituting Eqs. 93.4 and 93.5 into Eq. 93.6, Eq. 93.6 can be rewritten as:

$$\text{Max}(1 + r^*) W_t + q_{t+1}{}'(x_{t+1} - r^* P_t) - (b/2) q_{t+1}{}' S q_{t+1.} \tag{93.7}$$

Differentiating Eq. 93.7, one can solve the optimal portfolio as:

$$q_{t+1} = b^{-1} S^{-1} (x_{t+1} - r^* P_t). \tag{93.8}$$

Under the assumption of homogeneous expectation, or by assuming that all the investors have the same probability belief about future return, the aggregate demand for risky securities can be summed as:

$$Q_{t+1} = \sum_{k=1}^{m} q_{t+1}^{k} = cS^{-1}[E_t P_{t+1} - (1 + r^*) P_t + E_t D_{t+1}], \tag{93.9}$$

where $c = \Sigma(b^k)^{-1}$.

In the standard CAPM, the supply of securities is fixed, denoted as Q^*. Then, Eq. 93.9 can be rearranged as $P_t = (1/r^*)(x_{t+1} - c^{-1} S Q^*)$, where c^{-1} is the market price of risk. In fact, this equation is similar to the Lintner's (1965) well-known equation in capital asset pricing.

93.2.2 Supply Function of Securities

An endogenous supply side to the model is derived in this section, and we present our resulting hypotheses, mainly regarding market imperfections. For example, the existence of taxes causes firms to borrow more since the interest expense is tax-deductible. The penalties for changing contractual payment (i.e., direct and indirect bankruptcy costs) are material in magnitude, so the value of the firm would be reduced if firms increase borrowing. Another imperfection is the prohibition of short sales of some securities.[4] The costs generated by market imperfections reduce the value of a firm, and, thus, a firm has incentives to minimize these costs. Three more related assumptions are made here. First, a firm cannot issue a risk-free security; second, these adjustment costs of capital structure are quadratic; and third, the firm is not seeking to raise new funds from the market.

It is assumed that there exists a solution to the optimal capital structure and that the firm has to determine the optimal level of additional investment. The one-period objective of the firm is to achieve the minimum cost of capital vector with adjustment costs involved in changing the quantity vector, $\mathrm{Q}_{\mathrm{i,\ t+1}}$:

$$\begin{aligned}&\text{Min } \mathrm{E_t}D_{\mathrm{i,t+1}}\mathrm{Q}_{\mathrm{i,t+1}} + (1/2)\left(\Delta\mathrm{Q}_{\mathrm{i,t+1}}{}'\mathrm{Ai}\Delta\mathrm{Q}_{\mathrm{i,t+1}}\right),\\ &\text{subject to} P_{\mathrm{i,t}}\Delta\mathrm{Q}_{\mathrm{i,t+1}} = 0,\end{aligned} \tag{93.10}$$

where $\mathrm{A_i}$ is a $\mathrm{n_i} \times \mathrm{n_i}$ positive-definite matrix of coefficients measuring the assumed quadratic costs of adjustment. If the costs are high enough, firms tend to stop seeking raise new funds or retire old securities. The solution to Eq. 93.10 is

$$\Delta\mathrm{Q}_{\mathrm{i,t+1}} = \mathrm{A_i}^{-1}\left(\lambda_{\mathrm{i}}P_{\mathrm{i,t}} - \mathrm{E_t}D_{\mathrm{i,t+1}}\right), \tag{93.11}$$

where λ_i is the scalar Lagrangian multiplier.

Aggregating Eq. 93.11 over N firms, the supply function is given by

$$\Delta\mathrm{Q}_{\mathrm{t+1}} = \mathrm{A}^{-1}(\mathrm{B}P_{\mathrm{t}} - \mathrm{E_t}D_{\mathrm{t+1}}), \tag{93.12}$$

where $A^{-1} = \begin{bmatrix} A_1^{-1} & & & \\ & A_2^{-1} & & \\ & & \ddots & \\ & & & A_N^{-1} \end{bmatrix}$, $B = \begin{bmatrix} \lambda_1 I & & & \\ & \lambda_2 I & & \\ & & \ddots & \\ & & & \lambda_N I \end{bmatrix}$, and

$$Q = \begin{bmatrix} Q_1 \\ Q_2 \\ \vdots \\ Q_N \end{bmatrix}.$$

[4]Theories as to why taxes and penalties affect capital structure are first proposed by Modigliani and Miller (1958) and then Miller (1977). Another market imperfection, prohibition on short sales of securities, can generate "shadow risk premiums" and, thus, provide further incentives for firms to reduce the cost of capital by diversifying their securities.

Equation 93.12 implies that a lower price for a security will increase the amount retired of that security. In other words, the amount of each security newly issued is positively related to its own price and is negatively related to its required return and the prices of other securities.

93.2.3 Multiperiod Equilibrium Model

The aggregate demand for risky securities presented by Eq. 93.9 can be seen as a difference equation. The prices of risky securities are determined in a multiperiod framework. It is also clear that the aggregate supply schedule has similar structure. As a result, the model can be summarized by the following equations for demand and supply, respectively:

$$\mathrm{Q}_{t+1} = \mathrm{cS}^{-1}(\mathrm{E}_t P_{t+1} - (1 + \mathrm{r}^*)P_t + \mathrm{E}_t D_{t+1}), \tag{93.9}$$

$$\Delta\mathrm{Q}_{t+1} = \mathrm{A}^{-1}(\mathrm{B}P_t - \mathrm{E}_t D_{t+1}). \tag{93.12}$$

Differencing Eq. 93.9 for period t and t+1 and equating the result with Eq. 93.12, a new equation relating demand and supply for securities is

$$\mathrm{cS}^{-1}[\mathrm{E}_t P_{t+1} - \mathrm{E}_{t-1}P_t - (1 + \mathrm{r}^*)(P_t - P_{t-1}) + \mathrm{E}_t D_{t+1} - \mathrm{E}_{t-1}D_t] = \mathrm{A}^{-1}(\mathrm{B}P_t - \mathrm{E}_t D_{t+1}) + \mathrm{V}_t, \tag{93.13}$$

where V_t is included to take into account the possible discrepancies in the system. Here, V_t is assumed to be random disturbance with zero expected value and no autocorrelation.

Obviously, Eq. 93.13 is a second-order system of stochastic differential equation in P_t and conditional expectations $\mathrm{E}_{t-1}P_t$ and $\mathrm{E}_{t-1}D_t$. By taking the conditional expectation at time t−1 on Eq. 93.13, and because of the properties of $\mathrm{E}_{t-1}[\mathrm{E}_t P_{t+1}] = \mathrm{E}_{t-1}P_{t+1}$ and $\mathrm{E}_{t-1}\mathrm{E}(\mathrm{V}_t) = 0$, Eq. 93.13 becomes

$$\begin{aligned}&\mathrm{cS}^{-1}[\mathrm{E}_{t-1}P_{t+1} - \mathrm{E}_{t-1}P_t - (1 + \mathrm{r}^*)(\mathrm{E}_{t-1}P_t - P_{t-1}) + \mathrm{E}_{t-1}D_{t+1} - \mathrm{E}_{t-1}D_t]\\ &= \mathrm{A}^{-1}(\mathrm{B}\mathrm{E}_{t-1}P_t - \mathrm{E}_{t-1}D_{t+1}).\end{aligned} \tag{93.13$'$}$$

Subtracting Eq. 93.13′ from Eq. 93.13,

$$\begin{aligned}&\left[(1 + \mathrm{r}^*)\mathrm{cS}^{-1} + \mathrm{A}^{-1}\mathrm{B}\right](P_t - \mathrm{E}_{t-1}P_t) = \mathrm{cS}^{-1}(\mathrm{E}_t P_{t+1} - \mathrm{E}_{t-1}P_{t+1})\\ &+\left(\mathrm{cS}^{-1} + \mathrm{A}^{-1}\right)(\mathrm{E}_t D_{t+1} - \mathrm{E}_{t-1}D_{t+1}) - \mathrm{V}_t.\end{aligned} \tag{93.14}$$

Equation 93.14 shows that prediction errors in prices (the left hand side) due to unexpected disturbance are a function of expectation adjustments in price (first term on the right hand side) and dividends (the second term on the right hand side) two periods ahead. This equation can be seen as a generalized capital asset pricing model.

One important implication of the model is that the supply side effect can be examined by assuming the adjustment costs are large enough to keep the firms from seeking to raise new funds or to retire old securities. In other words, the assumption of high enough adjustment costs would cause the inverse of matrix A in Eq. 93.14 to vanish. The model is, therefore, reduced to the following certain equivalent relationship:

$$P_t - E_{t-1}P_t = (1+r^*)^{-1}(E_tP_{t+1} - E_{t-1}P_{t+1}) + (1+r^*)^{-1}(E_tD_{t+1} - E_{t-1}D_{t+1}) + U_t, \tag{93.15}$$

Where $U_t = -c^{-1}S(1 + r^*)^{-1}V_t$.

Equation 93.15 suggests that current forecast error in price is determined by the sum of the values of the expectation adjustments in its own next-period price and dividend discounted at the rate of 1 + r*.

93.2.4 Derivation of Simultaneous Equation System

From Eq. 93.15, if price series follow a random walk process, then the price series can be represented as $P_t = P_{t-1} + a_t$, where a_t is white noise. It follows that $E_{t-1}P_t = P_{t-1}$, $E_tP_{t+1} = P_t$and $E_{t-1}P_{t+1} = P_{t-1}$. According to the results in Appendix 1, the assumption that price follows a random walk process seems to be reasonable for both datasets. As a result, Eq. 93.14 becomes

$$-\left(r^*cS^{-1} + A^{-1}B\right)(P_t - P_{t-1}) + \left(cS^{-1} + A^{-1}\right)(E_tD_{t+1} - E_{t-1}D_{t+1}) = V_t. \tag{93.16}$$

Equation 93.16 can be rewritten as

$$G\,p_t + H\,d_t = V_t, \tag{93.17}$$

where
$G = -\ (r * cS^{-1} + A^{-1}B)$
$H = (cS^{-1} + A^{-1})$
$d_t = E_tD_{t+1} - E_{t-1}D_{t+1}$
$p_t = P_t - P_{t-1}$.

If Eq. 93.17 is exactly identified and matrix G is assumed to be nonsingular, then as shown in Greene (2004), the reduced form of this model may be written as[5]

$$p_t = \Pi d_t + U_t, \tag{93.18}$$

[5]The identification of the simultaneous equation system can be found in Appendix 2.

where Π is a n-by-n matrix of the reduced form coefficients and U_t is a column vector of n reduced form disturbances. Or

$$\Pi = -G^{-1}H, \text{and } U_t = G^{-1}V_t. \tag{93.19}$$

Equations 93.18 and 93.19 are used to test the existence of supply effect in the next section.

93.2.5 Test of Supply Effect

Since the simultaneous equation system as in Eq. 93.17 is exactly identified, it can be estimated by the reduced form as Eq. 93.18. A proof of identification problem of Eq. 93.17 is shown in Appendix 2. That is, Eq. 93.18, $p_t = \Pi d_t + U_t$, can be used to test the supply effect. For example, in the case of two portfolios, the coefficient matrix G and H in Eq. 93.17 can be written as[6]

$$G = \begin{bmatrix} g_{11} & g_{12} \\ g_{21} & g_{22} \end{bmatrix} = \begin{bmatrix} -(r^* cs_{11} + a_1 b_1) & -r^* cs_{12} \\ -r^* cs_{21} & -(r^* cs_{22} + a_2 b_2) \end{bmatrix},$$

$$H = \begin{bmatrix} h_{11} & h_{12} \\ h_{21} & h_{22} \end{bmatrix} = \begin{bmatrix} cs_{11} + a_1 & cs_{12} \\ cs_{21} & cs_{22} + a_2 \end{bmatrix}. \tag{93.20}$$

Since $\Pi = -G^{-1}H$ in Eq. 93.21, Π can be calculated as

$$\begin{aligned} -G^{-1}H &= \begin{bmatrix} r^* cs_{11} + a_1 b_1 & r^* cs_{12} \\ r^* cs_{21} & r^* cs_{22} + a_2 b_2 \end{bmatrix}^{-1} \begin{bmatrix} cs_{11} + a_1 & cs_{12} \\ cs_{21} & cs_{22} + a_1 \end{bmatrix} \\ &= \frac{1}{|G|} \begin{bmatrix} r^* cs_{22} + a_2 b_2 & -r^* cs_{12} \\ -r^* cs_{21} & r^* cs_{11} + a_1 b_1 \end{bmatrix} \begin{bmatrix} cs_{11} + a_1 & cs_{12} \\ cs_{21} & cs_{22} + a_1 \end{bmatrix} \\ &= \frac{1}{|G|} \begin{bmatrix} (r^* cs_{22} + a_2 b_2)(cs_{11} + a_1) - r^* cs_{12} cs_{21} & (r^* cs_{22} + a_2 b_2) cs_{12} - r^* cs_{12}(cs_{22} + a_1) \\ -r^* cs_{21}(cs_{11} + a_1) + (r^* cs_{11} + a_1 b_1) cs_{21} & -r^* cs_{21} cs_{12} + (r^* cs_{11} + a_1 b_1)(cs_{22} + a_1) \end{bmatrix} \\ &= \begin{bmatrix} \pi_{11} & \pi_{12} \\ \pi_{21} & \pi_{22} \end{bmatrix}. \end{aligned} \tag{93.21}$$

From Eq. 93.21, if there is a high enough quadratic cost of adjustment, or if $a_1 = a_2 = 0$, then with $s_{12} = s_{21}$, the matrix would become a scalar matrix in which diagonal elements are equal to $r^* c^2 (s_{11} s_{22} - s_{12}^2)$, and the off-diagonal elements are all zero. In other words, if there is high enough cost of adjustment, firm tends to stop seeking to raise new funds or to retire old securities. Mathematically, this will be represented in a way that all off-diagonal elements are all zero and all diagonal

[6] s_{ij} is the ith row and jth column of the variance-covariance matrix of return. a_i and b_i are the supply adjustment cost of firm i and overall cost of capital of firm i, respectively.

elements are equal to each other in matrix Π. In general, this can be extended into the case of more portfolios. For example, in the case of N portfolios, Eq. 93.18 becomes

$$\begin{bmatrix} p_{1t} \\ p_{2t} \\ \vdots \\ p_{Nt} \end{bmatrix} = \begin{bmatrix} \pi_{11} & \pi_{12} & \cdots & \pi_{1N} \\ \pi_{21} & \pi_{22} & \cdots & \pi_{2N} \\ \vdots & \vdots & \ddots & \vdots \\ \pi_{N1} & \pi_{N2} & \cdots & \pi_{NN} \end{bmatrix} \begin{bmatrix} d_{1t} \\ d_{2t} \\ \vdots \\ d_{Nt} \end{bmatrix} + \begin{bmatrix} u_{1t} \\ u_{2t} \\ \vdots \\ u_{Nt} \end{bmatrix}. \tag{93.22}$$

Equation 93.22 shows that if an investor expects a change in the prediction of the next dividend due to additional information (e.g., change in earnings) during the current period, then the price of the security changes. Regarding the US equity market, if one believes that how the expectation errors in dividends are built into the current price is the same for all securities, then, the price changes would be only influenced by its own dividend expectation errors. Otherwise, say if the supply of securities is flexible, then the change in price would be influenced by the expectation adjustment in dividends of all other stocks as well as that in its own dividend.

Therefore, two hypotheses related to supply effect to be tested regarding the parameters in the reduced form system shown in Eq. 93.18 are as follows:

Hypothesis 1: All the off-diagonal elements in the coefficient matrix Π are zero if the supply effect does not exist.

Hypothesis 2: All the diagonal elements in the coefficients matrix Π are equal in the magnitude if the supply effect does not exist.

These two hypotheses should be satisfied jointly. That is, if the supply effect does not exist, price changes of a security should be a function of its own dividend expectation adjustments, and the coefficients should all be equal across securities. In the model described in Eq. 93.16, if an investor expects a change in the prediction of the next dividend due to the additional information during the current period, then the price of the security changes.

Under the assumption of the efficiency in the domestic stock market, if the supply of securities is fixed, then the expectation errors in dividends are built in the current price is the same for all securities. This phenomenon implies that the price changes would only be influenced by its own dividend expectation adjustments. If the supply of securities is flexible, then the change in price would be influenced by the expectation adjustment in dividends of all other securities as well as that of its own dividend.

93.3 Data and Empirical Results

In this section, we derive the test by analyzing the US domestic stock market. Most details of the model, the methodologies, and the hypotheses for empirical tests are previously discussed in Sect. 93.2. However, before testing the hypotheses, some other details of the related tests that are needed to support the assumptions used in the model are also briefly discussed in this section.

This section examines the hypotheses derived earlier for the US domestic stock market by using the companies listed in S&P 500 and, then, by using the companies listing in Dow Jones Index. If the supply of risky assets is responsive to its price, then large price changes, which are due to the change in expectation of future dividend, will be spread over time. In other words, there exists supply effect in the US domestic stock markets. This implies that the dynamic instead of static CAPM should be used for testing capital assets pricing in the equity markets of the United States.

93.3.1 Data and Descriptive Statistics

Three hundred companies are selected from the S&P 500 and grouped into ten portfolios with equal numbers of 30 companies by their payout ratios. The data are obtained from the Compustat North America industrial quarterly data. The data starts from the first quarter of 1981 to the last quarter of 2002. The companies selected satisfy the following two criteria. First, the company appears on the S&P 500 at some time period during 1981 through 2002. Second, the company must have complete data available – including price, dividend, earnings per share, and shares outstanding – during the 88 quarters (22 years). Firms are eliminated from the sample list if one of the following two conditions occurs:

(i) Reported earnings are either trivial or negative.
(ii) Reported dividends are trivial.

Three hundred fourteen firms remain after these adjustments. Finally, excluding those seven companies with highest and lowest average payout ratio, the remaining 300 firms are grouped into ten portfolios by the payout ratio. Each portfolio contains 30 companies. Figure 93.1 shows the comparison of S&P 500 index and the value-weighted index of the 300 firms selected (M). Figure 93.1 shows that the trend is similar to each other before the third quarter of 1999. However, there exist some differences after third quarter of 1999.

To group these 300 firms, the payout ratio for each firm in each year is determined by dividing the sum of four quarters' dividends by the sum of four quarters' earnings; then, the yearly ratios are further averaged over the 22-year period. The first 30 firms with highest payout ratio comprise portfolio one, and so on. Then, the value-weighted average of the price, dividend, and earnings of each portfolio is computed. Characteristics and summary statistics of these ten portfolios are presented in Tables 93.1 and 93.2, respectively. Table 93.1 presents information of return, payout ratio, size, and beta for ten portfolios. From the results of this table, there appears to exist an inverse relationship between return and payout ratio, payout ratio and beta. However, the relationship between payout ratio and beta is not so clear. This finding is similar to that of Fama and French (1992).

Table 93.2 shows the first four moments of quarterly returns of the market portfolio and ten portfolios. The coefficients of skewness, kurtosis, and Jarque-Bera statistics show that one cannot reject the hypothesis that log return of most

10	0.0454	0.1381	284,600	1.1007

[a]The first 30 firms with highest payout ratio comprise portfolio one, and so on
[b]The price, dividend, and earnings of each portfolio are computed by value-weighted of the 30 firms included in the same category
[c]The payout ratio for each firm in each year is found by dividing the sum of four quarters' dividends by the sum of four quarters' earnings; then, the yearly ratios are then computed from the quarterly data over the 22-year period

portfolios is normal. The kurtosis statistics for most sample portfolios are close to three, which indicates that heavy tails are not an issue. Additionally, Jarque-Bera coefficients illustrate that the hypotheses of Gaussian distribution for most portfolios are not rejected. It seems to be unnecessary to consider the problem of heteroskedasticity in estimating domestic stock market if the quarterly data are used.

Table 93.2 Summary statistics of portfolio quarterly returns[a]

Country	Mean (quarterly)	Std. dev. (quarterly)	Skewness	Kurtosis	Jarque-Bera

93.3.2 Dynamic CAPM with Supply Side Effect

If one believes that the stock market is efficient (i.e., if one believes the way in which the expectation errors in dividends are built in the current price is the same for all securities), then price changes would be influenced only by its own dividend expectation errors. Otherwise, if the supply of securities is flexible, then the change in price would be influenced by the expectation adjustment in dividends of other portfolios as well as that in its own dividend. Thus, two hypotheses related to supply effect are to be tested and should be satisfied jointly in order to examine whether there exists a supply effect.

Recalling from the previous section, the structural form equations are exactly identified, and the series of expectation adjustments in dividend, d_t, are exogenous variables (d_t can be estimated from earnings per share and dividends per share by using a partial adjustment model as presented in Appendix 3). Now, the reduced form equations can be used to test the supply effect. That is, Eq. 93.22 needs to be examined by the following hypotheses:

Hypothesis 1: All the off-diagonal elements in the coefficient matrix Π are zero if the supply effect does not exist.

Hypothesis 2: All the diagonal elements in the coefficients matrix Π are equal in the magnitude if the supply effect does not exist.

These two hypotheses should be satisfied jointly. That is, if the supply effect does not exist, price changes of each portfolio would be a function of its own dividend expectation adjustments, and the coefficients should be equal across all portfolios.

The estimated coefficients of the simultaneous equation system for ten portfolios are summarized in Table 93.3.[7] Results of Table 93.3 indicate that the estimated

[7]The results are similar when using either the FIML or SUR approach. We report here the estimates of the SUR method.

[a]Standard errors in ( ) and t-statistics in [ ]

diagonal elements seem to vary across portfolios and most of the off-diagonal elements are significant from zero. However, simply observing the elements in matrix Π directly cannot justify either accept or reject the null hypotheses derived for testing the supply effect. Two tests should be done separately to check whether these two hypotheses are both satisfied.

For the first hypothesis, the test of supply effect on off-diagonal elements, the following regression in accordance with Eq. 93.22 is run for each portfolio:

$$p_{i,t} = \beta_i d_{i,t} + \Sigma_{j \neq i} \beta_j d_{j,t} + \varepsilon_{i,t}, \mathrm{i}, \mathrm{j} = 1, \ldots, 10. \tag{93.23}$$

The null hypothesis then can be written as H_0: $\beta_j = 0$, $j = 1, \ldots, 10$, $j \neq i$. The results are reported in Table 93.4. Two test statistics are reported. The first test uses an F distribution with 9 and 76 degrees of freedom, and the second test uses a chi-squared distribution with 9 degrees of freedom. The null hypothesis is rejected at 5 % significance level in six out of ten portfolios, and only two portfolios cannot be rejected at 10 % significance level. This result indicates that the null hypothesis can be rejected at conventional levels of significance.

For the second hypothesis of supply effect on all diagonal elements of Eq. 93.22, the following null hypothesis needs to be tested:

$$H_0 : \pi_{i,i} = \pi_{j,j} \quad \text{for all } i, j = 1, \ldots, 10.$$

To do this null hypothesis test, we need to estimate Eq. 93.22 simultaneously, and then, we calculate Wald statistics by imposing nine restrictions on this equation system. Under the above nine restrictions, the Wald test statistic has a chi-square distribution with 9 degrees of freedom. The statistic is 18.858, which is greater than 16.92 at 5 % significance level. Since the statistic corresponds to a p-value of 0.0265, one can reject the null hypothesis at 5 %, but it cannot reject H_0 at a 1 % significance level. In other words, the diagonal elements are not similar to each other in magnitude. In conclusion, the above empirical results are sufficient to reject two null hypotheses of nonexistence of supply effect in the US stock market.

In order to check whether the individual stocks can hold up to the same testing, we use individual stock data as many as 30 companies in one group. The results are summarized in Table 93.5. From Table 93.5, we find that the above conclusion seems to be sustainable if we use individual stock data. More specifically, the diagonal elements are not equal to each other at any conventional significant level and the off-diagonal elements are significantly from zero in each group composed of 30 individual stocks.

We also find that one cannot reject the existence of supply effect by using the stocks listed in the Dow Jones Index. Again, to test the supply effect on off-diagonal elements, Eq. 93.23 is run as the following for each company:

$$p_{i,t} = \beta_i d_{i,t} + \Sigma_{j \neq i} \beta_j d_{j,t} + \varepsilon_{i,t}, \quad \mathrm{i}, \mathrm{j} = 1, \ldots, 29. \tag{93.23$'$}$$

Table 93.4 Test of supply effect on off-diagonal elements of matrix $\Pi^{a,b}$

[a] $p_{i,\,t} = \beta_i{}' d_{i,\,t} + \Sigma_{j \neq i}\beta_j{}' d_{j,\,t} + \varepsilon'_{i,\,t}$ i, $j = 1, \ldots, 10$.
Hypothesis: all $\beta_j = 0, j = 1, \ldots, 10, j \neq i$
[b] The first test uses an F distribution with 9 and 76 degrees of freedom, and the second uses a chi-squared distribution with 9 degrees of freedom
*, **, and *** denote statistical significance at the 10 %, 5 %, and 1 % level, respectively

The null hypothesis then can be written as H_0: $\beta_j = 0$, $j = 1, \ldots, 29$, $j \neq i$. The results are summarized in Table 93.6. The null hypothesis is rejected at 1 % significance level in 26 out of 29 companies. For the second hypothesis of supply effect on all diagonal elements, the following null hypothesis is also tested: H_0: $\pi_{i,\,i} = \pi_{j,\,j}$, for all i, j = 1, . . ., 29.

The Wald test statistic has a chi-square distribution with 28 degrees of freedom. The statistic is 86.35. That is, one can reject this null hypothesis at 1 % significance level.

93.4 Summary

We examine an asset pricing model that incorporates a firm's decision concerning the supply of risky securities into the CAPM. This model focuses on a firm's financing decision by explicitly introducing the firm's supply of risky securities into the static CAPM and allows the supply of risky securities to be a function of security price. And thus, the expected returns are endogenously determined by both demand and supply decisions within the model. In other words, the supply effect may be one important factor in capital assets pricing decisions.

Our objective is to investigate the existence of supply effect in the US stock markets. We find that supply effect is important in the US stock market. This finding holds as we break the companies listed in the S&P 500 into ten portfolios. It also holds if we use individual stock data. These test results show that two null hypotheses of the nonexistence of supply effect do not seem to be satisfied jointly. In other words, this evidence seems to be sufficient to support the existence of supply effect and, thus, imply a violation of the assumption in the one-period static CAPM, or to imply a dynamic asset pricing model may be a better choice in the US domestic stock markets.

For the future research, we will first modify the simultaneous equation asset pricing model defined in Eqs. 93.9 and 93.12 to allow for testing the existence of market disequilibrium in dynamic asset pricing. Then, we will use disequilibrium estimation methods developed by Amemiya (1974), Fair and Jaffe(1972), and Quandt (1988) to test whether there is price adjustment in response to an excess demand in equity market.

Appendix 1: Modeling the Price Process

In Sect. 93.2.3, Eq. 93.16 is derived from Eq. 93.15 under the assumption that all countries' index series follow a random walk process. Thus, before further discussion, we should test the order of integration of these price series. From Hamilton (1994), we know that two widely used unit root tests are the Dickey-Fuller (DF) and the augmented Dickey-Fuller (ADF) tests. The former can be represented as $P_t = \mu + \gamma P_{t-1} + \varepsilon_t$, and the latter can be written as $\Delta P_t = \mu + \gamma\, P_{t-1} + \delta_1 \Delta P_{t-1} + \delta_2 \Delta P_{t-2} + \ldots + \delta_p \Delta P_{t-p} + \varepsilon_t$.

Test the off-diagonal elements: $p_{i,t} = \beta_i{}' d_{i,t} + \Sigma_{j \neq i} \beta_j{}' d_{j,t} + \varepsilon'_{i,t}$, for i, $j = 1, \ldots, 29$, null hypothesis H_0: all $\beta_j = 0, j = 1, 2, \ldots, 29, j \neq i$

Test of supply effect on the diagonal elements; H_0: $\pi_{ii} = \pi_{jj}$ for all i, $j = 1, 2, \ldots, 29$ Result: $\chi^2 = 86.35$, p-value $= 0.0000 \rightarrow$ Reject H_0 at 1 %

Microsoft Corp. is not included since it had paid dividends twice for the whole sample period

Similarly, in the US stock markets, the Phillips-Perron test is used to check whether the value-weighted price of market portfolio follows a random walk process. The results of the tests for each index are summarized in Table 93.7. It seems that one cannot reject the hypothesis that all indices follow a random walk process since, for example, the null hypothesis of unit root in level cannot be rejected for all indices but are all rejected if one assumes there is a unit root in the first-order difference of the price for each portfolio. This result is consistent with most studies that find that the financial price series follow a random walk process.

Appendix 2: Identification of the Simultaneous Equation System

Note that given G is nonsingular, $\Pi = -G^{-1}H$ in Eq. 93.19 can be written as

$$\text{where } A = [G \quad H] = \begin{pmatrix} g_{11} & g_{12} & \cdots\cdots & g_{1n} & h_{11} & h_{12} & \cdots\cdots & h_{1n} \\ g_{21} & g_{22} & \cdots\cdots & g_{1n} & h_{21} & h_{22} & \cdots\cdots & h_{2n} \\ . & & & & & & . & \\ . & & & & & & . & \\ g_{n1} & g_{n2} & \cdots\cdots & g_{nn} & h_{n1} & h_{n2} & \cdots\cdots & h_{nn} \end{pmatrix}$$

$$W = [\Pi \quad I_n]' = \begin{pmatrix} \pi_{11} & \pi_{12} & \cdots & \pi_{1n} & 1 & 0 & \cdots\cdots & 0 \\ \pi_{21} & \pi_{22} & \cdots & \pi_{1n} & 0 & 1 & \cdots\cdots & 0 \\ . & & & & & & . & \\ . & & & & & & . & \\ \pi_{n1} & \pi_{n2} & \cdots & \pi_{nn} & 0 & 0 & \cdots\cdots & 1 \end{pmatrix} \tag{93.24}$$

That is, A is the matrix of all structure coefficients in the model with dimension of $(n \times 2n)$, and W is a $(2n \times n)$ matrix. The first equation in Eq. (93.24) can be expressed as

$$A_1 W = 0, \tag{93.25}$$

where A_1 is the first row of A, i.e., $A_1 = [g_{11}\ g_{12} \ldots.\ g_{1n}\ h_{11}\ h_{12} \ldots..\ h_{1n}]$.

Since the elements of Π can be consistently estimated, and I_n is the identity matrix, Eq. 93.25 contains 2n unknowns in terms of πs. Thus, there should be n restrictions on the parameters to solve Eq. 93.25 uniquely. First, one can try to impose normalization rule by setting g_{11} equal to 1 to reduce one restriction. As a result, there are at least n−1 independent restrictions needed in order to solve Eq. 93.25.

It can be illustrated that the system represented by Eq. 93.17 is exactly identified with three endogenous and three exogenous variables. It is entirely similar to those cases of more variables. For example, if $n = 3$, Eq. 93.17 can be expressed in the form

$$\begin{aligned}&-\begin{pmatrix} r*cs_{11}+a_1b_1 & r*cs_{12} & r*cs_{13} \\ r*cs_{21} & r*cs_{22}+a_2b_2 & r*cs_{23} \\ r*cs_{31} & r*cs_{32} & r*cs_{33}+a_3b_3 \end{pmatrix}\begin{pmatrix} p_{1t} \\ p_{2t} \\ p_{3t} \end{pmatrix} \\ &+\begin{pmatrix} cs_{11}+a_1 & cs_{12} & cs_{13} \\ cs_{21} & cs_{22}+a_2 & cs_{23} \\ cs_{31} & cs_{32} & cs_{33}+a_3 \end{pmatrix}\begin{pmatrix} d_{1t} \\ d_{2t} \\ d_{3t} \end{pmatrix} = \begin{pmatrix} v_{1t} \\ v_{2t} \\ v_{3t} \end{pmatrix}\end{aligned} \tag{93.26}$$

where
r^* = scalar of risk-free rate
s_{ij} = elements of variance-covariance matrix of return
a_i = inverse of the supply adjustment cost of firm i
b_i = overall cost of capital of firm i

For example, in the case of $n = 3$, Eq. 93.17 can be written as

$$\begin{pmatrix} g_{11} & g_{12} & g_{13} \\ g_{21} & g_{22} & g_{23} \\ g_{31} & g_{32} & g_{33} \end{pmatrix}\begin{pmatrix} p_{1t} \\ p_{2t} \\ p_{3t} \end{pmatrix} + \begin{pmatrix} h_{11} & h_{12} & h_{13} \\ h_{21} & h_{22} & h_{23} \\ h_{31} & h_{32} & h_{33} \end{pmatrix}\begin{pmatrix} d_{1t} \\ d_{2t} \\ d_{3t} \end{pmatrix} = \begin{pmatrix} v_{1t} \\ v_{2t} \\ v_{3t} \end{pmatrix}. \tag{93.27}$$

Comparing Eq. 93.26 with Eq. 93.27, the prior restrictions on the first equation take the form $g_{12} = -r^*h_{12}$ and $g_{13} = -r^*h_{13}$ and so on.

Thus, the restriction matrix for the first equation is of the form

$$\Phi = \begin{pmatrix} 0 & 1 & 0 & 0 & r^* & 0 \\ 0 & 0 & 1 & 0 & 0 & r^* \end{pmatrix} \tag{93.28}$$

Then, combining Eq. 93.25 and the parameters of the first equation gives

$$[g_{11} \quad g_{12} \quad g_{13} \quad h_{11} \quad h_{12} \quad h_{13}]\begin{pmatrix} \pi_{11} & \pi_{12} & \pi_{13} & 0 & 0 \\ \pi_{21} & \pi_{22} & \pi_{13} & 1 & 0 \\ \pi_{31} & \pi_{32} & \pi_{33} & 0 & 1 \\ 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & r* & 0 \\ 0 & 0 & 1 & 0 & r* \end{pmatrix}[0 \;\; 0 \;\; 0 \;\; 0 \;\; 0]. \tag{93.29}$$

That is, extending Eq. 93.29, we have

$$\begin{aligned} &g_{11}\pi_{11} + g_{12}\pi_{21} + g_{13}\pi_{31} + h_{11} = 0,\\ &g_{11}\pi_{12} + g_{12}\pi_{22} + g_{13}\pi_{32} + h_{12} = 0,\\ &g_{11}\pi_{13} + g_{12}\pi_{23} + g_{13}\pi_{33} + h_{13} = 0,\\ &g_{12} + r^*h_{12} = 0, \text{and}\\ &g_{13} + r^*h_{13} = 0. \end{aligned} \tag{93.30}$$

The last two ($n-1 = 3-1 = 2$) equations in Eq. 93.30 give the value h_{12} and h_{13}, and the normalization condition, $g_{11} = 1$, allows us to solve Eq. 93.25 in terms of πs uniquely. That is, in the case $n = 3$, the first equation represented by Eq. 93.25, $A_1W = 0$, can be finally rewritten as Eq. 93.30. Since there are three unknowns, g_{12}, g_{13}, and h_{11}, left for the first three equations in Eq. 93.30, the first equation A_1 is exactly identified. Similarly, it can be shown that the second and the third equations are also exactly identified.

Appendix 3: Derivation of the Formula Used to Estimate d_t

To derive the formula for estimating d_t, we first define the partial adjustment model as

$$D_t = a_1 + a_2D_{t-1} + a_3E_t + u_t \tag{93.31}$$

where D_t = dividend per share in period t, D_{t-1} = dividend per share in period t−1, E_t = earnings per share in period t are dividends and earnings, and u_t = error term in period t. Similarly,

$$D_{t+1} = a_1 + a_2D_t + a_3E_{t+1} + u_{t+1}. \tag{93.31$'$}$$

And thus,

$$\mathrm{E}_{t-1}[D_t] = a_1 + a_2D_{t-1} + a_3\mathrm{E}_{t-1}[E_t], \tag{93.32}$$

$$\mathrm{E}_t[D_{t+1}] = a_1 + a_2D_t + a_3\mathrm{E}_t[E_{t+1}], \tag{93.33}$$

$$\mathrm{E}_{t-1}[D_{t+1}] = a_1 + a_2\mathrm{E}_{t-1}[D_t] + a_3\mathrm{E}_{t-1}[E_{t+1}]. \tag{93.34}$$

Substituting Eq. 93.32 to Eq. 93.34, we have

$$E_{t-1}[D_{t+1}] = a_1 + a_1a_2 + a_2^2D_{t-1} + a_2a_3\mathrm{E}_{t-1}[E_t] + a_3\mathrm{E}_{t-1}[E_{t+1}]. \tag{93.34$'$}$$

Subtracting Eq. 93.34′ from Eq. 93.33 on both hand sides, we have

$$\begin{aligned} \mathrm{E}_t[D_{t+1}] - \mathrm{E}_{t-1}[D_{t+1}] = &-a_1a_2 + a_2D_t - a_2^2D_{t-1} - a_2a_3\mathrm{E}_{t-1}[E_t]\\ &+ a_3\mathrm{E}_t[E_{t+1}] - a_3\mathrm{E}_{t-1}[E_{t+1}]. \end{aligned} \tag{93.35}$$

Equation Eq. 93.35 can be investigated depending upon whether E_t is following a random walk.

Case 1 E_t follows an AR(p) process.

If the time series of E_t is assumed to be stationary and follows an AR(p) process, then after taking the seasonal differences, we obtain

$$dE_t = \rho_0 + \rho_1 dE_{t-1} + \rho_2 dE_{t-2} + \rho_3 dE_{t-3} + \rho_4 dE_{t-4} + \varepsilon_t, \tag{93.36}$$

where $dE_t = E_t - E_{t-4}$.

The expectation adjustment in seasonally differenced earnings, or the revision in forecasting future seasonally differenced earnings, can be solved as

$$\mathrm{E}_t[dE_{t+1}] - \mathrm{E}_{t-1}[dE_{t+1}] = \rho_1(-\rho_0 + dE_t - \rho_1 dE_{t-1} - \rho_2 dE_{t-2} - \rho_3 dE_{t-3} - \rho_4 dE_{t-4}). \tag{93.37}$$

Since $\mathrm{E}_t[dE_{t+1}] - \mathrm{E}_{t-1}[dE_{t+1}] = \mathrm{E}_t[E_{t+1}] - \mathrm{E}_{t-1}[E_{t+1}]$, we have

$$\mathrm{E}_t[E_{t+1}] - \mathrm{E}_{t-1}[E_{t+1}] = \rho_1(-\rho_0 + dE_t - \rho_1 dE_{t-1} - \rho_2 dE_{t-2} - \rho_3 dE_{t-3} - \rho_4 dE_{t-4}). \tag{93.38}$$

Furthermore, from Eq. 93.36, we have

$$\mathrm{E}_{t-1}[dE_t] = \rho_0 + \rho_1 dE_{t-1} + \rho_2 dE_{t-2} + \rho_3 dE_{t-3} + \rho_4 dE_{t-4}. \tag{93.39}$$

Similarly, $\mathrm{E}_{t-1}[dE_t] = \mathrm{E}_{t-1}[E_1 - E_{t-4}] = \mathrm{E}_{t-1}[E_t] - E_{t-4}$; thus, $\mathrm{E}_{t-1}[E_t]$ can be found by

$$\mathrm{E}_{t-1}[E_t] = \rho_0 + \rho_1(dE_{t-1}) + \rho_2(dE_{t-2}) + \rho_3(dE_{t-3}) + \rho_4(dE_{t-4}) + E_{t-4}. \tag{93.40}$$

Finally, the expectation adjustment in dividends, d_t, can be found by plugging Eqs. 93.38 and 93.40 into Eq. 93.35:

$$\begin{aligned} d_t \equiv \mathrm{E}_t[D_{t+1}] - \mathrm{E}_{t-1}[D_{t+1}] &= -a_1 a_2 + a_2 D_t - a_2^2 D_{t-1} \\ &\quad - a_2 a_3(\rho_0 + \rho_1 dE_{t-1} + \rho_2 dE_{t-2} + \rho_3 dE_{t-3} + \rho_4 dE_{t-4} + E_{t-4}) \\ &\quad + a_3 \rho_1(-\rho_0 + dE_t - \rho_1 dE_{t-1} - \rho_2 dE_{t-2} - \rho_3 dE_{t-3} - \rho_4 dE_{t-4}) \end{aligned} \tag{93.41}$$

Or

$$\begin{aligned} d_t = C_0 + C_1 D_t + C_2 D_{t-1} + C_3 dE_t + C_4 dE_{t-1} + C_5 dE_{t-2} + C_6 dE_{t-3} \\ + C_7 dE_{t-4} + C_8 E_{t-4} \end{aligned} \tag{93.42}$$

where C_0 to C_8 are functions of a_1 to a_1 and ρ_0 to ρ_4.

That is, the expectation adjustment in dividends, d_t, can be found by the coefficients estimated in Eqs. 93.31 and 93.36, i.e., a_1 to a_3 and ρ_0 to ρ_4, and the observable data from the time series of D_t and E_t.

Case 2 E_t follows a random walk process.

If the series of earnings, E_t, follows a random walk process, i.e., $\mathrm{E}_t[E_{t+1}] = E_t$, $\mathrm{E}_{t-1}[E_t] = E_{t-1}$, and $\mathrm{E}_{t-1}[E_{t+1}] = E_{t-1}$, then Eq. 93.35 can be redefined:

$$d_t \equiv \mathrm{E}_t[D_{t+1}] - \mathrm{E}_{t-1}[D_{t+1}] = C_0 + C_1 D_t + C_2 D_{t-1} + C_3 E_t + C_4 E_{t-1} \quad (93.43)$$

where $C_0 = -a_1 a_2$ $C_1 = a_2$, $C_2 = -a_2^2$, $C_3 = a_3$, and $C_4 = -a_3(1 + a_2)$.

That is, the expectation adjustment in dividends, d_t, can be found by the observable data from the time series of D_t and E_t.

In this study, we assumed that E_t follows a random walk process. Therefore, we used Eq. 93.43 instead of Eq. 93.42 to estimate d_t in Eqs. 93.22 and 93.23 in the text.

Abstract

Under martingale and joint-normality assumptions, various optimal hedge ratios are identical to the minimum variance hedge ratio. As empirical studies usually reject the joint-normality assumption, we propose the generalized hyperbolic distribution as the joint log-return distribution of the spot and futures. Using the parameters in this distribution, we derive several most widely used optimal hedge ratios: minimum variance, maximum Sharpe measure, and minimum generalized semivariance. Under mild assumptions on the parameters, we find that these hedge ratios are identical. Regarding the equivalence of these optimal hedge ratios, our analysis suggests that the martingale property plays a much important role than the joint distribution assumption.

To estimate these optimal hedge ratios, we first write down the log-likelihood functions for symmetric hyperbolic distributions. Then we estimate these parameters by maximizing the log-likelihood functions. Using these MLE parameters for the generalized hyperbolic distributions, we obtain the minimum variance hedge ratio and the optimal Sharpe hedge ratio. Also based on the MLE parameters and the numerical method, we can calculate the minimum generalized semivariance hedge ratio.

Keywords

Optimal hedge ratio • Generalized hyperbolic distribution • Martingale property • Minimum variance hedge ratio • Minimum generalized semivariance • Maximum Sharpe measure • Joint-normality assumption • Hedging effectiveness

94.1 Introduction

Because of their low transaction cost, high liquidity, high leverage, and ease of short position, stock index futures are among the most successful innovations in the financial markets. Besides the speculative trading, they are widely used to hedge against the market risk of the spot position. One of the most important issues for investors and portfolio managers is to calculate the optimal futures hedge ratio, the proportion of the position taken in futures to the size of the spot so that the risk exposure can be minimized.

The optimal hedge ratios typically depend on the objective functions under consideration. In literature on futures hedging, there are two different types of objective functions: the risk function to be minimized and the utility function to be maximized. Johnson (1960) obtains the minimum variance hedge ratio by minimizing the variance of the change in the value of the hedged portfolios. On the other hand, as Adams and Montesi (1995) indicate, corporate managers are more concerned with the downside risk rather than the upside variation. A measure of the downside risk is the generalized semivariance (GSV) where the risk is computed from the expectation of a power function of shortfalls from the target return (Bawa 1975, 1978; Fishburn 1977). De Jong et al. (1997) and Lien and Tse (1998, 2000, 2001) have calculated several GSV-minimizing hedge ratios. Regarding the utility function approach, we consider the Sharpe measure (SM) criteria, i.e., the ratio of the portfolio's excess return to its volatility. Howard and D'Antonio (1984) formulate the optimal hedge ratio by maximizing the Sharpe measure.

Normally, these optimal hedge ratios under different approaches are not the same. However, with the joint-normality and martingale assumptions, they are identical to the minimum variance hedge ratio. Unfortunately, many empirical studies indicate that major markets typically reject the joint-normality assumption (Chen et al. 2001; Lien and Tse 1998). In particular, the fat-tail property of the return distribution affects the hedging effectiveness substantially. It will be useful to find out the nature of the optimal hedge ratios under more realistic assumption. In this paper we introduce the bivariate generalized hyperbolic distributions as alternative joint distributions for returns in the spot and futures markets.

Barndorff-Nielsen (1977, 1978) develops the generalized hyperbolic (GH) distributions as a mixture of the normal distribution and the generalized inverse Gaussian (GIG) distribution first proposed in 1946 by Etienne Halphen. The class of the generalized hyperbolic distributions includes the hyperbolic distributions, the normal inverse Gaussian distributions, and the variance-Gamma distributions, while the normal distribution is a limiting case of the generalized hyperbolic distributions. Uses of the generalized hyperbolic distributions have been increasing in finance literature. To model the log returns of some financial assets, Eberlein and Keller (1995) consider the hyperbolic distribution and Barndorff-Nielsen (1995) proposes the normal inverse Gaussian distribution. For more recent applications of the generalized hyperbolic distributions in finance, see Bibby and Sørensen (2003), Eberlein et al. (1998), Rydberg (1997, 1999), Kücher et al. (1999), and Bingham and Kiesel (2001).

In terms of the parameters for the bivariate hyperbolic distributions, we have developed in this paper the minimum variance hedge ratio, GSV-minimizing hedge ratio, and the SM-maximizing hedge ratio. Moreover, the relationships between these hedge ratios are explored. In particular, under the martingale assumption, we can still obtain the result that these hedge ratios are the same as the minimum variance hedge ratio (see Theorems 2.1, 2.4 and Proposition 2.2). Based on the maximum likelihood estimation of the parameters and the numerical methods, we calculate and compare the different hedge ratios for TAIEX futures and S&P 500 futures.

The chapter is divided into five sections. Section 94.1 first introduces the definitions and some basic properties for GIG and GH distributions. In Sect. 94.2, we study the optimal hedge ratios under different approaches and estimate these ratios in terms of the parameters for GH distributions. In Sect. 94.3, we discuss the kernel density estimators and MLE method for parameter estimation problem. The last section provides the concluding remarks.

94.2 GIG and GH Distributions

94.2.1 The Generalized Hyperbolic Distributions

To introduce the generalized hyperbolic distribution, we first recall some basic properties of generalized inverse Gaussian (GIG) distributions. Note that for any $\delta, \psi > 0$ and $\lambda \in R$, the function

$$d_{GIG(\lambda,\delta,\psi)}(x) = \frac{(\psi/\delta)^{\lambda}}{2K_{\lambda}(\delta\psi)} x^{\lambda-1} e^{-\frac{1}{2}\left(\delta^2 x^{-1} + \psi^2 x\right)}, \qquad x > 0 \tag{94.1}$$

is a probability density function on $(0, \infty)$. Here, the function

$$K_{\lambda}(x) = \frac{1}{2}\int_0^{\infty} u^{\lambda-1} e^{-\frac{1}{2}x\left(u^{-1}+u\right)} du, \quad x > 0 \tag{94.2}$$

is the Bessel functions of the third kind with index λ. The distribution with the density function $d_{GIG(\lambda,\ \delta,\ \psi)}(x)$ on the positive half-line is called a generalized inverse Gaussian (GIG) distribution with parameters λ, δ, ψ and denoted by $GIG(\lambda, \delta, \psi)$. The moment generating function of the generalized inverse Gaussian distribution is given by

$$M_{GIG(\lambda,\ \delta,\ \psi)}(u) = \int_0^{\infty} e^{ux} d_{GIG(\lambda,\ \delta,\ \psi)}(x)dx = \left(\frac{\psi}{\sqrt{\psi^2 - 2u}}\right)^{\lambda} \frac{K_{\lambda}\left(\delta\sqrt{\psi^2 - 2u}\right)}{K_{\lambda}(\delta\psi)} \tag{94.3}$$

with the restriction $2u < \psi^2$. From this, we obtain

$$\mathbb{E}[GIG] = \frac{\delta}{\psi}\frac{K_{\lambda+1}(\delta\psi)}{K_{\lambda}(\delta\psi)}$$

$$\mathrm{Var}[GIG] = \left(\frac{\delta}{\psi}\right)^2 \left[\frac{K_{\lambda+2}(\delta\psi)}{K_{\lambda}(\delta\psi)} - \frac{K_{\lambda+1}^2(\delta\psi)}{K_{\lambda}^2(\delta\psi)}\right].$$

Barndorff-Nielsen (1977) introduced the class of generalized hyperbolic (GH) distributions as mean-variance mixtures of normal distributions. More precisely, one says that a random variable Z has the generalized hyperbolic distribution $GH(\lambda, \alpha, \beta, \delta, \mu)$ if

$$Z|Y = y \sim N(\mu + \beta y, y),$$

where Y is a random variable with distribution $GIG\left(\lambda, \delta, \sqrt{\alpha^2 - \beta^2}\right)$ and $N(\mu + \beta y, y)$ denotes the normal distribution with mean $\mu + \beta y$ and variance y. From this, one can easily verify that the density function for $GH(\lambda, \alpha, \beta, \delta, \mu)$ is given by the formula

$$\begin{aligned} d_{GH(\lambda,\alpha,\beta,\delta,\mu)}(x) &= \int_0^\infty d_{N(\mu+\beta y, y)}(x) d_{GIG\left(\lambda,\delta,\sqrt{\alpha^2-\beta^2}\right)}(y)dy \\ &= \left(\frac{\psi}{\delta}\right)^\lambda \frac{e^{(x-\mu)\beta}}{\sqrt{2\pi}K_\lambda(\delta\psi)} \left[\frac{\delta^2 + (x-\mu)^2}{\alpha^2}\right]^{\frac{\lambda-\frac{1}{2}}{2}} K_{\lambda-\frac{1}{2}}\left(\alpha\sqrt{\delta^2 + (x-\mu)^2}\right) \end{aligned}$$

where $\psi = \sqrt{\alpha^2 - \beta^2}$.

The class of hyperbolic distributions is the subclass of GH distributions obtained when λ is equal to 1. We write $H(\alpha, \beta, \delta, \mu)$ instead of $GH(1, \alpha, \beta, \delta, \mu)$. Using the fact that $K_{1/2}(z) = (\pi/2z)^{1/2}e^{-z}$, one obtains the density for $H(\alpha, \beta, \delta, \mu)$ is

$$d_{H(\alpha,\beta,\delta,\mu)}(x) = \frac{\sqrt{\alpha^2 - \beta^2}}{2\alpha\delta K_1\left(\delta\sqrt{\alpha^2-\beta^2}\right)} e^{-\alpha\sqrt{\delta^2+(x-\mu)^2} + \beta(x-\mu)}. \qquad (94.4)$$

The normal inverse Gaussian (NIG) distributions were introduced to finance in Barndorff-Nielsen (1995). It is a subclass of the generalized hyperbolic distributions obtained for λ equal to $-1/2$. The density of the NIG distribution is given by

$$d_{NIG(\alpha,\beta,\delta,\mu)}(x) = \frac{\delta}{\pi}\left[\frac{\alpha^2}{\delta^2 + (x-\mu)^2}\right]^{\frac{1}{2}} e^{\delta\psi + (x-\mu)\beta} K_1\left(\alpha\sqrt{\delta^2+(x-\mu)^2}\right).$$

94.2.2 Multivariate Modeling

In finance one does not look at a single asset, but at a bunch of assets. Since the assets in the market are typically highly correlated, it is natural to use multivariate distributions. A straightforward way for introducing multivariate generalized hyperbolic (MGH) distributions is via the mixtures of multivariate normal distributions with the generalized inverse Gaussian distributions. In fact the multivariate generalized hyperbolic distributions were introduced and investigated in Barndorff-Nielsen (1978).

Let Δ be a symmetric positive-definite $d \times d$- matrix with determinant $|\Delta| = 1$. Assume that $\lambda \in R$, β, $\mu \in R^d$, $\delta > 0$, and $\alpha^2 > \beta'\Delta\beta$. We say that a d-dimensional random vector Z has the multivariate generalized hyperbolic distribution $MGH(\lambda, \alpha, \beta, \delta, \mu, \Delta)$ with parameters $(\lambda, \alpha, \beta, \delta, \mu, \Delta)$ if

$$\mathbf{Z}|Y = y \sim N_d(\mu + y\Delta\beta, y\Delta),$$

where $Nd(A, B)$ denotes the d-dimensional normal distribution with mean vector A and covariance matrix B, *and Y distribution as* $GIG\left(\lambda, \delta, \sqrt{\alpha^2 - \beta' \Delta\beta}\right)$. Here we notice that the generalized hyperbolic distributions are symmetric if and only if $\beta = (0, \ldots, 0)'$. For $\lambda = (d + 1)/2$ we obtain the multivariate hyperbolic distributions. For $\lambda = -1/2$ we obtain the multivariate normal inverse Gaussian distribution.

The density function of the distribution $MGH(\lambda, \beta, \delta, \mu, \Delta)$ is given by the formula

$$d_{MGH}(x) = c_d \frac{K_{\lambda-d/2}\left(\alpha\sqrt{\delta^2 + (x-\mu)'\Delta^{-1}(x-\mu)}\right)}{\left(\alpha^{-1}\sqrt{\delta^2 + (x-\mu)'\Delta^{-1}(x-\mu)}\right)^{d/2-\lambda}} e\left(\beta'(x-\mu)\right) \tag{94.5}$$

where $c_d = \frac{\left[\left(\alpha^2 - \beta'\Delta\beta\right)/\delta^2\right]^{\lambda/2}}{(2\pi)^{d/2}K_\lambda\left(\delta\sqrt{\alpha^2-\beta'\Delta\beta}\right)}$. The mean and covariance of MGH are given by

$$\mathbb{E}[MGH(\lambda, \alpha, \beta, \delta, \mu, \Delta)] = \mu + \Delta\beta\mathbb{E}[GIG(\lambda, \delta, \psi)], \tag{94.6}$$

$$\begin{aligned} \mathrm{Var}[MGH(\lambda, \alpha, \beta, \delta, \mu, \Delta)] = {} & \Delta\mathbb{E}[GIG(\lambda, \delta, \psi)] \\ & + \Delta\beta\beta'\Delta\mathrm{Var}[GIG(\lambda, \delta, \psi)] \end{aligned} \tag{94.7}$$

where $\psi = \sqrt{\alpha^2 - \beta'\Delta\beta}$. (For details, see, e.g., Blæsid (1981).)

94.3 Futures Hedge Ratios

We consider a decision maker. At the decision date ($t = 0$), the agent engages in the production of $Q(Q > 0)$ commodity units for sale at the terminal date ($t = 1$) at the random cash price $P1$. In addition, at the decision date the agent can sell X commodity units in the futures market at the price F_0 but must repurchase them back at the terminal date at the random futures price F_1. Let the initial wealth be $V_0 = P_0 Q$ and the end-of-period wealth be $V_1 = P_1 Q + (F_0 - F_1)X$. Then we consider the wealth return that is

$$\begin{aligned} \widetilde{r}_\theta &= \frac{V_1 - V_0}{V_0} = \frac{P_1 Q + F_0 X - F_1 X - P_0 Q}{P_0 Q} \\ &= \frac{P_1 - P_0}{P_0} - \frac{F_1 - F_0}{F_0}\left(\frac{F_0}{P_0}\frac{X}{Q}\right) = \widetilde{r}_p - \theta\widetilde{r}_f \end{aligned} \tag{94.8}$$

where $\widetilde{r}_p = (P_1 - P_0)/P_0$ and $\widetilde{r}_f = (F_1 - F_0)/F_0$ are one-period returns on the spot and futures positions, respectively. $h = X/Q$ is the hedge ratio and $\theta = h(F_0/P_0)$. (Note that θ is so-called the adjusted hedge ratio.)

The main objective of hedging is to choose the optimal hedge ratio θ. However, the optimal hedge ratio will depend on a particular objective function to be optimized. We recall some most widely used theoretical approaches to the optimal futures hedge ratios and compute explicitly these optimal ratios in terms of the parameters for MGH distributions. For a comprehensive review of futures hedge ratios, see Chen et al. (2003).

94.3.1 Minimum Variance Hedge Ratio

The most widely used hedge ratio is the minimum variance hedge ratio which is known as the MV hedge ratio. The objective function to be minimized is the variance of $\widetilde{r}_\theta$.

Clearly we have $\mathrm{Var}[\widetilde{r}_\theta] = \sigma_{r_p}^2 + \theta^2\sigma_{r_f}^2 - 2\theta\rho\sigma_{r_p}\sigma_{r_f}$, where σ_{rp} and σ_{rf} are standard deviations of $\widetilde{r}_p$ and $\widetilde{r}_f$, respectively, and ρ is the correlation coefficient between $\widetilde{r}_p$ and $\widetilde{r}_f$. The MV hedge ratio is obtained by minimizing $\mathrm{Var}[\widetilde{r}_\theta]$. Simple calculation shows that the MV hedge ratio is given by

$$\theta_{MV}^* = \rho\frac{\sigma_{r_p}}{\sigma_{r_f}}. \tag{94.9}$$

Theorem 2.1 *Assume* $(\widetilde{r}_f, \widetilde{r}_p)'$ *is distributed as MGH*$(\lambda, \alpha, \beta, \delta, \mu, \Delta)$, *where* $\beta = (\beta_1, \beta_2)'$, $\mu = (\mu_1, \mu_2)'$, *and* $\Delta = \begin{pmatrix} \Delta_{11} & \Delta_{12} \\ \Delta_{21} & \Delta_{22} \end{pmatrix}$ *is symmetry. Then we have*

$$\theta^*{}_{MV} = \frac{\Delta_{12}\mathbb{E}[GIG] + \delta_{fp}}{\Delta_{11}\mathbb{E}[GIG] + \delta_{ff}} \tag{94.10}$$

where $GIG = GIG\left(\lambda, \delta, \sqrt{\alpha^2 - \beta'\Delta\beta}\right)$ *and*

$$\begin{aligned}\delta_{ff} &= \left[\beta_1^2\Delta_{11}^2 + 2\beta_1\beta_2\Delta_{11}\Delta_{12} + \beta_2^2\Delta_{12}^2\right]\mathrm{Var}[GIG]\\ \delta_{fp} &= \left[\beta_1^2\Delta_{11}\Delta_{12} + \beta_1\beta_2\left(\Delta_{11}\Delta_{22} + \Delta_{12}^2\right) + \beta_2^2\Delta_{12}\Delta_{22}\right]\mathrm{Var}[GIG].\end{aligned}$$

In particular, if $\beta = (0, \ldots, 0)'$, *then* $\theta_{MV}^* = \frac{\Delta_{12}}{\Delta_{11}}$.

94.3.2 Sharpe Hedge Ratio

We consider the optimal hedge ratio that incorporates both risk and expected return. Howard and D'Antonio (1984) considered the optimal level of futures contracts by maximizing the ratio of the portfolio's excess return to its volatility, that is,

$$\max_\theta \frac{\mu_{r_p} - \theta\mu_{r_f} - r_L}{\sigma_\theta}, \tag{94.11}$$

where σ_θ is the standard deviation of $\widetilde{r}_\theta, \mu_{r_p}, \mu_{r_f}$ are expected values for $\widetilde{r}_p$ and $\widetilde{r}_f$, respectively, and r_L is the risk-free interest rate.

Consider the function

$$r(\theta) = \frac{\mu_{r_p} - \theta\mu_{r_f} - r_L}{\sigma_\theta}.$$

Then we have

$$r'(\theta) = \frac{\theta\left[-\sigma_{r_f}^2\left(\mu_{r_p} - r_L\right) + \mu_{r_f}\sigma_{r_f r_p}\right] + \left(\mu_{r_p} - r_L\right)\sigma_{r_p r_f} - \sigma_{r_p}^2\mu_{r_f}}{\sigma_\theta^3} \tag{94.12}$$

where $\sigma_{r_f r_p} = \mathrm{Cov}\left(\widetilde{r}_p, \widetilde{r}_f\right)$ and, hence, the critical point for $r(\theta)$ is given by

$$\theta_s^* = \frac{\left(\frac{\sigma_{rp}}{\sigma_{rf}}\right)^2\mu_{rf} - \rho\frac{\sigma_{rp}}{\sigma_{rf}}\left(\mu_{r_p} - r_L\right)}{\rho\frac{\sigma_{rp}}{\sigma_{rf}}\mu_{rf} - \left(\mu_{r_p} - r_L\right)}. \tag{94.13}$$

It follows from Eq. 94.12 that if $\mu_{r_p} - \mu_L > \rho\frac{\sigma_{rp}}{\sigma_{r_f}}\mu_{rf}$, then $r'(\theta) > 0$ for $\theta < \theta_s^*$ and $r'(\theta) < 0$ for $\theta > \theta_s^*$. Hence, θ_s^* is the optimal hedge ratio (Sharpe hedge ratio) for Eq. 94.11. Similarly, if $\mu_{r_p} - \mu_L < \rho\frac{\sigma_{rp}}{\sigma_{r_f}}\mu_{rf}$, then $r(\theta)$ has a minimum at θ_s^*. (Note that if $\mu_{r_p} - \mu_L = \rho\frac{\sigma_{rp}}{\sigma_{r_f}}\mu_{rf}$, then $r(\theta)$ is strictly monotonic in θ_s^*.)

The measure of hedging effectiveness (abbreviated HE) is given in Howard and D'Antonio (1984) by

$$\mathrm{HE} = r\left(\theta_s^*\right)/\left(\frac{\mu_{r_p} - r_L}{\sigma_{r_p}}\right). \tag{94.14}$$

Write

$$\zeta = \frac{\mu_{r_f}/\sigma_{r_f}}{\left(\mu_{r_p} - \mathrm{r_L}\right)/\sigma_{r_p}}. \tag{94.15}$$

(ζ is also called the risk-return relative.) Then we have

$$\theta_s^* = \frac{\sigma_{rp}}{\sigma_{rf}}\left(\frac{\rho - \zeta}{1 - \zeta\rho}\right)$$

and

$$\mathrm{HE} = \sqrt{\frac{(\rho - \zeta)^2}{1 + \rho^2} + 1}.$$

Clearly the last equality implies that

$$HE\begin{cases} > 1 & \text{when} \quad \rho \neq \zeta \\ = 1 & \text{when} \quad \rho = \zeta. \end{cases}$$

Moreover, without any distribution assumption, we have the following relationship between θ_s^* and θ_{MV}^*. In particular, if the expected return on the futures contract is zero and $\mu_{r_p} > r_L$, then the Sharpe hedge ratio reduces to the minimum variance hedge ratio.

Proposition 2.2 *Assume $\mu_{r_p} > r_L$ and $1 > \zeta\rho$. Then we have*

$$\begin{cases} \theta_s^* > \theta_{MV}^* & \text{when} \quad \mu_f < 0 \\ \theta_s^* = \theta_{MV}^* & \text{when} \quad \mu_f = 0 \\ \theta_s^* < \theta_{MV}^* & \text{when} \quad 0 < \mu_f. \end{cases}$$

Recall that $\sigma_{r_f r_p} = \mathrm{Cov}\left(\widetilde{r}_p, \widetilde{r}_f\right)$. Then we have

$$\theta_s^* = \frac{\sigma_{r_p}^2 \mu_{r_f} - \sigma_{r_f r_p}\left(\mu_{r_p} - r_L\right)}{\sigma_{r_f r_p}\mu_{r_f} - \sigma_{r_f}^2\left(\mu_{r_p} - r_L\right)}. \tag{94.16}$$

From this and by Eqs. 94.6 and 94.7, we obtain

Theorem 2.3 *Assume $\left(\widetilde{r}_f, \widetilde{r}_p\right)'$ is distributed as in Theorem 2.1. Assume that $\zeta_{fp}[(\mu_1 + \beta_1\Delta_{11} + \beta_2\Delta_{12})\mathbb{E}[GIG]] < \zeta_{ff}[(\mu_2 + \beta_1\Delta_{21} + \beta_2\Delta_{22})\mathbb{E}[GIG] - \mathrm{r_L}]$.*

Then we have

$$\theta_s^* = \frac{\zeta_{pp}[(\mu_1 + \beta_1\Delta_{11} + \beta_2\Delta_{12})\mathbb{E}[GIG]] - \zeta_{fp}[(\mu_2 + \beta_1\Delta_{21} + \beta_2\Delta_{22})\mathbb{E}[GIG] - \mathrm{r_L}]}{\zeta_{fp}[(\mu_1 + \beta_1\Delta_{11} + \beta_2\Delta_{12})\mathbb{E}[GIG]] - \zeta_{ff}[(\mu_2 + \beta_1\Delta_{21} + \beta_2\Delta_{22})\mathbb{E}[GIG] - \mathrm{r_L}]} \tag{94.17}$$

where δ_{ff}, δ_{fp}, GIG are the same as in Theorem 2.1 and

$$\begin{aligned} \delta_{pp} &= \left[\beta_1^2\Delta_{21}^2 + 2\beta_1\beta_2\Delta_{21}\Delta_{22} + \beta_2^2\Delta_{22}^2\right]\mathrm{Var}[GIG] \\ \zeta_{ff} &= \Delta_{11}\mathbb{E}[GIG] + \delta_{ff} \\ \zeta_{fp} &= \Delta_{12}\mathbb{E}[GIG] + \delta_{fp} \\ \zeta_{pp} &= \Delta_{22}\mathbb{E}[GIG] + \delta_{pp}. \end{aligned}$$

94.3.3 Minimum Generalized Semivariance Hedge Ratio

In this case, the optimal hedge ratio is obtained by minimizing the generalized semivariance (GSV) given below:

$$L_n(c, X) = \int_{-\infty}^{c} (c - x)^n dF(x), \quad n > 0, \tag{94.18}$$

where $F(\cdot 7)$ is the probability distribution function of the return X. The GSV is specified by two parameters: the target return c and the power of the shortfall n. (Note that if the density function of X is symmetric at c, then we obtain $L_2(c, X) = \mathrm{Var}(X)/2$. Hence, in this case, the GSV approach is the same as that of the minimum variance.) The GSV, due to its emphasis on the returns below the target return, is consistent with the risk perceived by managers (see Lien and Tse 2001). For futures hedge, we consider $L_n(c, \theta) = L_n\left(c, \widetilde{r}_p - \theta \widetilde{r}_f\right)$.

Under some conditions on the joint distribution, we obtain that the minimum GSV hedge ratio is the same as the minimum variance hedge ratio.

Theorem 2.4 *Assume* $\left(\widetilde{r}_f, \widetilde{r}_p\right)$ *is the same as in Theorem 2.1. If* $\beta = 0$ *and* $\mu_1 = \mu_{rf} = 0$, *then the minimum GSV hedge ration is the same as the minimum variance hedge ration i.e.,* $\left(\theta^*_{GSV} = \theta^*_{MV}, = \frac{\Delta 12}{\Delta 11}\right)$.

In empirical studies, the true distribution is unknown or complicated. Then θ^*_{GSV} can be estimated from the sample by using the so-called empirical distribution method adapted in, e.g., Price et al. (1982) and Harlow (1991). Suppose we have m observations of $\left(\widetilde{r}_f, \widetilde{r}_p\right)$, say, $(r_f(i), r_p(i))$, $i = 1, 2, \ldots, m$. From this, the GSV can be estimated by the formula

$$L_n^{obs}(c, \theta) = \frac{1}{m} \sum_{i=1}^{m} \left(c - r_{i,\theta}\right)^n I_{ri,\theta \le c}, \tag{94.19}$$

where $r_{i,\theta} = r_p(i) - \theta r_f(i)$. Given c and n, numerical methods can be used to search the hedge ratio that minimizing the sample GSV, $L_n^{obs}(c,\theta)$.

94.4 Estimation and Simulation

94.4.1 Kernel Density Estimators

Assumed that we have n independent observations $x_1, \ldots, x_n$ from the random variable X with the unknown density function f. The kernel density estimator for the estimation of f is given by

$$\hat{f}_h(x) = \frac{1}{nh} \sum_{i=1}^{n} K\left(\frac{x - x_i}{h}\right), \quad x \in R \tag{94.20}$$

where K is a so-called kernel function and h is the bandwidth. In this chapter we work with the Gaussian kernel: $K(x) = 1/\sqrt{2\pi}\ \exp\left\{-x^2/2\right\}$ and $h = (4/3)^{1/5} \sigma n^{\frac{-1}{5}}$.

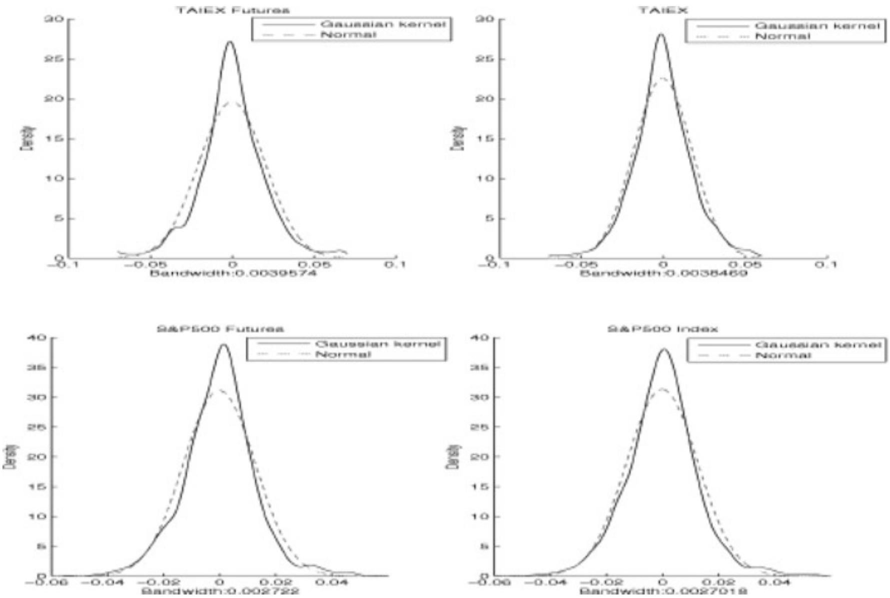

Fig. 94.1 Normal density and Gaussian kernel density estimators

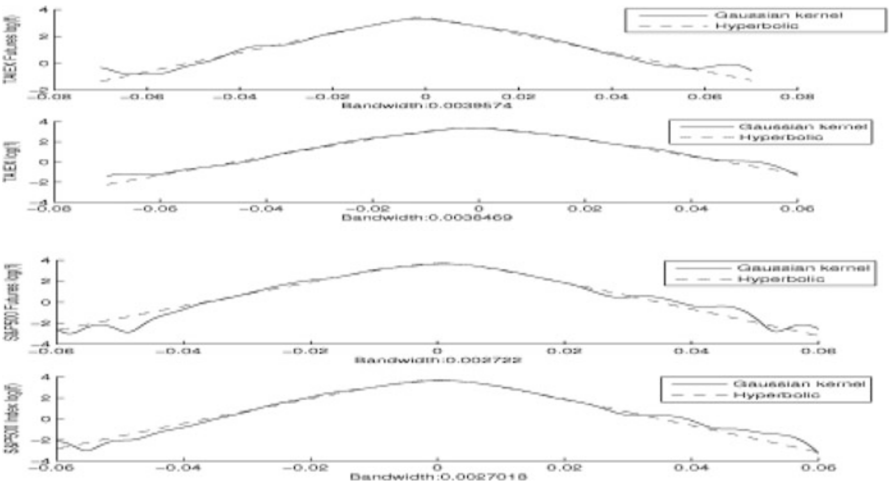

Fig. 94.2 Log-densities of daily log returns of major indices and futures (2000–2004)

(For more details, see Scott (1979).) Meanwhile it is worth noting that Lien and Tse (2000) proposed the kernel density estimation method to estimate the probability distribution of the portfolio return for every θ, and then grid search methods were adapted to find the optimum GSV hedge ratio (Figs. 94.1 and 94.2).

94.4.2 Maximum Likelihood Estimation

We focus on how to estimate the parameters of a density function $f(x; \Theta)$, where Θ is the set of parameters to be estimated. Suppose that we have m independent observations $x1, \ldots, xn$ of a random variable X with the density function $f(x; \Theta)$. The maximum likelihood estimator $\hat{\theta}_{MLE}$ is the parameter set that maximizes the likelihood function

$$L(\Theta) = \prod_{i=1}^{n} f(x_i; \Theta).$$

Clearly this is equivalent to maximizing the logarithm of the likelihood function

$$\log\ L(\Theta) = \sum_{i=1}^{n} \log\ f(x_i; \Theta).$$

The log-likelihood function for hyperbolic distribution $H(\alpha, \beta, \delta, \mu)$ is given by

$$\ell_{H(\alpha,\beta,\delta,\mu)}(\Theta) = n\left(\log\sqrt{\alpha^2 - \beta^2} - \log\ 2 - \log\ \alpha - \log\ \delta - \log\ K_1\left(\delta\sqrt{\alpha^2 - \beta^2}\right)\right) + \sum_{i=1}^{n}\left[-\alpha\sqrt{\delta^2 + (x_i - \mu)^2} + \beta(x_i - \mu)\right].$$

The symmetric MGH density function is given by the formula

$$\frac{(\alpha/\delta)^{\lambda}}{(2\pi)^{d/2} K_{\lambda}(\alpha\delta)} \frac{K_{\lambda-\frac{d}{2}}\left(\alpha\sqrt{\delta^2 + (x-\mu)'\Delta^{-1}(x-\mu)}\right)}{\left(\alpha^{-1}\sqrt{\delta^2 + (x-\mu)'\Delta^{-1}(x-\mu)}\right)^{\frac{d}{2}-\lambda}},$$

and, in particular, the two-dimensional symmetric hyperbolic distributions (i.e., $\beta = 0$ and $\lambda = 3/2$) have the density

$$\mathbf{H}_2 = \frac{(\alpha/\delta)^{3/2}}{2^{3/2}\sqrt{\pi\alpha K_{\frac{3}{2}}(\alpha\delta)}} e^{-\alpha}\sqrt{\delta^2 + (x - \mu')\Delta^{-1}(x-\mu).}$$

From this, we obtain the log-likelihood function for two-dimensional symmetric hyperbolic distributions (Figs. 94.3 and 94.4):

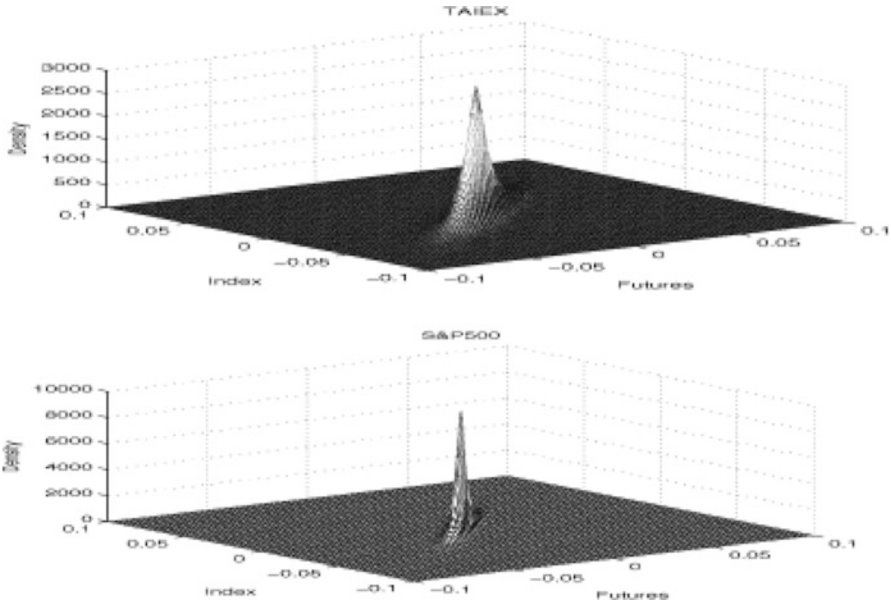

Fig. 94.3 Estimated symmetric H_2 distributions

$$\ell_{\mathbf{H}_2} = n\left[\frac{3}{2}\log\frac{\alpha}{\delta} - \frac{3}{2}\log\ 2 - \frac{1}{2}\log\ \pi - \log\ \alpha - \log\ K_{\frac{3}{2}}(\alpha\delta)\right] - \alpha\sum_{i=1}^{n}\sqrt{\delta^2 + (x_i - \mu)'\Delta^{-1}(x_i - \mu)}.$$

94.4.3 Simulation of Generalized Hyperbolic Random Variables

From the representation of GH distribution as a conditional normal distribution mixed with the generalized inverse Gaussian, a schematic representation of the algorithm reads as follows:

1. Sample Y from GIG(λ, δ, ψ) distribution
2. Sample ε from $N(0, 1)$
3. Return $X = \mu + \beta Y + \sqrt{Y}\varepsilon$

Similarly, for simulating an MGH distributed random vector, we have:

1. Set $\Delta = L^T L$ via Cholesky decomposition
2. Sample Y from GIG(λ, δ, ψ) distribution
3. Sample Z from $N(0, I)$, where I is $d \times d$-identity matrix
4. Return $X = \mu + Y\Delta\beta + \sqrt{Y}L^T Z$

The efficiency of the above algorithms depends on the method of sampling the generalized inverse Gaussian distributions. Atkinson (1982) applied the method of rejection algorithm to sampling GIG. We adopt their method for simulation of estimated hyperbolic random variables.

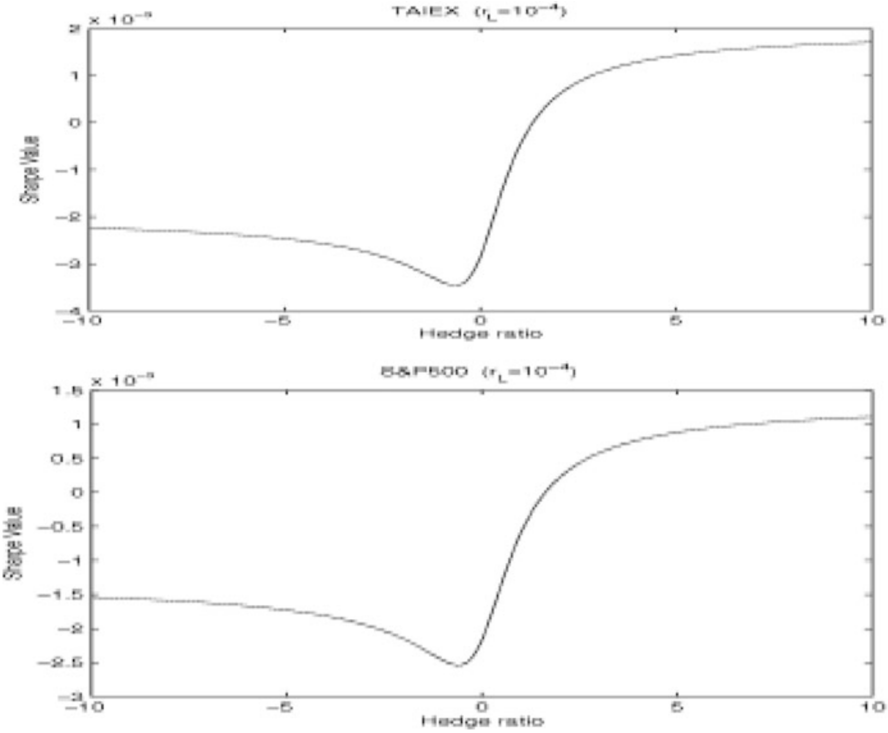

Fig. 94.4 Sharpe value

94.5 Concluding Remarks

Although there are many different theoretical approaches to the optimal futures hedge ratios, under the martingale and joint-normality assumptions, various optimal hedge ratios are identical to the minimum variance hedge ratio. However, empirical studies show that major market data reject the joint-normality assumption. In this paper we propose the generalized hyperbolic distribution as the joint log-return distribution of the spot and futures. In terms of the parameters for generalized hyperbolic distributions, we obtain several most widely used optimal hedge ratios: minimum variance, maximum Sharpe measure, and minimum generalized semivariance. In particular, under mild assumptions on the parameters, we show that these theoretical approaches are equivalent.

To estimate these optimal hedge ratios, we first write down the log-likelihood functions for symmetric hyperbolic distributions. Then we calculate these parameters by maximizing the log-likelihood functions. Using these MLE parameters for the GH distributions, we obtain the MV hedge ratio and the optimal Sharpe hedge ratio by Theorems 2.1 and 2.3, respectively. Also based on the MLE parameters and the numerical method, we calculate the minimum generalized semivariance hedge ratio.

Regarding the equivalence of these three optimal hedge ratios, our results suggest that the martingale property plays a much important role than the joint distribution assumption.

However, conditional heteroskedasticity and stochastic volatility are observed in many spot and futures price series. This implies that the optimal hedge strategy should be time-dependent. To account for this dynamic property, parametric specifications of the joint distribution are required. Based on our work here, it is interesting to extend the results to time-varying hedge ratios.

Instrumental Variables Approach to Correct for Endogeneity in Finance

95

Chia-Jane Wang

Contents

Abstract

The endogeneity problem has received a mixed treatment in corporate finance research. Although many studies implicitly acknowledge its existence, the literature does not consistently account for endogeneity using formal econometric methods. This chapter reviews the instrumental variables (IV) approach to endogeneity from the point of view of a finance researcher who is implementing instrumental variables methods in empirical studies. This chapter is organized into two parts. Part I discusses the general procedure of the instrumental variables approach, including two-stage least square (2SLS) and generalized method

of moments (GMM), the related diagnostic statistics for assessing the validity of instruments, which are important but not used very often in finance applications, and some recent advances in econometrics research on weak instruments. Part II surveys corporate finance applications of instrumental variables. We found that the instrumental variables used in finance studies are usually chosen arbitrarily, and very few diagnostic statistics are performed to assess the adequacy of IV estimation. The resulting IV estimates thus are questionable.

Keywords
Endogeneity • OLS • Instrumental variables (IV) estimation • Simultaneous equations • 2SLS • GMM • Overidentifying restrictions • Exogeneity test • Weak instruments • Anderson-Rubin statistic • Empirical corporate finance

95.1 Introduction

Corporate finance often involves a number of decisions that are intertwined and endogenously chosen by managers and/or debtholders and/or shareholders. For example, in order to maximize value, firms must form an effective board of directors and grant their managers an optimal pay-performance compensation contract. Debtholders have to decide how much debt and with what features (junior or senior, convertible, callable, maturity length, etc.) should the debt be structured. Given that these endogenously chosen variables are interrelated and are often partially driven by unobservable firm characteristics, the endogeneity problem can make the standard OLS results hard to interpret (Hermalin and Weisbach 2003).

The usual approach to the endogeneity problem is to implement the instrumental variables estimation method. In particular, one chooses instrumental variables that are correlated to the endogenous regressors, but uncorrelated to the structural equation errors and then employs a two-stage least square (2SLS) procedure.

The endogeneity problem has received a mixed treatment in corporate finance research. Although many studies implicitly acknowledge its existence, the literature does not consistently account for endogeneity using formal econometric methods. There is an increasing emphasis on addressing the endogeneity problem in recent work, and the simultaneous equations model is now being used more commonly. However, the instrumental variables are often chosen arbitrarily and few diagnostic statistics are performed to assess the adequacy of IV estimation.

This chapter reviews the instrumental variables approach to endogeneity from the point of view of a finance researcher who is implementing instrumental variables methods in empirical studies. We do not say much on the distribution theory and the mathematical proofs of estimation methods and test statistics as they are well covered in econometrics textbooks and articles. The chapter proceeds as follows: Sect. 95.2 describes the statistical issue raised by endogeneity. Section 95.3 discusses the commonly used instrumental variables approaches to endogeneity: the two-stage least squares estimation (2SLS) and the generalized method of moments (GMM) estimation. Section 95.4 discusses the conditions of a valid instrument and the related diagnostic statistics, which are critical but not frequently used in finance applications. Section 95.5 considers the weak instrument problem, that is, the instruments are exogenous but have weak explanatory power for explaining the endogenous regressor. Some recent advances in econometrics research on statistical inference with weak instruments are briefly discussed. Section 95.6 surveys corporate finance applications of instrumental variables. Section 95.7 concludes.

95.2 Endogeneity: The Statistical Issue

To illustrate the endogeneity issue, assume that we wish to estimate parameter β of a linear regression model for a population of firms

$$Y = X\beta + u \tag{95.1}$$

where Y is the dependent variable, which is typically an outcome such as return or profitability, X is the regressor that explains the outcome, and u is the unobservable random disturbance or error. If u satisfies the classical regression conditions, the parameters β can be consistently estimated by the standard OLS procedures. This can be shown from the probability limit of OLS estimator

$$\text{Plim } \beta_{OLS} = \beta + \text{Cov}(X, u)/\text{Var}(X) \tag{95.2}$$

When the disturbance and the regressor are not correlated and hence the second term is zero, the OLS estimator will be consistent. But if the disturbance is correlated with the regressor, that is, the explanatory variable in Eq. 95.1 is potentially endogenous,[1] the usual OLS estimation generally results in biased estimator.

In applied finance work, endogeneity is often caused by omitted variables and/or simultaneity. Omitted variables problem arises when the explanatory variable X is hard to measure or depends on some unobservable factors, which are part of the error term u, thus X and u are correlated. The correlation of explanatory variables with unobservable may be due to self-selection: the firm makes the choice of X for the reason that is unobservable. An example is the private information held by a firm in making a debt issue, in which the terms and structure of the debt offering are likely to be correlated with unobserved private information held by the firm. The Heckman two-step procedure (Heckman 1979) is extensively used in corporate

[1]Traditionally, a variable is defined as endogenous if it is determined within the context of a model. However, in applied econometrics the "endogenous" variable is used more broadly to describe the situation where an explanatory variable is correlated with the disturbance and the resulting estimator is biased (Wooldridge 2002).

finance for modeling this omitted variable.[2] Endogeneity may also be caused by simultaneity, in which one or more of the explanatory variables are determined simultaneously along with the dependent variable. For example, if Y is firm value and X is management compensation, the management compensation contract is partly determined by the anticipated firm value Y from choosing X, and the general OLS estimator is biased in this situation.

95.3 Instrumental Variable Approach to Endogeneity

95.3.1 Instrumental Variables and Two-Stage Least Square (2SLS)

The method of instrumental variable (IV) approach provides a general solution to the problem of endogenous explanatory variables. To see how, consider the following setup:

$$Y = X\beta + u \tag{95.3}$$

where Y is $N \times 1$ vector of observations on the dependent variable, X is $N \times K$ matrix of explanatory variables, and u is unobservable mean-zero $N \times 1$ vector of disturbance correlated with some elements of X.

To use the IV approach, we need instruments at least as many as explanatory variables in the model. The instruments should be sufficiently correlated with the endogenous explanatory variables but asymptotically uncorrelated with u, and the explanatory variables that are exogenous can serve as their own instruments as they are uncorrelated with u. Specifically, the valid instruments must satisfy the orthogonality condition and there must be no linear dependencies among the exogenous variables.

In a just-identified setup, using an $N \times K$ matrix Z to instrument for X, the IV estimator can be solved as

$$\beta_{IV} = (Z'X)^{-1}(Z'Y) + (Z'X)^{-1}Z'u \tag{95.4}$$

$$\beta_{IV} = \beta + (Z'X)^{-1}Z'u \tag{95.5}$$

If Z and u are not correlated and $Z'X$ has full rank

$$E(Z'u) = 0 \tag{95.6}$$

$$E(Z'X) = K \tag{95.7}$$

[2]The finance literature using self-selection models has little interest in estimating the endogenous decision itself (the parameter β in Eq. 95.1) but is more interested in using self-selection models to reveal and test for the private information that influences the decision. In contrast, this chapter focuses on how to implement IV approach to estimate the parameter consistently. The readers interested in finance application of self-selection models are referred to Li and Prabhala (2007).

The second term of the right hand side of Eq. 95.5 becomes 0, β_{IV} will be consistent and the unique solution for the true parameters β when the conditions (95.6) and (95.7) hold.

When we have more exogenous variables than needed to identify the parameters, for example, if the instrumental variables Z is an $N \times L$ matrix, where $L > K$, the model is said to be overidentified, and there are $(L - K)$ overidentifying restrictions because $(L - K)$ instruments could be discarded and the parameters can still be identified. If $L < K$, the parameters cannot be identified. Therefore, the order condition $L \geq K$ is necessary for the rank condition, which requires that Z is sufficiently related to X so $Z'K$ has full column rank K. In an overidentifying model, any linear combinations of the instruments can also be used as instruments. Under homoskedasticity, the two-stage least square (2SLS) is the most efficient IV estimator out of all possible linear combinations of the valid instruments since the method of 2SLS chooses the most highly correlated with the endogenous explanatory variable.

The name "two-stage least squares" comes from its two-step procedure:

Step 1: Obtain the fitted value of each endogenous explanatory variable from regressing each endogenous explanatory variable on all instrumental variables. This is called the first-stage regression. Using the matrix notation, the matrix of the fitted values can be expressed as $\hat{X} = Z(Z'Z)^{-1}Z'X$ (if any x_i is exogenous, its fitted value is itself).

Step 2: Run the OLS regression of the dependent variable on the exogenous explanatory variables in the structural Eq. 95.1 and the fitted values obtained from the first-stage regression in place of the observations on the endogenous variables. This is the second-stage regression. The IV/2SLS estimator that uses the instruments $\hat{X}$ can be written as $\hat{\beta} = \left(\hat{X}'X\right)^{-1}\hat{X}'Y$. Substitute $Z(Z'Z)^{-1}Z'X$ for $\hat{X}$; this 2SLS estimator can be written as

$$\hat{\beta} = \left[X'Z(Z'Z)^{-1}Z'X\right]^{-1}X'Z(Z'Z)^{-1}Z'Y \tag{95.8}$$

In practice, it is best to use a software package with 2SLS command rather than carry out the two-step procedure because the reported OLS standard errors of the second-stage regression are not the 2SLS standard errors. The 2SLS residuals and covariance matrix are calculated by the original observations on the explanatory variables instead of the fitted values of the explanatory variables.

In searching valid instrument, both the orthogonality condition and the rank condition are equally important. When an instrument is not fully exogenous and the correlation between the instrument and the explanatory variable is too small, the bias in IV estimator may not be smaller than the bias in OLS estimator. To see this, we compare the bias in the OLS estimator with the bias in the IV estimator for model (95.3):

$$\beta_{OLS} - \beta = Cov(X, u)/Var(X) = \sigma_u \rho_{x,u}/\sigma_x \tag{95.9}$$

$$\beta_{IV} - \beta = \mathrm{Cov}(Z, u)/\mathrm{Cov}(X, Z) = \sigma_u \rho_{z,u}/\sigma_x \rho_{x,z} \tag{95.10}$$

where $\rho_{i,j}$ is the correlation coefficient between variable i and variable j. Thus, the IV estimator has smaller bias than OLS estimator only if $\rho^2_{x,z}$ is larger than $\rho^2_{z,u}/\rho^2_{x,u}$.[3] Although this comparison involves the population correlations with unobservable variable *u* and cannot be estimated directly, it indicates that when the instrument is only weakly correlated to the endogenous regressor, the IV estimator is not likely to improve upon on the OLS (see Bartels 1991 for the discussions of quasi-instrumental variables). Even if the instruments are perfectly exogenous, the low relevance of the instruments can increase asymptotic standard errors and reduce the power of the tests. We can see from Eq. 95.10 that the inconsistency in the IV estimator can get extremely large if the correlation between X and Z gets close to zero and makes the IV estimator undesirable.

The orthogonality of an instrument is difficult to ascertain because we cannot test the correlation between one observable instrument and the unobservable disturbance. But in the case of overidentifying model (i.e., the number of instruments exceeding the number of regressors), the overidentifying restrictions test can be used to evaluate the validity of the additional instruments under the assumption that at least one instrument is valid. We will discuss the tests for validity of the instrument in Sect. 95.4. For checking the rank condition, often we estimate the reduced form for each endogenous explanatory to make sure that at least one of the instruments not in X is significant. If the reduced form regression fits poorly, the model is said to suffer from weak instrument problem and the standard asymptotic theory cannot be employed to make inference. We will discuss the weak instruments problem in Sect. 95.5.

95.3.2 Hypothesis Testing with 2SLS

Testing hypotheses about a single parameter estimate in model (95.3) is straightforward using an asymptotic t-statistic. For testing restrictions on multiple parameters, Wooldridge (2002) provides a method to compute a residual-based F-statistic. Rewrite the Eq. 95.3 into a partitioned model

$$Y = X_1\beta_1 + X_2\beta_2 + u \tag{95.11}$$

where X_1 is $N \times K_1$, X_2 is $N \times K_2$, and $K_1 + K_2 = K$. Let Z denote an $N \times L$ matrix of instruments and assume the rank and the orthogonality conditions hold. Our interest is to test the K_2 restrictions:

$$H_0 : \beta_2 = 0 \text{ against } H_1 : \beta_2 \neq 0 \tag{95.12}$$

In order to calculate the F-statistics for 2SLS, we need to calculate the sum of squared residuals from the restricted second-stage regression, denoted as $\hat{SSR}_r$; the sum of squared residuals from the unrestricted second-stage regression, denoted as $\hat{SSR}_{ur}$; and the sum of squared residuals from unrestricted 2SLS, denoted as SSR_{ur}.

The F-statistics is calculated as

$$F \equiv \frac{\left(S\hat{S}R_r - S\hat{S}R_{ur}\right)}{SSR_{ur}} \cdot \frac{(N-K)}{K_2} \sim F_{K2,\,N-K} \tag{95.13}$$

When the homoskedasticity assumptions cannot be made, we need to calculate the heteroskedasticity-robust standard errors for 2SLS. Some statistical packages compute these standard errors using a simple command. Wooldridge (2002) shows the robust standard errors can be computed in the following steps:

Step 1: Apply 2SLS procedures and obtain the 2SLS residual, denoted $\hat{u}_i$ for each observation i, $i = 1\ldots N$, then use $\hat{u}_i$ to calculate the SSR and $\hat{\sigma}^2$, where $\hat{\sigma}^2 \equiv \frac{SSR}{N-K}$, and $\mathrm{Var}\left(\hat{\beta}_j\right)$, where $\mathrm{Var}\left(\hat{\beta}_j\right) = \hat{\sigma}^2\left(\hat{X}'\hat{X}\right)^{-1}$, and the standard error is denoted as $se\left(\hat{\beta}_j\right)$, $j = 1\ldots K$.

Step 2: Obtain the fitted value of each explanatory variables, denoted as $\hat{x}_{ij}$, $j = 1\ldots K$.

Step 3: Regress each element of $\hat{x}_{ij}$ on all other $\hat{x}_{ik}$ where $k \neq j$, and obtain the residuals from the regressions, denoted as $\hat{r}_{ij}$for each j.

Step 4: Compute the heteroskedasticity-robust standard errors of $\hat{\beta}_j$, denoted as $se_{heter}\left(\hat{\beta}_j\right)$:

$$se_{heter}\left(\hat{\beta}_j\right) = \left[\frac{N}{(N-K)}\right]^{1/2}\left[\frac{se\left(\hat{\beta}_j\right)}{\hat{\sigma}}\right]^2\left[\frac{1}{\hat{m}_j}\right]^{1/2}, \text{where } \hat{m}_j = \sum_{i=1}^{N} \hat{r}_{ij}\hat{u}_i \tag{95.14}$$

95.3.3 Instrumental Variables and Generalized Method of Moments (GMM)

When we have a system of equations, with sufficient instruments we can still apply 2SLS procedure to each single equation in the system to obtain acceptable results. However, in many cases we can obtain more efficient estimators by estimating parameters in the system equations jointly. This system instrumental variables estimation approach is based on the principle of the generalized method of moments (GMM). As discussed in the previous section, the orthogonality conditions require that the valid instruments are uncorrelated to the disturbance, i.e., the population moment condition $E(Z'\mu)$ is equal to zero. Thus, by this principle the optimal parameter estimate is chosen so that the corresponding sample moment is also equal to zero. To show this, reconsider the linear model (95.3) for a random sample from the population, with Z as an $N \times L$ matrix of instruments orthogonal to u for the set of L linear equations in K unknowns and assume the rank condition holds, the sample moment condition must satisfy

$$N^{-1}\sum_{i=1}^{N} Z_i'(Y_i - X_i\hat{\beta}) = 0 \tag{95.15}$$

where the *i* subscript is included for notational clarity. When we have an exactly identified model where $L = K$ and $Z'X$ is invertible, we can solve for the generalized method of moments (GMM) estimator $\hat{\beta}$ in full matrix notation as $\hat{\beta} = (Z'X)^{-1} Z'Y$, which is the same IV estimator obtained in Eq. 95.4. When $L > K$, the model is overidentified; we cannot choose K unknowns to satisfy the L equations and generally the Eq. 95.15 will not have a solution. If we cannot set the sample moment condition exactly equal to zero, we can at least choose the parameter estimate $\hat{\beta}$ so that the vector in Eq. 95.15 is as close to zero as possible. One idea is to minimize the squared Euclidean length of the $L \times 1$ vector in Eq. 95.15 and the optimal GMM estimator $\hat{\beta}$ is the minimizer.

The starting point for GMM estimation is to specify the GMM criterion function $Q\left(\hat{\beta}, Y\right)$, which is the sample moment in Eq. 95.15 in a quadratic form with an $L \times L$ symmetric and positive definite weighting matrix $\hat{W}$:

$$Q\left(\hat{\beta}, Y\right) \equiv \left[\sum_{i=1}^{N} Z_i'\left(Y_i - X_i\hat{\beta}\right)\right]' \hat{W} \left[\sum_{i=1}^{N} Z_i'\left(Y_i - X_i\hat{\beta}\right)\right] \tag{95.16}$$

The GMM estimator $\hat{\beta}$ can be obtained by minimizing the criterion function $Q\left(\hat{\beta}, Y\right)$ over $\hat{\beta}$ and the unique solution in full matrix notation is

$$\hat{\beta} = \left(X'Z\hat{W}Z'X\right)^{-1}\left(X'Z\hat{W}Z'Y\right) \tag{95.17}$$

It can be shown that if the rank condition holds and the chosen weighting matrix $\hat{W}$ is positive definite, the resulting GMM estimator is asymptotically consistent. There is no shortage of such matrix. However, it is important that we choose the weighting matrix that produces the GMM estimator with the smallest asymptotic variance. To do this, first we need to find the asymptotic variance matrix of $\sqrt{N}\left(\hat{\beta} - \beta\right)$. Plug Eq. 95.17 into Eq. 95.3 to get

$$\hat{\beta} = \beta + \left(X'Z\hat{W}Z'X\right)^{-1}\left(X'Z\hat{W}Z'u\right) \tag{95.18}$$

Thus, the asymptotic variance matrix Avar $\sqrt{N}\left(\hat{\beta} - \beta\right)$ can be shown as

$$\begin{aligned} \mathrm{Avar}\sqrt{N}\left(\hat{\beta} - \beta\right) &= \mathrm{Var}\left[(C'WC)^{-1}C'WZ'u\right] \\ &= (C'WC)^{-1}C'WSWC(C'WC)^{-1} \end{aligned} \tag{95.19}$$

where $Z'X \equiv C$, $S \equiv \mathrm{Var}(Z'u)$. It can be shown that if the weighting matrix W is chosen such that $W = S^{-1}$, the GMM estimator has the least asymptotic variance. The details can be found in Hayashi (2000, p. 212). By setting $W \equiv S^{-1}$, the Eq. 95.19 can be simplified as

$$\text{Avar}\,\sqrt{N}\left(\hat{\beta}-\beta\right)=\left(C'S^{-1}C\right)^{-1}=\left(X'ZS^{-1}ZX\right)^{-1} \tag{95.20}$$

Therefore, the efficiency of the GMM estimator depends on if we can consistently estimate S (the variance of the asymptotic distribution of $Z'u$). Since the 2SLS estimator is consistent though not necessarily efficient, it can be used as an initial estimator to obtain the residuals, which in turn can be used as the estimator for S. The two-step efficient GMM procedure is given in Wooldridge (2002) as follows:

Step 1: Use the 2SLS estimator as an initial estimator since it is consistent, denoted as $\widetilde{\beta}$, to obtain the 2SLS residuals by $\widetilde{\mu}_i = Y_i - X_i\widetilde{\beta}$, $i = 1, 2, \ldots, N$. For a system of equations, apply 2SLS equation by equation. This allows the possibility that different instruments are used for different system equations.

Step 2: Estimate S, the variance of the asymptotic distribution of $Z'u$ by

$$\hat{S}=N^{-1}\sum_{i=1}^{N}Z_i'\widetilde{u}_i\widetilde{u}_i'Z_{ii} \tag{95.21}$$

Then use $W=\hat{S}^{-1}$ as the weighting matrix to obtain the efficient GMM estimator. We can plug $\hat{S}^{-1}$ into Eq. 95.17 and obtain the efficient GMM estimator

$$\hat{\beta}=\left(X'Z\hat{S}^{-1}Z'X\right)^{-1}\left(X'Z\hat{S}^{-1}Z'Y\right) \tag{95.22}$$

Following Eq. 95.19, the asymptotic variance matrix $\hat{V}$ of the optimal GMM estimator can be estimated as

$$\hat{V}=\left(X'Z\hat{S}^{-1}ZX\right)^{-1} \tag{95.23}$$

The square roots of diagonal elements of this matrix $\hat{V}$ are the asymptotic standard errors of the optimal GMM estimator.

95.3.4 Hypothesis Testing Using GMM

The t-statistics for the hypothesis testing after GMM estimation can be directly computed by using the asymptotic standard errors obtained from the variance matrix $\hat{V}$. For testing multiple restrictions, the GMM criterion function can be used to calculate the statistic. For example, suppose our interest is to test Q restrictions for the K unknowns in the system; thus, the Wald statistics is a limiting null χ^2_Q. To apply this statistics, we need to assume the optimal weighting matrix $W = S^{-1}$ is chosen to obtain the GMM estimator with and without imposing the Q restrictions. Define the residuals evaluated at the unrestricted GMM estimator $\hat{\beta}_u$ as $\hat{u}_u \equiv Y_i - X_i\hat{\beta}_u$ and the residuals evaluated at the restricted GMM estimator $\hat{\beta}_r$ as $\hat{u}_r \equiv Y_i - X_i\hat{\beta}_r$. By plugging the calculated residuals $\hat{u}_u$ and $\hat{u}_r$ into the criterion function (95.16) for the unrestricted model and the restricted model, respectively, the criterion function statistic is computed as the difference between the two criterion function values, divided by the sample size N. The criterion function statistic has chi-square distribution with Q degrees of freedom.

95.4 Validity of Instrumental Variables

95.4.1 Test for Exogeneity of Instruments

When researchers explore various alternative ways to solve the endogeneity problem and consider the instrumental variables estimation to be the most promising econometric approach, the next step is to find and justify the instruments used. The orthogonality condition (95.6) is the sufficient condition in order for a set of instruments to be valid. When the condition is not satisfied, the IV estimator is inconsistent. In practice, we cannot test whether an observable instrument is uncorrelated with the unobservable disturbance. But when we have more instruments than needed to identify an equation, we can use any subset of the instruments for estimation and the estimates should not be significantly different if the instruments are valid. Following the principle of Hausman (1978), we can test whether the additional instruments are valid by comparing the estimates of an overidentified model with those of a just-identified model.

The model we wish to test is

$$Y = X\beta + u \tag{95.24}$$

where X is a vector of $1 \times K$ explanatory variables with some elements correlated with u, Z is a vector of $1 \times L$ instruments, and $L > K$ so the model has $L - K$ overidentifying restrictions and we can use any $1 \times K$ subset of Z as instruments for X. Let Z_1 be a vector of $1 \times (L - K)$ extra instruments. The overidentifying restrictions require that $E(Z_1{}' u) = 0$. The LM statistic can be computed by regressing the 2SLS residuals from the original model (95.24) on the full set of instruments Z and use the obtained uncentered R^2 times N. The asymptotic distribution of the statistic is χ^2_{L-K}. Another way to test the overidentifying restrictions is to use a test statistic based on the difference between the minimized values of the IV criterion function for the overidentified model and the just-identified model. By the moment condition, the minimized value of the criterion function is equal to zero for the just-identified model. Thus, the test statistic is the minimized value of the criterion function for the overidentified model (95.24), divided by the estimate of the error variance from the same model. This test is called Sargan's test, after Sargan (1958), and numerically the Sargan's test is identical to the LM statistic discussed above.

The usefulness of the overidentifying restrictions test is that if we cannot reject the null, we can have some confidence in the overall set of instruments used. This suggests that it is preferable to have an overidentified model for empirical application, because the overidentifying restrictions can and should always be tested. However, we also need to note that the overidentifying restrictions test is performed under the assumption that at least one instrument is valid. If this assumption does not hold, we will have a situation that all instruments have similar bias and the test will not reject the null. It could also be that the test has low power [4] for detecting the endogeneity of some of the instruments.

The heteroskedasticity-robust test can be computed as follows. Let H be any $1 \times (L - K)$ subset of Z. Regress each element of H onto the fitted value of X and collect the residuals, denoted as $\hat{v}$. The asymptotic χ^2_{L-K} test statistic is obtained as N minus the sum of squared residuals from regressing 1 on $\hat{u}'\hat{v}$.

For the system equations using GMM estimation, the test of overidentifying restrictions can be computed by using a similar criterion function-based procedure. The overidentification test statistic is the minimized criterion function (95.16) evaluated at the optimal (efficient) GMM estimator, and there is no need to be divided by an estimator of error variance because the GMM criterion function takes account of the covariance matrix of the error terms:

$$\left[N^{-1/2}\sum_{i=1}^{N} Z_i'\left(Y_i - X_i\hat{\beta}\right)\right]' \hat{W}\left[N^{-1/2}\sum_{i=1}^{N} Z_i'\left(Y_i - X_i\hat{\beta}\right)\right] \sim \chi^2_{L-K} \tag{95.25}$$

The GMM estimator using the optimal weighting matrix is called the minimum chi-square estimator because the GMM estimator $\hat{\beta}$ is chosen to make the criterion function minimum. If the chosen weighting matrix is not optimal, the expression (95.25) fails to hold. This test statistic is often called Hansen's J-statistic after Hansen (1982) or Hansen-Sargan statistic for its close relationship with the Sargan's test in the IV/2SLS estimation. The Hansen's J-statistic is distributed as chi-square in the number of overidentifying restrictions, $(L - K)$, since K degrees of freedom are lost for having estimated K parameters,[5] and it is consistent in the presence of heteroskedasticity.

It is strongly suggested that an overidentifying restrictions test on instruments should always be performed before formally using the IV estimation, but we also need to be cautious in interpreting the test results. There are several situations in which the null will be rejected. One possibility is that the model is correctly specified, and some of the instruments are indeed correlated with the disturbance and thus are invalid. The other possibility is that the model is not correctly specified, for instance, some variables are omitted from the regression function. In either case, the overidentifying test statistic leads us to reject the null hypothesis but we cannot be certain about which is the case. Another problem is that in small samples, the actual size of the Hansen's J-test far exceeds the nominal size and the test usually rejects too often.

---

[4] If the instruments are only weakly related to the endogenous explanatory variables, the power of the test can be low.

[5] A potential problem is that the test is not consistent against some failures of the orthogonality condition due to the loss of degrees of freedom from K to K-L.

95.4.2 Whether IV Estimator Is Really Needed

In many cases, we may suspect that certain explanatory variables are endogenous but do not know whether the IV estimation is reasonably preferred to the OLS estimation. However, it is important to know that using instrumental variable to solve for the endogeneity problem in empirical research is like a trade-off between efficiency and consistency. As discussed in Bartels (1991), the asymptotic mean square error of the IV estimator can be partitioned into three components:

$$\mathrm{AMSE}\left(\hat{\beta}_{\mathrm{IV}}\right) = \left[\sigma^2{}_{\mathrm{u}}/\mathrm{N}\sigma^2{}_{\mathrm{X}}\right]\left[1 + \left(1 - \sigma^2{}_{\mathrm{XZ}}\right)/\sigma^2{}_{\mathrm{XZ}} + \mathrm{N}\sigma^2{}_{\mathrm{Zu}}/\sigma^2{}_{\mathrm{XZ}}\right] \quad (95.26)$$

where u is the structural error, X is the explanatory variable, Z is the instrumental variable, and N is the sample size. The first term in the second bracket of (95.26) corresponds to the asymptotic variance of the OLS estimator, the second term corresponds to the additional asymptotic variance produced by using IV estimator rather than the OLS estimator, and the third term captures the inconsistency if the instruments are not truly exogenous. Thus, even when we find perfectly exogenous instruments so that $\sigma^2{}_{\mathrm{Zu}} = 0$, the standard error for the IV estimator will exceed the standard error for the OLS estimator by $1/\sigma^2{}_{\mathrm{XZ}}$. As the correlation between X and Z gets close to zero, the standard error for the IV estimator can get extremely large.

Because the IV estimator is less efficient than the OLS estimator, unless we have strong evidence that the explanatory variable is endogenous, the IV estimation is not preferred to the OLS estimation. Therefore, it is always useful to run a test for endogeneity before using the IV approach. This endogeneity test dates back to Durbin (1954), subsequently extended by Wu (1973) and Hausman (1978). Thus, we refer to the test of this type as Durbin-Wu-Hausman tests. To illustrate the procedure, write a population model as

$$\mathrm{Y}_1 = \beta\mathrm{Y}_2 + \gamma\mathrm{Z}_1 + \mathrm{u} \quad (95.27)$$

where Y_1 is the dependent variable, Y_2 is $1 \times \mathrm{K}_2$ vector of the possible endogenous explanatory variables, Z_1 is $1 \times \mathrm{K}_1$ vector of exogenous explanatory variables, and $\mathrm{K}_1 + \mathrm{K}_2 = \mathrm{K}$; also Z_1 is a subset of the $1 \times \mathrm{L}$ exogenous variables Z, assuming Z satisfies the orthogonality condition and $\mathrm{E}(\mathrm{Z}'\mathrm{Y}_2)$ has full rank.

Our interest is to test the null hypothesis that Y_2 is actually exogenous:

$$\begin{aligned} \mathrm{H}_0 &: \mathrm{Y}_1 = \beta\mathrm{Y}_2 + \gamma\mathrm{Z}_1 + \mathrm{u}, \mathrm{E}(\mathrm{Y}_2{}'\mathrm{u}) = 0 \text{ against} \\ \mathrm{H}_1 &: \mathrm{Y}_1 = \beta\mathrm{Y}_2 + \gamma\mathrm{Z}_1 + \mathrm{u}, \mathrm{E}(\mathrm{Y}_2{}'\mathrm{u}) \neq 0 \end{aligned}$$

Under H_0 both IV and the OLS estimators are consistent, and they should not differ significantly. Under H_1 only the IV estimator is consistent. Thus, the original idea of the endogeneity test is to check whether the IV estimator is significantly different from the OLS estimator. The test can also be made by just comparing the estimated coefficients of the parameters of interest, which is $\hat{\beta}$ in our case. The suitable Hausman statistic thus can be calculated as $\left(\hat{\beta}_{IV}-\hat{\beta}_{OLS}\right)'\left[\mathrm{Var}\left(\hat{\beta}_{IV}\right)-\mathrm{Var}\left(\hat{\beta}_{OLS}\right)\right]^{-1}\left(\hat{\beta}_{IV}-\hat{\beta}_{OLS}\right)$.[6]

We often use Hausman (1978) regression-based form of the test, which is easier to compute and asymptotically equivalent to the original endogeneity test. Following the procedure described in Wooldridge (2002), the first step is to regress each element of the K_2 possibly endogenous variables against all exogenous variables Z. The $1 \times K_2$ vector of the obtained reduced form error is denoted as ν. Since Z is uncorrelated to the structural error u and the reduced form error ν, Y_2 is endogenous if and only if u and ν are correlated. To test this, we can project *u* onto ν as

$$u = \lambda\nu + e \tag{95.28}$$

where ν is uncorrelated to *e* and *e* is uncorrelated to Z; thus, the test of whether Y_2 is exogenous is equivalent to test whether the joint test of λ (the K_2 restrictions) is significantly different from 0.

By plugging Eqs. 95.9 into 95.8, we have the equation

$$Y_1 = \beta Y_2 + \gamma Z_1 + \lambda\nu + e \tag{95.29}$$

Since e is uncorrelated to ν, Z_1, and Y_2 by construction, the test of the null hypothesis can be done by using a standard joint F-test on λ in an OLS regression (for the single endogenous variable, a t-statistic can be used in the same procedure), and the F-statistic has the $F(K_2, N\text{-}K\text{-}K_2)$ distribution. If we reject the null H_0: $\lambda = 0$, there is evidence that at least some elements of Y_2 are indeed endogenous. So the use of IV approach is justified assuming the instruments are valid. If the heteroskedasticity is suspected under H_0, the test can be made robust to heteroskedasticity in μ (since $\mu = e$ under H_0) by computing the heteroskedasticity-robust standard errors.[7] Another use of this regression-based form of the test is that the OLS estimates of β and λ for Eq. 95.29 should be identical to their 2SLS estimates for the Eq. 95.27 using Z as the instruments (see Davidson and MacKinnon 1993 for the details), and that allows us to examine whether the differences in the OLS and 2SLS point estimates are practically significant.

[6]If the assumption of homoskedasticity cannot be made, this standard error is invalid because the asymptotic variance of the difference is no longer the difference in asymptotic variances.

[7]Since the robust (Hubert-White) standard errors are asymptotically valid to the presence of heteroskedasticity of unknown form including homoskedasticity, these standard errors are often reported in empirical research especially when the sample size is large. Several statistical packages such as Stata now report these standard errors with a simple command, so it is easy to obtain the heteroskedasticity-robust standard errors.

95.5 Identification and Inferences with Weak Instruments

95.5.1 Problems with Weak Instruments and Diagnosis

As stated in the very beginning of this chapter, a valid instrument should be asymptotically uncorrelated with the structural error (orthogonality) but sufficiently correlated with the endogenous explanatory variable for which it is supposed to serve as instrument (relevance). The relevance condition is critical for the structural model to be identified. If the instruments have little relevance, the instruments will not enter the first-stage regression, then the sampling distribution of IV statistics are generally not normal and the IV estimates and standard tests are unreliable.

A simple way to detect the presence of weak instruments is to look at the first-stage F-statistic for the null hypothesis that the instruments are jointly equal to zero. Staiger and Stock (1997) suggest that the instruments are considered to be weak if the first-stage F-statistic is less than 10. Some empirical studies use R^2 in the first-stage regression as a measure of instrument relevance. However, Shea (1997) argues that for the model with multiple endogenous regressors, when instruments are highly collinear, IV may work poorly even if R^2 is high for each first-stage regression. For instance, suppose both the vector of endogenous regressors X and the vector of instruments Z have rank of 2, while only one element of Z is highly correlated to X. In this situation the regression of each element of X onto Z will have high R^2 even though β in the structural model may not be identified. Instead, Shea (1997) proposes a partial R^2, which measures the instrument relevance by taking intercorrelations among the instruments into account. The idea is that the instruments should work best when the part of instruments important to one endogenous regressor is linearly independent of the part important to the other endogenous regressor. Taking the example above, Shea's partial R^2 is the squared correlation between the component of one endogenous regressor X_1 orthogonal to the other endogenous regressor X_2 (i.e., the residuals from regressing X_1 onto X_2) and the component of the fitted values of X_1 orthogonal to the fitted values of X_2 (i.e., the residuals from regressing the fitted values of X_1 onto the fitted values of X_2). Shea's partial R^2 can be corrected for the degrees of freedom by

$$\overline{R}_p^2 = 1 - [(N-1)/(N-K)] \times \left(1 - R_p^2\right) \tag{95.30}$$

where $\overline{R}_p^2$ is the corrected partial R^2, R_p^2 is uncorrected partial R^2, N is the sample size, and K is the number of exogenous variables in the system.

Another type of the tests for instrument relevance is testing whether the equation is identified. Rothenberg et al. (1984) shows that at a formal level the strength of instruments can be characterized in terms of the so-called concentration parameter associated with the first-stage regression. He considers a simple linear model with a single endogenous regressor X and without included exogenous regressors:

$$Y = X\beta + u \tag{95.31}$$

$$X = Z\prod + v \tag{95.32}$$

where Y and X are N × 1 vectors of observations on endogenous variables, Z is an N × K matrix of instruments, and u and v are N × 1 error vectors. The errors are assumed to be i.i.d. as N(0, $\boldsymbol{\Sigma}$) where σ^2_u, σ^2_{uv}, and σ^2_v are elements of $\boldsymbol{\Sigma}$, and the correlation between the error terms $\rho = \sigma^2_{uv}/(\sigma_u\sigma_v)$. In matrix notation the 2SLS estimator can be written as $\hat{\beta}_{2SLS} = (X'P_ZX)^{-1}(X'P_ZY)$, where the idempotent matrix $P_Z = Z'(Z'Z)^{-1}Z'$. The concentration parameter μ^2 associated with the first-stage reduced form is defined as

$$\mu^2 = \prod{}'Z'Z\prod/\sigma^2_v \tag{95.33}$$

The concentration parameter μ^2 can be interpreted in terms of F, the first-stage F-statistic for testing the hypothesis $\Pi = 0$ (i.e., the instruments do not enter the first-stage regression). Let $\widetilde{F}$ be the infeasible counterpart of F using the true value of σ^2_v. Then $K\widetilde{F}$ has a chi-squared distribution of K degrees of freedom and noncentrality parameter μ^2. When the sample size is large, the $E\left(K\widetilde{F}\right) \cong \mu^2/K + 1$; thus, for large values of μ^2/K, (F − 1) can be used as an estimator for μ^2/K. Rothenberg et al. (1984) shows that the concentration parameter μ^2 plays an important role in the approximation to the distributions of 2SLS estimators and test statistics. He emphasizes that for the normal approximation to the distribution of the 2SLS estimator to be precise, the concentration parameter μ^2 must be large. Thus, a small F-statistic (i.e., a smaller value of μ^2/K) can indicate the presence of weak instruments. There are several tests developed using the concentration matrix to test for weak identification. Cragg and Donald (1993) proposed a statistic using the minimum eigenvalue of the concentration parameter to test the null hypothesis of underidentification, which occurs when the concentration matrix is singular.

Stock and Yogo (2002) argue that when the concentration matrix is nonsingular but its eigenvalues are sufficiently small, the inferences based on conventional normal approximation distributions are misleading even though the parameters might be identified. Thus, the minimum eigenvalues of the concentration matrix μ^2/K can be used to detect the presence of weak instruments. By this principle Stock and Yogo (2002) develop two alternative quantitative definition of the weak instrument. A set of instruments is considered to be weak if μ^2/K is small enough, so the bias in IV estimator to the bias in OLS estimator exceeds a certain threshold, depending on the researcher's tolerance, for example, 10 %. Alternatively, a set of instruments is considered to be weak if μ^2/K is small enough, so the conventional α-level Wald test-based IV statistic has an actual size exceeding a certain threshold, again depending on the researcher's tolerance. Stock and Yogo (2002) propose using the first-stage F-statistic for making inferences about μ^2/K and develop the critical values of F-statistic corresponding to the weak instrument threshold μ^2/K. For example, if a researcher requires the 2SLS relative bias no more than 10 %, for a model with three instruments, the computed first-stage F-statistic has to be larger than 9.08 for the threshold value μ^2/K larger than 3.71, so the null hypothesis that the 2SLS relative bias is less than or equal to 10 % (i.e., instruments are weak) will be rejected. The readers are referred to Stock and Yogo (2002) for a tabulation of the critical values for weak instrument tests with multiple endogenous regressors.

95.5.2 Possible Cures and Inferences with Weak Instruments

Many of the key issues of weak instruments have been studied for decades, however, most of the research on the estimation and inferences robust to weak instruments is quite recent and their applications in finance still remain to be seen. Therefore, this section just simply touches upon this topic and refers the reader to the original articles for details.

In their survey of weak instrument and identification, Stock et al. (2002) considered the Anderson-Rubin statistic as "fully robust" to weak instruments, in the sense that this procedure has the correct size regardless of the value of concentration parameter. For testing the null hypothesis for $\beta = \beta_0$, the Anderson-Rubin statistic (Anderson and Rubin 1949) is computed as

$$\mathrm{AR}(\beta_0) = \frac{(\mathrm{Y} - \mathrm{X}\beta_0)'\mathrm{P_Z}(\mathrm{Y} - \mathrm{X}\beta_0)/\mathrm{K}}{(\mathrm{Y} - \mathrm{X}\beta_0)'\mathrm{M_Z}(\mathrm{Y} - \mathrm{X}\beta_0)/(\mathrm{N} - \mathrm{K})} \sim \mathrm{F_{K,\,N-K}} \tag{95.34}$$

where $\mathrm{P_Z} = \mathrm{Z}(\mathrm{Z'Z})^{-1}\mathrm{Z'}$ and $\mathrm{M_Z} = \mathrm{I} - \mathrm{P_Z}$. Testing the null hypothesis that the coefficients of the endogenous regressors in the structural equation are jointly equal to zero is numerically equivalent to estimating the reduced form of the equation (with the full set of instruments as regressors) and testing that the coefficients of the excluded instruments are jointly equal to zero. Therefore, the AR statistic is often used for testing overidentifying restrictions. The Anderson-Rubin procedure provides valid tests and confidence set under weak instrument asymptotics,[8] but it has low power when too many instruments are added (see Dufour 2003). Berkowitz et al. (2012) argue that when there is a mild violation of the orthogonality condition, the Anderson and Rubin (1949) test may be oversized. In order to correct this problem, the authors fractionally resampled Anderson-Rubin test by modifying Wu's (1990) resampling technique and obtain valid but more conservative critical values.

Other fully robust tests discussed in Stock et al. (2002) include Moreira's conditional test by Moreira (2002), which fixes the size distortion of the test in the presence of weak instruments and can be used to make reliable inference about the coefficients of endogenous variables in the structural equation, and Kleibergen's

[8] Stock et al. (2002) defines weak instrument asymptotics as the alternative asymptotics methods that can be used to analyze IV statistics in the presence of weak instruments. Weak instrument asymptotics involves a sequence of models chosen to keep concentration parameters constant as sample size $\mathrm{N} \to \infty$ and the number of instruments held fixed.

statistic by Kleibergen (2002), which is robust under both conventional and weak instrument asymptotics.

Stock et al. (2002) considered several k-class estimators that are "partially robust" to weak instruments, in the sense that these k-class estimators are more reliable than 2SLS. The k-class is a set of estimators defined by the following estimating equation with an arbitrary scalar k:

$$\hat{\beta}(k) = [X'(I - kM_Z)X]^{-1}[X'(I - kM_Z)Y] \tag{95.35}$$

This class includes 2SLS, LIML, and Fuller-k. 2SLS is a k-class estimator with k equal to 1; LIML is a k-class estimator with k equal to the LIML eigenvalue; Fuller-k or called Fuller's modified LIML, proposed by Fuller (1977), sets $k = k_{LIML} - \alpha/(N - K)$, where K is the total number of instruments and α is the Fuller constant, and the Fuller estimator with $\alpha = 1$ yields unbiased results to second order with fixed instruments and normal errors; Jackknife 2SLS estimator, proposed by Angrist et al. (1999), is asymptotically equivalent to k-class estimator with $k = 1 + K/(N - K)$ (Chao and Swanson 2005). For a discussion of LIML and k-class estimators, see Davidson and MacKinnon (1993).

Stock et al. (2002) found that LIML, Fuller-k, and Jackknife estimators have lower critical value for weak instrument test than 2SLS (so the null will not be rejected too often) and thus are more reliable when the instruments are weak. Anderson et al. (2010, 2011) show that LIML estimator has good performance in terms of the bounded loss functions and probabilities in the presence of many weak instruments. However, Hahn et al. (2004) argued that due to the lack of finite moment, LIML sometimes performs well but sometimes poorly in the weak instrument situation. They found that the interquartile range and the root MSE of the LIML often far exceed those of the 2SLS and hence suggested extreme caution in using the LIML in the presence of weak instrument. Instead, Hahn et al. (2004) recommend the Jackknife 2SLS estimator and Fuller-k estimator because the two estimators do not have the "no moment" problem that LIML has. Theoretical calculations and simulations show that Jackknife 2SLS estimator improves on 2SLS when many instruments are used and thus the weak instrument problem usually occurs (see Chao and Swanson (2005) and Angrist et al. (1999)). Hahn et al. (2004) also find that the bias and mean square error using Fuller-k estimator are smaller than those using 2SLS and LIML.

95.6 Empirical Applications in Corporate Finance

In order to provide some insight into the use of IV estimation by finance researchers, we follow the methodology used by Larcker and Rusticus (2010) to conduct a search using the key words "2SLS," "simultaneous equations," "instrumental variables," and "endogeneity" for papers published in *Journal of Finance*, *Journal of Financial Economics*, *Review of Financial Studies*, and *Journal of Financial and Quantitative Analysis* during the period from 1997 to 2012.

Table 95.1 Finance research that uses instrumental variable methods

Capital structure/leverage ratio	Debt covenants
Faulkender and Petersen (RFS 2006)	Dennis et al. (JFQA 2000)

Cho (JFE 1998)	Brown et al. (JF 2008)
Wei et al. (JFQA 2005)	Conrad et al. (JFE 2003)
Daines (JFE 2001)	Kavajecz and Odders-White (RFS 2001)
Coles et al. (JFE 2012)	**Diversification/acquisition**
Wintoki et al. (JFE forthcoming)	Campa and Kedia (JF 2002)
Pricing of public offering	Hsieh and Walkling (JFE 2005)
Cliff and Denis (JF 2004)	**Venture capital/private equity**
Lee and Wahal (JFE 2004)	Gompers and Lerner (JFE 2000)
Lowry and Shu (JFE 2002)	

The sample is based on an electronic search for the term "2SLS," "instrumental variables," "simultaneous equations," and "endogeneity" for papers published in *Journal of Finance*, *Journal of Financial Economics*, *Review of Financial Studies*, and *Journal of Financial and Quantitative Analysis* during the period from 1997 to 2008

As shown in Table 95.1, our search produced 30 published articles that use instrumental variables approach to solve the endogeneity bias in the study of capital structure, agency/ownership structure, pricing of public offering, debt covenants, financial institutions, microstructure, diversification/acquisition, venture capital/ private equity, product market, and macroeconomics. Compared with the survey of Larcker and Rusticus (2010) for the IV applications in accounting research (which found 42 such articles in the recent decade), our list shows that the IV estimation is less commonly used in finance research[9] and often employed in corporate finance-related studies.

Similar to the finding of Larcker and Rusticus (2010) on IV applications in accounting research, there is little attempt in empirical finance research to develop a formal structural equation to identify endogenous and exogenous variables in the first place. Most take the endogeneity in the variables of interest as granted and only

[9]Another reason we found a smaller number of finance papers using IV may be that we limit our keywords to appearing in the abstract. Thus, our data may be more representative of the general situation of the finance research using IV as their main tests.

Table 95.2 Descriptive statistics for finance research that uses instrumental variables methods

A. Types of IV applications
Standard two-stage least squares

Overidentifying restrictions test	2 (11 %)	0	4 (66 %)	6 (20 %)
Concerns on WI	1 (6 %)	1 (17 %)	2 (33 %)	4 (13 %)
Total	18	6	6	

17 % conducted the endogeneity test (Hausman test). Almost all decided using IV approach to solve the endogeneity problem directly without considering the alternatives. As we discussed in Sects. 95.3.1 and 95.5.1, without valid instruments, the IV estimator can produce even more biased results than the OLS estimator and finding good instruments can be very challenging. Therefore, the researcher should investigate the nature of the endogeneity and explores alternative methods before selecting the IV approach. We found that only Sorensen (2007) and Mitton (2006)

evaluated the situation and chose alternative methods and fixed effects model instead to solve the endogeneity problem for the lack of good instruments.

Table 95.2 shows that the standard two-stage least square regression method is the most commonly used procedure (18 out of 30), and the GMM/3SLS procedure is more concentrated on the study of financial economics. Half of the research did not discuss formally why a specific variable is selected as an instrumental variable, and even fewer explicitly justify theoretically or statistically the validity of selected instruments by examining the orthogonality and relevance of the instruments. All studies have overidentified models but only 20 % performed the overidentifying restrictions test to examine the orthogonality of the instruments. One study even cited the low R^2 in the first stage as evidence that the instruments do not appear to be related to the error terms. It raises a great concern about the validity of the instruments used and the possible bias in the resulted IV estimates.

Forty percent reported the first-stage results along with R^2; however, it should be noted that the first-stage R^2 does not represent the relevance of the excluded instruments but the overall explanatory power of all exogenous variables. Thus, the strength of instruments can be overstated if judged by the first-stage R^2. Only 27 % formally performed the first-stage F-statistic for the instrument relevance, one study also used Shea's partial R^2 (Shea 1997), and none used Cragg and Donald's underidentification test (Cragg and Donald 1993) or Stock and Yogo's weak instrument test Stock and Yogo (2002). Given the absence of the weak instrument test in most finance studies, many of the estimation results using IV approach are questionable. It is also not surprising that only four studies among all addressed the concerns with the weak instrument problem. Ljungqvist et al. (2006) used five bank pressure proxies as instruments for analyst behavior in their two-step Heckman MLE model for competing underwriting mandates but detected the weak instrument problem by the low F-statistic. They interpreted the insignificant estimates in the second step as possibly a result of weak instrument. Beck et al. (2000) discussed the possible weak instrument problem (though not judged by any test) associated with a difference estimator using the lagged value of the dependent variable, and then decided to use the alternative method by estimating the regression in difference jointly with the regression in level to reduce the potential finite sample bias. It appears that the recently developed weak-instrument-robust estimators and inferences have not yet applied in finance research.

95.7 Conclusion

The purpose of this chapter is to present a practical procedure for using the instrumental variables approach to solve the endogeneity problem in empirical finance studies. The endogeneity problem has received a mixed treatment in finance research. The literature does not consistently account for endogeneity using formal econometric methods. When the IV approach is used, the instrumental variables are often chosen arbitrarily and few diagnostic statistics are performed to assess the adequacy of IV estimation.

Given the challenge of finding good instruments, it is important that the researcher analyzes the nature of the endogeneity and the direction of the bias if possible, and then explores alternative empirical approaches so the problem can be solved more appropriately. For example, in the presence of omitted variables, if the unobservable effects, which are part of the error term, can be treated as random variables rather than the parameters to be estimated, panel data models can be used to obtain consistent estimates. When the IV approach is considered to be the most appropriate estimation method, the researcher need to find and justify the instruments theoretically and statistically. One way to describe an instrumental variable is that a valid instrument Z for the potential endogenous variable X should be redundant in the structural equation when X is already included, which means that Z will not affect the dependent variable Y in any way other than through X. To examine the orthogonality statistically, an overidentified model is preferred and hence the overidentifying restrictions can be used. If the OID test cannot be rejected, we then can have some confidence in the orthogonality of the overall instruments. To examine the instrument relevance, the partial R^2 and the first-stage F-statistic on the joint significance of the instruments should be performed at the minimum. The newly developed weak instrument tests (Cragg and Donald 1993; Stock and Yogo 2002) can also be used as robust check, especially for the finite samples. The researcher should keep in mind that the IV estimation method provides a general solution to the endogeneity problem, however; without strong and exogenous instruments, the IV estimator is more biased and inconsistent than the simple OLS estimator.

Application of Poisson Mixtures in the Estimation of Probability of Informed Trading

96

Emily Lin and Cheng-Few Lee

Contents

Abstract

This research first discusses the evolution of probability for informed trading in finance literature. Motivated by asymmetric effects, e.g., return and trading volume in up and down markets, this study modifies a mixture of the Poisson

Probability of informed trading (*PIN*) • Expectation–maximization (EM) algorithm • A mixture of Poisson distribution • Asset-pricing returns • Order imbalance • Information asymmetry • Bid–ask spreads • Market microstructure • Trade direction • Errors in variables • GARCH

96.1 Introduction

This study investigates the probability of informed trading *PIN* which is widely used in existing literature and is introduced by Easley et al. (1996). Easley et al. (1996, 2002, 2008) have proposed the same arrival rate of informed orders μ for both bad and good events, and the likelihood is given by

$$L(\theta|B,S) = (1-\alpha)e^{-\varepsilon_b}\frac{\varepsilon_b^B}{B!}e^{-\varepsilon_s}\frac{\varepsilon_s^S}{S!} + \alpha\delta e^{-\varepsilon_b}\frac{\varepsilon_b^B}{B!}e^{-(\mu+\varepsilon_s)}\frac{(\mu+\varepsilon_s)^S}{S!} + \alpha(1-\delta)e^{-(\mu+\varepsilon_b)}\frac{(\mu+\varepsilon_b)^B}{B!}e^{-\varepsilon_s}\frac{\varepsilon_s^S}{S!} \tag{96.1}$$

where α is the probability of new information, δ is the probability that new information is bad news, μ is the arrival rate of informed buy orders and also that of informed sell orders, and ε_b and ε_s are the arrival rates of uninformed buyers and sellers. Until Easley, Engle, O'Hara and Wu (2008) models a time-varying arrival rate of informed and uninformed traders, the model has been a static approach.

We allow the arrival rate of informed buyers to be different from that of informed sellers in order to match the empirical environment. Furthermore, we examine on intraday data and allow more than one informational event per day. The modified model is given by

$$L(\theta|B,S) = (1-\alpha)e^{-\varepsilon_b}\frac{\varepsilon_b^B}{B!}e^{-\varepsilon_s}\frac{\varepsilon_s^S}{S!} + \alpha\delta e^{-\varepsilon_b}\frac{\varepsilon_b^B}{B!}e^{-(\mu_s+\varepsilon_s)}\frac{(\mu_s+\varepsilon_s)^S}{S!} + \alpha(1-\delta)e^{-(\mu_b+\varepsilon_b)}\frac{(\mu_b+\varepsilon_b)^B}{B!}e^{-\varepsilon_s}\frac{\varepsilon_s^S}{S!} \tag{96.2}$$

where μ_b is the arrival rate of informed buyers and μ_s is the arrival rate of informed sellers. The function provides the structure necessary to exact information on the parameters $\theta = (\alpha, \delta, \mu, \varepsilon_b, \varepsilon_s)$ from the observable variables, buys and sells, to measure $PIN = \frac{\alpha\mu}{\alpha\mu + \varepsilon_s + \varepsilon_b}$. For the parameters in our model, $\theta^* = (\alpha, \delta, \mu_b, \mu_s, \varepsilon_b, \varepsilon_s)$ and probability of informed trading $PIN^* = \frac{\alpha(\delta|\mu_s| + (1-\delta)|\mu_b|)}{\alpha(\delta|\mu_s| + (1-\delta)|\mu_b|) + \varepsilon_s + \varepsilon_b}$. The buys and sells follow one of three Poisson processes on each day. The likelihood of observing any sequence of orders that contains B buys and S sells on a no-event day is given by

$$e^{-\varepsilon_b} \frac{\varepsilon_b^B}{B!} e^{-\varepsilon_s} \frac{\varepsilon_s^S}{S!} \tag{96.3}$$

Similarly, on a bad-event day, the likelihood of observing any sequence of orders that contains B buys and S sells is

$$e^{-\varepsilon_b} \frac{\varepsilon_b^B}{B!} e^{-(\mu + \varepsilon_s)} \frac{(\mu + \varepsilon_s)^S}{S!} \tag{96.4}$$

Finally, on a good-event day, this likelihood is

$$e^{-(\mu + \varepsilon_b)} \frac{(\mu + \varepsilon_b)^B}{B!} e^{-\varepsilon_s} \frac{\varepsilon_s^S}{S!} \tag{96.5}$$

To estimate the order arrival rates of the buy and sell processes, we need only consider the total number of buys, B, and the total number of sells, S, on any day. The likelihood of observing B buys and S sells on a day of unknown type is a mixture of the Poisson distribution, the weighted average of Eqs. 96.3, 96.4, and 96.5 using the probabilities of each type of day occurring to obtain Eq. 96.1.

Church and Gale (1995) claim that a mixture of the Poisson distribution fits the data better than the standard Poisson, producing more accurate estimates of the variance. Johnson and Kotz (1969, pp. 135–136) survey a number of applications of the negative binomial in a variety of fields and conclude that "the negative binomial is frequently used as a substitute for the Poisson, when the strict requirements of the Poisson is doubtful." This is due to the negative binomial, which can be viewed as a continuous mixture of infinitely many Poissons, as suggested by Bookstein and Swanson (1974, p. 317).

Because days are independent, the likelihood of observing the data $M = (B_i, S_i)_{i=1}^I$ over I days is just the product of the daily likelihoods. Therefore,

$$L(\theta|M) = \prod_i^I L(\theta|B_i, S_i), \tag{96.6}$$

To estimate the parameter vector θ from any data set M, we maximize the likelihood defined in Eq. 96.6.

96.2 The Problem with *PIN*

The derivation of *PIN* requires the classification of trades into buyer- or seller-initiated trades, and therefore errors can occur by possible misclassification. Ellis et al. (2000) present that in the case of NASDAQ trades, the Lee and Ready (1991) trade classification algorithm correctly classifies 81.05 % of the trades, with the lowest rate of success among trades that take place inside the spread. Specifically, the authors admit that "the success rate for classifying trades inside the quotes . . . is substantially lower, falling to approximately 60 % for midpoint trades and to only 55 % for trades that are inside the quotes but not at the midpoint." In the case of NYSE trades, Odders-White (2000) reports a success rate of 85 % for the entire sample. Boehmer et al. (2007) and Lei and Wu (2005) also point out that misappropriation of trades may bias *PIN* estimates and arrival rates may not be symmetric and time varying.

To avoid this criticism or error, Popescu and Kumar (2008) use observed bid and ask quotes, assume different depth at the bid and the ask, and include order processing costs for estimating the probability of informed trading by extending the model developed by Copeland and Galai (1983),[1] which is the first model to examine intraday informed trading under an option framework. The measure of Popescu and Kumar (2008) can be computed at any point in time and thus can be used to estimate changes in the level of information asymmetry over a short interval. Although this methodology does not require trades to be distinguished between buyer initiated and seller initiated, the estimation of order processing costs based on three bid–ask spread structure models may introduce bias on the estimated *PIN*. These three models include Glosten and Harris (1988) and Madhavan and Smidt (1991) which model revision in trade price and a proposed model which combines Hasbrouck (1991), Foster and Viswanathan (1993), and Brennan and Subrahmanyam (1996) to model transaction size and price revision.

Copeland and Galai (1983) extend Bagehot (1971) which employs bid–ask spread to derive an adverse selection cost, use an option idea to describe the quote spread of market maker to contain an option value, and consider the trade value of straddle strategy as an adverse selection cost. Bollen et al. (2004) also follow the same strategy by Copeland and Galai (1983) to measure an adverse selection cost. Because the bid–ask spread carries unrealized price information and hides future value, it seems more reasonable to observe the bid–ask spread from the idea of an option.

[1]Copeland and Galai (1983) model informed trading as $(1 - P_I)[P_{BL}(A - S_0) + P_{SL}(B - S_0) + P_{NL}.0]$, where B is the bid price, A is the ask price, S_0 is the dealer's estimate of the "true" value of a security ($B < S_0 < A$), and P_I is the probability that the next trade originates from an informed trader, while P_{BL}, P_{SL}, and P_{NL} are the conditional probabilities that the next liquidity trader will buy, sell, or not trade when he/she faces the market maker. Popescu and Kumar (2008) revise it into $(1 - P_I)[P_{BL}.\, D_A.\, (A - S_0) + P_{SL}.\, D_B.\, (B - S_0) + P_{NL}.0]$, where D_A and D_B denote the depth at the ask and at the bid.

Based on the setting of Easley et al. (1996, 2002, 2008), the informed order imbalance is unavailable. We attain informed order imbalance in November 2008 and our work is the first to measure informed trading based on an order imbalance signal. Although not fully explored here, this measure allows one to measure informed order imbalance by $(\mu_b - \mu_s)/(\mu_b + \mu_s)$. The measure is a proxy for informed trading and is discussed in Lin et al. (2013), while the relationship between *PIN* and arbitrage opportunity is determined in Chang and Lin (2014). Like *PIN*, this measure is an estimate variable, and so it is potentially subject to errors-in-variables bias. To correct the errors-in-variables problem in *PIN*, Easley et al. (2002) suggest to create an instrument variable to use in place of the variable in question. Lee and Chen (2012) include five other methods[2] which can correct this bias. Duarte and Young (2009) also allow the arrival rate of informed buyers μ_b to be different from that of informed sellers μ_s and overcome the estimation dilemma of standard *PIN*. In addition, Duarte and Young (2009) apply a time-varying technique to examine whether *PIN* is priced and includes symmetric order-flow shocks to capture the positive correlation they find between buys and sells. Chang and Lin (2014) ignore to do so as they observe no significant correlation between buys and sells in the data.

Easley et al. (2012) take a similar approach with a time-varying technique, easing the estimation of *PIN* in high-volume markets and referring it to *VPIN*. Easley et al. (2012) claim *VPIN* is updated in volume time and does not require the intermediate estimation of nonobservable parameters or the application of numerical methods.

Nevertheless, Easley et al. (2002) show that *PIN* as a proxy for the risk of informed trading is priced. The results of Easley et al. (2002) provide evidence that information plays a deeper role beyond what is captured in spreads. Duarte and Young (2009) propose a model that decomposes *PIN* into two components, one related to asymmetric information and one related to illiquidity. On the contrary, they find the *PIN* component related to asymmetric information is not priced, while the *PIN* component related to illiquidity is priced. This contrary finding makes itself an open question for finance researchers.

96.3 The Estimation Methodology

To solve the likelihood function in Eqs. 96.1 and 96.2, we apply an expectation–maximization (EM) algorithm. In statistics, an expectation–maximization (EM) algorithm is an iterative method for finding a maximum likelihood or maximum posteriori estimates of parameters in statistical models, where the model depends on unobserved latent variables. The EM iteration alternates between

[2]The other five methods are (i) classical estimation method: either unconstrained or constrained type, (ii) grouping method, (iii) mathematical programming method, (iv) maximum likelihood method, and (v) LISREL and MIMIC methods.

performing an expectation (E) step, which creates a function for the expectation of the log-likelihood evaluated using the current estimate for the parameters, and a maximization (M) step, which computes parameters maximizing the expected log-likelihood found in step E. These parameter estimates are then used to determine the distribution of the latent variables in the next E step. We can derive a set of equations for maximum likelihood estimation when the observed data consists of complete pairs. These equations are encoded in a SAS Macro utilizing SAS/IML for implementation of the methodology. McLachlan and Krishnan (2008) have discussed this algorithm in detail. In addition, Appendix 2 has presented the estimation procedure of *PIN*.

96.4 Empirical Results

It is *PIN* that affects asset-pricing return consistent with economic analysis motivates the empirical work in Chang and Lin (2014) to explore how *PIN* under various cross-section and time-series sample splits is related to cash-futures basis, defined as futures price minus stock price. *PIN* is calculated as per Eq. 96.1 or 96.2 to test this relationship. The resulting higher significant regression coefficient of *PIN* derived from different arrival rates of informed trades at buy side and sell side confirms a conjecture that the revised *PIN* appears to capture the asymmetric information in cash-futures basis spread better than does standard *PIN*. To deeply understand the difference of these two *PIN* measures, this study furthermore compares the distribution of the parameters in each model. The comparison estimates the parameters of the two models using 5-min intraday data sourced from Taiwan index futures and Taiwan stock index markets. To appropriate a trade direction, two general approaches are used to infer the direction of a trade: (1) compare the trade price to the bid/ask prices of the prevailing quote or (2) compare the trade price to adjacent trades (the techniques commonly known as "tick tests"). In this study, the algorithm of Ready and Lee (1991) is used for classifying index futures data, while tick test[3] is used for stock index data because of lack of quote price at market level.

96.4.1 Preliminary Results

Both Tables 96.1 and 96.2 contain time-series averages from March 24, 1999, through September 22, 2005, of means, medians, standard deviations, and the

[3]Tick test classifies each trade into four categories: an uptick, a downtick, a zero-uptick, and a zero-downtick. A trade is an uptick (downtick) if the price is higher (lower) than the price of the previous trade. When the price is the same as the previous trade (a zero tick) and if the last price was an uptick, then the trade is a zero-uptick. Similarly, if the last price change was a downtick, then the trade is a zero-downtick.

median of parameter standard errors from the likelihood estimation. Parameters as per Eqs. 96.1 and 96.2 are estimated for the index futures and stock index in the Taiwan market. We achieve the parameters for the Taiwan index futures market $\hat{\theta}_{fut} = \left(\hat{\alpha}, \hat{\delta}, \hat{\mu}, \hat{\varepsilon}_b, \hat{\varepsilon}_s\right) = (0.42, 0.51, 173, 76, 82)$ and $\widehat{PIN}_{fut} = 0.2997$ for the case of the same arrival rate of informed trades, μ_{fut}, at the buy side and sell side. Meanwhile, we achieve $\hat{\theta}^*_{fut} = \left(\hat{\alpha}, \hat{\delta}, \hat{\mu}_b, \hat{\mu}_s, \hat{\varepsilon}_b, \hat{\varepsilon}_s\right) = (0.60, 0.55, 147, 27, 77, 129)$ and $\widehat{PIN}^*_{fut} = 0.3046$ for the case of different arrival rates of informed trades, μ_b^{fut} and μ_s^{fut}, at buy side and sell side. There are 1,005 out of 1,645 days (61 %) that the value of μ^{fut} is between μ_b^{fut} and μ_s^{fut}.

Similarly, we achieve the parameters for the Taiwan stock index $\hat{\theta}_{ind} = \left(\hat{\alpha}, \hat{\delta}, \hat{\mu}, \hat{\varepsilon}_b, \hat{\varepsilon}_s\right) = (0.65, 0.52, 903591, 579489, 577863)$ and $\widehat{PIN}_{ind} = 0.3343$ for the case of the same μ^{ind}, and meanwhile we obtain $\hat{\theta}^*_{ind} = \left(\hat{\alpha}, \hat{\delta}, \hat{\mu}_b, \hat{\mu}_s, \hat{\varepsilon}_b, \hat{\varepsilon}_s\right) = (0.66, 0.52, 892352, 907195, 577746, 574816)$ and $\widehat{PIN}^*_{ind} = 0.3366$ for the case of different arrival rates, μ_b^{ind} and μ_s^{ind}. There are 1,637 out of 1,650 days (99 %) that the value of μ^{ind} is between μ_b^{ind} and μ_s^{ind}.

In Table 96.1, each parameter in the two models has a similar distribution, except μ and the arrival rate of uninformed sell orders, ε_s, while in Table 96.2, there is no such exception for the distribution of each parameter in the two models. The *PIN* value estimated from each model is similar for both index futures and stock index markets. The differential results of these two models may result from volatile data or order imbalance between buys and sells. We observe that the Taiwan index futures behave much more volatile than the Taiwan stock index. The model of Easley et al. assumes a sole informed arrival rate for buys on a good-event day and for sells on a bad-event day. The assumption might fit an individual stock level better than a market level because information tends to be just good or bad for an individual stock than for a market. Meanwhile, the model of Easley et al. appears more appropriate for a stable or a less order imbalance market.

96.4.2 Application of PIN

Maturity effect may also play an information role in the market by helping the market incorporate certain types of information into prices. In Table 96.3, *PIN*, as derived from differential arrival rate of informed trades for index futures denoted by pin(f) and stock index denoted by pin(s), is calculated to explore how they

Table 96.3 Asymmetry of maturity effect

Panel A. Volume effect			
Dependent variables	A/F 2000/10/24	B/F 2000/10/24	P-value
Rhat	1.5039	1.2485	0.0004
pin(f)	0.2960	0.2856	<0.0001
pin(s)	0.3290	0.3540	<0.0001
Panel B. Option introduction			
Dependent variables	A/F 2001/12/24	B/F 2001/12/24	P-value
Rhat	1.3697	1.2499	0.0364
pin(f)	0.2869	0.3075	<0.0001
pin(s)	0.3318	0.3359	<0.0001

This table compares sample split means using 5-min data. Rhat is the ratio of standard deviation for index futures return over that for the spot index return calculated by $\sigma_{fut}/\sigma_{ind}$. Panel A investigates the day futures volume reached 10,000 contracts for the first time and Panel B examines the day options were introduced to the market, respectively. Results reflect a testing period from March 1999 to September 2005. P-values reflect the significance of the difference in means derived from t-tests evolve before and after the day index futures volume reached 10,000 contracts for the first time and before and after the introduction of index futures options. *Rhat* is the ratio of standard deviation for index futures return over standard deviation for the spot index return. MacKinlay and Ramaswamy (1988) find that no arbitrage implies equal volatility in the spot and futures markets. Therefore, the standard deviation ratio *Rhat* should be one if arbitrage is tightly enforced. As shown in Table 96.3, *Rhat* is generally higher than one for both markets indicating that futures are more volatile than spot. In addition, *Rhat* increases after volume effect and option introduction which signals market maturity. Increased pin(f) and smaller pin(s) suggest volume effect facilitates price discovery in the futures market, and this improvement seems to be switched from the spot market. Similarly, reduced pin(f) and pin(s), in particular pin(f), indicate option introduction induces much of the price discovery moved from the futures market to the option market. The occurrence of price discovery in the option market may result from the higher leverage trait of option trading.

96.5 Conclusion

The study focuses on comparing the estimation of probability of informed trading for the model of Easley et al. and of our extension. The study introduces mixtures of Poisson distribution, reports the evolution of *PIN* development, summarizes the problems with *PIN*, and estimates *PIN* by EM algorithm. By using Taiwan stock index and Taiwan index futures, this study examines the distribution of the two model parameters and the price discovery effect before and after futures volume effect and option introduction. The study finds *PIN* calculated by Easley et al.'s model is similar to the *PIN* calculated by different arrival rate of informed trading. This evidences Easley et al.'s simplified assumption has no loss of generalization for obtaining *PIN*, whereas the assumption of ours better fits volatile data and allows us to capture order imbalance of informed trading.

Appendix 1: Poisson Mixtures

Generalized Poisson Mixtures

Poisson mixtures can be thought of as a generalization of two Poisson models where the mixing parameter, a, is replaced with an arbitrary density function, f. The density function f is intended to capture dependencies on hidden variables. The general form of a Poisson mixture is

$$\Pr(x) = \int_0^\infty \phi(\omega)\pi(\omega, x)d\omega \quad \text{for } x = 0, 1, \ldots$$

where π is a Poisson

$$\pi(\omega, k) = \frac{e^{-\theta}\omega^k}{k!} \quad \text{for } k = 0, 1, \ldots$$

and ϕ is an arbitrary density function. A density function should integrate to 1. That is, $\int_0^\infty \phi(\omega)d\omega = 1.$

Binomial Poisson Mixtures

We give an application of Poisson mixtures, e.g., binomial Poisson mixture as follows:

Generate $X_1, X_2, \ldots, X_n$, i.i.d. from

$$\Pr(X_i = k) = 1 - P + P\frac{e^{-\lambda}\lambda^k}{k!}, k = 0, 1, \ldots$$

That is, the random variable X_i has a probability P of being from a Poisson distribution with $\lambda > 0$ and has a probability $1 - P$ of being zero, $0 < P < 1$. When $k = 0$, it degenerates to a Poisson distribution. When $k > 0$, it is a binomial 1, otherwise 0.

Appendix 2: Estimation by EM Algorithm

To write a likelihood function by a framework of mixtures of Poisson distribution, we define, for each $i \in I$, a vector Z_i by $Z_i = (Z_{i1}, Z_{i2}, Z_{i3}) = (1,0,0)$, $(0,1,0)$, or $(0,0,1)$ depending if i has either no event, a good event, or a bad event, respectively.

$$\sum_{j=1}^{3} Z_{ij} = 1, \text{for each } i.$$

$$M^* = (B_i, S_i, Z_i)_{i=1}^{I} \sim \prod_{j=1}^{3} P_j^{Z_{ij}} f_j^{Z_{ij}}(B_i, S_i), \text{then}$$

$$L(\theta|B_i, S_i, Z_i) \sim \prod_{j=1}^{3} P_j^{Z_{ij}} f_j^{Z_{ij}}(B_i, S_i),$$

where $P_1 = 1 - \alpha$, $P_2 = \alpha\delta$, $P_3 = \alpha(1 - \delta)$, P_2 and P_3 are independent, $P_1 = 1 - P_2 - P_3, Z_{ij}, i$ is for date i, state j, and $f_j^{Z_{ij}}$ equals 1 when $Z_{ij} = 0$, while $f_j^{Z_{ij}}$ is one of Eqs. 96.3, 96.4, and 96.5 as $Z_{ij} = 1$.

Let $V = L(\theta|M^*) = \prod_{i=1}^{I} L(\theta|B_i, S_i, Z_i)$, then $V(B,S,Z) \sim \prod_{\mathrm{i}=1}^{I}\prod_{j=1}^{3} P_j^{Z_{ij}} f_j^{Z_{ij}}(B_i,S_i)$.

By taking logarithm and letting $\ell = \ln(V|B,S) = \sum_{i=1}^{I}\sum_{j=1}^{3}\left\{Z_{ij}\ \ln P_j + Z_{ij}\ \ln f_j(B_i,S_i)\right\}$, we start to perform E-step of EM algorithm.

Assume

$$Q = E(\ln\, V|B,S) = \sum_{i=1}^{I}\sum_{j=1}^{3}\left\{E\left(Z_{ij}|B_i,S_i\right)\ln P_j + E\left(Z_{ij}|B_i,S_i\right)\ln\, f_j(B_i,S_i)\right\}, \tag{96.7}$$

where

$$\begin{aligned} E\left(Z_{ij}|B_i,S_i\right) = P\left(Z_{ij}=1|B_i,S_i\right) &= \frac{P\left(Z_{ij}=1, B_i=b, S_i=s\right)}{P(B_i=b,S_i=s)} \\ &= \frac{P_j f_j(b,s)}{P_1 f_1(b,s) + P_2 f_2(b,s) + P_3 f_3(b,s)}. \end{aligned}$$

Then r-step estimator is given by

$$\begin{aligned} Q = &\sum_{i=1}^{I}\sum_{j=1}^{3}\left\{\frac{P_j f_j(b,s)}{P_1 f_1(b,s) + P_2 f_2(b,s) + P_3 f_3(b,s)}\ln P_j \right. \\ &\left. + \frac{P_j f_j(b,s)}{P_1 f_1(b,s) + P_2 f_2(b,s) + P_3 f_3(b,s)}\ln\, f_j(b,s)\right\} \\ = &\sum_{i=1}^{I}\sum_{j=1}^{3} a_{ij}^{(r)} \ln P_j^{(r)} + C, \end{aligned}$$

where $a_{ij}^{(r)} = \frac{P_j^{(r)} f_j^{(r)}(b,s)}{P_1^{(r)} f_1^{(r)}(b,s) + P_2^{(r)} f_2^{(r)}(b,s) + P_3^{(r)} f_3^{(r)}(b,s)}$, and C is a constant.

The M-step is to maximize Q. We find the result of the first-order condition for P_j is independent of j and the result is shown as follows:

$$\begin{aligned} &\frac{\partial Q}{\partial P_j} = \sum_{i=1}^{I}\left(\frac{a_{ij}^{(r)}}{P_j} - \frac{a_{i1}^{(r)}}{P_1}\right) = 0, \quad \text{then} \\ &\sum_{i=1}^{I}\frac{a_{ij}^{(r)}}{P_j} = \sum_{i=1}^{I}\frac{a_{i1}^{(r)}}{P_1} = d, \quad \text{where } d \text{ is a constant} \end{aligned}$$

$$\sum_{i=1}^{I} a_{ij}^{(r)} = dP_j, \forall j = 1,2,3.$$

Since $\sum_{j=1}^{3} P_j = 1$, and $\sum_{j=1}^{3} a_{ij}^{(r)} = 1$, we obtain $\sum_{i=1}^{I} a_{ij}^{(r)} = I$ and $dP_j = d$ and solve

$$P_j = \frac{1}{I}\sum_{\mathrm{i}=1}^{\mathrm{I}} a_{ij}^{(r)}, \forall j = 1,2,3. \tag{96.8}$$

Applying EM algorithm in the estimation of *PIN*, we can simplify the estimation procedure as the following steps:

1. A naïve guess (or estimation) for initials of parameters, e.g., $P_j^{(0)}$, $\varepsilon_b^{(0)}$, $\varepsilon_s^{(0)}$, $\mu^{(0)}$
2. Apply r-step $P_j^{(r)}$, $\varepsilon_b^{(r)}$, $\varepsilon_s^{(r)}$, $\mu^{(r)}$ into

$$E\left(Z_{ij}^{(r)}|B,S\right) = \frac{P_j^{(r)} f_j^{(r)}(B_i,S_i)}{P_1^{(r)} f_1^{(r)}(B_i,S_i) + P_2^{(r)} f_2^{(r)}(B_i,S_i) + P_3^{(r)} f_3^{(r)}(B_i,S_i)} = a_{ij}^{(r)}.$$

3. After step (2), the function becomes complete-data MLE. We maximize likelihood function Q to estimate five parameters, $P_1^{(r)}$, $P_2^{(r)}$, $\varepsilon_b^{(r)}$, $\varepsilon_s^{(r)}$, and $\mu^{(r)}$, and derive $P_j^{(r+1)}$ and $Z_{ij}^{(r+1)}$. We obtain

$$P_j^{(r+1)} = \frac{1}{I}\sum_{i=1}^{\mathrm{I}} a_{ij}^{(r)}$$

and

$$Z_{ij}^{(r+1)} = \frac{P_j^{(r+1)} f_J^{(r)}(B_i,S_i)}{P_1^{(r+1)} f_1^{(r)}(B_i,S_i) + P_2^{(r+1)} f_2^{(r)}(B_i,S_i) + P_3^{(r+1)} f_3^{(r)}(B_i,S_i)}. \tag{96.9}$$

Numerical Example

Below are the results by using real data. An initial naïve guess for $(P_1^{(0)}, P_2^{(0)}, P_3^{(0)}, \varepsilon_b^{(0)}, \varepsilon_s^{(0)}, \mu^{(0)}) = (0.3, 0.4, 0.3, 1, 1, 1)$ when buys, $B_i = 193$ and sells, $S_i = 179$ during a 5-min interval. By Eqs. 96.3, 96.4, and 96.5, we calculate the following:

$$f_1^{(0)}(B_i,S_i) = e^{-\varepsilon_b}\frac{\varepsilon_b^B}{B_i!}e^{-\varepsilon_s}\frac{\varepsilon_s^S}{S_i!} = \frac{e^{-1}\times 1\times e^{-1}\times 1}{193!\times 179!},$$

$$f_2^{(0)}(B_i,S_i) = e^{-\varepsilon_b}\frac{\varepsilon_b^B}{B_i!}e^{-(\mu+\varepsilon_s)}\frac{(\mu+\varepsilon_s)^S}{S_i!} = \frac{e^{-1}\times 1\times e^{-2}\times 2}{193!\times 179!}$$

$$f_3^{(0)}(B_i,S_i) = e^{-(\mu+\varepsilon_b)}\frac{(\mu+\varepsilon_b)^B}{B_i!}e^{-\varepsilon_s}\frac{\varepsilon_s^S}{S_i!} = \frac{e^{-2}\times 2\times e^{-1}\times 1}{193!\times 179!}$$

and

$$a_{i1}^{(0)} = Z_{i1}^{(0)} = \frac{0.3 \times f_1^{(0)}(B_i, S_i)}{0.3 \times f_1^{(0)} + 0.4 \times f_2^{(0)} + 0.3 \times f_3^{(0)}}$$
$$a_{i2}^{(0)} = Z_{i2}^{(0)} = \frac{0.4 \times f_2^{(0)}(B_i, S_i)}{0.3 \times f_1^{(0)} + 0.4 \times f_2^{(0)} + 0.3 \times f_3^{(0)}}$$
$$a_{i3}^{(0)} = Z_{i3}^{(0)} = \frac{0.3 \times f_3^{(0)}(B_i, S_i)}{0.3 \times f_1^{(0)} + 0.4 \times f_2^{(0)} + 0.3 \times f_3^{(0)}}.$$

Hence,

$$P_1^{(1)} = \frac{1}{I}\sum_{\mathrm{i=1}}^{\mathrm{I}} a_{i1}^{(0)}, P_2^{(1)} = \frac{1}{I}\sum_{\mathrm{i=1}}^{\mathrm{I}} a_{i2}^{(0)}, P_3^{(1)} = \frac{1}{I}\sum_{\mathrm{i=1}}^{\mathrm{I}} a_{i3}^{(0)}.$$

By Eq. 96.9, we obtain

$$Z_{i1}^{(1)} = \frac{P_1^{(1)} f_1^{(0)}(B_i, S_i)}{P_1^{(1)} f_1^{(0)}(B_i, S_i) + P_2^{(1)} f_2^{(0)}(B_i, S_i) + P_3^{(1)} f_3^{(0)}(B_i, S_i)}$$
$$Z_{i2}^{(1)} = \frac{P_2^{(1)} f_2^{(0)}(B_i, S_i)}{P_1^{(1)} f_1^{(0)}(B_i, S_i) + P_2^{(1)} f_2^{(0)}(B_i, S_i) + P_3^{(1)} f_3^{(0)}(B_i, S_i)}$$
$$Z_{i3}^{(1)} = \frac{P_3^{(1)} f_3^{(0)}(B_i, S_i)}{P_1^{(1)} f_1^{(0)}(B_i, S_i) + P_2^{(1)} f_2^{(0)}(B_i, S_i) + P_3^{(1)} f_3^{(0)}(B_i, S_i)}$$

The complete-data MLE becomes

$$G = \ln V = \sum_{i=1}^{I}\sum_{j=1}^{3}\left\{Z_{ij}\ln\ P_j + Z_{ij}\ln\ f_j(B_i, S_i)\right\}.$$

When the observed data consists of complete pairs, we derive a set of equations for maximum likelihood estimation. The first-order condition is

$$\frac{\partial G}{\partial P_j} = \sum_{i=1}^{I}\frac{Z_{ij}}{P_j} = 0, \forall \mathrm{j} = 1, 2, 3.$$

If $j = 3$, then $\frac{\partial G}{\partial P_3} = 0$, and $P_3 = \frac{1}{I}\sum_{i=1}^{I} Z_{i3}$

If $j = 2$, then $\frac{\partial G}{\partial P_2} = 0$, and $P_2 = \frac{1}{I}\sum_{i=1}^{I} Z_{i2}$

If $j = 1$, then $P_1 = 1 - \frac{1}{I}\sum_{i=1}^{I} Z_{i3} - \frac{1}{I}\sum_{i=1}^{I} Z_{i3}$.

To solve ε_b, the first-order condition is

$$\frac{\partial Q}{\partial \varepsilon_b} = \sum_{i=1}^{I}\left(Z_{i1}\frac{\partial \ln f_1}{\partial \varepsilon_b} + Z_{i2}\frac{\partial \ln f_2}{\partial \varepsilon_b} + Z_{i3}\frac{\partial \ln f_3}{\partial \varepsilon_b}\right) = 0 \tag{96.10}$$

where

$$\begin{aligned}
\ln f_1 &= -\varepsilon_b + B_i \ln \varepsilon_b - \ln(B_i!) - \varepsilon_s + S_i \ln \varepsilon_S - \ln(S_i!),\\
\ln f_2 &= -\varepsilon_b + B_i \ln \varepsilon_b - \ln(B_i!) - (\mu + \varepsilon_s) + S_i \ln(\mu + \varepsilon_S) - \ln(S_i!),\\
\ln f_3 &= -(\mu + \varepsilon_b) + B_i \ln(\mu + \varepsilon_b) - \ln(B_i!) - \varepsilon_s + S_i \ln \varepsilon_S - \ln(S_i!).
\end{aligned}$$

We then rewrite Eq. 96.10 as

$$\sum_{\mathrm{i}=1}^{\mathrm{I}}\left(Z_{i1}\left(-1 + \frac{B_i}{\varepsilon_b}\right) + Z_{i2}\left(-1 + \frac{B_i}{\varepsilon_b}\right) + Z_{i3}\left(-1 + \frac{B_i}{\mu + \varepsilon_b}\right)\right) = 0$$

and then reorganize it to

$$\sum_{i=1}^{I}(Z_{i1} + Z_{i2} + Z_{i3}) = \sum_{i=1}^{I}\left(\frac{Z_{i1}B_i + Z_{i2}B_i}{\varepsilon_b} + \frac{Z_{i3}B_i}{\mu + \varepsilon_b}\right).$$

Since $\sum_{i=1}^{I}(Z_{i1} + Z_{i2} + Z_{i3}) = I$ and $\sum_{i=1}^{I}\left(\frac{Z_{i1}B_i + Z_{i2}B_i}{\varepsilon_b} + \frac{Z_{i3}B_i}{\mu + \varepsilon_b}\right) = a_b x_b + b_b y_b$, we simplify the equation to

$$\mathrm{I} = a_b x_b + b_b y_b, \ \ldots \text{(i)}$$

$$\text{where} \quad x_b = \frac{1}{\varepsilon_b}, y_b = \frac{1}{\mu + \varepsilon_b}.$$

In a similar way, we can attain

$$\begin{aligned}
&\frac{\partial Q}{\partial \varepsilon_s} = \sum_{i=1}^{I}\left(Z_{i1}\frac{\partial \ln f_1}{\partial \varepsilon_s} + Z_{i2}\frac{\partial \ln f_2}{\partial \varepsilon_s} + Z_{i3}\frac{\partial \ln f_3}{\partial \varepsilon_s}\right) = 0.\\
&I = a_s x_s + b_s y_s, \ \ldots \text{(ii)}\\
&\text{where} \quad x_s = \frac{1}{\varepsilon_s}, y_s = \frac{1}{\mu + \varepsilon_s}.
\end{aligned}$$

$$\begin{aligned}
&\frac{\partial Q}{\partial \mu} = \sum_{i=1}^{I}\left(Z_{i1}\frac{\partial \ln f_1}{\partial \mu} + Z_{i2}\frac{\partial \ln f_2}{\partial \mu} + Z_{i3}\frac{\partial \ln f_3}{\partial \mu}\right) = 0,\\
&I - \sum_{i=1}^{I} Z_{i1} = b_s y_s + b_b y_b.
\end{aligned}$$

By substitute $b_b y_b$ and $b_s y_s$ from equations (i) and (ii),

$$\sum_{i=1}^{I} Z_{i1} + I = a_s x_s + a_b x_b, \ \ldots \text{(iii)}.$$

We can rewrite x_b, y_b, and y_s to

$$x_b = \frac{\sum_{i=1}^{I} Z_{i1} + I - a_s x_s}{a_b}, \ y_b = \frac{a_s x_s - \sum_{i=1}^{I} Z_{i1}}{b_b}, \text{ and } y_s = \frac{I - a_s x_s}{b_s}.$$

To solve four variables, we need four equations. We hence artificially develop equation (iv), substitute x_b, y_b, and y_s to

$$\frac{1}{y_b} - \frac{1}{x_b} = \frac{1}{y_s} - \frac{1}{x_s} \ldots \text{(iv)}$$

and organize equation (iv) into

$$\frac{b_b}{a_s x_s - \sum_{i=1}^{I} \mathrm{Z}_{\mathrm{i}1}} - \frac{a_b}{\sum_{i=1}^{I} \mathrm{Z}_{\mathrm{i}1} + \mathrm{I} - a_s x_s} = \frac{b_s}{\mathrm{I} - a_s x_s} - \frac{1}{x_s}.$$

Finally, we mathematically process fractions to a common denominator and achieve a function:

$$f(x) = a_3 x_s^3 - a_2 x_s^2 + a_1 x_s - a_0$$

where

$$\begin{aligned}
a_3 &= a_b a_s^2 + a_s^3 + a_s^2 b_s + a_s^2 b_s, \\
a_2 &= a_b a_s I + 2a_s^2 I + 2a_s b_b I + a_s b_s I + a_b a_s \sum_{i=1}^{I} Z_{i1} + 2a_s^2 \sum_{i=1}^{I} Z_{i1} + a_s b_b \sum_{i=1}^{I} Z_{i1} \\
&\quad + 2a_s b_s \sum_{i=1}^{I} Z_{i1}, \\
a_1 &= a_s I^2 + a_b I \sum_{i=1}^{I} Z_{i1} + 3a_s I \sum_{i=1}^{I} Z_{i1} + b_s I \sum_{i=1}^{I} Z_{i1} + a_s \Big(\sum_{i=1}^{I} Z_{i1}\Big)^2 + b_s \left(\sum_{i=1}^{I} Z_{i1}\right)^2 \\
&\quad + b_b I^2 + b_b I \sum_{i=1}^{I} Z_{i1}, \\
a_0 &= I^2 \sum_{i=1}^{I} Z_{i1} + I\Big(\sum_{i=1}^{I} Z_{i1}\Big)^2.
\end{aligned} \tag{96.11}$$

Numerical Analysis Method

To solve x_s in Eq. 96.11, we employ Newton's method. In numerical analysis, Newton's method (also known as the Newton–Raphson method) is a method for finding successively superior approximations to the roots of a real-valued function.[4] The Newton–Raphson method for our case is implemented as follows.

Given our function $f(x)$ defined over the real x_s and its derivative $f'(x_s)$, we begin with a first guess $x_s^{(0)}$ for a root of the function $f(x_s)$. Provided that the function is reasonably well behaved, a better approximation $x_s^{(1)}$ is

$$x_s^{(1)} = x_s^{(0)} - \frac{f\left(x_s^{(0)}\right)}{f'\left(x_s^{(0)}\right)}.$$

Geometrically, $(x_s^{(1)}, 0)$ is the intersection with the x-axis of a line tangent to f at $(x_s^{(0)}, f(x_s^{(0)}))$.

The process is repeated as

$$x_s^{(n+1)} = x_s^{(n)} - \frac{f\left(x_s^{(n)}\right)}{f'\left(x_s^{(n)}\right)}$$

until a sufficiently accurate value is reached.

The Precision of Parameter Estimation

Information on μ, ε_b, ε_s accumulates at a rate approximately equal to the square root of the number of trade outcomes. On the other hand, information on α and δ accumulates at a rate approximately equal to the square root of the number of trading days. The difference in information accumulation rates dictates that the precision of μ, ε_b, ε_s will exceed that of α and δ estimates.

Different μ (μ_b, μ_s) Case

As shown in Eq. 96.2, the arrival rate of informed buyers differs from that of informed sellers. For our model, Eqs. 96.4 and 96.5 are rewritten as

$$f_2 = e^{-\varepsilon_b} \frac{\varepsilon_b^B}{B_i!} e^{-(\mu_s + \varepsilon_s)} \frac{(\mu_s + \varepsilon_s)^S}{S_i!} \tag{96.4*}$$

[4]Newton's method can also be extended to complex functions and to systems of equations.

$$f_3 = e^{-(\mu_b + \varepsilon_b)} \frac{(\mu_b + \varepsilon_b)^B}{B_i!} e^{-\varepsilon_s} \frac{\varepsilon_s^S}{S_i!} \tag{96.5*}$$

The parameters are estimated jointly. The empirical work of our case is discussed in Chang and Lin (2014). We estimate the rate of informed and uninformed trading on a particular day for index futures and spot markets, as well as of the information event structure.

The logarithm of f_1 remains the same, but those of f_2 and f_3 change to

$$\begin{aligned}
\ln f_2 &= -\varepsilon_b + B_i \ln \varepsilon_b - \ln(B_i!) - (\mu_s + \varepsilon_s) + S_i \ln(\mu_s + \varepsilon_s) - \ln(S_i!),\\
\ln f_3 &= -(\mu_b + \varepsilon_b) + B_i \ln(\mu_b + \varepsilon_b) - \ln(B_i!) - \varepsilon_s + S_i \ln \varepsilon_S - \ln(S_i!),
\end{aligned}$$

We use the same method for same μ case to estimate ε_b, ε_s, μ_b, and μ_s. We find it easier to estimate $\theta^* = (\alpha, \delta, \mu_b, \mu_s, \varepsilon_b, \varepsilon_s)$ than $\theta = (\alpha, \delta, \mu, \varepsilon_b, \varepsilon_s)$ because there is one more condition for the case of different μ. The details of the estimation are shown as

$$\begin{aligned}
&\frac{\partial Q}{\partial \varepsilon_b} = \sum_{i=1}^{I} \left(Z_{i1} \frac{\partial \ln f_1}{\partial \varepsilon_b} + Z_{i2} \frac{\partial \ln f_2}{\partial \varepsilon_b} + Z_{i3} \frac{\partial \ln f_3}{\partial \varepsilon_b} \right) = 0\\
&I = a_b x_b + b_b y_b, \ \ldots \text{(v)}\\
&\text{where} \quad x_b = \frac{1}{\varepsilon_b}, y_b = \frac{1}{\mu_b + \varepsilon_b}
\end{aligned}$$

$$\begin{aligned}
&\frac{\partial Q}{\partial \varepsilon_s} = \sum_{i=1}^{I} \left(Z_{i1} \frac{\partial \ln f_1}{\partial \varepsilon_s} + Z_{i2} \frac{\partial \ln f_2}{\partial \varepsilon_s} + Z_{i3} \frac{\partial \ln f_3}{\partial \varepsilon_s} \right) = 0\\
&I = a_s x_s + b_s y_s, \ \ldots \text{(vi)}\\
&\text{where} \quad x_s = \frac{1}{\varepsilon_s}, y_s = \frac{1}{\mu_s + \varepsilon_s}
\end{aligned}$$

$$\begin{aligned}
&\frac{\partial Q}{\partial \mu_b} = \sum_{i=1}^{I} \left(Z_{i1} \frac{\partial \ln f_1}{\partial \mu_b} + Z_{i2} \frac{\partial \ln f_2}{\partial \mu_b} + Z_{i3} \frac{\partial \ln f_3}{\partial \mu_b} \right) = 0\\
&\sum_{i=1}^{I} Z_{i3} = b_b y_b, \ \ldots \text{(vii)}\\
&\text{where} \quad y_b = \frac{1}{\mu_b + \varepsilon_b}
\end{aligned}$$

$$\begin{aligned}
&\frac{\partial Q}{\partial \mu_s} = \sum_{i=1}^{I} \left(Z_{i1} \frac{\partial \ln f_1}{\partial \mu_s} + Z_{i2} \frac{\partial \ln f_2}{\partial \mu_s} + Z_{i3} \frac{\partial \ln f_3}{\partial \mu_s} \right) = 0\\
&\sum_{i=1}^{I} Z_{i3} = b_s y_s; \ldots \text{(viii)}\\
&\text{where} \quad y_s = \frac{1}{\mu_s + \varepsilon_s}
\end{aligned}$$

We can solve x_b, x_s, y_b, and y_s from the following equations:

$$\begin{aligned} &I = a_b x_b + b_b y_b, \ldots (\mathrm{v}) \\ &I = a_s x_s + b_s y_s, \ldots (\mathrm{vi}) \\ &\sum_{i=1}^{I} Z_{i3} = b_b y_b, \ldots (\mathrm{vii}) \\ &\sum_{i=1}^{I} Z_{i2} = b_s y_s. \ldots (\mathrm{viii}) \end{aligned}$$

From (vii), $y_b = \frac{\sum_{i=1}^{I} Z_{i3}}{b_b}, x_b = \frac{I - \sum_{i=1}^{I} Z_{i3}}{a_b}$, then $\varepsilon_b = \frac{a_b}{I - \sum_{i=1}^{I} Z_{i3}}, \mu_b = \frac{b_b}{\sum_{i=1}^{I} Z_{i3}} - \varepsilon_b.$

From (viii), $y_s = \frac{\sum_{i=1}^{I} Z_{i2}}{b_s}, x_s = \frac{I - \sum_{i=1}^{I} Z_{i2}}{a_s}$, then $\varepsilon_s = \frac{a_s}{I - \sum_{i=1}^{I} Z_{i2}}, \mu_s = \frac{b_s}{\sum_{i=1}^{I} Z_{i2}} - \varepsilon_s.$

Based on these parameters, we are ready to calculate Easley et al.'s probability of informed trading, $PIN = \frac{\alpha\mu}{\alpha\mu + \varepsilon_{st} + \varepsilon_b}$ and our revised $PIN^* = \frac{\alpha(\delta|\mu_s| + (1-\delta)|\mu_b|)}{\alpha(\delta|\mu_s| + (1-\delta)|\mu_b|) + \varepsilon_s + \varepsilon_b}$.

Acknowledgments Special thanks to professors Lii-Yuh Leu, Ren-Her Wang, and Charles Chang for their helpful comments and consultation. All errors are our own.

and/or reallocate their effort, and to possibly engage in gaming (such as opportunistic earnings and disclosure management) and hypothesize that these managerial behaviors will result in an increase in the complexity of forecasting and, hence, in less accurate analysts' forecasts. We also posit that analysts' optimistic forecast bias will increase as the level of stock options pay increases. We reason that as forecast complexity increases with stock options pay, analysts, needing greater access to management's information to produce accurate forecasts, have incentives to increase the optimistic bias in their forecasts. Alternatively, a higher level of stock options pay may lead to improved disclosure because it better aligns managers' and shareholders' interests. The improved disclosure, in turn, may result in more accurate and less biased analysts' forecasts.

Using ordinary least squares estimation, we test these hypotheses relating the level of CEO stock options pay to analysts' forecast accuracy and bias on a sample of firms from the Standard & Poor's ExecuComp database over the period 1993–2003. Our OLS models relate forecast accuracy and forecast bias (the dependent variables) to CEO stock options (the independent variable) and controls for earnings characteristics, firm characteristics, and forecast characteristics. We measure forecast accuracy as negative one times the absolute value of the difference between forecasted and actual earnings scaled by beginning of period stock price and forecast bias as forecasted minus actual earnings scaled by beginning of period stock price. We control for differences in earnings characteristics by including earnings volatility, whether the firm has a loss, and earnings surprise; for differences in firm characteristics by including firm size, growth (measured as book-to-market ratio, percentage change in total assets, and percentage change in annual sales), and corporate governance quality (measured as percentage of shares outstanding owned by the CEO, whether the CEO is also chairman of the board of directors, number of annual board meetings, and whether directors are awarded stock options); and for differences in forecast characteristics by including analyst following and analyst forecast dispersion. In addition, the models include controls for industry and year. We use four measures of options: new options, existing exercisable options, existing unexercisable options, and total options (sum of the previous three), all scaled by total number of shares outstanding, and estimate two models for each dependent variable, one including total options and the other including new options, existing exercisable options, and existing unexercisable options. We also use both contemporaneous as well as lagged values of options in our main tests.

Our results indicate that analysts' earnings forecast accuracy decreases and forecast optimism increases as the level of stock options (particularly new options and existing exercisable options) in CEO pay increases. These findings suggest that the incentive alignment effects of stock options are more than offset by the investment, effort allocation, and gaming incentives induced by stock options grants to CEOs. Given that analysts' forecasts are an important source of information to capital markets, our finding of a decline in the quality of

the information provided by analysts has implications for the level and variability of stock prices. It also has implications for information asymmetry and cost of capital, as well as for valuation models that rely on analysts' earnings forecasts.

97.1 Introduction

Firms grant equity incentives such as stock pay, restricted stock, and stock options to create incentives for executives to make decisions that benefit shareholders.[1] By linking executive compensation to shareholder wealth, stock options purportedly help reduce agency costs that arise from the separation of ownership and control in corporations. Over the last decade, stock options have become an increasingly larger component of executive compensation. Most large firms compensate their top executives through stock options which, on a Black-Scholes valuation basis, now represent the largest single component of managerial pay (Murphy 1999; Hall and Murphy 2003).

Several studies have examined the economic implications of stock options and other forms of equity compensation. Much of that research has focused on the relation between stock options compensation and firm performance (Core et al. 1999; Guay 1999; Hanlon et al. 2003; Lam and Chng 2006; Bauman and Shaw 2006), on the link between stock options and investment decisions (Smith and Watts 1992; Bizjak et al. 1993), and on the relation between stock options and dividend policy and dividend yield (Lambert et al. 1989; Atan et al. 2010). Other research has examined whether stock options and other equity-based compensation induce managers to increase short-term stock price through earnings management (Bartov and Mohanram 2004; Cheng and Warfield 2005; Cao and Laksmana 2010).[2] Efendi et al. (2007) provide evidence that the amount of stock options in-the-money is the most influential factor affecting the likelihood of a misstatement. Bergstresser and Philippon (2006) document that managers with a large proportion of stock and options holdings are more likely to use discretionary accruals to manipulate earnings. Chen (2002) finds a negative relationship between incentive compensation and stock ownership held by outside directors.

[1] Other reasons for granting stock options are to attract and retain executives, to conserve cash, to reduce reported accounting expense, and to defer taxes.

[2] Although there is evidence relating earnings management to stock options compensation, little is known about whether this earnings management actually results in higher payouts or about its effect on other goals of the firm.

The purpose of this study is to examine the implications of executive stock options compensation for the accuracy of and bias in analysts' earnings forecasts. Prior research has studied the links between stock options compensation and earnings/disclosure management and between disclosure quality/forecast complexity and analysts' forecast properties. However, it has not directly examined the link between stock options compensation and analysts' forecast accuracy and bias. Our study provides a direct test of this link. One contribution of our study is that it provides a triangulation of the relationships observed in prior research. If financial intermediaries such as analysts can see through the incentives for manipulation by managers with large stock options grants, then the quality of the information will not be affected. However, if analysts cannot see through this manipulation, it will affect the accuracy and bias of their forecasts, and, hence, it becomes an important issue. In this regard, it validates those findings by empirically documenting the relation between stock options compensation and the quality of analysts' earnings forecasts (a common proxy for a firm's information environment).

Higher levels of stock options may induce managers to undertake riskier projects, to change and/or reallocate their effort, and to possibly engage in gaming (such as opportunistic earnings and disclosure management). Consequently, the forecasting task will be more complex as the proportion of stock options compensation increases, leading to less accurate forecasts. While the above reasoning suggests that forecast accuracy may decrease as the level of stock options in CEO pay increases, higher stock options pay may also result in increased accuracy if it better aligns managers' and shareholders' interests. Hanlon et al. (2003) report an increase in future operating earnings associated with past stock options grants, providing empirical support for improved incentive alignment. Better incentive alignment likely improves managers' disclosures which, in turn, may lead to more accurate forecasts.

Analysts' compensation and reputation are, to a large extent, dependent on the accuracy of their forecasts. They can improve the accuracy of their forecasts if they have access to management's private information.[3] Such access becomes even more valuable as the difficulty of the forecasting task increases. Analysts can increase access to management's private information by developing better relations with management. One way of accomplishing this is by making optimistic forecasts. In so doing, analysts trade off forecast bias for improved accuracy. If forecasting difficulty increases with the level of stock options in CEO pay, then so will the optimistic bias in analysts' earnings forecasts. Alternatively, the improved management disclosures resulting from the increased incentive alignment effects of stock options may lead to less biased forecasts.

We present empirical evidence on the relation between the level of stock options in CEO pay and the accuracy and bias of analysts' earnings forecasts for firms in the Standard & Poor's ExecuComp database over the period 1993–2003.

[3]Ke and Yu (2006) and Chen and Matsumoto (2006) are examples of recent research on analysts' incentives for access to management, i.e., the management relations hypothesis.

We estimate the relations between the level of CEO stock options pay and analysts' forecast accuracy and bias using ordinary least squares estimation. We use four measures of options: new options, existing exercisable options, existing unexercisable options, and total options (sum of the previous three) all scaled by total number of shares outstanding. We estimate two models, one including total options and the other including new options, existing exercisable options, and existing unexercisable options. We also use both contemporaneous as well as lagged values of options in our main tests. Our results indicate that analysts' earnings forecast accuracy decreases and forecast optimism increases as the level of stock options (particularly for new options and existing exercisable options) in CEO pay increases. These findings suggest that the incentive alignment effects of stock options are more than offset by the investment, effort allocation, and gaming incentives induced by stock options grants to CEOs.

While stock options may help companies attract, retain, and motivate executives, they also have associated costs. Hall and Murphy (2003) indicate that stock options may be an inefficient form of compensation because the value to recipients who are undiversified and risk averse, and who neither can sell nor hedge against their risk, is less than the cost to the firm. Consequently, options are a costly form of compensation relative to cash or stock compensation. We document a decrease in the quality of analysts' earnings forecasts as the level of stock options in CEO pay increases. Given that analysts' forecasts are an important source of information to capital markets, a decline in the quality of the information provided by analysts has implications for the level and variability of stock prices. It also has implications for information asymmetry and cost of capital.

Our findings also have implications for investors, academics, and other users of financial analysts' forecasts. Because analysts' forecasts serve as expectations of a firm's future prospects, they play an important role in firm valuation. Analysts' forecasts are also commonly used as measures of the market's earnings expectations in studies that investigate the relation between earnings and stock returns and changes in analysts' forecasts are related to stock returns (Givoly and Lakonishok 1979; Imhoff and Lobo 1984; Stickel 1991; Barber et al. 2001; Jegadeesh et al. 2004). Furthermore, earnings forecasts serve as inputs to other research outputs such as stock recommendations (Loh and Mian 2006), target price forecasts (Bandyopadhyay et al. 1995), valuation models (Frankel and Lee 1998), and growth and return on equity investment models (Easton et al. 2002). By identifying the relations between the level of stock options in CEO pay and forecast accuracy and bias, our study provides investors, researchers, and other users with an ex ante indicator of the accuracy of analysts' forecasts.

The rest of this paper is organized as follows. Section 97.2 develops the research hypotheses, and Sect. 97.3 describes the sample selection and research design. Section 97.4 presents the results of the empirical analysis. Section 97.5 reports the results of sensitivity tests, and Sect. 97.6 contains the conclusions of the study.

97.2 Hypotheses

97.2.1 CEO Stock Options and Forecast Accuracy

An increase in stock options pay to CEOs may increase the complexity of the forecasting task for several reasons. *First*, the convex payoffs from options may induce otherwise risk-averse managers to undertake riskier projects going forward (Murphy 2003; Ross 2004). Theoretical models (Smith and Stulz 1985; Smith and Watts 1992; Bizjak et al. 1993) demonstrate that, because managers' investment decisions are particularly difficult to monitor, firms with substantial investment opportunities tend to encourage higher investment activities by aligning the interests of managers and shareholders through stock options grants. Consistent with this notion, Rajgopal and Shevlin (2002) find empirical evidence linking executive stock options and exploration risks in the oil and gas industry. Relatedly, Guay (1999) documents that equity risk is positively related to the convexity in executives' compensation schemes. These results are consistent with stock options providing managers with incentives to mitigate risk-related incentive problems.

Second, the incentive effect of stock options is to motivate managers to exert higher effort. Such contributions will translate into higher performance in both the current and future periods. Managers exert effort in multiple dimensions (Banker and Datar 1989; Holmstrom and Milgrom 1991). With new incentives, managers may also reallocate their effort contributions in addition to exerting higher effort. Stock options grants may induce managers to reallocate their effort mix from short-term effort that focuses more on improving current performance to long-term (or strategic) effort that places more emphasis on improving future performance (Bushman and Indjejikian 1993; Feltham and Xie 1994). To the extent that managers were short-term oriented prior to receiving stock options grants, the reallocation of effort mix could have a negative impact on current performance. The extent of this potential effect on current performance cannot be easily gauged because the reallocation of effort mix is not directly observable or predictable. This, in turn, may result in an increase in forecasting complexity.[4]

Third, managers with higher levels of stock options may engage in higher levels of gaming (Hall 2003). This gaming behavior can take many forms including opportunistic earnings and disclosure management. Lambert (2001) points out that earnings management strategies will be influenced by the shape of the compensation contract (i.e., whether it is linear, concave, or convex in a given region). An increase in stock options pay relative to cash compensation will increase the convexity of the compensation contract and result in increased incentives for earnings management that is anti-smoothing in nature. Consequently, managers

[4]Furthermore, Feltham and Xie (1994) show that, if there are multiple tasks and multiple public signals that are influenced by the manager's action, it is unlikely that the market price provides an efficient single performance measure. Therefore, overly relying on stock-based compensation may lead to incongruent behavior by CEOs, further increasing the difficulty of the forecasting task.

may increase their current earnings when earnings are high and reduce their current earnings when earnings are low. Such behavior will directly contribute to an increase in earnings volatility. Bartov and Mohanram (2004) provide evidence consistent with the above argument. They document that managers inflate earnings through accruals management in the period leading up to abnormally large stock options exercises. Other research has examined whether stock options and other equity-based compensation induce managers to engage in high levels of earnings management. For example, Cheng and Warfield (2005) document that managers with high equity incentives are more likely to manage earnings in order to boost stock price, and that this earnings management, in turn, increases personal gains from executives' insider trading. Bergstresser and Philippon (2006) also report that managers with a large proportion of stock and options holdings are more likely to use discretionary accruals to manipulate earnings.[5]

Another form of gaming could be voluntary disclosure management. Prior research (e.g., Yermack 1997; Aboody and Kaznik 2000) shows that the timing of corporate voluntary disclosures is related to the granting of stock options. Aboody and Kaznik (2000) observe that CEOs who receive their options before earnings are announced are significantly more likely to issue bad news forecasts and less likely to issue good news forecasts than are CEOs who receive their awards after the earnings announcement.[6] They also find that management forecasts issued during the 3 months prior to scheduled awards are significantly less optimistically biased than forecasts issued for the same firms during other months. Because managers receiving stock options employ such opportunistic disclosure strategies, the complexity of the forecasting task increases as stock options pay increases. This is especially true when CEOs get multiple stock options grants during the same fiscal year.

The above arguments suggest that an increase in the level of stock options in CEO compensation likely increases the difficulty of forecasting, resulting in less accurate forecasts. However, recent research provides evidence suggesting that stock options can improve the alignment between managers' and shareholders' interests. Hanlon et al. (2003) examine whether stock options granted to the top five executives are related to future operating earnings. Their results indicate that each

[5]However, in related research, Hribar and Nichols (2007) provide evidence that not controlling for operating volatility increases the risk of over-rejecting the null hypothesis of no earnings management.

[6]Although Aboody and Kaznik (2000) study only fixed schedule awards, we argue that the incentive to maximize the stock options pay by manipulating the stock price at the grant date is present for all stock options awards, and that the incentive is especially strong for firms that make multiple grants in a given year. We note that a large number of our sample firms made multiple grants in the same fiscal year thus increasing this incentive. It is also interesting to note that the stock options award dates are generally not publicly known until the issue of proxy statements which are available only 2–3 months after the fiscal year-end (Yermack 1997).

dollar of stock options granted is associated with more than one dollar of future operating earnings over the next 5 years.

Cheng and Warfield (2005) examine the link between stock options and stock ownership and earnings management. They provide evidence that managers with high equity incentives (stock options and stock ownership) are more likely to provide reported earnings meeting or just beating analysts' forecasts and are less likely to report large positive earnings surprises, suggesting that stock options motivate types of earnings management that might increase forecast accuracy.

Given that the literature provides mixed evidence, we present our hypothesis in null form:

H1 Analysts' earnings forecast accuracy is unrelated to the level of stock options in CEO pay.

The alternate hypothesis is that earnings forecast accuracy is either positively or negatively related to the level of stock options in CEO pay. Given that the alternate hypothesis is nondirectional, we test H1 using a two-tailed test.

97.2.2 CEO Stock Options and Forecast Bias

Lim (2001) presents a model demonstrating that statistically optimal forecasts, in terms of mean squared error, may be positively and predictably biased. In this model, analysts trade off forecast bias for forecast accuracy. Analysts have incentives to provide accurate forecasts in order to increase their compensation and market value. They need access to management's private information to improve their forecast accuracy. Consequently, they have to maintain favorable relations with management to ensure that they have access to such information. One way of accomplishing this is by issuing optimistically biased forecasts. Although forecast bias by itself is not desirable, analysts can increase their forecast accuracy by incorporating in their forecasts the private information that management makes available to them as a reward for their forecast optimism. And, because access to management's private information is more valuable when firms' earnings are less predictable, analysts have greater incentives to issue optimistic forecasts for such firms.

Lim (2001) and Das et al. (1998) provide empirical evidence that analysts' forecasts are more optimistically biased when earnings are less predictable and the forecasting task is more complex. Recent examples of research supporting the management relations hypothesis include Chen and Matsumoto (2006) and Ke and Yu (2006). Chen and Matsumoto (2006) find that analysts issuing more favorable recommendations experience a greater increase in their relative forecast accuracy compared with analysts who issue less favorable recommendations. Ke and Yu (2006) document that analysts produce more accurate forecasts and are less likely to be fired by their employers when they issue initial optimistic earnings forecasts.

A higher level of CEO stock options pay may increase the forecasting complexity because it may induce managers to undertake riskier investments, to change/reallocate their effort, to manipulate accounting earnings, and to issue opportunistic voluntary disclosures. Therefore, we expect analysts' optimistic forecast bias to increase as the level of stock options in CEO pay increases. However, as discussed in the previous section, there is also evidence suggesting that stock options can align the incentives of management and shareholders (see, e.g., Hanlon et al. 2003), which, in turn, may lead to better disclosure and less optimistic bias. Accordingly, we provide the following hypothesis stated in null form:

H2 Analysts' optimistic earnings forecast bias is unrelated to the level of stock options in CEO pay.

The alternate hypothesis is that earnings forecast bias either increases or decreases with the level of stock options in CEO pay. Given that the alternate hypothesis is nondirectional, we test H2 using a two-tailed test.

97.3 Data Description and Research Design

97.3.1 Sample Selection

Our sample comprises firms with data available in the ExecuComp, I/B/E/S, and Compustat databases for the period 1993–2003. We exclude financial institutions and agricultural firms[7] and observations for which the CEOs are not identified in ExecuComp. These selection criteria result in an initial sample of 6,272 firm-year observations.

We obtain compensation data from ExecuComp, earnings forecasts, actual earnings, and stock prices from I/B/E/S. I/B/E/S forecasts generally exclude extraordinary and other special items. By using forecast and actual earnings from I/B/E/S, we ensure greater consistency between these two variables (Philbrick and Ricks 1991). We test our hypotheses using forecasts made 9 months before the earnings announcement.[8] We obtain other required financial data from Compustat.

[7]To be consistent with the prior literature on executive pay (Core et al. 1999; Hanlon et al. 2003), we omit financial institutions and agricultural companies. However, for completeness, we also conducted the analysis with these companies included in the sample. Our main conclusions are unaffected by this inclusion.

[8]We repeat all our analyses using 3-month-ahead forecasts to examine the robustness of our results to the forecast horizon. Most results for the 3-month forecasts mirror those presented for the 9-month forecasts.

Table 97.1 Sample selection procedure

Total firm-year observations on ExecuComp data for years 1993–2003, where the CEO is identified and without financial and agricultural firms	11,016
Less: Observations lost when merging with I/B/E/S data	(4,744)
Subtotal	6,272
Less: Observations with total compensation less than $1 million	(718)
Subtotal	5,554
Less: Observations with missing financial data	(553)
Less: Deletion of extreme values and other restrictions	(568)
Final sample for tests on forecast accuracy	**4,433**

Additionally, we require firms to have stock prices greater than one dollar to avoid the small deflator problem, to have at least three analysts' forecasts available to obtain a reliable estimate of forecast dispersion, and to have total CEO pay of at least one million dollars to avoid including firms that have low CEO incentives. These restrictions, along with deletion of observations with values in the top and bottom 1 % of the variables used in the regressions, result in 4,433 firm-year observations for the 9-month-ahead forecast accuracy tests and 4,279 firm-year observations for the 9-month-ahead forecast bias tests.[9] Table 97.1 summarizes our sample selection criteria.

97.3.2 Variable Measurement

97.3.2.1 CEO Options (OPTIONS)

We measure the level of CEO options pay (OPTIONS) as the ratio of the number of options to total number of shares outstanding. This is consistent with the measure employed by Cheng and Warfield (2005). It is a simple parsimonious variable that measures the relative proportion of stock options in a CEO's compensation for a particular year. We use four measures of CEO options: new options, existing exercisable options, existing unexercisable options, and total options (sum of the previous three), all scaled by total number of shares outstanding. We also use both contemporaneous as well as lagged values of OPTIONS in our main tests.[10]

97.3.2.2 Forecast Accuracy (ACCURACY)

We measure forecast accuracy for the 9-month-ahead forecast as minus one times the absolute value of the deviation of the mean EPS forecast from the actual EPS for

[9]The sample firms represent a variety of industries, with the largest representation being retail (8 %), electronic equipment (6.7 %), business services (5.3 %), and telecommunications (6 %).

[10]As a sensitivity check, when using lagged OPTIONS, we delete observations that have a new CEO in the current year. Our main results are robust to deletion of these observations.

that year divided by stock price at the forecast date. This measure increases with forecast accuracy and is defined as

$$\mathrm{ACCURACY_{it}} = (-1) * \frac{\left|\mathrm{FEPS_{it}^{t-1}} - \mathrm{AEPS_{it}}\right|}{\mathrm{P_{i,t-1}}} \quad (97.1)$$

where, for firm i, $\mathrm{ACCURACY_t}$ is minus one times the absolute forecast error at time t, $\mathrm{FEPS_t^{t-1}}$ is the mean EPS forecast from I/B/E/S for year t made at time t − 1 (i.e., 9 months prior to the fiscal year-end), $\mathrm{AEPS_t}$ is the actual earnings per share obtained from I/B/E/S, and $\mathrm{P_{t-1}}$ is the stock price at the time of the forecast obtained from I/B/E/S.

97.3.2.3 Forecast Bias (BIAS)

We measure forecast bias for firm i at time t as the difference between the mean EPS forecast made 9 months prior to the fiscal year-end and the actual EPS, divided by stock price at the forecast date:

$$\mathrm{BIAS_{it}} = \frac{\mathrm{FEPS_{it}^{t-1}} - \mathrm{AEPS_{it}}}{\mathrm{P_{i,t-1}}} \quad (97.2)$$

The variable BIAS increases as the level of forecast optimism increases.

97.3.2.4 Other Factors Affecting Forecast Accuracy and Bias

In our empirical tests, we control for previously identified determinants of forecast accuracy and bias. These include earnings characteristics, firm characteristics, and forecast characteristics.

97.3.2.5 Earnings Characteristics

Prior research (Lang and Lundholm 1996; Das et al. 1998; Brown 2001; Duru and Reeb 2002) identifies earnings volatility (VOLROA), whether firms have accounting losses (LOSS), and absolute earnings surprise (ABSESUP) as earnings characteristics that negatively affect forecast accuracy. Kross et al. (1990) and Lim (2001) provide evidence that long-term earnings volatility is associated with less accurate forecasts. This is because the forecasting task is more difficult for firms with historically volatile earnings compared to firms with historically more stable earnings. Prior studies (Brown 2001) also document that analysts' forecasts of firms with losses are generally less accurate than those of firms with profits, partly due to the increased difficulty with estimating losses stemming from other managerial incentives such as "big baths." Lang and Lundholm (1996) and Duru and Reeb (2002), among others, find that larger earnings surprises are associated with less accurate forecasts. This may be due to the effect of anchoring to previously reported earnings.

Consistent with prior research, we measure VOLROA as the standard deviation of return on assets estimated using data from the prior 5 years, LOSS as an indicator variable representing firm-years with reported losses, and ABSESUP as the absolute value of the difference between the current year's EPS and the previous year's EPS, divided by stock price at the beginning of the year.

The same earnings characteristics also affect analysts' optimistic bias. In addition, Gu and Wu (2003) provide evidence that optimistic forecast bias is negatively associated with earnings skewness (SKEW) primarily due to mean-median differences in skewed earnings distributions. Prior research reports that earnings predictability variables, such as earnings volatility and whether the firm is a loss firm, are positively related to optimistic bias (Duru and Reeb 2002). However, after controlling for the level of earnings, Eames and Glover (2003) do not find a significant relation between forecast error and earnings predictability. Given this finding, we include level of earnings (LEVEARN), measured as annual earnings scaled by year-end market value of equity, as a control variable.[11] We include earnings surprise (ESUP) in place of absolute earnings surprise as a control variable for bias. This variable is measured as the difference between the current year's EPS and the previous year's EPS, divided by the price at the beginning of the year. We also include negative earnings surprise (NEGESUP), where NEGESUP equals 0 if ESUP is positive and equals ESUP if ESUP is negative. We include ESUP and NEGESUP to control for the anchoring behavior of analysts who tend to anchor their forecasts closely to previous period's actual results.

97.3.2.6 Firm Characteristics

We include size (SIZE), growth (GROWTH, CHASSETS, and CHSALES), and governance variables (SHROWN, CEOCHAIR, NUMMTGS, and DIROPT) as firm-specific control variables that are likely to be related to forecast accuracy and bias. We measure SIZE as the natural log of assets at the beginning of the year. Previous studies report that SIZE is related to analyst forecast accuracy and bias (Duru and Reeb 2002; Gu and Wu 2003; Ho and Tsay 2004). Because large firms have a richer information environment, we expect a positive relation between accuracy and size. From a strategic reporting bias standpoint, analysts have stronger incentives to issue optimistic forecasts for smaller firms to facilitate management communication since there is less public information available for these firms (Lim 2001; Gu and Wu 2003). Therefore, we expect the coefficient on SIZE to be negatively related to optimistic forecast bias.

We include the following three proxies for growth, GROWTH, CHASSETS, and CHSALES, where GROWTH is the ratio of the book value of equity at the beginning of the year to the market value of equity at the beginning of the year (i.e., the book-to-market ratio), CHASSETS is the percentage change in total assets at the beginning of the year, and CHSALES is the percentage

[11] Gu (2003) argues that inclusion of earnings level as a control variable will induce spurious relationships between the variable capturing forecast efficiency and other control variables. Our main results are stronger when we exclude earnings level as a control variable.

change in annual sales at the beginning of the year.[12] We include these measures of growth as control variables because firm growth is an important driver of forecast complexity; however, we do not offer directional predictions for these proxies for growth.[13]

Prior research (Byard et al. 2006) shows that analyst forecast accuracy is related to a firm's corporate governance quality. We include SHROWN, CEOCHAIR, NUMMTGS, and DIROPT as proxies for a firm's governance quality. We measure SHROWN as the number of shares owned by the CEO divided by the total number of shares outstanding. Extant evidence indicates that insider ownership generally serves to align insiders' interests with those of shareholders (e.g., McConnell and Servaes 1990). Additionally, higher insider ownership is negatively associated with earnings management (Warfield et al. 1995). Higher insider ownership induces insiders, including the CEO, to maximize shareholder wealth, thereby mitigating the agency problem. Therefore, we expect SHROWN to be positively related to accuracy. The variable CEOCHAIR is an indicator variable which equals one if the CEO is also the chairman of the board and zero otherwise. A CEO who is also chairman of the board of directors could undermine the effectiveness of the board by dissuading directors from expressing alternative viewpoints. Separation of the positions of Chairman and CEO is also an important indicator of board independence (Jensen 1993; Daily and Dalton 1997). Combining these positions leads to a conflict of interest and impairs the board's independence and effectiveness in executing its oversight and governance responsibilities.

The variable NUMMTGS indicates the number of board meetings held in a year. Boards that meet more frequently should be more effective monitors of management (Conger et al. 1998). In addition, Xie et al. (2003) find that the level of earnings management is lower for companies whose boards meet more frequently. The variable DIROPT is an indicator variable which equals one if the directors are awarded stock options in the year and zero otherwise. Directors receiving higher pay may be less vigilant in monitoring the management. This is especially true if the directors were appointed to the board by the same CEO. Although CEOCHAIR, NUMMTGS, and DIROPT are important proxies of a firm's governance quality, we do not offer directional predictions for these variables.

97.3.2.7 Forecast Characteristics

Prior research has identified two forecast characteristics that are related to forecast accuracy and bias – number of analysts following a firm (Duru and Reeb 2002; Das et al. 1998) and dispersion in analysts' forecasts (Lang and Lundholm 1996; Gu and Wu 2003). This research finds that forecast accuracy is higher for firms with larger analyst following (FOLLOW) and lower for firms with

[12]Prior research on forecast accuracy and bias (e.g., Duru and Reeb 2002) does not control for differences in growth. Our results are robust to the exclusion of GROWTH as a control variable in the regressions.

[13]The variance inflation factors for variables in our main regressions are all below three, indicating that there are no severe multicollinearity problems.

higher analysts' forecast dispersion (DISP). It also documents that optimistic forecast bias decreases with analyst following and increases with forecast dispersion.

Forecast dispersion may also proxy for the degree of difficulty in forecasting earnings, with high analysts' forecast dispersion firms exhibiting lower levels of earnings predictability. Therefore, we also expect forecast dispersion to be negatively related to forecast accuracy and positively related to forecast bias.

97.3.3 Empirical Models

We estimate the following regression model to test our first hypothesis on forecast accuracy:

$$\begin{aligned}\mathrm{ACCURACY}_{it} = {} & a_0 + a_1\mathrm{OPTIONS}_{it} + a_2\mathrm{VOLROA}_{i,t-1} + a_3\mathrm{LOSS}_{it} + a_4\mathrm{ABSESUP}_{it} \\ & + a_5\mathrm{GROWTH}_{i,t-1} + a_6\mathrm{SIZE}_{i,t-1} + a_7\mathrm{FOLLOW}_{i,t-1} + a_8\mathrm{DISP}_{i,t-1} \\ & + a_9\mathrm{SHROWN}_{it} + a_{10}\mathrm{CEOCHAIR}_{it} + a_{11}\mathrm{NUMMTGS}_{it} \\ & + a_{12}\mathrm{DIROPT}_{it} + a_{13}\mathrm{GROWTH}_{i,t-1} + a_{14}\mathrm{CHASSETS}_{i,t-1} \\ & + a_{15}\mathrm{CHSALES}_{i,t-1} + \langle\text{Industry controls}\rangle + \langle\text{Year controls}\rangle \\ & + \varepsilon_{it}\end{aligned} \tag{97.3}$$

We include industry and year indicator variables to control for industry and year fixed effects. We employ the 48 industries (other than financial and agricultural) identified by Fama and French (1997) as our industry categories.

Hypothesis 1 predicts that forecast accuracy changes with the level of CEO stock options pay. Therefore, we expect a_1, the coefficient on OPTIONS, to be different from zero. Recall that we are using four measures of OPTIONS: new options, existing exercisable options, existing unexercisable options, and total options (sum of the previous three). We use two models to test our hypothesis. We use total options as the measure of OPTIONS in the first model, and we use new options, existing exercisable options, and existing unexercisable options as measures of OPTIONS in the second model. In addition, we use both contemporaneous as well as lagged values of OPTIONS in our tests.

We include VOLROA, LOSS, and ABSESUP in the model to control for cross-sectional differences in earnings characteristics because prior research documents that these variables affect forecast accuracy. We include SIZE, GROWTH, CHASSETS, and CHSALES to control for differences in firm characteristics, and we include FOLLOW and DISP to account for the effects of differences in forecast characteristics on forecast accuracy. We include SHROWN, CEOCHAIR, NUMMTGS, and DIROPT to control for cross-sectional differences in corporate governance. We discuss the expected signs on the control variables and present their definitions in Sect. 97.3.2.

We estimate the following regression model to test our second hypothesis on forecast bias:

$$\begin{aligned}\mathrm{BIAS}_{it} = {} & a_0 + a_1\mathrm{OPTIONS}_{it} + a_2\mathrm{SKEW}_{i,t-1} + a_3\mathrm{VOLROA}_{i,t-1} + a_4\mathrm{LOSS}_{it}\\ & + a_5\mathrm{LEVEARN}_{it} + a_6\mathrm{ESUP}_{it} + a_7\mathrm{NEGESUP}_{it} + a_8\mathrm{SIZE}_{i,t-1}\\ & + a_9\mathrm{FOLLOW}_{it} + a_{10}\mathrm{DISP}_{it} + a_{11}\mathrm{SHROWN}_{it} + a_{12}\mathrm{CEOCHAIR}_{it}\\ & + a_{13}\mathrm{NUMMTGS}_{it} + a_{14}\mathrm{DIROPT}_{it} + a_{15}\mathrm{GROWTH}_{i,t-1} + a_{16}\mathrm{CHASSETS}_{i,t-1}\\ & + a_{17}\mathrm{CHSALES}_{i,t-1} + \langle\text{Industry controls}\rangle + \langle\text{Year controls}\rangle + \varepsilon_{it}\end{aligned} \tag{97.4}$$

Hypothesis 2 predicts that forecast bias increases or decreases as the level of CEO stock options pay changes. Therefore, we expect a_1, the coefficient on OPTIONS, to be different from zero. Once again, we use two models to test hypothesis 2. The first model uses total options as the measure of OPTIONS. The second model uses new options, existing exercisable options, and existing unexercisable options as measures of OPTIONS. We also include both contemporaneous and lagged values of these four measures.

We include SKEW, VOLROA, LOSS, LEVEARN, ESUP, and NEGESUP in the model to control for cross-sectional differences in earnings characteristics that have been shown in prior research to affect forecast bias. We include SIZE, GROWTH, CHASSETS, and CHSALES to control for differences in firm characteristics, and we include FOLLOW and DISP to account for differences in forecast characteristics that affect forecast bias. We include SHROWN, CEOCHAIR, NUMMTGS, and DIROPT to control for cross-sectional differences in corporate governance. We discuss the expected signs on the control variables and present their definitions in Sect. 97.3.2.

97.4 Empirical Analysis

97.4.1 Descriptive Statistics

Table 97.2 presents descriptive statistics for the key variables. Consistent with prior research, the mean forecast bias (BIAS) is positive and 0.64 % of stock price. The median value of forecast bias is 0.37 %, which is consistent with prior research. The mean and median values of forecast accuracy (ACCURACY) are negative by construction. The mean value of forecast accuracy is −1.30 % of stock price. The level of new CEO stock options (NOPT) has a mean value of 0.21 % and a median value of 0.11 % indicating that, on average, a significant amount of CEO stock options are awarded relative to the number of shares outstanding.

Table 97.3 presents the correlation matrix for the stock options variables used in the regression analysis. Forecast accuracy is significantly negatively related to all

Table 97.2 Descriptive statistics on CEO options, forecast accuracy, forecast bias, and control variables

Variable	Obs.	Mean	Median	Standard deviation	25 %	75 %

Variable definitions:
NOPT = new stock options to CEO in the current year scaled by total number of shares outstanding
EOPT = existing exercisable stock options of CEO scaled by total number of shares outstanding
UEOPT = existing unexercisable stock options of CEO scaled by total number of shares outstanding
TOPT = sum of *NOPT*, *EOPT*, and *UEOPT*
ACCURACY = (−1) * absolute value of [mean EPS forecast − actual EPS]/price at forecast date
BIAS = signed forecast error measured as [mean EPS forecast − actual EPS]/price at forecast date
FOLLOW = number of analysts following the firm
DISP = forecast dispersion, measured as the standard deviation of analysts' forecasts deflated by price at the forecast date
SKEW = difference between the mean and the median forecast scaled by price at the forecast date
VOLROA = earnings volatility measured as the standard deviation of return on assets for the previous 5-year period
ABSESUP = earnings surprise measured as the absolute value of the difference between the current year's EPS and the last year's EPS, divided by price at the beginning of the year
ESUP = change in earnings (CHG_EPS) measured as the difference between the current year's EPS and the last year's EPS, divided by price at the beginning of the year
LOSS = a dummy variable which equals to 1 when earnings are negative and 0 otherwise
LEVEARN = annual earnings scaled by the year-end market value of equity
SIZE = firm size measured as the natural log of beginning assets
GROWTH = beginning book value of equity divided by the beginning market value of equity
CHASSETS = annual percentage change in total assets at the beginning of the year
CHSALES = annual percentage change in total sales at the beginning of the year
SHROWN = number of shares owned by the CEO divided by the total number of shares outstanding
CEOCHAIR = an indicator variable which equals "1" if the CEO is also the chairman of the board and "0" otherwise
NUMMTGS = the number of board meetings held in a year
DIROPT = an indicator variable which equals "1" if the directors are awarded stock options in the year and "0" otherwise

UEOPT					1.000	0.771 (0.00)	0.778 (0.00)	0.644 (0.00)
UEOPT, $t-1$						1.000	0.682 (0.00)	0.817 (0.00)
TOPT							1.000	0.833 (0.00)

p-values are reported in parentheses
Variable definitions:
ACCURACY = (−1) * absolute value of [mean EPS forecast − actual EPS]/price at forecast date
BIAS = signed forecast error measured as [mean EPS forecast − actual EPS]/price at forecast date
NOPT = new stock options to CEO in the current year scaled by total number of shares outstanding
EOPT = existing exercisable stock options of CEO scaled by total number of shares outstanding
UEOPT = existing unexercisable stock options of CEO scaled by total number of shares outstanding
TOPT = sum of *NOPT*, *EOPT*, and *UEOPT*

four components of CEO options, and forecast bias is significantly positively related to all four components.

97.4.2 Estimation Results

Tables 97.4 and 97.5 present estimation results of our empirical models on forecast accuracy and bias respectively. In each table, we present the results for our two models, one using total options and the other using new options, existing exercisable options, and existing unexercisable options. We present the results using contemporaneous measures of OPTIONS in Panel A and the results using lagged values in Panel B.

Table 97.4 presents estimation results for Eq. 97.3. This specification is used to test our first hypothesis that analyst forecast accuracy is unrelated to CEO stock options.[14] For the total options measure (model 1 in Table 97.4), the coefficient on TOPT is negative and statistically significant at the 1 % level for both contemporaneous and lagged values, indicating rejection of hypothesis H1. Model 2 results also indicate rejection of hypothesis H1 as both new options (NOPT) and existing exercisable options (EOPT) have strong negative relations (significant at the 5 % level or better) with forecast accuracy. Additionally, the relations between forecast accuracy and the control variables are generally consistent with expectations and with prior research. In particular, negative earnings (LOSS), absolute earnings surprise (ABSESUP), and dispersion in analysts' forecasts (DISP) are all negatively related to forecast accuracy as predicted, and their coefficients are statistically significant at the 1 % level in both Panel A and Panel B. Earnings volatility (VOLROA) is also negative, as expected, and significant at the 5 % level in all regressions.

Analyst following (FOLLOW) and firm size (SIZE) are positively related to forecast accuracy, as expected, but neither is significant. Among the variables without predicted signs, number of board meetings (NUMMTGS) is negative and significant at 1 % when contemporaneous values are used, and change in sales (CHSALES) is negative and significant for all specifications.

The above findings are consistent with the notion that the increased forecasting complexity accompanying the increase in CEO stock options compensation adversely affects the forecasting ability of financial analysts. This adverse effect leads to a decline in the accuracy of their forecasts. The above result strongly holds for total options in model 1 and new options and existing exercisable options in model 2.

Table 97.5 presents estimation results for Eq. 97.4. This specification is used to test hypothesis H2. If a_1, the coefficient on OPTIONS, is significantly different

[14]We also estimate the regression without the absolute value of earnings surprise (ABSESUP) that might be mechanically related to accuracy. The main results are not affected by the exclusion of that variable. We note that inclusion of ABSESUP can only weaken the hypothesized relationship between ACCURACY and OPTIONS because ABSESUP is closely related to ACCURACY.

Table 97.4 Stock options and forecast accuracy

		Model 1		Model 2	
	Sign	Coefficient	t-Statistics	Coefficient	t-Statistics

Variable definitions:
NOPT = new stock options to CEO in the current year scaled by total number of shares outstanding
EOPT = existing exercisable stock options of CEO scaled by total number of shares outstanding
UEOPT = existing unexercisable stock options of CEO scaled by total number of shares outstanding
TOPT = sum of *NOPT*, *EOPT*, and *UEOPT*
ACCURACY = (−1) * absolute value of [mean EPS forecast − actual EPS]/price at forecast date
FOLLOW = number of analysts following the firm
DISP = forecast dispersion, measured as the standard deviation of analysts' forecasts deflated by price at the forecast date
VOLROA = earnings volatility measured as the standard deviation of return on assets for the previous 5-year period
ABSESUP = earnings surprise measured as the absolute value of the difference between the current year's EPS and the last year's EPS, divided by price at the beginning of the year
LOSS = a dummy variable which equals to 1 when earnings are negative and 0 otherwise
SIZE = firm size measured as the natural log of beginning assets
GROWTH = beginning book value of equity divided by the beginning market value of equity
CHASSETS = annual percentage change in total assets at the beginning of the year
CHSALES = annual percentage change in total sales at the beginning of the year
SHROWN = number of shares owned by the CEO divided by the total number of shares outstanding
CEOCHAIR = an indicator variable which equals "1" if the CEO is also the chairman of the board and "0" otherwise
NUMMTGS = the number of board meetings held in a year
DIROPT = an indicator variable which equals "1" if the directors are awarded stock options in the year and "0" otherwise

from zero, the empirical results will reject our hypothesis H2 stated in the null. Once again, to test H2, we use two models, one with total options for OPTIONS and the second with new options, existing exercisable options, and existing unexercisable options for OPTIONS. As before, we present the results for both contemporaneous (Panel A) and lagged (Panel B) values of OPTIONS.[15]

[15]We also estimate the model without earnings surprise (ESUP), negative earnings surprise (NEGESUP), and level of earnings (LEVEARN) that might be mechanically related to bias. The relationship between level of options and bias is not affected by the omission of those variables.

***Significant at the 0.01 level, **Significant at the 0.05 level, *Significant at the 0.10 level. Significance levels are based on two-tailed tests

For the total options measure (model 1 in Table 97.5), the coefficient on TOPT is positive and statistically significant at the 1 % level for both contemporaneous and lagged values, indicating rejection of hypothesis H2. The model 2 results also indicate rejection of hypothesis H2 as both new options (NOPT) and existing exercisable options (EOPT) have strong positive relations (significant at the 5 % level or better) with forecast bias. These results are consistent with the management relations hypothesis.

Additionally, the relations between forecast bias and the control variables are generally consistent with the prior literature. We document a positive relation between forecast bias and volatility of return on assets (VOLROA) and loss firms (LOSS). We furthermore document a negative relation between forecast bias and growth (GROWTH) for all the regressions. These results are consistent with the results reported in prior research (Das et al. 1998; Duru and Reeb 2002; Eames and Glover 2003).

The evidence presented in Tables 97.4 and 97.5 supports the predictions that analysts' earnings forecast accuracy decreases and forecast optimism increases as the level of stock options (in particular, new options and exercisable options) in CEO pay increases. These results are robust to the time period (current versus prior year) when the options are granted.

97.4.3 Additional Analysis

As an additional test, we examine the relations between an alternate measure of CEO stock options and forecast accuracy and bias while controlling for endogeneity in the model. Since the results reported in Tables 97.4 and 97.5 are most pronounced for new options, we focus on an alternate proxy for new options, the proportion of stock options pay in CEO total compensation (compensation mix, COMPMIX). We measure this variable as the ratio of the Black-Scholes value of the new options granted to the CEO in a given year to the total compensation granted to the CEO in that year, where total compensation is the value of stock options plus cash compensation (i.e., salary plus bonus). This is consistent with the measure employed by Klassen and Mawani (2000) and Ittner et al. (2003). We also control for endogeneity as this may be a potential problem if both the level of CEO stock options pay and analysts' forecast accuracy/bias are determined by common variables such as a firm's fundamentals. To address this potential endogeneity problem, we examine the relations between CEO options and analysts' forecast accuracy/bias using two-stage least squares regression analysis (2SLS).

In the first stage, we regress the level of CEO options, the dependent variable, on previously identified, firm-specific determinants of stock options grants as well as control variables (Core et al. 1999; Aggarwal and Samwick 1999). These additional variables, related to cross-sectional differences in options compensation, include the prior year's return on assets (ROA), leverage ratio (LEV), and standard deviation of monthly returns for the prior 12-month period (STD). Three sets of variables are common to both regressions: growth (GROWTH), firm size (SIZE), and share

ownership (SHROWN). In the second stage, we use the models described in Eqs. 97.3 and 97.4 with compensation mix (COMPMIX) as the proxy for OPTIONS.

The results reported in Table 97.6 are consistent with the results presented in Tables 97.4 and 97.5. That is, for compensation mix (COMPMIX), we observe a negative association between accuracy and COMPMIX and a positive association between bias and COMPMIX.

97.5 Sensitivity Analyses

We conduct several additional tests to examine the robustness of our findings. First, we control for cross-sectional correlation, since our tests are based on pooled cross-sectional and time series data. Although we include fixed industry and year effects in our primary tests, we conduct Fama-MacBeth estimation with industry controls to account for residual cross-sectional correlation as an additional test. The Fama-MacBeth t-statistics of the coefficient on total options in model 1 and new options and exercisable options in model 2 are statistically significant at the 5 % level or higher for all the tests.

Second, we assess the sensitivity of our results to use of the median analysts' forecast in place of the mean forecast for computing forecast accuracy and bias. We estimate models (3) and (4) using these alternative measures of forecast accuracy and bias as dependent variables and without earnings skewness as an independent variable. We find that the results reported in Tables 97.4 and 97.5 are robust to the choice of median analysts' forecasts in place of mean forecasts.

Finally, since our sample period of years 1993–2003 includes both pre- and post-SOX periods, we delete years 2002 and 2003 and carry out a subsample analysis without the post-SOX periods. For the pre-SOX subsample, consistent with our main results in Tables 97.4 and 97.5, total options in model 1 and new options and exercisable options in model 2 have a significant negative association (at the 5 % level or better) with forecast accuracy and a significant positive association (at the 5 % level or better) with forecast bias.

97.6 Summary and Conclusions

We examine the relation between the level of CEO stock options and the accuracy and bias of analysts' earnings forecasts. We use four different measures of stock options: new options, existing exercisable options, existing unexercisable options, and total options (sum of the previous three). We also use both contemporaneous as well as the lagged values of options compensation in our tests. We hypothesize that forecast accuracy is related to the level of CEO stock options pay. This is because higher levels of stock options may induce managers to undertake riskier projects, to change and/or reallocate their effort, and to possibly engage in gaming (such as opportunistic earnings and disclosure management). However, higher levels of stock options may also better align managers' incentives with those of shareholders and lead to more accurate forecasts. We also hypothesize that forecast bias is related to the level of stock options in CEO pay. The underlying rationale for this is that as the forecast complexity increases with stock options pay, analysts, who need greater access to management's information to produce accurate forecasts, increase the optimistic bias in their forecasts. Alternatively, because higher levels of CEO stock options may better align managers' and shareholders' incentives, they may lead to less biased forecasts.

Our results indicate that analysts' earnings forecast accuracy decreases and forecast optimism increases as the level of stock options in CEO pay increases. Furthermore, our results are robust to the measure of CEO stock options and to the use of current or prior year values of options. These findings suggest that the incentive alignment effects of stock options are more than offset by the investment, effort allocation, and gaming incentives induced by stock options grants to CEOs.

Our study contributes to the current debate on the costs and benefits of the stock options pay to managers. It demonstrates that the level of stock option compensation in CEO pay is an important determinant of analysts' earnings forecast accuracy and bias. Analysts are an important information intermediary in capital markets. The decline in the quality of their forecasts with increased stock options compensation indicates that stock option compensation indirectly affects the quality of the information available to market participants.

Acknowledgments We thank Zhaoyang Gu, Emad Mohd, Mohamed Shehata, K. (Shiva) Sivaramakrishnan, Scott Whisenant, Yoonseok Zang, Jian Zhou, the anonymous reviewers, and workshop participants at the University of Houston, Drexel University, Wilfrid Laurier University, the 2005 American Accounting Association Meeting, the 2005 Canadian Academic Accounting Association Meeting, and the 2005 European Accounting Association Meeting for their helpful comments and Alper Ozesen and Li Wang for their research assistance. We gratefully acknowledge the contribution of Thompson Financial for providing forecast data, available through the Institutional Brokers Estimate System (I/B/E/S). These data have been provided as part of a broad academic program to encourage earnings expectations research. We also thank the Social Sciences and Humanities Research Council of Canada (SSHRC) for their financial support.

comprehensive empirical study demonstrating whether and by how much each generalized feature will improve option pricing and hedging performance.

This chapter fills this gap by first developing an implementable option model in closed form that admits both stochastic volatility and stochastic interest rates and that is parsimonious in the number of parameters. The model includes many known ones as special cases. Based on the model, both delta-neutral and single-instrument minimum-variance hedging strategies are derived analytically. Using S&P 500 option prices, we then compare the pricing and hedging performance of this model with that of three existing ones that respectively allow for (i) constant volatility and constant interest rates (the Black–Scholes), (ii) constant volatility but stochastic interest rates, and (iii) stochastic volatility but constant interest rates. Overall, incorporating stochastic volatility and stochastic interest rates produces the best performance in pricing and hedging, with the remaining pricing and hedging errors no longer systematically related to contract features. The second performer in the horse race is the stochastic volatility model, followed by the stochastic interest rate model and then by the Black–Scholes.

Keywords

Stock option pricing • Stochastic volatility • Stochastic interest rates • Hedge ratios • Hedging • Pricing performance and Hedging performance

98.1 Introduction

Option pricing has, in the last two decades, witnessed an explosion of new models that each relaxes some of the restrictive assumptions underlying the seminal Black and Scholes (1973) model. In doing so, most of the focus has been on the counter-factual constant volatility and constant interest-rate assumptions. For example, Merton's (1973) option pricing model allows interest rates to be stochastic but keeps a constant volatility for the underlying asset, while Amin and Jarrow (1992) develop a similar model where, unlike in Merton's, interest rate risk is also priced. A second class of option models admits stochastic conditional volatility for the underlying asset but maintains the constant interest-rate assumption. These include the Cox and Ross (1976) constant elasticity of variance model and the stochastic volatility models of Bailey and Stulz (1989), Bates (1996b, 2000), Heston (1993), Hull and White (1987a), Scott (1987), Stein and Stein (1991), and Wiggins (1987). Recently, Bakshi and Chen (1997) and Scott (1997) have developed closed-form equity option formulas that admit both stochastic volatility and stochastic interest rates.[1] Their efforts have, in some sense, helped reach the ultimate possibility of

[1] Amin and Ng (1993), Bailey and Stulz (1989), and Heston (1993) also incorporate both stochastic volatility and stochastic interest rates, but their option pricing formulas are not given in closed form, which makes applications difficult. Consequently, comparative statics and hedge ratios are difficult to obtain in their cases.

completely relaxing the Black–Scholes assumptions of constant volatility and constant interest rates. As a practical matter, these sufficiently general pricing formulas should in principle result in significant improvement in pricing and hedging performance over the Black–Scholes model. While option pricing theory has made such impressive progress, the empirical front is nonetheless far behind.[2] Will incorporating these general features improve both pricing and hedging effectiveness? If so, by how much? Can these relaxed assumptions help resolve the well-known empirical biases associated with the Black–Scholes formula, such as the volatility smiles [e.g., Rubinstein (1985, 1994)]? These empirical questions must be answered before the potential of the general models can be fully realized in practical applications.

In this chapter, we first develop a practically implementable version of the general equity option pricing models in Bakshi and Chen (1997) and Scott (1997) that admits stochastic interest rates and stochastic volatility, yet resembles to the extent possible the Black–Scholes model in its implementability. We present procedures for applying the resulting model to price and hedge option-like derivative products. Next, we conduct a complete analysis of the relative empirical performance, in both pricing and hedging, of the four classes of models that respectively allow for (i) constant volatility and constant interest rates (*the BS model*), (ii) constant volatility but stochastic interest rates (*the SI model*), (iii) stochastic volatility but constant interest rates (*the SV model*), and (iv) stochastic volatility and stochastic interest rates (*the SVSI model*). As the SVSI model has all the other three models nested, one should expect its static pricing and dynamic hedging performance to surpass that of the other classes. But, this performance improvement must come at the cost of potentially more complex implementation steps. In this sense, conducting such a horse race study can at least offer a clear picture of possible trade-offs between costs and benefits that each model may present.

Specifically, the SVSI option pricing formula is expressed in terms of the underlying stock price, the stock's volatility, and the short-term interest rate. The spot volatility and the short interest rate are each assumed to follow a Markov mean-reverting square-root process. Consequently, seven structural parameters need to be estimated as input to the model. These parameters can be estimated using the Generalized Method of Moments (GMM) of Hansen (1982), as is done in, for instance, Andersen and Lund (1997), Chan et al. (1992).

[2]There have been a few empirical studies that investigate the pricing, but not the hedging, performance of versions of the stochastic volatility model, relative to the Black–Scholes model. These include Bates (1996b, 2000), Dumas et al. (1998), Madan et al. (1998), Nandi (1996), and Rubinstein (1985). In Bates' work, currency and equity index options data are used to test a stochastic volatility model with Poisson jumps included. Nandi does investigate the pricing and hedging performance of Heston's stochastic volatility model, but he focuses exclusively on a single-instrument minimum-variance hedge that involves only the S&P 500 futures. As will be clear shortly, we address in this chapter both the pricing and the hedging effectiveness issues from different perspectives and for four distinct classes of option models.

Or, they can be backed out from the pricing model itself by using observed option prices, as is similarly done for the BS model both in the existing literature and in Wall Street practice.

In our empirical investigation, we will adopt this implied parameter approach to implement the four models. In this regard, it is important to realize that the BS model is implemented as if the spot volatility and the spot interest rates were assumed to be time varying within the model, that is, the spot volatility is backed out from option prices each day and used, together with the current yield curve, to price the following day's options. The SI and the SV models are implemented with a similarly internally inconsistent treatment, though to a lesser degree. Since this implementation is how one would expect each model to be applied, we chose to follow this convention in order to give the alternatives to the standard BS model the "toughest hurdle." Clearly, such a treatment works in the strongest favor of the BS model and is especially biased against the SVSI model.

Based on 38,749 S&P 500 call (and put) option prices for the sample period from June 1988 to May 1991, our empirical investigation leads to the following conclusions. First, on the basis of two out-of-sample pricing error measures, the SVSI model is found to perform slightly better than the SV model, while they both perform substantially better than the SI (the third-place performer) and the BS model. That is, when volatility is kept constant, allowing interest rates to vary stochastically can produce respectable pricing improvement over the BS model. However, in the presence of stochastic volatility, doing so no longer seems to improve pricing performance much further. Thus, modeling stochastic volatility is far more important than stochastic interest rates, at least for the purpose of pricing options. It is nonetheless encouraging to know that based on our sample, both the SVSI and the SV models typically reduce the BS model's pricing errors by more than half, whereas the SI model helps reduce the BS pricing errors by 20 % or more. While all four models inherit moneyness- and maturity-related pricing biases, the severity of these types of bias is increasingly reduced by the SI, the SV, and the SVSI models. In other words, the SVSI model produces pricing errors that are the least moneyness or maturity related. This conclusion is also confirmed when the Rubinstein (1985) implied-volatility-smile diagnostic is adopted to examine each model.

Two types of hedging strategy are employed in this study to gauge the relative hedging effectiveness. The first type is the conventional delta-neutral hedge, in which as many distinct hedging instruments as the number of risk sources affecting the hedging target's value are used so as to make the net position completely risk immunized (locally). Take the SVSI model as an example. The call option value is driven by three risk sources: the underlying price shocks, volatility shocks, and shocks to interest rates. Accordingly, we employ the underlying stock, a different call option, and a position in a discount bond to create a delta-neutral hedge for a target call option. That closed-form expressions are derived for each hedge ratio is of great value for devising hedging strategies analytically. Similarly, for the SV model, we only need to rely on the underlying stock and an option contract to design a delta-neutral hedge. Based on the delta-neutral hedging errors, the same performance ranking of the four models obtains as that determined by their static pricing performance, except that now the SVSI and the SV models and the SI and the BS models are respectively pairwise virtually indistinguishable. This reenforces the view that adding stochastic interest rates may not affect performance much. However, it is found that the average hedging errors by the SVSI and the SV models are typically less than one-third of the corresponding BS model's hedging errors. Furthermore, reducing the frequency of hedge rebalancing does not tend to reduce the SV and the SVSI models' hedging effectiveness, whereas the BS and the SI models' hedging errors are often doubled when rebalancing frequency changes from daily to once every 5 days. Therefore, after stochastic volatility is controlled for, the frequency of hedge rebalancing will have relatively little impact on hedging effectiveness. This finding is in accord with Galai's (1983a) results that in any hedging scheme, it is probably more important to control for stochastic volatility than for discrete hedging [see Hull and White (1987b) for a similar, simulation-based result for currency options].

To see how the models perform under different hedging schemes, we also look at minimum-variance hedges involving only a position in the underlying asset. As argued by Ross (1995), the need for this type of hedges may arise in contexts where a perfect delta-neutral hedge may not be feasible, either because some of the underlying risks are not traded or even reflected in any traded financial instruments or because model misspecifications and transaction costs render it undesirable to use as many instruments to create a perfect hedge. In the present context, both volatility risk and interest rate risk are, of course, traded and hence can, as indicated above, be controlled for by employing an option and a bond. But, a point can be made that it is sometimes more preferable to adopt a single-instrument minimum-variance hedge. To study this type of hedges, we again calculate the absolute and the dollar-value hedging errors for each model. Results from this exercise indicate that the SV model performs the best among all four, while the BS and the SV models outperform their respective stochastic interest rate counterparts, the SI and the SVSI models. Therefore, under the single-instrument hedges, incorporating stochastic interest rates actually worsens hedging performance. It is also true that hedging errors under this type of hedges are always significantly higher than those under the conventional delta-neutral hedges, for each given moneyness and maturity option category. Thus, whenever possible, including more instruments in a hedge will in general produce better hedging effectiveness.

While our discussion is mainly focused on results obtained using the entire sample period and under specific model implementation designs, robustness of these empirical results is also checked by examining alternative implementation designs, different subperiods, as well as option transaction price data. Especially, given the popularity of the "implied-volatility matrix" method among practitioners, we will also implement each of the four models and compare their pricing and hedging performance, by using only option contracts from a given moneyness–maturity category. It turns out that this alternative implementation scheme does not change the rankings of the four models.

The rest of the chapter proceeds as follows. Section 98.2 develops the SVSI option pricing formula. It discusses issues pertaining to the implementation of the formula and derives the hedge ratios analytically. Section 98.3 provides a description of the S&P 500 option data. In Sect. 98.4 we evaluate the static pricing and the dynamic hedging performance of the four models. Concluding remarks are offered in Sect. 98.5.

98.2 The Option Pricing Model

Consider an economy in which the instantaneous interest rate at time t, denoted $R(t)$, follows a Markov diffusion process:

$$dR(t) = [\theta_R - \overline{\kappa}_R R(t)]dt + \sigma_R \sqrt{R(t)} d\omega_R(t) \quad t \in [0, T], \tag{98.1}$$

where $\overline{\kappa}_R$ regulates the speed at which the interest rate adjusts to its long-run stationary value $\frac{\theta_R}{\overline{\kappa}_R}$ and $\omega_R = \{\omega_R(t) : t \in [0, T]\}$ is a standard Brownian motion.[3] This single-factor interest rate structure of Cox et al. (1985) is adopted as it requires the estimation of only three structural parameters. Adding more factors to the term structure model will of course lead to more plausible formulas for bond prices, but it can make the resulting option formula harder to implement.

Take a generic non-dividend-paying stock whose price dynamics are described by

$$\frac{dS(t)}{S(t)} = \mu(S, t)dt + \sqrt{V(t)} d\omega_S(t) \quad t \in [0, T], \tag{98.2}$$

where $\mu(S, t)$, which is left unspecified, is the instantaneous expected return and ω_S a standard Brownian motion. The instantaneous stock return variance, $V(t)$, is assumed to follow a Markov process:

$$dV(t) = [\theta_v - \overline{\kappa}_v V(t)]dt + \sigma_v \sqrt{V(t)} d\omega_v(t) \quad t \in [0, T], \tag{98.3}$$

where again ω_v is a standard Brownian motion and the structural parameters have the usual interpretation. We refer to $V(t)$ as the spot volatility or, simply, volatility. This process is also frugal in the number of parameters to be estimated and is similar to the one in Heston (1993). Letting ρ denote the correlation coefficient between ω_S and ω_v, the covariance between changes in $S(t)$ and in $V(t)$ is

[3]Here we follow a common practice to assume from the outset a structure for the underlying price and rate processes, rather than derive them from a full-blown general equilibrium. See Bates (1996a), Heston (1993), Melino and Turnbull (1990, 1995), and Scott (1987, 1997). The simple structure assumed in this section can, however, be derived from the general equilibrium model of Bakshi and Chen (1997).

$Cov_t[dS(t), dV(t)] = \rho\sigma_S\sigma_v S(t)V(t)dt$ which can take either sign and is time varying. According to Bakshi et al. (1997, 2000), Bakshi and Chen (1997), Bates (1996a), Cao and Huang (2008), and Rubinstein (1985), this additional feature is important for explaining the skewness and kurtosis-related biases associated with the BS formula. Finally, for ease of presentation, assume that the equity-related shocks and the interest rate shocks are uncorrelated[4]: $Cov_t(d\omega_S, d\omega_R) = Cov_t(d\omega_v, d\omega_R) = 0$.

By a result from Harrison and Kreps (1979), there are no free lunches in the economy if and only if there exists an equivalent martingale measure with which one can value claims as if the economy were risk neutral. For instance, the time t price $B(t, \tau)$ of a zero-coupon bond that pays \$1 in τ periods can be determined via

$$B(t,\tau) = E_Q\left\{\exp\left(-\int_t^{t+\tau} R(S)ds\right)\right\}, \tag{98.4}$$

where E_Q denotes the expectation with respect to an equivalent martingale measure and conditional on the information generated by $R(t)$ and $V(t)$. Assume that the factor risk premiums for $R(t)$ and $V(t)$ are, respectively, given by $\lambda_R R(t)$ and $\lambda_v V(t)$, for two constants λ_R and λ_v. Bakshi and Chen (1997) provide a general equilibrium model in which risk premiums have precisely this form and in which the interest rate and stock price processes are as assumed here. Under this assumption, we obtain the risk-neutralized processes for $R(t)$ and $V(t)$ below:

$$dR(t) = [\theta_R - \kappa_R R(t)]dt + \sigma_R\sqrt{R(t)}d\omega_R(t) \tag{98.5}$$

[4]This assumption on the correlation between stock returns and interest rates is somewhat severe and likely counterfactual. To gauge the potential impact of this assumption on the resulting option model's performance, we initially adopted the following stock price dynamics:

$$\frac{dS(t)}{S(t)} = \mu(S,t)dt + \sqrt{V(t)}d\omega_S(t) + \sigma_{S,R}\sqrt{R(t)}d\omega_R(t) \quad t \in [0,T],$$

with the rest of the stochastic structure remaining the same as given above. Under this more realistic structure, the covariance between stock price changes and interest rate shocks is $Cov_t[dS(t), dR(t)] = \sigma_{S,R}\sigma_R R(t)S(t)dt$, so bond market innovations can be transmitted to the stock market and vice versa. The obtained closed-form option pricing formula under this scenario would have one more parameter $\sigma_{S,R}$ than the one presented shortly, but when we implemented this slightly more general model, we found its pricing and hedging performance to be indistinguishable from that of the SVSI model studied in this chapter. For this reason, we chose to present the more parsimonious SVSI model derived under the stock price process in Eq. 98.2. We could also make both the drift and the diffusion terms of $V(t)$ a linear function of $R(t)$ and $\omega_R(t)$. In such cases, the stock returns, volatility, and interest rates would all be correlated with each other (at least globally), and we could still derive the desired equity option valuation formula. But, that would again make the resulting formula more complex while not improving its performance.

$$dV(t) = [\theta_v - \kappa_v V(t)]dt + \sigma_v \sqrt{V(t)} d\omega_v(t), \tag{98.6}$$

where $\kappa_R \equiv \overline{\kappa}_R + \lambda_R$ and $\kappa_v \equiv \overline{\kappa}_v + \lambda_v$. The risk-neutralized stock price process becomes

$$\frac{dS(t)}{S(t)} = R(t)dt + \sqrt{V(t)} d\omega_S(t), \tag{98.7}$$

that is, under the martingale measure, the stock should earn no more and no less than the risk-free rate. With these adjustments, we solve the conditional expectation in Eq. 98.4 and obtain the familiar bond price equation below:

$$B(t,\tau) = \exp[-\varphi(\tau) - \varrho(\tau)R(t)], \tag{98.8}$$

where $\varphi(\tau) = \frac{\theta_R}{\sigma_R^2}\left\{(\varsigma - \kappa_R)\tau + 2\ln\left[1 - \frac{(1-e^{-\varsigma\tau})(\varsigma - \kappa_R)}{2\varsigma}\right]\right\}, \varrho(\tau) = \frac{2(1-e^{-\varsigma\tau})}{2\varsigma - [\varsigma - \kappa_R](1-e^{-\varsigma\tau})}$, and $\varsigma \equiv \sqrt{\kappa_R^2 + 2\sigma_R^2}$. See Cox et al. (1985) for an analysis of this class of term structure models.

98.2.1 Pricing Formula for European Options

Now, consider a European call option written on the stock, with strike price K and term to expiration τ. Let its time t price be denoted by $C(t, \tau)$. As (S, R, V) form a joint Markov process, the price $C(t, \tau)$ must be a function of $S(t)$, $R(t)$, and $V(t)$ (in addition to τ). By a standard argument, the option price must solve

$$\begin{aligned}&\frac{1}{2}VS^2\frac{\partial^2 C}{\partial S^2} + RS\frac{\partial C}{\partial S} + \rho\sigma_v VS\frac{\partial^2 C}{\partial S \partial V} + \frac{1}{2}\sigma_v^2 V\frac{\partial^2 C}{\partial V^2} + [\theta_v - \kappa_v V]\frac{\partial C}{\partial V}\\&+\frac{1}{2}\sigma_R^2 R\frac{\partial^2 C}{\partial R^2}[\theta_R - \kappa_R R]\frac{\partial C}{\partial R} - \frac{\partial C}{\partial \tau} - RC = 0,\end{aligned} \tag{98.9}$$

subject to $C(t + \tau, 0) = \max\{S(t + \tau) - K, 0\}$. In the Appendix 1 it is shown that

$$C(t,\tau) = S(t)\Pi_1(t,\tau;S,R,V) - KB(t,\tau)\Pi_2(t,\tau,S,R,V), \tag{98.10}$$

where the risk-neutral probabilities, $\prod_1$ and $\prod_2$, are recovered from inverting the respective characteristic functions [see Heston (1993) and Scott (1997) for similar treatments]:

$$\prod\nolimits_j(t,\tau;S(t),R(t),V(t)) = \frac{1}{2} + \frac{1}{\pi}\int_0^\infty Re\left[\frac{e^{-i\phi\,\ln[K]}f_j(t,\tau,S(t),R(t),V(t);\phi)}{i\phi}\right]d\phi, \tag{98.11}$$

for $j = 1, 2$. The characteristic functions f_j are given by

$$\begin{aligned} f_1(t,\tau) \quad &= \exp\left\{ -\frac{\theta_R}{\sigma_R^2}\left[2\ln\left(1 - \frac{[\xi_R - \kappa_R]\left(1 - e^{-\xi_R \tau}\right)}{2\xi_R} \right) + [\xi_R - \kappa_R]\tau \right] \right. \\ &- \frac{\theta_v}{\sigma_v^2}\left[2\ln\left(1 - \frac{[\xi_v - \kappa_v + (1 + i\phi)\rho\sigma_v]\left(1 - e^{-\xi_v \tau}\right)}{2\xi_v} \right) \right] \\ &- \frac{\theta_v}{\sigma_v^2}[\xi_v - \kappa_v + (1 + i\phi)\rho\sigma_v]\tau + i\phi \ln[S(t)] + \frac{2i\phi\left(1 - e^{-\xi_R \tau}\right)}{2\xi_R - [\xi_R - \kappa_R](1 - e^{-\xi_R \tau})} R(t) \\ &\left. + \frac{i\phi(i\phi + 1)\left(1 - e^{-\xi_v \tau}\right)}{2\xi_v - [\xi_v - \kappa_v + (1 + i\phi)\rho\sigma_v](1 - e^{-\xi_v \tau})} V(t) \right\}, \end{aligned} \tag{98.12}$$

and

$$\begin{aligned} f_2(t,\tau) \quad &= \exp\left\{ -\frac{\theta_R}{\sigma_R^2}\left[2\ln\left(1 - \frac{\left[\xi_R^* - \kappa_R\right]\left(1 - e^{-\xi_R^* \tau}\right)}{2\xi_R^*} \right) + \left[\xi_R^* - \kappa_R\right]\tau \right] \right. \\ &- \frac{\theta_v}{\sigma_v^2}\left[2\ln\left(1 - \frac{\left[\xi_v^* + i\phi\rho\sigma_v\right]\left(1 - e^{-\xi_v^* \tau}\right)}{2\xi_v^*} \right) + \left[\xi_v^* - \kappa_v + i\phi\rho\sigma_v\right]\tau \right] \\ &+ i\phi \ln[S(t)] - \ln[B(t,\tau)] + \frac{2(i\phi - 1)\left(1 - e^{-\xi_R^* \tau}\right)}{2\xi_R^* - \left[\xi_R^* - \kappa_R\right](1 - e^{-\xi_R^* \tau}} R(t) \\ &\left. + \frac{i\phi(i\phi - 1)\left(1 - e^{-\xi_v^* \tau}\right)}{2\xi_v^* - \left[\xi_v^* - \kappa_v + i\phi\rho\sigma_v\right]\left(1 - e^{-\xi_v^* \tau}\right)} V(t) \right\}, \end{aligned} \tag{98.13}$$

where $\xi_R = \sqrt{\kappa_R^2 - 2\sigma_R^2 i\phi}$, $\xi_v = \sqrt{[\kappa_v - (1 + i\phi)\rho\sigma_v]^2 - i\phi(i\phi + 1)\sigma_v^2}$, $\xi_R^* = \sqrt{\kappa_R^2 - 2\sigma_R^2(i\phi - 1)}$, and $\xi_v^* = \sqrt{[\kappa_v - i\phi\rho\sigma_v]^2 - i\phi(i\phi - 1)\sigma_v^2}$. The price of a European put on the same stock can be determined from the put–call parity.

The option valuation model in Eq. 98.10 has several distinctive features. First, it applies to cases with stochastically varying interest rates and volatility. It contains as special cases most existing models, such as the SV models, the SI models, and clearly the BS model. Second, as mentioned earlier, it allows for a flexible correlation structure between the stock return and its volatility, as opposed to the perfect correlation assumed in, for instance, Heston's (1993) model. Furthermore, the volatility risk premium is time varying and state dependent. This is a departure from Hull and White (1987), Scott (1987), Stein and Stein (1991), and Wiggins (1987) where the volatility risk premium is either a constant or zero. Third, when compared to the general models in Bakshi and Chen (1997) and Scott (1997), the formula in Eq. 98.10 is parsimonious in the number of parameters; especially, it is given only as a function of identifiable variables such that all parameters can be estimated based on available financial market data.

The pricing formula in Eq. 98.10 applies to European equity options. But, in reality most of the traded option contracts are American in nature. While it is beyond the scope of the chapter to derive a model for American options, it is nevertheless possible to capture the first-order effect of early exercise in the following manner. For options with early-exercise potential, compute the Barone-Adesi and Whaley (1987) or Kim (1990) early-exercise premium, treating it as if the stock volatility and the yield curve were time invariant. Adding this early-exercise adjustment component to the European option price in Eq. 98.10 should deliver a reasonable approximation of the corresponding American option price [e.g., Bates (1996b)].

98.2.2 Hedging and Hedge Ratios

One appealing feature of a closed-form option pricing formula, such as the one in Eq. 98.10, is the possibility of deriving comparative statics and hedge ratios analytically. In the present context, there are three sources of stochastic variations over time, price risk $S(t)$, volatility risk $V(t)$, and interest rate risk $R(t)$. Consequently, there are three deltas:

$$\Delta_S(t,\tau;K) \equiv \frac{\partial C(t,\tau)}{\partial S} = \Pi_1 > 0 \tag{98.14}$$

$$\Delta_V(t,\tau;K) \equiv \frac{\partial C(t,\tau)}{\partial V} = S(t)\frac{\partial \Pi_1}{\partial V} - KB(t,\tau)\frac{\partial \Pi_2}{\partial V} > 0 \tag{98.15}$$

$$\Delta_R(t,\tau;K) \equiv \frac{\partial C(t,\tau)}{\partial R} = S(t)\frac{\partial \Pi_1}{\partial V} - KB(t,\tau)\left\{\frac{\partial \Pi_2}{\partial V} - \varrho(\tau)\Pi_2\right\} > 0, \tag{98.16}$$

where, for $g = V, R$ and $j = 1, 2$,

$$\frac{\partial \Pi_j}{\partial g} = \frac{1}{\pi}\int_0^\infty Re\left[(i\phi)^{-1}e^{-i\ \phi \ln[K]}\ \frac{\partial f_j}{\partial g}\right]d\phi. \tag{98.17}$$

The second-order partial derivatives with respect to these variables are provided in the Appendix.

As $V(t)$ and $R(t)$ are both stochastic in our model, these deltas will in general differ from their Black–Scholes counterpart. To see how they may differ, let us resort to an example in which we set $R\,(t) = 6.27\ \%$, $S\,(t) = 279$, $\sqrt{V(t)} = 22.12\ \ \%$, $K_R = 0.481$, $\theta_R = 0.037$, $\sigma_R = 0.049$, $K_v = 1.072$, $\theta_v = 0.041$, $\sigma_v = 0.284$, and $\rho = -0.60$. These values are backed out from the S&P 500 option prices as of July 5, 1988. Fix $K = \$270$ and $\tau = 45$ days. Let Δ_S be as given in Eq. 98.14 for the SVSI model and Δ_S^{bs} its BS counterpart, with Δ_S^{bs} calculated using the same implied volatility.

In unreported results, we plot the difference between Δ_S and Δ_S^{bs}, across different spot price levels and different correlation values. The correlation coefficient ρ is chosen to be the focus as it is known to play a crucial role in determining the skewness of the stock return distribution. When ρ is at -0.50 and -1.0, the difference between the deltas is W shaped, and it reaches the highest value when the option is at the money. The reverse is true when ρ is positive. Thus, Δ_S is generally different from Δ_S^{bs}. Analogous difference patterns emerge when the other option deltas are compared with their respective BS counterpart.

We also plot $Delta_V$ and $Delta_R$ and observe the following. (i) The volatility hedge ratio Δ_V from the SVSI model is, at each spot price, lower than its BS counterpart (except for deep in-the-money options when $\rho < 0$ and for deep out-of-the-money options when $\rho > 0$).[5] (ii) The interest rate delta, Δ_R, and its BS counterpart, Δ_S^{bs}, are almost not different from each other for slightly out-of-the-money options but can be dramatically different for at-the-money options as well as for sufficiently deep in-the-money or deep out-of-the-money calls. For example, pick $\rho = -1.0$. When $S = \$315$, we have $\Delta_R = 30.94$ and $\Delta_R^{bs} = 32.35$; when $S = \$226$, we have $\Delta_R = 0.003$ and $\Delta_R^{bs} = 0.430$. (iii) As expected, out-of-the-money options are overall less sensitive to changes in the spot interest rate, regardless of the model used. In summary, if a portfolio manager/trader relies, in an environment with stochastic interest rates and stochastic volatility, on the BS model to design a hedge for option positions, the manager/trader will likely fail.

Analytical expressions for the deltas are useful for constructing hedges based on an option formula. Below, we present two types of hedges by using the SVSI model as an example.

98.2.2.1 Delta-Neutral Hedges

To demonstrate how the deltas may be used to construct a delta-neutral hedge, consider an example in which a financial institution intends to hedge a short position in a call option with τ periods to expiration and strike price K. In the stochastic interest rate–stochastic volatility environment, a perfectly delta-neutral hedge can be achieved by taking a long position in the replicating portfolio of the call. As three traded assets are needed to control the three sources of uncertainty, the replicating portfolio will involve a position in (i) some $X_S(t)$ shares of the underlying stock (to control for the $S(t)$ risk), (ii) some $X_B(t)$ units of a τ-period discount bond (to control for the $R(t)$ risk), and (iii) some $X_C(t)$ units of another call option with strike price $\overline{K}$ (or any option on the stock with a different maturity) in order to control for the volatility risk $V(t)$. Denote the time t price of the replicating portfolio by $G(t) : G(t) = X_0(t) + X_S(t)S(t) + X_B(t)B(t,\tau) + X_C(t)C\left(t,\tau;\overline{K}\right)$, where $X_0(t)$ denotes the amount put into the instantaneously maturing risk-free bond and it serves as a residual "cash position." Deriving the dynamics for $G(t)$ and comparing them with those of $C(t, \tau; K)$, we find the following solution for the delta-neutral hedge:

$$X_C(t) = \frac{\Delta_V(t,\tau;K)}{\Delta_V\left(t,\tau;\overline{K}\right)} \tag{98.18}$$

$$X_S(t) = \Delta_S(t,\tau;K) - \Delta_S\left(t,\tau;\overline{K}\right)X_C(t) \tag{98.19}$$

$$X_B(t) = \frac{1}{B(t,\tau)\varrho(\tau)}\left\{\Delta_R\left(t,\tau;\overline{K}\right)X_C(t) - \Delta_R(t,\tau;K)\right\} \tag{98.20}$$

and the residual amount put into the instantaneously maturing bond is

$$X_0(t) = C(t,\tau;K) - X_S(t)S(t) - X_C(t)C\left(t,\tau;\overline{K}\right) - X_B(t)B(t,\tau), \tag{98.21}$$

where all the primitive deltas, Δ_S, Δ_R, and Δ_V, are as determined in Eqs. 98.14, 98.14, and 98.16. Like the option prices, these hedge ratios all depend on the values taken by $S(t)$, $V(t)$, and $R(t)$ and those by the structural parameters. Such a hedge created using the general option pricing model should in principle perform better than using the BS model. In the latter case, only the underlying price uncertainty is controlled for, but not the uncertainties associated with volatility and interest rate fluctuations.

In theory this delta-neutral hedge requires continuous rebalancing to reflect the changing market conditions. In practice, of course, only discrete rebalancing is possible. To derive a hedging effectiveness measure, suppose that portfolio rebalancing takes place at intervals of length Δt. Then, precisely as described above, at time t the short call option goes long in (i) $X_S(t)$ shares of the underlying asset, (ii) $X_B(t)$ units of the τ-period bond, and (iii) $X_C(t)$ contracts of a call option with the same term to expiration but a different strike price $\overline{K}$, and invests the residual, X_0, in an instantaneously maturing risk-free bond. After the next interval, compute the hedging error according to

$$\begin{aligned} H(t+\Delta t) = {} & X_0 e^{R(t)\Delta t} + X_S(t)S(t+\Delta t) + X_B(t)B(t+\Delta t,\tau-\Delta t) \\ & + X_C(t)C\left(t+\Delta t,\tau-\Delta t;\overline{K}\right) - C(t+\Delta t,\tau-\Delta t;K). \end{aligned} \tag{98.22}$$

Then, at time $t + \Delta t$, reconstruct the self-financed portfolio, repeat the hedging error calculation at time $t + 2\Delta t$, and so on. Record the hedging errors $H(t + j\Delta t)$, for $j = 1, \cdots, J \equiv \frac{\tau - t}{\Delta t}$. Finally, compute the average absolute hedging error as a function of rebalancing frequency $\Delta t : H(\Delta t) = \frac{1}{J}\sum_{j=1}^{J}|H(t+j\Delta t)|$ and the average dollar-value hedging error: $\overline{H}(\Delta t) = \frac{1}{J}\sum_{j=1}^{J}H(t+j\Delta t)$.

In comparison, if one relies on the BS model to construct a delta-neutral hedge, the hedging error measures can be similarly defined as in Eq. 98.22, except that

$X_B(t)$ and $X_C(t)$ must be restricted to zero and $X_S(t)$ must be the BS delta. Likewise, if the SI model is applied, the only change is to set $X_C(t)$ to zero with Δ_S and Δ_R determined by the SI model; in the case of the SV model, set $X_B(t) = 0$ and let Δ_S and Δ_V be as determined in the SV model. The Appendix provides in closed form an SI option pricing formula and an SV option formula.

98.2.2.2 Single-Instrument Minimum-Variance Hedges

As discussed before, consideration of such factors as model misspecification and transaction costs may render it more practical to use only the underlying asset of the target option as the hedging instrument. Under this single-instrument constraint, a standard design is to choose a position in the underlying stock so as to minimize the variance of instantaneous changes in the value of the hedge. Letting $X_S(t)$ again be the number of shares of the stock to be purchased, solving the standard minimum-variance hedging problem under the SVSI model gives

$$X_S(t) = \frac{Cov_t[ds(t), dC(t,\tau)]}{Var[dS(t)]} = \Delta_S + \rho\sigma_v \frac{\Delta_V(t,\tau)}{S(t)}, \tag{98.23}$$

and the resulting residual cash position for the replicating portfolio is

$$X_0(t) = C(t,\tau) - X_S(t)S(t). \tag{98.24}$$

This minimum-variance hedge solution is quite intuitive, as it says that if stock volatility is deterministic (i.e., $\sigma_v = 0$) or if stock returns are not correlated with volatility changes (i.e., $\rho = 0$), one only needs to long $\Delta_S(t)$ shares of the stock and no other adjustment is necessary. However, if volatility is stochastic and correlated with stock returns, the position to be taken in the stock must control not only for the direct impact of underlying stock price changes on the target option value but also for the indirect impact of that part of volatility changes which is correlated with stock price fluctuations. This effect is reflected in the last term in Eq. 98.23, which shows that the additional number of shares needed besides Δ_S is increasing in ρ (assuming $\sigma_v > 0$).

As for the previous case, suppose that the target call is shorted and that $X_S(t)$ shares are bought and $X_0(t)$ dollars are put into the instantaneous risk-free bond, at time t. The combined position is a self-financed portfolio. At time $t + \Delta t$, the hedging error of this minimum-variance hedge is calculated as

$$H(t+\Delta t) = X_S(t)S(t+\Delta t) + X_0(t)e^{R(t)\Delta t} - C(t+\Delta t, \tau - \Delta t). \tag{98.25}$$

Unlike in Nandi (1996) where he uses the remaining variance of the hedge as a hedging effectiveness gauge, we compute, based on the entire sample period, the average absolute and the average dollar hedging errors to measure the effectiveness of the hedge.

Minimum-variance hedging errors under the SV model as well as under the SI model can be similarly determined accounting for their modeling differences. In the case of the SV model, there is still an adjustment term for the single stock position as in Eq. 98.23. But, for the SI model, the corresponding $X_S(t)$ is the same as its Δ_S. For the BS model, this single-instrument minimum-variance hedge is the same as the delta-neutral hedge. Both types of hedging strategy will be examined under each of the four alternative models.

98.2.3 Implementation

In addition to the strike price and the term to expiration (which are specified in the contract), the SVSI pricing formula in Eq. 98.10 requires the following values as input:

- The spot stock price. If the stock pays dividends, the stock price must be adjusted by the present value of future dividends.
- The spot volatility.
- The spot interest rate.
- The matching τ-period yield to maturity (or the bond price).
- The seven structural parameters: $\{\kappa_R, \theta_R, \sigma_R, \kappa_v, \theta_v, \sigma_v, \rho\}$

For computing the price of a European option, we offer two alternative two-step procedures below. One can implement these steps on any personal computer:

Procedure A

Step 1. Obtain a time series each for the short rate, the stock return, and the stock volatility. Jointly estimate the structural parameters, $\{\kappa_R, \theta_R, \sigma_R, \kappa_v, \theta_v, \sigma_v, \rho\}$, using Hansen's (1982) GMM.

Step 2. Determine the risk-neutral probabilities, Π_1 and Π_2, from the characteristic functions in Eqs. 98.12 and 98.13. Substitute (i) the two probabilities, (ii) the stock price, and (iii) the yield to maturity into (98.10) to compute the option price.

While offering an econometrically rigorous method to estimate the structural parameters, Step 1 in Procedure A may not be as practical or convenient, because of its requirement on historical data. A further difficulty with this approach is its dependence on the measurement of stock volatility. In implementing the BS model, practitioners predominantly use the implied volatility from the model itself rather than relying on historical data. This practice has not only reduced data requirement dramatically but also resulted in significant performance improvement [e.g., Bates (2000) and Melino and Turnbull (1990, 1995)]. Clearly, one can also follow this practice to implement the SVSI model.

Procedure B

Step 1. Collect N option prices on the same stock and taken from the same point in time (or same day), for any $N \geq 8$. Let $\hat{C}_n(t, \tau_n, K_n)$ be the observed price and $C_n(t, \tau_n, K_n)$ the model price as determined by Eq. 98.10 with $S(t)$ and $R(t)$ taken from the market, for the n-th option with τ_n periods to expiration and strike price K_n and for each $n = 1, \ldots, N$. Clearly, the difference between $\hat{C}_n$ and C_n is a function of the values taken by $V(t)$ and by $\Phi \equiv \{\kappa_R, \theta_R, \sigma_R, \kappa_v, \theta_v, \sigma_v, \rho\}$. Define

$$\epsilon_n[V(t), \Phi] \equiv \hat{C}_n(t, \tau_n, K_n) - C_n(t, \tau_n, K_n), \tag{98.26}$$

for each n. Then, find $V(t)$ and parameter vector Φ (a total of eight), so as to minimize the sum of squared errors:

$$\sum_{n=1}^{N} \left| \epsilon_n[V(t), \Phi]^2 \right|. \tag{98.27}$$

The result from this step is an estimate of the implied spot variance and seven structural parameter values, for date t. See Bates (1996b, 2000), Dumas et al. (1998), Longstaff (1995), Madan et al. (1998), and Nandi (1996) where they adopt this technique for similar purposes.

Step 2. Based on the estimate from the first step, follow Step 2 of Procedure A to compute date-(t + 1)'s option prices on the same stock.

In the existing literature, the performance of a new option pricing model is often judged relative to that of the BS model when the latter is implemented using the model's own implied volatility and the time-varying interest rates. Since volatility and interest rates in the BS are assumed to be constant over time, this internally inconsistent practice will clearly and significantly bias the application results in favor of the BS model. But, as this is the current standard in judging performance, we will follow Procedure B to implement the SVSI model and similar procedures to implement the BS, the SV, and the SI models. Then, the models will be ranked relative to each other according to their performance so determined.

98.3 Data Description

For all the tests to follow, we use, based on the following considerations, S&P 500 call option prices as the basis. First, options written on this index are the most actively traded European-style contracts. Recall that like the BS model, formula (98.10) applies to European options. Second, the daily dividend distributions are available for the index (from the S&P 500 Information Bulletin). Harvey and Whaley (1992a, b), for instance, emphasize that critical pricing errors can result when dividends are omitted from empirical tests of any option valuation model. Furthermore, S&P 500 options and options on S&P 500 futures have been the focus of many existing empirical investigations including Bates (2000), Dumas et al. (1998), Madan et al. (1998), Nandi (1996), and Rubinstein (1994). Finally, we also used S&P 500 put option prices to estimate the pricing and hedging errors of all four models and found the results to be similar, both qualitatively and quantitatively, to those reported in the chapter. To save space, we chose to focus on the results based on the call option prices.

The sample period extends from June 1, 1988 through May 31, 1991. The intradaily transaction prices and bid–ask quotes for S&P 500 options are obtained from the Berkeley Option Database. Note that the recorded S&P 500 index values are not the daily closing index levels. Rather, they were the corresponding index levels at the moment when the recorded option transaction took place or when an option price quote was recorded. Thus, there is no nonsynchronous price issue here, except that the S&P 500 index level itself may contain stale component stock prices at each point in time.

The data on the daily Treasury bill bid and ask discounts with maturities up to 1 year are hand collected from the *Wall Street Journal* and provided to us by Hyuk Choe and Steve Freund. By convention, the average of the bid and ask Treasury bill discounts is used and converted to an annualized interest rate. Careful attention is given to this construction since Treasury bills mature on Thursdays, while index options expire on the third Friday of the month. In such cases, we utilize the two Treasury bill rates straddling the option's expiration date to obtain the interest rate of that maturity, which is done for each contract and each day in the sample. The Treasury bill rate with 30 days to maturity is the surrogate used for the short rate in Eq. 98.1 (and in the determination of the probabilities in Eq. 98.10).

For European options, the spot stock price must be adjusted for discrete dividends. For each option contract with τ periods to expiration from time t, we first obtain the present value of the daily dividends $D(t)$ by computing

$$\overline{D}(t,\tau) = \sum_{S=1}^{\tau-t} e^{-R(t,s)s} D(t+s), \tag{98.28}$$

where $R(t, s)$ is the s-period yield to maturity. This procedure is repeated for all option maturities and for each day in our sample. In the next step, we subtract the present value of future dividends from the time t index level, in order to obtain the dividend-exclusive S&P 500 spot index series that is later used as input into the option models.

Several exclusion filters are applied to construct the option price data set. First, option prices that are time stamped later than 3:00 p.m. Central Daytime are eliminated. This ensures that the spot price is recorded synchronously with its option counterpart. Second, as options with less than 6 days to expiration may induce liquidity-related biases, they are excluded from the sample. Third, to mitigate the impact of price discreteness on option valuation, option prices lower than $\$\frac{3}{8}$ are not included. Finally, quote prices that are less than the intrinsic value of the option are taken out of the sample.

We divide the option data into several categories according to either moneyness or term to expiration. A call option is said to be at the money (ATM) if its $\frac{S}{K} \in (0.97, 1.03)$, where S is the spot price and K the strike; out-of-the-money (OTM) if $\frac{S}{K} \leq 0.97$; and in-the-money (ITM) if $\frac{S}{K} \geq 1.03$. A finer partition resulted in nine moneyness categories. By the term to expiration, each option can be classified as [e.g., Rubinstein (1985)] (i) extremely short term (<30 days), (ii) short term

Table 98.1 Sample properties of S&P 500 index options

Moneyness	Term to expiration (days)						
S/K	<30	30–60	60–90	90–120	120–180	≥180	Subtotal
<0.93	0.78	1.33	1.99	2.84	4.88	7.82

Subtotal	{6,436}	{8,687}	{3,471}	{3,889}	{7,483}	{8,783}	{38,749}

The reported numbers are respectively the average quoted bid–ask midpoint price and the number of observations. Each option contract is consolidated across moneyness and term-to-expiration categories. The sample period extends from June 1, 1988 through May 31, 1991 for a total of 38,749 calls. Daily information from the last quote of each option contract is used to obtain the summary statistics. *S* denotes the spot S&P 500 index level and K is the exercise price

(30–60 days), (iii) near term (60–120 days), (iv) middle maturity (120–180 days), and (v) long term (>180 days). The proposed moneyness and term-to-expiration classifications resulted in 54 categories for which the empirical results will be reported.

Table 98.1 describes sample properties of the S&P 500 call option prices used in the tests. Summary statistics are reported for the average bid–ask midpoint price and the total number of observations, for each moneyness–maturity category. Note that there is a total of 38,749 call price observations, with deep in-the-money and at-the-money options, respectively, taking up 32 % and 28 % of the total sample and that the average call price ranges from \$0.78 for extremely short term, deep out-of-the-money options to \$59.82 for long-term, deep in-the-money options.

98.4 Empirical Tests

This section examines the relative empirical performance of the four models. The analysis is intended to present a complete picture of what each generalization of the benchmark BS model can really buy in terms of performance improvement and whether each generalization produces a worthy tradeoff between benefits and costs. We will pursue this analysis by using three yardsticks: (i) the size of the out-of-sample cross-sectional pricing errors (*static performance*); (ii) the size of model-based hedging errors (*dynamic performance*); and (iii) the existence of systematic biases across strike prices or across maturities (i.e., *does the implied volatility still smile*?).

Based on Procedure B of Sect. 98.2.3, Table 98.2 reports the summary statistics for the daily estimated structural parameters and the implied spot standard deviation, respectively, for the SVSI, the SV, the SI, and the BS models. Take the SVSI model as an example. Over the entire sample period 06:1988–05:1991, $\kappa_v = 0.906$, $\theta_v = 0.042$, and $\sigma_v = 0.414$. These estimates imply a long-run mean of 21.53 % for the volatility process. The implicit (average) half-life for variance mean reversion is 9.18 months. These estimates are similar in magnitude to those reported in Bates (1996b, 2000) for S&P 500 futures options. The estimated parameters for the (risk neutralized) short-rate process are also reasonable and comparable to those in Chan et al. (1992). The presented correlation estimate for ρ is -0.763. The average implied standard deviation is 19.27 %. As seen from the reported standard errors in Table 98.2, for each given model the daily parameter and spot volatility estimates are quite stable from subperiod to subperiod. Histogram-based inferences (not reported) indicate that the majority of the estimated values are centered around the mean.

In estimating the structural parameters and the implied volatility for a given day, we used all S&P 500 options collected in the sample for that day (regardless of maturity and moneyness). This is the treatment applied to the SI, the SV, and the SVSI models. For the BS model, however, Whaley (1982) makes the point that ATM options may give an implied-volatility estimate which produces the best pricing and hedging results. Based on his justification, we used, for each given day, one ATM option that had at least 15 days to expiration to back out the BS model's implied-volatility value. This estimate was then used to determine the next day's pricing and hedging errors of the BS model. See Bates (1996a) for a review of alternative approaches to estimating the BS model's implied volatility.

Observe in Table 98.2 that for the overall sample period, the average implied standard deviation is 19.27 % by the SVSI model, 19.02 % by the SV, 18.14 % by the SI, and 18.47 % by the BS model, where the difference between the highest and the lowest is only 1.13 %. For each subperiod the implied-volatility estimates are similarly close across the four models. This is somewhat surprising. It should, however, be recognized that this comparison is based only on the average estimates over a given period. When we examined the day-to-day time-series paths of the four models' implied-volatility estimates, we found the difference between the two models' implied standard deviations to be sometimes as high as 6 %. Economically, option prices and hedge ratios are generally quite sensitive to the volatility input (see Figlewski 1989). Even small differences in the implied-volatility estimate can lead to significantly different pricing and hedging results.

Each day in the sample, the structural parameters of a given model are estimated by minimizing the sum of squared pricing errors between the market price and the model-determined price for each option. The daily average of the estimated parameters is reported first, followed by its standard error in parentheses. The average implied volatility obtained from inverting the Black–Scholes model (using a short-term at-the-money option) is, respectively, 18.47 %, 17.72 %, 17.41 %, and 20.52 % over the sample periods 06:1988–05:1991, 06:1988–05:1989, 06:1989–05:1990, and 06:1990–05:1991

98.4.1 Static Performance

To examine out-of-sample cross-sectional pricing performance for each model, we use *previous day's* option prices to back out the required parameter values and then use them as input to compute *current day's* model-based option prices. Next, subtract the model-determined price from the observed market price, to compute both the absolute pricing error and the percentage pricing error. This procedure is repeated for each call and each day in the sample, to obtain the average absolute and the average percentage pricing errors and their associated standard errors. These steps are separately followed for each of the BS, the SI, the SV, and the SVSI models. The results from this exercise are reported in Table 98.3.

Let's first examine the relative performance in pricing OTM options. Overpricing of OTM options is often considered a critical problem for the BS model (e.g., McBeth and Merville 1979 and Rubinstein 1985). Panel A of Table 98.3 reports the absolute and the percentage pricing error estimates for OTM options. According to both error measures, the overall ranking of the four models is consistent with our priors: the SVSI model outperforms all others, followed by the SV, the SI, and finally the BS model. For extremely short-term (<30 days) and extremely out-of-the-money ($\frac{S}{K} < 0.93$) options, for example, the average absolute pricing error by the SVSI model is \$0.23 versus \$0.53 by the BS, \$0.28 by the SI, and \$0.25 by the SV model. For this category, the BS model's absolute pricing error is cut by more than a half by each of the other three models. Fix the moneyness category at $\frac{S}{K} \in (0.93, 0.95)$. Then, for medium-term (120–180 days) options, the SVSI model produces an average absolute pricing error of \$0.44 versus \$1.38 by the BS, \$0.72 by the SI, and \$0.39 by the SV model. For short-term (30–60 day) calls, the absolute pricing errors are \$0.44 by the SVSI, \$0.48 by the SV, \$0.73 by the SI, and \$0.90 by the BS model. Clearly, the performance improvement is significant for each moneyness and maturity category in Panel A, from the BS to the SI, to the SV, and to the SVSI model. This pricing performance ranking of the four models can also be seen using the average percentage pricing errors, as given in the same table. Here, the SVSI model produces percentage pricing errors that are the lowest in magnitude. As an example, take OTM options with term to expiration of 30–60 days and with $\frac{S}{K} \in (0.93, 0.95)$ In this category the BS, the SI, the SV, and the SVSI models, respectively, have average percentage pricing errors of -54.50 %, -46.20 %, -26.16 %, and -18.85 %. For long-term options with $\frac{S}{K} \in (0.93, 0.95)$ and with $\frac{S}{K} \in (0.95, 0.97)$, the SVSI model results in a percentage pricing error that is as low as 0.71 % and 0.30 %, respectively.

For ATM calls, recall that the BS model's implied-volatility input is backed out from the (previous day's) short-term ATM options, which should give the BS model a relative advantage in pricing ATM options. In contrast, the implied spot variance for the other models is obtained by minimizing the sum of squared errors for all options of the previous day. Thus, for ATM options, one would expect the BS model to perform relatively better. As seen from Panel B of Table 98.3, except for the shortest-term ATM calls, the SVSI model typically generates the lowest absolute and percentage pricing errors (especially for longer-term options), followed by the SV, by the SI,

For a given model, compute the price of each option using previous day's implied parameters and implied stock volatility. The reported percentage pricing error is the sample average of the market price minus the model price divided by the market price. The reported absolute pricing error is the sample average of the absolute difference between the market price and the model price for each call. The corresponding standard errors are recorded in parentheses. The sample period is 06:1988–05:1991, with a total of 38,749 call option prices and finally by the BS model. For the shortest-term options with $\frac{S}{K} \in (0.97, 0.99)$ and $\frac{S}{K} \in (0.99, 1.01)$, the BS and the SI models perform somewhat better than the other two.

Panel C of Table 98.3 reports the average absolute and percentage pricing errors of ITM calls by all four models. While the previous ranking of the models based on OTM and ATM options is preserved by Panel C, it can be noted that the average percentage pricing error is below 1.0 % for 12 out of the 18 categories in the case of the SVSI model, for 8 out of the 18 categories in the case of the SV model, for three categories out of 18 for the SI model, and for none of the 18 categories in the case of the BS model. The pricing improvement by the SV and the SVSI models over the BS and the SI is quite substantial for ITM options, especially for long-term options.

Some patterns of mispricing can, however, be noted across all moneyness–maturity categories. First, all four models produce negative percentage pricing errors for options with moneyness $\frac{S}{K} \leq 0.99$ and positive percentage pricing errors for options with $\frac{S}{K} \geq 1.03$, subject to their time to expiration not exceeding 120 days. This means that the models systematically overprice OTM call options while underprice ITM calls. But the magnitude of such mispricing varies dramatically across the models, with the BS producing the strongest and the SVSI model the weakest systematic biases. Next, according to the absolute pricing error measure, the SV model seems to perform slightly better than the SVSI in pricing calls with more than 90 days to expiration. This pattern is, however, not supported by the percentage pricing errors reported in Table 98.3, possibly because for these relatively long-term calls the two models produce pricing errors that have mixed signs, in which case taking the average absolute value of the pricing errors can sometimes distort the picture. According to the percentage pricing errors, the SVSI model does slightly better than the SV in pricing those longer-term options. Finally, for the BS model, its absolute pricing error has a U-shaped relationship (i.e., "smile") with moneyness, and the magnitude of its percentage pricing error increases as the call goes from deep in the money to deep out of the money, regardless of time to expiration. These patterns are reduced by each relaxation of the BS model assumptions.

98.4.2 Dynamic Hedging Performance

Recall that in implementing a hedge using any of the four models, we follow three basic steps. First, based on Procedure B of Sect. 98.2.3, estimate the structural parameters and spot variance by using day 1's option prices. Next, on day 2, use previous day's parameter and spot volatility estimates and current day's spot price and interest rates, to construct the desired hedge as given in Sect. 98.2.2. Finally, rely on either Eqs. 98.22 or 98.25 to calculate the hedging error as of day 3. We then compute both the average absolute and the average dollar hedging errors of all call options in a given moneyness–maturity category, to gauge the relative hedging performance of each model.

It should be recognized that in both the delta-neutral and the minimum-variance hedging exercises conducted in the two subsections below, the spot S&P 500 index, rather than an S&P 500 futures contract, is used in place of the "spot asset" for the hedges devised in Sect. 98.2.2. This is done out of two considerations. First, the spot S&P 500 and the immediate-expiration-month S&P 500 futures price generally have a correlation coefficient close to one. This means that whether the spot index or the futures price is used in the hedging exercises, the qualitative as well as the quantitative conclusions are most likely the same. In other words, if it is demonstrated using the spot index that one model results in better hedging performance than another, the same hedging performance ranking of the two models will likely be achieved by using an S&P 500 futures contract. After all, our main interest here lies in the relative performance of the models. Second, when a futures contract is used in constructing a hedge, a futures pricing formula has to be adopted. That will introduce another dimension of model misspecification (due to stochastic interest rates), which can in turn produce a compounded effect on the hedging results. For these reasons, using the spot index may lead to a cleaner comparison among the four option models.

98.4.2.1 Effectiveness of Delta-Neutral Hedges

Observe that the construction and the execution of the hedging strategy in Eq. 98.22 requires, in the cases of the SV and the SVSI models, (i) the availability of prices for four time-matched target and hedging-instrumental options, $C(t,\tau;K)$, $C(t,\tau;\overline{K})$, $C(t+\Delta t,\tau-\Delta t;K)$, and $C(t+\Delta t,\tau-\Delta t;\overline{K})$, and (ii) the computation of Δ_S, Δ_V, and Δ_R for the target and the instrumental option. Due to this requirement, it is important to match as closely as possible the time points at which the target and the instrumental option prices were respectively taken, in order to ensure that the hedge ratios are properly determined. For this reason, we use as hedging instruments only options whose prices on both the hedge construction day and the following liquidation day were quoted no more than 15 s apart from the times when the respective prices for the target option were quoted. This requirement makes the overall sample for the hedging exercise smaller than that used for the preceding pricing exercise, but it nonetheless guarantees that the deltas for the target and instrumental options on the same day are computed based on the same spot price. The remaining sample contains 15,041 matched pairs when hedging revision occurs at 1-day intervals and 11,704 matched pairs when rebalancing takes place at 5-day intervals. In addition, we partition the target options into three maturity classes, less than 60 days, 60–180 days, and greater than 180 days, and report hedging results accordingly.

In theory, a call option with any expiration date and any strike price can be chosen as a hedging instrument for any given target option. In practice, however, different choices can mean different hedging effectiveness, even for the same option pricing model. Out of this consideration, we employ as a hedging instrument the call option which has the same expiration date as the target option and whose strike price is the closest, but not identical, to the target option's.

Table 98.4 presents delta-neutral hedging results for the four models. Several patterns emerge from this Table. First, the BS model produces the worst hedging performance by most measures, the SI shows noticeable improvement according to the average dollar hedging errors (especially in the 5-day hedging revision categories) but not so according to the average absolute hedging errors, while the SV and the SVSI models have average absolute and average dollar hedging errors that are typically one-third of the corresponding BS hedging errors, or lower. The improvement by the SV and the SVSI is thus remarkable. Second, as portfolio adjustment frequency decreases from daily to once every 5 days, hedging effectiveness deteriorates, regardless of the model used. The deterioration is especially apparent for OTM and ATM options with $\frac{S}{K} \leq 1.05$. It should, however, be noted with emphasis that for both the SV and the SVSI models, their hedging effectiveness is relatively stable, whether the hedges are rebalanced each day or once every 5 days. For the BS and the SI models, such a change in revision frequency can mean doubling their hedging errors. This finding is strong evidence in support of the SV and the SVSI models for hedging.

Third, the BS model-based delta-neutral hedging strategy always overhedges a target call option, as its average dollar hedging error is negative for each moneyness–maturity category and at either frequency of portfolio rebalancing. In contrast, the dollar hedging errors based on the SV and the SVSI models are more random and can take either sign. Therefore, the BS formula has a systematic hedging bias pattern, whereas the SV and the SVSI do not.

Fourth, the SVSI model is indistinguishable from the SV according to their absolute hedging errors, but is slightly better than the latter when judged using their average dollar hedging errors. Similarly, the SI model has worse hedging performance than the BS according to their absolute hedging error values, but the reverse is true according to their dollar hedging errors. This phenomenon exists possibly because with stochastic interest rates there are larger hedging errors of opposite signs, so that when added together, these errors cancel out, but the sum of their absolute values is nonetheless large.

Finally, no matter which model is used, there do not appear to be moneyness- or maturity-related bias patterns in the hedging errors. In other words, hedging errors do not seem to "smile" across exercise prices or times to expiration, as pricing errors do. This is a striking disparity between pricing and hedging results.

98.4.2.2 Effectiveness of Single-Instrument Minimum-Variance Hedges

If one is, for reasons given before, constrained to using only the underlying stock to hedge a target call option, dimensions of uncertainty that move the target option value but are uncorrelated with the underlying stock price cannot be hedged by any position in the stock and will necessarily be uncontrolled for in such a single-instrument minimum-variance hedge. Based on the sample option data, the average absolute and the average dollar hedging errors, with either a daily or a 5-day rebalancing frequency, are given in Table 98.5 for each of the four models and each of the moneyness–maturity categories. With this type of hedges, the relative performance of the models is no longer clear-cut. For OTM options with $\frac{S}{K} \leq 1.97$,

For each call option, calculate the hedging error, which is the difference between the market price of the call and the replicating portfolio. The average dollar hedging error and the average absolute hedging error are reported for each model. The standard errors are given in parentheses. The sample period is 06:1988–05:1991. In calculating the hedging errors generated with daily (once every 5 days) hedge rebalancing, 15,041 (11,704) observations are used

For each call option, calculate the hedging error, which is the difference between the market price of the call and the replicating portfolio. The average dollar hedging error and the average absolute hedging error are reported for each model. The standard errors are shown in parentheses. The sample period is 06:1988–05:1991. In calculating the hedging errors generated with daily (once every 5 days) hedge rebalancing, 15,041 (11,704) observations are used the SV model has, regardless of the hedging error measure used and the hedge revision frequency adopted, the lowest hedging errors, followed by the SVSI, then by the BS, and lastly by the SI model. For ATM options, the hedging performance by the BS and the SV models is almost indistinguishable, but still better, by a small margin, than that by both the SI and the SVSI models, whereas the latter two models' performance is also indistinguishable. Finally, for ITM options, the BS model has the best hedging performance, followed by the SV, the SVSI, and then by the SI model. Having said the above, it should nonetheless be noted that for virtually all cases in Table 98.5, the hedging error differences among the BS, the SV, and the SVSI models are economically insignificant because of their low magnitude. Only the SI model's performance appears to be significantly poorer than the others'.

The fact that the SI model performs worse than the BS and that the SVSI model performs slightly worse than the SV suggests that adding stochastic interest rates to the option pricing framework actually make the single-instrument hedge's performance worse. This can be explained as follows. In the setup of the chapter, interest rate shocks are assumed to be independent of shocks to the stock price and/or to the stochastic volatility. Therefore, in the single-instrument minimum-variance hedges, there is no adjustment in the optimal position in the underlying stock to be taken. The hedging results in Table 98.5 have shown that if interest rate risk is not to be controlled by any position in the hedging instrument, then it is perhaps better to design a single-instrument hedge based on an option model that assumes no interest rate risk. Assuming interest rate risk in an option pricing model and yet not controlling for this risk in a hedge can make the hedging effectiveness worse.

In the case of the SV versus the BS model, the situation is somewhat different from the above. As volatility shocks are assumed to be correlated with stock price shocks, the position to be taken in the underlying stock (i.e., the hedging instrument) needs to be adjusted relative to the BS model-determined hedge, so that this single position not only helps contain the underlying stock's price risk but also neutralize that part of volatility risk which is related to stock price fluctuations (see Eq. 98.23). Thus, by rendering it possible to use the single hedging position to control for both stock price risk and volatility risk, introducing stochastic volatility into the BS framework helps improve the single-instrument hedging performance, albeit by a small amount. Nandi (1996) uses the remaining variance of a hedged position as a hedging effectiveness measure, according to which he finds the SV model performs better than the BS model. Our single-instrument hedging results are hence consistent with his, regarding the SV versus the BS model.

It is useful to recall that all four models are implemented allowing both the spot volatility and the spot interest rates to vary from day to day, which is, except in the sole case of the SVSI model, not consistent with the models' assumptions. Given this practical ad hoc treatment, it may not come as a surprise that when only the underlying asset is used as the hedging instrument, the four models performed virtually indifferently, with the magnitude of their hedging error differences being generally small. As easily seen, if all four models were implemented in a way consistent with the respective model setups, the single-instrument hedges based on the SVSI model would for sure perform the best.

Comparing Tables 98.4 and 98.5, one can conclude that based on a given option model, the conventional delta-neutral hedges perform far better than their single-instrument counterparts, for every moneyness–maturity category. This is not surprising as the former type of hedges involves more hedging instruments (except under the BS model).

98.4.3 Regression Analysis of Option Pricing and Hedging Errors

So far we have examined pricing and hedging performance according to option moneyness–maturity categories. The purpose was to see whether the errors have clear moneyness- and maturity-related biases. By appealing to a regression analysis, we can more rigorously study the association of the errors with factors that are either contract specific or market condition dependent. Fix an option pricing model, and let $\epsilon_n(t)$ denote the n-th call option's percentage pricing error on day t. Then, run the regression below for the entire sample:

$$\begin{aligned}\epsilon_n(t) = \beta_0 + \beta_1 \frac{S(t)}{K_n} + \beta_2\tau_n + \beta_3 SPREAD_n(t)\\ +\beta_5 LAGVOL(t-1) + \beta_4 SLOPE(t) + \eta_n(t),\end{aligned} \tag{98.29}$$

where K_n is the strike price of the call, τ_n the remaining time to expiration, and $SPREAD_n(t)$ the percentage bid–ask spread at date t of the call (constructed by computing $\frac{Ask-Bid}{0.5(Ask+Bid)}$, all of which are contract-specific variables. The variable, $LAGVOL(t-1)$, is the (annualized) standard deviation of the previous day's intraday S&P 500 returns computed over 5-min intervals, and it is included in the regression to see whether the previous day's volatility of the underlying may cause systematic pricing biases. The variable, $SLOPE(t)$, represents the yield differential between 1-year and 30-day Treasury bills. This variable can provide information on whether the single-factor Cox et al. (1985) term structure model assumed in the chapter is sufficient to make the resulting option formula capture all term structure-related effects on the S&P 500 index options. In some sense, the contract-specific variables help detect the existence of cross-sectional pricing biases, whereas $LAGVOL(t-1)$ and $SLOPE(t)$ serve to indicate whether the pricing errors over time are related to the dynamically changing market conditions. Similar regression analyses have been done for the BS pricing errors in, for example, Galai (1983b), George and Longstaff (1993), and Madan et al. (1998). For each given option model, the same regression as in Eq. 98.29 is also run for the conventional delta-neutral hedging errors, with $\epsilon_n(t)$ in Eq. 98.29 replaced by the dollar hedging error for the n-th option on day t.

Table 98.6 reports the regression results based on the entire sample period, where the standard error for each coefficient estimate is adjusted according to the White (1980) heteroskedasticity-consistent estimator and is given in the parentheses. Let us first examine the pricing error regressions. For every option

Table 98.6 Regression analysis of pricing and hedging errors

	Percentage pricing errors				Hedging errors			
Coefficient	BS	SI	SV	SVSI	BS	SI	SV	SVSI
Constant	−0.05	0.28	0.24	0.11	−0.41	−0.30	0.00	−0.03
	(0.03)	(0.03)	(0.02)	(0.02)	(0.11)	(0.10)	(0.05)	(0.05)

	(0.03)	(0.02)	(0.01)	(0.02)	(0.09)	(0.08)	(0.04)	(0.04)
τ	−0.04	0.04	0.08	0.05	0.03	0.08	0.00	0.00
	(0.01)	(0.01)	(0.01)	(0.01)	(0.02)	(0.02)	(0.01)	(0.01)
SPREAD	−5.24	−4.48	−2.13	−1.57	2.26	1.04	0.32	0.34
	(0.12)	(0.11)	(0.07)	(0.08)	(0.48)	(0.32)	(0.23)	(0.23)
SLOPE	2.29	1.33	0.32	0.34	−2.09	−2.01	−0.39	−0.39
	(0.16)	(0.13)	(0.08)	(0.11)	(0.58)	(0.65)	(0.26)	(0.25)
LAGVOL	−0.16	0.12	0.06	0.04	−0.31	−0.51	−0.06	−0.05
	(0.02)	(0.02)	(0.01)	(0.01)	(0.07)	(0.05)	(0.02)	(0.02)
Adj. R^2	0.29	0.22	0.12	0.07	0.01	0.01	0.00	0.00

The regression results below are based on the equation:
$\epsilon_n(t) = \beta_0 + \beta_1 \frac{S(t)}{K_n} + \beta_2\tau_n + \beta_3 SPREAD_n(t) + \beta_4 SLOPPE(t) + \beta_4 LAGVOL(t-1) + \eta_n(t)$,
where $\epsilon_n(t)$ denotes either the percentage pricing error or the dollar hedging error of the n-th call on date t; S/K and τ_n, respectively, represent the moneyness and the term to expiration of the option contract; the variable $SPREAD_n(t)$ is the percentage bid–ask spread; $SLOPE(t)$ the yield differential between the 1-year and the 30-day Treasury bill rates; and $LAGVOL(t-1)$ the previous day's (annualized) standard deviation of S&P 500 index returns computed from 5-min intradaily returns. The standard errors, reported in parenthesis, are White's (1980) heteroskedastically consistent estimator. The sample period is 06:1988–05:1991 for a total of 38,749 observations

model, each independent variable has statistically significant explanatory power of the remaining pricing errors. That is, the pricing errors from each model have some moneyness, maturity, intraday volatility, bid–ask spread, and term structure-related biases. The magnitude of each such bias, however, decreases from the BS to the SI, to the SV, and to the SVSI model. For instance, the BS percentage pricing errors will on the average be 2.29 points higher when the yield spread $SLOPE(t)$ increases by one point, whereas the SV and the SVSI percentage errors will only be, respectively, 0.32 and 0.34 points higher in response. Thus, a higher yield spread on the term structure means higher pricing errors, regardless of the option model used. This points out that *a possible direction to further improve pricing performance is to include the yield spread as a second factor in the term structure model of interest rates*. Other noticeable patterns include the following. The BS pricing errors are decreasing, while the SI, the SV, and the SVSI pricing errors are increasing, in both the option's time to expiration and the underlying stock's volatility on the previous day. The deeper in the money the call or the wider its bid–ask spread, the lower the SI's, the SV's, and the SVSI model's mispricing. But, for the BS model, its mispricing increases with moneyness and decreases with bid–ask spread.

Even though all four models' pricing errors are significantly related to each independent variable, the collective explanatory power of these variables is not so impressive. The adjusted R^2 is 29 % for the BS formula's pricing errors, 22 % for the SI's, 12 % for the SV's, and 7 % for the SVSI model's. Therefore, while both the BS and the SI model have significant overall biases related to contract terms and market conditions (indicating systematic model misspecifications), the remaining pricing errors under the SV and the SVSI are not as significantly associated with these variables. About 93 % of the SVSI model's pricing errors cannot be explained by these variables!

As reported in Table 98.6, delta-neutral hedging errors by the BS and the SI model tend to increase with the moneyness and the bid–ask spread of the target call, but decrease with the non-contract-specific yield spread and lagged stock volatility variables. Therefore, the two models are misspecified for hedging purposes, and they lead to systematic hedging biases. But, overall, these variables can explain only 1 % of the hedging errors by the two models. And, even more impressively, none of the included independent variables can explain any of the remaining hedging errors by the SV and the SVSI model, as their R^2 values are both zero.

Finally, when the dollar pricing errors are used to replace the percentage pricing errors or when the percentage hedging errors are employed to replace the dollar hedging errors in the above regressions, the sign of each resulting coefficient estimate and the magnitude of each R^2 value in Table 98.6 remain unchanged. Thus, the conclusions drawn from Table 98.6 are independent of the choice of the pricing or hedging error measure. Results from these exercises are not reported here but available upon request.

98.4.4 Robustness of Empirical Results

Using the entire sample period data, we have concluded that the evidence, based on both static performance and dynamic performance measures, is in favor of both the SVSI and the SV model. However, it is important to demonstrate that this conclusion still holds when alternative test designs and different sample periods are used. Below we briefly report results from two controlled experiments.

According to Rubinstein (1985), the volatility smile pattern and the nature of pricing biases are time period dependent. To see whether our conclusion may be reversed, we separately examined the pricing and hedging performance of the models in three subperiods: 06:1988–05:1989, 06:1989–05:1990, and 06:1990–05:1991. Each subperiod contains about 10,000 call option observations. As the results are similar for each subperiod, we provide the percentage pricing errors in Panel A and the absolute delta-neutral hedging errors in Panel B of Table 98.7, for the subperiod 06:1990–05:1991. It is seen that these results are qualitatively the same as those in Tables 98.3 and 98.4.

We examined the pricing and hedging error measures of each model when the structural parameters were not updated daily. Rather, retain the structural parameter values estimated from the options of the first day of each month, and then, for the remainder of the month, use them as input to compute the corresponding model-based price for each traded option, except that the implied spot volatility

The reported percentage pricing error is the sample average of the market price minus the model price divided by the market price. The sample period is 06:1990–05:1991 for a total of 11,979 call options

The average absolute hedging error for each model is reported based on the subsample period 06:1990–05:1991 (with a total of 6,440 observations) is updated each day based on the previous day's option prices. The obtained absolute pricing errors for the subperiod 06:1990–05:1991 indicate that the performance ranking of the four models remains the same as before.

In addition, when we used only ATM (or only ITM or only OTM) option prices to back out each model's parameter values, the resulting pricing and hedging errors did not change the performance ranking of the models either. This means that even if one would estimate and use a matrix of implied volatilities (across moneynesses and maturities) to accordingly price and hedge options in different moneyness–maturity categories, it would still not change the fact that the SV and the SVSI models are better specified than the other two for pricing and hedging. Given that the implied-volatility matrix method has gained some popularity among practitioners, our results should be appealing. On the one hand, they suggest that with the SV and the SVSI models, there is far less a need to engage in moneyness- and maturity-related fitting. On the other hand, if one is still interested in the matrix method, the SV and the SVSI models should be better model choices.

Early in the project we used only option transaction price data for the pricing and hedging estimations. But, that meant a far smaller data set, especially for the hedging estimations. Nonetheless, the results obtained from the transaction prices were similar to these presented and discussed in this chapter.

98.5 Concluding Remarks

We have developed and analyzed a simple option pricing model that admits both stochastic volatility and stochastic interest rates. It is shown that this closed-form pricing formula is practically implementable, leads to useful analytical hedge ratios, and contains many known option formulas as special cases. This last feature has made it relatively straightforward to conduct a comparative empirical study of the four classes of option pricing models.

According to the pricing and hedging performance measures, the SVSI and the SV models both perform much better than the SI and the BS models, as the former typically reduce the pricing and hedging errors of the latter by more than a half. These error reductions are also economically significant. Furthermore, the hedging errors by the SV and the SVSI models are relatively insensitive to the frequency of portfolio revision, whereas those of the SI and the BS models are sensitive. Given that both the SV and the SVSI models can be easily implemented on a personal computer, they should thus be better alternatives to the widely applied BS formula. A regression-based analysis of the pricing and hedging errors indicates that while the BS and the SI models show significant pricing biases related to moneyness, time to expiration, bid–ask spread, lagged stock volatility, and interest rate term spread, pricing errors by the SV and the SVSI models are not as systematically related to either contract-specific or market-dependent variables. Overall, the results lend empirical support to the claim that incorporating stochastic interest rates and, especially, stochastic volatility can both improve option pricing and hedging performance substantially and resolve some known empirical biases associated with the BS model.

The empirical issues and questions addressed in this chapter can also be reexamined using data from individual stock options, American-style index options, options on futures, currency and commodity options, and so on. Eventually, the acceptability of option pricing models with the added features will be judged not only by its easy implementability or even its impressive pricing and hedging performance as demonstrated in this chapter using European-style index calls but also by its success or failure in pricing and hedging other types of options. These extensions are left for future research.

Appendix 1

Proof of the Option Pricing Formula in Eq. 98.10. The valuation PDE in Eq. 98.9 can be rewritten as

$$\begin{aligned}&\frac{1}{2}\frac{\partial^2 C}{\partial L^2}+\left(R-\frac{1}{2}V\right)\frac{\partial C}{\partial L}+\rho\sigma_v V\frac{\partial^2 C}{\partial L\partial V}+\frac{1}{2}\sigma_v^2 V\frac{\partial^2 C}{\partial V^2}\\&+[\theta_v-\kappa_v V]\frac{\partial C}{\partial V}+\frac{1}{2}\sigma_R^2 R\frac{\partial^2 C}{\partial R^2}+[\theta_R-\kappa_R R]\frac{\partial C}{\partial R}-\frac{\partial C}{\partial \tau}-RC=0,\end{aligned} \tag{98.30}$$

where we have applied the transformation $L(t) \equiv \ln[S(t)]$. Inserting the conjectured solution in Eq. 98.10 into Eq. 98.30 produces the PDEs for the risk-neutralized probabilities, Π_j for $j = 1, 2$:

$$\begin{aligned}&\frac{1}{2}\frac{\partial^2 \prod_1}{\partial L^2}+\left(R+\frac{1}{2}V\right)\frac{\partial \prod_1}{\partial L}+\rho\sigma_v V\frac{\partial^2 \prod_1}{\partial L\partial V}+\frac{1}{2}\sigma_v^2 V\frac{\partial^2 \prod_1}{\partial V^2}\\&+[\theta_v-(\kappa_v-\rho\sigma_v)V]\frac{\partial \prod_1}{\partial V}+\frac{1}{2}\sigma_R^2 R\frac{\partial^2 \prod_1}{\partial R^2}+[\theta_R-\kappa_R R]\frac{\partial \prod_1}{\partial R}-\frac{\partial \prod_1}{\partial \tau}=0,\end{aligned} \tag{98.31}$$

and

$$\begin{aligned}&\frac{1}{2}\frac{\partial^2 \prod_2}{\partial L^2}+\left(R-\frac{1}{2}V\right)\frac{\partial \prod_2}{\partial L}+\rho\sigma_v V\frac{\partial^2 \prod_2}{\partial L\partial V}+\frac{1}{2}\sigma_v^2 V\frac{\partial^2 \prod_2}{\partial V^2}+[\theta_v-\kappa_v V]\frac{\partial \prod_2}{\partial V}\\&+\frac{1}{2}\sigma_R^2 R\frac{\partial^2 \prod_2}{\partial R^2}+\left[\theta_R-\left(\kappa_R-\frac{\sigma_R^2}{B(t,\tau)}\frac{\partial B(t,\tau)}{\partial R}\right)R\right]\frac{\partial \prod_2}{\partial R}-\frac{\partial \prod_2}{\partial \tau}=0.\end{aligned} \tag{98.32}$$

Observe that Eqs. 98.31 and 98.32 are the Fokker–Planck forward equations for probability functions. This implies that Π_1 and Π_2 must indeed be valid probability functions, with values bounded between 0 and 1. These PDEs must be separately solved subject to the terminal condition:

$$\prod_j (t+\tau, 0) = 1_{L(t+\tau)\geq K}\; j = 1, 2. \tag{98.33}$$

The corresponding characteristic functions for Π_1 and Π_2 will also satisfy similar PDEs:

$$\begin{aligned}&\frac{1}{2}\frac{\partial^2 f_1}{\partial L^2} + \left(R + \frac{1}{2}V\right)\frac{\partial f_1}{\partial L} + \rho\sigma_v V\frac{\partial^2 f_1}{\partial L \partial V} + \frac{1}{2}\sigma_v^2 V\frac{\partial^2 f_1}{\partial V^2}\\ &+[\theta_v - (\kappa_v - \rho\sigma_v)V]\frac{\partial f_1}{\partial V} + \frac{1}{2}\sigma_R^2 R\frac{\partial^2 f_1}{\partial R^2} + [\theta_R - \kappa_R R]\frac{\partial f_1}{\partial R} - \frac{\partial f_1}{\partial \tau} = 0,\end{aligned} \tag{98.34}$$

and

$$\begin{aligned}&\frac{1}{2}\frac{\partial^2 f_2}{\partial L^2} + \left(R - \frac{1}{2}V\right)\frac{\partial f_2}{\partial L} + \rho\sigma_v V\frac{\partial^2 f_2}{\partial L \partial V} + \frac{1}{2}\sigma_v^2 V\frac{\partial^2 f_2}{\partial V^2} + [\theta_v - \kappa_v V]\frac{\partial f_2}{\partial V}\\ &+\frac{1}{2}\sigma_R^2 R\frac{\partial^2 f_2}{\partial R^2} + \left[\theta_R - \left(\kappa_R - \frac{\sigma_R^2}{B(t,\tau)}\frac{\partial B(t,\tau)\partial f_2}{\partial R}\right)R\right]\frac{\partial f_2}{\partial R} - \frac{\partial f_2}{\partial \tau} = 0,\end{aligned} \tag{98.35}$$

with the boundary condition:

$$f_j(t+\tau, 0; \phi) = e^{i\phi L(t+\tau)}\; j = 1, 2. \tag{98.36}$$

Conjecture that the solution to the PDEs (98.34) and (98.35) is, respectively, given by

$$\begin{aligned}f_1(t+\tau, S(t), V(t), R(t); \phi) = \exp\{&u_r(\tau) + u_v(\tau) + x_r(\tau) + R(t)\\ &+x_v(\tau)V(t) + i\phi\ln[S(t)]\}\end{aligned} \tag{98.37}$$

$$\begin{aligned}f_2(t, \tau, S(t), V(t), R(t); \phi) = \exp\{&z_r(\tau) + z_v(\tau) + y_r(\tau)\,R(t)\\ &+y_v(\tau)V(t) + i\phi\ln[S(t)] - \ln[B(t,\tau)]\}\end{aligned} \tag{98.38}$$

with $u_r(0) = u_v(0) = x_r(0) = x_v(0) = 0$ and $z_r(0) = z_v(0) = y_r(0) = y_v(0) = 0$. Solving the resulting system of differential equations and noting that $B(t + \tau, 0) = 1$ will respectively produce the desired characteristic functions in Eqs. 98.12 and 98.13.

Both the constant interest rate–stochastic volatility and constant volatility–stochastic interest rate option pricing models are nested in Eq. 98.10. In the constant interest rate–stochastic volatility model, for instance, the partial derivatives with respect to R vanish in Eq. 98.30. The general solution in Eqs. 98.37, 98.38, and 98.40 will still apply except that now $R(t) = R$ (a constant), $B(t, \tau) = e^{-R\tau}$, $x_r(\tau) = i\phi\tau$, $y_r(\tau) = (i\phi - 1)\tau$, and $u_r(\tau) = z_r(\tau) = 0$. The final characteristic functions $\hat{f}_j$ for the constant interest rate–stochastic volatility option model are respectively given by

$$\hat{f}_1 = \exp\left\{-i\phi\ln[B(t,\tau)] - \frac{\theta_v}{\sigma_v^2}\left[2\ln\left(1 - \frac{[\xi_v - \kappa_v + (1+i\phi)\rho\sigma_v]\left(1-e^{-\xi_v\tau}\right)}{2\xi_v}\right)\right]\right.$$
$$-\frac{\theta_v}{\sigma_v^2}[\xi_v - \kappa_v + (1+i\phi)\rho\sigma_v]\tau + i\phi\ln[S(t)]$$
$$\left.+\frac{i\phi(i\phi+1)\left(1-e^{-\xi_v\tau}\right)}{2\xi_v - [\xi_v - \kappa_v + (1+i\phi)\rho\sigma_v](1-e^{-\xi_v\tau})}V(t)\right\}, \quad (98.39)$$

and

$$\hat{f}_2 = \exp\left\{-i\phi\ln[B(t,\tau)] - \frac{\theta_v}{\sigma_v^2}\left[2\ln\left(1 - \frac{\left[\xi_v^* - \kappa_v + i\phi\rho\sigma_v\right]\left(1-e^{-\xi_v^*\tau}\right)}{2\xi_v^*}\right)\right]\right.$$
$$\left.-\frac{\theta_v}{\sigma_v^2}\left[\xi_v^* - \kappa_v + i\phi\rho\sigma_v\right]\tau + i\phi\ln[S(t)] + \frac{i\phi(i\phi+1)\left(1-e^{-\xi_v^*\tau}\right)}{2\xi_v^* - \left[\xi_v^* - \kappa_v + i\phi\rho\sigma_v\right]\left(1-e^{-\xi_v^*\tau}\right)}V(t)\right\}, \quad (98.40)$$

Similarly, the constant volatility–stochastic interest rate option model obtains with $V(t) = V$ (a constant), $x_v(\tau) = \frac{1}{2}i\phi(1+i\phi)\tau$, $y_v(\tau) = \frac{1}{2}i\phi(i\phi-1)\tau$, and $u_v(\tau) = z_v(\tau) = 0$. The final characteristic functions $\widetilde{f}_j$ for the stochastic interest rate–constant volatility model are

$$\widetilde{f}_1 = \exp\left\{\frac{1}{2}i\phi(1+i\phi)V\tau + i\phi\ln[S(t)]\right.$$
$$-\frac{\theta_R}{\sigma_R^2}\left[2\ln\left(1 - \frac{[\xi_R - \kappa_R]\left(1-e^{-\xi_R\tau}\right)}{2\xi_R}\right) + [\xi_R - \kappa_R]\tau\right]$$
$$\left.+\frac{2i\phi\left(1-e^{-\xi_R\tau}\right)}{2\xi_R - [\xi_R - \kappa_R](1-e^{-\xi_R\tau})}R(t)\right\}, \quad (98.41)$$

and

$$\widetilde{f}_2 = \exp\left\{\frac{1}{2}i\phi(i\phi-1)V\tau + i\phi\ln[S(t)] - \ln[B(t,\tau)]\right.$$
$$-\frac{\theta_R}{\sigma_R^2}\left[2\ln\left(1 - \frac{\left[\xi_R^* - \kappa_R\right]\left(1-e^{-\xi_R^*\tau}\right)}{2\xi_R^*}\right) + \left[\xi_R^* - \kappa_R\right]\tau\right], \quad (98.42)$$
$$\left.+\frac{2(i\phi-1)\left(1-e^{-\xi_R^*\tau}\right)}{2\xi_R^* - \left[\xi_R^* - \kappa_R\right]\left(1-e^{-\xi_R^*\tau}\right)}R(t)\right\}$$

Expressions for the Gamma Measures. The various second-order partial derivatives of the call price in Eq. 98.10, which are commonly referred to as Gamma measures, are given below:

$$\Gamma_S \equiv \frac{\partial^2 C(t,\tau)}{\partial S^2} = \frac{\partial \prod_1}{\partial S} = \frac{1}{\pi}\int_0^\infty Re\left[(i\phi)^{-1} e^{-i\phi \ln[K]} f_1 \frac{i\phi}{S}\right] d\phi. > 0. \tag{98.43}$$

$$\Gamma_V \equiv \frac{\partial^2 C(t,\tau)}{\partial V^2} = S(t)\frac{\partial^2 \prod_1}{\partial V^2} - KB(t,\tau)\frac{\partial^2 \prod_2}{\partial V^2} \tag{98.44}$$

$$\Gamma_R \equiv \frac{\partial^2 C(t,\tau)}{\partial R^2} = S(t)\frac{\partial^2 \prod_1}{\partial R^2} - KB(t,\tau)\left\{\frac{\partial^2 \prod_2}{\partial R^2} 2\varrho(\tau)\frac{\partial \prod_2}{\partial R} + \varrho^2(\tau)\prod\nolimits_2\right\}. \tag{98.45}$$

$$\Gamma_{S,V} \equiv \frac{\partial^2 C(t,\tau)}{\partial S \partial V} = \frac{\partial \prod_1}{\partial V} = \frac{1}{\pi}\int_0^\infty \mathrm{Re}\left[(i\phi)^{-1} e^{-i\phi \ln[K]} \frac{\partial^2 f_1}{\partial V}\right] d\phi. \tag{98.46}$$

where for $g = V, R$ and $j = 1, 2$

$$\frac{\partial^2 \prod_j}{\partial g^2} = \frac{1}{\pi}\int_0^\infty \mathrm{Re}\left[(i\phi)^{-1} e^{-i\phi \ln[K]} \frac{\partial^2 f_j}{\partial g^2}\right] d\phi. \tag{98.47}$$

The Le Châtelier Principle of the Capital Market Equilibrium

99

Chin W. Yang, Ken Hung, and Matthew D. Brigida

Contents

Abstract

This chapter purports to provide a theoretical underpinning for the problem of the Investment Company Act. The theory of the Le Chatelier principle is well known in thermodynamics. The system tends to adjust itself to a new equilibrium as far as possible. In capital market equilibrium, added constraints on portfolio investment in each stock can lead to inefficiency manifested in the right-shifting efficiency frontier. According to the empirical study, the potential loss can amount to millions of dollars coupled with a higher risk-free rate and greater transaction and information costs.

99.1 Introduction

In the wake of a growing trend of deregulation in various industries (e.g., utility, banking, and airline), it has become more and more important to study the responsiveness of the market to the exogenous perturbations as the system is gradually constrained. According to the law of thermodynamics, the system tends to adjust itself to a new equilibrium by counteracting the change as far as possible. This law, the Le Chatelier principle, was applied to economics by Samuelson (1949, 1960, 1972), Silberberg (1971, 1974, 1978), and to a class of spatial equilibrium models: linear programming, fixed demand, quadratic programming, full-fledged spatial equilibrium model by Labys and Yang (1996). Recently, it has been applied to optimal taxation by Diamond and Mirrlees (2002).

According to subchapter M of the Investment Company Act of 1940, a diversified mutual fund cannot have more than 5 % of total assets invested in any single company and the acquisition of securities does not exceed 10 % of the acquired company's value. By meeting this diversification threshold, funds are considered "pass-through" entities enabling capital gains and income taxes to accrue to the fund's investors. This diversification rule, on the one hand, reduces the portfolio risk according to the fundamental result of investment theory. On the other hand, more and more researchers begin to raise questions as to the potential inefficiency arising from the Investment Company Act (see Elton and Gruber 1991; Roe 1991; Francis 1993; Kohn 1994). Further, Almazan et al. (2004) document inefficiencies from a broad set of mutual fund investment constraints. With the exception of the work by Cohen and Pogue (1967), Frost and Savarino (1988), and Loviscek and Yang (1997), there is very little evidence to refute or favor this conjecture.

Empirical findings (e.g., Loviscek and Yang 1997) suggest that over 300 growth mutual funds evaluated by Value Line show that the average weight for the company given the greatest share of a fund's assets was 4.29 %. However, the Le Chatelier principle in terms of the Investment Company Act has not been scrutinized in the literature of finance. The objective of this chapter is to investigate the Le Chatelier principle applied to the capital market equilibrium in the framework of the Markowitz portfolio selection model.

99.2 The Le Chatelier Principle of the Markowitz Model

In a portfolio of n securities, Markowitz (1952, 1956, 1959, 1990, 1991) formulated the portfolio selection model in the form of a quadratic programming as shown below:

$$\min_{x_i x_j} \upsilon = \sum\nolimits_{i \in I} \sum\nolimits_{j \in J} x_i x_j \sigma_{ij} \tag{99.1}$$

subject to

$$\sum\nolimits_{i \in I} r_i x_i \geq k \tag{99.2}$$

$$\sum\nolimits_{i \in I} x_i = 1 \tag{99.3}$$

$$x_i \geq 0 \ \ \forall \ \ i \in I \tag{99.4}$$

where
x_i = proportion of investment in security i
σii = variance of rate of return of security i
σij = covariance of rate of return of security i and j
r_i = expected rate of return of security i
k = minimum rate of return of the portfolio
I and J are sets of positive integers
The resulting Lagrange function is therefore

$$L = \upsilon + \lambda\left(k - \sum r_i x_{ij}\right) + \gamma\left(1 - \sum x_i\right) \tag{99.5}$$

The solution to the Markowitz is well known (1959). The Lagrange multiplier of constraint Eq. 99.2 assumes the usual economic interpretation: change in total risk in response to an infinitesimally small change in k while all other decision variables adjust to their new equilibrium levels, i.e., $\lambda = dv/dk$. Hence, the Lagrange multiplier is of utmost importance in determining the shape of the efficiency frontier curve in the capital market. Note that values of x_{is} are unbounded between 0 and 1 in the Markowitz model. However, in reality, the proportion of investment on each security many times cannot exceed a certain percentage to ensure adequate diversification. As the maximum investment proportion on each security decreases from 99 % to 1 %, the solution to the portfolio selection model becomes more constrained, i.e., the values of optimum xs are bounded within a narrower range as the constraint is tightened. Such impact on the objective function v is straightforward: as the system is gradually constrained, the limited freedom of optimum xs gives rise to a higher and higher risk level as k is increased. For example, if parameter k is increased gradually, the Le Chatelier principle implies that in the original Markowitz minimization system, isorisk contour has the smallest curvature to reflect the most efficient adjustment mechanism:

$$abs\left(\frac{\partial^2 \upsilon}{\partial k^2}\right) \leq abs\left(\frac{\partial^2 \upsilon^*}{\partial k^2}\right) \leq abs\left(\frac{\partial^2 \upsilon^{**}}{\partial k^2}\right) \tag{99.6}$$

where v^* and v^{**} are the objective function (total portfolio risk) corresponding to the additional constrains of $x_i < s^*$ and $x_i < s^{**}$ for all i and $s^* > s^{**}$ represent different investment proportions allowed under V^* and V^{**} and abs denotes absolute value. Via the envelope theorem (Dixit 1990) we have

$$\frac{d\{L(x_i(k),k) = \upsilon(x_i(k))\}}{dk} = \frac{\partial\{L(x_i(k),k) = \upsilon(x_i(k))\}}{\partial k} = \lambda|x_i = x_i(k) \tag{99.7}$$

Hence, Eq. 99.6 can be rewritten as

$$abs\left(\frac{\partial \lambda}{\partial k}\right) \leq abs\left(\frac{\partial \lambda^*}{\partial k}\right) \leq abs\left(\frac{\partial \lambda^{**}}{\partial k}\right) \tag{99.8}$$

Equation 99.8 states that the Lagrange multiplier of the original Markowitz portfolio selection model is less sensitive to an infinitesimally small change in k than that of the model when the constraints are gradually tightened. Note that the Lagrange multiplier λ is the reciprocal of the slope of the efficiency frontier curve frequently drawn in investment textbooks. Hence, the original Markowitz model has the steepest slope for a given set of x_i s. However, the efficiency frontier curve of the Markowitz minimization system has a vertical segment corresponding to a range of low ks and a constant v. Only within this range do the values of optimum xs remain equal under various degrees of constraints. Within this range constraint Eq. 99.2 is not active; hence the Lagrange multiplier is zero. As a result, equality relation holds for Eq. 99.8. Outside this range, the slopes of the efficiency frontier curve are different owing to the result of Eq. 99.8.

99.3 Simulation Results

To verify the result implied by the Le Chatelier principle, we employ a five-stock portfolio with $x_i < 50\ \%$ and $x_i < 40\ \%$. The numerical solutions are reported in Table 99.1. An examination of Table 99.1 indicates that the efficiency frontier curve is vertical and all optimum xs are identical between $0.001 < k < 0.075$. After that, the solutions of xs begin to change for the three models. Note that the maximum possible value for x_4 remains 0.4 throughout the simulation for $k > 0.075$ for the model with the tightest constraint xi < 0.4. In the case of $x_i < 0.5$, a relatively loosely constrained Markowitz system, all the optimum values of decision variables remain the same as the original Markowitz model between $0.01 < k < 0.1$. Beyond that range, the maximum value of x_4 is limited to 0.5. As can be seen from Table 99.1, the total risk v responds less volatile to the change in k in the original unconstrained Markowitz system than that in the constrained systems. In other words, the original Markowitz minimization system guarantees

Table 99.1 Simulation Results

Least constrained solution (original Markowitz model)							Solution with $x_i \leq 0.5$						Solution with $x_i \leq 0.4$

a smallest possible total risk due to the result of the Le Chatelier principle: a thermodynamic system (risk-return space) can most effectively adjust itself to the parametric change (temperature or minimum rate of return of a portfolio or k) if it is least constrained.

99.4 Policy Implications of the Le Chatelier Principle

As shown in the previous section, the efficiency frontier curve branches off to the right first for the most binding constraint of $x_i < s^{**}$. Consequently, the tangency point between the efficiency frontier curve and a risk-free rate on the vertical axis must occur at a higher risk-free rate. As the value of maximum investment proportion for each stock s decreases, i.e., the constraint becomes more binding, there is a tendency for the risk-free rate to be higher in order to sustain an equilibrium (tangency) state. Second, one can assume the existence of a family of isowelfare functions (or indifference curves) in the v-k space. The direct impact of the Le Chatelier principle on the capital market equilibrium is a lower level of welfare measure due to the right branching-off of the efficiency frontier curve. In sum, as the constraint on the maximum investment proportion is tighter, the risk-free rate will be higher and investors in the capital market will in general experience a lower welfare level. In particular, the 5 % rule carries a substantial cost in terms of shifting of the efficiency frontier to the right. The study by Loviscek and Yang (1997) based on a 36-security portfolio indicates the loss is about 1–2 percentage points and the portfolio risk is 20–60 % higher. Given the astronomical size of a mutual fund, 1–2 percentage point translates into millions of dollars potential loss in daily return. Furthermore, over diversification would incur greater transaction and information cost, which speaks against the Investment Company Rule.

99.5 Concluding Remarks

In this note, we apply the Le Chatelier principle in the thermodynamics to the Markowitz portfolio selection model. The analogy is clear: as a thermodynamic system (or the capital market in the v-k space) undergoes some parametric changes (temperature or minimum portfolio rate of change k), the system will adjust most effectively if it is least constrained. The simulation shows that as the constraint becomes more and more tightened, the optimum investment proportions are less and less sensitive. Via the envelop theorem, it is shown that investors will be experiencing a higher risk-free rate and a lower welfare level in the capital market, if a majority of investors in the capital market experience the same constraint, i.e., maximum investment proportion on each security. Moreover, the potential loss in daily returns can easily be in millions on top of much greater transaction and information costs.
